SHORT COMMUNICATION

The alternative Pharaoh approach: stingless bees mummify beetle parasites alive

Abstract Workers from social insect colonies use different defence strategies to combat invaders. Nevertheless, some parasitic species are able to bypass colony defences. In particular, some beetle nest invaders cannot be killed or removed by workers of social bees, thus creating the need for alternative social defence strategies to ensure colony survival. Here we show, using diagnostic radioentomology, that stingless bee workers (*Trigona carbonaria*) immediately mummify invading

adult small hive beetles (*Aethina tumida*) alive by coating them with a mixture of resin, wax and mud, thereby preventing severe damage to the colony. In sharp contrast to the responses of honeybee and bumblebee colonies, the rapid live mummification strategy of *T. carbonaria* effectively prevents beetle advancements and removes their ability to reproduce. The convergent evolution of mummification in stingless bees and encapsulation in honeybees is another striking example of co-evolution between insect societies and their parasites.

Introduction

Social insects live in colonies exploited by parasites which feed on stored food or brood (Roubik 1989; Schmid-Hempel 1998), generating the need for efficient defence mechanisms (Breed 2003; Breed et al. 2004, 2007; Lehmborg et al. 2008). Parasitizing beetles pose particular difficulties for social insects because their exoskeletons protect them from direct primary defence strategies such as biting or stinging. The small hive beetle (SHB), *Aethina tumida* (Coleoptera: Nitidulidae), is such a parasite. It scavenges honeybee (*Apis mellifera*) colonies endemic to sub-Saharan Africa (Lundie 1940; El-Niweiri et al. 2008; Neumann and Ellis 2008) and has become an invasive species with established populations in North America and Australia (Neumann and Ellis 2008). SHB invade nests to feed on brood, stored food or dead bees (Lundie 1940; Schmolke 1974; Neumann and Elzen 2004; Spiewok and Neumann 2006a) often causing complete destruction of nests, especially from their feeding larval stages (Neumann and Elzen 2004). Although adult SHB are

vigorously attacked by workers (Elzen et al. 2001), they usually bypass the bees' nest entrance defences and remain difficult to kill or eject due to their hard exoskeleton and defence behaviours (Neumann et al. 2001; Neumann and Elzen 2004). Cape honeybees, *A. m. capensis*, display alternative defence mechanisms by encapsulating small hive beetles in tombs made from resin (Neumann et al. 2001; Ellis et al. 2003). Despite the lack of co-evolution between host and parasite, European honeybees also encapsulate small hive beetles (Ellis et al. 2003) suggesting that encapsulation appears to be part of the general alternative defence of honeybee colonies.

Recent evidence suggests that SHB also parasitize colonies of bumblebees (*Bombus impatiens*, Spiewok and Neumann 2006b; Hoffmann et al. 2008) and stingless bees (*Trigona carbonaria*; Anne Dollin, personal observations). Analogous to propolis usage by honeybees, stingless bees use batumen to seal nest cavities (Michener 1961). Therefore, we hypothesised that stingless bees may show an analogue to honeybee social encapsulation of SHB, by restricting parasite advancement and reproduction. We tested this hypothesis by observing experimental infestations of *T. carbonaria* colonies using diagnostic radioentomology.

Materials and methods

Laboratory reared (Muerrle and Neumann 2004) adult SHB with BaSO₄-marked elytra, were introduced to entrances of five *T. carbonaria* hives, $N=10$ beetles per hive, via transparent plastic observation tubes (Hoffmann et al. 2008). Beetle–bee interactions at hive entrances were visually observed (5 min). To non-invasively monitor movements of beetles that managed to bypass guards, hives were CT-scanned at 5-min intervals for 90 min in a human body scanner (GE HiSpeed 64 Slice, General Electric Company; Greco et al. 2006). Beetle distributions in hives were assessed using BeeView 3D rendering software (Disect Systems Ltd; Suffolk, UK). Two-dimensional images were created to enable precise measurements of vector distances of SHB from hive entrances with on-screen linear callipers (Greco et al. 2005) and 3D images were generated to provide visual spatial representation of SHB with respect to hive structures. One hive was randomly selected after scanning and snap frozen with liquid nitrogen for visual screening to compare SHB positions with respect to scanned images. We applied a linear mixed model in a block design, with “colonies” as five random blocks and “time” as a fixed factor with ten observations of distances for each time point, to assess any “colony” or “time” effects (it was not possible to fit a ‘repeated

measurements’ model because beetles were not identified as individuals):

$$Y_{ijk} = \mu + C_i + t_j + \varepsilon_{ijk}$$

where,

Y_{ijk} was k th distance measured in colony i at time j

μ was global mean

C_i was effect of colony I , $I=1,2,\dots,5$ (random)

t_j was effect of time j , $j=0, 5, 10$ (fixed)

ε_{ijk} was the random error of the k th observation in colony i at time j , $k=1,2,\dots,10$

$$C_i \sim N(0, \sigma^2)$$

$$\varepsilon_{ijk} \sim N(0, \sigma^2).$$

We also tested a model of diffusion (random walk) to assess whether SHB were prevented from normal random walk distributions. If we assume the beetles to move randomly and free of attacks then the model of “random walk” can be helpful for modelling the distribution of measured distances at a given time. This is equivalent to the process of diffusion of a solute in a solvent and can be checked statistically by a Chi-square goodness-of-fit test with the normal distribution of the measured distances. For all statistical analyses we used Systat Software Inc, Chicago, IL 60606, USA.

