Elephants, the largest living land mammals, have evolved a specialized foot morphology to help reduce locomotor pressures while supporting their large body mass. Peak pressures that could cause tissue damage are mitigated passively by the anatomy of elephants' feet, yet this mechanism does not seem to work well for some captive animals. This study tests how foot pressures vary among African and Asian elephants from habitats where natural substrates predominate but where foot care protocols differ. Variations in pressure patterns might be related to differences in husbandry, including but not limited to trimming and the substrates that elephants typically stand and move on. Both species' samples exhibited the highest concentration of peak pressures on the lateral digits of their feet (which tend to develop more disease in elephants) and lower pressures around the heel. The trajectories of the foot's centre of pressure were also similar, confirming that when walking at similar speeds, both species load their feet laterally at impact and then shift their weight medially throughout the step until toe-off. Overall, we found evidence of variations in foot pressure patterns that might be attributable to husbandry and other causes, deserving further examination using broader, more comparable samples.

1. Introduction

Elephant feet have evolved to resist locomotor stresses while carrying a large body mass (up to approx. 8000 kg in African elephants). Considering the importance of foot morphology for helping to support the body weight of elephants, the largest living terrestrial mammals, an understanding of any links between foot mechanics and the development of pathologies is vital. There have been important basic scientific studies that describe quasi-normal foot form and function in elephants. African elephants (like Asian species) walk on their 'tip-toes' (subunguligrade), yet their feet are effectively flat (i.e. functionally plantigrade) due to a large, compliant fat pad that fills the space behind the toes [1]. Elephants also have enlarged false toes called 'predigits' embedded in those fat pads that help transmit loads from the sole of the foot proximally up the limbs [2]. When compressed, the fat pad acts to evenly distribute locomotor stresses across the sole of the foot, especially behind the toes [3–5]. Evolutionarily, there appears to be a strong correlation between body mass, foot posture and development of a fat pad in elephants. The fossil record reveals that the foot bones in small-bodied early elephants (stem Proboscidea) were held relatively flat (near-plantigrade) and had no evidence of an enlarged fat pad; however, as elephants evolved larger body mass and became more terrestrial, their foot posture became more plantar-flexed and they evolved fat pads along with predigits [2]. Similar trends showing evidence for correlated evolution of larger foot pads, more digitigrade foot postures and increases of body mass have been proposed for ornithomimid dinosaurs [6]. The presence of the fat pad in large-bodied land animals such as elephants may thus be a mechanism to reduce locomotor stresses that could impact the animals' health and welfare.

Panagiotopoulou *et al.*'s [4] study of *in vivo* foot pressures in captive Asian elephants showed that peak pressures (i.e. the maximum pressure over time at a particular location) were focused towards the tips of the outermost (lateral) toes (digits III, IV and V) where pathologies are most prevalent in elephants in general, and that the lowest pressures were in the middle and towards the rear of the feet, directly under the fat pad. Pressure reduction underneath the fat pad can be attributed to the compliance of the tissue but also to the observation that elephants minimize heel-only contact while walking, using mainly the front part of their feet to produce vertical forces as they roll over the fat pad during ground contact [4].

Foot anatomy and locomotor behaviour in elephants should reduce peak pressures that could cause foot disease. However, a major problem that hinders conservation efforts with elephants in captivity is that some elephants develop foot disorders, apparently uncommon in wild populations [7–10]. The causes of foot disorders in captive elephants are complex, with obesity, space availability and time spent on hard substrates being major suspects [11–14]. The latter suspicion is consistent with studies conducted on cattle that reported a higher incidence of lameness and pathogenesis in animals housed on hard surfaces (e.g. [15,16]). An investigation into the welfare and quality of elephants in zoos in the United Kingdom found a high prevalence of gait and foot abnormalities in animals kept in enclosures with unnatural, hard substrates [13]. In that study, 80.4% of the elephants included showed foot problems, ranging from cracks to infection, and 85.7% had abnormal gait, ranging from slightly abnormal to severely lame [13]. A recent study in Asian and African elephants in North American zoos using medical examinations, clinical records and demographic characteristics showed a close relationship between foot pathologies and the time the animals spent on hard substrates [14]. In particular, Miller *et al.* estimated that elephants exposed to hard substrates for 4 h daily were more likely to develop joint stiffness or limb lameness than those exposed to hard substrates for 2.5 h per day. Furthermore, within a population of 215 elephants that received physical examinations, 145 had foot abnormalities, with 92.4% showing nail abnormalities (such as inflammation, cracks, defects and horn growth), 13.1% with pad abnormalities and 22.8% with abnormalities in their interdigital spaces [14].

Management of foot disease in elephants is very challenging because treatment is often unsuccessful or it can have life-threatening effects. Physical examination using observations on gait abnormalities can be informative but solely when foot conditions have advanced [14]. Examination using diagnostic techniques is costly and can negatively affect animal health because it may require general anaesthesia (e.g. [17]) or other 'hands-on' methods that are impractical especially in settings (e.g. protected/non-contact) where interaction of captive elephants and their human keepers is minimal or absent. These challenges, coupled with the tendency for foot disease in elephants to become evident when it has progressed to irreversible levels, make euthanasia a frequent end result of foot disease [7–10,17]. Wildlife reserves and safari parks are also classified as captive settings; however, these tend to better mimic the natural habitats of elephants, often presumed to provide a healthier living environment. Elephants kept in larger outdoor spaces with natural terrain are thought to remain more athletic and have better health and gait compared with those in less spacious, more unnatural environments [13,14]. Elephants in natural environments exercise their feet by digging the ground, walking on rocks, and rubbing their

pads against mud and sand pits (electronic supplementary material, movie S1) [18,19]. These behaviours help ensure that elephants' feet remain moist, their fat pads stay supple and their nails receive natural trimming [18,19]. Walking on unnatural substrates may dry out the sole (slipper) or encourage cracks to develop [14,18,19].

