Some participants did not reliably reject control items (i.e., at least 5 out of 7 correct), and their data were excluded from further analyses; 35 participants were excluded overall. The rest of the participants were very accurate in recognizing previously studied items (on average over 83% of correct recognitions across the target categories) and in rejecting items from novel categories (over 97% of correct rejections across categories).

However, the rates of false recognition in each target condition increased substantially, compared to the baseline

in Experiment 1. Proportions of hits (i.e., correct recognitions), false alarms on Target distracters (FA), and accuracy scores (Hits – FA) for each target category are presented in Table 1.

Table 1: Proportions of false alarms (FA), and Accuracy scores (Hits – FA) across target categories in Experiment 2.

Target Category	Hits	FA	Accuracy (Hits – FA)
Birds	.84	.50	.34
Fish	.80	.47	.33
Squirrels	.80	.61	.19
Cats	.80	.62	.18
Bears	.88	.79	.09

Overall results of Experiments 1 and 2 are presented in Figure 2. Data in the figure indicate that recognition accuracy markedly decreased in Experiment 2 compared to Experiment 1. This differential accuracy was the result of a processing manipulation introduced in Experiment 2 (i.e., an induction task) that focused participants on the category-level properties of stimuli, as opposed to item-specific properties in Experiment 1. Data in the figure also suggest that the decrease in accuracy in Experiment 2 was not proportional to the level of performance in Experiment 1. This task by condition interaction, F (4, 181) = 3.7, MSE = .21, $p < .05$, suggests that when participants are focused on category-level properties, they form mainly category-level representations, as opposed to mainly item-level representation in the Baseline. However, it is possible that decrease in memory accuracy obtained in Experiment 2 can be explained by increased task demands of Experiment 2 compared to Experiment 1 (performing an induction task versus no task during the study phase). It is also possible that overall accuracy in Experiment 2 decreased because participants were not warned about a subsequent memory test. Experiment 3 was designed to test these alternative explanations.

Experiment 3

The goal of Experiment 3 was to eliminate potential confounds of Experiment 2 by introducing a task that would force participants to engage in item-based processing. Similar to Experiment 2 participants were not warned about a subsequent memory test. Therefore, if accurate memory performance is obtained in Experiment 3, both of alternative explanations for the results of Experiment 2 will be eliminated.

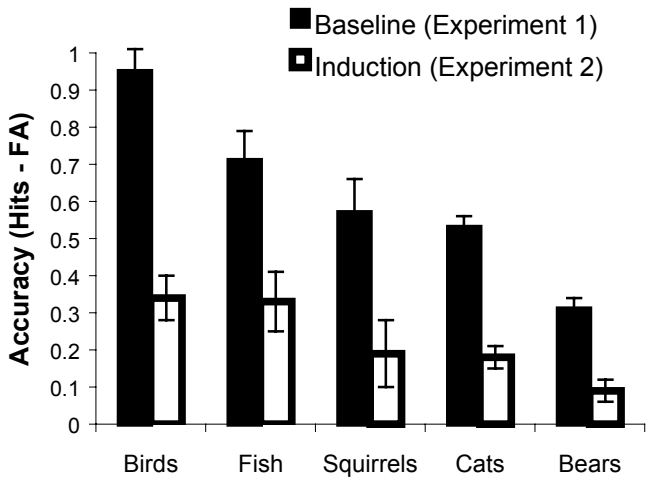

Figure 2: Mean accuracy (Hits – FA) across target categories in Experiment 1 and 2.

Method

Participants Participants were introductory psychology students at a large Midwestern university (N = 24, M age= 20.2 years, SD = 1.6 years; 9 women and 15 men) who received a partial credit for participation.

Design, Materials and Procedure Overall structure of the task was similar to Experiment 2, however only one target category (*Cats*) was tested, and participants were presented with a different question during the study phase. Participants were first presented with a picture of a cat, and told the animal was young. Then they were presented with 30 pictures of animals from 3 different categories (10 cats, 10 bears, and 10 birds), and asked to determine whether each animal was young or mature. Participants received random feedback, thus blocking any possible categorization. Similar to Experiment 2, participants were not warned about a subsequent memory test.

