Abstract Myelin is a multilamellar membrane structure primarily composed of lipids and myelin proteins essential for proper neuronal function. Since myelin is a target structure involved in many pathophysiological conditions such as metabolic, viral, and autoimmune diseases and genetic myelin disorders, a reliable myelin detection technique is required that is equally suitable for light- and electron-microscopic analysis. Here, we report that single myelinated fibers are specifically stained by the gold phosphate complex, Black gold, which stains myelin in the brain, spinal cord, and peripheral nerve fibers in a reliable manner. Electron-

microscopic and morphometric analyses have revealed that gold particles are equally distributed in the inner, compact, and outer myelin layers. In contrast to Luxol fast blue, the gold dye stains proteinase-sensitive myelin structures, indicating its selective labeling of myelin-specific proteins. Aiming at defining the target of gold staining, we performed staining in several mouse myelin mutants. Gold complex distribution and myelin staining in MBP^{-/-}/shiverer mouse mutants was comparable with that seen in wild-type mice but revealed a more clustered Black gold distribution. This gold staining method thus provides a sensitive and specific high-resolution marker for both central and peripheral myelin sheaths; it also allows the quantitative analysis of myelinated fibers at the light- and electron-microscopic level suitable for investigations of myelin and axonal disorders.

Introduction

Myelin in the central nervous system (CNS) is an essential structure for the proper functioning of neuronal signal transmission. This specialized structure surrounding axons exhibits a multilamellar, spirally wrapped extension of the plasma membranes originating from oligodendrocytes in the CNS and of Schwann cells in the peripheral nervous system (PNS; Morell et al. 1994). Serving as an axonal insulator, myelin sheaths allow saltatory impulse conduc-

tion and thereby reduce energy and space expenditure by the nerve cell (Henderson et al. 2001). However, myelin also exhibits growth-inhibitory properties for axons that have been shown to contribute to lack of functional recovery following neurotrauma (for a review, see Yiu and He 2006). The clinical significance of myelin is reflected by its disturbance in CNS pathologies such as immune-mediated, virus-mediated, metabolic, and inherited demyelinating diseases (Lazzarini 2004).

Over 70% of the dry weight of myelin consists of lipids (Cammer and Norton 1976), and the remainder comprises myelin-specific proteins such as myelin-associated glycoprotein (MAG), oligodendrocyte-myelin glycoprotein (Omgp), myelin basic protein (MBP), proteolipid protein (PLP), 2',3'-cyclic nucleotide phosphodiesterase, protein P₀, PMP-22, and reticulon-4 (Rtn-4)/Nogo (Campagnoni and Macklin 1988; Smith 1992; Taylor et al. 2004; Dumont et al. 2007). A common approach for the detection of myelin is antibody-based immunocytochemistry staining for surrogate marker proteins of oligodendrocytes and myelin-specific proteins. However, the disadvantage of this approach is the requirement for specific antibodies suitable for immunostaining, and hence, the dynamic expression of the antigen of interest during the course of development and injury impacts staining results. A conceptually different approach aims to detect the specific lipid composition of myelin. Thus, many existing methods for myelin staining are based upon a high affinity to myelin lipids and non-soluble phospholipids: diamine silver (Gallyas 1979), Sudan black (Meier 1976), potassium dichromate hematoxylin stain (Weigert 1884), Oil red O, or Luxol fast blue (LFB; Kluver and Barrera 1953). However, when single fiber resolution is required, these staining approaches do not meet the necessary contrast and resolution quality. For these aspects, silver staining techniques first developed by Gallyas (1979) are utilized and remain, with modifications, the standard (Pistorio et al. 2006). Other than its applicability for postembedding procedures, the disadvantages of this technique are the unpredictability of the signal-to-noise ratio (time of development and background), the significant time input, and the complex staining procedure.

By comparison, gold-based staining techniques represent an alternative that meets the criteria of high resolution and reproducibility (Meier et al. 2003, 2004; Schmued and Slikker 1999). In this study, we have performed a morphometric and ultrastructural analysis of myelin in the PNS and CNS by using an improved gold-based staining method (product launched as Black gold; BG) and have investigated the target of gold-particle staining. We show that BG stains all myelin layers with the same affinity (inner, compact, and outer myelin layers), independently of the axonal diameter. In addition, the structures showing affinity for BG are mostly proteinase-sensitive, indicating that the gold complex stains

myelin-specific proteins or protein-lipid complexes. To unravel the molecular target of gold affinity further, we have tested various mouse strains deficient for myelin proteins such as MAG, NogoA (Rtn-4) and shiverer/MBP.