To prevent the development of foot diseases in captive elephants, especially in habitats with less natural substrates, many elephant keepers perform regular trimming on the feet [18,19]. Trimming is usually performed every three to four weeks, using sharp blades attached to handles. The amount of tissue removed during trimming depends on the thickening of the skin, according to the keepers' observations [11]. Trimming techniques are beneficial in cases of fungal growth, cracks and divots when performed locally; however, excessive trimming of the sole may have adverse effects such as inducing soft tissue infections (e.g. [20]). In addition, trimming approaches may vary between African and Asian species to take into consideration those elephants' adaptations to different environments (e.g. simply put, more savannah-based versus more forest-based) [19].

Although epidemiological and pathological studies have increased our understanding of the prevalence of foot diseases in captive elephants, they are based on observations and measurements that come from elephants that already have foot problems and/or from cadaveric tissues and museum specimens. In both cases, such data may come with limited background information and little or no direct mechanistic basis. It is still not known how changes in habitats' substrate properties or foot management influence locomotor pressures and foot pathogenesis in living elephants, or the biomechanical mechanisms underlying their formation, especially longitudinally across the lifetime of an elephant (approx. 80 years).

This study's primary aim is to quantify variations of the pressure patterns among the feet of African elephants, for comparison to existing data on Asian elephants [4]. Prior studies of these species showed that their locomotor mechanics are not appreciably different (e.g. [21,22]), and differences in their foot anatomy are minor [1,23]. For this reason, we do not expect to find drastic differences in the centre of pressure (COP) trajectories (i.e. mean paths of the vertical ground reaction forces on the feet) and pressure patterns between species. Thus, we predict that any variations in pressure patterns may be related to differences in their husbandry, including but not limited to trimming and the substrates they typically stand and move on.

2. Material and methods

2.1. Subjects

Five healthy adult African elephants from a safari park (Adventures with Elephants, Limpopo, Bela Bela, South Africa) were selected to participate in this study (table 1). The elephants' weights could not be measured during data collection and all body masses were thus based on approximations by the park keepers. The African elephants were kept under near-wild conditions in a 380 hectare grassland habitat with natural substrate properties and ample space to move and forage (electronic supplementary material, movie S1). As a result, all elephants seemed to naturally trim their feet and did not directly receive foot care from their keepers. The health of the animals' feet was visually assessed daily by their keepers during the safari interactions with tourists. It was not possible to collect data from wild African elephants due to experimental constraints and accessibility issues.

The Asian elephants in Panagiotopoulou *et al.* [4] were reared in more typical captive safari park environments from two zoological parks in Bedfordshire, UK (the Zoological Society of London's Whipsnade Zoo and Woburn Safari Park) and received regular foot trimming for disease prevention. Their age and body mass at the time of data collection varied from 31 days and 120 kg to 27 years and 3332 kg.

2.2. Data collection

Experiments were conducted at the safari park using two pressure platforms that were specifically built to dynamically measure pressure distributions and COP trajectories of elephants for this study (Zebris Medical GmbH, Biomechanix, Munich). Each platform had sampling frequency of 100 Hz, and outer dimensions 0.605 m width \times 2.122 m length. Each platform contained an array of sensors arranged 44 \times 160 to total 7040 sensors per platform (14 080 sensors in total; approx. 0.55 sensors cm⁻²). The platforms used in this study were nearly twice as large as the pressure platform used in previous studies on Asian elephants, allowing the collection of a greater number of steps, but had lower resolution

Table 1. Subject characteristics (*Loxodonta africana*) and number of experimental trials and steps. Circumferences for the right fore and hind feet (RFF, RHF) were measured twice by independent individuals and the mean is shown here. Mean \pm s.e. given for each mean peak (maximum) pressure during the whole stance.

than this previous study ([4]; $1.0 \text{ m} \times 0.4 \text{ m}$, 8192 sensors, $2.05 \text{ sensors cm}^{-2}$). The pressure platforms were calibrated as per manufacturer's instructions and were aligned parallel to each other, with their longitudinal axes aligned to the direction of travel (figure 1). This allowed measurements of multiple footfalls from a single stride, maximizing the collection of spatially complete data, while accounting for the animals' wide gait. Both platforms were placed on levelled natural ground and covered with 0.5 mm thick rubber matting in order to avoid recognition of the plates' locations by the animals. Pressure readings were zeroed after being covered by the rubber matting and prior to starting each data collection session.

All elephants were trained to walk over the set-up prior to the experiments. Training lasted approximately 1 h, during which time each animal was guided by the keepers to walk over the set-up

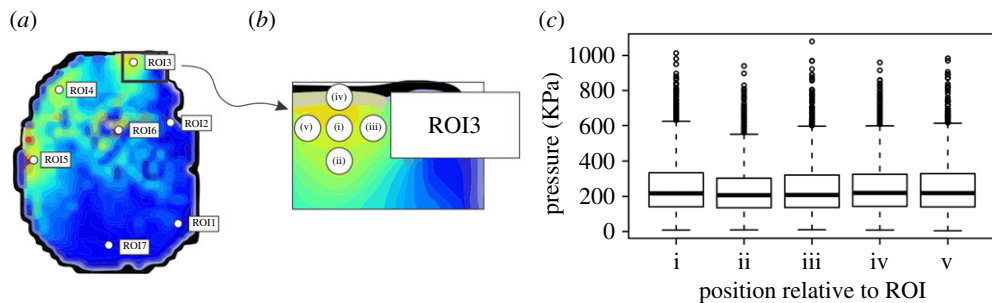

Figure 2. Sensitivity analysis for the placement of each region of interest (ROI) in a representative left fore foot (Subject 1). (a) Placement of the seven ROIs. (b) Detailed section of the area around ROI3, showing the placement of each sensitivity analysis point around it. (c) Box plot showing the effect of placement among all trials and subjects ($n = 7350$). Boxes represent the median, with hinges representing the first and third quartiles. Whiskers represent the 95% CIs, and dots represent outliers.

