Shwetha Sivakaminathan, [s.sivakaminathan@imb.uq.edu.au](mailto:s.sivakaminathan@imb.uq.edu.au), Prof Ben Hankamer, [b.hankamer@imb.uq.edu.au](mailto:b.hankamer@imb.uq.edu.au)

30 **Acknowledgements**

31 We would like to recognise the work of John Srnka who collaborated on the design of the  
32 TECAN's LED lighting system and conducted all related programming, trouble-shooting and  
33 electrical work; Dr Nick Hamilton and James Lefevre for their helpful input on the statistical  
34 analysis reported in the manuscript. We also gratefully acknowledge the support of the  
35 Australian Research Council (Linkage grant LP150101147), University of Queensland  
36 International Scholarship (UQI) and the Science and Industry Endowment Fund (John  
37 Stocker Postdoctoral Fellowship PF16-087).

38 **Competing Interests statement**

39 The authors certify that they have no conflict of interest to declare.

40 **Author Contributions**

41 Jennifer Yarnold, Juliane Wolf and Ben Hankamer conceived and designed the experiments.  
42 Shwetha Sivakaminathan and Jennifer Yarnold performed the experiments. Shwetha  
43 Sivakaminathan, Jennifer Yarnold and Juliane Wolf analysed the data. Shwetha  
44 Sivakaminathan, Jennifer Yarnold and Juliane Wolf drafted the article. Ben Hankamer  
45 revised it critically and provided the funds and infrastructure for conducting the research at  
46 the Institute for Molecular Bioscience.

47 All authors take responsibility for the integrity of the work as a whole, from inception to  
48 finished article.

49 Final approval of the article: Jennifer Yarnold ([j.yarnold@imb.uq.edu.au](mailto:j.yarnold@imb.uq.edu.au)) and Juliane Wolf  
50 ([j.wolf@imb.uq.edu.au](mailto:j.wolf@imb.uq.edu.au)) would serve as corresponding authors.

59 1. Abstract

60 **Microalgae biotechnologies** are rapidly developing into new commercial settings. Several  
61 high value products already exist on the market, and systems development is focused on cost  
62 reduction to open up future economic opportunities for *food*, *fuel* and *freshwater* production.  
63 Light is a key environmental driver for photosynthesis and optimising light capture is  
64 therefore critical for low cost, high efficiency systems. Here a novel high-throughput screen  
65 that simulates fluctuating light regimes in mass cultures is presented. The data was used to  
66 model photosynthetic efficiency ( $PE_{\mu}$ , mol photon<sup>-1</sup> m<sup>2</sup>) and chlorophyll fluorescence of two  
67 green algae, *Chlamydomonas reinhardtii* and *Chlorella* sp. Response surface methodology  
68 defined the effect of three key variables: *density factor* ( $D_f$ , ‘culture density’), *cycle time* ( $t_c$ ,  
69 ‘mixing rate’), and *maximum incident irradiance* ( $I_{max}$ ). Both species exhibited a large rise in  
70  $PE_{\mu}$  with decreasing  $I_{max}$  and a minimal effect of  $t_c$  (between 3-20 s). However, the optimal  $D_f$   
71 of 0.4 for *Chlamydomonas* and 0.8 for *Chlorella* suggested strong preferences for dilute and  
72 dense cultures respectively. *Chlorella* had a two-fold higher optimised  $PE_{\mu}$  than  
73 *Chlamydomonas*, despite its higher light sensitivity. These results demonstrate species-  
74 specific light preferences within the green algae clade. Our high-throughput screen enables  
75 rapid strain selection and process optimisation.

76  
77 **Key words:** Biotechnology, *Chlamydomonas*, *Chlorella*, fluctuating light, high-throughput  
78 screen, microalgae, photobioreactor, photosynthetic efficiency, photosynthesis.

81

82

## 83 2. Background

84 Green algae are oxygenic photosynthetic organisms which, like higher plants and  
85 cyanobacteria, have evolved over 3 billion years to tap into the huge energy resource of the  
86 sun. This energy is used to fix CO<sub>2</sub>, releasing O<sub>2</sub> as a by-product and producing biomass rich  
87 in proteins, lipids, starch, bioactive compounds and phytonutrients. Consequently, single  
88 celled green algae (microalgae) are increasingly being integrated into industrial production  
89 systems to realise solar driven biotechnologies. Microalgae technologies are already being  
90 exploited commercially to produce high value commodities (e.g. functional foods, feeds,  
91 protein therapeutics and chemicals)<sup>1-3</sup> and the knowledge gained is driving down production  
92 costs toward the levels required to expand low value market opportunities including fuels and  
93 fertilisers as well as ecosystem services (e.g. water treatment and CO<sub>2</sub> sequestration)<sup>4-6</sup>. The  
94 first step of all solar driven microalgae processes is light capture and conversion to chemical  
95 energy (ATP, NADPH), and the optimisation of this step is therefore essential to develop  
96 high-efficiency economic solutions<sup>7-9</sup>. In outdoor mass cultures, the light reaching the  
97 surface of the pond or bioreactor is highly variable over the day, ranging from light limiting  
98 during early/late hours of the day or periods of high cloud cover, to photo-inhibiting  
99 conditions (up to 2,000 μmol m<sup>-2</sup> s<sup>-1</sup>) during mid-day in locations receiving high solar  
100 radiation. Within the culture itself, cells are exposed to high light gradients as they cycle from  
101 the illuminated surface (e.g. often inhibitory light levels) to deep within the culture (i.e.  
102 limiting or dark conditions). This fluctuating light regime within the mass culture is governed  
103 by the optical properties of the culture (based on cell size, cell number and pigment content)  
104 while the frequency with which cells cycle between the light and dark zones is regulated by  
105 mixing rate as well as the photobioreactor geometry which influences the light distribution  
106 through the optical pathlength and the surface to volume ratio. The relatively rapid light  
107 fluctuations within the culture affect the photo-regulatory response, while the relatively slow  
108 environmental light fluxes affect photoacclimation, both leading to changes in the overall  
109 productivity of the culture<sup>10-12</sup>.

110 Defining and optimising the effects and interactions of the variables that govern a given light  
111 regime is a challenge that requires comparatively large experimental datasets which can be  
112 laborious and expensive to obtain using traditional pilot- or even laboratory-scale bioreactors.  
113 The high-throughput light screen method presented here has been designed to simulate light  
114 regimes encountered in mass cultured photobioreactors under ‘typical’ outdoor production  
115 conditions to enable process optimisation, model guided system design, species selection and  
116 a better extrapolation of laboratory results to field trials.

117 The light screen collected data from LED illuminated microwells, and Response Surface  
118 Methodology was employed to predictively model photosynthetic efficiency ( $PE_{\mu}$ ), to define  
119 both main effects and the pair-wise interactions between the light factors that govern it and to  
120 identify the conditions that yield optimum productivity. As fluctuating light can effect  
121 photoregulation and photoacclimation, we also investigated some of these underlying  
122 mechanisms to assess the extent of their effect on  $PE_{\mu}$ .

123 A full factorial experimental design was employed, with quadratic models fitted to the data to  
124 measure the  $PE_{\mu}$  in response to variations of three key factors that govern the light regime to  
125 which cells in mass culture are exposed: density factor ( $D_f$ , -), defined as the proportion of  
126 the time that cells are in the dark zone ( $t_{\text{dark}}$ , s) compared with the total time in both light  
127 ( $t_{\text{light}}$ , s) and dark zones; *cycle time* ( $t_c$ , s), which is defined by the mixing rate, or the total  
128 time of a cell's fluctuation between light and dark zones for one cycle along the culture  
129 depth; and maximum irradiance ( $I_{\text{max}}$ ,  $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ ) defined as the irradiance entering  
130 the photobioreactor at the illuminated surface (Figure 1A). Dark was defined as  $<5 \mu\text{mol}$   
131 PAR at which respiration typically exceeds photosynthesis (the compensation point)<sup>13,14</sup>. The  
132 three factors ( $D_f$ ,  $T_c$ ,  $I_{\text{max}}$ ) affect the average irradiance ( $I_{\text{avg}}$ ), which is the integration of light  
133 experienced by the cells over the entire light cycle (Figure 1B). Our miniaturised and  
134 automated screen enables the analysis of the interactions between the three light-dependent  
135 factors and generates a strain-specific model that can be used to optimise production  
136 conditions or predict productivities for different production scenarios.

137 This empirical model is an alternative approach to traditional models based on photosynthetic  
138 irradiance (P-I) curves. It only requires knowledge of the density factor, incident irradiance  
139 and mixing rate. The  $D_f$  for a given species and reactor geometry can be easily found (indoor  
140 or outdoor) for a given incident irradiance by measuring the depth of culture at the point  
141 where light is reduced to  $<5 \mu\text{mol m}^{-2} \text{s}^{-1}$  (i.e. start of the “dark zone”) and calculating the  
142 ratio of this depth to the total culture depth (usually fixed). This can be correlated to a range  
143 of optical densities (or biomass dry weight) to provide a simple method to establish what  $D_f$  a  
144 reactor will have at a known culture density, pathlength and incident irradiance. Since  $D_f$  has  
145 been determined as a critical factor in this and other studies, we believe that this is another  
146 useful modelling tool for process design.

