10 **Abstract.** Emissions of dimethylsulfide (DMS) from the polar oceans play a key role in atmospheric processes and climate. Therefore, it is important we increase our understanding of how DMS production in these regions may respond to environmental change. The polar oceans are particularly vulnerable to ocean acidification (OA). However, our understanding of the polar DMS response is limited to two studies conducted in Arctic waters, where in both

15 cases DMS concentrations decreased with increasing acidity. Here, we report on our findings from seven summertime shipboard microcosm experiments undertaken in a variety of locations in the Arctic Ocean and Southern Ocean. These experiments reveal no significant effects of short term OA on the net production of DMS by planktonic communities. This is in contrast to identical experiments from temperate NW European shelf waters where surface

20 ocean communities responded to OA with significant increases in dissolved DMS concentrations. A meta-analysis of the findings from both temperate and polar waters ($n = 18$ experiments) reveals clear regional differences in the DMS response to OA. We suggest that these regional differences in DMS response reflect the natural variability in carbonate chemistry to which the respective communities may already be adapted. Future temperate

25 oceans could be more sensitive to OA resulting in a change in DMS emissions to the atmosphere, whilst perhaps surprisingly DMS emissions from the polar oceans may remain

relatively unchanged. By demonstrating that DMS emissions from geographically distinct regions may vary in response to OA, our results may facilitate a better understanding of Earth's future climate. Our study suggests that the way in which processes that generate DMS
30 respond to OA may be regionally distinct and this should be taken into account in predicting future DMS emissions and their influence on Earth's climate.

1 Introduction

The trace gas dimethylsulfide (DMS) is a key ingredient in a cocktail of gases that exchange between the ocean and atmosphere. Dissolved DMS is produced via the enzymatic
35 breakdown of dimethylsulfoniopropionate (DMSP), a secondary algal metabolite implicated in a number of cellular roles, including the regulation of carbon and sulfur metabolism via an overflow mechanism (Stefels 2000) and protection against oxidative stress (Sunda et al. 2002). Oceanic DMS emissions amount to 17 - 34 Tg S y⁻¹, representing 80 - 90% of all marine biogenic S emissions, and up to 50% of global biogenic emissions (Lana et al. 2011).
40 DMS and its oxidation products play vital roles in atmospheric chemistry and climate processes. These processes include aerosol formation pathways that influence the concentration of cloud condensation nuclei (CCN) with implications for Earth's albedo and climate (Charlson et al. 1987; Korhonen et al. 2008), and the atmospheric oxidation pathways of other key climate gases, including isoprene, ammonia and organohalogens (von Glasow
45 and Crutzen 2004; Johnson and Bell 2008; Chen and Jang 2012). Thus, our ability to predict the climate into the future requires an understanding of how marine DMS production may respond to global change (Carpenter et al. 2012; Woodhouse et al. 2013).

The biologically-rich seas surrounding the Arctic pack ice are a strong source of DMS to the Arctic atmosphere (Levasseur 2013). A seasonal cycle in CCN numbers can be related to
50 seasonality in the Arctic DMS flux (Chang et al. 2011). Indeed, observations confirm that

DMS oxidation products promote the growth of particles to produce aerosols that may influence cloud processes and atmospheric albedo (Bigg and Leck 2001; Korhonen et al. 2008; Chang et al. 2011; Rempillo et al. 2011). Arctic new particle formation events and peaks in aerosol optical depth (AOD) occur during summertime clean air periods (when
55 levels of anthropogenic black carbon diminish), and have been linked to chlorophyll *a* maxima and the presence of biogenic aerosols formed from DMS oxidation such as methanesulfonate (MSA). The atmospheric oxidation products of DMS - SO₂ and H₂SO₄ - contribute to both the growth of existing particles and new particle formation (NPF) in the Arctic atmosphere (Sharma et al. 2012; Leaitch et al. 2013; Gabric et al. 2014). Thus, the
60 ongoing and projected rapid loss of seasonal Arctic sea ice may influence the Arctic radiation budget via changes to both the DMS flux and the associated formation and growth of cloud-influencing particles (Sharma et al. 2012).

During its short but highly productive summer season, the Southern Ocean is a hotspot of DMS flux to the atmosphere, influenced by the prevalence of intense blooms of DMSP-rich
65 *Phaeocystis antarctica* (Schoemann et al. 2005) and the presence of persistent high winds particularly in regions north of the sub-Antarctic front (Jarníková and Tortell 2016). Around 3.4 Tg of sulfur is released to the atmosphere between December and February, a flux that represents ~15 % of global annual emissions of DMS (Jarníková and Tortell 2016). Elevated CCN numbers are seen in the most biologically active regions of the Southern Ocean, with a
70 significant contribution from DMS-driven secondary aerosol formation processes (Korhonen et al. 2008; McCoy et al. 2015). DMS-derived aerosols from this region are estimated to contribute 6 to 10 W m⁻² to reflected short wavelength radiation, similar to the influence of anthropogenic aerosols in the polluted Northern Hemisphere (McCoy et al. 2015). Given this important influence of polar DMS emissions on atmospheric processes and climate, it is vital

75 we increase our understanding of the influence of future ocean acidification on DMS
production.

The polar oceans are characterised by high dissolved inorganic carbon (DIC) concentrations
and a low carbonate system buffering capacity, mainly due to the increased solubility of CO₂
in cold waters (Sabine et al. 2004; Orr et al. 2005). This makes these regions particularly
susceptible to the impacts of ocean acidification (OA). For example, extensive carbonate
80 mineral undersaturation is expected to occur in Arctic waters within the next 20 – 80 years
(McNeil and Matear 2008; Steinacher et al. 2009). OA has already led to a 0.1 unit decrease
in global surface ocean pH, with a further fall of ~0.4 units expected by the end of the century
(Orr et al. 2005). The greatest declines in pH are likely in the Arctic Ocean with a predicted
85 fall of 0.45 units by 2100 (Steinacher et al. 2009). The potential effects of OA on marine
organisms, communities and ecosystems could be wide-ranging and severe, due in part to the
speed and extent of a change not seen on Earth for at least 300 Ma (Raven et al. 2005;
Hönisch et al. 2012). Despite the imminent threat to polar ecosystems and the importance of
DMS emissions to atmospheric processes, our knowledge of the response of polar DMS
90 production to OA is limited to a single mesocosm experiment performed in a coastal fjord in
Svalbard (Archer et al. 2013; Riebesell et al. 2013) and one shipboard microcosm experiment
with seawater collected from Baffin Bay (Hussherr et al. 2017). Both studies reported
significant reductions in DMS concentrations with increasing levels of *p*CO₂ during seasonal
phytoplankton blooms. However, these two studies may not be fully representative of the
95 response of the open Arctic or Southern Oceans due to their coastal locations.

Mesocosm experiments are a critical tool for assessing OA effects on surface ocean
communities. Initial studies focused on the growth and decline of blooms with (Engel et al.
2005; Kim et al. 2006; Engel et al. 2008; Schulz et al. 2008; Hopkins et al. 2010; Kim et al.
2010; Schulz et al. 2013; Webb et al. 2015), or without (Crawford et al. 2016; Webb et al.

100 2016) the addition of inorganic nutrients. The response of DMS to OA has been examined
several times, predominantly at the same site in Norwegian coastal waters (Vogt et al. 2008;
Hopkins et al. 2010; Avgoustidi et al. 2012; Webb et al. 2015). There have also been two
studies in Korean coastal waters (Kim et al. 2010; Park et al. 2014), as well as the single
mesocosm study in the coastal (sub) Arctic waters of Svalbard (Archer et al. 2013).
105 Mesocosm enclosures, ranging in volume from ~11,000 – 50,000 L, allow the response of
surface ocean communities to a range of CO₂ treatments to be monitored under near-natural
light and temperature conditions over time scales (weeks - months) that allow a ‘winners vs
loser’ dynamic to develop. The response of DMS cycling to elevated CO₂ is generally driven
by changes to the microbial community structure (Engel et al. 2008; Hopkins et al. 2010;
110 Archer et al. 2013; Brussaard et al. 2013). The size and construction of the mesocosms has
limited their deployment to coastal/sheltered waters, resulting in minimal geographical
coverage, and leaving large gaps in our understanding of the response of open ocean
phytoplankton communities to OA.

Here, we adopt an alternative but complementary approach to explore the effects of OA on
115 the cycling of DMS with the use of short-term shipboard microcosm experiments. We build
on the previous temperate NW European shelf studies of Hopkins & Archer (2014) by
extending our experimental approach to the Arctic and Southern Oceans. Vessel-based
research enables multiple short term (days) identical incubations to be performed over
extensive spatial scales, that encompass natural gradients in carbonate chemistry, temperature
120 and nutrients (Richier et al. 2014; Richier et al. under review). This allows an assessment to
be made of how a range of surface ocean communities, adapted to a variety of environmental
conditions, respond to the same driver. The focus is then on the effect of short-term CO₂
exposure on physiological processes, as well as the extent of the variability in adaptive
capacity between communities. The level of adaptive capacity within an ecosystem

125 determines the level of resilience to changing environmental conditions. Therefore, do
spatially-diverse communities respond differently to short term OA, and can this be explained
by the range of environmental conditions to which each is presumably already adapted? The
rapid CO₂ changes implemented in this study, and during mesocosm studies, are far from
representative of the predicted rate of change to seawater chemistry over the coming decades.
130 Nevertheless, our approach can provide insight into the physiological response of a variety of
polar surface ocean communities, as well as their potential adaptive capacity to future OA
when compared between environments that differ in carbonate chemistry (Stillman and
Paganini 2015), alongside the implications this may have for DMS production.