Our data reveal that BG stains myelin sheaths of mature axons in the adult brain and myelin in peripheral nerves. Furthermore, the gold stain detects subtle alterations in myelin in genetically modified animals such as in shiverer mice. Thus, we provide here a simple method for staining myelin at high resolution and contrast at the single fiber level suitable for the detection of myelin under neuropathological conditions.

Materials and methods

Animals and tissue preparation

Wistar male rats (200–300 g body weight) and adult wild-type and mutant mice (Shiverer/MBP^{-/-}, MAG^{-/-}; NogoA^{-/-} (Rtn-4), MAG/NogoA double mutants) housed under standard laboratory conditions. Animals were deeply anesthetized with an overdose of the anesthetic mixture of Ketanest (Gödecke/Park-Davis, Germany), Rompun (Bayer, Germany), and Ventranquil (Sanofi-Ceva, Germany) and transcardially perfused with 200 ml saline followed by 250 ml 4% paraformaldehyde (PFA) containing 0.2%–2% glutaraldehyde dissolved in 0.1 M phosphate buffer (PB) for gold phosphate (BG) staining. The tissue was postfixed in 20% sucrose in 4% PFA solution for 2 days, shock-frozen in the gaseous phase of liquid nitrogen, and stored at –80°C. Animals used for LFB staining were decapitated, after which the brains, sciatic nerves, spinal cord, kidney, and liver were immediately removed, frozen, and stored at –80°C. All sections were cut on a cryostat microtome (Leica) at a thickness of 20–50 µm.

Myelin staining technique with gold particles

A 0.2% working solution of gold chloride (AuCl₄; Merck, Darmstadt, Germany) or gold phosphate (BG granulate; Histo-Chem, Jefferson, USA) was prepared in 0.9% NaCl, briefly heated at 60°C, and, for full equilibration, stored in the dark overnight at room temperature. Cryocut sections were washed with 0.1 M PB and subsequently stained with 0.2% gold phosphate solution, warmed to 45–60°C, for 15 to 40 min according to Jabonero (1953). To intensify the staining, the sections were incubated in 0.2% potassium tetrachloroaurate (Sigma-Aldrich Chemie, Germany) dissolved in 0.9 % NaCl for 15 min. For fixation, sections were incubated for 3 min in 2% sodium chlorate (Merck) dissolved in 0.9% NaCl. This procedure proved suitable for the myelin staining of free-floating sections, giving the same results as on sections attached to slides, and allowed counterstaining to be performed. Sections were stained for

1.5 min in a 0.1% acetic acid solution of 0.4% malachite green (Sigma-Aldrich Chemie), rinsed in distilled water for 1 min, and differentiated in 70% ethanol to remove background staining. In between each step, the sections were carefully rinsed three times in 0.1 M PB for 5 min. The free-floating sections were mounted on SuperFrostPlus slides (Menzel-Glaeser, Berlin, Germany), air-dried, dehydrated in graded ethanol, cleared in xylene, and coverslipped with Entellan (Merck).

LFB staining

The tissue was postfixed in -20°C cold methanol for 2 min and then transferred to an ethanol/acetic acid mixture (96%/4%) for 5 min. Sections were stained in a 0.1% LFB solution dissolved in the same ethanol/acetic acid mixture at 60°C for 3 h, rinsed in 96% ethanol, postfixed in 0.05% Li_2CO_3 for 1 min, washed in 70% ethanol for a few seconds, counterstained with Harris' hematoxylin for 1–2 min, dehydrated in graded ethanol, and coverslipped with Entellan (Merck).

Protein digestion

Sections were incubated with 50 $\mu\text{g/ml}$ proteinase K (Boehringer, Germany) dissolved in 0.01 M TRIS (pH 8.0) and 0.1 % SDS at 37°C for 40 min or with 0.25 % trypsin in a dilution buffer containing 0.04% KCl, 0.22% NaHCO_3 , 0.68% NaCl, 0.1% glucose and then stained with BG or LFB as described above.

Electron microscopy

BG sections were osmicated (1% OsO_4 in 6.84% sucrose/PB for 5 min), dehydrated in graded ethanol, and flat-embedded in Epon between silane-coated slides. Ultrathin sections were cut on a Reichert Ultratome (Germany), mounted on single-slot grids coated with Formvar film, and stained with lead citrate and uranyl acetate. A Zeiss EM 900 electron microscope was used for examination, and microphotographs were taken with a digital camera (Zeiss, Jena, Germany).