147 Two biotechnologically relevant microalgae strains were analysed in this study:  
148 *Chlamydomonas reinhardtii* (*Chlamydomonas*), the model alga most used in photosynthetic  
149 studies<sup>15,16</sup> and for heterologous protein expression<sup>17,18</sup>, and a strain of *Chlorella* sp, 11\_H5  
150 (*Chlorella*) isolated in Australia which was found to have high biomass productivity at  
151 laboratory and pilot scale<sup>19,20</sup>. *Chlamydomonas* (originally isolated from soil)<sup>21</sup> has

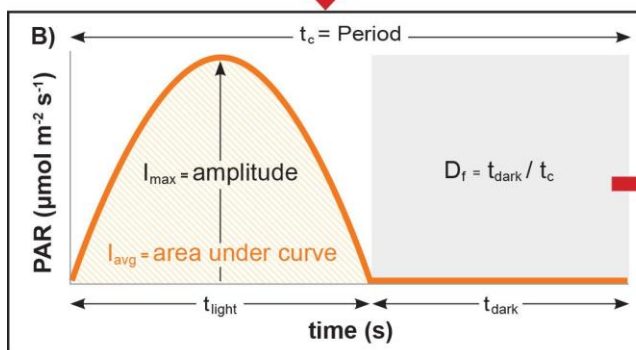

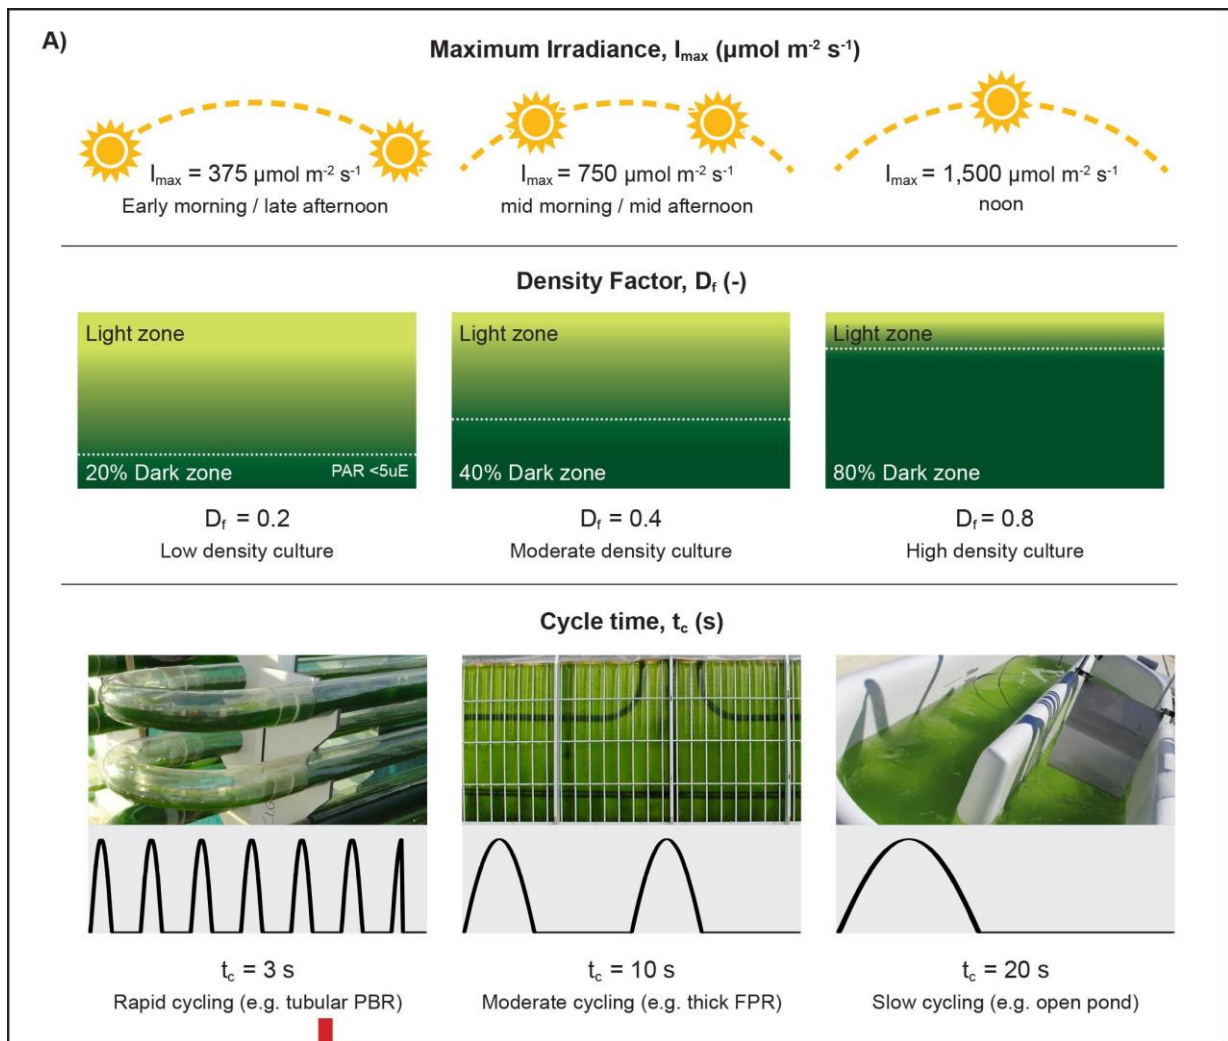

152 successfully transitioned from land to water in laboratory conditions, arguably owing to its  
153 robust and evolved photosynthetic machinery that protects it from oxidative stress and  
154 changing environmental conditions<sup>22</sup>. Hence, understanding the interplay between  
155 photosynthetic regulation, photoacclimation and its effect on growth and biomass  
156 productivity would determine the feasibility of delivering functional microalgae  
157 biotechnologies. This paper presents a high-throughput miniaturised light optimisation screen  
158 (allowing up to 18 different combinations of light regime and up to 1,728 conditions),  
159 designed to identify species-specific illumination conditions that maximise photosynthetic  
160 efficiency and productivity to fast track systems optimisation.

### 161 3. Results

162 3.1. High-throughput screen (HTS) of simulated light regimes in mass cultures  
163 To analyse the effects of varying levels of  $D_f$ ,  $I_{max}$  and  $t_c$  (Figure 1B) on the  $PE_{\mu}$  of  
164 microalgae, light simulations were performed on dilute 150  $\mu$ l microwell cultures (5mm  
165 pathlength)<sup>23</sup>, each illuminated using individual LEDs (Figure 1C). The intensity of  
166 photosynthetically active radiation (400-700 nm, PAR) emitted by the LEDs was  
167 programmed (Arduino® integrated circuit and controller) to mimic a sinusoidal trajectory of  
168 a cell cycling in a one-dimensionally illuminated culture (i.e. an open pond) between the  
169 illuminated surface and the dark zone (Figure 1B)<sup>10</sup>. In this way, the light regime encountered  
170 by the incubated cells in each well was a function of the LED's illumination profile, thereby  
171 allowing tight control of the levels of each factor ( $D_f$ ,  $I_{max}$  and  $t_c$ ), (Figure 1A). A robotic arm  
172 is programmed to take the plates to a reader at determined time intervals where rapid  
173 measurements of optical density and fluorescence can be taken. Here, two strains were  
174 analysed for the initial HTS light simulations, however, this method can rapidly be used to  
175 model up to 32 strains run in triplicate in one experiment.

176 Figure 1A depicts the three levels of each factor ( $D_f$ ,  $t_c$ ,  $I_{max}$ ) and the real-world phenomena  
177 they represent based on information from literature<sup>24-26</sup> and on experimental data<sup>27-29</sup>. A low  
178 (0.2) or high (0.8)  $D_f$  represents a low or high cell/biomass density respectively (e.g. dilute  
179 cultures at the beginning of cultivation *versus* dense cultures at harvest in a batch production  
180 regime). The system is able to analyse any range between 10 ms fluctuations to constant  
181 light. The cycle time of 3-20 s represents typical 'mixing' cell cycle rates through the optical  
182 pathlength of photobioreactors, where a  $t_c$  of 3, 10, and 20 s represents rapid, moderate or  
183 slow mixing, as might occur in a tubular PBR, thick flat panel PBR and open pond  
184 respectively. The  $t_c$  is influenced by mixing and/or sparging rates, reactor pathlength, or a  
185 combination of the two, which can vary for individual reactors depending on cultivation

186 regime. The  $I_{\max}$  values represent the incident solar radiation in the early morning and late  
 187 afternoon ( $375 \mu\text{mol m}^{-2} \text{s}^{-1}$ ), mid-morning and -afternoon ( $750 \mu\text{mol m}^{-2} \text{s}^{-1}$ ), and noon ( $1500$   
 188  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ) respectively.  $I_{\max}$  values are based on the average annual solar radiation levels  
 189 for Brisbane, Australia<sup>30,31</sup>, and are representative of other high solar regions that are suitable  
 190 for outdoor microalgae production. The simulation of these three factors at three levels each  
 191 via programmed changes in LED light flux over time are depicted in Figure 1B. This  
 192 approach provided a complete factorial design ( $3^3$ ) of 27 combinations for model fitting of  
 193 the main response variable,  $PE_{\mu}$  (Table 1) and underlying responses at the level of PSII  
 194 (Table 2).