During the recognition phase participants were presented with 28 pictures: 14 previously studied pictures (7 cats and 7 bears), and 14 new pictures (7 novel cats and 7 squirrels, which served as control items). Participants were asked to determine whether each picture presented during the recognition phase was "old" (i.e., exactly the same as previously seen in the study phase) or "new".

All participants were tested individually, and had all instructions and stimuli presented to them on a computer screen in a self-paced manner.

Results and Discussion

Three participants did not reliably reject control items (i.e., at least 5 out of 7 correct), and their data were excluded from further analyses. The rest of the participants were very accurate in recognizing previously studied items (over 87% of correct recognitions versus 86% in Experiment 1), and in

rejecting items from novel categories (95% and 99% of correct rejections respectively). Levels of false recognitions were also comparable to the baseline in Experiment 1 (38% and 33% respectively). Results of Experiment 3 suggest that differential accuracy on a recognition memory test in Experiment 1 and 2 cannot by attributed to the difference in task demands or difference in instruction, since memory performance in Experiments 3 was very close to performance in Experiment 1, despite a task added to the study phase, and a lack of warning about a subsequent memory test. These findings indicate that the level of processing required by a task (item-specific versus category-specific) influences the level of false recognition on a recognition memory test.

General Discussion

The present study replicated earlier findings that DRM-type intrusions are possible with pictorially presented stimuli, and generalized these earlier findings to multiple categories. The study also demonstrated that processing manipulations (rather than differential task demands) influence the levels of false recognition. Specifically, tasks that focus participants on category-level properties result in category-level representations, and lead to decreased memory accuracy compared to the tasks that focus participants on the item-specific properties of stimuli. This decrease, however, is not proportional to the level of memory performance in the Baseline condition: as a result of performing induction, memory accuracy decreases drastically, and becomes more comparable for all types of Targets.

The reported findings, indicating that DRM-type memory intrusions persist even with pictures, seem to weaken the source monitoring explanation of memory intrusions. Even if source-monitoring errors play a role in memory intrusions with word-lists, these errors are highly unlikely to generate recognition errors when stimuli are presented pictorially. Therefore, assuming that the same mechanism underlies DRM-type intrusion with verbally and pictorially presented materials, it seems reasonable to conclude that monitoring errors are unlikely to be the only source of DRM-type intrusions with verbally presented materials. Given that memory intrusions with pictures are isomorphic to those with word-lists (i.e., both modes of presentation elicit high levels of false recognition and different intrusion rates across different lists), the assumption does not seem unreasonable. Therefore, the reported results seem to support the idea that that DRM-type intrusions stem from category-level or "gist" representations rather than from source monitoring errors.

The finding that performance on an induction task results in an increased level of memory intrusions is theoretically important for the study of inductive reasoning as well as memory. In particular, researchers debate whether or not induction is category-based at different points of development (see Sloutsky, 2003), and the study of effects of induction on memory accuracy may bring critical evidence to this debate.

In short, the reported research brings new evidence to research on memory and induction: category-based induction results in the formation of category-level or "gist" representations, which in turn increase false recognition of new items from studied categories.

Abstract

The ability to perform inductive generalizations has been demonstrated to develop very early in life. We argue that while adults use their conceptual knowledge when performing induction, young children perform induction by computing the similarity among presented entities. We further argue that this differential processing underlying children's and adults' induction results in different memory traces, and affects accuracy on a subsequent memory test. Experiment 1 demonstrates that while performing induction decreases memory accuracy of adults and 12-year-olds, it does not affect memory accuracy of 5-, and 7-year-olds. In Experiment 2, 5- and 7-year-olds were trained to perform category-based induction, which resulted in a decrease of their memory accuracy. In Experiment 3, a delayed transfer task was used to examine whether 5- and 7-year-olds could retain their learning over time. Overall, results of the reported experiments point to a developmental trend from similarity-based to category-based induction.

Introduction

The ability to make inductive generalizations is undoubtedly crucial for humans, for not only does it facilitate acquisition of new knowledge and skills, but also aids survival: "our knowledge that leopards can be dangerous leads us to keep a safe distance from jaguars" (Sloman, 1993, p.321).