five times. Prior to data collection, reflective markers were placed on the elephant's body at shoulder and hip height for the recording of speed. Walking speed was recorded using an uncalibrated GoPro Hero 3 (GoPro Inc., San Mateo, California, USA) camera at 24 Hz sampling frequency. The camera was placed approximately 2 m away from the platforms and faced perpendicular to the walkway. We did not collect data from running gaits as they were deemed unsafe, and comparative foot pressure data do not exist for such gaits in Asian elephants. All unstable or unsteady walking trials, such as when the elephants stopped mid-way, accelerated/decelerated or walked in an obviously abnormal manner, were excluded from further analysis.

During the experiments, the elephants were guided by their keepers to walk over the walkway an average of 40 times each (electronic supplementary material, movie S2). The experimental approach was similar to that previously used by Panagiotopoulou *et al.* [4] and did not cause any discomfort to the animals.

2.3. Data processing

Initial data analysis was conducted in Canopy v. 1.4.1 using SciPy v. 0.14, NumPy 1.8.1 and Matplotlib 1.4 (Enthought Inc., Austin, TX, USA). The raw pressure data (x, y, time) of all individual footsteps were exported from the Zebris system, isolated algorithmically using spatio-temporal gaps between clusters of non-zero pressure voxels and were assessed for spatio-temporal completeness as per Panagiotopoulou *et al.* [4]. Spatio-temporally complete images were then identified as manus (forefeet) or pes (hindfeet) and right/left. For homologous comparisons between footsteps and within feet, all images were registered (aligned) manually using a computer keyboard [24]. Existing automatic pedobarographic registration algorithms that have been previously developed for human feet [24] do not perform well on elephant data due to their symmetrical shapes. Manual registration has been shown to provide results that are as good as optimal algorithmic registration [24], and we previously used this method in a foot pressure study on captive Asian elephants [4]. The template image (isocontour of threshold 5 kPa), with which all other images were aligned, was the first image to meet the inclusion criteria (see Panagiotopoulou *et al.* [4]: Material and Methods). Source (non-template) images were manually translated and rotated using the keyboard to align them with the template of each foot (fore left (FL), fore right (FR), hind left (HL), hind right (HR)). The translation and rotation manually applied to each source image were re-applied to the pressure images' time series.

Following registration, seven anatomical regions of interest (ROIs) were selected on the mean images as per Panagiotopoulou *et al.* [4] (figure 2a). The ROIs represented chosen homologous anatomical structures of the African elephants' feet where peak pressures of the whole stance phase were extracted for analysis. ROIs 1–5 represented the middle of the bottom surfaces of the nails of digits i–v, respectively, ROI 6 represented the middle of the foot sole (slipper) and ROI 7 represented the caudal-most (heel) aspect of the sole. The peak pressures (kPa) per subject, trial and foot were extracted from a 3-pixel area for each digitized ROI using a Gaussian kernel with a standard deviation of one pixel.

Manual identification of ROIs is a standard approach to calculate pressure magnitudes in functional studies but can be biased because single values do not necessarily represent neighbouring data [24]. To account for this limitation, we conducted a sensitivity analysis to evaluate the effect of ROI location

by moving the selected points by one pixel. To do this, we defined another four points, directly above, below, to the left and right of each ROI (figure 2b) and estimated the sensitivity to digitizing error by using a linear mixed effects model using the `lmer.R` function from the `lmerTest` package [25] in R v. 3.1.1 software (R Development Core Team, Auckland, New Zealand). The random effects of subject, foot and ROI were included. The P threshold was set at 0.05 and all significance values were estimated using the Satterthwaite's approximation, as implemented in `lmerTest`.

To measure peak foot-pressure magnitudes during the stance phase and to determine pressure variations among ROI and feet, we similarly used a linear mixed effect model including subject as a random effect in R. To compare variations between feet, we calculated the mean COP trajectories for each foot and performed a pair-wise comparison within feet using Pearson's correlation along the cranio-caudal axis (Y_r) and the mediolateral axis (X_r), the root mean square error (RMSE) on untransformed data, and the root mean square deviation on transformed data (RMSD). Data were transformed using a Procrustes analysis in R using the function `procOPA.R` from the `shapes` package [26], with both scale and reflect set to TRUE.

The COP data from the African elephants were then compared with the COP data from Asian elephants collected using similar methods from Panagiotopoulou *et al.* [4]. Means were calculated for each foot from each dataset, excluding the juvenile subject 1 (120 kg) from the Asian elephant dataset, considering its different COP trajectories when compared against the other Asian elephant subjects, probably due to its young age [4]. Other subjects were not excluded, although the Asian subjects 2 and 3 were younger than the African elephants in our new sample and thus smaller (500 and 1024 kg body masses), so age differences might contribute to other factors underlying any differences between elephants.

Considering the likely differences in feet circumferences between the two species due to size and trimming parameters, a direct comparison between the two species was not possible. For this reason, all data were transformed using a Procrustes analysis in R as above, which allowed the COP trajectory to be scaled and reflected to maximize similarity. Unlike the analysis among feet, which compared both the original and transformed data, this analysis used only the transformed values in the comparison between African and Asian elephants.

3. Results

The mean walking speed of all African elephants was 1.2 ms^{-1} (table 1). This corresponded to a Froude number ([27]; $Fr = \text{velocity}^2 \times [9.81 \text{ ms}^{-2} \times \text{hip height}]^{-1}$) of 0.07 for all subjects (table 1), indicative of a slow walk (electronic supplementary material, Data S1). This speed was comparable with the mean speed of the Asian elephants in Panagiotopoulou *et al.* [4] (mean $Fr = 0.10$).

