12 **Abstract**

13 The structures and textures preserved in lava domes reflect underlying magmatic and eruptive

14 processes, and may provide evidence of how eruptions initiate and evolve. This study explores the

15 remarkable cycles in lava extrusion style produced between 1922 and 2012 at the Santiaguito lava

16 dome complex, Guatemala. By combining an examination of eruptive lava morphologies and textures

17 with a review of historical records, we aim to constrain the processes responsible for the range of

18 erupted lava type and morphologies. The Santiaguito lava dome complex is divided into four domes

19 (El Caliente, La Mitad, El Monje, El Brujo), containing a range of proximal structures (e.g. spines)

20 from which a series of structurally contrasting lava flows originate. Vesicular lava flows (with a'a

21 like, yet non-brecciated flow top) have the highest porosity with interconnected spheroidal pores and

22 may transition into blocky lava flows. Blocky lava flows are high volume and texturally variable with

23 dense zones of small tubular aligned pore networks and more porous zones of spheroidal shaped

24 pores. Spines are dense and low volume and contain small skeletal shaped pores, and subvertical

25 zones of sigmoidal pores. We attribute the observed differences in pore shapes to reflect shallow

26 inflation, deflation, flattening or shearing of the pore fraction. Effusion rate and duration of the

27 eruption define the amount of time available for heating or cooling, degassing and outgassing prior to

28 and during extrusion, driving changes in pore textures and lava type. Our new textural data when

29 reviewed with all the other published data allow a cyclic model to be developed. The cyclic eruption

30 models are influenced by viscosity changes resulting from (1) initial magmatic composition and

31 temperature, and (2) effusion rate which in turn affects degassing, outgassing and cooling time in the

32 conduit. Each lava type presents a unique set of hazards and understanding the morphologies and

33 dome progression is useful in hazard forecasting.

34 1   Introduction

35 The morphology and textures of lava preserve a story of the conditions and processes taking place

36 during its ascent. Recognising and understanding conditions for various extrusive and eruptive

37 products can provide insights to future timing of events and associated hazards (Calder et al., 2015).

38 At lava domes worldwide, lava morphology and surface textures have been shown to form in response to

39 several emplacement variables, including variations in effusion rate (Watts et al., 2002), emplacement

40 stress regime (Fink et al., 1990; Hale and Wadge, 2008), changes in volatile content (Anderson and Fink,

41 1990), crystallinity or composition (Watts et al., 2002), fragmentation processes (Wadge et al., 2009), and

42 sintering (Kendrick et al., 2016). Insights into the interacting variables are preserved in the crystal and

43 pore textures of the lava and further supplemented by compositional analysis and observations during

44 eruption. At dome volcanoes, the volatile content, and consequently bubbles, are considered

45 particularly important as the system is often on the boundary betweeen explosive and effusive

46 behavior (e.g., Edmonds and Herd, 2007; Mueller et al., 2011).

47 Bubbles are considered stationary rather than mobile in highly-crystalline high viscosity magmas, as

48 the viscous forces dominate over the buoyant forces acting on the bubbles, promoting a coupled rise

49 of melt and bubbles (Sparks, 2003). Where magma is rising slowly, permeable magma foam

50 (Eichelberger et al., 1986; Jaupart and Allègre, 1991; Rust and Cashman, 2011), or cracked magma

51 (Tuffen et al., 2003; Lavallée et al., 2013) allows outgassing along the outer shear margin of the

52 magmatic column (Gaunt et al., 2014; Hornby et al., 2015) and/ or out into the surrounding country

53 rock, developing a partially or periodically open system (Castro et al., 2012; Cashman and Sparks,

54 2013; Kendrick et al., 2013). Evidence of continual outgassing and a periodically open system can

55 both be observed at Santiaguito (Stoiber and Rose, 1969; Johnson, 2004; Bluth and Rose, 2004;

56 Holland et al., 2011; Scharff et al., 2012; Ball et al., 2013).

57 Here we consider degassing as the shallow process of volatiles exsolving from the melt— typically

58 forming bubbles (pores). This process is controlled by the volatile overpressure and solubility, and

59 equilibrium conditions permitting bubble nucleation and growth (Cashman and Sparks, 2013). In

60   contrast, we view outgassing as the process of the exsolved volatiles escaping from the lava, which

61   requires a permeable pathway. A prerequisite for the effusion of high-viscosity lava domes is the

62   partial development of open system degassing and outgassing (Calder et al., 2015). In an open

63   system, gas is able to escape from the magma, reducing gas pressure and decreasing the chance of

64   explosive eruptions (Cashman et al., 2000; Gonnermann and Manga, 2007; Holland et al., 2011;

65   Mueller et al., 2011). Both degassing and outgassing are affected by temperature, pressure, stress

66   conditions and the residence time of magma in the shallow conduit. In particular, residence time in

67   the conduit is important for high-viscosity magmas for which the physical processes associated with

68   bubble growth, coalescence and collapse, is sluggish.

69   Santiaguito comprises four domes (El Caliente, La Mitad, El Monje, El Brujo) which are aligned

70   along an overall E-W trend (Figure 1). Extrusion began in 1922, and has continued uninterrupted,

71   with nine documented cycles of extrusion (Harris et al., 2003; Rose, 1973b; Ebmeier et al., 2012).

72   Santiaguito has experienced a range of activity during this time including lava dome, lava flow and

73   spine extrusions. Extrusive activity is punctuated by explosive events which has resulted in

74   Vulcanian gas- and ash-plumes (Figure 1A) and occasionally pyroclastic density currents. El Caliente

75   vent is the only site to have been continuously active since 1922. The three other domes are mostly

76   inactive, except for mild gas emission, and are thus accessible for textural analysis. Evolution of the

77   domes has been extensively described and documented (Sapper, 1926; Williams, 1932; Stoiber and

78   Rose, 1969, 1970; Rose, 1972b, 1973a,b, 1987b; Rose et al., 1970, 1976; Smithsonian Institution,

79   1980–present; Anderson et al., 1995; Andres and Rose, 1995; Harris et al., 2002, 2003, 2004; Bluth

80   and Rose, 2004; Sahetapy-Engel et al., 2004, 2008; Sahetapy-Engel and Harris, 2008; Forbes, 2010;

81   Sanderson et al., 2010; Brill, 2011; Holland et al., 2011; Ebmeier et al., 2012) providing a first order

82   basis for the detailed textural and morphological analysis of lava dome emplacement attempted

83   herein. Extrusion cycles have been classified based on extrusion rate (Rose, 1973b; Harris et al.,

84   2003), but as yet classification of lava types and how they fit into the eruption sequence has not been

85   investigated. Thus, here we aim to classify lava types according to their texture and morphology,

86   place them in within the eruptive sequence, and explain the origins of these textural variations and

87   lava cycles.

88   **2   Geological and volcanological context**

89   Santa Maria is located on the southern edge of the Xela Caldera and is part of the Central American

90   Volcanic Arc which extends from Mexico to El Salvador (Figure 2; Duffield et al., 1993; Bennati et

91   al., 2011). Eruptive activity at Santa Maria began around 103 ka, and the edifice was constructed in

92   four stages before a 25 thousand-year period of quiescence prior to 1902 (Rose, 1987a; Rose et al.,

93   1977; Conway et al., 2013). Numerous lineations cut through the Santa Maria and Santiaguito

94   edifices with a rough east to west orientation (Figure 2; Escobar-Wolf et al., 2010).

95   In 1902 Santa Maria underwent a devastating Plinian eruption, generating at least 8.5 km^3 dense rock

96   equivalent (DRE) of dacite as ash- and pumice lapilli-fall deposits, and leaving an explosion crater or

97   collapse scar on the southern base of the edifice (Figures 1 and 2; Rose, 1972a; Williams and Self,

98   1983, Singer et al., 2013; Andrews, 2014). After a period of quiescence of 20 years, volcanic activity

99   resumed in 1922, with the extrusion of Caliente dome in the crater excavated in 1922 (Figure 1B).