It has been demonstrated that infants and very young children can perform simple induction tasks (Gelman & Markman, 1986; Sloutsky, Lo, & Fisher, 2001, Welder & Graham, 2001). The process underlying this basic ability is, however, still open to debate.

According to one view, children's inductive generalizations are driven by *a priori* conceptual assumptions (Keil, Smith, Simons, & Levin, 1998, Gelman & Hirschfeld, 1999). Under this view, which has traditionally been referred to as a *naïve theory* position, even early in development, induction is driven by the category assumption – a belief that entities are members of categories, and members of the same category have much in common. Thus, in the course of induction, children first identify presented entities as members of categories, and then perform inductive inferences on the basis of this categorization, because they presumably believe that members of the same categories share many unobservable properties.

According to another position, young children perform induction (as well as categorization) by detecting multiple correspondences, or similarities, among presented entities (e.g., see Jones & Smith, 2002; McClelland & Rogers, 2003; Sloutsky & Fisher, in press-a; Sloutsky, 2003). Because members of a category often happen to be more similar to each other than they are to nonmembers, young children are more likely to induce unobserved properties to members of the category. One such similarity-based model, SINC (abbreviated for Similarity, Induction, and Categorization) was proposed recently by Sloutsky and colleagues (Sloutsky et al., 2001; Sloutsky, 2003, Sloutsky & Fisher, in press-a). Under this view, conceptual knowledge (i.e., knowledge that that members of the same category share many unobservable properties) is a product of learning and development rather than an *a priori* assumption.

In short, under the former view, induction is category-based (i.e., it is a product of categorization), whereas under the latter view, induction is a product of computation of similarity. One of the goals of this research is to distinguish between these positions.

Traditionally, inductive inference in children has been studied directly, by asking participants to perform inductive generalizations and assessing their performance. However, this approach may not be an optimal way of examining representations underlying performance on induction tasks. An alternative framework has been recently suggested (Sloutsky & Fisher, in press-b). In this framework, representations underlying induction performance are studied by examining memory traces formed in the course of Induction. Participants are first presented with sets of pictures of familiar animals, and are asked to make inductive inferences about these animals. Later participants are given a surprise recognition memory test, in which they are presented with some old pictures (i.e., pictures they had previously reasoned about in the induction task), and some Critical Lures (i.e., "new" pictures that belong to the same category as "old" pictures). If participants perform induction in a similarity-based manner, they should form

item-specific representations, and exhibit high accuracy on a recognition test. At the same time, if participants form category-level representations (which might be the case if induction is category-based), they should poorly distinguish between Old Targets and Critical Lures.

Results reported by Sloutsky and Fisher (in press-b) indicate that young children exhibit high recognition accuracy for Critical Lures (thus pointing to similarity-based induction), whereas adults exhibit low recognition accuracy for Critical Lures (thus suggesting category-based induction). It has also been demonstrated that adults' category-based induction results in a decrease in memory accuracy compared to the Baseline memory tasks, while young children's similarity-based induction does not.

The goal of the series of experiments presented below is to compare the two theoretical positions by examining the pattern of development of inductive inference. The similarity-based position assumes a gradual transition from similarity-based to category-based induction in the course of learning and development, whereas no such transition is predicted by the naïve theory position. According to this position, even young children perform category-based induction. Another goal is to provide a learning account of the transition from similarity-based to category-based induction.

Experiment 1

Method

Participants Participants were 45 5 year-olds (19 girls, 26 boys, *M* age= 5.2 years, *SD* = .32 years), 35 7 year-olds (21 girls, 14 boys, *M* age= 7.9 years, *SD* = .54 years), 39 12 year-olds, (18 girls, 21 boys, *M* age = 12.1 years, *SD* = .48), and 30 introductory psychology students at a large Midwestern university (12 women and 18 men, *M* age= 19.5 years, *SD* = .99 years).

Materials, Design and Procedure Materials were 44 color photographs of animals presented against the white background. All animals were highly familiar to both children and adults, with familiarity established in a separate experiment (Sloutsky & Fisher, in press-b). Examples of the photographs used are presented in Figure 1. During the study phase, participants were presented with 30 pictures, one picture at a time, from three different categories (10 cats, 10 bears, and 10 birds). During the recognition phase, they were presented with 28 pictures, one picture at a time, and were asked whether they had seen each picture during the study phase. Half of the recognition pictures were previously presented during the study phase, and the other half were new pictures. The recognition pictures represented animals from three different categories: cats (7 of which were old and 7 were new), bears (all 7 of which were old), and squirrels (all 7 of which were new).