The ROI sensitivity analysis indicated a significant effect of the topological location of each ROI on peak pressure magnitudes ($F_{4,7314} = 8.22$, $p < 0.001$) (electronic supplementary material, Data S2). An ANOVA implemented using the `aov.R` function also indicated a significant interaction between the ROI placement location, with both foot ($p < 0.001$) and ROI ($p < 0.001$). A Tukey *post hoc* test showed that this effect was largely a result of position ii (ii in figure 2b) showing significantly lower pressures than each other position (figure 2c). Interactions between other positions (i, iii, iv, v) were not significant ($p > 0.05$). To account for the effect of the topological location of each ROI on pressure magnitudes, the mean peak pressure value for each topological location and each ROI was used for further processing.

To determine the variation among ROIs and among feet, we used a linear mixed effect model including subject as a random effect. Mean peak pressure during the whole stance phase varied significantly with both the ROI ($F_{6,1456} = 403$, $p < 0.001$) and the foot ($F_{3,1459} = 6.58$, $p < 0.001$), with a significant interaction between the terms ($F_{18,1438} = 25.8$, $p < 0.001$). Mean peak pressure among all feet was variable, with the front feet tending to support more pressure. When combined into fore and hind pairs, the forefeet showed significantly higher mean peak foot pressures based on ANOVA (fore 264 ± 5.31 , hind 246 ± 5.09 ; $F_{1,1468} = 5.22$, $p = 0.022$). This finding, although only a mean 7% difference between the fore and hind foot pressures, is loosely in accord with the observation that elephants' forelimbs carry more weight; approximately 60% of the animal's body weight [28–31]. A *post hoc* test among all feet showed a significant difference between the FL versus HL and the FL versus HR, with no other interaction being significant.

Peak pressures were also compared across ROIs using ANOVA with *post hoc* tests. When combined in a single analysis, all ROIs displayed significant variation from one another with the exception of regions 1 versus 7 ($p = 0.707$), 2 versus 6 ($p = 0.131$) and 4 versus 5 ($p = 0.171$). However, as indicated