Communities of the NW European shelf consistently responded to acute OA with significant
135 increases in net DMS production, likely a result of an increase in stress-induced algal
processes (Hopkins and Archer 2014). Do polar phytoplankton communities, which are
potentially adapted to contrasting biogeochemical environments, respond in the same way?
By expanding our approach to encompass both polar oceans, we can assess regional contrasts
in response. To this end, we combine our findings for temperate waters with those for the
140 polar oceans into a meta-analysis to advance our understanding of the regional variability and
drivers in the DMS response to OA.

2 Material and Methods

2.1 Sampling stations

This study presents new data from two sets of field experiments carried out as a part of the
145 UK Ocean Acidification Research Programme (UKOA) aboard the RRS James Clark Ross in
the sub-Arctic and Arctic in June-July 2012 (JR271) and in the Southern Ocean in January-
February 2013 (JR274). Data are combined with the results from an earlier study on board the
RRS Discovery (D366) described in Hopkins & Archer (2014). In total, 18 incubations were

performed; 11 in temperate and sub-Arctic waters of the NW European shelf and North
150 Atlantic, 3 in Arctic waters and 4 in the Southern Ocean. Figure 1 shows the cruise tracks,
surface concentrations of DMS and total DMSP (DMSPt) at CTD sampling stations as well
as the locations of sampling for shipboard microcosms (See Table 1 for further details).

2.2 Shipboard microcosm experiments

The general design and implementation of the experimental microcosms for JR271 and
155 JR274 was essentially the same as for D366 and described in Richier et al. (2014) and
Hopkins & Archer (2014), but with the additional adoption of trace metal clean sampling and
incubation techniques in the low trace metal open ocean waters (see Richier et al. (under
review)). At each station water was collected pre-dawn within the mixed layer from three
successive separate casts of a trace-metal clean titanium CTD rosette comprising twenty-four
160 10 L Niskin bottles. Each cast was used to fill one of a triplicated set of experimental bottles
(locations and sample depths, Table 1). Bottles were sampled within a class-100 filtered air
environment within a trace metal clean container to avoid contamination during the set up.
The water was directly transferred into acid-cleaned 4.5 L polycarbonate bottles using acid-
cleaned silicon tubing, with no screening or filtration.

165 The carbonate chemistry within the experimental bottles was manipulated by addition of
equimolar HCl and NaHCO_3^- (1 mol L^{-1}) to achieve a range of target CO_2 values (550, 750,
1000, 2000 μatm) (Gattuso et al. 2010). For the sub-Arctic/Arctic microcosms, additions
were used to attain three target CO_2 levels (550 μatm , 750 μatm and 1000 μatm). For
Southern Ocean experiments, two experiments (*Drake Passage* and *Weddell Sea*) underwent
170 combined CO_2 and Fe additions (ambient, Fe (2 nM), high CO_2 (750 μatm), Fe (2 nM) + high
 CO_2 (750 μatm) (only high CO_2 treatments will be examined here; no response to Fe was
detected in DMS or DMSP concentrations). Three CO_2 treatments (750 μatm , 1000 μatm ,
2000 μatm) were tested in the last two experiments (*South Georgia* and *South Sandwich*).

After first ensuring the absence of bubbles or headspace, the bottles were sealed with high
175 density polyethylene (HDPE) lids with silicone/ polytetrafluoroethylene (PTFE) septa and
placed in the incubation container. Bottles were incubated inside a custom-designed
temperature- and light-controlled shipping container, set to match the *in situ* water
temperature at the time of water collection. A constant light level ($100 \mu\text{E m}^{-2} \text{s}^{-1}$) was
provided by daylight simulating LED panels (Powerpax, UK). The light period within the
180 microcosms was representative of *in situ* conditions. For the sub-Arctic/Arctic Ocean
stations, experimental bottles were subjected to continuous light representative of the 24 h
daylight of the Arctic summer. For Southern Ocean stations, an 18:6 light: dark cycle was
used. Each bottle belonged to a set of triplicates, and sacrificial sampling of bottles was
performed (see Table 1 for chosen time points). Use of three sets of triplicates for each time
185 point allowed for the sample requirements of the entire scientific party (3 x 3 bottles, x 2 time
points (T_1 , T_2), x 4 CO_2 treatments = 72 bottles in total). Incubation times were extended for
Southern Ocean stations *Weddell Sea*, *South Georgia* and *South Sandwich* (see Table 1) as
minimal CO_2 response, attributed to slower microbial metabolism at low water temperatures,
was observed for the first Southern Ocean station *Drake Passage* over 96 h (see also Richier
190 et al. (under review)). Samples for carbonate chemistry measurements were made first,
followed by sampling for DMS, DMSP and related parameters.

2.3 Standing stocks of DMS and DMSP

Methods for the determination of seawater concentrations of DMS and DMSP are identical to
those described in Hopkins & Archer (2014) and will therefore be described in brief here.
195 Seawater DMS concentrations were determined by cryogenic purge and trap, with gas
chromatography and pulsed flame photometric detection (Archer et al., 2013). Samples for
total DMSP concentrations were fixed by addition of 35 μl of 50 % H_2SO_4 to 7 mL of

seawater (Kiene and Slezak 2006), and analysed within 2 months of collection (Archer et al. 2013). Concentrations of DMSPp were determined at each time point by gravity filtering 7
200 ml of sample onto a 25 mm GF/F filter and preserving the filter in 7 ml of 35 mM H₂SO₄ in
MQ-water. DMSP concentrations were subsequently measured as DMS following alkaline
hydrolysis. DMS calibrations were performed using alkaline cold-hydrolysis (1 M NaOH) of
DMSP sequentially diluted three times in MilliQ water to give working standards in the range
0.03 – 3.3 ng S mL⁻¹. Five point calibrations were performed every 2 – 4 days throughout the
205 cruise.

2.4 *De novo* DMSP synthesis

De novo DMSP synthesis and gross production rates were determined for all microcosm
experiments at each experimental time point, using methods based on the approach of Stefels
et al. (2009) and described in detail in Archer et al. (2013) and Hopkins and Archer (2014).
210 Triplicate rate measurements were determined for each CO₂ level. For each rate measurement
three x 500 mL polycarbonate bottles were filled by gently siphoning water from each
replicate microcosm bottle. Trace amounts of NaH¹³CO₃, equivalent to ~6 % of *in situ*
dissolved inorganic carbon (DIC), were added to each 500 mL bottle. The bottles were
incubated in the microcosm incubation container with temperature and light levels as
215 described earlier. Samples were taken at 0 h, then at two further time points over a 6 - 9 h
period. At each time point, 250 mL was gravity filtered in the dark through a 47 mm GF/F
filter, the filter gently folded and placed in a 20 mL serum vial with 10 mL of Milli-Q and
one NaOH pellet, and the vial was crimp-sealed. Samples were stored at -20°C until analysis
by proton transfer reaction-mass spectrometer (PTR-MS) (Stefels et al. 2009).
220 The specific growth rate of DMSP (μDMSP) was calculated assuming exponential growth
from:

$$\mu_t(\Delta t^{-1}) = \alpha_k \times \text{AVG} \left[\ln \left(\frac{{}^{64}\text{MP}_{\text{eq}} - {}^{64}\text{MP}_{t-1}}{{}^{64}\text{MP}_{\text{eq}} - {}^{64}\text{MP}_t} \right), \ln \left(\frac{{}^{64}\text{MP}_{\text{eq}} - {}^{64}\text{MP}_t}{{}^{64}\text{MP}_{\text{eq}} - {}^{64}\text{MP}_{t+1}} \right) \right]$$

1

(Stefels et al. 2009) where ${}^{64}\text{MP}_t$, ${}^{64}\text{MP}_{t-1}$, ${}^{64}\text{MP}_{t+1}$ are the proportion of $1 \times {}^{13}\text{C}$ labelled DMS relative to total DMS at time t , at the preceding time point ($t-1$) and at the subsequent time point ($t+1$), respectively. Values of ${}^{64}\text{MP}$ were calculated from the protonated masses of DMS as: $\text{mass } 64 / (\text{mass } 63 + \text{mass } 64 + \text{mass } 65)$, determined by PTR-MS. ${}^{64}\text{MP}_{\text{eq}}$ is the theoretical equilibrium proportion of $1 \times {}^{13}\text{C}$ based on a binomial distribution and the proportion of tracer addition. An isotope fractionation factor α_k of 1.06 is included, based on laboratory culture experiments using *Emiliania huxleyi* (Stefels et al. 2009). Gross DMS production rates during the incubations ($\text{nmol L}^{-1} \text{h}^{-1}$) were calculated from μDMS and the initial particulate DMS (DMSPP) concentration of the incubations (shown in Figure 4).

