### **ABSTRACT**

Wastewater biological treatment with microalgae can be an effective technology, removing nutrients and other contaminants while reducing chemical oxygen demand. This can be particularly interesting for the meat producing industry which produces large volumes of wastewater from the slaughtering of animals and cleaning of their facilities. The main purpose of this research was the treatment of poultry wastewater using Scenedesmus obliquus in an economical and environmentally sustainable way. Two wastewaters were collected from a Portuguese poultry slaughterhouse (poultry raw - PR and poultry flocculated - PF) and the bioremediation was evaluated. The performance of microalga biomass growth and biochemical composition were assessed for two illumination sources (fluorescent vs LEDs). S. obliquus achieved positive results when grown in highly contaminated agro-industrial wastewater from the poultry industry, independently of the light source. The wastewater bioremediation revealed results higher than 97% for both ammonium and phosphate removal efficiency, for a cultivation time of 13 days. The saponifiable matter obtained from the biomass of the microalga cultures was, on average, 11% and 27% (m/m<sub>alga</sub>) with PR and PF wastewater, respectively. In opposition, higher sugar content was obtained from microalgae biomass grown in PR wastewater (average 34% m/m $_{alga}$ ) in comparison to PF wastewater (average 23 $^{\circ}$  m/m $_{alga}$ ), independently of the illumination source. Therefore, biomass obtained with PR wastewater will be more appropriate as a raw material for bioethanol/biohydrogen production (higher sugar content) while biomass produced in PF wastewater will have a similar potential as feedstock for both biodiesel and bioethanol/biohydrogen production (similar lipid and sugar content).

## 1. Introduction

Global food production is estimated to be responsible for between 20% and 50% of anthropogenic environmental impacts [1] with the livestock sector accounting for more than the direct emissions from the transport sector [2].

While meat consumption is projected to increase by 70% by 2050, chicken meat has become one of the most extensively consumed food products in the world [3]. Portugal ranks ninth in chicken production among European Union countries and broiler chicken represents 75% of the total meat consumption in this country [4]. Nevertheless, chicken has been described as the most environmentally friendly meat in several Life Cycle Assessment (LCA) studies (e.g. [1]). González-García

et al. [4] studied a Portuguese broiler chicken production unit, namely the environmental impacts from the processes involved in a slaughterhouse (e.g. transport, packaging and waste treatment), with direct water emissions (e.g. P, COD) playing a significant impact in eutrophication potential. In fact, the meat processing sector produces large volumes of wastewaters due to the slaughtering of animals and cleaning of the slaughterhouse facilities and meat processing plants. This sector uses 24% of the total freshwater consumed by the food and beverage industry and up to 29% of that consumed by the agricultural sector worldwide [5]. In poultry processing, water is used primarily for feather removal (scalding), bird washing (before and after
