TABLE OF CONTENTS SUMMARY: This study shows the burden of post-discharge mortality in Southern Mozambique, identifying predictors which could efficiently stratify children with higher risk of dying following a hospital discharge.

WHAT'S KNOWN ON THIS SUBJECT: Post-discharge mortality is an important contributor to child mortality, ranging between 3.3% and 13%, although it is poorly recognized. No predictive models of post-discharge mortality among all cause-admissions in resource-constrained hospitals or among infants have been developed to date.

WHAT THIS STUDY ADDS: Predictive models presented in this study could be applied at hospital discharge and children at risk of dying could be identified through their use. This could allow designing a better post-discharge planning, health education to the families and follow-up care.

AUTHORS' CONTRIBUTIONS

Dr. Madrid conceptualized and designed the study, cleaned and analyzed data, interpreted data set results, drafted the initial manuscript, and reviewed and revised the manuscript. Drs. Bassat and Cousins conceptualized and designed the study, interpreted data set results, and critically reviewed the manuscript for its content.

Drs. Alonso, Menéndez, Macete, Sacoor, Varo, Siteo, Acacio, Nhampossa and Sigaúque, coordinated and supervised data collection, and critically reviewed the manuscript for its scientific content.

Sergio Massora and Dr. Inacio Mandomando were responsible for laboratory procedures, quality of CISM laboratories facilities and interpretation of results. Mr. Quintó and Miss Casellas led the data analysis, interpreted data set results, and critically reviewed the manuscript.

All authors approved the initial manuscript (and subsequent versions) as submitted and agreed to be accountable for all aspects of the work.

ABSTRACT

Background: Although the burden of post-discharge mortality (PDM) in low-income settings appears significant, no clear recommendations have been proposed in relation to follow-up care after hospitalization. We aimed to determine the burden of paediatric PDM and develop predictive models to identify children at risk of dying following discharge.

Methods: Deaths after hospital discharge among children aged <15 years in the last 17 years were reviewed in an area under demographic and morbidity surveillance in Southern Mozambique. We determined PDM over time (up to 90 days) and derived predictive models of PDM using easily collected variables upon admission.

Results: Overall PDM was high (3.6%), with half of deaths occurring in the first 30 days. One primary predictive model for all ages included young age, moderate/severe malnutrition, history of diarrhoea, clinical pneumonia symptoms, prostration, bacteraemia, positive HIV status, rainy season and transfer or absconding, with an area under the curve (AUC) of 0.79 (0.75-0.82) at day 90 after discharge. Alternative models for all ages including simplified clinical predictors had a similar performance. A model specific to infants <3 months identified as predictors: being a neonate, low WAZ score, breathing difficulties, hypothermia or fever, oral candidiasis and history of absconding or transfer to another hospital, with an AUC of 0.76 (0.72-0.91) at day 90 of follow-up.

Conclusions: Death following discharge is an important although poorly recognized contributor to child mortality. A simple predictive algorithm based on easily recognizable variables could readily identify most infants and children at high risk of dying after discharge.

BACKGROUND

The last 25 years have witnessed a significant (49%) reduction in under-5 child mortality globally¹, but an insufficient one to meet the two thirds reduction objective set by the fourth millennium development goal, particularly among many low-income countries (LIC)².

In the last decades, algorithms for diagnosis and treatment of sick children have been implemented in order to address the management of disease during the acute phase and have contributed to improve child survival³. Such guidelines and recommendations, however, have historically failed to address the days immediately following hospitalization, a critical period for child survival⁴.

Contrary to what occurs in industrialized countries, where post-discharge mortality (PDM) is limited to certain small, high-risk groups^{5, 6}, children in LIC appear to be at increased risk of mortality following hospitalisation for any illness^{4, 7-13}. Previous studies among admitted children, albeit scarce, have estimated risk of PDM to range between 3.3% and 13%^{9, 14, 15}. For specific diseases, PDM risks have ranged between 2.0-2.6% for malaria^{16, 17}, 2.9 to 7% for diarrhoea^{18, 19}, 2.7-11.6% for anaemia²⁰, 1-15% for pneumonia^{15, 21}, and 2.8% for invasive bacterial infections⁷. Most of these deaths have been described to cluster in the first 30 days¹³ and main predictors of PDM include a history of previous hospitalizations, young age, HIV infection and hospitalizations related to malnutrition or pneumonia⁴.

A rigorous follow-up of all hospital discharged children would be unfeasible and unaffordable for resource-constrained settings¹³. Thus, early identification of vulnerable children appears essential to design more targeted interventions to prevent PDM¹³.

Improving the discharge process and post-discharge care will be a critical step to further

1
2
3 continue reducing child mortality⁴. We therefore aimed to determine the burden of
4
5 paediatric PDM in a semi-rural area from southern Mozambique, to identify predictors
6
7 of mortality following discharge and to derive models that could efficiently stratify
8
9 children according to PDM risk.
10