100   Volcanic activity has occurred without interruption, although at varying effusion rates. Thus far, four

101   domes have been constructed— El Caliente (1922–1939; 1972–present day), La Mitad (1939–1949),

102   El Monje (1949–1958) and El Brujo (1958–1986), extruding a combined total of ~1 km^3 of magma

103   (Harris et al., 2003). Following dome growth at El Caliente, La Mitad, El Monje and El Brujo grew

104   sequentially, moving progressively to the west until activity renewed at El Caliente coincident with

105   activity at El Brujo in 1972 (Figure 1; Harris et al., 2003). The growth of the domes has been

106   described by Rose et al. (1970) and Rose (1972b, 1987b) and units mapped with respect to time by

107   Escobar-Wolf et al. (2010). El Caliente has been termed the main vent as it remained active with

108   intense fumarolic activity throughout growth of the lateral vents, and has been the only centre of

109   activity since 1977 (Rose, 1972b, 1987b).

2.1   Cyclic Lava Extrusion

111   This study builds on and supports the view of Harris et al. (2003) that lava extrusion is cyclic, with 3

112   to 6 year-long episodes of high extrusion rate (0.5–2.1 m^{3}s^{-1}) followed by 3 to 11 year periods of low

113   extrusion rate (≤0.2 m^{3}s^{-1}). El Caliente is the most active dome at Santiaguito, experiencing multiple

114   cycles of extrusion, at times coeval with activity at the other domes. Visual observations have

115   documented multiple active vents at Caliente (e.g. April 1967: Rose, 1973b). To date, nine different

116   cycles have occurred (Harris et al., 2003), with the latest emplacement of four lava flows >2 km in

117   length in 2011 to 2015 signaling the start of a new cycle. [Note that during the writing of this study

118   (late 2015 to early 2017), Santiaguito lava dome has experienced a period of heightened activity as

119   explosions have lessened in frequency, increased in magnitude and excavated a large crater inside El

120   Caliente, before resuming a lava dome growth phase.]

121   Activity prior to 1929 was endogenous, characterised by subsurface build-up of magma to inflate and

122   uplift the carapace of the El Caliente dome. Between 1929 and 1958 a combination of endogenous

123   and exogenous behavior occurred. Post 1958 growth has been solely exogenous, where lava extrudes

124   at the surface (Rose, 1987b; Harris et al., 2003). In December 2012 (i.e., at the time of our field

125   campaign), activity consisted of regular explosions (≤ 2 h^{-1}) producing gas- and ash-plumes reaching

126   heights of <1 km (Lavallée et al., 2015; De Angelis et al., 2016), and simultaneous lava flow

127   extrusion accompanied by frequent incandescent rock falls. The recent observed behavior is

128   consistent with activity at Santiaguito throughout its growth.

129   **2.2 Lava Composition**

130   The chemical composition of Santiaguito dome lavas has been thoroughly analysed by Scott et al.

131   (2012, 2013), as well as by Rose (1972b), Avard and Whittington (2012), and Singer et al. (2013).

132   The first Santiaguito dome lavas extruded in 1922 were very similar to the 1902 eruption products:

133   porphyritic dacites dominated by phenocrysts of plagioclase feldspar (~20–30%), and less than five

134   percent in total of pyroxene, titanomagnetite, and sometimes amphibole (Rose, 1972b; Singer et al.,

135   2011; Scott et al., 2013). Although the phenocryst assemblage and abundance has not notably

136   changed over time, the bulk SiO_2 content of erupted magma has become progressively less evolved

137   with a decrease from 66 to 62 wt.% SiO_2 (Scott et al., 2013). Samples from Harris et al. (2003)

138   indicated that this decrease happened gradually post 1970, but more recent research by Scott et al.

139   (2013) suggest that the shift began as early as the 1930's and has been driven by magma mixing and

140   fractional crystallisation. Scott et al. (2012) suggest that the magma chamber developed in the lower

141   crust, 12 to 24 km deep, with no evidence of a shallow storage zone. A stratified magma chamber

142   model has been proposed with a vertical gradient in composition from a deep basaltic magma to a

143   shallow dacitic magma. This model may explain the progressive depletion in silica content in

144   eruptive products through time and the eruption of andesite at this stage (Scott et al., 2012).

145   Previous studies have highlighted that the various lava dome structures may be associated with

146   distinct geochemical signatures (e.g., Rose, 1972b; Avard and Whittington, 2012). Most lava

147   structures occur over the entire compositional range with a couple of exceptions. Spine structures

148   only seem to have developed from dacitic lava with 64 to 66 wt.% SiO_2. Blocky lava flows that have

149   reached distances exceeding 2.5 km from the vent seem to be characteristic of andesitic lavas with 62

150   to 64 wt.% SiO_2 (Rose, 1972b; Harris et al., 2003; Scott et al., 2012, 2013). Although there is a

151   general trend associated with lava types and composition, various lava types and structures are

152 observed within short periods of constant magmatic composition, and throughout the eruptive history
153 at Santiaguito.

154 **3　Material and methods**

155 3.1　**Characterisation**

156 Mapping and sample collection at Santiaguito was carried out during a four-week field campaign in
157 November to December 2012. The outlines of units were based on high-resolution aerial
158 orthophotographs taken in 2006 by the Instituto Geografico Nacional (IGN) of Guatemala. Features
159 such as the outline of the main lava flows were adapted (in consultation with the authors) from Escobar-
160 Wolf et al. (2010) and Ball et al. (2013). The focus of this study was on mapping summit features such as
161 individual spines and lobes, their strikes and dips, and unique textural or structural features associated
162 with them. Samples were taken from a range of these features on the dome summits and the recent lava
163 flows, ranging in age from 1940 to 2012.

164 3.2　**Porosity**

165 The density and porosity of samples were measured by pycnometry of 25 mm diameter cylindrical
166 samples using a Helium Ultrapycnometer 1000 at Massey University, New Zealand. We used dry rock
167 equivalent densities of 2616 ±4 kg m^{-3} for summit dome samples, and 2630 ±4 kg m^{-3} for the 2012 lava
168 flows (the closest spatially and temporally corresponding units from Avard and Whittington (2012)).

169 3.3　**2D and 3D textural analysis**

170 Textural analysis was undertaken to constrain the range of physical attributes of the lavas erupted. This
171 was achieved quantitatively in 2D and 3D using a combination of techniques. Thin sections were
172 prepared from rocks impregnated with epoxy containing a fluorescent dye, which eased the observation
173 and delineation of pore space in UV light source. Complementarily, the crystal fraction was imaged under
174 plane polarised light (PPL). A combination of manual tracing and ImageJ processing were used to
175 threshold out and calculate the phenocryst crystallinity. Microlite crystal content required further analysis
176 and 3–4 mm samples were prepared for backscatter imagery at the Scanning Electron Microscope (SEM)
177 at the University of Canterbury. The microlites were traced out in Inkscape and quantified using ImageJ.

178 3D microtomography reconstructions aided with the interpretation of pore shapes from the
179 flourescent thin sections and visually displayed their connectivity. Cross-sectional images of 10-mm
180 diameter samples were obtained using the Imaging and Medical beamline (IMBL) at the Australian
181 Synchrotron in Clayton, Victoria and reconstructed and analysed as 3D-image stacks in ImageJ. The

182　　scan energy of the beam was changed from 30–45 KeV as the samples varied in density. Pixel sizes

183　　of 2D images were either 6.10 µm or 13.73 µm, equivalent to voxel sizes in reconstructed 3D stacks

184　　of 227 µm^3 and 2,588 µm^3.

185　　3.4　　**Timing**

186　　The timing and interpretation of events was constructed from an exhaustive review of the literature and

187　　was aided by bulletins and photographs from: Smithsonian Institution Scientific Event Alert Network

188　　(SEAN) bulletins, Santiaguito Volcano Observatory (OVSAN) photographs, Instituto Nacional de

189　　Sismología, Vulcanología, Meteorología e Hidrología (INSIVUMEH) volcanic alert bulletins and NASA

190　　Landsat images. Photos and information from visiting and local scientists and observers also contributed

191　　(Bill Rose, Jessica Ball, Kyle Brill, Rudiger Escobar-Wolf, Julio Cornejo).

192　　**4　　Results**

193　　4.1　　**Lava type characterisation**

194　　Our historical summary, fieldwork, and textural analysis divide the lava types at Santiaguito into

195　　three main types: vesicular lava flows, blocky lava flows and spines. Crystallinity (percentage of

196　　phenocrysts and microlites) are consistent between the lava types (Table 1). Typically lava domes

197　　with high crystallinities have pore shapes controlled by crystals, producing irregularly shaped pores

198　　with ragged pore walls reflecting the inward protrusion of crystals (microlites and phenocrysts)

199　　(Hammer et al., 2000; Kendrick et al., 2013). This is also the case for the Santiaguito lavas. Despite

200　　this, a significant range of porosity and pore textures are exhibited and we use these in combination

201　　with morphology to characterise the lava types.