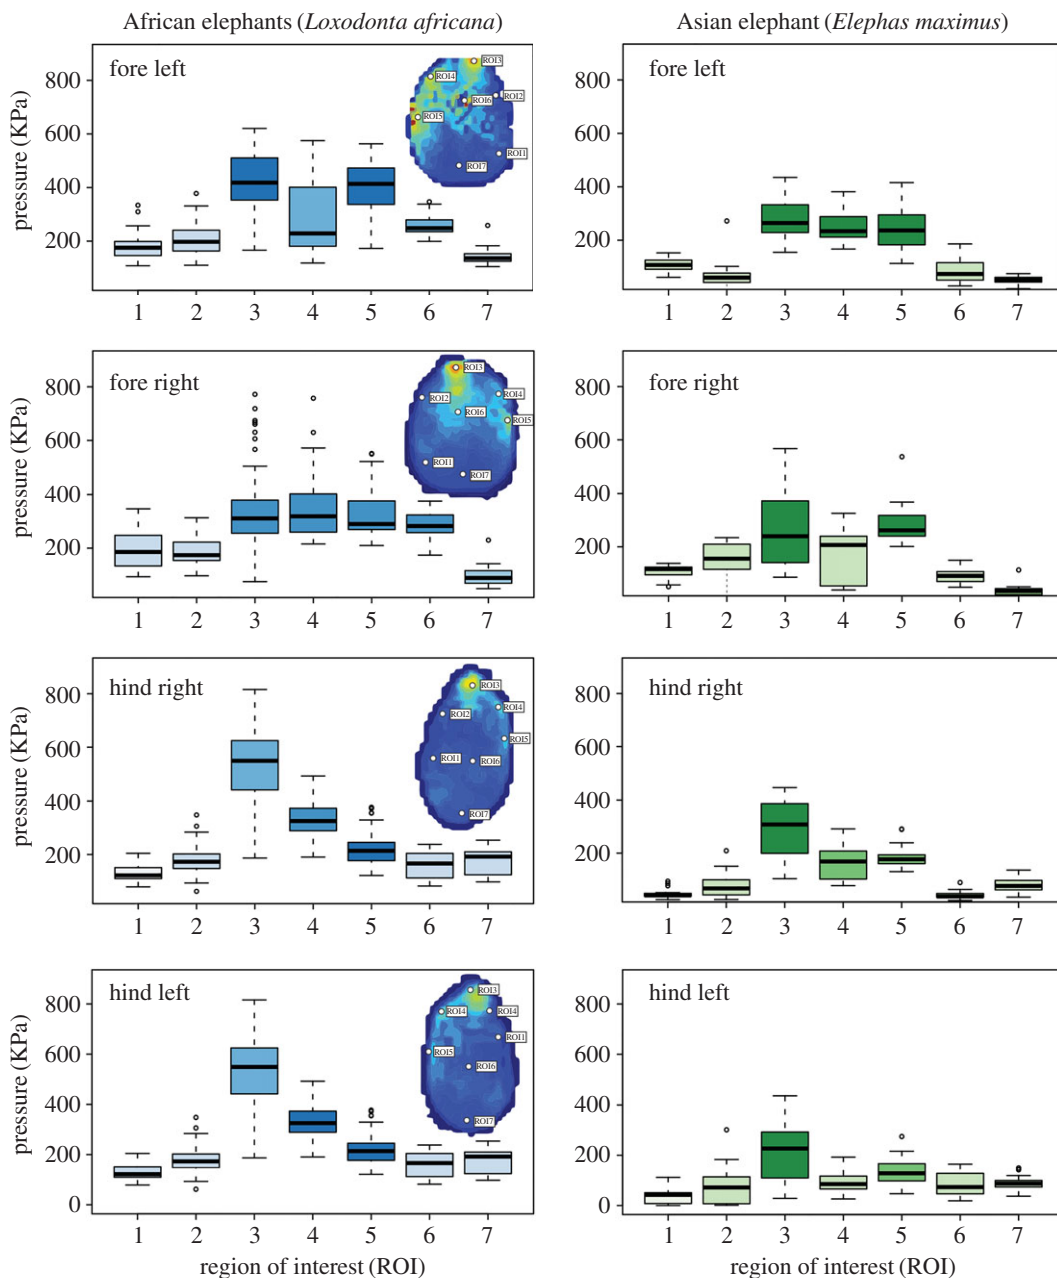

Figure 3. Pattern of mean peak pressure distributions during the whole stance phase for the feet of the African elephants (left; this study) and Asian elephants (right; [4]). Regions of interest (ROIs) are shown for each foot, and the variation among them is shown in the box plots. Where possible, we have attempted to show statistically similar ROIs through similar colour shadings. Boxes represent the median, with hinges representing the first and third quartiles. Whiskers represent the 95% CIs, and dots represent outliers.

by the significant interaction between ROI and foot, this pattern did show some variation among the feet (figure 3). ROIs 3–6 of the forefeet showed moderately higher mean peak pressures than regions 1, 2 and 7. The hind feet, however, presented the significantly highest mean peak pressures in digit III (ROI 3), with the lateral digits (ROI 4, 5) showing moderate pressures, and the medial digits (ROI 1, 2) and the central (ROI 6) and caudal (ROI 7) aspects of the sole exhibiting the lowest pressures (figures 3 and 4).

The mean peak pressures during the whole stance phase among all ROIs, feet and subjects in the African elephants were 946 kPa (electronic supplementary material, Data S2). The mean peak pressure value from the Asian elephants in Panagiotopoulou *et al.* [4] was 567 kPa after excluding Subject 1 (electronic supplementary material, Data S3), indicating that the mean peak pressures of our African elephants were almost 1.7 times those of the Asian elephants sampled.

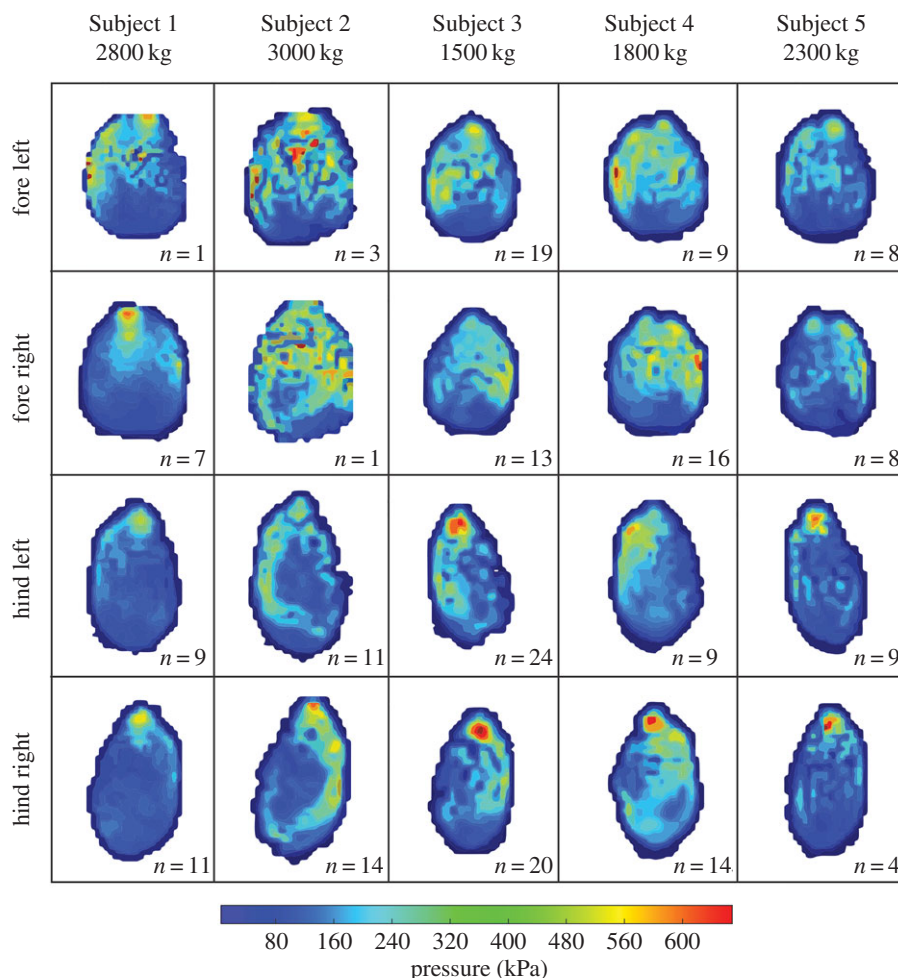

Figure 4. Means of the peak pressure patterns created from the peak pressure sample during the whole stance phase for each subject and each foot. Peak pressure patterns shown here were smoothed (using a Gaussian blur) to interpolate between pressure grid points.

The COP trajectories of the African elephant feet throughout the stance phase are shown in figure 5 (for raw COP data see electronic supplementary material, Data S4). COP traces were variable among subjects and among feet. The greatest variation was evident between the fore and hind feet. The patterns of the COP trajectories were the best conserved between the hind feet pairs, at least when COP shape was transformed via the Procrustes analysis using the function `procOPA.R` from the `shapes` package [26], with both `scale` and `reflect` set to `TRUE` (table 2). Among the untransformed data, the forefeet showed the lowest variation. Almost all of the variation between the pairs was around the medial-lateral axis, with a more predictable heel-to-toe, caudal-to-cranial movement of the COP present in all feet.