11 12 13 **METHODS**

14 15 **Study site and population**

16
17 This study was conducted in Manhiça, southern Mozambique, a semi-rural setting with
18
19 a predominantly young population (45% <15 years of age). In 2015, the national under-
20
21 5 mortality rate was 78.5/1000 live births²². Manhiça Health Research Centre (CISM),
22
23 runs a demographic surveillance system (DSS) in the area, and a paediatric morbidity
24
25 surveillance system (MSS) has been implemented for nearly two decades at the
26
27 neighbouring Manhiça District Hospital (MDH) and five additional peripheral health
28
29 posts, accurately capturing standardized morbidity data for ~3000 admissions and
30
31 >75,000 annual outpatient visits, annually. Human immunodeficiency virus (HIV)
32
33 prevalence in the area is among the highest in the world²³, with adult community
34
35 prevalence peaking at 40%²⁴. Vertical transmission of HIV has been estimated at around
36
37 9%²⁵ and contributing 10% to the under-5 mortality nationally²⁶. A detailed description
38
39 of CISM and study area can be found elsewhere^{27, 28}.
40
41
42
43
44
45

46 47 **Study design and definitions**

48
49 A retrospective cohort study of children <15 years discharged from MDH for a 17 year-
50
51 long period was conducted, using the DSS and MSS databases. We analysed burden of
52
53 PDM over three different time-periods: First (1-30 days), second (31-60 days) and third
54
55 month (61-90 days) post-discharge. PDM among infants <3 months old was analysed
56
57
58
59
60

1
2
3 separately to check whether identified predictors differed from those of the older cohort.
4
5 Only children living in the study area were included. We used a single-discharge
6
7 approach, considering the first admission as reference admission, and not considering
8
9 ulterior re-admissions within the following 90 days to avoid re-starting the period at risk
10
11 every time. Post-discharge death was defined as a death occurring >24 hours after and
12
13 within 90 days of discharge from MDH; community death as a death occurring outside a
14
15 health facility within 90 days after discharge; and facility death as a death occurring at
16
17 any health facility within 90 days following discharge from MDH. Children dying
18
19 during a readmission within the follow-up period were considered as a hospital death
20
21 within follow-up (supplementary figure S1). Supplementary table S1 summarizes other
22
23 relevant definitions.
24
25
26
27
28

29 **Morbidity surveillance system.**

30
31 Morbidity surveillance data routinely collected for all children <15 years during the
32
33 study period were analysed, including clinical data, basic laboratory investigations
34
35 (malaria microscopy, haematocrit and glycaemia) and International Statistical
36
37 Classification of Diseases-based diagnoses (ICD-10) since 2003. All diagnoses prior to
38
39 July 2003 were coded according to a list of codes created by the CISM since 1996.
40
41 Outcome and medications prescribed were also analysed. For admitted children, blood
42
43 culture results, systematically performed for all children <2 years and, in older children,
44
45 in those with severe disease, were available. HIV status information, although not
46
47 routinely collected, was available for those patients with suspected immunosuppression.
48
49
50
51

52 **Demographic Surveillance System**

53
54
55
56
57
58
59
60

1
2
3 CISM's DSS, which started in 1996, now covers the entire Manhiça District (2380 km²;
4 total population of ~183000 inhabitants). DSS captures socio-demographic data and
5 other major events like migration, marital status, pregnancy and outcome results, births
6 and deaths and is updated twice annually. During periods in which the entire district
7 was not covered, analysis only included inpatients being part of the DSS. Through a
8 unique identifier number, DSS and MSS databases can be linked.
9
10
11
12
13
14
15
16
17

18 **Data management and data analysis**

19
20 A survival analysis was performed to model events within 90 days of discharge. The
21 discharge date+1 day was used as date of entry to the study whilst post-discharge death,
22 loss to follow-up or end of follow-up period (90 days after discharge), considered the
23 exit time. For each variable with a high proportion of missing values (<15%) but
24 suspected to be a strong confounder, a "missing or unknown" category was created. In
25 order to achieve the study objectives, data analysis was split in two parts: a)
26 Determining burden and identifying associations: Descriptive statistics were calculated
27 for all explanatory variables. Kaplan-Meier (KM) curves were produced for all
28 categorical predictors to look for differences in survival with different values of the
29 predictor. Associations between potential predictors and risk of death after discharge
30 were explored in univariable Cox regression models. b) Selecting and validating
31 predictive models: The dataset was randomly split into two subsets (training set
32 containing 80% of data and the validation set with the remaining 20%) which were then
33 compared to confirm that there were no important differences between the two subsets.
34 Those predictors showing evidence of an association (p-value ≤ 0.05) with the outcome
35 in a univariable analysis were selected for potential inclusion in a multivariable Cox
36 regression model (primary model). Three additional models were also examined based
37

1
2
3 on their suitability for different contexts: Model 2), which uses the primary model as
4 reference, but includes only variables with minimal costs; Model 3) based exclusively
5 on clinical variables collected on admission; and Model 4) predictors of PDM restricted
6 to infants <3months. The area under the curve (AUC) was plotted for each model over
7 time using the training set (formula: $H(t) = H_0(t) \times \exp(b_1X_1 + b_2X_2 + b_3X_3 + \dots +$
8 $b_kX_k)$). Confidence intervals of AUC were estimated by 1000 bootstrap replicates using
9 the bias-corrected percentile method²⁹. As there could be more than one admission for
10 some children, the models described above were estimated taking into account within-
11 child clustering. Analyses used Stata Statistical software (*Release 15*). Graphical
12 representation of AUC curves was done in R (R Core Team; 2017) using
13 the *survivalROC* package.