195

196 Figure 1. Experimental design for high-throughput light simulations of cells cycling in outdoor  
197 microalgae mass cultures. **A)** Depicts the 3 factors that affect the light regime experienced by cells  
198 cycling in mass cultures:  $D_f$ ,  $I_{max}$  and  $t_c$ , and the levels used for the full factorial experimental design  
199 which are based on ‘typical’ outdoor conditions. **B)** Each combination of light factors was  
200 programmed by changing the light intensity of the LEDs over the cycle time, assuming cell cycling  
201 occurs in a sinusoidal trajectory. Here,  $I_{max}$ , is the amplitude of the sine, simulating the maximum  
202 irradiance that a cell would receive when at the ‘surface’ of a mass culture,  $D_f$  is the proportion of  
203 time that PAR is below  $5 \mu\text{mol m}^{-2} \text{s}^{-1}$  in one period; this simulates the fraction of time that a cell  
204 spends in the dark, depending on the culture density, and  $t_c$  is the period of one sine wave, that  
205 simulates the time required for a cell to cycle through the reactor.  $I_{avg}$  is the integration of light  
206 received, simulating the average irradiance or light dose received the by cell. Here  $t_{light}$  and  $t_{dark}$  are the  
207 time cells receive PAR ( $>5 \mu\text{mol m}^{-2} \text{s}^{-1}$ ) and no PAR ( $<5 \mu\text{mol m}^{-2} \text{s}^{-1}$ ) respectively. **C)** The  
208 programmed LEDs form part of an 18-plate microwell robotic system. *Chlamydomonas* and *Chlorella*  
209 were incubated in 96-well plates placed on LED arrays with one LED per microwell and one unique  
210 light regime per plate. All light regimes occurred over a photoperiod of  $16 \text{ h day}^{-1}$  and a dark period of  
211  $8 \text{ h day}^{-1}$ .

212 A further dataset with a  $D_f$  of 0.6 (at each level of  $I_{max}$  and  $t_c$ ) provided 9 independent data  
213 points used for model validation and goodness of fit (Table 1, validation data are indicated by  
214 ‘\*’. See section 3.3.1 for results). For all treatments, the combination of each  $D_f$  and  $I_{max}$  also  
215 resulted in 12 unique integrated average irradiance levels,  $I_{avg}$  ( $\text{mol photons m}^{-2} \text{ h}^{-1}$ ).

216 Additional experiments compared the  $PE_{\mu}$  between cells exposed to fluctuating regimes with  
217 cells exposed to constant illumination (control) with the same  $I_{avg}$  to compare the effect of  
218 light regime and light dose (Figure 2C, Supplementary Table S1, Supplementary Figure S4)).

219 Light screen experiments were conducted over 3 days in a controlled semi-continuous  
220 cultivation regime. As light acclimation occurs on a timescale of several hours to days,  
221 sufficient time was given for the cells to acclimate to the light regime that they were exposed  
222 to. To minimise cell shading effects with increasing OD, cultures were diluted back to the  
223 same initial  $OD_{750}$  of 0.1 (pathlength 5 mm) each day. Quasi-steady-state growth rates,  $\mu$  ( $\text{h}^{-1}$ )  
224 were calculated (Equation 3) from 3-hourly  $OD_{750}$  measurements (Supplementary Figure S1  
225 and S2) on Day 2 during the exponential phase (after  $\sim 38$  hours of light regime exposure) and  
226 normalised to the light received to estimate the photosynthetic efficiency ( $PE_{\mu}$ ) (Equation 4).