The experiment included two between-subject conditions: Baseline and Induction. The recognition phase was identical in both conditions, whereas the study phase differed across conditions.

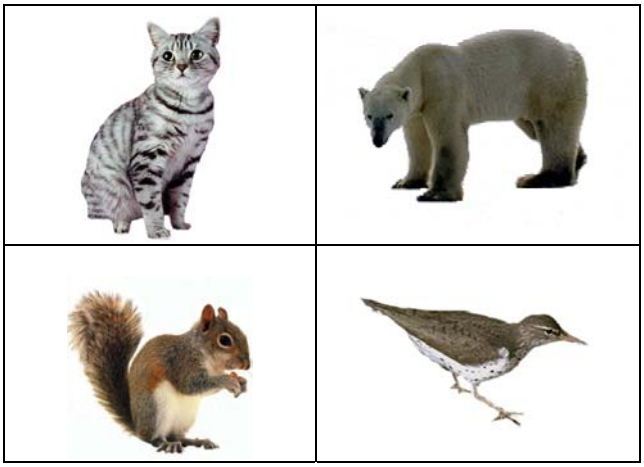

Figure 1: Examples of stimuli in Experiment 1.

In the study phase of the Baseline condition participants were presented with 30 pictures of animals, and their task was to remember these pictures for a subsequent recognition test. In the study phase of the Induction condition participants were first presented with a picture of a cat, and informed that it had "beta-cells inside its body". Participants were then presented with 30 pictures of animals (identical to those presented in the Baseline condition), and asked whether each of the animals also had beta-cells inside. After responding, participants were provided with "yes/no" feedback, indicating that only cats, but not bears or birds, had beta-cells. The recognition test was not mentioned in the study phase of this condition.

During the recognition phase, which immediately followed the study phase, participants were presented with 28 pictures and were asked to determine whether each was "old" (i.e., exactly the one presented during the study phase) or "new." No feedback was provided during the recognition phase

Children were tested individually in their day care centers by female hypothesis-blind experimenters. Undergraduate students were tested individually in a laboratory on campus. For all participants, stimuli were presented on a computer screen, and stimuli presentation was controlled by Super Lab Pro 2 software (Cedrus Corporation, 1999).

Results and Discussion

Although participants in every age group were very accurate in the study phase of the Induction condition, adults and 12 year-olds were somewhat more accurate (averaging 91% and 94% of correct inductions respectively) than 5- and 7-year-olds (74% and 84% of correct inductions respectively), $F(3, 78) = 5.9$, $p < .01$, post-hoc Tukey test, ps $< .05$ for all differences.

In the recognition phase of the experiment all participants were highly accurate in rejecting non-target distracters (i.e., squirrels), averaging over 91% of correct responses across conditions.

However, participants exhibited differential accuracy for the Targets (items previously presented during the study phase, i.e. old cats and bears) and Critical Lures (new items from the same category as the Targets, i.e., new cats) in the Induction and the Baseline. To examine the ability of participants to discriminate previously presented Targets from Critical Lures, memory sensitivity A-prime scores were computed. A-prime is a non-parametric analogue of the signal-detection statistics d-prime (Snodgrass & Corwin, 1988). If participants do not discriminate old Targets from Critical Lures, A-prime is at or below 0.5. The greater the discrimination accuracy, the closer A-prime scores are to 1. Proportions of hits (i.e., correct recognitions), false alarms on Critical Lures (FA), and A-prime scores by age group and condition are presented in Table 1.

Data in the table indicate that 5-, 7- and 12-year-olds well discriminated old items from Critical Lures in the Induction as well as the Baseline condition (A-primes > 0.5, one-sample *t*s > 2.8, *p*s < .01). At the same time, adults were accurate in the Baseline condition (A-primes > .5, one-sample t (14) 16.1, $p < .001$), whereas they were not accurate in the Induction condition: unlike children, adults' A-primes in this condition were not different from 0.5, one-sample $t < 1$, indicating no discrimination between old items and Critical Lures. Furthermore, adults' accuracy was lower than that of 5-year-olds or 7-year-olds, both independent sample *t*s > 2, *p*s <.05.