202　　Here, we present the morphology (Figure 3) and distribution (Figure 4), bubble and crystal textures

203　　(Figures 5–7) and relationships between the lava types (Figure 8). A summary of results is provided

204　　in Table 1.

205　　**4.1.1 Vesicular Lava Flows**

206　　These refer to lava flows with coherent, vesicular (a'a-like, yet unbrecciated) flow top and a steep

207　　rounded front (Figure 3). [Note that this is not easily classified by existing lava flow morphology

208　　nomenclature, i.e it is not a'a or blocky, thus we are limited to the use of "vesicular lava" in this

209　　study] Vesicular lava flows are restricted to the summit zone of the domes (Figure 4). An example of

210　　vesicular lava was witnessed extruding from El Caliente after moderate dome and summit lava flow

211　　collapse on November 28th 2012 (this field expedition; Figure 3A). In most cases vesicular lava flows

212   are overprinted by subsequent eruptions and not preserved (i.e. the November 2012 flow was

213   overprinted by unit Rcs). The units Rbe (erupted in 1978) and the beginning of Rma (erupted in the

214   1950's) are examples of vesicular lava flows (Figure 4). There are numerous historical accounts and

215   photographs of vesicular lava at Santiaguito, most notably following the explosion and dome collapse

216   in 1929, and when activity returned to El Caliente in 1972 (Anderson et al., 1995).

217   In our samples of vesicular lava from El Brujo (flow top and interior) porosity is high, ranging from

218   35 to 70% (Figure 5). The pores are spheroidal and interconnected, with dominantly convex edges

219   and with concave remnant pore wall protrusions (Figure 6). In thin section, pores reach a maximum

220   diameter of 10 mm in size, however tomography (Figure 6) and connected porosity data (Figure 5)

221   show that these pores form a connected network reaching total lengths of several centimeters and

222   extending beyond the dimensions of our 40-mm samples. Pores from the top of the flow are not

223   strongly aligned, though thicker horizontal bands of coalesced pores are present.

224   **4.1.2 Blocky Lava Flows**

225   Blocky lava flows generally have a coherent interior, and a top surface composed of smooth sided,

226   angular–subrounded blocks 0.1 m to 2 m in size (Figure 3). Blocky lava flows extrude from low

227   points in the active dome, however their thickness causes their upper surface to be ~10 m above the

228   vent rim. The flows reach 70 m thick, 500 m wide and vary in length from 400 m to 4 km (Figure 4).

229   These flows follow local depressions, typically river channels. Blocky lava flows vary significantly

230   in volume and have been divided up by length into summit blocky flows and long blocky flows for

231   some of our results (Figures 4 and 8).

232   Summit blocky lava flows are low-volume flows, which extend a short distance down the sides of the

233   dome, but never reach the base. The Units Rbf and Rbh (erupted in 1975) are examples of summit

234   blocky lava flows (Figure 4). These flows repeatedly collapse at the flow toe due to their low volume

235   and the high slope angle (≥35°) from the eruptive summit to the flank of the dome, producing block

236   and ash flows. This collapse dynamic may have prevented the flow front from reaching the base of

237   the dome.

238   Long blocky lava flows are the highest volume end member, and largest volume extrusive products at

239   Santiaguito. The units Rbb (erupted in 1959–1963) and Rcm (erupted in 2001–2004) are examples of

240   long blocky lava flows (Figure 4). A single long blocky lava flow may continue growing for a few

241   years and as a result these flows have the most pronounced ogives (pressure ridges) and levees

242   (Figures 3 and 4). Regular small block and ash flows and avalanches (>1 min^{-1}, reaching up to 400

243   m) initiate from collapse of both the flow front and sides. Flow fronts of long flows may collapse to

244   form block and ash flows reaching kilometers from the flow front such as in 1976 (Rose et al., 1976).

245   Vesicularity is heterogeneous, at both outcrop scale and micro scale. The top 5–10 m of long blocky

246   lava flows are more vesicular than the bulk of the interior as seen on La Mitad (this study) and on El

247   Brujo (Rose 1972). This vesicularity difference is reflected in the samples from the blocky top (3–

248   79%; Figure 5). Pores range in shape and size between and within samples, including larger round

249   pores as seen in vesicular lava flows, and slim tube shaped interconnected pores with varying degrees

250   of flattening and shearing that are unique to blocky lava flows (Figure 6).

251   As with vesicular lava flows, in thin section pores reach a maximum diameter of 10 mm; however

252   tomography and connected porosity show that these pores form connected networks reaching total

253   lengths of several centimeters and extending beyond the dimensions of our 40-mm samples (Figures

254   5 and 6). Pores in the samples with the highest porosity have dominantly convex pore surfaces with

255   concave remnants of bubble-wall protrusions, which indicate pore coalescence and/ or collapse by

256   shearing. These convex pores are the largest pores in blocky lava flows and are usually connected to

257   other large pores. Many of these interconnected pores show preferential long-axis alignment, and are

258   more aligned than the vesicular lava flow pores.

259   In the densest samples the pores have smaller maximum diameters. Some pores have both concave

260   and convex surfaces and evidence of remnant pore-wall protrusions, but have little alignment, which

261   are similar to some pores seen in spines. However, in most cases this pore morphology is aligned,

262   with dominantly convex pore walls and little evidence of pore-wall protrusions. These pores form

263   networks of interconnected tubes, and are unique to blocky lava flows. All pore types are dominantly

264   located adjacent to phenocrysts and lithic inclusions (Figure 6). Blocky lava flows can be preceded or

265   followed by spine extrusion.

266   **4.1.3 Spines**

267   Spines are dense, coherent masses of lava that extrude sub-vertically above the vent along linear

268   fault-controlled planes (Figure 3). They are low volume, and limited to the summit zone of the

269   domes. The largest spines reach 200 m long, 50 m wide and 70 m tall and the smallest spines are only

270   3 m x 5 m (Figure 4). The spines exposed on the domes today are commonly characterised by zones

271   of fractured dense material (>3 m wide), separated by regularly spaced subvertical scoriaceous or

272   brecciated zones (<1 m, here termed "shear zones") (Figure 3). Observations of spine extrusion at
273   Santiaguito report that sections of spines regularly collapse forming block and ash flows that reach
274   the base of the dome, or are repeatedly disrupted by explosive events (Williams, 1932; Rose, 1973b).

275   Most spines appear to have extruded near-vertically, whereas a few spines have curvilinear surfaces
276   that appear drooped and folded exhibiting some features similar to whaleback structures at
277   Monsterrat described by Watts et al. (2002). The difference between these low angle spines and the
278   lava flows is that they are much denser and have shear zones on the outer edges. Similar features
279   have been described at Unzen volcano (Smith et al., 2001; Hornby et al., 2015), Soufriere Hills
280   (Watts et al., 2002) and Mount St. Helens (Gaunt et al., 2014; Kendrick et al., 2014).

281   The largest of the exposed spines form the prominent ridges on La Mitad and El Monje domes (units
282   Re (erupted in 1931) and Rm (erupted in 1950); Figure 4). These spines tend to have multiple widely
283   spaced shear zones marked by more vesicular rinds at the edge of each dense core (Figure 3).
284   Commonly a vertical gap is observed in the centre of, and parallel to, a shear zone. The gaps widen
285   towards the top of the spine, implying that the denser sections of the spines may have moved apart
286   laterally at the weaker shear zones during extrusion. On a larger scale the major shear zones
287   interweave. Note that shear zones are distinct from cooling joints, which are not marked by a change
288   of texture or vesicularity.

289   The inside of the spines are dense, but the outside surface may either be smooth, or have a thin
290   brecciated or vesicular rind— "shear zones" (Figure 3). The dense zones within the spines have low
291   porosity (4–22%; Figure 5), and the pores are similar in shape and size between samples. In thin
292   section the pores reach a maximum of 5 mm in diameter; however tomography and connected
293   porosity data show that the pores form large interconnected networks within the 40-mm sample size.