40 **RESULTS**

41 **Overall characteristics of study population**

42
43 From 1st January 2000 to 31st December 2016, 58990 inpatient records were checked of
44 which 29574 (50%) were initially excluded (figure 1). 3097 observations of children
45 living in study area readmitted within follow-up (supplementary figure S1), hospital
46 deaths (2.5%, 662/26319 of remaining children) and 25 deaths in the first 24 hours
47 (<0.1%) were also excluded (figure 1). Thus, 25632 inpatient records of 18023 children
48 <15 years old admitted to MDH were included in the analysis (Table 1). 2055
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 observations of 2049 infants <3months were also analysed separately ([supplementary](#)
4 [table S2](#)).

9 **Incidence of post-discharge deaths and potential predictors of PDM**

10
11 During the 90-day follow-up period, 935 (3.6%) deaths after discharge occurred among
12 the 25632 admissions, with 783/935 (83.7%) occurring at the community level and
13 488/935 (52.2%) within the first 30 days of discharge. Median time to death was 28
14 days (IQR 11-53). The risk of post-discharge deaths varied over time ([figure 2A and](#)
15 [supplementary figure S2](#)) and by age ([figure 2B](#)) similarly to the risk of inpatient
16 mortality ([figure 2C](#)).

17
18 Forty-five variables were tested for their univariable association with PDM (table 1).
19
20 Infants <3months were more likely to die than older children ([figure 3A; supplementary](#)
21 [table S2](#)). Similarly, poorer nutritional levels were clearly linked to PDM ([figure 3B](#)).

33 **Predictive models and validation**

34
35 [Supplementary table S3](#) presents the comparison of the training and validation sets.
36
37 Nineteen variables were associated with higher risk of PDM in the multivariate analysis
38 ([primary model, table 2](#)). Infants less than 3 months had the highest rate of PDM and
39 this decreased with increasing age ($p<0.001$) ([supplementary table S4](#)). The rate of
40 PDM varied between rainy and dry seasons (HR 1.22, 95% CI 1.03-1.43). Severe acute
41 malnutrition (SAM) (HR 3.26, 95% CI (2.08-5.12) as well as other 13 clinical variables
42 were associated with PDM. Children with a positive blood culture (HR 1.68, 95% CI
43 1.33-2.12) and a positive HIV test (HR 1.77, 95% CI 1.07-2.91) also had a higher rate
44 of death during the follow-up period. Absconding (HR 5.23, 95% CI 4.22-6.50) or
45 referral to a higher level of health care (HR 4.48, 95% CI 3.31-6.05) were clearly
46
47
48
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 associated with death. Children with a malaria diagnosis had a lower risk of PDM (HR
4 0.44, 95% CI 0.36-0.54). The AUC for this model was around 0.80 during the 90 days
5 follow-up period, being, at day 90, 0.79 (95% CI 0.75 - 0.82). At a HR cut-off point of
6
7 1.08, it had a sensitivity of 80%, specificity of 60% and a positive predictive value
8 (PPV) of 6.9% (figure 4 and table 3). According to this model, 1.9% of all discharges
9 will die in the first 90 days after discharge.
10
11
12
13
14
15
16
17

18 Time-varying AUC of the two additional simplified models (table 2), is compared in
19 supplementary figure S3A. *Model 2*, which excluded blood culture but maintained
20 minimal cost tests, performed similarly to the primary model, with an AUC around
21 0.80% until 60 days after discharge. *Model 3*, which included only clinical variables,
22 performed slightly worse, with an AUC ~0.75 during the whole period. *Model 4*, limited
23 to infants <3months, included variables such as breastfeeding and weight-for-age
24 (WAZ) to assess nutritional status, on account of the excess of missing height data.
25 Neonates appeared to have the highest risk of PDM among this age group
26 (supplementary table S4). This model had an AUC at day 30 of 0.84 (95% CI 0.72 -
27 0.91) and at day 90 of 0.76 (95% CI 0.72 - 0.91). At a HR cut-off point of 0.5, it had a
28 sensitivity of 79%, specificity of 53% and a PPV of 12.8% (table 3 and supplementary
29 figure S3B). AUC and model's characteristics at probability cut-offs ensuring
30 sensitivity of >80% are shown in table 5. CI of AUC between training and validation set
31 and between primary model and the other models overlapped, meaning no significant
32 differences between them were found.

52 DISCUSSION

53
54
55
56
57
58
59
60

1
2
3 This analysis, based on more than 20000 hospital discharges and 935 post-discharge
4 deaths, is the largest study to date evaluating PDM in the first three months following
5 hospital discharge from a rural district hospital in a LIC, and represents a systematic
6 approach to ascertain predictors of PDM in a resource-constrained environment.
7
8
9

10
11 The cumulative three-month post discharge mortality found in this study (3.6%) is
12 lower than that reported in the 1990s from other African settings, where incidence risk
13 was estimated between 6.1% and 13%^{14, 15}, but similar to other more recent PDM
14 studies^{7, 9, 10, 18}. Importantly, inpatient mortality found in our cohort (2.5%) aligned
15 closely with that reported in other settings^{13, 14}.
16
17
18
19
20
21
22
23
24
25