Table 1: Proportions of Hits, False Alarms (FA) and A-prime scores by age group and condition.

Age group	Baseline			Induction		
	Hits	FA	A-prime	Hits	FA	A-prime
5 year-olds	.82	.59	.66	.71	.56	.69
7 year-olds	.75	.40	.72	.77	.45	.74
12 year-olds	.79	.39	.78	.79	.59	.63
Adults	.88	.40	.84	.81	.74	.54

These findings are summarized in Figure 2, which presents a change in the A-prime scores in the Induction condition compared to the Baseline. Data in the figure indicate that in the Induction condition recognition memory was somewhat reduced in 12 year-olds and dramatically attenuated in adults, while Induction had virtually no effect on the recognition accuracy of 5- and 7-year-olds. The significant age by condition interaction was confirmed by the two-way (age by experimental condition) ANOVA performed on the A-prime scores, $F(3, 141) = 5.7$, $p < .001$.

We argue that high recognition accuracy of younger participants of Experiment 1 was due to the fact that they were engaged in item-specific processing regardless of the experimental condition. Adult participants, on the contrary, demonstrated high memory accuracy only in the task that forced them to perform item-based processing, the Baseline condition. In the Induction condition, however, adults demonstrated low memory accuracy, due to engagement in category-level processing. Results of Experiment 1 therefore point to a developmental trend from similarity-based to category-based induction: memory sensitivity of younger children does not decrease at all in the Induction compared to the Baseline, while sensitivity of 12 year-olds decreases somewhat, and sensitivity of adults reduces dramatically.

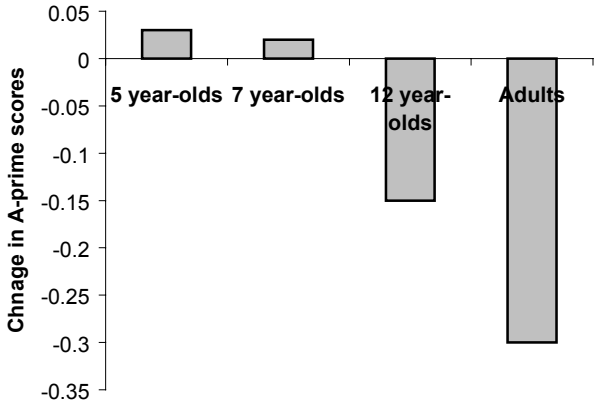

Figure 2: Change in the A-prime scores in the Induction condition compared to the Baseline across age groups.

Experiment 2 was designed to provide a learning account of the category-based induction found in adults, by training 5- and 7-year-olds to perform induction in the category-based manner. If training is successful, that is if memory accuracy of younger children can be reduced to the level of adults, this would further undermine the claim that reasoning in young children is *a priori* conceptually constrained.

Experiment 2

Method

Participants Participants were 27 5 year-olds (16 girls, 11 boys, *M* age= 5.2 years, *SD* = .26 years), and 15 7 year-olds (11 girls, 4 boys, *M* age= 7.6 years, *SD* = .44 years).

Materials, Design and Procedure Materials were identical to those of Experiment 1, however, participants were tested in the Induction condition only. The procedure of Experiment 2 was different from Experiment 1 in that prior to the study phase, participants were trained to perform category-based induction. Children were taught that animals that have the same names belong to the same category, and

that animals that belong to the same category share unobservable properties. Picture cards representing rabbits, dogs, and lions were used for the training procedure; none of these categories of animals were used in the experiment proper.

Upon completing the training, participants were presented with the experimental task, which was identical to the Induction condition of Experiment 1. Hypothesis-blind female experimenters tested children individually in their schools and child care centers.

Results and Discussion

Overall participants were highly accurate during the study phase of Experiment 2, averaging over 92% of correct inductions. Similar to Experiment 1, participants were also very accurate in rejecting non-target distracters (i.e. squirrels), giving on average 98% of correct responses.