The COP comparisons between the African elephants from this study and the Asian elephants from Panagiotopoulou *et al.* [4] showed similar trajectories (figure 6). In both species, the caudal-to-cranial pattern of movement predominated, with small lateral deviations at foot impact (table 3).

4. Discussion

This study characterized locomotor pressure distributions over discrete foot regions (ROIs) in walking African elephants reared in near-wild captive conditions in Africa and compared these data with previously published data on Asian elephants [4] reared in more typical captive (zoo/park) environments in the United Kingdom. Our records of mean peak pressures corresponded to a fairly typical (if slightly slow) walk of 1.2 ms^{-1} . Pressures are expected to increase at faster speeds, although our limited samples of Asian elephants [4] at $Fr \sim 0.1$ and African elephants (this study) at $Fr \sim 0.07$ instead showed higher pressures in (slower-moving) African elephants, so across this narrow speed range at least, pressure may not change greatly. While the uncalibrated GoPro camera may have influenced the speed, Hutchinson *et al.* [21] found that elephants often self-selected similar speeds

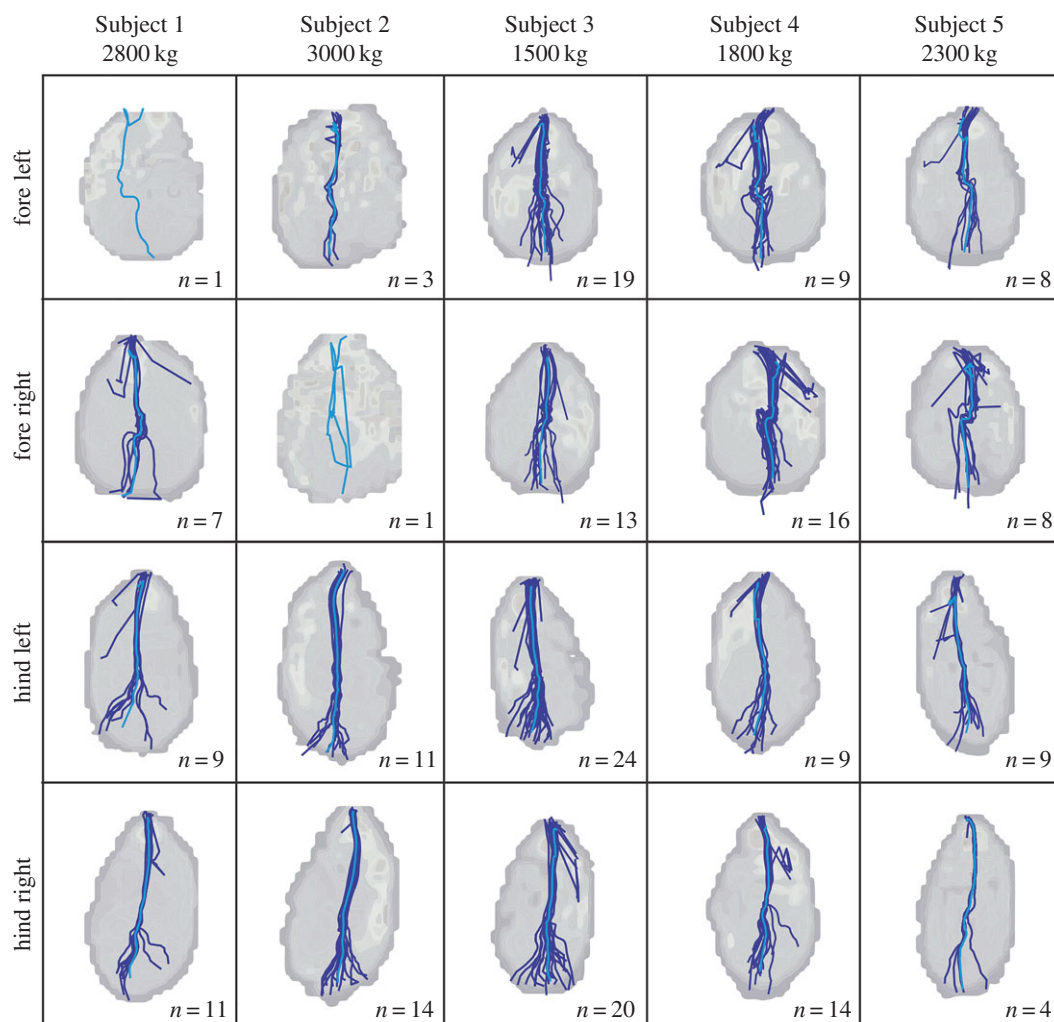

Figure 5. The patterns of the centre of pressure (COP) throughout the stance phase for each foot of each subject. Individual trials are indicated in dark blue, with the mean of all trials indicated with the lighter blue line.

Table 2. Pair-wise comparisons between different feet for the African elephant subjects. The comparison included Pearson's correlations along the cranial-caudal axis (Y_r) and the medial-lateral axis (X_r), the root mean square error (RMSE) for untransformed data, and the root mean square deviation for transformed data (RMSD).

pair-wise comparison	X_r	Y_r	RMSE	procOPA.R RMSD
FL–FR	−0.76	0.97	1.613	1.38
FL–HL	−0.53	0.98	1.797	1.15
FL–HR	−0.14	0.98	2.361	1.26
FR–HL	0.21	0.91	2.934	1.91
FR–HR	0.21	0.91	2.621	1.95
HL–HR	−0.59	0.99	2.219	0.39

($Fr \sim 0.1$), which may seem slow but larger animals tend to choose relatively slower speeds as per [32]. We found that during slow walking both species showed similar COP trajectories. We also recorded the highest mean peak pressure values during the whole stance phase for the African species on the third, fourth and fifth digits of both the fore and hind feet, yet pressures on the forefeet were higher, related to bearing more weight (figure 3). This finding is similar to the Asian elephants' results from Panagiotopoulou *et al.* [4] (figure 3).