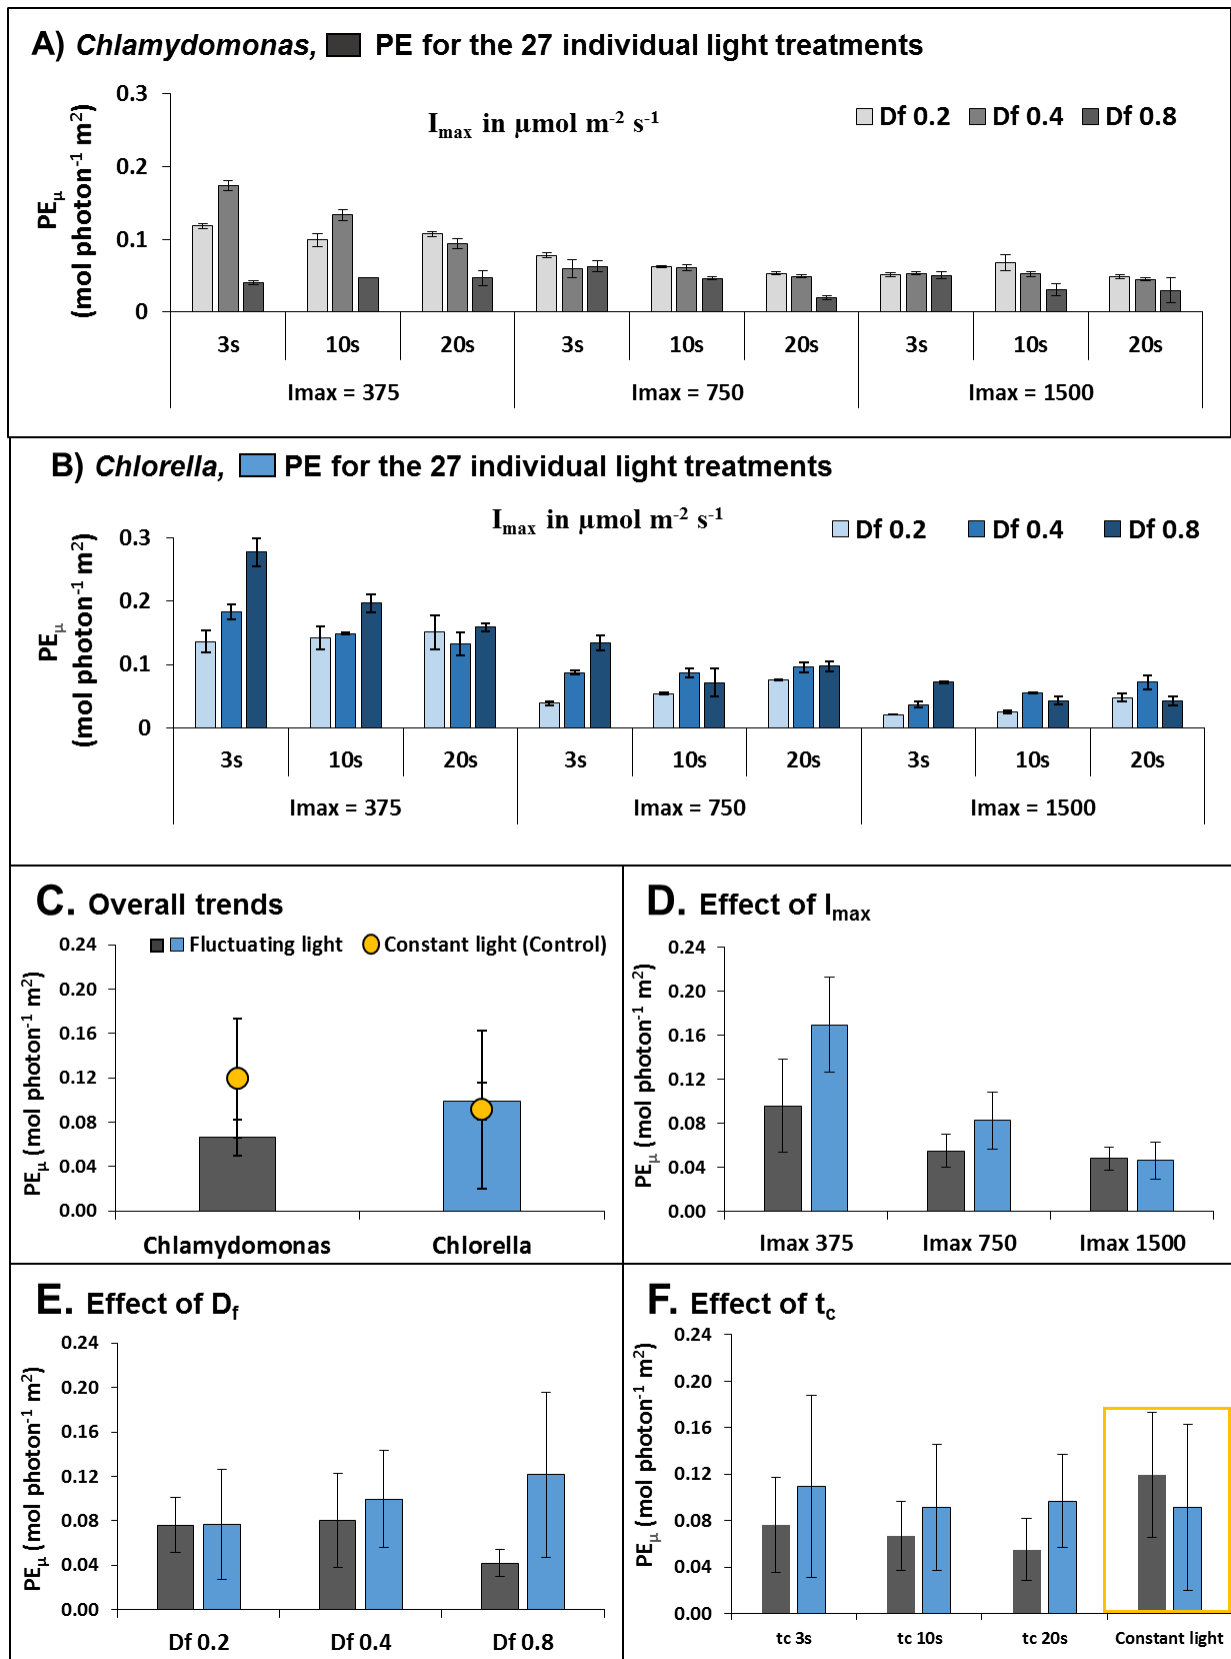

### 227 3.2. Photosynthetic efficiency under different light regimes

228 The  $PE_{\mu}$  of *Chlamydomonas* and *Chlorella* under all 27 fluctuating light regimes are shown  
229 in Figure 2A and B. Some similarities in the general trends of *Chlamydomonas* and *Chlorella*  
230 are evident, such as the effect of  $I_{max}$ , where a large increase in  $PE_{\mu}$  occurred with decreasing  
231  $I_{max}$ . To better depict  $PE_{\mu}$  trends, individual treatments were averaged for each species over  
232 all factors (Figure 2C), and over all but one factor (Figure 2D-F). Overall, *Chlorella*  
233 exhibited a  $\sim 50\%$  higher  $PE_{\mu}$  than *Chlamydomonas* (average  $PE_{\mu}$  of  $0.099 \pm 0.060 \text{ mol}$

234  $\text{photon}^{-1} \text{m}^2$  and  $0.066 \pm 0.034 \text{ mol photon}^{-1} \text{m}^2$  respectively, Figure 2C), in line with  
 235 previous reports<sup>32</sup>.

236

237  
 238

239 Figure 2. Trends in photosynthetic efficiency ( $PE_{\mu}$ ) under different light regimes of  
 240 *Chlamydomonas* (grey bars) and *Chlorella* (blue bars). A) and B) individual  $PE_{\mu}$  data of the  
 241 27 light treatments for *Chlamydomonas* and *Chlorella*, respectively ( $n=3$ ), C) the overall  
 242 trends in averaged  $PE_{\mu}$  values over all conditions of  $D_f$ ,  $I_{max}$  and  $t_c$  tested ( $n=27$ ), D) the  
 243 averaged  $PE_{\mu}$  values of  $D_f$  and  $t_c$  combined to show effect of  $I_{max}$  ( $n=9$ ), E) the averaged  $PE_{\mu}$   
 244 values of  $I_{max}$  and  $t_c$  combined to show effect of  $D_f$  ( $n=9$ ) and F) the averaged  $PE_{\mu}$  values of  
 245  $D_f$  and  $I_{max}$  combined to show effect of  $t_c$  ( $n=9$ ). Error bars represent the standard deviation  
 246 (SD) of individual treatments within biological triplicates (A-B) and between different  
 247 treatments (C-F).

248 Table 1.  $PE_{\mu}$  of *Chlamydomonas* and *Chlorella* under the experimental matrix of light  
 249 regimes. All data are the mean of 3 replicates  $\pm$  standard deviation. \* indicates data used for  
 250 model validation. ‘Coded’ refers to the normalised values used for the quadratic model  
 251 (Equation 2).

252

253 Figure 2C also shows the mean  $PE_{\mu}$  obtained under constant light was ~80% higher in  
 254 *Chlamydomonas* but approximately the same for *Chlorella* (-7.5%) than that obtained under  
 255 fluctuating light of the same  $I_{avg}$ . For *Chlamydomonas*, this result concurs with other studies  
 256 showing a negative impact of fluctuating light on time-integrated photosynthesis and growth  
 257 rates<sup>10,12,33,34</sup>. Interestingly, for this strain of *Chlorella* fluctuating light had little effect  
 258 compared to constant light conditions.

259 For main effects of each factor, Figure 2D shows at the lowest  $I_{max}$  value, the mean  $PE_{\mu}$   
 260 increased up to two-fold for *Chlamydomonas* and 3.67-fold for *Chlorella*, respectively,  
 261 indicating that photosynthetic light utilisation is compromised under high incident light (i.e.  
 262 at noon under outdoor conditions),<sup>35-37</sup> especially for *Chlorella*.

263 The trends of  $D_f$  (Figure 2E) resulted in diametrically opposing responses:  $PE_{\mu}$  in  
 264 *Chlamydomonas* performed best at a low  $D_f$  (increasing up to 83% from  $D_f=0.8$  to  $D_f=0.2$ )  
 265 while *Chlorella* at a high  $D_f$  ( $PE_{\mu}$  increased up to 58% from  $D_f=0.2$  to  $D_f=0.8$ ). Since mass  
 266 cultures operating under high cell densities is advantageous to reduce downstream processing  
 267 costs, these results suggest that *Chlorella* is more suited to mass cultivation than  
 268 *Chlamydomonas*.

269 For both species, the effect of  $t_c$  seemed minor (Figure 2F). Cell cycling in the range analysed  
 270 ( $t_c = 3, 10, 20$  s) exhibited a modest increase in  $PE_{\mu}$  with decreasing  $t_c$  values (39% for  
 271 *Chlamydomonas* and 13% for *Chlorella*). While large improvements of  $PE_{\mu}$  have been  
 272 reported under sub-second cycle times approaching the ‘flashing light effect’<sup>28,38,39</sup>, this is in  
 273 line with other studies that have reported similar modest improvements for *Chlamydomonas*  
 274 below cycle times of 10 s<sup>12</sup> and little effect in the seconds range for other *Chlorella* sp. and  
 275 other algae.<sup>11,40</sup>

276 3.3. Modelling light factor interactions using response surface methodology  
 277 Response surface methodology of the complete factorial design<sup>41-46</sup> was next employed to  
 278 model and explore the interactions between the three input factors ( $D_f$ ,  $t_c$ , and  $I_{max}$ ) to  $PE_{\mu}$ .  
 279 Furthermore, to determine the influence of photoregulation under fluctuating light on  $PE_{\mu}$ ,  
 280 supporting parameters at the level of PSII regulation for *Chlamydomonas* and *Chlorella* were  
 281 also modelled from chlorophyll fluorescence data. These are: the operating efficiency of PSII

282 ( $\phi$ PSII) – a measure of the proportion of absorbed light used for photochemistry; maximum  
283 quantum efficiency of PSII photochemistry ( $F_v/F_m$ ) – an indicator of PSII inactivation via  
284 photoinhibition; and non-photochemical quenching (NPQ) – the apparent rate constant for  
285 heat loss from PSII<sup>45</sup>. These parameters provide clues as to the underlying mechanisms of the  
286 observed  $PE_\mu$ .

287 The three levels of each factor (Table 1) were coded with the mid-point (coded as ‘0’) and  
288 this was halved and doubled in the experimental design such that the coded factors of the  
289 independent variables were calculated using the logarithmic equation,

$$290 \quad x_i = (1.4427 \ln(X_i) + A_i) \quad \text{Equation 1}$$

291 where,  $x$  is the coded factor level,  $X$  is the actual value of the factor,  $i = 1, 2, 3$ ;  $A$  is the  
292 intercept value of the logarithmic function for each factor with  $A_1 = 1.3219$ ,  $A_2 = -9.5507$  and  
293  $A_3 = -3.3219$  for  $D_f$ ,  $I_{\max}$  and  $t_c$  respectively.