Results

Upon introduction of SHB, visual observations confirmed that workers from all hives immediately attacked and coated introduced beetles with batumen. The attacks by workers (Fig. 1a) caused most beetles to remain motionless in the turtle defence posture (Neumann et al. 2001). When not attacked, beetles were observed moving further into the hive. However, most *T. carbonaria* bees continuously attacked, thereby keeping the SHB in the turtle defence posture until mummified (Fig. 1b). Although three beetles (mummified on the spot, <5 mm from hive entrance) did not progress, 47 did (Table 1). In one hive, two SHB reached a distance of 170 mm from the entrance, just below the brood (Fig. 2a). All SHB advancements ceased within 10 min of introduction (Fig. 2b). After 90 min, mean distance from hive entrances was 64 ± 51 mm (maximum distance=170 mm, minimum distance=2 mm, $N=50$ measurements). The linear mixed model showed that there was a significant “time” and “colony” effect on beetle distribution, $p < 0.05$ and < 0.001

Fig. 1 A *T. carbonaria* worker mummifies a live small hive beetle by coating it with batumen on the beetle's elytra and legs (a) and visual confirmation of a mummified beetle on the floor of a *T. carbonaria* hive (b)

respectively. Beetles travelled furthest between time 0 and 5 min and travelled least in colony 1 and furthest in colony 4. At “time” 0 to 5 min the model for diffusion or “random walk” was accepted, $\text{Chi}^2=4.12$, $p=0.53$ (5 min), $\text{df}=5$, showing that beetles were able to disperse between 0 and 5 min. At “time” 10 min the model for diffusion or “random walk” was rejected, $\text{Chi}^2=24.11$, $p<0.001$, showing that beetles were unable to disperse freely between 5 and 10 min. Dissection of the snap frozen hive confirmed positions and batumen coatings which corresponded to previously scanned images (Fig. 2c and d).

Discussion

Our data clearly show that *T. carbonaria* workers efficiently prevented SHB advancements and subsequent

Beetles did not advance further into the hives after 10 min

^aThree beetles were mummified at hive entrances

Fig. 2 Live mummification of adult small hive beetles in *T. carbonaria* hives: **a** 3D CT image of *T. carbonaria* brood (single arrow) and two small hive beetles below brood (double arrows); **b** 2D CT image of small hive beetles (short arrows) in entrance of *T. carbonaria* hive demonstrating no change in position after 10 min; **c** 2D CT image, taken 90 min after introduction to the hive, of an adult small hive beetle which has been mummified by guards of *T. carbonaria* and **d** visual confirmation of the beetle's position and evidence of the batumen coating, applied by guard bees, which prevented further movements by the beetle

reproduction within 10 min by coating them with batumen directly on their bodies. Here we adopt the term mummification because honeybees do not coat live beetles directly with propolis but instead confine them in prisons (Neumann et al. 2001; Ellis et al. 2003). Mummification

by stingless bees appears to be more effective than social encapsulation by honeybees because in sharp contrast to *A. mellifera* (Neumann et al. 2001), all introduced SHB were affected.

A number of native nitidulid species has been reported in *Trigona* nests (*Brachypeplus auritus*, *Brachypeplus basalis* Lea 1910; *Carpophilus planatus* Lea 1912, *Brachypeplus planus* and *Brachypeplus meyricki* Rayment 1935). As with *Cychramus luteus* in *A. mellifera* colonies (Neumann and Ritter 2004), these endemic beetles do not normally harm the colony (personal observations AD), nevertheless mummification may have evolved to prevent them and other invaders from reproducing in the nest. Social encapsulation of live intruders in wax or propolis confinements has been described from *A. mellifera* (Neumann et al. 2001). Likewise, *Bombus* and stingless bees have been reported to coat intruders with resin (Kerr and Lello 1962; Michener 1974; Nates and Cepeda 1983; Roubik 1989; Betz and Koelsch 2004). However, to our knowledge, this is the first report of mummification of live nest intruders in colonies of social bees.

When SHB beetles adopt the turtle defence posture most honeybee workers eventually leave the beetles, which then scurry into hiding or progress further into the colony (Neumann et al. 2001). In contrast, *T. carbonaria* workers continuously attack, thereby keeping the SHB in the turtle defence posture, which enables other workers to mummify live beetles with batumen. Indeed, our data suggest that many beetles are immobilised between 5 and 10 min, thus, unable to move unhindered according to a model assuming random walk. It appears that the combination of continuous attacks and quick recruitment of mummifying workers underlies this efficient alternative defence mechanism of *T. carbonaria*. There have, however, been reports of heat-stressed *T. carbonaria* colonies being destroyed by small hive beetles (MG, personal observations), suggesting that this invasive species may still pose some threat to native pollinators.

In conclusion, a single stingless bee worker is not able to eject or kill beetle parasites unaided. Only a team with individuals performing specific tasks (e.g. wrestling or gluing) can overcome parasite advancements. Live encapsulation of SHB by stingless bees has probably evolved as an alternative defence mechanism to prevent successful reproduction of nest parasites. It is evidently effective, because beetles are quickly immobilised, preventing successful reproduction. This seems especially important in light of the high reproductive potential and high infestation numbers of SHB (Spiewok et al. 2007). The convergent evolution of live mummification of nest parasites in stingless bees and social encapsulation in honeybees is another striking example of evolution between insect societies and their parasites.