294   The most common pore type is very thin, skeletal-shaped interconnected pores (Figure 6). These
295   have both convex and concave pore surfaces, evidence of remnant bubble-wall protrusion, and the
296   largest examples always border phenocrysts. Tomography shows that these pores form skeletal-like
297   networks of interconnected pores that are aligned extrusion-parallel in our samples. In contrast to the
298   thin tubular pores in the lava flows, the pore networks predominantly align in thin, tightly spaced
299   vertical planes, with lesser lateral connectivity than vertical. Occasional convex surfaces, bulbous
300   pores, and pore-wall remnants characteristic of more round interconnected pores are observed within
301   the porous network.

302   Shear zones within the spines generally have a higher porosity (11–79%) than the dense spine

303   interior (4–22%; Figure 5) and are texturally variable. The shear zones can broadly be differentiated

304   into two end members: vesicular and brecciated. Tomography and thin-section show that the

305   vesicular samples have an en-echelon pattern of interconnected sigmoidal pores (Figure 7). The

306   sigmoidal pores have convex and concave pore surfaces. Pores may be large and widely spaced or

307   thin and closely spaced and the largest examples always border phenocrysts and have evidence of

308   remnant bubble-wall protrusion.

309   In thin section the shear zone pores reach a maximum of 10 mm in diameter; however tomography

310   and connected porosity data show that the pores form interconnected networks within the 40-mm

311   sample size (Figures 5 and 7). Small sigmoidal interconnected pores also form along flow bands

312   within the dense spine interior. In thin section the dense interior shows local en-echelon bands with

313   remnants of previous rounded or thin interconnected pores. The length of the chain often extends

314   beyond the length of the 40 mm thin sections and thus cannot account for the full scale of the feature

315   observed in the field. Yet, the geometrical relationship observed in the micro- as well as the macro-

316   textures, such as S-C fabrics (showing the intersection of S-planes oblique to shear surface and C-

317   planes parallel to shear surface), sigmoidal pores and crystal alignments suggest simple shear in these

318   regions of strain localisation.

319   The brecciated shear zones host the dense rocks from the spine interior. We note that the porosity

320   increases slightly and the crystal size decreases along the edge of the spine. The clasts in the shear

321   zones are generally highly brecciated at the macro-scale (clasts 1–30 mm in size) and partially

322   fragmented internally at the microscopic scale. This may be analogous to the cataclasite zones

323   described at Mount St. Helens (Pallister et al., 2012) and have similar properties to those described in

324   the 1994–95 spine erupted at Unzen (e.g., Smith et al., 2001).

4.2   **Timing of lava types at Santiaguito**

326   The characterisation of lava types allowed a re-examination of the timing and progression of lava

327   types at Santiaguito. This synthesis of data is presented in Figure 7, with an accompanying map of all

328   the currently exposed extrusive products in Figure 4. The timeline builds on and supports Harris et al.

329   (2003) view that lava extrusion is cyclic.

330   A typical eruption cycle begins with an increase in extrusion rate and the early extrusion of spines,

331   often from a new vent. Spine growth is generally preceded by or coincident with endogenous growth

332 as the extrusion rate was low but steadily increasing. As the extrusion rate increases, lava flows of

333 increasing length are emplaced. Towards the end of a cycle the extrusion rate declines again, and the

334 trend is reversed culminating in spine growth. The next phase of activity typically resumes at a new

335 location.

336 Over time the lava type end members in the cycles changed. Prior to 1980, alternation between spine

337 formation and blocky lava flows of moderate lengths dominated the eruptive sequence. Since 1980,

338 blocky lava flows of variable lengths were erupted from the summit of Caliente dome. Blocky lava

339 flows in excess of 2.5 km in length were not extruded prior to 1965 and have become increasingly

340 dominant since. This transition has coincided with the less frequent spines, becoming significantly

341 smaller in size and volume, and no spines have been extruded since 1990.

342 Infrequent larger eruptions and dome or lava flow collapse events have caused larger ash plumes (<6

343 km) and block and ash flows (Rose, 1973a; Rose et al., 1976; Fink and Kieffer, 1993). The most

344 notable of which occurred in 1929 when a collapse and explosion at El Caliente sent a pyroclastic

345 density current 11 km downstream, killing ~ 5000 inhabitants in the town of El Palmar (Rose et al.,

346 1976; Simkin et al., 1994). Vesicular lava often follows collapse events.

347 The timeline highlights how lava types correspond with and respond to the extrusion rate and

348 eruption history, including the effects of slope, cooling, degassing and crystallization during

349 emplacement.

350 **5   Discussion**

351 5.1   **Controls on lava dome morphology**

352 This review, synthesis and new data concerning timing of lava types has revealed remarkable cycles

353 in lava extrusion style. Lava domes may extrude varying lava styles, from endogenous lobes to

354 exogenous lobes or spines (e.g., Manley, 1996; Fink and Griffiths, 1998; MacKay et al., 1998;

355 Nakada et al., 1999; Harris et al., 2002, 2004; Navarro-Ochoa et al., 2002). The development of

356 varying lava styles depends on lava viscosity and extrusion rate (Anderson and Fink, 1989; Swanson

357 and Holcomb, 1990; Zobin et al., 2002; Watts et al., 2002; Pallister et al., 2012), which dictates the

358 development of the shear zones that control extrusion dynamics (e.g., Lavallée et al., 2007, 2013;

359 Tuffen et al., 2013; Kendrick et al., 2014). We attribute the changes in morphology to (1) an evolving

360 source composition and temperature decrease over time (Scott et al., 2013), and (2) conduit processes

361   such as degassing, outgassing and strain rate driven viscosity changes and the evidence for this is

362   preserved in the pore shapes and sizes.

363   Several variables have been suggested to control the viscosity of dome lavas; principally melt

364   composition and temperature (Giordano et al., 2008; Mueller et al., 2009) as well as crystallinity

365   (Caricchi et al., 2007), porosity (Caricchi et al., 2011) and strain rate (Cordonnier et al., 2009;

366   Lavallée et al., 2007, 2013; Kendrick et al., 2013).

367   Consistent with the bulk rock composition, interstitial glass analyses of Santiaguito lavas display a

368   large range in composition (rhyolite–trachyte–dacite), broadly decreasing in SiO_2 with time, although

369   the SiO_2 content of the glass in individual samples (within a given eruptive unit) may range by up to

370   10 wt.% (Scott et al., 2012). Along with the composition, the temperature of the reservoir feeding

371   Santiaguito has likely increased (Table 2). The early Santiaguito lavas were very similar to the 1902

372   eruption products (Rose, 1972b; Singer et al., 2011; Scott et al., 2013) and may represent a pocket of

373   left-over dacite in the magma reservoir (e.g., Scott et al., 2013; Singer et al., 2013); thus we assume

374   that they erupted at a temperature similar to the Santa Maria eruption of around 850 °C (Scaillet et

375   al., 1998; Singer et al., 2013; Andrews, 2014;). Over time as progressively more andesitic magma

376   was erupted we expect that the temperature of the magma increased, to reach a maximum of 950 °C,

377   as estimated by Sahetapy-Engel et al. (2004), and supported by Scott et al. (2013) based on

378   amphibole geothermometry. Similarly, there have been <8% changes in crystal fractions and Scott et

379   al. (2012) hypothesised that crystallisation may be limited at shallow depths due to a "final quench"

380   where microlites stop nucleating and growing.

381   To a certain extent, magma chamber stratification and resultant shift in composition and temperature

382   has influenced the lava structures and extrusion cycles over time. In particular spines only formed

383   when dacitic lava was extruded and flows extending over 2.5 km only formed in andesitic lavas.

384   However, various lava types and structures are observed within short periods of similar and arguably

385   relatively constant pre-eruptive composition, temperature and crystallinity, and indicate that the pre-

386   eruptive conditions (i.e the physico-chemical state in the reservoir before ascent) are not the only

387   control on lava morphology.

388   Our evidence suggests that in addition to composition, conduit processes such as degassing, pore

389   configurations, strain rate and thermal shifts during ascent also drive the viscosity changes

390   responsible for the variations in dome eruption style at Santiaguito. The relatively open magmatic

391   system (Bluth and Rose, 2004; Holland et al., 2011) and the slow magma ascent likely allowed for

392   efficient outgassing through the interconnected porous network, which is observed in all lava types

393   (Figure 6), and obvious from continuous gas emission observations at Santiaguito. The amount of

394   dissolved water in the melt during extrusion is unknown at Santiaguito owing to a number of

395   challenging issues arising in these dome lavas. As such, here, we turn to pore textures as evidence of

396   degassing and outgassing and a schematic model of pore development is presented in Figure 9.