294 Quadratic models (Equation 2) were fitted to the data:

$$295 \quad Y = \beta_0 + \sum_{i=1}^k \beta_i x_i + \sum_{i=1}^{k-1} \sum_{j=i+1}^k \beta_{ij} x_i x_j + \sum_{i=1}^k \beta_{ii} x_i^2 \quad \text{Equation 2}$$

296 In Equation 2,  $Y$  is the predicted response variable ( $PE_\mu$ ,  $\phi$ PSII,  $F_v/F_m$  or NPQ);  $\beta_0$ ,  $\beta_i$ ,  $\beta_{ij}$  and  
297  $\beta_{ii}$  are the coefficients for intercept, linear, interaction and quadratic effects respectively;  $x_1$ ,  
298  $x_2 \dots x_k$  are the coded values of the input factors ( $i \neq j$ ); and  $k=3$ . Multiple regression of the  
299 data was used to obtain the regression coefficients.

300 3.3.1 Model validation shows that the light factors  $D_f$ ,  $I_{\max}$  and  $t_c$  can be used to predict  $PE_\mu$   
301 accurately in *Chlorella* and moderately in *Chlamydomonas*.

302 For the primary response,  $PE_\mu$ , the quadratic model demonstrated a moderate and high  
303 goodness of fit for *Chlamydomonas* ( $R^2 = 0.67$ ) and *Chlorella* ( $R^2 = 0.93$ ), respectively.

304 To assess whether the model fit was adequate to predict  $PE_\mu$  within the range analysed, the  
305 quadratic models were validated using an additional set of experimental data at  $D_f = 0.6$  at  
306 each level of  $I_{\max}$  and  $t_c$  (9 experimental sets for each strain) (Table 1.). Comparing the fitted  
307 models against the actual data gave a low  $R^2$  of 0.456 for *Chlamydomonas* and a high  $R^2$  of  
308 0.882 for *Chlorella* (Supplementary Fig. S5). In general, the residuals showed a normal  
309 distribution and the Cook’s distance plot showed only a small number of outliers for  
310 *Chlamydomonas* and *Chlorella* (Supplementary Fig. S5).

311 For *Chlorella*, these results indicated that the three light factors accounted for a high  
312 proportion of variation in  $PE_\mu$  observed and can be used to adequately predict their

313 relationship to  $PE_{\mu}$ . For *Chlamydomonas*, it seems there are more complex regulations of the  
 314 photosynthetic machinery, which cannot be modelled with these factors alone.

315 3.3.2 The light factors of  $I_{max}$  and  $D_f$  significantly affect  $PE_{\mu}$  under fluctuating light.

316 The coefficient terms tabulated in Table 2 show the relative size and direction that effect each  
 317 factor has on the response variables, while the three dimensional (3D) response surface plots  
 318 and 2D contour plots graphically depict the interactions of two factors on the primary  
 319 response of  $PE_{\mu}$ , where the third factor is set to the midpoint (Figure 3).

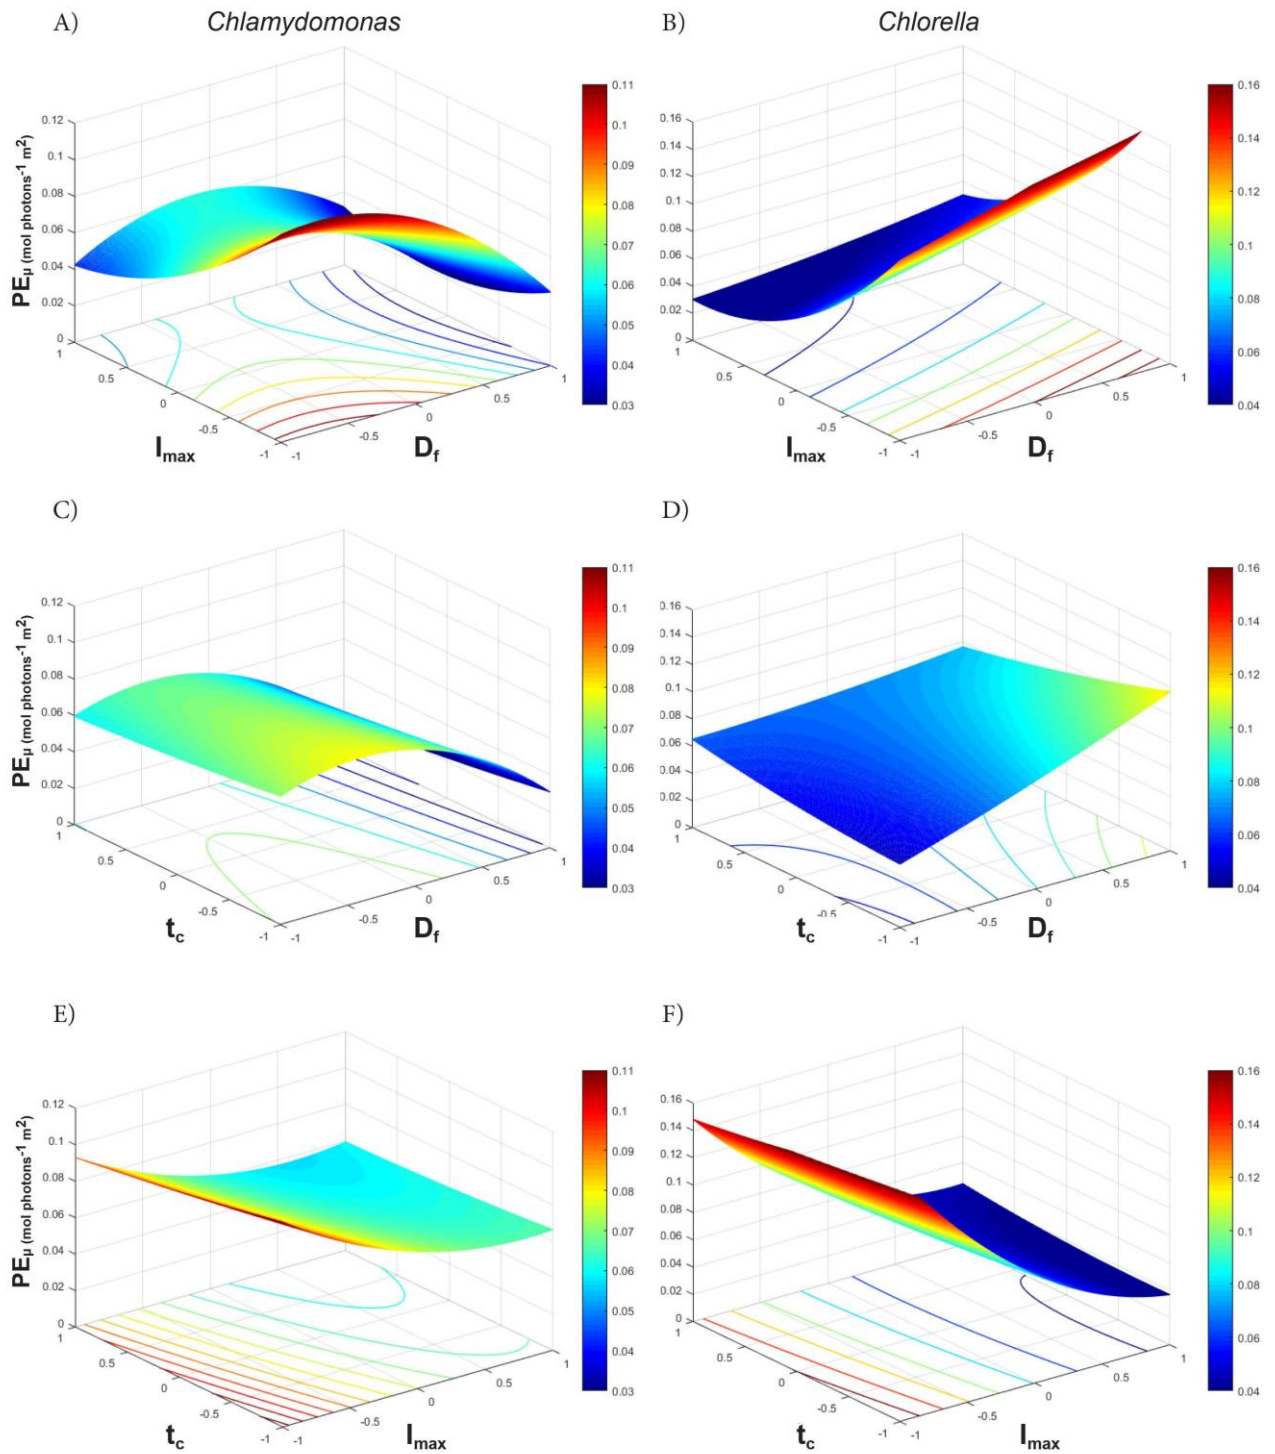

320 For *Chlamydomonas*, the most significant factors affecting  $PE_{\mu}$  were:  $I_{max}$  (p-value =  $3.83E^{-08}$ )  
 321  $^{08}$ ),  $D_f$  (p-value =  $1.04E^{-08}$ ), and the interaction of  $D_f$ - $I_{max}$  (p-value  $1.05E^{-04}$ ) (Table 2). Here,  
 322 both high  $D_f$  and high  $I_{max}$  had similar negative impacts on  $PE_{\mu}$ , yet the interaction of  $D_f$ - $I_{max}$   
 323 had a positive effect, suggesting that dense cultures may offer some protection under high  
 324 light whilst dilute cultures may improve  $PE_{\mu}$  under low light. As expected, the 3D plots show  
 325 the highest  $PE_{\mu}$  values at a combination of low  $D_f$  (i.e. not light limited) and low  $I_{max}$  (i.e. not  
 326 photo-inhibited) (Figure 3A), however, the slight saddle shape of the interaction plot at high  
 327  $I_{max}$  shows that the optimal  $D_f$  is around 0.4 (at the mid-point) for *Chlamydomonas*.