2.5 Seawater carbonate chemistry analysis

The techniques and methods used to determine both the *in situ* and experimental carbonate chemistry parameters, and to manipulate seawater carbonate chemistry within the microcosms, are described in Richier et al. (2014) and will be only given in brief here. Experimental T_0 measurements were taken directly from CTD bottles, and immediately measured for total alkalinity (T_A) (Apollo SciTech Ct analyser (AS-C3) with LI-COR 7000) and dissolved inorganic carbon (DIC) (Apollo SciTech AS-Alk2 Alkalinity Titrator). The CO2SYS programme (version 1.05) (Lewis and Wallace 1998) was used to calculate the remaining carbonate chemistry parameters including $p\text{CO}_2$.

Measurements of T_A and DIC were made from each bottle at each experimental time point and again used to calculate the corresponding values for $p\text{CO}_2$ and pH_T . The data at T_1 and T_2

of each experiment and each CO₂ treatment level are summarised in Supplementary Table S1 and Supplementary Table S2 (T₀ data are given in Table 1).

245 2.6 Chlorophyll *a* (Chl *a*) determinations

Concentrations of Chl *a* were determined as described in Richier et al. (2014). Briefly, 100 mL aliquots of seawater from the incubation bottles were filtered through either 25 mm GF/F (Whatman, 0.7 µm pore size) or polycarbonate filters (Whatman, 10 µm pore size) to yield total and >10 µm size fractions, with the <10 µm fraction calculated by difference. Filters

250 were extracted in 6 mL HPLC-grade acetone (90%) overnight in a dark refrigerator.

Fluorescence was measured using a Turner Designs Trilogy fluorometer, which was regularly calibrated with dilutions of pure Chl *a* (Sigma, UK) in acetone (90%).

2.7 Relative growth rate (RGR)

Relative growth rate (RGR), an indicator of the level of net autotrophy within the

255 experimental microcosms, was calculated as the change in Chl *a* concentrations between the first two experimental time points:

$$RGR = \frac{(\ln(C_1)) - (\ln(C_0))}{T_1 - T_0} \quad 2$$

Where C₀ and C₁ are Chl *a* concentration at experimental time points T₀ and T₁, and T is time in days.

260 2.8 Data handling and statistical analyses

Permutational analysis of variance (PERMANOVA) was used to analyse the difference in response of DMS and DMSP concentrations to OA, both between and within the two polar cruises in this study. Both dependant variables were analysed separately using a nested factorial design with three factors; (i) Cruise Location: Arctic and Southern Ocean, (ii)

265 Experiment location nested within Cruise location: E1- E4/E5, and (iii) CO₂ level: 385, 550, 750, 1000 and 2000 µatm. Main effects and pairwise comparisons of the different factors were analysed through unrestricted permutations of raw data. If a low number of permutations were generated then the *p*-value was obtained through random sampling of the asymptotic permutation distribution, using Monte Carlo tests.

270 One-way analysis of variance was used to identify differences in ratio of >10 µm Chl *a* to total Chl *a* ($\text{chl}_{>10\mu\text{m}} : \text{chl}_{\text{tot}}$, see Discussion). Initially, tests of normality were applied ($p < 0.05$ = not normal), and if data failed to fit the assumptions of the test, linearity transformations of the data were performed (logarithmic or square root), and the ANOVA proceeded from this point. The results of ANOVA are given as follows: *F* = ratio of mean squares, *df* = degrees of
275 freedom, *p* = level of confidence. For those data still failing to display normality following transformation, a rank-based Kruskal-Wallis test was applied (*H* = test statistic, *df* = degrees of freedom, *p* = level of confidence).

3 Results

3.1 Sampling stations

280 Seawater temperatures at the microcosm sampling stations ranged from -1.5°C at sea-ice influenced stations (*Greenland Ice-edge* and *Weddell Sea*) up to 6.5°C for *Barents Sea* (Fig. 2 A). Salinity values at all the Southern Ocean stations were <34, whilst they were ~35 at all the Arctic stations with the exception of *Greenland Ice-edge* which had the lowest salinity of 32.5 (Fig. 2 B). Phototrophic nanoflagellate abundances were variable, with >3 × 10⁴ cells
285 mL⁻¹ at *Greenland Gyre*, 1.5 × 10⁴ cells mL⁻¹ at *Barents Sea* and <3 × 10³ cells mL⁻¹ for all other stations (Fig. 2 D). Total bacterial abundances ranged from 3 × 10⁵ cells mL⁻¹ at *Greenland Ice-edge* up to 3 × 10⁶ cells mL⁻¹ at *Barents Sea* (Fig. 2 E). Chl *a* concentrations were similarly variable, exceeding 4 µg L⁻¹ at *South Sandwich* and 2 µg L⁻¹ at *Greenland Ice-*

edge, whilst the remaining stations ranged from $0.2 \mu\text{g L}^{-1}$ (*Weddell Sea*) to $1.5 \mu\text{g L}^{-1}$ (Fig. 2
290 F).

The high Chl *a* concentrations at *South Sandwich* are reflected in low in-water irradiance
levels at this station (Fig. 2 C). Surface DMS concentrations ranged from $1 - 3 \text{ nmol L}^{-1}$, with
the exception of *South Sandwich* where concentrations of $\sim 12 \text{ nmol L}^{-1}$ were observed (Fig. 2
G). DMSP generally ranged from $12 - 20 \text{ nmol L}^{-1}$, except *Barents Sea* where surface
295 concentrations exceeded 60 nmol L^{-1} (Fig. 2 H).

3.2 Response of DMS and DMSP to OA

The temporal trend in DMS concentrations showed a similar pattern for the three Arctic
Ocean experiments. Initial concentrations of $1 - 2 \text{ nmol L}^{-1}$ remained relatively constant over
the first 48 h and then showed small increases of $1 - 4 \text{ nmol L}^{-1}$ over the incubation period
300 (Figure 3 A – C). No significant effects of elevated CO_2 on DMS concentrations were
observed. Initial DMSP concentrations were more variable, from 6 nmol L^{-1} at *Greenland
Ice-edge* to 12 nmol L^{-1} at *Barents Sea*, and either decreased slightly (net loss $1 - 2 \text{ nmol L}^{-1}$
GG), or increased slightly (net increase $\sim 4 \text{ nmol L}^{-1}$ *Greenland Ice-edge*, $\sim 3 \text{ nmol L}^{-1}$ *Barents
Sea*) (Figure 4 A – C). DMSP concentrations were found to increase significantly in response
305 to elevated CO_2 after 48 h for *Barents Sea* (Fig. 4 C, $t = 2.05$, $p = 0.025$), but no other
significant responses in DMSP were identified.

The range of initial DMS concentrations was greater at Southern Ocean sampling stations
compared to the Arctic, from 1 nmol L^{-1} at *Drake Passage* up to 13 nmol L^{-1} at *South
Sandwich* (Figure 3 D – G). DMS concentrations showed little change over the course of 96 –
310 168 h incubations and no effect of elevated CO_2 , with the exception of *South Sandwich* (Fig.
3 G). Here, concentrations decreased sharply after 96 h by between 3 and 11 nmol L^{-1} .
Concentrations at 96 h were CO_2 -treatment dependent, with significant decreases in DMS

concentration occurring with increasing levels of CO₂ (PERMANOVA, $t = 2.61$, $p = 0.028$).

Significant differences ceased to be detectable by the end of the incubations (168 h).

315 Initial DMSP concentrations were higher than for Arctic stations, ranging from 13 nmol L⁻¹
for *Weddell Sea* to 40 nmol L⁻¹ for *South Sandwich* (Figure 4 D – G). Net increases in DMSP
occurred throughout, and were on the order of between <10 nmol L⁻¹ - >30 nmol L⁻¹ over the
course of the incubations. Concentrations were not generally pCO₂-treatment dependent with
the exception of the final time point at *South Georgia* (144 h) when a significant decrease in
320 DMSP with increasing CO₂ was observed (PERMANOVA, $t = -5.685$, $p < 0.001$).