397   We attribute the observed differences in pore shapes and volume to be initially reflecting shallow

398   inflation, deflation, and coalescence of the exsolved bubble volume. Inflated interconnected pores

399   such as in vesicular lava flows and high porosity zones of blocky lava flows show complex pore

400   shapes and remnant pore wall protrusions from coalescence. In deflated interconnected pores such as

401   in spines and dense zones of blocky lava flows, the remnant pore-wall protrusions are smoothed as

402   decreasing gas pressure due to outgassing allows surface-tension-driven deformation (e.g., Kennedy

403   et al., 2016). Inflated pores likely indicate a lower viscosity and perhaps a residual water content in

404   the vesicular and blocky lavas.

405   Pores may have additionally undergone a degree of flattening and stretching, indicating preferential

406   compaction or shear (Rust et al., 2003; Wright et al., 2006; Kendrick et al., 2013; Ashwell et al.,

407   2015). Stretching of deflated pores results in a network of tube-shaped pores with a preferential

408   alignment in lava flows, or skeletal-shaped pore networks that are aligned along "extrusion-parallel"

409   planes developed in spines (Figure 6). Stretching of inflated pores produces sheet-like pores that

410   form flow bands in the lavas. Shear can additionally facilitate outgassing and deflation by increasing

411   the connectivity between pores (e.g., Okumura et al., 2009; Caricchi et al., 2011). This was shown

412   experimentally on Santiaguito samples by Avard and Whittington (2012) at strain rates representative

413   of long blocky lava flows, and is observed in our dense zones of blocky lava flow samples (Figure 6).

414   A distinct form of flow bands with en-echelon sigmoidal pores form along spine margins (Figure 7).

415   These are characteristic of dilation where brittle failure of magma results in tension gashes that rotate

416   into sigmoidal shapes and are influenced by phenocryst and remnant pore location (Kendrick et al.,

417   2012; Lavallée et al., 2013). The ragged pore walls in places indicate the magma was torn slowly

418   (unlike straight failure planes produced at high shear rates; see Lavallée et al., 2013). Such tearing

419   structures have also been observed at Unzen, Yakedake and Daisen by Smith et al. (2001). The high

420   porosity and connectivity of these shear zones likely contribute to outgassing. The considerable

14

421   evidence of pore collapse in the dense core of spines, bordered by elongate, shear-driven porous

422   bands in these lavas suggest efficient outgassing during ascent and extrusion.

423   5.2   **Advances to the understanding of cyclic lava extrusion at Santiaguito**

424   Here we incorporate our observations and textural analysis with previously published models to build

425   on the growing understanding of cyclic lava extrusion at Santiaguito. The textures and eruption

426   history support a model of a gradually changing reservoir composition and temperature, which is

427   modified by conduit outgassing and localised shear, to dramatically change the viscosity and eruption

428   style of the lava. The timing of the lava types illustrated in Figure 8 highlights how lava types

429   correspond with and respond to the extrusion rate and extrusion history documented by others.

430   At Santiaguito, extrusion rate is cyclical with 3 to 6 year-long phases of high extrusion rate (0.5–2.1

431    $m^3 s^{-1}$), followed by a longer (3–11 year) phase of low extrusion rate (0.2 $m^3 s^{-1}$) (Harris et al., 2003).

432   Extrusion rate determines the time in the shallow conduit available for (1) outgassing, reflected in the

433   pore volume and structures, and (2) cooling, influencing viscosity. Lavas at Santiaguito have a

434   viscosity measured to range between ~10^9 and 10^{12} Pa.s (Harris et al., 2002; Avard and Whittington,

435   2012), with spine structures likely on the upper end of this, as at other domes worldwide spines are

436   generally lower temperature and higher viscosity than flows (Nakada and Motomura, 1999;

437   Schneider and Vallance, 2008; Cordonnier et al., 2009). The lava types reveal a progression from

438   porous short flows with inflated pores and coherent flow tops through long lava flows with varied

439   pore morphology and blocky flow tops to spines with deflated pores and well developed porous shear

440   bands. A model for lava type progression is presented in Figure 10.

441   Activity at Caliente, Mitad and Monje all commenced with endogenous growth (Figure 10).

442   Although we do not have good time constraints of endogenous growth it probably accompanied all

443   lava types prior to 1958, and we refer to this phase as 'leaky' endogenous. Growth at El Caliente was

444   mostly endogenous until the second extrusion cycle began in 1929 (Harris et al., 2003).

445   Perhaps the most notable event in extrusion cycle II was the November 1929 dome collapse, as the

446   extrusion rate was increasing at El Caliente. The collapse was followed by the extrusion of vesicular

447   lava.

448   The most porous lava type, vesicular lava, is extruded after large eruptions or dome collapses (Figure

449   10). The clearing of overlying, more-degassed lava allows fresh magma to ascend relatively quickly,

450   without significant degassing; as a result the lavas vesiculate late at (or near) the surface forming

451   spheroidal vesicles. The vesicular lava flow extrusions coincide with less regular gas explosions, e.g.,

452   after the November 2012 collapse. Upon continued extrusion and flow, the flow top of the initially

453   summit-limited, vesicular lava (Figure 11a) apparently evolves in time and space into blocky lava

454   (Figure 11b). Simultaneously in the flow core of the blocky lavas, vesicles progressively collapse and

455   outgas during shearing and flow advancement. In Figure 11c, we show that other proximal lavas

456   exhibit a moderate degree of flow-top brecciation as they spill from a collapse scar with a surface

457   morphology intermediate between the coherent flow tops of the vesicular lavas and the blocky lavas.

458   Blocky lava flows extrude at high and low extrusion rates and have a connected network of inflated

459   and deflated pores. The longest lava flows were emplaced during constant, high-extrusion rates that

460   can last up to 2 years (Figure 8; Harris et al., 2003). Eruptions and fumarolic activity occur

461   simultaneously with long blocky lava flow extrusion (Rose 1973a; Bluth and Rose 2004; Johnson

462   2004; Brill 2011; Holland et al. 2011) indicating outgassing in conduit. Outgassing continues as the

463   lava flows downslope. This is evidenced by further vesicle reconfiguration, localised shear flattening,

464   stretching and deflation (e.g., Manley and Fink, 1987; Avard and Whittington, 2012, Ashwell and

465   Kendrick et al., 2015; Kennedy et al., 2016) in the flow core. Gas percolates through the permeable

466   network locally creating layers of highly vesicular lava immediately below the dense blocky top.

467   These spatially heterogeneous processes are reflected in the spatial heterogeneity of porosities

468   (vesicles and fractures) in the flows. At any time during flow, lava may be quenched at the flow front

469   or edges, preserving a complex history of pore inflation, deflation and shear from different parts of

470   the flow.

471   During periods of low extrusion rates, lava flows of decreasing length develop, and prior to 1990 the

472   dacitic composition favoured conditions suitable for spine growth (Figure 8). Spines precede and

473   follow blocky lava flows and have dense interiors containing small, connected, deflated pore

474   networks. Intermittent planar vesicular shear zones with en-echelon sigmoidal pores separate the

475   dense interiors. The low extrusion rate allows time for prolonged degassing, outgassing (evidenced

476   by pore deflation) and cooling in the conduit likely causing viscosity increases that may prompt spine

477   extrusion (Figure 10). Extrusion is accompanied by mild steam eruptions (Williams, 1932; Rose,

478   1973b), likely initiated along the planar vesicular shear zones, further aiding outgassing.

479   The recent andesitic eruptive period (1990–2016) switches between the extrusion of vesicular and

480   blocky lavas with length corresponding to extrusion rate, dome collapses and eruptions. Hence the

16

481 progressive change in the geochemistry of the erupted lavas in the last century from dacite to andesite

482 (e.g., Scott et al., 2013) may have influenced the temporal occurrence of switches in eruptive activity.

483 **6   Conclusions and Implications**

484 Our new mapping and textural data allowed us to categorise lava types at Santiaguito. Following this

485 an extensive review of all lava types and timing was conducted to create a timeline of extrusive

486 activity.

487   (1) There are three main lava types at Santiaguito: vesicular lava flows, blocky lava flows and

488   spines. These types reveal a progression from porous short flows with inflated pores through

489   to long lava flows with varied pore morphology to spines with deflated pores and well

490   developed porous shear bands. There is no significant differences in crystal content between

491   these lava types.

