The Risk of Adverse Events Associated With Atropine Administration During Dobutamine Stress Echocardiography in Cardiac Transplant Patients: A 28-Year Single-Center Experience

JAMES WANG JI, MD², SIQIN YE, MD¹, JENNIFER HAYTHE, MD¹, P. CHRISTIAN SCHULZE, MD¹, and DAICHI SHIMBO, MD¹¹Department of Medicine, Columbia University Medical Center, New York, New York²Division of Cardiology, Columbia University Medical Center, New York, New York

Abstract

Background—Although dobutamine stress echocardiography (DSE) is performed in heart transplant patients, the safety profile of atropine administration in DSE in this setting is unclear.

Methods and Results—We identified heart transplant patients who received atropine during DSE from January 1984 to August 2011 at our institution and compared them with a propensity-scored matched control group of heart transplant patients who underwent DSE without atropine. Adverse events were defined as significant arrhythmias (sinus arrest, Mobitz type II heart block, complete heart block, ventricular tachycardia, or ventricular fibrillation), hypotension requiring hospitalization, syncope or presyncope, myocardial infarction, and death. Forty-five heart transplant patients (median age 62 years, 82% male) received 0.2–1 mg atropine during DSE. Of these, 1 patient (2.2%) developed temporary complete heart block. No adverse events were identified in the control group of 154 patients who received dobutamine without atropine.

Conclusions—Our findings suggest that complete heart block can occur infrequently with the administration of atropine in heart transplant patients undergoing DSE. Therefore, patients should be appropriately monitored for these adverse events during and after DSE.

Keywords

Atropine; dobutamine; stress echocardiography

Invasive coronary angiography is the recommended primary method for detecting allograft coronary artery disease (CAD) in patients who have undergone orthotopic heart transplantation.¹ Nevertheless, dobutamine stress echocardiography (DSE) is commonly performed as an alternate modality that can provide complementary assessment of functional perfusion.^{2–10} When dobutamine alone is insufficient to achieve target heart rate during

Disclosures

None.

stress echocardiography, atropine can be administered to augment the heart rate response.^{5,7,11} However, evidence from small studies suggests that adverse events can occur with the use of atropine in heart transplant patients, including sinus arrest or complete heart block that can result in syncope or require ventricular pacing.^{12,13} Notably, none of those studies were conducted in the setting of concurrent dobutamine infusion. Previous reports of heart transplant patients who received atropine during DSE did not report any significant side effects, but these studies were small and did not primarily examine the safety profile of atropine when given concurrently with dobutamine.^{5,11,14–17} To examine whether atropine can be safely administered during DSE, we examined the use of atropine during DSE for heart transplant patients at our institution.

Methods

Study Design

We used the electronic health record (EHR) to retrospectively identify all heart transplant patients who underwent DSE with atropine at the Columbia University Medical Center (CUMC) from January 1, 1984, to August 18, 2011, and selected as control subjects propensity score–matched heart transplant patients who underwent DSE without atropine during the same time period. To accomplish this, we queried DSE reports of all heart transplant patients followed at CUMC during that time period with the use of the terms “dobutamine” and “atropine.” From all heart transplant recipients, we identified 2,157 patients who had undergone DSE and of these 45 patients who received both dobutamine and atropine. Of these 45 patients, each underwent exactly 1 DSE during which they received atropine. To identify a suitable control population, we randomly selected a group of 400 transplant patients who underwent DSE but did not receive atropine. Using a standardized data extraction template for both groups (heart transplant patients that received dobutamine and atropine during DSE, and those who received dobutamine only), we manually abstracted from the medical record each patient’s demographic and medical covariates at the time of DSE, including age, sex, time since transplant, beta-blocker use, calcium channel blocker use, and history of known transplant CAD (based on left heart catheterization). We performed nearest-neighbor propensity score matching^{18,19} on the 400 randomly selected heart transplant patients who underwent DSE but did not receive atropine to further identify a subset of 154 patients who were matched to those who received both dobutamine and atropine on the aforementioned baseline characteristics (age, sex, time from transplant, beta-blocker use, calcium channel blocker use, and known transplant CAD). For patients in the control group who had undergone >1 DSE, the most recent DSE was included for analysis. The results did not change when earlier DSE studies were used in the analyses for these patients. We then abstracted height, weight, body mass index (BMI), left ventricular ejection fraction (LVEF), history of hypertension, diabetes, or ischemic cardiomyopathy, existing bundle branch block (defined as QRS duration >120 ms) before DSE, and use of immunosuppressants (including corticosteroids, tacrolimus, mycophenolate, sirolimus, and cyclosporine) for all 45 atropine recipients and 154 propensity score–matched patients who did not receive atropine during DSE.