26 These findings highlight that risk of dying is greatest in the first 30 days immediately
27 following discharge^{7, 10}, the most critical period for survival^{10, 15, 18}. Overall, trends of
28 post-discharge mortality for all ages changed over time. PDM rates increased over the
29 period from 2000-2010, subsequently declining. This trend cannot be explained by an
30 increase in inpatient mortality, as this was progressively decreasing since 2001 (figure
31 2C). One could speculate that variations in the epidemiology of a single disease may
32 have played a significant role in PDM variations (Supplementary figure S4). For
33 instance, malaria used to be highly endemic in the area at the beginning of the study
34 period, with a subsequent declining trend observed from the year 2005 onwards, trends
35 inversely proportional to those of the PDM curve. Children admitted with malaria,
36 readily treatable and with a rapid recovery, are probably less likely to be associated with
37 post-discharge complications. This could partly explain why a diagnosis of clinical
38 malaria has been shown to be an overall protective factor against PDM (HR 0.44, 95%
39 CI 0.36-0.54) a finding also reported in Kenya⁹. Similarly, although HIV incidence is
40 now much higher in the area than it was a decade ago, the increasing uptake of
41

1
2
3 antiretroviral drugs probably implies a better control of this infection on PDM in recent
4
5 years when more admissions due to HIV have been registered. Trends in the proportion
6
7 of children admitted with other diseases with greater incidence of post-discharge deaths,
8
9 such as SAM, showed an overall tendency parallel to the PDM curve over time.
10
11 However, the declining trend of PDM seen at the end of the study period cannot be
12
13 exclusively explained by malaria, HIV or SAM trends. The progressive introduction of
14
15 other life-saving interventions, such as vaccination against Hib (2009), pneumococcus
16
17 (2013), and rotavirus (2015) have reduced hospital admissions and, may also have
18
19 contributed to these decreasing trends. PDM trends over time among infants <3 months
20
21 differed slightly from other age groups, with a peak in 2003, and stable rates thereafter.
22
23 In this highly vulnerable age group, effective interventions specifically designed to
24
25 reduce mortality, have not been fully implemented in the study area.
26
27
28
29
30
31

32 The primary model, including all available useful variables performed remarkably well,
33
34 particularly to predict risk of dying in the first month following discharge. This model
35
36 predicts that 1.9% of children discharging from the hospital will die in the first 90 days
37
38 following discharge. Applying a score based on this model to a population similar to
39
40 ours and using a HR cut-off of 1.08, roughly 80% of children likely to die following
41
42 discharge would be identified and the referral population would have a mortality risk of
43
44 approximately 7%. This model however includes blood culture results, an expensive
45
46 determination that requires laboratory infrastructures seldom available in poor settings.
47
48 The two alternative simplified models, including more easy-to-collect lab results
49
50 (Model 2) or only clinical variables (Model 3) seem more applicable, and still showed a
51
52 good predictive capacity for PDM. Importantly, model 4, developed for infants <3
53
54 months old, uses only few variables, all of them easily and readily obtainable in most
55
56
57
58
59
60

1
2
3 resource constrained contexts and could identify 0.85 of infants <3months at risk of
4
5 dying in the first days after discharge and nearly 0.80 during the remaining follow-up
6
7 period.
8
9

10 Severe acute malnutrition is a recognized predictor of PDM^{8-10, 13, 18} as our models
11 confirm. The chronicity of malnutrition, the fact that it can predispose to an array of co-
12 infections and complications, and its association with HIV infection in Manhiça³⁰, may
13
14 all contribute to explain its associated prolonged mortality risk. On the other hand,
15
16 children with unknown nutritional status had higher risk of dying compared to well-
17
18 nourished children. This may be partly explained in cases of severe disease, where the
19
20 severity of the child upon admission did not allow collecting anthropometric
21
22 measurements. HIV positivity, a clear predictor of PDM^{13, 20}, remained in our model a
23
24 strong independent predictor, even after adjusting for malnutrition. Rainy season was
25
26 also associated to higher risk of PDM as more children are admitted during this season,
27
28 likely due to the greater number of admissions and severe disease occurring in this
29
30 season.
31
32
33
34
35

36 In this series, type of outcome at discharge, and particularly being transferred or
37
38 absconding from hospital, were the greatest predictors of PDM. In this setting, children
39
40 are usually transferred to a higher-level health facility whenever they are very sick or
41
42 when they require a more specialized evaluation or supportive care, justifying their
43
44 greatest PDM risk. Children absconding against medical recommendations (3.1% of the
45
46 study sample) had an extremely high risk of post-discharge mortality, and represent one
47
48 out of every five deaths in our series. In Manhiça, absconding is a cultural and financial
49
50 phenomenon, typically occurring when families anticipate a bad outcome and prefer
51
52 their children to die at home, additionally sparing costs associated with the transport of
53
54
55
56
57
58
59
60

1
2
3 a corpse. Socio-behavioural studies addressing this phenomenon and the perceptions of
4 health professionals of its serious consequences are needed.
5
6
7

8
9 The majority (83.7%) of deaths following hospital discharge occurred at the
10 community, in the absence of any further contact with the health system. A study
11 investigating cause of death in Manhiça using verbal autopsies documented that 53% of
12 all paediatric deaths occurred at home²⁸. These alarming figures reflect the generalized
13 challenges in access to care, which become even more blatant following hospital
14 discharge.
15
16
17
18
19
20
21

22
23 Effective models for identifying children at risk of PDM should take into consideration
24 the existing resources but consider illness as a continuum transcending the information
25 that the admission snapshot can provide. A score or similar algorithm to that proposed
26 by IMCI, based in predictive models and applied at discharge, could pinpoint children
27 requiring a more rigorous follow-up after hospitalization. However, the identification of
28 high risk does not imply that risk can be reduced. Future research should consider
29 validation of these models in different contexts and prospectively assessing their
30 accuracy to identify children at risk of dying after discharge in resource-constrained
31 settings. Once identified, these children at higher risk of PDM could benefit from
32 strategies to prevent post-discharge death and these strategies should especially focus in
33 the first 30 days after discharge as it is the period with the highest risk of PDM.