492

493   (2) The timing of the lava types highlights how they may respond to the extrusion rate and

494   extrusion history (including the effect of slope, cooling and degassing). Blocky lava flows of

495   increasing length develop at high extrusion rates and spines extrude at the beginning and end

496   of an extrusion cycle at low extrusion rates. A collapse or eruption may cause a shift to

497   extrusion of vesicular lava flows.

498

499   (3) Our new textural data when reviewed with all the other published data allows a model to be

500   developed: The model demonstrates the importance of (1) initial magmatic composition and

501   temperature, and (2) effusion-rate-driven degassing, outgassing and cooling in the conduit,

502   and hence viscosity, in controlling the eruption style and associated lava types.

503 Each lava type presents a unique set of hazards:

504   (1) Vesicular lava has the highest temperature and may correlate with higher volatile contents,

505   and therefore the greatest potential for decompression-driven explosive fragmentation.

506   However, they are short lived and low volume following vent-clearing eruptions or collapses

507   until conditions for blocky lava flows again prevail.

508

509   (2) Blocky lava flows produce regular small collapses from the flow fronts and flow sides. The

510   higher volume the flow (i.e. the higher the extrusion rate), the greater the hazard potential.

17

511   Flow fronts of long flows may collapse to form block and ash flows such as in September

512   1976 (Rose et al., 1976). In addition, large eruptions historically occur during an increase in

513   extrusion rate and blocky lava flow development (i.e. November 1929, April 1973, November

514   2012). Loose debris associated with large volume flows is transported down river channels by

515   destructive lahars (Harris et al., 2006).

516

517   (3)   Spines are cooler and degassed prior to extrusion and collapse regularly along fractures

518   during growth, producing a broad talus blanket and historically only small volume block and

519   ash flows. Spines may be destroyed by subsequent vent-clearing eruptions.

520

521   Eruptions, small pyroclastic flows and collapses are associated with all lava types. However, the

522   trends presented above provide an added understanding on the development of lava types and

523   sequencing useful in continued hazard forecasting.

777   **Tables**

778   Tables should be inserted at the end of the manuscript. Tables must be provided in an editable format
779   e.g., Word, Excel. Tables provided as jpeg/tiff files will **not be accepted**. Please note that very large
780   tables (covering several pages) cannot be included in the final PDF for reasons of space. **These**
781   **tables will be published as Supplementary Material on the online article page at the time of**
782   **acceptance. The author will be notified during the typesetting of the final article if this is the**
783   **case.**

784

785 **Table 1: Summary of lava properties by type**

	Vesicular Summit Lava Flow	Blocky Lava Flow	Spine
Description	Short very vesicular flow with a rounded coherent top	Short to long lava flow with mixed porosity and a blocky top	Dense sub-vertically extruded units
Rough Volume	Low <300 000 m^3	Low - High 200 000–1 600 000 m^3	Low <400 000 m^3
Dip	Low 5°–30° With steep dipping flow fronts (approx. >50°)	Low 5°–30° With shallow 32°ᵛ to steep 70° dipping flow fronts	High 38°–90°
Porosity (range)	35–70%	3†–79%	4–23%
Pore Textures	Round, interconnected pores	Zones of larger round and smaller tubular interconnected pores with evidence of flattening and stretching	Small skeletal interconnected pores (primary) and dilational pores with ragged pore walls (minor)
Crystallinity	31–34%	30–35%	27–34%
Microlites (% of groundmass)	37–40%	40–43%	41–45%
Composition	62–65 wt.% SiO$_2$	62–65 wt.% SiO$_2$ Note blocky lava flows that exceed distances of 2.5 km from the vent: 62–64 wt.% SiO$_2$	64–65 wt.% SiO$_2$
Extrusion Rate	High	Low – High (0.2–2.1 m^3 s$^-$)	Low (≤0.2 m^3 s$^-$).

787   **Table 2: Temperatures at Santiaguito.**

788

Reference	Temperature	Extrusive Unit and Method	Eruptive/ Pre-eruptive Temperature
Andrews (2014)	840–850 °C	Phase equlibria experiments of natural pumice and phenocryst compositions of the 1902 Santa Maria dacite.	Pre-eruptive (Santa Maria)
Singer et al. (2013)	870 °C	Fe-Ti oxide + two pyroxene geothermometry and melt inclusion compositions.	Pre-eruptive (Santa Maria)
Scott et al. (2013)	900–1000 °C	Phenocrysts from Santa Maria pumice using the thermobarometer of Ridolfi, et al. (2010).	Pre-eruptive (Santa Maria)
Scott et al. (2012)	940–980 °C (±20 °C)	Matches amphibole rim widths and best represents geochemistry conditions at Santiaguito over its history.	Pre-eruptive (Santiaguito)
Sahetapy-Engel et al. (2004)	850–950 °C	Maximum temperatures calculated at the surface of the El Caliente vent in 2002 using an infrared thermometer, spectroradiometer and digital video camera.	Eruptive at vent (Andesite, high eruption rate and extrusion of 4km blocky lava flow)
Harris et al. (2002, 2003)	496–531 °C	Highest direct measurements taken of the 1999–2002 (Rcm) flow front core 2.5 km from vent. Note: used eruption temperatures 833 °C from Scaillet et al. (1998) for thermal modelling.	Eruptive at the flow front (Andesite, high eruption rate and extrusion of 4km blocky lava flow)
Scaillet et al. (1998)	833 °C (800–850 °C)	Fe-Ti oxide geothermometry on the Santa Maria pumice. Used method from Ghiorso and Sack (1991).	Pre-eruptive (Santa Maria)

791 6.1 **Figures**
Figure 1. (A) Photo of Santiaguito and Santa Maria from the south, showing a typical eruption from El Caliente. The four different domes are labelled. Quetzaltenango is Guatemala's second largest city and is located 10 km north. Photo from Jessica Ball. **(B)** Photo from a similar location in 1922, the first year of extrusion at El Caliente Dome inside the Santa Maria explosion crater. Photo source unknown, 1922.