Dobutamine Stress Echocardiography Protocol

For DSE, a standard protocol was used for all patients, beginning with dobutamine infusion at $10 \mu\text{g kg}^{-1} \text{min}^{-1}$ and increasing by $10 \mu\text{g kg}^{-1} \text{min}^{-1}$ every 3 minutes, until a maximum infusion rate of $40 \mu\text{g kg}^{-1} \text{min}^{-1}$. For patients who also received atropine, 0.2–1 mg atropine was administered during the final stage. All patients were monitored by electrocardiogram and blood pressure recordings during DSE and monitored on telemetry for ~1 hour after DSE was completed. We abstracted baseline and peak heart rates and the doses of dobutamine and atropine administered. For adverse outcomes, all patients were monitored for occurrence of adverse events until time of discharge to home, and we manually searched the EHR for any events that occurred within 30 days after DSE for each patient, defined a priori as clinically significant arrhythmias (sinus arrest, Mobitz type II or complete heart block, ventricular tachycardia, or ventricular fibrillation), hypotension requiring hospitalization, syncope or presyncope, myocardial infarction, and death. None of the participants were lost to follow-up during this period.

Statistical Analysis

Demographic and clinical characteristics were compared for patients who received atropine during DSE and for those who did not. Demographic characteristics that were compared include age, sex, and time since transplant. Clinical characteristics that were compared include BMI, presence of diabetes and hypertension, ischemic cardiomyopathy before transplantation, presence of baseline bundle branch block, LVEF, use of beta-blockers and calcium channel blockers, and presence of transplant CAD based on catheterization. We examined all variables for normality of distribution. In addition, we compared DSE test characteristics, including dobutamine dose, heart rate at rest and peak heart rate, and number of adverse events during DSE between the 2 groups. For normally distributed variables, Pearson chi-square tests or Fisher exact tests were used for comparison between categorical variables, and independent *t* tests were used for continuous variables. For non-normally distributed variables, nonparametric testing with the use of the Mann-Whitney *U* test was performed for comparison. A *P* value of $<.05$ was considered to be statistically significant. All calculations were performed with the use of the statistical packages IBM SPSS Statistics for Windows 17.0 and Stata IC version 10. Propensity score matching was performed using the Stata module *psmatch2* by Leuven and Sianesi.²⁰

Results

Of the 45 heart transplant patients who received dobutamine and atropine during DSE, the median (25th–75th percentiles) age at DSE was 62 (49–69) years, and the median (25th–75th percentiles) time between heart transplantation and DSE was 7 (4–10) years. Thirty-seven patients (82%) were male. As expected, the propensity score–matched control group of heart transplant patients who received dobutamine without atropine was not significantly different from the group who received both dobutamine and atropine in age, sex, time since heart transplantation, beta-blocker and calcium channel blocker usage, and known transplant CAD. Other baseline patient characteristics also were similar, including BMI, comorbidities, immunosuppressive medications, prevalence of baseline bundle branch block, and LVEF (Table 1).

In the group that received dobutamine and atropine, each patient underwent exactly 1 DSE in which they received both medications. These 45 patients all received a maximum rate of dobutamine infusion at $40 \mu\text{g kg}^{-1} \text{min}^{-1}$; 24 (53%) of the 45 heart transplant patients received a maximum dose of 1 mg atropine. The median (25th–75th percentiles) dose of atropine received was 1 (0.5–1) mg, corresponding to a weight-based dose of 0.01 (0.006–0.013) mg/kg. In the group that received dobutamine without atropine (Table 2), the median (25th–75th percentiles) maximum rate of dobutamine infusion was 30 (20–40) $\mu\text{g kg}^{-1} \text{min}^{-1}$, which was significantly lower than the dose of dobutamine in patients who did not receive atropine ($P < .005$). Compared with patients who received both dobutamine and atropine, patients who received dobutamine without atropine had significantly higher resting and peak heart rates ($P < .005$ for both), and were more likely to achieve maximum predicted heart rate for age (MPHR) of 80% ($P < .005$) and 85% ($P < .005$; Fig. 1; Table 2).

