THE OHIO CORN PERFORMANCE TESTS: 1945 and 1946

G. H. STRINGFIELD and H. L. PFAFF * †

This publication presents the seventh report of the Ohio Corn Performance Tests, the last report‡ being for the years 1943 and 1944.

Experimental Procedures

Typically an individual test contained 30 entries which were compared in 2- by 10-hill plots replicated 5 times and laid out in a modified Latin square of 5 ranges (30 plots side by side) and 5 columns (7 plots wide by 5 plots long) at right angles to the ranges. The sequence of entries was random with the restrictions that each entry fall once in each range and once in each column. Exceptions to this field design were that the two tests in Adaptation Area 7 were in a simple lattice design of four replications and two of the tests in Adaptation Area 5 were in threefold replication of single-row plots in randomized blocks and were harvested mechanically without gleaning. All other tests were harvested by hand and thoroughly gleaned. Four seeds were planted per hill without subsequent thinning.

Field weights were adjusted to stand by the following procedures: All plots in a given test were classified according to stand (the number of plants) and without regard to entries. Stands were thrown into groups having class values of five with the modal stand at the center of one of the groups. Thus, if the modal stand were 63, all plots with stands of 61 to 65, inclusive, would fall in one group. Adjacent groups would be 56 to 60, and 66 to 70. The groups were extended in each direction so long as there were 15 or more plots in a group. Mean group plot yields were plotted against mean group stands on graph paper with stand on the horizontal axis and plot weights on the vertical axis. The intersecting points were approximately connected with a free-hand curve to indicate the relation of plot yield to stand. For a given stand this curve might indicate a plot weight of 2 pounds less than was indicated at the modal stand. In that case 2 pounds would be added as an adjustment for stand. A subtraction would be made for a stand at which the curve indicated a yield higher than for the modal stand.

Exceptions to the above method for adjusting for stand were that the two tests in Adaptation Area 7 were adjusted for missing hills only, using the conventional formula based upon the assumption that a missing hill results in a yield reduction of seven-tenths the weight of the corn from an average hill. No stand adjustments were attempted in the single-row plots in the two tests in Adaptation Area 5.

Where the silking periods were measured, counts of the number of plants in

* G. H. Stringfield, Senior Agronomist, Division of Cereal Crops and Diseases, Bureau of Plant Industry, Soils, and Agricultural Engineering, Agricultural Research Administration, U. S. Department of Agriculture, and Associate in Agronomy, Ohio Agricultural Experiment Station; H. L. Pfaff, Agent, Division of Cereal Crops and Diseases, U. S. Department of Agriculture, and Crop Breeding Foreman, Ohio Agricultural Experiment Station.

† The writers are much indebted to the personnel of the Ohio Seed Improvement Association for providing composites of inspection seed samples of all hybrids inspected by them; to the Marsh Foundation Farms, Van Wert, for providing facilities for conducting the two tests that were harvested mechanically; to the George Foster Farm, Chillicothe, for land and assistance needed to conduct the tests in Area 7; to the Ohio Hybrid Seed Corn Producers for financial assistance; and to the assisting personnel at The Ohio State University and the District and County Experiment Farms for necessary help in planting, field culture, harvesting, record taking, typing, and other details.

‡ Stringfield, G. H., R. D. Lewis, and H. L. Pfaff. 1946. The Ohio Corn Performance Tests: 1943 and 1944. Ohio Agricultural Experiment Station Special Circular 71.

silk were made on alternate days during the silking period. By interpolation, the day when half the plants were in silk was calculated for each plot.

A plant was counted as root-lodged if at harvest time it leaned to the extent that the ear was half way or more across a row space. Stalks broken below the point of ear attachment were counted as broken.

Samples for the determination of moisture content of grain were taken by removing two kernel rows from each ear of usually four systematically chosen hills. Moisture contents were found electrically.

All acre-grain yields were adjusted to bushels of shelled grain carrying 15½ percent of moisture.

Tables 1 to 14

Tables 1 and 2 give the results for Ohio Adaptation Area 1, which is in the northeast corner of the state, and which requires earlier corn than any other area.

Tables 3 to 8, inclusive, give the results for Adaptation Areas 2 to 5, inclusive. These combined areas occupy roughly the northern half of the state not included in Area 1.

Tables 9 to 12, inclusive, give the results for Adaptation Area 6, which occupies roughly the southern half of the state, excepting certain river bottom lands.

Tables 13 and 14 give the results from Adaptation Area 7, which includes the better river bottom soils along the Ohio, lower Scioto, and some tributaries.

Significant Differences

Assuming the error in these tests to be comparable to that found in 100 similar tests previously conducted, the least significant differences in grain yields would be as follows:

Between two entries in one test, 9.0 bushels

Between two entries in two tests, 6.4 bushels

Between two entries in three tests, 5.2 bushels

The difficulty of measuring differences in yielding capacity between hybrids becomes obvious after a study of table 15. Ohio K24 and Ohio W36 were in the same 50 tests covering the period 1943 to 1946, inclusive. The grain yield of Ohio K24 was subtracted from that of Ohio W36 for each test. The two hybrids are closely related and differ only slightly in seasonal requirement. The table shows that in 34 (68 percent) of the tests the two hybrids gave close to the same yields. We may safely conclude that there is very little difference between them on the average, but in three of the tests they were as much as 15 bushels apart. That is why so little confidence can be placed in the results of only a few tests.

Combination Tables

A total of 27 tests were conducted in the 2 years. After deleting a few experimental hybrids which were obviously of no further interest, all the remaining data were gathered into 4 tables. Combining several experiments into one table, where the experiments do not have exactly the same entries in common, has the disadvantage that the variation in relative performance of entries from location to location cannot be shown. In consequence, the unimportance of small and often inconsistent differences is poorly evident. There is also the objection that the results of those entries not in all of the tests must be expressed as relative instead of actual values. Obviously the actual yields of an entry tested in fields of low productivity would be of no value for direct comparison of that entry with one which was tested in fields of high productivity.

The method used here to provide a more or less common basis for the comparison

of all entries within a table was as follows: Three hybrids were designated as controls and were entered uniformly in each test. The average grain yield, moisture in grain at harvest, and number of days from planting to mid-silking was found for these three controls in each test. The performance of each entry in the test was then compared with the average of the controls. For instance, if a given hybrid averaged 2 bushels more than the controls, its yield as given in the table would be the average of the controls in all tests plus 2 bushels. That would be true regardless of how many of the tests the hybrid was in. The formula for the computation is:

$$\text{Adjusted yield} = C + (H - C_1) \text{ where:}$$

C = the average of all controls in all tests

H = the average of the hybrid

C₁ = the average of the controls in the tests containing the hybrid

Data on root lodging and stalk breaking are more difficult to summarize, since the incidence of either might be zero in some tests and anywhere from a trace to very high in other tests. The actual averages for these two measures are presented in the tables, and, along with them, averages of the controls in comparable tests are presented for comparison.

The entries in the combination tables are arranged in decreasing moisture content of the grain at harvest. The hybrid of lowest moisture in the grain at harvest is first and the hybrid of highest moisture is last. This arrangement places the hybrids roughly in order of increasing lateness, and it makes it possible quickly to compare the performance of any hybrid with others of approximately the same seasonal requirements. (Tables 16 to 19.)