Quantification of myelinated fibers and axonal diameters

For densitometric measurements of the myelinated fibers, we used a computerized videodensitometry system (MetaMorph, Universal Imaging, Downingtown, Pa., USA). A visually established pixel intensity threshold was set to remove the unlabeled portion of the image. Statistical analysis was performed with the Mann-Whitney *U*-test (StatViewII, Abacus, USA). The levels of significance were set at $*P<0.05$, $**P<0.01$, and $***P<0.001$.

Results

Myelinated fibers in CNS detected with gold staining

First, we assessed BG staining on brain sections of adult rats. BG staining specifically appeared as red-brown coloration in white matter areas at low resolution, whereas gray matter areas were stained to a lower extent, in parallel with their myelin content (Fig. 1). The BG staining suitably reflected the myeloarchitecture of the CNS, staining the main white matter tracts such as corpus callosum and anterior commissure (Fig. 1a, b). In addition, higher magnification revealed single thin gold-positive fibers in the cortex and olfactory bulb, whereas neuronal cell bodies remained unstained (Fig. 1b–d). In the cortex, the majority of stained myelinated axons were vertically oriented. BG stain uncovered cortical neurites intermingled with horizontally running fibers, which formed a fine dense network (Fig. 1e, f). Staining of the entorhino-hippocampal formation visualized both the afferent and efferent axonal projections, such as the perforant path, alveus, and the fimbria-fornix system (Figs. 1, 2). Staining intensity varied in between the various hippocampal subfields reflecting the laminar organization of the fiber projections, e.g., the strong gold labeling in the stratum lacunosum-moleculare of the cornu ammonis 1 (CA1) and stratum radiatum of CA1–CA3 (Fig. 2a). Myelinated fibers formed a dense network in the neuropil and were often observed surrounding the neuronal somata of the granule and pyramidal cells (Fig. 2b). Electron-microscopic analysis revealed single gold particles distributed along myelin sheaths (Fig. 2c). Other subcellular structures and organelles, such as mitochondria, nuclei, or endoplasmic reticulum, remained unstained (Figs. 2, 3). Subsequent quantitative analysis revealed that gold particles surrounded mature axons and were equally distributed in the inner, compact, and outer layers of the myelin spirals (33 ± 8 particles/ $5\ \mu\text{m}^2$; mean \pm S.D., Mann-Whitney *U*-test). Gold particles were also located along myelin sheaths surrounding axons of various diameters ranging from 120 nm to 260 nm, whereas dendritic processes were BG-negative.

We subsequently analyzed spinal cord sections stained with this dye. Gold-positive fibers could be found in all white matter fiber tracts with prominent staining of descending fibers (i.e., fasciculus gracilis, cerebrospinal and anterior spinothalamic tracts; Fig. 3). Myelinated fibers from the dorsal root entering the gray matter were also positively stained for BG (Fig. 3b). Ultrastructural analysis confirmed the nature of gold-positive fibers as being myelinated (Fig. 3c, d), with gold particles being distributed irregularly along the myelin sheaths without preference for the inner, compact, or outer layers of myelin spirals (Fig. 3c, d).

Myelinated fibers in PNS detected with gold staining

Since the composition of peripheral myelin differs remarkably from that found in the CNS (Uyemura et al. 1995; Avila et al. 2007), we have addressed the question as to whether BG is also a suitable dye for myelin detection in the PNS. We therefore stained the sciatic nerve with BG, by

applying the same procedure and tissue treatment as above. In the peripheral nerves, the distribution of the gold stain was comparable with that found in CNS myelin. Gold particles were clustered around all myelin sheaths (inner, compact, and outer loops of myelin spirals), whereas the axonal plasma and the extracellular space were almost free of any staining (Fig. 4). Within the myelin structure, non-

compact myelin such as Schmidt-Lanterman incisures and Schwann cell cytoplasm were almost devoid of BG particles (Fig. 4). Overall, BG staining in peripheral myelin revealed almost the same contrast and staining intensity as that found in CNS myelin structures.