Community-based interventions driven by community-health workers consisting in pre
and post-natal home visits, supporting low birth-weight (LBW) infants and sepsis case
management, facilitating referral in case of need have reduced neonatal and infant
mortality in several countries³¹. Although these interventions have not been explored in
children after a hospital admission, their impact reducing PDM could be similar.

1
2
3 Alternative strategies, utilizing the prophylactic use of antimicrobials in those children
4 at high risk should also be explored. A recent clinical trial conducted in Kenya
5 exploring the efficacy of daily post-discharge co-trimoxazole prophylaxis in children
6 admitted with complicated SAM without HIV found however no reduction in mortality
7 during the first year after admission³².
8
9

10
11
12
13 Continued investment in child mortality data collection and understanding
14 circumstances of paediatric death following a hospital discharge is needed in order to
15 design innovative, effective and feasible strategies to reduce the risk of childhood
16 preventable deaths after hospitalization.
17
18
19
20
21

22
23
24 This study has several limitations, including its retrospective nature. Selection bias may
25 arise due to the fact that almost half of children admitted to MDH between 2000 and
26 2016 were excluded and this might affect the representativeness of the study sample.
27
28
29 Another limitation includes the fact that all clinical predictors were collected at the time
30 of admission, and some these clinical variables may have changed throughout the
31 hospitalization. We decided to use a single-discharge approach within 90 days of
32 follow-up to avoid double counting time at risk, excluding observations of children re-
33 admitted during the follow-up period. This strategy may have resulted in a clearer
34 picture of the true community PDM but also in an underestimation of the likely higher
35 real-life true incidence. Another factor potentially underestimating PDM is the
36 exclusion of deaths occurring in the first 24 hours after discharge, as they were
37 considered as hospital deaths. However, they merely represented <0.1%. The inclusion
38 of children who were transferred or absconded from the hospital may be overestimating
39 the incidence of PDM since they were not officially discharged, but this is an extremely
40 frequent occurrence in African settings, and needs to be taken into consideration,

3 particularly in the light of the strength and magnitude of the statistical associations
4 found. Importantly, we could not assess the role of LBW in infants as a likely risk factor
5 for PDM, since this information was not available. On the other hand, the low
6 specificity and positive predictive value found could compromise feasibility of
7 interventions to prevent PDM, as a high number of children would be classed as high
8 risk of dying after discharge. However, these models would allow the identification of
9 the majority of children with risk of PDM. Finally, our predictive models lack an
10 external validation.

22 **Conclusion**

23
24 This study highlights the importance and oversight of post discharge mortality as a
25 significant portion of the childhood mortality pie. Simple models including predictors
26 easily collected with minimal cost, such as those presented in this article, need to be
27 prospectively validated in different circumstances and settings. Specific interventions
28 targeting children identified to be at higher risk and guaranteeing their adequate follow-
29 up at the hospital or even at the household level could possibly increase their survival
30 possibilities. Implementation of such strategies could prevent avoidable deaths,
31 especially among neonates and infants who suffer the highest burden of PDM.

Figure S2: Number of admissions and post-discharge deaths in the first 90 days of follow-up by year.

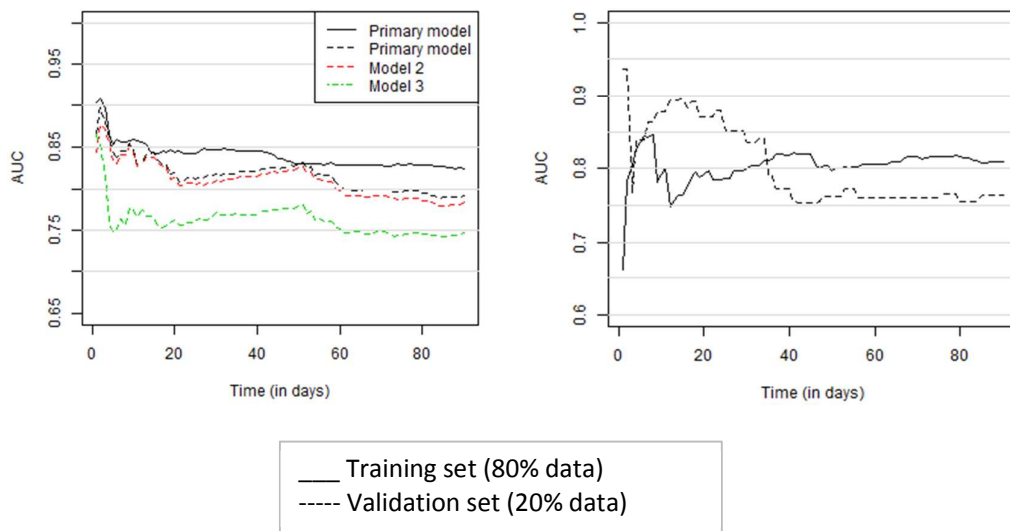

Figure S3: Time-varying area under the curve of predictive models estimated from primary model.

A) Comparison among primary model and estimated models 2 and 3. B) Comparison between training and validation set of estimated model 4 which includes exclusively infants <3 months.