3.3 Response of de novo DMSP synthesis and production to OA

Rates of *de novo* DMSP synthesis (μ DMSP) at initial time points (T₀) ranged from 0.13 d⁻¹
(*Weddell Sea*, Fig. 5 G) to 0.23 d⁻¹ (*Greenland Ice-edge*, Fig. 5 C), whilst DMSP production
ranged from 0.4 nmol L⁻¹ d⁻¹ (*Greenland Gyre*, Fig. 5 B) to 2.27 nmol L⁻¹ d⁻¹ (*Drake Passage*,
325 Fig. 5 F). Maximum rates of μ DMSP of 0.37 -0.38 d⁻¹ were observed at *Greenland Ice-edge*
after 48 h of incubation in all CO₂ treatments (Fig. 5 C). The highest rates of DMSP
production were observed at *South Georgia* after 96 h of incubation, and ranged from 4.1 –
6.9 nmol L⁻¹ d⁻¹ across CO₂ treatments (Fig. 5 J). Rates of DMSP synthesis and production
were generally lower than those measured in temperate waters (Hopkins and Archer 2014)
330 (Initial rates: μ DMSP 0.33 – 0.96 d⁻¹, 7.1 – 37.3 nmol L⁻¹ d⁻¹), but were comparable to
measurements made during an Arctic mesocosm experiment (Archer et al. 2013) (0.1 – 0.25
d⁻¹, 3 – 5 nmol L⁻¹ d⁻¹ in non-bloom conditions). The lower rates in cold polar waters likely
reflect slower metabolic processes and are reflected by standing stock DMSP concentrations
which were also lower than in temperate waters (5 – 40 nmol L⁻¹ polar, 8 – 60 nmol L⁻¹
335 temperate (Hopkins and Archer 2014)). No consistent evidence of CO₂ sensitivity was seen in
either DMSP synthesis or production, similar to findings for DMSP standing stocks. Some

notable but conflicting differences between CO₂ treatments were observed. There was a 36% and 37% increase in μDMSP and DMSP production respectively at 750 μatm for the *Drake Passage* after 96 h (Figure 5 E, F), and a 38% and 44% decrease in both at 750 μatm after
340 144 h for *Weddell Sea* (Figure 5 G, H). Nevertheless, no consistent and significant effects of high CO₂ were observed for rates of *de novo* DMSP synthesis or DMSP production in polar waters.

4 Discussion

4.1 Regional differences in the response of DMS(P) to OA

345 We combine our findings from the polar oceans with those from temperate waters into a meta-analysis in order to assess the regional variability and drivers in the DMS(P) response to OA. Figures 6 and 7 provide an overview of the results discussed so far in this current study, together with the results from Hopkins & Archer (2014) as well as the results from 4 previously unpublished microcosm experiments from the NW European shelf cruise and a
350 further 2 temperate water microcosm experiments from the Arctic cruise (*North Sea* and *Iceland Basin*, Table 1). This gives a total of 18 microcosm experiments, each with between 1 and 3 high CO₂ treatments.

Hopkins & Archer (2014) reported consistent and significant increases in DMS concentration in response to elevated CO₂ that were accompanied by significant decreases in DMSPt
355 concentrations. Bacterially-mediated DMS processes appeared to be insensitive to OA, with no detectable effects on dark rates of DMS consumption and gross production, and no consistent response seen in bacterial abundance (Hopkins and Archer 2014). In general, there were large short-term decreases in Chl *a* concentrations and phototrophic nanoflagellate abundance in response to elevated CO₂ in these experiments (Richier et al. 2014).

360 The relative treatment effects ($[x]_{\text{highCO}_2}/[x]_{\text{ambientCO}_2}$) for DMS and DMSP (Figure 6), Chl *a*,
phototrophic nanoflagellate abundance and relative growth rates (Figure 7) are plotted
against the ratio of DIC to total alkalinity (DIC/Alk) of the sampled waters, in order to place
our findings in context of the total experimental data set. The value of DIC/Alk ranges from
0.84 – 0.95 within the mixed layer, and increases towards high latitude waters (Egleston et al.
365 2010). Thus, stations with DIC/Alk above ~0.91 represent the seven polar stations (right of
red dashed line Fig. 6 and 7). The surface waters of the polar oceans have a reduced
buffering capacity due to higher CO₂ solubility in colder waters, and so are less resistant to
local variations in DIC and Alk (Sabine et al. 2004). Thus, the relationship between
experimental response and DIC/Alk is a simple way of demonstrating how the CO₂
370 sensitivity of different surface ocean communities relates to the *in situ* carbonate chemistry.
The effect of elevated CO₂ on DMS concentrations at polar stations, relative to ambient
controls, was minimal at both T₁ and T₂, and is in strong contrast to the results from identical
experiments performed on the NW European shelf. At temperate stations, DMSP displayed a
clear negative treatment effect, whilst at polar stations a positive effect was evident under
375 high CO₂, and particularly at T₁ (Fig. 6 C and D). *De novo* DMSP synthesis and DMSP
production rates show a similar relationship with DIC/Alk (Fig. 7 A and B), with a tendency
towards suppression of these rates in temperate waters at elevated CO₂ and a tendency
towards a positive effect in polar waters. However, the smaller number of data makes the
relationships less definitive. At T₁, Chl *a* showed little response to elevated CO₂ at polar
380 stations, whereas a strong negative response was seen in temperate waters (Fig. 8A). A slight
positive response in Chl *a* was seen at most temperate stations by T₂, with generally little
response at polar stations (Fig. 8 B).

In general, phototrophic nanoflagellates responded to high CO₂ with large decreases in
abundance in temperate waters (Richier et al. 2014), and increases in abundance in polar

385 waters (Fig. 8 C and D), with some exceptions: *North Sea* and *South Sandwich* gave the
opposite response. The impacts had lessened by T₂. In contrast, bacterial abundance did not
show the same regional differences in response to high CO₂ (see Hopkins and Archer (2014)
for temperate waters, and Figure S1, supplementary information, for polar waters). Bacterial
abundance in temperate waters gave variable and inconsistent responses to high CO₂. For all
390 Arctic stations, *Drake Passage* and *Weddell Sea*, no response to high CO₂ was observed. For
South Georgia and *South Sandwich*, bacterial abundance increased at 1000 and 2000 µatm,
with significant increases for *South Georgia* after 144 h of incubation (ANOVA $F = 137.936$,
 $p < 0.001$).

The treatment effect on relative growth rate (RGR) (Fig. 8 E and F) at T₁ was minimal across
395 all stations, with the exception of some outliers. Treatment effects were more discernible by
T₂, with a strong negative impact in temperate waters, contrasting with a minimal to positive
effect at polar stations. Additionally, at Arctic stations *Greenland Gyre* and *Greenland Ice-*
edge, no overall effect of increased CO₂ on rates of DOC release, total carbon fixation or
POC : DOC was observed (Poulton et al. 2016).

400 In summary, the relative response in both DMS(P) and a range of biological parameters to
CO₂ treatment in polar waters follows a distinctly different pattern to experiments performed
in temperate waters. In the following sections we explore the possible drivers of the regional
variability in response to OA.

4.2 Influence of community cell-size composition on DMS response

405 It has been proposed that variability in the concentrations of carbonate species (e.g. $p\text{CO}_2$,
 HCO_3^- , CO_3^{2-}) experienced by phytoplankton is related to cell size, such that smaller-celled
taxa (<10 µm) with a reduced diffusive boundary layer are naturally exposed to relatively less
variability compared to larger cells (Flynn et al. 2012). Thus, short-term and rapid changes in

carbonate chemistry, such as the kind imposed during our microcosm experiments, may have
410 a disproportionate effect on the physiology and growth of smaller celled species. Larger cells
may be better able to cope with variability as normal cellular metabolism results in significant
cell surface changes in carbonate chemistry parameters (Richier et al. 2014). Indeed, the
marked response in DMS concentrations to short term OA in temperate waters has been
attributed to this enhanced sensitivity of small phytoplankton (Hopkins and Archer 2014).
415 Was the lack of DMS response to OA in polar waters therefore a result of the target
communities being dominated by larger-celled, less carbonate-sensitive species?

Size-fractionated Chl *a* measurements give an indication of the relative contribution of large
and small phytoplankton cells to the community. For experiments in temperate waters, the
mean ratio of >10 μm Chl *a* to total Chl *a* (hereafter >10 μm : total) of 0.32 ± 0.08 was lower
420 than the ratio for polar stations of 0.54 ± 0.13 (Table 2). Although the difference was not
statistically significant, this might imply a tendency towards communities dominated by
larger cells in the polar oceans, which may partially explain the apparent lack of DMS
response to elevated CO₂. However, this is not a consistent explanation for the observed
responses. For example, the Arctic *Barents Sea* station had the lowest observed >10 μm :
425 total of 0.04 ± 0.01 , suggesting a community comprised almost entirely of <10 μm cells; yet
the response to short term OA differed to the response seen in temperate waters. No
significant CO₂ effects on DMS or DMSP concentrations or production rates were observed
at this station, whilst total Chl *a* significantly increased under the highest CO₂ treatments
after 96 h (PERMANOVA $F = 33.239$, $P < 0.001$). Thus, our cell size theory does not hold for
430 all polar waters, suggesting that regardless of the dominant cell size, polar communities are
more resilient to OA. In the following section, we explore the causes of this apparent
resilience in terms of the environmental conditions to which the communities have
presumably adapted.