Figure 6. Comparison between the mean COP patterns of the African elephants (red) and the Asian elephants (orange; cf. [4, fig. 9]). Data for the Asian elephants were transformed via Procrustes analysis in R using the function `procOPA.R` from the `shapes` package [25], with both `scale` and `reflect` set to `TRUE`. *L.a* and *E.m* respectively refer to *Loxodonta africana* and *Elephas Maximus*.

Table 3. Pair-wise comparisons between African and Asian elephants using transformed values of COP paths. Values were transformed via Procrustes analysis in R.

pair-wise comparison	χr^{\dagger}	γr^{\dagger}	RMSE [†]	RMSD
FL	0.17	0.99	0.548	0.77
FR	0.52	0.96	0.852	1.21
HL	0.42	0.99	0.752	1.06
HR	0.84	0.99	0.858	1.21

While the ROI approach is a useful technique to measure pressures on specific foot regions, it overlooks intra-region variability by assuming that all zones are functionally independent. Our sensitivity analysis showed a significant interaction between the topological location of each ROI and the pressure magnitudes (figure 2), confirming that the ROI approach underestimates intra-region variability and can influence pressure magnitudes, making the inclusion of sensitivity analysis to measure the degree of variation an essential prerequisite. Nevertheless, this limitation did not influence the credibility of this study, which is focused on the overall similarities and differences in pressure patterns between the two samples of elephants, rather than the exact pressure magnitudes.

Direct comparisons of pressure magnitudes between the Asian and African elephant species showed an approximately $1.7\times$ increase in mean peak pressures in the African species, compared with the Asian participants from Panagiotopoulou *et al.* [4]. However, it is likely that this difference is at least partly caused by disparities in the body masses of the animal participants and the equipment differences between the two experiments. Some of the Asian and African participants had similar body masses, yet the African sample had a higher number of spatially and temporarily complete steps due to the larger width and length of the pressure plates. Taking sample numbers from each individual into account results in a weighted average mass of 2060 kg for African elephants, but only 1156 kg for the Asian elephants, owing to the largest individuals of the latter species being represented by the fewest trials [4]. This difference probably explains the variation in the absolute pressure magnitudes between the studies. Given that body mass values for African elephants here were estimates only, we were

reluctant to provide body mass-corrected values for comparison. The differences in the foot management of the two species may also have influenced pressure distributions, yet more rigorous comparisons of captive substrates and foot-trimming protocols using controlled experiments are needed for statistically sound conclusions to be drawn and strongly evidence-based animal husbandry guidelines to be established.

The pressure pattern comparisons between the two species showed that both African and Asian elephant samples endured the greatest pressures on the forefeet. In addition, the mean peak pressures for both samples were concentrated on the lateral toes (digits iii, iv, v), where foot diseases are usually found, and the minimum pressures were on the medial toes and under the digital cushion [4, figs 5 and 8]. This finding supports our hypothesis that the two species' samples will have similar foot pressure patterns mainly due to their similarities in foot anatomy [23] and locomotor mechanics [21,22]. Anatomically, differences in the feet of the two species are mainly restricted to the number of toenails [20]. While African elephants tend to have four toenails on their forefeet, Asian elephants have five toenails on the manus and four on the pes [19]. Biomechanically, the differences between general limb function in African and Asian elephants appear to be negligible [21,33].

The similarities in locomotion between the two species are further supported by the similarities in the COP trajectories we measured in this study (figure 6). Overall, both species loaded their feet more laterally at impact, shifted their weight medially at mid-stance and the COP followed the mid-central sole during toe-off. Thus, the lack of peak pressures on the caudal part of the foot (around the heel) can be attributed to the fact that elephants minimized heel contact while walking, concentrating pressures on the front part of their feet. It has been hypothesized that the pressures on the central part of the foot are minimal due to the presence of the compliant fat pad that fills the space behind the toes to evenly distribute locomotor stresses across the central part of the sole, and potentially acts as a venous pump [1,4,34].

Elephants often need to be kept in captive enclosures for protection from poachers or other threats, as well as for touristic and educational purposes. Our current and previous [4] studies have shown that elephants kept in captive environments with natural substrates that may imitate the diversity of their natural habitats concentrate mean peak pressures on the lateral digits (regardless of species) and maintain the lowest pressures around the fat pad. Captivity in enclosures with hard ground such as concrete or tarmac may prevent animals from moving their distal limb joints and stretching various connective tissues the same ways they can in more wild conditions (e.g. [19]). As a result, the locomotor pressures on their lateral digits may increase and thus pathogenesis of foot diseases might, in some circumstances, be accelerated (e.g. [14,17]). Despite some differences in management regimes and other aspects of the elephants in the two samples that we have focused on in this study, we found some remarkable similarities in how these elephants load their feet. However, we also found more subtle (or ambiguous) differences whose causes are too uncertain to draw conclusions from.

Our sample size (as in [4]) was admittedly small; nevertheless, despite the small sample size there was sufficient statistical power to infer differences among the ROIs. Null results including ANOVA interactions could have been secondary to small sample size and inadequate statistical power, but because our hypotheses did not pertain directly to those effects we believe that sample size and power were adequate for this study. There are no currently published data that indicate the optimal sample size to use in locomotor studies on foot pressures. Sample size depends largely on a number of factors including variability of the traits measured and accessibility of the animal participants. In this study, we have measured the maximum number of elephants available. Comparisons of small numbers of individuals are of course limited statistically, constituting more of a descriptive/anecdotal sample than a truly robust one in statistical terms, but we have reported the variability in our data, and are conservative with our comparisons and conclusions. We seek to describe broad patterns of movement in these species, and describe interesting similarities and differences. Larger sample sizes of more elephants with controlled environments and related parameters, maximizing comparability of those samples, are needed to fully test how different management regimes, habitats, ages, body weights, species' evolutionary backgrounds or other factors influence the normal and pathological functioning of elephant feet, which could lead to future improvements in elephant welfare.