Figure S4: Number of admissions due to specific diseases over time

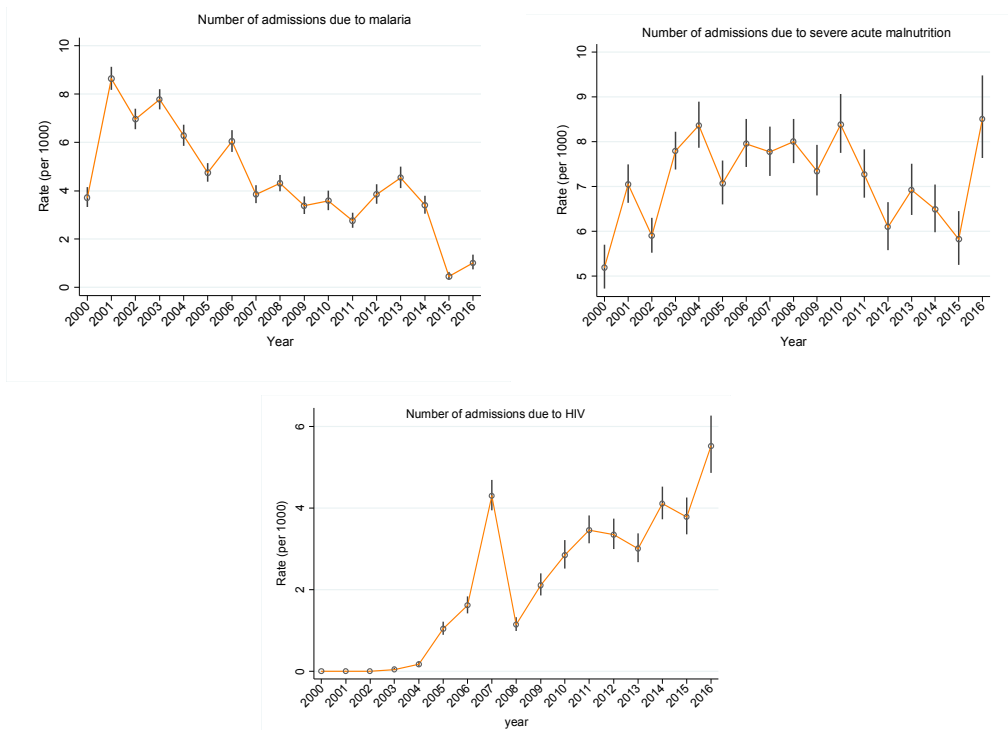

Table S1: Definitions

Rainy Season	November to April
Blantyre coma scale (BCS):	Based on pain response, cry or verbal response, eyes movement. Score 0 to 5
	<ul style="list-style-type: none"> · Normal: 5 · Impaired consciousness: 3-4 · Coma: ≤ 2
WHZ	Weight-for-height z-score calculated using the WHO growth chart
	<ul style="list-style-type: none"> · >-1 DS: well nourished · >-2 to <-1DS: mild acute malnutrition · >-3 to <-2DS: moderate acute malnutrition · <-3DS: severe acute malnutrition
WAZ	Weight-for-age z-score calculated using the WHO growth chart
	<ul style="list-style-type: none"> · <-3DS: underweight
Malaria	A malaria case was defined as a child admitted with a clinical diagnosis of malaria with a positive <i>P. falciparum</i> asexual parasitaemia.
Increased Respiratory Rate (IRR)	<ul style="list-style-type: none"> • IRR in < 2 months old children = respiratory rate ≥ 60 • IRR in 2 - <12 months old children = respiratory rate ≥ 50 • IRR in 12 - <60 months old children = respiratory rate ≥ 40 • IRR in 60 - <120 months old children = respiratory rate ≥ 30 • IRR ≥ 120 months old children = respiratory rate ≥ 20
Heart rate normal ranges in beats per minute:	
	<ul style="list-style-type: none"> · 0 to 1 year: 110-160 · 1 -2 years: 100-150 · 2-5 years:95-140 · 5-12 years: 80-120 · >12 years: 60-100
Non-severe anaemia	<ul style="list-style-type: none"> · Children ≤ 28 days old with a packed cell volume (PCV) between 25- $<42\%$ · Children >28 days: PCV between 15- $<33\%$
Severe anaemia	<ul style="list-style-type: none"> · Children ≤ 28 days old= PCV $<25\%$ · Children >28 days: PCV $<15\%$
Hypoglycaemia	Blood glucose levels <3.0 mmol/L (categorized as severe if <2.5 mmol/L)
Hyperglycaemia	Blood glucose levels >11.0 mmol/L (categorized as severe if >20.0 mmol/L)
Hypothermia	Axillary temperature $< 35^{\circ}\text{C}$
Verbal autopsy	Research method based on a structured interview conducted to family members of the deceased individual that helps to determine the probable causes of death in cases where there was no medical record or formal medical attention given, validated by World Health Organization

Table S2: Socio-demographic, clinical characteristics and univariate analysis of predictors on admission associated to post-discharge mortality among 2055 observations of infants less than 3 months of age and 126 post-discharge deaths in southern Mozambique.