Regarding adverse events, of the 45 heart transplant patients who received dobutamine and atropine, 1 patient (2.2%) experienced complete heart block along with ventricular asystole 20 seconds after receiving 0.5 mg (0.01 mg/kg) atropine, leading to hypotension and syncope (Fig. 2). This patient was a 55-year-old woman 12 years after transplantation with normal allograft cardiac function, baseline right bundle branch block, and no known history of coronary disease, bradycardia, complete heart block, syncope, or hypotension. Chest compressions were administered within 5 seconds of heart block and the patient reverted to normal sinus rhythm with gradual recovery of consciousness. The patient was subsequently hospitalized and an electrophysiology study was conducted the following day which showed no conduction block at or below the level of the His bundle and no evidence of intrinsic conduction disease. She was discharged without further events or need for pacemaker implantation. The remaining 44 patients did not experience any adverse clinical events during or after DSE, and no events were identified within 30 days of DSE. No adverse events were identified in the control group for any of the DSEs performed during the follow-up period.

Discussion

The present study represents one of the largest cohort of heart transplant patients who received atropine during DSE and the first to primarily focus on the safety of atropine administration during dobutamine infusion. We examined the use of atropine during DSE in heart transplant patients in a real-world clinical setting, and we found that atropine administration was associated with complete heart block, an infrequent yet idiosyncratic adverse event.

The paradoxical complete heart block induced by atropine alone without dobutamine in heart transplant patients has been described previously.^{12,13} Brunner–la Rocca et al reported that 3 (13%) of 23 heart transplant patients who received atropine without dobutamine developed syncope with 2nd-degree atrioventricular block or complete heart block 15–150 minutes after receiving atropine.¹² Similarly, a study by Bernheim et al showed that atropine administration without dobutamine was associated with complete heart block and sinus arrest in 5 (20%) out of 25 patients in a non-dose-dependent manner, and the lowest atropine dose associated with an adverse event was 0.004 mg/kg.¹³ Our results extend the

findings of those earlier studies by examining the risk of complete heart block with atropine in heart transplant patients undergoing concurrent administration of dobutamine.

A few studies of atropine use in heart transplant patients undergoing DSE have been conducted, but they were smaller and did not primarily focus on the risk of adverse events.^{5,11,14–17} A retrospective study by Kociolek et al included 21 transplant patients who received atropine during DSE, and a similar study by Flox et al included 14 transplant patients who also received both agents.^{11,16} The patient populations in those studies were similar to ours, though the study by Flox et al did not include patients using beta-blockers. Although there were slight protocol differences, such as higher doses of atropine and dobutamine in the study by Kociolek et al, no adverse events were reported in either study. In contrast, our study, which primarily focused on the safety of atropine administration in heart transplant patients undergoing DSE, found a possible, but low, risk of paradoxical heart block.

Although several studies have associated atropine with causing bradycardia in nontransplanted patients,^{21–23} reports of atropine associated with high-degree atrioventricular (AV) block are rare.^{24–26} One study described a patient who was administered atropine for anesthesia-induced sinus arrest,²⁶ and another case study described a patient that was administered atropine for anesthesia-induced sinus bradycardia²⁴; both patients developed high-degree AV block (though not complete heart block) after atropine was given. A third case-series described 12 patients who developed Mobitz type I heart block in the setting of acute inferior wall myocardial infarction; 3 of those patients developed complete heart block after atropine was administered.²⁵ In all 3 studies, confounding by indication may have contributed to the results: Atropine was given to patients who had acutely abnormal AV conduction, and therefore the association between atropine and high-degree heart block may merely be a consequence of the deteriorating condition of the patients. In contrast, the present study describes the development of complete heart block after atropine administration in a heart transplant patient receiving dobutamine and whose rhythm was stable.

There is currently no standard recommended duration of monitoring in heart transplant patients once DSE has been completed, particularly for those patients that received atropine.^{27,28} Atropine has a longer half-life (2–3 h) than dobutamine (2 min).²² In our study, the one adverse event occurred 20 seconds after receiving atropine. However, given the half-life of atropine, and the idiosyncratic nature of the adverse event, it may be prudent for heart transplant patients who receive atropine to be monitored closely not only during DSE, but also during the period immediately after DSE.

The mechanism of the paradoxical heart block in heart transplant patients who receive atropine is unknown, but earlier investigators speculated that alterations in receptor response to atropine after heart transplantation may be responsible.^{12,13} It has been theorized that changes in muscarinic receptor expression or function may occur after heart transplantation, leading to a parasympathomimetic response after atropine administration.¹² Alternatively, it has been suggested that atropine could decrease automaticity and prolong the atrial refractory period in poorly re-innervated transplanted hearts.²⁹

Although our study is focused on safety rather than on efficacy of atropine as a chronotropic agent, we did find that only 2 (4.5%) of 45 patients achieved heart rate \geq 85% MPPHR, which is lower than the findings of earlier studies.^{11,16} This difference could be due in part to protocol differences such as the maximum doses of dobutamine and atropine that were given. Doses of dobutamine and atropine for each patient in our study were determined by the supervising physician. Of the 45 patients, 16 (36%) were able to achieve \geq 80% MPPHR. As there is some evidence suggesting that this heart rate (80% MPPHR) provides adequate sensitivity for detecting CAD in heart transplant patients,^{4,17} it is possible that physicians at our institution may have targeted a lower maximum heart rate during DSE.