328 The  $PE_{\mu}$  of *Chlorella* was most significantly adversely affected by high  $I_{max}$  (p-value  $9.92E^{-37}$ )  
 329  $^{37}$ ), and unlike *Chlamydomonas*, showed a significant positive response for increasing  $D_f$  (p-  
 330 value  $4.67E^{-12}$ ). The  $I_{max}$ - $D_f$  interaction showed an exponential increase in  $PE_{\mu}$  with a  
 331 reduction of  $I_{max}$  and an increase in  $D_f$  (Figure 3B). However, the significant negative  
 332 interaction of  $D_f$ - $t_c$  (Table 2) suggests that long cycle times could adversely affect  
 333 productivity in high density cultures (Figure 3D). Overall, for *Chlamydomonas* a low  $I_{max}$  and  
 334 low  $D_f$  (Figure 3A) and for *Chlorella* a low  $I_{max}$  and high  $D_f$  (with moderate benefits of low  
 335  $t_c$ ) (Figure 3 B and D) resulted in the highest  $PE_{\mu}$ .

336 Table 2. Comparison of the factor coefficients of the quadratic model obtained from analysis  
 337 of variance (ANOVA) for A)  $PE_{\mu}$ , B)  $\Phi_{PSII}$  and C)  $F_v/F_m$  parameters for *Chlamydomonas* and  
 338 *Chlorella*. \* represents significant effects at p-value<0.05.  $n = 3$  ( $PE_{\mu}$ ),  $n=2$  ( $\Phi_{PSII}$  &  $F_v/F_m$ ).

340 Figure 3. Response surface (3D) and contour (2D) plots of two-way interactions of factors  
341 affecting the  $PE_{\mu}$  ( $\text{mol photon}^{-1} \text{m}^2$ ) of *Chlamydomonas* (A, C, E) and *Chlorella* (B, D, F).  
342 The colour bar depicts high  $PE_{\mu}$  values in red and lower  $PE_{\mu}$  values in blue.

343 3.4. PSII regulation has a strong effect on  $PE_{\mu}$  under fluctuating light.  
344 To assess some underlying mechanisms that may affect  $PE_{\mu}$ , chlorophyll fluorescence  
345 measurements were taken to assess levels of stress and photo-inhibition ( $F_v/F_m$ ), the operating  
346 efficiency of PSII ( $\Phi_{PSII}$ ) and non-photochemical quenching (NPQ). The data was fitted to the  
347 quadratic model (Equation 2) to compare the magnitude of effect of the three light factors.  
348 Additionally, changes in the ratio of  $OD_{680}/OD_{750}$  were used as a high-throughput proxy to  
349 determine photoacclimation via changes in chlorophyll content.

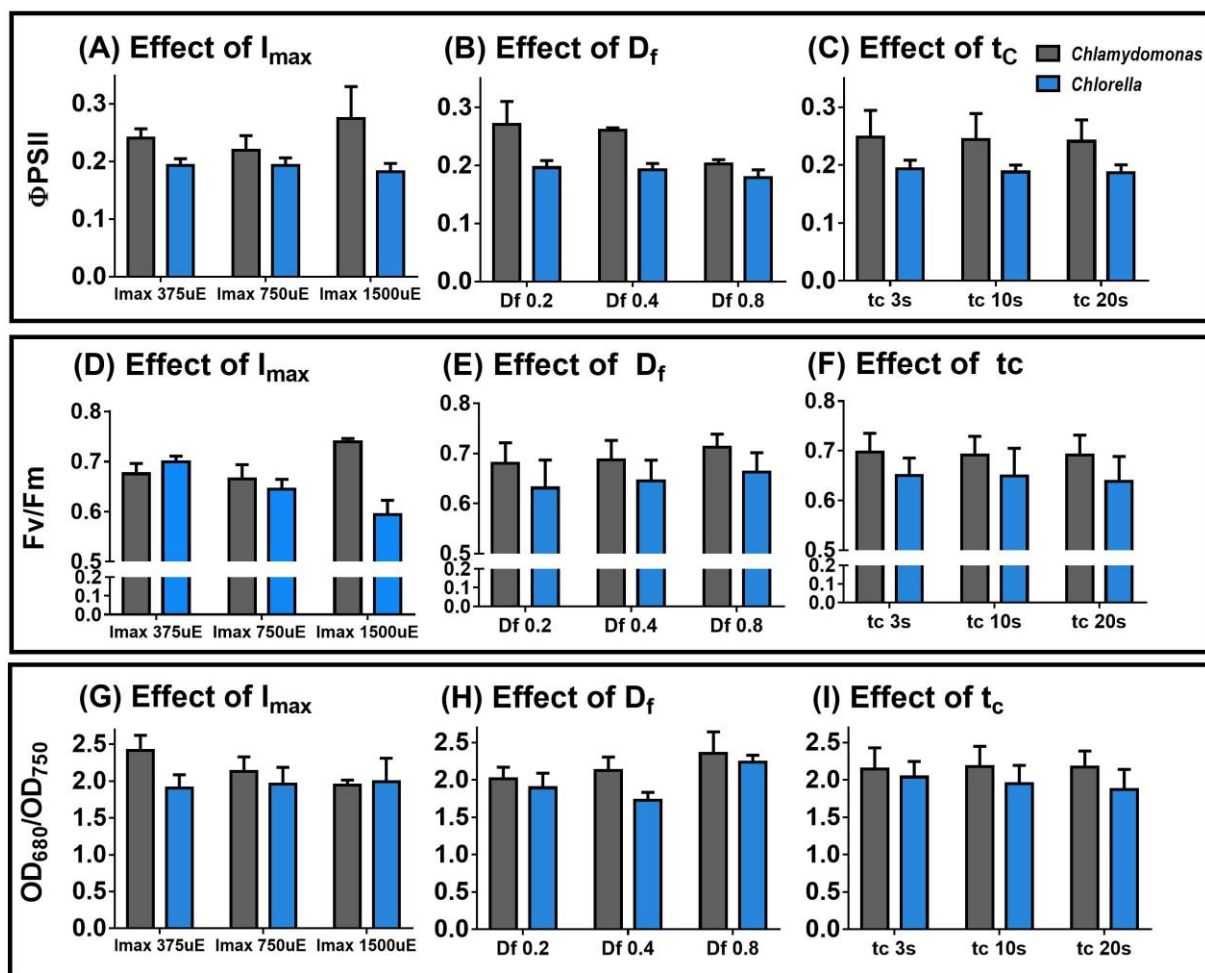

350 A high goodness of fit to the quadratic model was observed in *Chlamydomonas* for  $\Phi_{PSII}$  ( $R^2$   
351 = 0.89) and  $F_v/F_m$  ( $R^2 = 0.74$ ) and, in *Chlorella*, for  $F_v/F_m$  ( $R^2 = 0.91$ ), suggesting that PSII  
352 regulation is highly affected by the three light factors examined in this study and is a  
353 contributing factor to the observed  $PE_{\mu}$ . Remarkably, all treatments for both species showed  
354 low NPQ ( $< 0.3$ ) relative to average values reported in literature (up to  $\sim 2$  for  
355 *Chlamydomonas* and  $\sim 1.5$  for *Chlorella*)<sup>15,47,48,49</sup> and a poor goodness of fit to the quadratic  
356 model for both strains (see Supplementary Table S2). Other stressors, such as nutrient  
357 limitation, are also known to increase NPQ<sup>50</sup>. Since both strains were cultivated on optimised  
358 nutrients this may have contributed to reduced NPQ in this study.