4.3 Adaptation to a variable carbonate chemistry environment

435 The variation in *in situ* surface ocean carbonate chemistry parameters for all three cruises (see
Tynan et al. 2016 for details), is summarised in Figure 9. These data demonstrate both the
latitudinal differences in surface ocean carbonate chemistry between temperate and polar
waters, as well as the within-region variability which is controlled by the respective buffer
capacities. Thus, a narrow range of values for all carbonate parameters was observed in the
440 NW European shelf waters relative to the less well-buffered Arctic and Southern Ocean
waters. The polar waters sampled during our study were characterised by pronounced
gradients in carbonate chemistry over small spatial scales, such that surface ocean
communities are more likely to have experienced fluctuations between high $\text{pH}/\Omega_{\text{aragonite}}$ and
low $\text{pH}/\Omega_{\text{aragonite}}$ over short time scales (Tynan et al. 2016). For example, pH_T varied by only
445 0.15 units (8.20 - 8.05) in NW European shelf waters, compared to 0.35 units (8.05 - 7.7) in
the Arctic, and 0.40 units (8.25 - 7.85) in the Southern Ocean. Our data represent only a
snapshot (4 – 6 weeks) of a year, so the annual variability in carbonate chemistry is likely to
be much greater. Adaptation to such natural variability may induce resilience to abrupt
changes within the biological community (Kapsenberg et al. 2015). This resilience is
450 manifested here as negligible impacts on rates of *de novo* DMSP synthesis and net DMS
production. The few published studies in polar waters have reported similar findings.
Phytoplankton communities were able to tolerate a $p\text{CO}_2$ range of 84 – 643 μatm in ~12 d
minicosm experiments (650 L) in Antarctic coastal waters, with no effects on
nanophytoplankton abundance, and enhanced abundance of picophytoplankton and
455 prokaryotes (Davidson et al. 2016; Thomson et al. 2016). In experiments under the Arctic ice,
microbial communities demonstrated the capacity to respond either by selection or
physiological plasticity to elevated CO_2 during short term experiments (Monier et al. 2014).
Our findings support the notion that, relative to temperate communities, polar microbial

communities are already adapted to, and are able to tolerate, large variations in carbonate
460 chemistry. Thus by performing multiple, highly replicated experiments over a broad
geographic range, the findings of this study imply that the DMS response may be both a
reflection of: (i) the level of sensitivity of the community to changes in the mean state of
carbonate chemistry, and (ii) the levels of regional variability in carbonate chemistry
experienced by different communities. This highlights the limitations associated with simple
465 extrapolation of results from a small number of geographically-limited experiments e.g. Six
et al. (2013). Such an approach lacks a mechanistic understanding that would allow a model
to capture the regional variability in response that is apparent from the microcosms
experiments presented here.

4.4 Comparison to an Arctic mesocosm experiment

470 The DMS responses to OA within our short term microcosm experiments contrast with the
results of an earlier Arctic mesocosm experiment (Archer et al. 2013). Whilst no response in
DMS concentrations to OA was generally seen in the microcosm experiments discussed here,
a significant decrease in DMS with increasing levels of CO₂ in the earlier mesocosm study
was reported. We now explore and consider the reasons behind these differences.

475 The short duration of the microcosm experiments (maximum of 4 – 7 d) allows the
physiological (phenotypic) capacity of the community to changes in carbonate chemistry to
be assessed. In other words, how well is the community adapted to variable carbonate
chemistry and how does this influence its ability to acclimate to change? Although the
mesocosm experiment considered a longer time period (4 weeks), the first few days can be
480 compared to the microcosms. No differences in DMS or DMSP concentrations were detected
for the first week of the mesocosm experiment, implying a certain level of insensitivity of
DMS production to the rapid changes in carbonate chemistry. In fact, when taking all
previous mesocosm experiments into consideration, differences in DMS concentrations have

consistently been undetectable during the first 5 – 10 days, implying there is a limited short-
485 term physiological response by the in situ communities (Vogt et al. 2008; Hopkins et al.
2010; Kim et al. 2010; Avgoustidi et al. 2012; Park et al. 2014). This is in contrast to the
strong response in the temperate microcosms from the NW European shelf (Hopkins and
Archer 2014). However, all earlier mesocosm experiments have been performed in coastal
waters, which like polar waters, can experience a large natural range in carbonate chemistry.
490 In the case of coastal waters this is driven to a large extent by the influence of riverine
discharge and biological activity (Fassbender et al. 2016). Thus coastal communities may
also possess a higher level of adaptation to variable carbonate chemistry compared to the
open ocean communities of the temperate microcosms reported here (Fassbender et al. 2016).
The later stages of mesocosm experiments address a different set of hypotheses, and are less
495 comparable to the microcosms reported here. With time, an increase in number of generations
leads to community structure changes and taxonomic shifts, driven by selection on the
standing genetic variation in response to the altered conditions. Moreover, the coastal Arctic
mesocosms were enriched with nutrients after 10 days, and the resultant relief from nutrient
limitation allowed differences between $p\text{CO}_2$ treatments to be exposed, including a strong
500 DMS(P) response (Archer et al. 2013; Schulz et al. 2013). During this period of increased
growth and productivity, CO_2 increases drove changes which reflected both the physiological
and genetic potential within the community, and resulted in taxonomic shifts. The resultant
population structure was changed, with an increase in abundance of dinoflagellates,
particularly *Heterocapsa rotundata*. Increases in DMSP concentrations and DMSP synthesis
505 rates were attributed to the population shift towards dinoflagellates. The drivers of the
reduced DMS concentrations were less clear, but may have been linked to reduced DMSP-
lyase capacity within the dominant phytoplankton, a reduction in bacterial DMSP lysis, or an
increase in bacterial DMS consumption rates (Archer et al. 2013). Again, this is comparable

to all other mesocosm experiments, wherein changes to DMS concentrations can be
510 associated with CO₂-driven shifts in community structure (Vogt et al. 2008; Hopkins et al.
2010; Kim et al. 2010; Avgoustidi et al. 2012; Park et al. 2014; Webb et al. 2015). However,
given the lack of further experiments of a similar location, design and duration to the Arctic
mesocosm, it is unclear how representative the mesocosm result is of the general community-
driven response to OA in high latitude waters.

515 As expected, given the shorter duration of the microcosms, we did not generally see any
broad-scale CO₂-effects on community structure in polar waters. This can be demonstrated by
a lack of significant differences in the mean ratio of >10 μm Chl *a* to total Chl *a* (>10 μm :
total) between CO₂ treatments, implying there were no broad changes in community
composition (Table 2). *South Sandwich* was an exception to this, where large and significant
520 increases in the mean ratio of >10 μm : *total* were observed at 750 μatm and 2000 μatm CO₂
relative to ambient CO₂ (ANOVA, $F = 207.144$, $p < 0.001$, $df = 3$). Interestingly, this was also
the only polar station that exhibited any significant effects on DMS after 96 h of incubation
(Figure 3G). However, given the lack of similar response at 1000 μatm, it remains equivocal
whether this was driven by a CO₂-effect or some other factor. The results of our microcosm
525 experiments suggest resilience in *de novo* DMSP production and net DMS production in the
microbial communities of the polar open oceans in response to short term changes in
carbonate chemistry. This may be driven by a high level of adaptation within the targeted
phytoplankton communities to naturally varying carbonate chemistry.

In contrast to our findings, a recent single 9 day microcosm experiment (Hussherr et al.,
530 2017) performed in Baffin Bay (Canadian Arctic) saw a 25% decrease in DMS
concentrations during spring bloom-like conditions. This implies that polar DMS production
may be sensitive to OA at certain times of the year, such as during the highly productive

spring bloom, but less sensitive during periods of stable productivity, such as the summer months sampled during this study. This emphasises the need to gain a more detailed understanding of both the spatial and seasonal variability in the polar DMS response to changing ocean acidity.

5 Conclusions

We have shown that net DMS production by summertime polar open ocean microbial communities is resilient to OA during multiple, highly replicated short term microcosm experiments. We provide further evidence that, in contrast to temperate communities (Hopkins and Archer 2014), polar communities we sampled were relatively insensitive to variations in carbonate chemistry (Davidson et al. 2016; Richier et al. under review), manifested here as a minimal effect on net DMS production. Our findings contrast with two previous studies performed in coastal Arctic waters (Archer et al. 2013, Hussherr et al. 2017) which showed significant decreases in DMS in response to OA. These discrepancies may be driven by differences in the sensitivity of microbial communities to changing carbonate chemistry between coastal and open ocean waters, or by variability in the response to OA depending on the time of year, nutrient availability, and ambient levels of growth and productivity. This serves to highlight the complex spatial and temporal variability in DMS response to OA which warrants further investigation to improve model predictions.

Our findings should be considered in the context of timescales of change (experimental vs real world OA) and the potential of microbial communities to adapt to a gradually changing environment. Microcosm experiments focus on the physiological response of microbial communities to short term OA. Mesocosm experiments consider a timescale that allows the response to be driven by community composition shifts, but are not long enough in duration to incorporate an adaptive response. Neither approach is likely to accurately simulate the

response to the gradual changes in surface ocean pH that will occur over the next 50 – 100 years, nor the resulting changes in microbial community structure and distribution. However, results from our study indicate that the DMS response to OA should be considered not only in
560 relation to experimental perturbations to carbonate chemistry, but also in relation to the magnitude of background variability in carbonate chemistry experienced by the DMS-producing organisms and communities. Our findings suggest a strong link between the DMS response to OA and background regional variability in the carbonate chemistry.