EXAMPLE: Reviewer 1's comment	EXAMPLE: A brief response to this reviewer's comment. The text now states: "insert relevant changed text here"	EXAMPLE 1: Page 7, lines 10-22 EXAMPLE 2: No change	
Editor comment 1: Change the main title (both in your paper and in online Step 1) to: Post-Discharge Mortality Prediction in Sub-Saharan Africa	Change applied	Page 1 and online step 1	
Editor comment 2: Change the short title (both in your paper and in online Step 1) to: Post-Discharge Mortality Prediction	Change applied	Page 2 and online step 1	
Reviewer 1's comments:			
Concise, well written to frame the problem. I have one clarification re: page 6, lines 44-46: in terms of risk factors for reference 4 on PDM, it seems as though there is some collinearity between those 4 risk factors. Were all 4 significant on	These risk factors are coming up from a systematic review performed by Wiens et al (see reference 4 in the main text). They didn't perform a meta-analysis. Some of studies included in this systematic review found some of these variables significant in multivariate analysis (ref 7, 8 and 9)	NA	

<p>1 multivariate analyses?</p> <p>2 To clarify, were you able to track mortality</p> <p>3 even if children presented to 1 hospital,</p> <p>4 were admitted/discharged, and then</p> <p>5 presented to another hospital at the time</p> <p>6 of the second visit? Do most children</p> <p>7 present to the same facilities over time?</p> <p>8</p>	<p>There are two hospital which admit children in Manhiça district, Manhiça district Hospital (MDH), which is the main hospital in the study area, where the study was conducted and where most of admissions of study area occur & Chinavane Hospital, a small hospital about 60 minutes away from Manhiça town and who was created to support the staff and villagers working at a nearby Sugar Cane factory. This second hospital only admits a few paediatric patients per week. We have only captured admissions to MDH where morbidity surveillance is going on.</p>	<p>NA</p>	
<p>9 Page 8, line 38: the study period predates</p> <p>10 the advent of ICD-10; were patients in the</p> <p>11 earlier years reclassified into ICD-10? I</p> <p>12 am curious, as ICD-10 has a greater level</p> <p>13 of detail required for coding than earlier</p> <p>14 systems, and some of us find it</p> <p>15 challenging to assign ICD-10 codes</p> <p>16 prospectively, hence the challenge of</p> <p>17 applying this retrospectively.</p> <p>18</p> <p>19</p> <p>20</p> <p>21</p>	<p>All diagnoses prior to July 2003 were coded according to a list of codes created by the CISM since 1996. We started using ICD10 in 2003 and we also produced a conversion table for the previous codes. That table was developed by a group of experts including resident physicians, researchers of studies running in the area and statisticians. Certainly, the level of detail of the ICD10 is much higher than the other system and, therefore, the correspondence between both encodings was only possible at the level of ICD10 category (3 characters length). A brief explanation on this has been added in methods → Morbidity surveillance system: <i>“and International Statistical Classification of Diseases-based diagnoses (ICD-10) since 2003. All diagnoses prior to July 2003 were coded according to a list of codes created by the CISM since 1996”</i>.</p>	<p>Page 7, lines 16-18</p>	
<p>22 How many children had none of the risk</p> <p>23 factors identified in the model?</p> <p>24</p> <p>25</p> <p>26</p> <p>27</p> <p>28</p>	<p>In the training set, there is no case that does not have any risk factor of the primary model. The variable “age” is responsible for this. That is, all children under 3 months have some risk factor. However, if we do not take into account the variable “age”, we found 58 individuals who do not have any risk factor. Authors believe this information is not necessarily relevant for the manuscript, and therefore, we have opted for not including any further comment related to this.</p>	<p>NA</p>	
<p>29 Verbal autopsies were mentioned in the</p> <p>30 methods, but I did not see the results in</p> <p>31 either the main or the supplementary</p> <p>32 tables. If the results are not presented,</p> <p>33 please remove reference to the verbal</p> <p>34 autopsies from the methods (and then</p> <p>35 please ignore my last comments on the</p> <p>36 methods section).</p>	<p>Verbal autopsies in methods are described as part of HDSS. However, following reviewer recommendations, we have removed them.</p>	<p>Pag 8, lines 1-6</p>	
<p>37 Page 24: please provide figure header</p> <p>38 and legend for this graphic</p> <p>39</p> <p>40</p> <p>41</p> <p>42</p> <p>43</p>	<p>The title & legend of this graphic was entered through the submission website and updated in the corresponding figure. It is “The time-varying area under the curve of primary model comparing training and validation sets.”</p> <p>Legend: “___ Training set (80% data)</p> <p>----- Validation set (20% data)”.</p>	<p>Figure 4</p>	