However, unlike Experiment 1, memory sensitivity of participants in both age groups, as indicated by the A-primes scores, did not differ from chance, both one-sample *ts* < 1.7, *ps* > .1. Proportions of hits, false alarms on Critical Lures, and A-prime scores are presented in Table 2.

Results of Experiment 2 indicate that training to perform category-based induction significantly reduced memory accuracy of both 5- and 7-year-olds, bringing their recognition performance to chance and making it comparable to the performance of adult participants in Experiment 1.

Could it be that training had a non-specific effect on memory accuracy, such that, regardless of the experimental task, children participating in the training experiment exhibited reduced memory accuracy? This issue was addressed by Sloutsky and Fisher (in press-b), who demonstrated that training had no adverse effects on children's memory in the Baseline condition.

Table 2: Proportions of Hits, False Alarms (FA) and A-prime scores by age group in Experiment 2.

Age group	Training Condition		
	Hits	FA	A-prime
5 year-olds	.82	.65	.58
7 year-olds	.73	.59	.57

While demonstrating that both 5- and 7-year-olds were successful in learning to perform category-based induction, the experiments left an important question unanswered. In particular, it remained unclear whether effects of this training would be retained over time. Results of Experiment 2 together with the developmental trend found in Experiment 1 suggest that older children should be better able to retain what they learned during training over a time delay. Experiment 3 was designed to investigate the ability of 5- and 7-year-olds to retain this new knowledge over a time delay.

Experiment 3

Method

Participants Participants were 17 5 year-olds (11 girls, 7 boys, *M* age= 5.3 years, *SD* = .17 years), and 19 7 year-olds (4 girls, 15 boys, *M* age= 7.6 years, *SD* = .44 years).

Materials, Design and Procedure Materials and procedure were identical to those of Experiment 2 with one important difference: there was a delay between training to perform category-based induction and the experiment proper. The delay was on average 14.6 days (SD = 1.5 days, range 14 – 18 days). As in the previous experiments hypothesis-blind female experimenters tested children individually in their schools and child care centers.

Results and Discussion

Similar to previous experiments participants were highly accurate both in rejecting non-target distracters (averaging over 96% of correct rejections), and making correct inductions during the study phase (84% and 86 % of correct inductions in the groups of 5- and 7-year-olds respectively). However, in contrast to Experiment 2, participants demonstrated differential memory accuracy for Critical Lures. Proportions of hits, false alarms on Critical Lures, and A-prime scores are presented in Table 3. Memory accuracy of 7 year-olds indexed by the A-prime scores was close to chance (which was similar to their accuracy in Experiment 2), one-sample t (18) = 1.9, $p > .07$. On the other hand, recognition memory of 5 year-olds was clearly above chance, one-sample t (16) = 4.9, $p < .0001$.

Table 3: Proportions of Hits, False Alarms (FA) and A-prime scores by age group in Experiment 3.

Age group	Delayed Transfer Condition		
	Hits	FA	A-prime
5 year-olds	.82	.59	.67
7 year-olds	.91	.75	.59

Thus, results of Experiment 3 indicate that while 7 year-olds retained what they had learned during training over a two-week delay, 5 year-olds were unable to do so. Therefore, retaining of the learned ability to perform induction in a category-based manner seems to be a function of age.

Memory accuracy of 5- and 7-year-olds across three reported experiments is presented in Figure 3. Results presented in Figure 3 point to an interesting developmental pattern: while both 5- and 7-year-olds do not perform

category-based induction spontaneously (i.e., under the no-training condition of Experiment 1, their accuracy is high), children in both age groups can be successfully trained to perform category-based induction (as evidenced by their reduced accuracy in the training condition of Experiment 2). However, only 7 year-olds are able to retain the results of training over longer periods of time (i.e., after the delayed condition in Experiment 3, their accuracy remained low). At the same time, 5-year-olds reverted back to similarity-based induction (i.e., after the delayed condition in Experiment 3, their memory accuracy returned to the high pre-training level).