359 For *Chlamydomonas*, a significant ( $p\text{-value}=1.79\text{E-}17$ ) reduction in  $\Phi_{PSII}$  occurred at high  $D_f$   
360 (Table 2, Figure 2E). This suggests that efficient electron transfer is compromised under high  
361 dark fractions for this alga and links  $\Phi_{PSII}$  to the reduced  $PE_{\mu}$  trends under high  $D_f$  observed.  
362 Furthermore, increased  $OD_{680/750}$  measurement (a proxy for chlorophyll content per cell) was  
363 prominent with increasing  $D_f$  (Figure 4H), suggesting high dark fractions lead to increased  
364 cellular chlorophyll levels typical for low-light acclimation, which may further explain the  
365 lower efficiency of light utilisation (i.e. PE) at high  $D_f$  (Figure 2E). Remarkably, a high  $I_{\text{max}}$   
366 actually improved both  $\Phi_{PSII}$  (Figure 4A) and  $F_v/F_m$  (Figure 4D) and lowered  $OD_{680/750}$   
367 (Figure 4G), despite a reduction in  $PE_{\mu}$  (Figure 2D). This suggests that while photosynthetic  
368 rates improved in *Chlamydomonas* under high light, the over-saturating irradiance could not  
369 be fully utilised by the Calvin-Benson cycle, suggesting other downstream mechanisms such  
370 as alternative electron sinks<sup>51</sup> could become relevant under high light.

371 For *Chlorella*, the most significant factor corresponding directly to  $PE_{\mu}$  was the effect of  $I_{\text{max}}$   
372 on  $F_v/F_m$ , which gave a large negative coefficient in the model (Table 2) and showed a

373 noticeable decline in  $F_v/F_m$  with increasing  $I_{max}$  (Figure 4D). Like *Chlamydomonas*,  
 374 increasing  $D_f$  was found to have a positive effect on  $F_v/F_m$  (Figure 4E), also seen by the  
 375 relative magnitudes of coefficients and their significance (p-value=3.09E-07), and a  
 376 significant positive interaction between  $D_f$ - $I_{max}$  (p-value=5.19E-03). Similar to  
 377 *Chlamydomonas*, *Chlorella* exhibited an up-regulation of  $OD_{680/750}$  (indicative of higher  
 378 chlorophyll) at high  $D_f$  (Figure 4H, Supplementary Table S2).

379 In summary, these results suggest that *Chlorella* is sensitive to high light as seen by PSII  
 380 inactivation but less sensitive to light/dark fluctuations. In contrast, *Chlamydomonas* is  
 381 sensitive to strong light/dark fluctuations due to disrupted electron transport flows but seems  
 382 to have better acclimatization strategies to cope with high light. These results suggest that  
 383 maintaining *Chlamydomonas* at relatively dilute cultures is beneficial, whereas operating  
 384 *Chlorella* at high densities is preferable, especially under high light.

385  
 386 Figure 4. Trends in underlying photosynthetic mechanisms. Plots depict averaged effects of  $I_{max}$ ,  $D_f$   
 387 and  $t_c$  on  $\Phi_{PSII}$  (A, B and C) (n=2);  $F_v/F_m$  (D, E and F) and  $OD_{680}/OD_{750}$  (G, H and I) respectively for  
 388 *Chlamydomonas* (grey bars) and *Chlorella* (blue bars) (n=3, Error bars represent standard deviation).

389 3.5. Optimisation predicts a two-fold higher maximum  $PE_{\mu}$  for *Chlorella* compared to  
390 *Chlamydomonas*  
391 It is evident from the 3D surface plots (Figure 3) showing  $PE_{\mu}$  response that the maxima  
392 occur at the extremes in most instances. The maximum  $PE_{\mu}$  values (at the mid-point, i.e. level  
393 0) and their corresponding factor levels were used to obtain the maximum  $PE_{\mu}$  and optimum  
394 conditions. For both *Chlamydomonas* and *Chlorella*, the maximum  $PE_{\mu}$  values occurred at  
395 the minimum  $I_{max}$  (375  $\mu E$ ) and the minimum value of  $t_c$  (Table 3). Using this combination of  
396  $I_{max}$  and  $t_c$ , the optimal  $D_f$  values were found to be 0.24 and 0.8 for *Chlamydomonas* and  
397 *Chlorella* respectively. These combination of factor values results in a theoretical maximum  
398  $PE_{\mu}$  of 0.126 and 0.226 mol photon<sup>-1</sup> m<sup>2</sup> (Table 3), predicting a nearly 2-fold higher  
399 maximum  $PE_{\mu}$  for *Chlorella* than *Chlamydomonas*. As discussed in the section 3.3.1 the three  
400 light factors modelled only explains two thirds of the variation in  $PE_{\mu}$  for *Chlamydomonas*  
401 and these results are indicative only for this species.

402 Table 3. Optimisation of  $PE_{\mu}$  and the respective factor levels around the mid-point of each  
403 factor, and around the optimised point for total predicted maximum  $PE_{\mu}$  within the ranges of  
404 the full factorial design.

Species	Condition	Predicted max $PE_{\mu}$	$D_f$		$I_{max}$		$t_c$

<i>Chlamydomonas</i>	$t_c$ midpoint	0.116	-0.75	0.24	-1	375	0	10
	$I_{max}$ midpoint	0.079	-0.4	0.30	0	750	-1	5
	$D_f$ midpoint	0.113	0	0.40	-1	375	-1	5
	Optima	0.126	-0.73	0.24	-1	375	-1	5
<i>Chlorella</i>	$t_c$ midpoint	0.194	1	0.80	-1	375	0	10
	$I_{max}$ midpoint	0.117	1	0.80	0	750	-1	5
	$D_f$ midpoint	0.178	0	0.40	-1	375	-1	5
	Optima	0.226	1	0.80	-1	375	-1	5

#### 405 4. Concluding remarks

406 The HTS coupled with response surface methodology delivers a working statistical design for  
407 simultaneous light optimisation of several species of microalgae. This platform has been used  
408 to screen nutrients and organic carbon sources<sup>20,23</sup>, and can be extended to screen other  
409 parameters such as CO<sub>2</sub> or growth contaminants (e.g. herbicides, antibiotics, bacteria or  
410 predating organisms), and could monitor other response variables such as lipid accumulation  
411 (e.g. Nile Red) and protein expression using fluorescence tags. Some limitations imposed by  
412 the microwell HTS can include high variation between replicates when trialled at conditions  
413 that give very low growth rates; and some evaporation losses that limit the duration of the  
414 experiment due to the low culture volume. Radzun, K. A. *et al.* have reported that despite  
415 some evaporative losses observed in the TECAN robotic system, the RSD values were  
416 considerably lower than can be achieved through manual measurement. As the OD  
417 measurements in the plate reader are made vertically rather than horizontally, the reduction of  
418 depth due to evaporation is compensated for by the concomitant increase in cell concentration  
419 to maintain the same optical pathlength<sup>23</sup>. Furthermore, variation can be reduced by adding  
420 additional technical replicates (as done in this study), while evaporation can be addressed by

421 using a humidifier in the enclosed chamber system (currently being developed) and/or  
422 reducing the frequency of measurement readings which requires lid removal. Despite this, the  
423 HTS provides a cost-effective, rapid and efficient platform to obtain large data-sets for a wide  
424 array of solar driven microalgae applications, which would otherwise require significant  
425 investment of time, money and resources.

426 In most mass cultures, particularly those of outdoor raceway ponds, severe light limitation  
427 exists, typically where light penetrates only the first millimetres or centimetres at most and  
428 high dark fractions of 90% or greater are normal<sup>24,30</sup>. These dark fractions and cycling  
429 between light/dark zones can be detrimental for redox imbalances, as was shown to be the  
430 case for *Chlamydomonas*. Therefore, species such as the strain of *Chlorella* tested here, have  
431 a selective advantage for mass culture, as productivity was found to be unaffected by light  
432 fluctuations. Furthermore, it opens up new insights for the design of high efficiency cell lines,  
433 capable of handling both high light intensities and strong light/dark fluctuations. Improving  
434 light distribution deeper within the culture depth with minimal transmittance losses (e.g. by  
435 increasing surface to volume ratios or using specially designed light guides<sup>52</sup>) may be another  
436 strategy to improve  $PE_{\mu}$ , rather than adjusting cycle time (by increasing mixing rates, gas  
437 sparging) particularly as the latter would require higher energy inputs with minimal gains in  
438  $PE_{\mu}$ . Another important deduction of strain-specific characterisation for scale up was the  
439 detrimental effect of cycle time on  $PE_{\mu}$  for *Chlamydomonas* (~-46%) versus a similar effect  
440 for *Chlorella* as compared to constant light. This signifies the application of our HTS  
441 outcomes toward strain selection as well as growth platform selection (i.e. open pond (slow  
442 mixing) *versus* tubular PBRs (faster mixing) or other designs) when going from laboratory  
443 (constant light) to outdoor systems (fluctuating light). In both alga, as is typical of other  
444 species, high incident light has the most detrimental effect on  $PE_{\mu}$ . Therefore, efforts to  
445 diffuse light sources, such as done through the use of reflectors, or to use vertical flat panels  
446 or vertically stacked tubular photobioreactors to avoid direct sunlight at high light periods,  
447 may benefit from the 'light dilution effect'.