Our study has several possible limitations. Our study is a retrospective analysis of DSE in heart transplant patients performed at a single center, and the dosing of atropine was left at the discretion of the supervising physician for each DSE, which may limit the generalizability of our finding to other institutions. However, the dose of atropine used in our study is similar to or lower than those used in earlier studies, suggesting that the risk of complete heart block may occur even with judicious atropine dosing. It is possible that we did not capture short episodes of complete heart block that occurred hours or more after atropine administration when patients were not monitored. However, we searched for events up to a month after each DSE in our EHR, making it unlikely that any episodes of heart block that we missed would have been clinically significant.

In conclusion, the present study represents one of the largest studies to examine the safety of atropine administration during DSE in heart transplant patients. Our results suggest that in the presence of a chronotropic agent such as dobutamine, complete heart block can occur as an infrequent and idiosyncratic reaction to atropine in heart transplant patients. We recommend that patients who receive atropine should be appropriately monitored after DSE to detect these adverse events. Future studies are needed to better characterize the efficacy of using atropine to augment heart rate response in heart transplant patients undergoing DSE.

Table 1

Patient Characteristics

	Patients Who Did Not Receive Atropine (n = 154)	Patients Who Did Receive Atropine (n = 45)	P Value *
Median age, y (25–75th percentiles)	61 (51.5–70.5)	62 (49–69)	.55
Median time since transplant at time of DSE, y (25–75th percentiles)	7 (3.5–12)	7 (4–10)	.69
Male gender, n (%)	134 (87%)	37 (82%)	.62
Mean BMI, kg/m ² (SD)	27.7 (4.9)	28.0 (5.4)	.73
Diabetes, n (%)	81 (53%)	22 (49%)	.66
Hypertension, n (%)	67 (44%)	20 (44%)	.91
Ischemic cardiomyopathy before heart transplantation, n (%)	50 (33%)	16 (39%)	.30
On beta-blocker, n (%)	49 (32%)	15 (36%)	.85
On calcium channel blocker, n (%)	20 (13%)	4 (21%)	.46
Baseline bundle branch block, n (%)	33 (21%)	7 (16%)	.39
Mean no. of immunosuppressants (SD)	2.7 (0.5)	2.7 (0.5)	.47
Mean left ventricular ejection fraction, % (SD)	56 (8)	56 (7)	.94
Has transplant CAD by catheterization, n (%)	9 (5.8%)	2 (4.4%)	.72

BMI, body mass index; CAD, coronary artery disease, DSE, dobutamine stress echocardiography.

* *P* values were calculated with the use of chi-square tests for categorical variables and Student *t* tests for continuous variables, except for age and time since transplantation, for which Mann-Whitney *U* tests were used owing to skewed distributions.

Table 2

Test Characteristics in Heart Transplant Patients Who Did and Did Not Receive Atropine During DSE

	Patients Who Did Not Receive Atropine (n = 154)	Patients Who Did Receive Atropine (n = 45)	P Value*
Median maximum dobutamine dose, $\mu\text{g kg}^{-1} \text{min}^{-1}$ (25–75th percentiles)	30 (20–40)	40 [†]	<.005
Mean heart rate at rest, bpm (SD)	86 (12)	76 (9)	<.005
Mean peak heart rate, bpm (SD)	135 (17)	123 (14)	<.005
Mean peak heart rate, % MPHR (SD)	85 (9)	76 (7)	<.005
Achieved 80% MPHR, n (%)	128 (83%)	16 (36%)	<.005
Achieved 85% MPHR, n (%)	97 (63%)	2 (4.5%)	<.005

bpm, beats per minute; MPHR, maximum predicted heart rate for age.

* *P* values were calculated with the use of chi-squared tests for categoric variables and Student *t* tests for continuous variables, except for dobutamine dose, for which Mann-Whitney *U* tests were used owing to skewed distributions.

[†] All patients in this group received $40 \mu\text{g kg}^{-1} \text{min}^{-1}$.