Target of myelin gold-particle staining

To define the molecular target of gold staining, we performed staining of various organs that do not contain

myelin components, i.e., muscle, kidney, and liver. None of these tissues showed significant BG staining compared with samples from CNS or PNS (Fig. 5a, b). We therefore assumed that BG stains distinct myelin proteins specifically present in peripheral and central myelin structures. To test this, we utilized brain sections in which proteins were, at least in part, diminished by proteinase K and trypsin digestion. In such sections, BG staining was completely abolished (Fig. 5c). To control for these results, we used LFB, a dye with high affinity for non-soluble phospholipids

Fig. 3 Light and ultrastructural distribution of gold particles in the spinal cord. **a, b** Longitudinal and transversal sections, respectively, of the spinal cord at the thoracal level stained with BG. BG-positive fibers are found in all white matter areas of the spinal cord (*d* dorsal columns, *il* intermediate layer, *v* ventral columns). **c, d** Ultrastructural analysis of the spinal cord reveals BG particles (*arrows*) distributed over the myelin sheaths (*ax* axoplasm). **d** BG-positive fibers entering the gray matter arise from the dorsal roots (*top* dorsal columns of the spinal cord, *stars* mitochondria). (Kluver and Barrera 1953). As expected, this common myelin marker was unaffected by proteinase pretreatment (Fig. 5d). These data demonstrate that BG stains proteins or protein complexes specifically present in peripheral and central myelin.

These data prompted us to study the gold staining of brain sections from mice mutant for myelin proteins. Thus, in order to define further the molecular target of gold affinity present in myelin, we investigated sections from homozygous shiverer mouse mutants that lack one major myelin protein component, viz., MBP (Dupouey et al. 1979; Kirschner and Ganser 1980). In shiverer/MBP-deficient mice, BG staining was still detectable with the same intensity in white matter areas (Fig. 6). However, in contrast to the regular axon-like staining pattern of the white matter of the spinal cord from wild-type mice, we observed irregular, discontinuous, and more concentrated staining and a more clustered distribution of BG stain in shiverer mice (Fig. 6). This could reflect the light-microscopic correlate of reduced myelin lamellae sheaths and the membranous debris as found at the ultrastructural level in shiverer animals (Bird et al. 1978; Privat et al. 1979; Kirschner and Ganser 1980; Rosenbluth 1980).

However, since BG stain still remained in MBP-deficient mice, myelin proteins other than MBP are probably the high-affinity targets of gold particles.

Discussion

In this study, we have investigated, with an improved gold staining procedure, regional distinctions in myelinated fiber distribution in the PNS and CNS and in shiverer mutant mice. We have been able to show that gold dye is suitable for specifically and selectively staining myelin structures in the CNS and PNS with high resolution at the level of single fibers, facilitating axonal analysis at the light and ultrastructural levels.

Studies of myelin in the brain by using histochemical techniques have to be interpreted with some caution. Low signal-to-noise ratio, intensity, contrast, and considerable variability in staining and exposure time and the unknown molecular substrate that is being stained are some of the possible pitfalls and limitations. In addition, many histochemical techniques do not reliably distinguish between normal and pathological myelin structures. In addition,

Fig. 4 Distribution of gold staining in the peripheral nervous system. **a** Longitudinal section of sciatic nerve stained with BG. Particles of BG (arrows) are found in myelin sheaths along the nerve fibers but not in the axoplasm (ax) or extracellular space (arrowhead cytoplasmic Schwann cell process forming an inner mesaxon). **b** Higher magnification of peripheral myelin sheaths. Gold particles are found in all aspects of the myelin spirals. Magnification: $\times 30,000$ (a), $\times 40,000$ (b)

single fiber resolution is not achieved by some myelin staining procedures such as LFB, and therefore these techniques are insensitive for the assessment of dynamic and subtle axonal pathologies. Here, we have performed sets of experiments with the modified aurohalophosphate BG. Ultrastructural analysis has revealed that the gold complex stains inner, compact, and outer myelin layers with the same affinity, whereas dendritic processes do not stain for gold particles. Furthermore, BG stains all layers of myelin sheaths, independently of axonal diameter, in agreement with our previous studies on hippocampal development (Meier et al. 2003, 2004). In addition, this gold staining method is also applicable to myelin staining in the PNS. Here, we have found that gold grains are centered around all myelin sheaths with same preference as that seen in CNS myelin samples, suggesting that the components with the same affinity for gold particles must be present in both CNS myelin and PNS myelin.