800
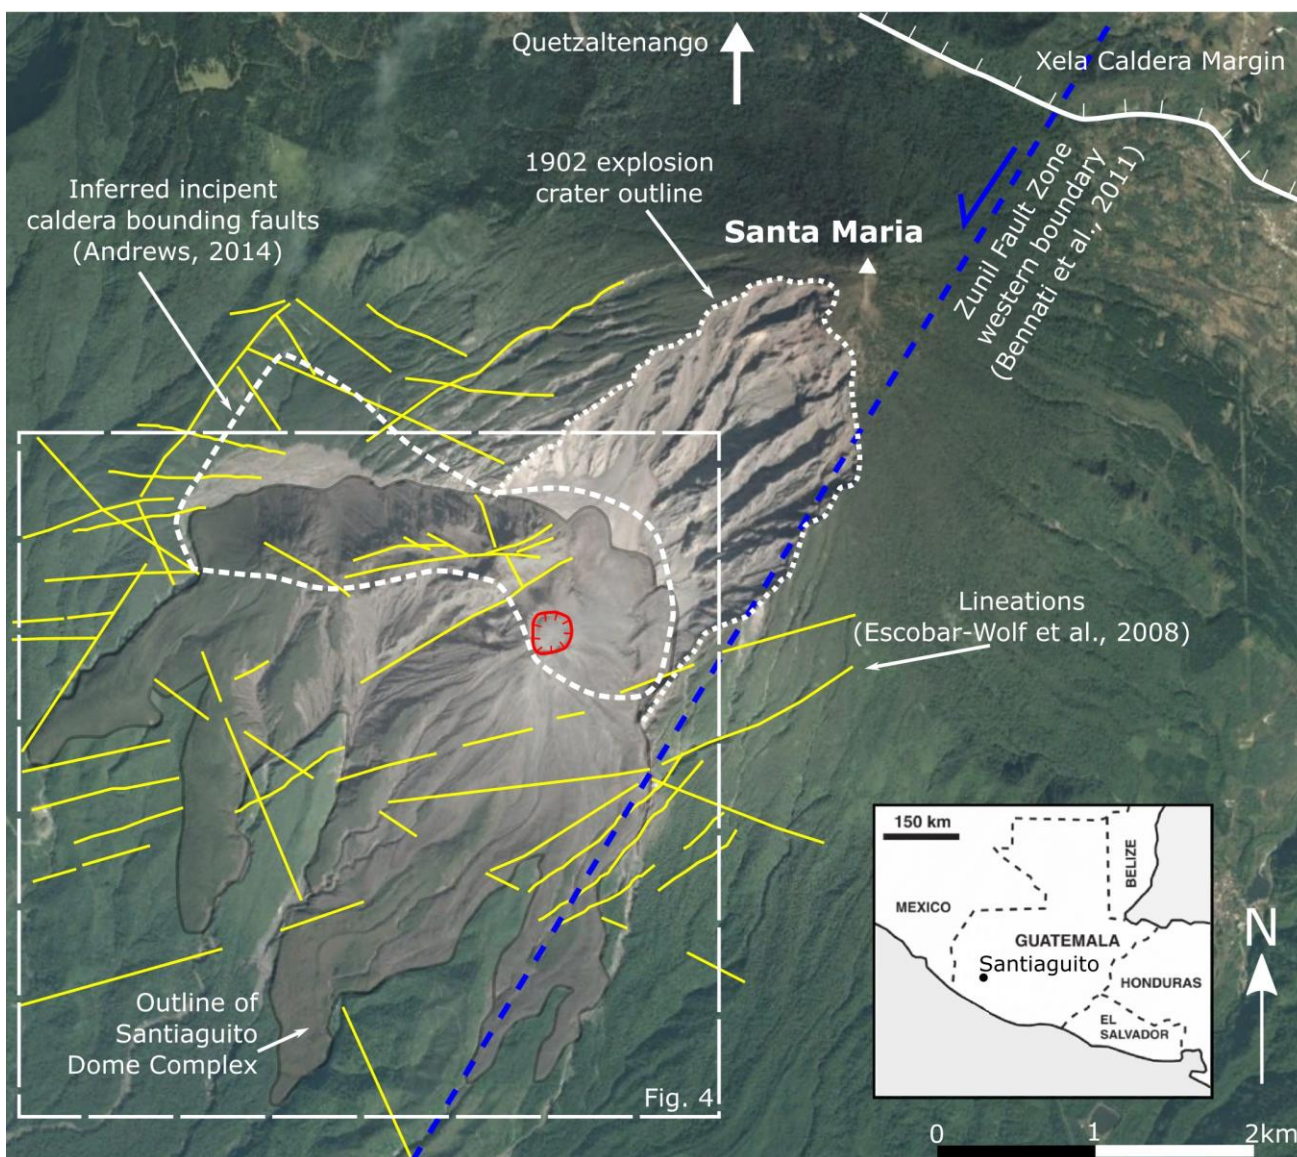

Figure 2. Major structural features at Santa Maria and Santiaguito. Santa Maria lies to the south-east of the Xela Caldera Margin (84–12 Ma; Duffield et al., 1993), and sits on the western margin of the Zunil Fault Zone, both mapped by Bennati et al. (2011). The ~1000 m high erosional explosion crater and inferred incipient caldera bounding margin (Andrews, 2014) formed during the 1902 eruption are marked with a white dotted and dashed line, respectively. Lineations, defined by the alignment of topographic and or geomorphic features, possibly related to faults or joints, are displayed in yellow and were mapped by Escobar-Wolf et al. (2011). Santiaguito is shaded grey with the active El Caliente crater marked in red. Aerial photograph sourced from Google Map data ©2018.
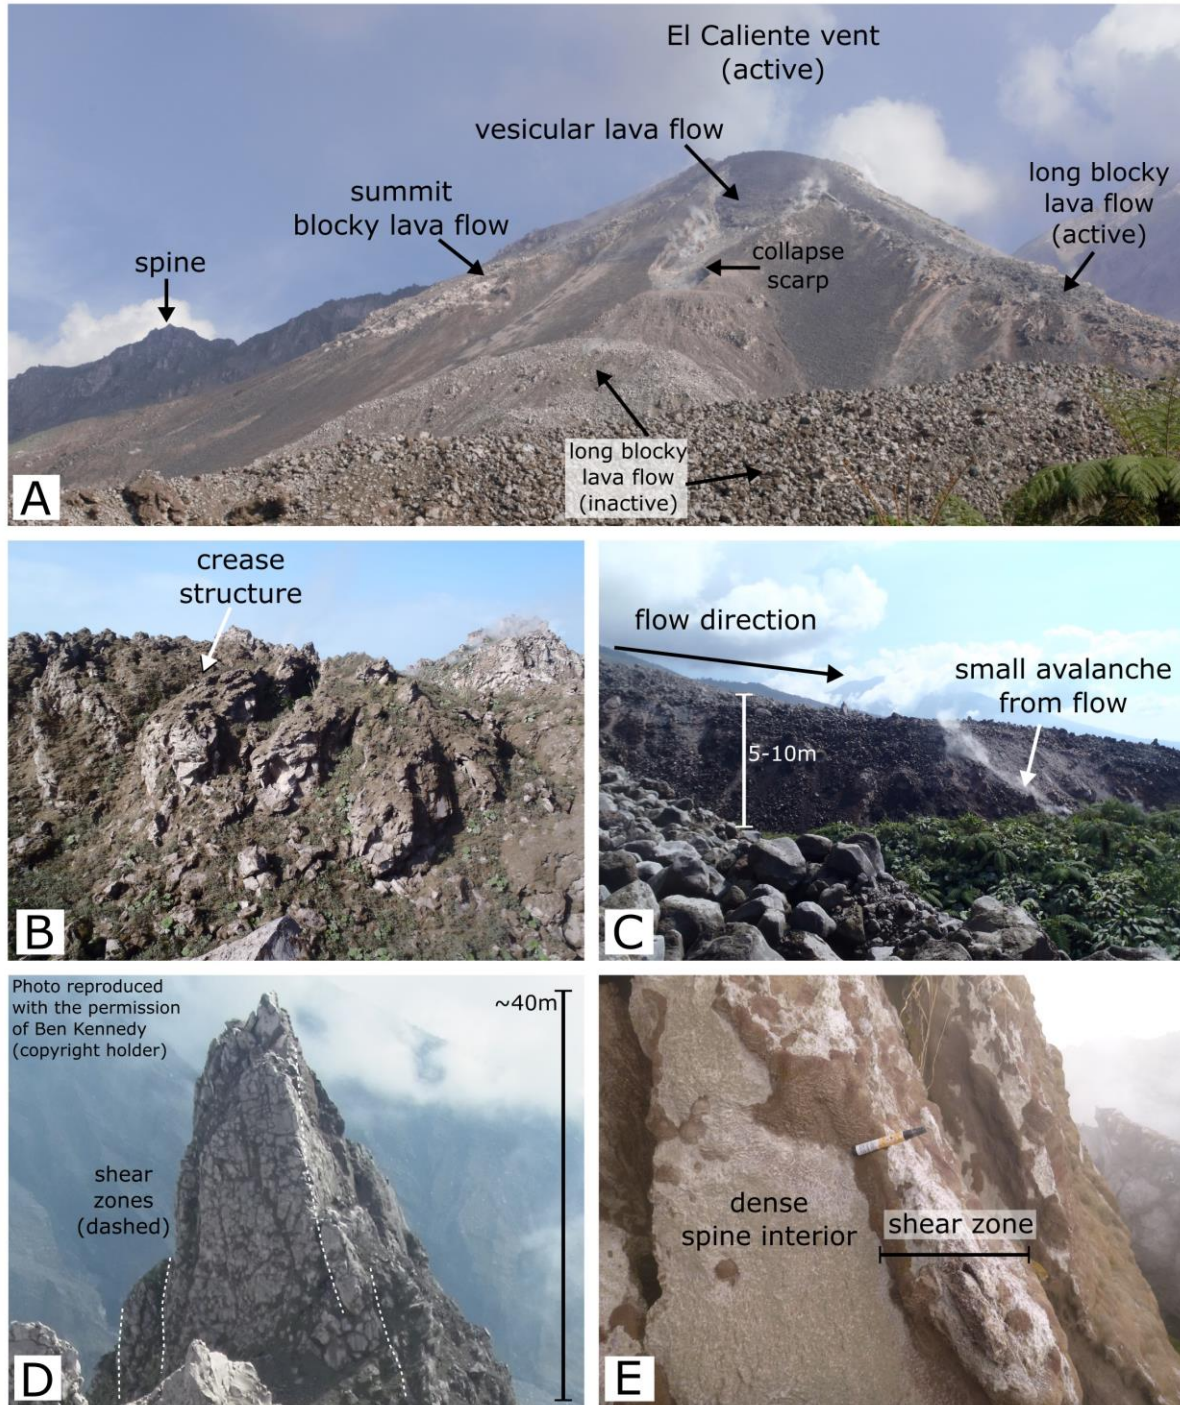

809

810 **Figure 3.** Photos of lava types. **(A)** El Caliente from the south, November 2012, where a vesicular
811 lava is infilling a recent collapse scarp, and long blocky lava flow and summit blocky lava flow are
812 also active. Spines from El Monje can be seen in the distance. **(B)** A vesicular lava flow on El Brujo,
813 this flow is semi-circle shaped and exhibits a crevasse with features similar to crease structures
814 described at Mount St. Helens by Anderson and Fink (1992). **(C)** A long blocky lava flow
815 approximately 1km from the vent. **(D)** A prominent spine on La Mitad. **(E)** Close up of a spine
816 showing the dense spine interior and shear zone rim.