Models suggest the climate may be sensitive to changes in the spatial distribution of DMS
565 emissions over global scales (Woodhouse et al. 2013). Such changes could be driven by both physiological and adaptive responses to environmental change. Accepting the limitations of experimental approaches, our findings suggest that net DMS production from polar oceans may be resilient to OA in the context of its short term effects on microbial communities. The oceans face a multitude of CO₂-driven changes in the coming decades, including OA,
570 warming, deoxygenation and loss of sea ice (Gattuso et al. 2015). Our study addresses only one aspect of these future ocean stressors, but contributes to our understanding of how DMS emissions from the polar oceans may alter, facilitating a better understanding of Earth's future climate.

Acknowledgements

575 This work was funded under the UK Ocean Acidification thematic programme (UKOA) via the UK Natural Environment Research Council (NERC) grants to PD Nightingale and SD Archer (NE/H017259/1) and to T Tyrell, EP Achterberg and CM Moore (NE/H017348/1). The UK Department for Environment, Food and Rural Affairs (Defra) and the UK Department of Energy and Climate Change (DECC) also contributed to funding UKOA. The
580 National Science Foundation, United States, provided additional support to SD Archer ((NSF

OCE-1316133). Our work and transit in the coastal waters of Greenland, Iceland and Svalbard was granted thanks to permissions provided by the Danish, Icelandic and Norwegian diplomatic authorities. We thank the captains and crew of the RRS Discovery (cruise D366) and RRS James Clark Ross (cruises JR271 and JR274), and the technical staff
585 of the National Marine Facilities and the British Antarctic Survey. We are grateful to Mariana Ribas-Ribas and Eithne Tynan for carbonate chemistry data, Elaine Mitchell and Clement Georges for flow cytometry data, and Mariana Ribas-Ribas and Rob Thomas (BODC) for data management.

866

867 Figure 1. Surface (<5 m) concentrations (nM) of DMS (A-C) and total DMSP (D-F) for
 868 cruises in the NW European shelf (D366) (A,D), the sub-Arctic and Arctic Ocean (JR271)
 869 (B,E) and the Southern Ocean (JR274) (C,F). Locations of sampling stations for microcosm
 870 experiments shown in letters/numbers. E01 – E05: see Hopkins & Archer 2014. NS = *North*
 871 *Sea*, IB = *Iceland Basin*, GI = *Greenland Ice-edge*, GG = *Greenland Gyre*, BS = *Barents Sea*,
 872 DP = *Drake Passage*, WS = *Weddell Sea*, SG = *South Georgia*, SS = *South Sandwich*.

873

874 Figure 2. Depth profiles at the seven polar sampling stations showing A. Temperature (°C),
 875 B. Salinity, C. Irradiance ($\mu\text{E m}^{-2} \text{s}^{-1}$), D. phototrophic nanoflagellate abundance (cells mL^{-1}),
 876 E. total bacteria abundance (cells mL^{-1}), F. total Chl a ($\mu\text{g L}^{-1}$), G. [DMS] (nM), H. total
 877 [DMSPt] (nM) and I. DMS/DMSPt from CTD casts at sampling stations for microcosm
 878 experiments in Arctic (red) and Southern Ocean (blue) waters. GG = *Greenland Gyre*, GI =
 879 *Greenland Ice-edge*, BS = *Barents Sea*, DP = *Drake Passage*, WS = *Weddell Sea*, SG =
 880 *South Georgia*, SS = *South Sandwich*

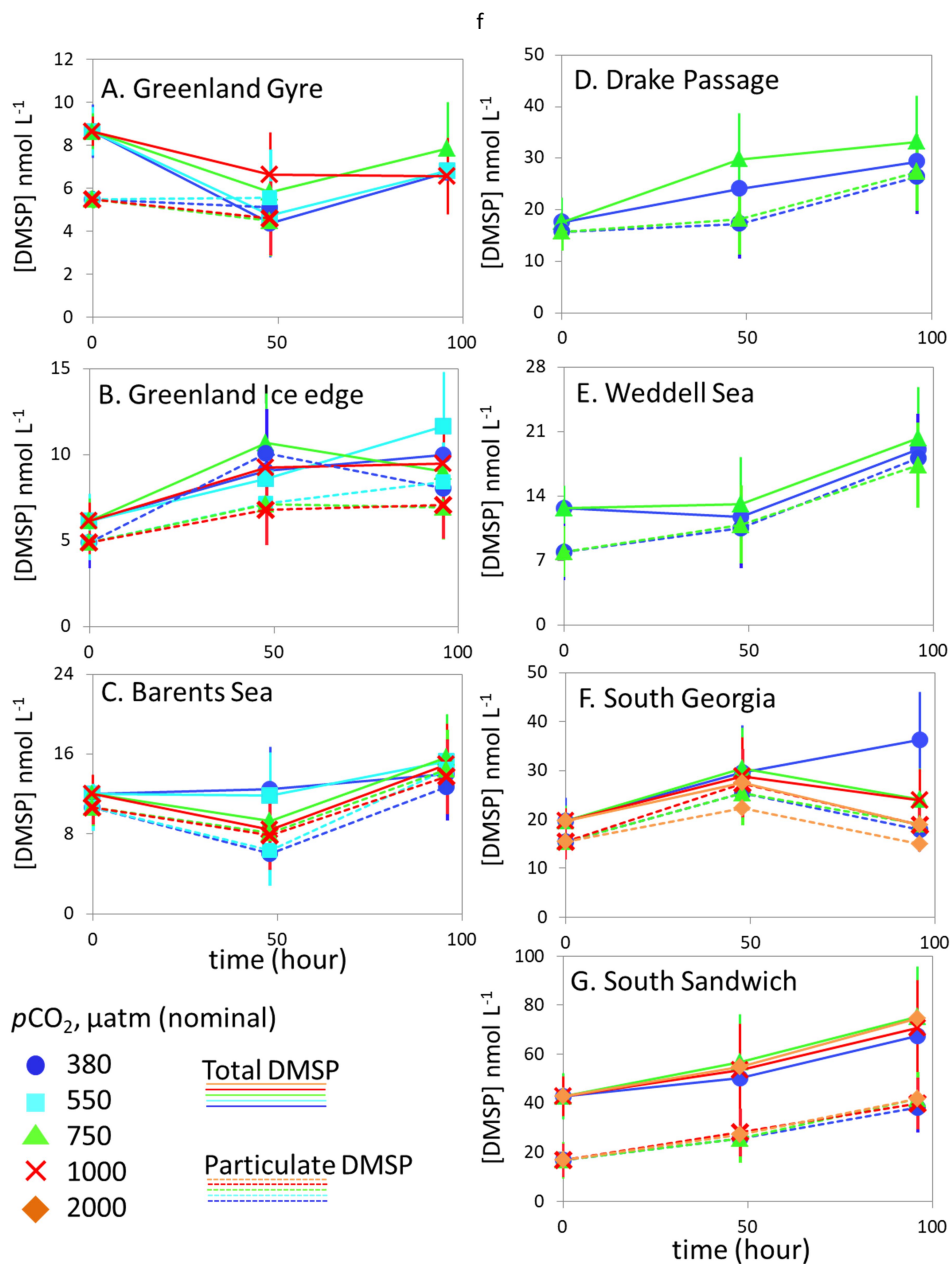

881

882 Figure 3. DMS concentrations (nmol L⁻¹) during experimental microcosms performed in
 883 Arctic waters (A - C) and in Southern Ocean waters (D - G). Error bars show standard error.
 884 Locations of water collection for microcosms shown in Figure 1 C - F.