<p>Table 1:</p> <p>o I assume that not all variables were documented for all patients; these would be a comprehensive list of variables to collect uniformly even with prospective data collection. Were variables assumed to be negative unless documented as positive? Given the challenges to documentation, this is probably not an accurate assumption. Would it be possible to provide the denominator for the # of children in whom a given symptom was documented (as positive or negative)?</p>	<p>We did not include missing values for all variables as given the number of variables studied, the table would be endless. We followed the following methodology: For those variables with high proportion of missing values (>15%), we generated a new category for each variable called unknown or test not done to assess the effect of missing values and allow inclusion of more observations in the final model.</p> <p>This was already explained in methods “Data management & analysis”, but we have added a further explanation: <i>“For each variable with a high proportion of missing values (<15%) but suspected to be a strong confounder, a “missing or unknown” category was created”</i></p>	<p>Page 8, lines 12-13</p>	
<p>The model created has a very high AUC. However, the model would also apply to a large percentage of children admitted to inpatient units. As such, how would you apply the findings prospectively to reduce post-discharge mortality? I think a particular challenge would be how to avoid PDM beyond 30 days, as this may be due to a different illness and may be less amenable to intervention strategies than the < 30d PDM.</p>	<p>More than half of deaths occurred in the first 30 days. Then strategies would focus in avoiding death in this period. As explained in figure 1 and discussion, and seen in AUC (figure 3 in supplementary information) the model is better to predict deaths in these first 30 days. We have added some comments on top of what was stated in the previous version: <i>“Once identified, these children at higher risk of PDM could benefit from strategies to prevent post-discharge death and these strategies should especially focus in the first 30 days after discharge as it is the period with the highest risk of PDM. Community-based interventions driven by community-health workers consisting in pre and post-natal home visits, supporting low birth-weight (LBW) infants and sepsis case management, facilitating referral in case of need have reduced neonatal and infant mortality in several countries³¹. Although these interventions have not been explored in children after a hospital admission, their impact reducing PDM could be similar. Alternative strategies, utilizing the prophylactic use of antimicrobials in those children at high risk should also be explored.”</i></p>	<p>Page 15, lines 18-25</p>	
<p>Why do you think there is higher mortality during the rainy season if it is not (page 11, line 50) associated with malaria?</p>	<p>This is because >60% of total admissions were in the rainy season and not only because of malaria but also due other causes including severe malnutrition (>60%) or HIV associated admissions (54%). Additionally, more children absconded (>60%) or were transferred to referral hospital (<60%) during the rainy season, and both are stronger predictors of PDM. We have added a comment in discussion: <i>“Rainy season was also associated to higher risk of PDM as more children are admitted during this season, likely due to the greater number of admissions and severe disease occurring in this season”</i></p>	<p>Page 14, lines 12-15</p>	
<ul style="list-style-type: none"> Why do you think children with unknown WHZ scores had the same hazard ratio for mortality as children with severe malnutrition? 	<p>We explained this fact in draft versions, but due to limitation of words, we decided to remove it. We have added to discussion the following comment: <i>“On the other hand, children with unknown nutritional status had higher risk of dying compared to well-nourished children. This may be partly explained in cases of</i></p>	<p>Page 14, lines 7-11.</p>	

1		<i>severe disease, where the severity of the child upon admission did not allow collecting anthropometrics measurements."</i>		
2	Reviewer 2's comments:			
3				
4	Given the lower specificity and PPV, the authors may need to recognize that many children will screen "positive" with their model. This does not mean it's still not a valuable output. It could, however, make interventions difficult. I think this warrants at least a line in the discussion. Given their AUC, spec / sens / PPV, I wouldn't be surprised if 50% of admitted children screened "positive". Doing an intervention in this case, would mean it needs to be really feasible. Might the model perhaps be most useful at identifying the kids who are unlikely to die rather than those most likely to die?	We agree with this comment and have added the following sentence in the discussion: <i>"On the other hand, the low specificity and positive predictive value found could compromise feasibility of interventions to prevent PDM, as a high number of children would be classed as high risk of dying after discharge. However, these models would allow the identification of the majority of children with risk of PDM."</i>	Page 17, lines 3-8

18	If the authors can reduce acronyms (e.g., U5 for "under five" is probably not necessary), it would help readability. I recommend trying to limit to only established abbreviations and minimizing use in the abstract.	We have removed some acronyms such as U5 through the manuscript. We have used four acronyms in the abstract, three of them internationally accepted (HIV, WAZ & AUC). The only acronym introduced by authors is postdischarge mortality (PDM).	Across the manuscript

22				
23				
24	The supplement definitions are important but pretty dense. This is in part because there are so many. An ideal world situation would be that the predictors are streamlined enough that these definitions could be included in the methods. Do they still feel each should remain?	Following the reviewer's suggestion, we have reduced the number of definitions, removing those clinical definitions which are internationally known.	Supplementary information, table S1

31	Related to this - did the authors consider using any statistical corrections for multiple testing?	Correction for multiple comparisons was not performed because of the exploratory character of the research to make sure that all important associations were identified. Therefore, both the hypotheses emanating from previous studies and the robustness of the findings of this study were two key issues for the discussion of the results.	NA

1 Can the authors please define what are 2 verbal autopsies.	We have included this definition in Supplementary information, supplementary 3 Table S1.	Supplementary 4 information, 5 table S1	
6 Can the authors please add what was the 7 high proportion threshold above which a 8 "missing" category was created?	As explained in a comment from reviewer #1, authors have added a further 9 explanation: <i>"For each variable with a high proportion of missing values (<15%) 10 but suspected to be a strong confounder, a "missing or unknown" category was 11 created"</i>	Page 8, lines 12- 12 13	

Instructions:

Please use this table format to answer the questions posed by the editors and reviewers of your paper. Copy and paste the editor/reviewer’s question in the “Comments” column and your answer to that question in the corresponding “Response” column. Be sure to ALSO paste the corrected text along with your response. For minor copyediting changes such as spelling and grammar corrections, you may simply state that the error was corrected, without pasting the altered text. * Use the page/line numbers from your revised .doc, .rtf, or .txt file; do *not* use the page/line numbers from the submission system’s auto-generated PDF.

For clarity, use one row per question. Make sure to list the page and line reference where your change can be found. If no change was made, please make sure to note that in your response in addition to your reasoning. You may delete the sample row and insert rows to this table as needed.