448 Previous transcriptomic and proteomic studies in *Chlamydomonas* have shown that  
449 acclimation to environmental stimuli is achieved by remodelling photosystem I and II  
450 antenna complexes, further highlighting the flexibility of their photosynthetic machinery<sup>53</sup>.  
451 While *Chlamydomonas* may possess the survival strategies required to acclimate to changing  
452 light conditions, typically for soil environments, they may not be tuned for high biomass  
453 productivity, unlike fast-growing strains like the *Chlorella* strain used in this study, which  
454 despite seemingly lacking the level of regulatory sophistication, might be better suited for  
455 mass cultivation.

456 In conclusion, the HTS method developed here enables a rapid approach to optimise systems  
457 design, scale up operational conditions and species selection to advance feasible solar-driven  
458 biotechnologies.

## 459 5. Materials and Methods

### 460 5.1 Strains and pre-culture conditions

461 Liquid pre-cultures were prepared in triplicate (40 mL culture in 100 ml flasks) and  
462 inoculated with either *C. reinhardtii* WT strain CC125<sup>54</sup> or *Chlorella* sp. 11\_H5<sup>19</sup> (Australian  
463 isolate) maintained on TAP<sup>55</sup> agar (1.5%) plates. To ensure nutrients were non-limiting,  
464 photoautotrophic medium previously optimised for each species was used for *C. reinhardtii*  
465 (PCM<sup>56</sup>, N source NH<sub>4</sub><sup>+</sup>) and *Chlorella* sp (OpM<sub>2</sub><sup>20</sup>, N source urea). Flasks were maintained  
466 on shakers (200 rpm) in an enclosed incubation system at 23 °C, 1% CO<sub>2</sub> and a 16/8 hour  
467 light/dark cycle, illuminated with 100 μmol m<sup>-2</sup> s<sup>-1</sup> of overhead white fluorescent light for 5  
468 days.

469 To ensure that the cultures were well synchronised to the light conditions being tested, flask  
470 pre-cultures first acclimated to a 16/8 h light/dark cycle were inoculated into microwell plates  
471 (150 μL), and gradually acclimated to the light intensity close to the mean I<sub>avg</sub> before the first  
472 measurement. For the higher intensity experiments (I<sub>max</sub> = 1500 μmol m<sup>-2</sup> s<sup>-1</sup>), care was taken  
473 not to shock the low density cultures by subjecting them to a step-wise gradually increasing  
474 light regime rather than directly subjecting them to the very high light regimes (a detailed  
475 summary of the acclimation regimes is provided in Supplementary Table S3).

### 476 5.2 Automated HTS and lighting design

477 The design, structure and operation of the HTS system (Tecan Freedom Evo 150, Tecan  
478 Group Ltd., Männedorf, Switzerland) is as previously described<sup>20,23</sup>. Briefly, the HTS system  
479 is an enclosed chamber fitted with three orbital shakers which hold six microwell plates each,  
480 a robotic manipulator arm that removes the plate lid and carries the plates to a reader (Infinite  
481 M200 PRO, Tecan Group Ltd., Männedorf, Switzerland, Figure 1C) and atmospheric CO<sub>2</sub>  
482 control. Each of the 18 microwell plate positions is fitted with 96 ‘warm white’ LEDs  
483 positioned directly under each well of a 96-well plate. Each of the LED arrays is controlled  
484 by user defined scripts on an Arduino® integrated circuit controller and software, permitting  
485 18 different light conditions to be tested in parallel. LEDs were fitted with a low pass LC  
486 filter to smooth the intensity signal from pulse width modulation to variable voltage, thereby  
487 eliminating ‘flashing light’ phenomena due to on/off signals. The spectrum of wavelengths of  
488 LEDs is compared against that of natural sunlight (see Supplementary Fig. S6). For

489 simplicity, a sinusoidal mixing regime was assumed to allow tight control of the factors of  $D_f$ ,  
 490  $t_c$  and  $I_{max}$ , as has been used in previous studies<sup>57,58</sup>. Pre-cultures were centrifuged (500 g, 20  
 491 min, 18 °C) and the pellet re-suspended in fresh medium. To minimise cell shading effects  
 492 and ensure tight light control, a volume of 150  $\mu$ l was chosen for a short pathlength of 5 mm  
 493 and a semi-continuous cultivation regime was applied by daily culture dilutions back to a  
 494 starting  $OD_{750}$  of 0.1. Each of the three biological replicates per species was inoculated into  
 495 each well of a 96-well plate. Since only two strains were tested in this study, all wells were  
 496 inoculated, providing 14 technical replicates per biological replicate. Of these, 10 wells were  
 497 used for automated  $OD_{750}$  and  $OD_{680}$  readings, the remaining wells (of two biological  
 498 replicates) were extracted on day 2 for manual PSII measurements. The final row of 12 wells  
 499 contained 150  $\mu$ l pure media to use as blank controls.

### 500 5.3 Growth rate and photosynthetic efficiency ( $PE_{\mu}$ ) measurements

501 Growth rates were calculated from 3-hourly  $OD_{750}$  measurements. High-throughput  
 502 automated measurements of  $OD_{750}$  were used as a proxy for growth from which growth rates,  
 503  $\mu$  ( $h^{-1}$ ), were calculated as the rate of change of  $OD_{750}$ ,

$$504 \quad \mu = (\ln OD_{750}(t_2) - \ln OD_{750}(t_1)) / (t_2 - t_1) \quad \text{Equation 3}$$

505 where,  $t_1$  and  $t_2$  are the time points at which  $OD_{750(t1)}$  and  $OD_{750(t2)}$  were measured.

506 A 3-hour measuring frequency during the light period was used for the growth curve  
 507 calculations. This frequency was chosen to limit evaporation and contamination issues. A  
 508 detailed description of the growth curves, sampling points and lighting schedule can be found  
 509 as Supplementary Figures S1 and S2.

510 The main response variable,  $PE_{\mu}$ , was assumed to be indicative of light utilisation efficiency  
 511 of the microalgae, where the growth rate normalised to the average integrated PAR received,

$$512 \quad PE = \mu / I_{avg} \quad \text{Equation 4}$$

513 And the  $I_{avg}$  is,

$$514 \quad I_{avg} = \int_0^{t_c} I(t) dt * 3.6 * 10^{-9} \quad \text{Equation 5}$$

515 In Equation 5,  $t_c$  is the cycle time,  $I(t)$  is the irradiance ( $\mu$ mol photons  $m^{-2} s^{-1}$ ) at a given  
 516 time of  $t_c$ , and  $3.6 * 10^{-9}$  is the conversion factor from  $\mu$ mol photons  $m^{-2} s^{-1}$  to mol photons  $m^{-2}$   
 517  $h^{-1}$ .

518 5.4 Chlorophyll fluorescence of photosystem II measurements  
 519 Photosystem II (PSII) kinetics were measured as a function of PSII chlorophyll  
 520 fluorescence<sup>10,59,60</sup>. Biological duplicates of each sample (dilution factor of 5) was added to a  
 521 Fluorimeter cuvette (Sigma), dark adapted for 20 minutes and processed using the FluoroWin  
 522 software (Photon Systems Instruments, Czech Republic). The quenching analysis protocol  
 523 had the following settings: measuring light: 20% V; saturating pulse: 0.9 s, 80% V; actinic  
 524 light: 51 s, 18.3 V (~800  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ). Weak infrared pulses (730 nm) were applied for 5 s  
 525 prior to measurement to quench  $Q_A$ . The PSII parameters calculated from the quenching  
 526 analysis were:  $F_v/F_m$  (maximum quantum efficiency of PSII),  $\Phi_{PSII}$  (PSII operating  
 527 efficiency), and  $NPQ$  (Non photochemical Quenching) using respectively,

$$528 \quad F_v / F_m = (F_m - F_0) / F_m \quad \text{Equation 6}$$

$$529 \quad \phi_{PSII} = (F_m' - F) / F_m' \quad \text{Equation 7}$$

$$530 \quad NPQ = (F_m / F_m') - 1 \quad \text{Equation 8}$$

#### 531 5.5 Photoacclimation via $OD_{680/750}$

532 Chlorophyll *a* has a maximum absorbance at 680 nm. Therefore,  $OD_{680}$  measurements were  
 533 normalised to  $OD_{750}$  ( $OD_{680/750}$ ) as a proxy of changes in chlorophyll absorption between  
 534 different light regimes.

#### 535 5.6 Statistical Analysis

536 All data are expressed as Mean  $\pm$  SD of three biological replicates (for automated readings)  
 537 and two biological replicates (for the manual PSII measurements), each with multiple  
 538 technical replicates as mentioned in section 5.2. MATLAB was used for the design and  
 539 analysis of the response surface methodology. A p-value  $< 0.05$  was used for determining  
 540 significant effects. Both contour and surface plots were developed for visualisation of the  
 541 data and to predict the relationship and interaction effects on the light utilisation efficiency.  
 542 Regression coefficient ( $R^2$ ) was used to resolve the goodness of fit. The fitted model using  
 543 the regression coefficients was validated with an additional experimental dataset.