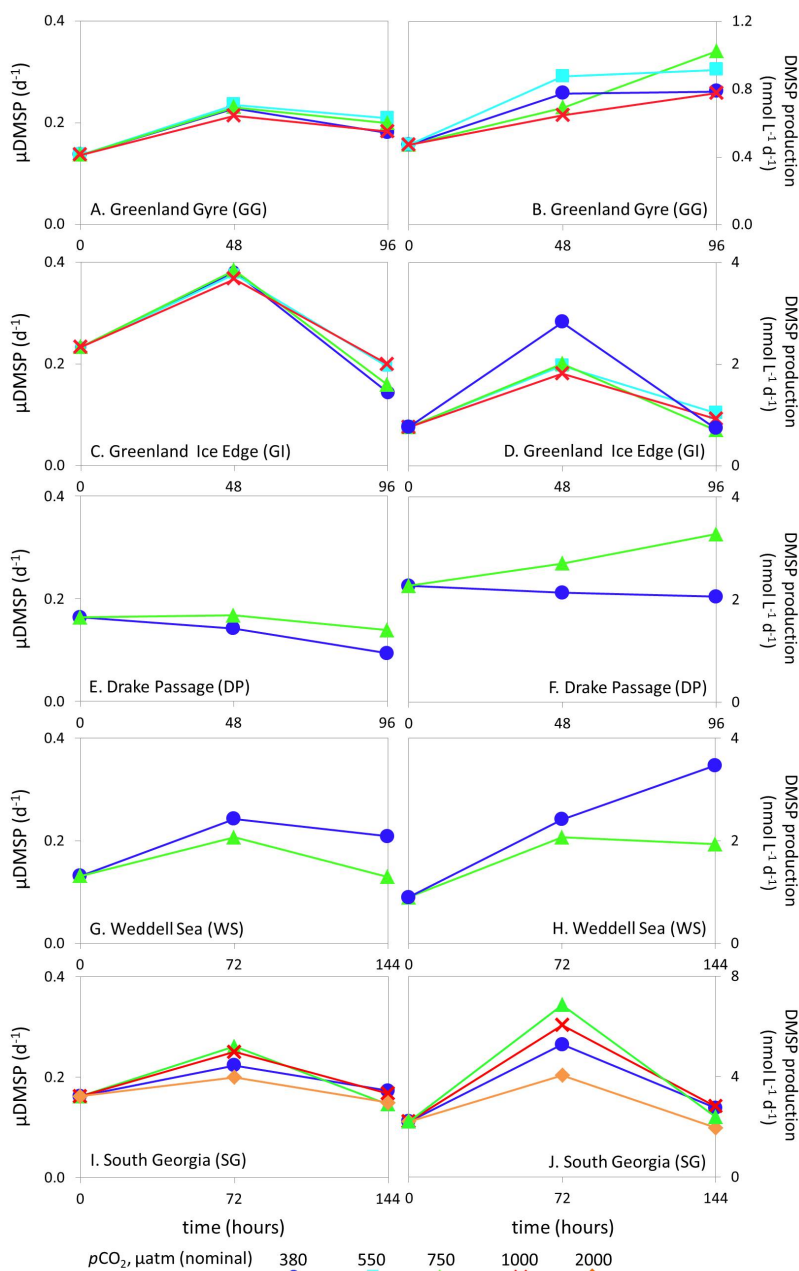

885

886

887 Figure 4. Total DMSP (solid lines) and particulate DMSP (dashed lines) concentrations (
 888 nmol L^{-1}) during experimental microcosms performed in Arctic waters (A - C) and in
 889 Southern Ocean waters (D - G). Error bars show standard error. Locations of water collection
 890 for microcosms shown in Figure 1 C - F. Particulate DMSP concentrations were used in
 891 calculations of DMSP production rates (Figure 5).

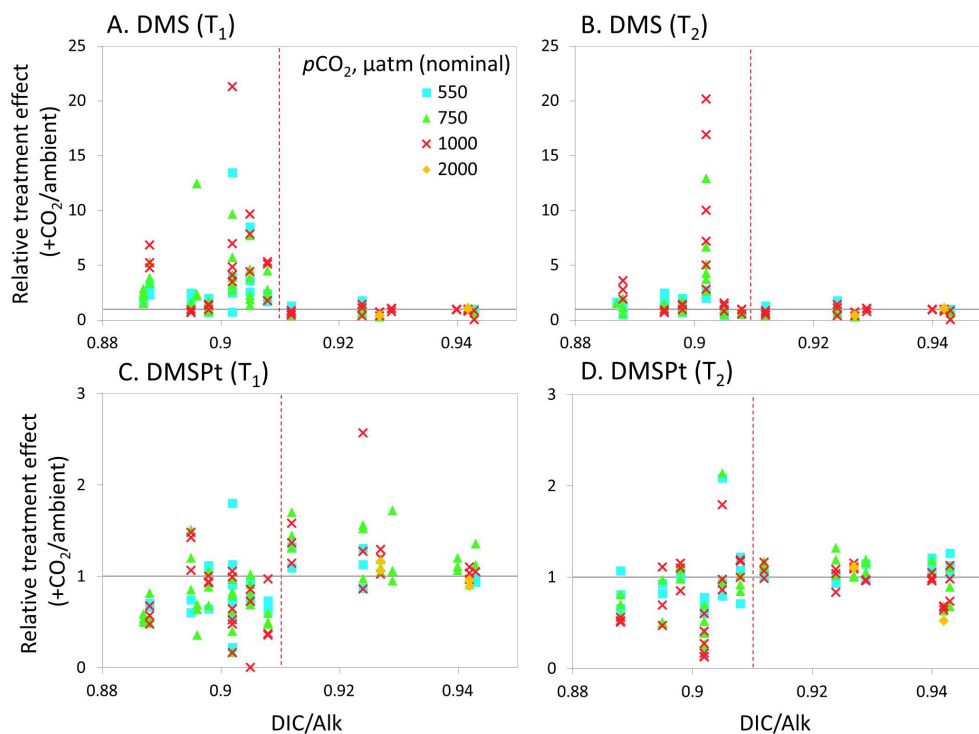

892

893 Figure 5. De novo synthesis of DMSP (μDMSP , d^{-1}) (left column) and DMSP production
 894 rates ($\text{nmol L}^{-1} \text{d}^{-1}$) (right column) for Arctic Ocean stations *Greenland Gyre* (A,B),
 895 *Greenland Ice-edge* (C, D) and Southern Ocean stations *Drake Passage* (E, F), *Weddell Sea*
 896 (G, H) and *South Georgia* (I, J). No data is available for *Barents Sea* (Arctic Ocean) or *South*
 897 *Sandwich* (Southern Ocean).