These results have prompted us to test which components are being stained by gold particles. Pretreatment of brain sections with trypsin or proteinase K prevents BG

staining. Conversely, the staining pattern of the phospholipid specific dye LFB is not affected by these treatments. These findings are not surprising, since the target to which LFB binds with high affinity are non-soluble phospholipids, which are resistant to this treatment (Kluver and Barrera 1953). However, our findings also indicate that BG-positive structures are proteinase-sensitive. These membrane structures may comprise myelin-specific proteins or specific lipid-protein complexes that are present in myelin and that are disrupted after protease treatment. In the first case, these myelin protein components must be located in all myelin layers, or their distribution overlaps in all myelin compartments, since gold complex deposits are found virtually in all myelin layers. This is of relevance since myelin proteins have various localizations. For instance, MAGs and NogoA are mostly located in the inner and outer loop of myelin layers, respectively, and myelin oligodendrocyte glycoprotein in the outer loop (Trapp et al. 1989; Huber et al. 2002). In contrast, MBP, PLP, and P₀ are predominantly found in compact central and peripheral myelin. We speculate that MBP might be a target structure recognized by gold particles since it is present in CNS myelin and PNS myelin, in contrast to CNS myelin proteins such as Rtn4/NogoA and Omgp. Thus, we have tested various mouse myelin mutants. Brain samples from NogoA^{-/-}, MAG^{-/-}, and NogoA^{-/-}/MAG^{-/-} double-mutant mice show almost no differences compared with wild-type littermates (data not shown) indicating that either these two proteins do not have high affinity for gold particles or do not make up the majority of gold-labeled myelin proteins, and thus, their genetic lack is below detection levels. Shiverer mice, which are mutant for the MBP protein, might be devoid of staining and should serve as a negative control for target identification of gold labeling. However, the overall staining pattern is not altered, although a slight alteration in staining intensity and a clustered distribution of gold-stained fibers are visible at the light microscopic level. These changes in BG staining in shiverer mice might reflect the described altered myelin membrane lamellae and membrane debris found at the ultrastructural level (Bird et al. 1978; Privat et al. 1979; Kirschner and Ganser 1980; Rosenbluth 1980). Central and peripheral myelin is composed of several proteins such as PLP (Campagnoni et al. 1976), MAG (Li et al. 1996; McKerracher et al. 1994; Mukhopadhyay et al. 1994), P₀ (Greenfield et al. 1973), Omgp (Wang et al. 2002; Kottis et al. 2002), chondroitin-sulfate proteoglycans (Dou and Levine 1994; Niederost et al. 1999), and Rtn-4/NogoA (Chen et al. 2000; GrandPre et al. 2000; Prinjha et al. 2000), which could all be candidate targets with different affinity for the gold stain. Since gold particles are distributed all over the central and peripheral myeloarchitecture, the gold stain probably has high affinity to more

Fig. 5 Gold particles are highly specific for myelin and stain proteinase-sensitive myelin components. **a** BG-treated cross sections of kidney reveal no staining. **b** BG-positive bundles of fibers in the abducens nerve (arrows single fine myelinated axons). **c** Following proteinase K digestion of a brain section, almost no fibers are stained for BG (arrows slight BG-positive staining). **d** Positive staining with Luxol fast blue (LFB) still appears after proteinase K digestion (arrowheads border of white matter). LFB staining appears in dark blue (upper region) and the gray matter in light blue (lower region). Hematoxylin-positive nuclei appear as dark blue spots. Bars 10 μm (**a**; applies also to **b**), 50 μm (**d**; applies also to **c**)

then one myelin-specific protein component present both in CNS and PNS. Future studies will concentrate on the investigation of gold staining on two major myelin protein components of the PNS and CNS. Analysis of $PLP^{-/-}$ and $PO^{-/-}$ mice should help to define whether lack of these major myelin protein components correlates with an altered gold-particle distribution and intensity at the quantitative level. Indeed, a prerequisite for a novel dye becoming a standard staining method for myelin pathologies would ideally be knowledge of its target and its intensity correlation with disease progression. In myelin disorders, myelin proteins might be mislocated or altered in abundance, or myelin spirals might be disturbed with regard to

their thickness or ultrastructure. We thus need to show that BG can detect all these features.

Taken together, these data indicate that the method described here is suitable for the detection of myelin and myelinated axons in the CNS and PNS. In addition, the gold stain detects the myelin sheaths of degenerating and newly emerging axons (Meier et al. 2004). Thus, this gold staining method allows for a wide range of applications ranging from developmental to regeneration studies. In summary, we provide here a staining method with a reliable general myelin dye that is suitable for histochemical staining concomitantly at the light and ultrastructural level.

Fig. 6 Distribution of gold-phosphate-positive fibers in the shiverer mouse ($MBP^{-/-}$) mutant. Longitudinal sections of the spinal cord at the thoracal level of a wildtype (WT) mouse (**a**) and a shiverer (SHI) mouse (**b**) stained with gold phosphate. BG-positive fibers are found in all white matter areas of the spinal cord (arrows scattered but concentrated gold staining). Bar 15 μm (applies also to **a**)