Despite its limitations, this study is the first to show that, regardless of species, captive elephants reared in outdoor spaces with natural substrates and sufficient space for the animals to remain athletic, load the most the lateral aspect of their feet while walking. This loading pattern coupled with the reduced pressure below the fat pad seems to be an effective mechanism for large-bodied mammals to maintain foot functional integrity and potentially balance while carrying their large body mass. Nevertheless, while this mechanism works well for animals reared in wild and semi-natural habitats, it may not

be effective in captive conditions where unnatural substrates predominate [11–14]. To date, it is not clear how hard substrates can disrupt the mechanics of elephant feet but elephants kept in confined spaces for long hours or housed in small yards with hard substrates (asphalt and concrete) are more prone to foot disease than their counterparts reared in semi-wild environments [14,18,19]. Confined environments with surfaces covered in lingering faeces and urine can exacerbate infections around the pads and nails [18]. We speculate that captivity-induced foot infections around the fat pad will influence the compliance of the fat pad tissue and reduce its ability to dissipate locomotor pressures. An infected or cracked fat pad will thus potentially increase loading on the distal part of the lateral digits of the elephant's foot and accelerate foot disease.

Foot disease in elephants is not always detectable at its early stages using physical examinations of the foot. However, the techniques used and the hardware developed in our study (also [4]) could provide a new diagnostic measurement that can be integrated by veterinarians or keepers to monitor elephant foot health, in the same way that podiatrists use pressure mapping to diagnose and treat human foot disorders. Elephants, which trim their feet naturally by walking in diverse substrates, are expected to load more the lateral aspect of their foot at impact and keep pressures low below the fat pad. Changes in the COP trajectories, patterns and magnitudes within individuals may be indicative of pain or early stages of foot disease. The use of our proposed methodology to regularly monitor foot pressure trajectories and magnitudes in captive elephants might allow animal keepers to detect abnormalities at early stages (when foot problems are not evident with physical examination) and create subject-specific foot management protocols that can prevent or slow down disease progression. Such protocols could include different trimming techniques for captive elephants. Trimming is a popular foot care approach to remove any cracks and divots in cases when elephants walk in less natural habitats. Nevertheless, trimming protocols vary and their effect on the foot function is still unknown. This is particularly uncertain when trimming is conducted on the whole sole rather than on concentrated areas. Better monitoring of the foot pressures in captive elephants using pressure platforms may allow keepers to decide upon subject-specific trimming protocols that will remove cracks and overgrowths but will not affect foot mechanics. In addition, trimming could be used in combination with orthotics in pathological cases to shift the load away from the diseased digits. With foot disorders being one of the most debilitating afflictions affecting the health and well-being of captive elephants, our study could help guide future animal husbandry and foot care techniques and thus contribute to improvements in those areas.

5. Conclusion

Using custom-written software, we analysed the foot pressure distributions and COP trajectories between African and Asian elephants reared on natural substrates but with different foot care protocols. We have shown that COP trajectories and mean peak pressure patterns do not differ (admittedly with a descriptive rather than statistically robust sample) between species, further supporting their similarities on locomotor behaviour and mechanics. Variations in pressure magnitudes can be due to age, body mass and measurement variations, among other factors, thus it is not possible to conclude from this study the effect of different foot management approaches or substrate habitats on the elephant foot pressure. Our study is also the first to show that foot pressures in elephants reared on natural substrates are concentrated on the lateral part of their foot. We speculated that exposure to hard substrates and captivity in constrained environments may upset the natural mechanics of the foot, increase foot pressures and induce foot disease on the lateral digits, which are more prone to pathogenesis (also see [4]). We anticipate our data and methods might be used as controls to monitor pressure patterns in captive elephants with the scope to detect abnormalities at early stages and improve elephant husbandry.

Ethics. Animal experiments were approved by the University of Queensland Animal Ethics Committee (SBS/309/13/REG).

Data accessibility. All raw data are reported as the electronic supplementary material.

Authors' contribution. O.P. designed, conceived and coordinated the study, was involved in the design of the hardware, collected the experimental data, assisted in the processing of the data and prepared the first draft; T.C.P. wrote the software for data processing and participated in the design of the study; M.D. processed the foot pressure data under the supervision of O.P.; M.C.H. and S.H. collected the data with O.P.; J.R.H. assisted in the design of the study and the preparation of the first draft; C.J.C. carried out the statistical tests. All authors edited the drafts and gave final approval for publication.

Competing interests. Sean and Michael Hensman are the owners of the Adventures with Elephants safari park, PO Box 1500, Bela Bela 0480, Limpopo, South Africa and the Founder of the Rory Hensman Conservation and Research Unit (RHCRU). Olga Panagiotopoulou is a Research Affiliate with RHCRU.

Funding. This research was funded by School of Biomedical Sciences, Faculty of Medicine and Biomedical Sciences, The University of Queensland, Project grant no. (606441) to O.P.

Acknowledgements. We thank all keepers from the Adventures with Elephants in Bela Bela for their endless support and help during data collection and all elephants for participating in our study. We also thank Glen Lichtwark from the University of Queensland for his assistance and very useful discussions during data processing. We are grateful to Zebris Medical GmbH for the manufacture of the pressure plates and Anita Hayburn from Australian Customs Professionals for her assistance with the shipping of the equipment to South Africa. We thank the two anonymous reviewers for their constructive criticisms of this manuscript.