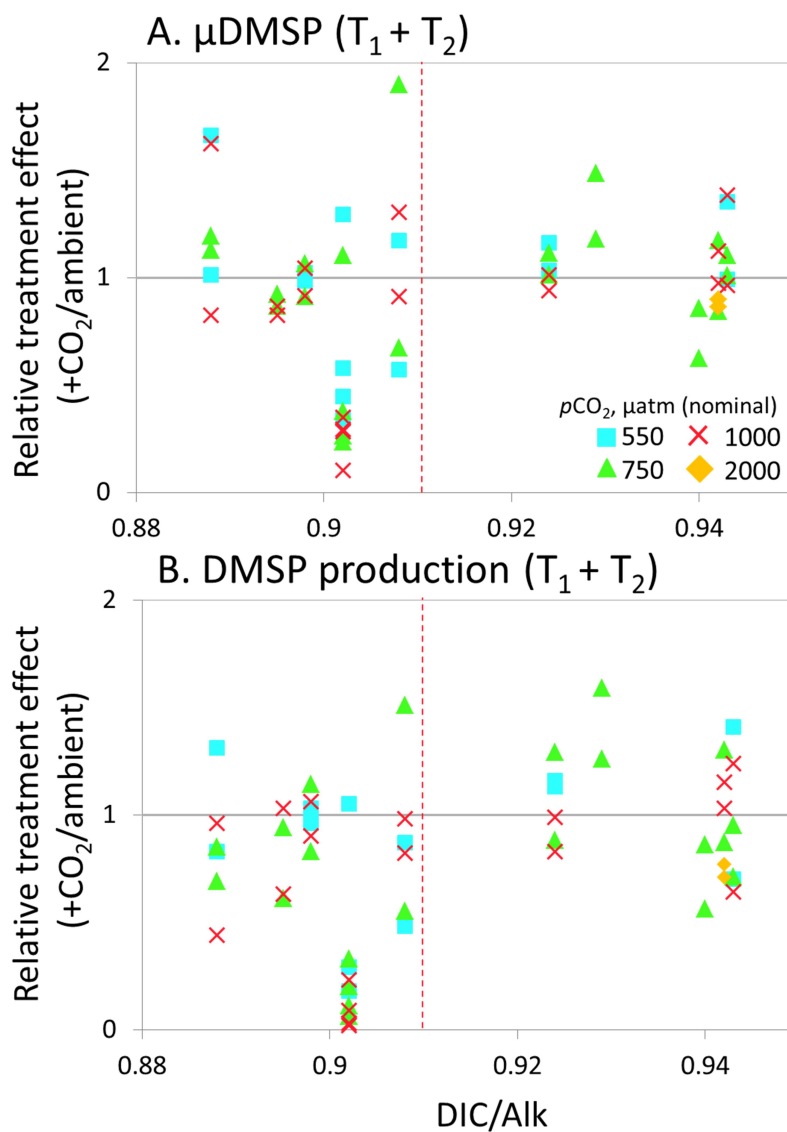

898

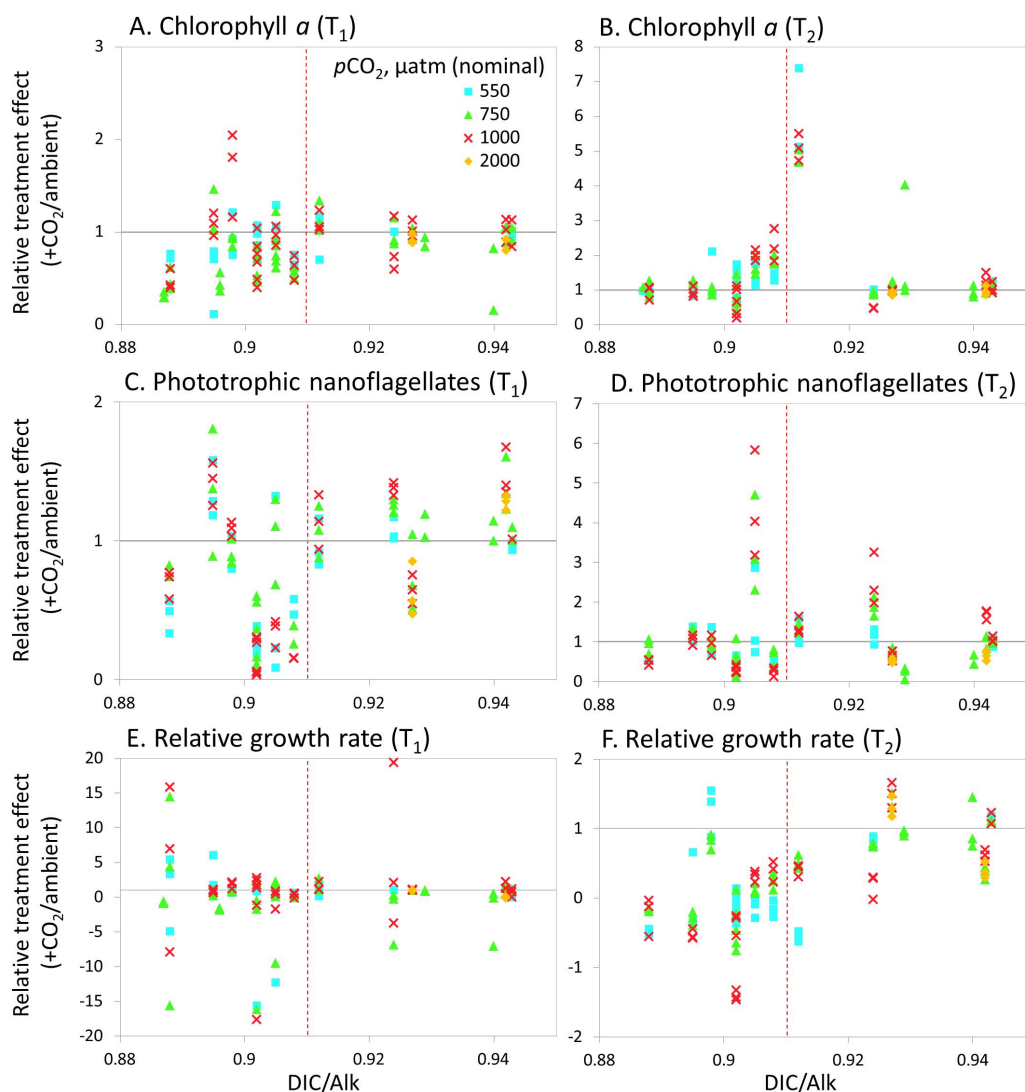

899

900 Figure 6. Relationship between the ratio of DIC to total alkalinity (DIC/Alk) of the sampled
 901 water and the relative CO₂ treatment effect at $([x]_{\text{highCO}_2}/[x]_{\text{ambientCO}_2})$ for concentrations of
 902 DMS at T₁ (A) and T₂ (B), and for total DMSp concentrations at T₁ (C) and T₂ (D) for all
 903 microcosm experiments performed in NW European waters, sub-Arctic and Arctic waters,
 904 and the Southern Ocean. Grey solid line (= 1) indicates no effect of elevated CO₂. DIC/Alk
 905 >0.91 = polar waters (indicated by red dashed line). T₁ = 48 h, except for WS and SG (72 h)
 906 and SS (96 h). For detailed analyses of the NW European shelf data, see Hopkins & Archer
 907 (2014).

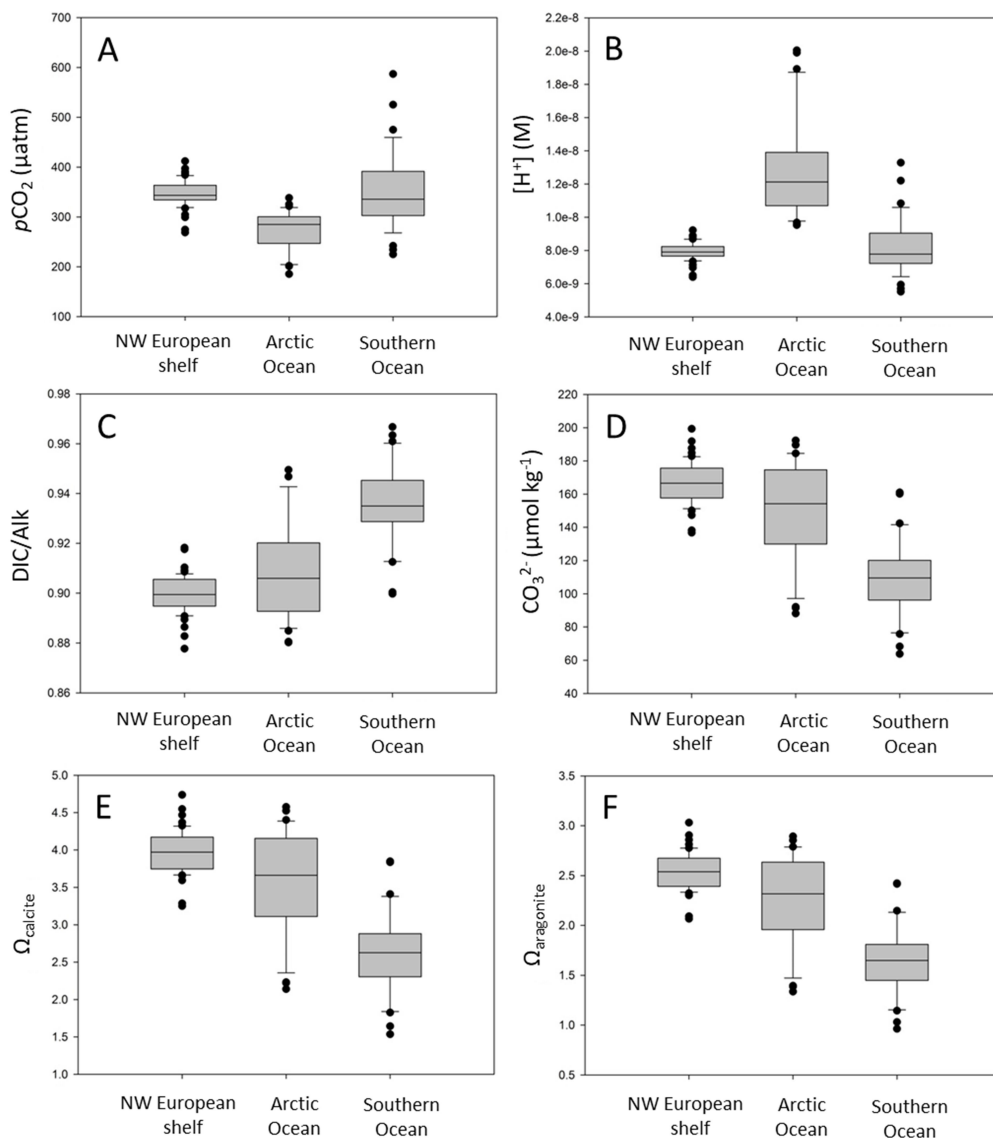

908

909 Figure 7. Relationship between the ratio of DIC to alkalinity (DIC/Alk) of the sampled water
 910 and the relative CO₂ treatment effect at $([x]_{\text{highCO}_2}/[x]_{\text{ambientCO}_2})$ for de novo DMSP synthesis
 911 ($\mu\text{DMSP}, \text{d}^{-1}$) at T₁ (A) and T₂ (B), and DMSP production rate ($\text{nmol L}^{-1} \text{d}^{-1}$) at T₁ (C) and T₂
 912 (D) for microcosm experiments performed in NW European waters, sub-Arctic and Arctic
 913 waters, and the Southern Ocean. Grey solid line (= 1) indicates no effect of elevated CO₂.
 914 DIC/Alk > 0.91 = polar waters (indicated by red dashed line). T₁ = 48 h, except for WS and
 915 SG (72 h). For discussion of the NW European shelf data, see Hopkins & Archer (2014).

916

917 Figure 8. Relationship between the ratio of DIC to total alkalinity (DIC/Alk) of the sampled
 918 water and the relative CO₂ treatment effect ($[x]_{\text{highCO}_2}/[x]_{\text{ambientCO}_2}$) for chlorophyll *a*
 919 concentrations at T₁ (A) and T₂ (B), phototrophic nanoflagellate abundance at T₁ (C) and T₂
 920 (D), and relative growth rate at T₁ (E) and T₂ (F) for all microcosm experiments performed in
 921 NW European waters, sub-Arctic and Arctic waters, and the Southern Ocean. Grey solid line
 922 (= 1) indicates no effect of elevated CO₂. DIC/Alk > 0.91 = polar waters (indicated by red
 923 dashed line). T₁ = 48 h, except for WS and SG (72 h) and SS (96 h).

924

925 Figure 9. Variation in underway surface ocean carbonate chemistry parameters across the
926 NW European shelf, Arctic Ocean and Southern Ocean for each of the cruises in this study.
927 A. Seawater $p\text{CO}_2$ (μatm), B. Seawater $[\text{H}^+]$ (M), C. DIC to total alkalinity ratio (DIC/Alk),
928 D. Carbonate ion concentration (CO_3^{2-}) ($\mu\text{mol kg}^{-1}$), E. Calcite saturation state (Ω_{calcite}), F.
929 Aragonite saturation state ($\Omega_{\text{aragonite}}$).

930