817

Figure 4. Lava type map of the Santiaguito Lava Dome Complex. This map is developed as a companion map to Escobar-Wolf et al. (2010) and Ball et al. (2013). Pre–2010 dome and lava flow

821   features were mapped by Escobar-Wolf et al. (2010) and Ball et al. (2013) from aerial 0.5 m pixel
822   resolution aerial orthophotos 1860-II-14 and 1860-II-19 (acquired between November 2005 and
823   April 2006 by the by the Instituto Geográfico Nacional) as well as by direct field mapping. Recent
824   post–2011 collapses and lava flows were mapped from NASA ASTER images, field observations,
825   INSIVUMEH photos, and Google Earth.

826
827

828   **Figure 5.** Total porosity of extrusive products at Santiaguito. Circles are data from this study, and
829   crosses are values from Avard and Whittington (2012). Blocky lava flows are separated into: summit
830   blocky flows (yellow), blocky lava flows that reach the base of the cone but do not extend further
831   than 2.5 km length (orange), and blocky lava flows >2.5 km (red). Less than 1% of the porosity was
832   isolated in all the samples used in this study, so only total porosity is shown, equivalent to the
833   connected porosity.

834
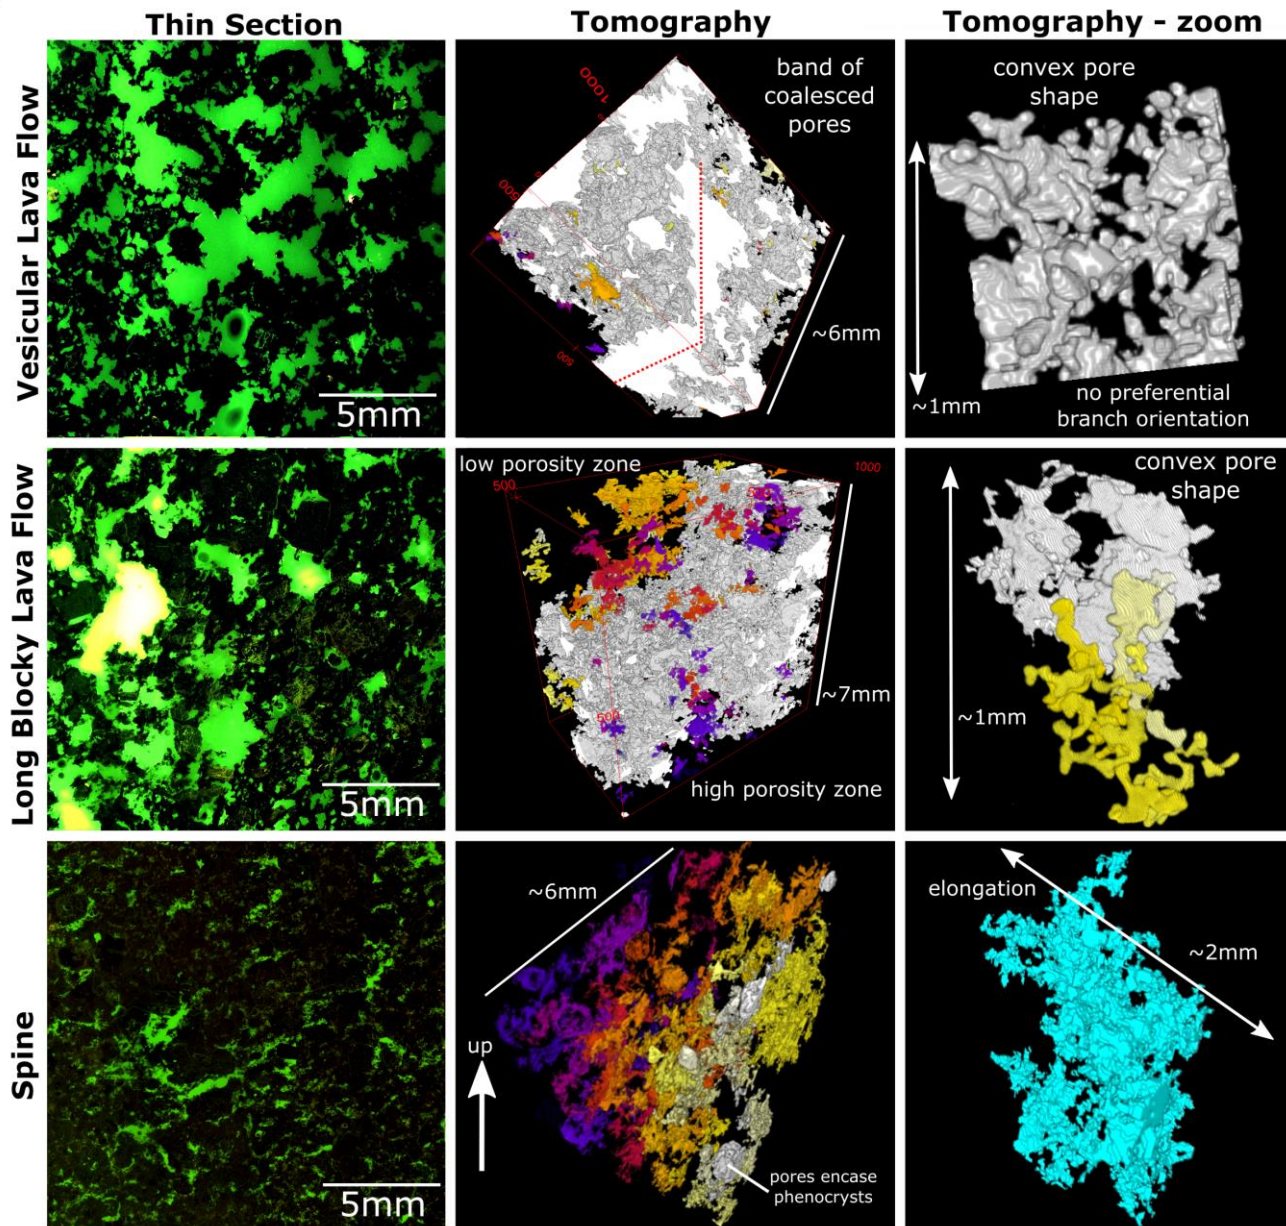

Figure 6. Ultra-violet pictomicrographs and tomography imaging of pores in vesicular and blocky lava flows, and of the dense interior of spines. Different colours in tomography images represent connected pores, and the 100 largest pores are displayed in the images.

838

839

840
Figure 7. (A) Tomography of pores in a vesicular zone bordering a spine. The 100 largest pores are displayed in the image in different colours. Note the high connectivity of dilational pores (white) and zone of lower porosity with lower connectivity (bottom corner). **(B)** UV photo of flow band in a spine showing interconnected dilational pores and phenocryst control on pore shape. Most pore walls are concave and convex in this example. **(C)** UV photo of a shear zone with ragged pore walls marked by the protrusion of groundmass fragments and phenocrysts. Remnant concave pore walls of previous pores are also visible. Note subvertical alignment of pores.
Figure 8. Timing of extrusive activity and eruptive and collapse events at Santiaguito with reference to extrusion cycles (Harris et al., 2003), composition (Scott et al., 2013), and extrusion rate (Rose, 1973b; Harris et al., 2003).

7   Conflict of Interest

8   Author Contributions

ER undertook field mapping and sample collection, compiled the timeline, and carried out textural analysis. BK and ER conceptualized models and wrote/edited the final manuscript. YL assisted with the field campaign provided constructive reviews on/ edited the final manuscript. AH assisted with field work. ME assisted with tomography processing. GH was our scientific liaison in Guatemala and provided access to the domes.