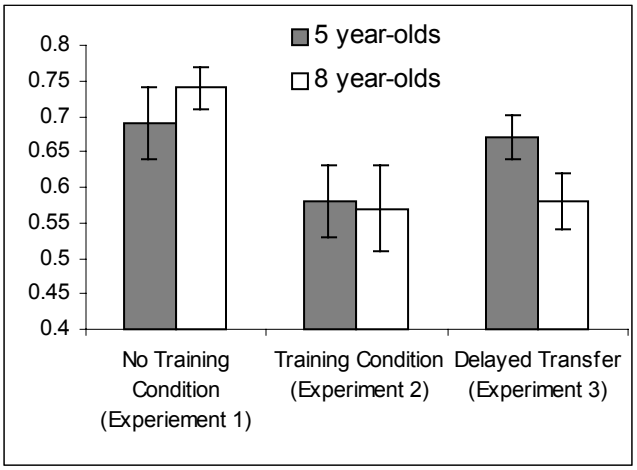

Figure 3: A-prime scores for 5- and 7-year-olds in the Induction task across Experiments 1 – 3.

General Discussion

Several important findings stem from the three reported experiments. First, there is a clear trend in the development of induction: induction task attenuates memory accuracy for individual items of 12-year-olds and adults, whereas 5- and 7-year-olds exhibit accurate memory for individual items. Furthermore, in the Induction (but not in the Baseline) condition younger participants exhibit greater memory accuracy than older participants or adults. Second, training to perform category-based induction leads to a decrease in memory accuracy of 5- and 7-year-olds to the level of adults. And third, 7-year-olds retain training over longer periods of time than 5-year-olds: 5-year-olds sooner than 7-year-olds exhibit high levels of memory accuracy for individual items, returning to their pre-training high accuracy.

These results indicate that: (1) while 12-year-olds and adults perform category-based induction (which results in mostly category-level representations), 5- and 7-year-olds perform similarity-based induction (which results in item-level representations); (2) there is a gradual developmental transition from similarity-based to category-based induction; and (3) category-based induction does not have to be *a priori*, it can be learned and retained over time (although the length of retention is a function of age). These results support predictions of the similarity-based account of induction, while presenting challenges to the naïve theory approach. In what follows, we consider theoretical implication of these results.

Induction and Memory Accuracy Across Development

The results support the contention of the similarity-based approach that early in development children perform induction by computing similarity among compared entities. As a result, these participants form item-specific representations, and accurately remember individual items encountered in the course of induction. At the same time, older children and adults perform category-based induction (i.e., they first categorize entities, and then generalize properties to members of the same category), and as a result they form category-level, but not item-specific representation, thus exhibiting poor memory for individual items encountered in the course of induction. Note that older children and adults have no difficulty remembering individual items, in the Baseline condition, in which they are not required to perform induction. Furthermore, there is additional evidence that category-based induction affects memory accuracy for individual items: when younger participants were trained to perform category-based induction, their memory accuracy in the Induction (but not in the Baseline) condition dropped to the level of adults.

Taken together, these findings do not support the contention of the naïve theory position that induction in young children is category-based, but they rather support the contention of SINC that induction in young children is similarity-based.

The Development and Learning of Category-Based Induction

The reported results also present developmental and learning accounts of category-based induction. First, category-based induction gradually emerges in the course of development: there is little evidence that 5- or 7-year-olds spontaneously perform category-based induction, whereas 12-year-olds are more likely to perform it than younger children, and adults are more likely to perform it than 12-year-olds. Second, people do not need *a priori* category assumption – young children can be trained to perform category-based induction. However, the retention of this training is a function of age – 7-year-olds are more likely to retain training over time than younger children. Therefore, it seems reasonable to conclude that (a) there is a transition from similarity-based to category-based induction, and this transition is gradual; (b) category-based induction can be successfully learned; and (c) the retention of learning is a function of age. These findings provide a learning account of category-based induction suggesting that it is unnecessary to posit that conceptual knowledge is *a priori*. Recall that in Experiment 2, participants were taught that (a)

similar things that have the same name belong to the same kind, (b) things that belong to the same kind share many non-observable properties, and (c) things that have the same name share many non-observable properties. It is possible that (a) and (b) are taught in school, whereas (c) is a direct consequence of (a) and (b). Therefore, results of Experiment 2 may explain the transition from the similarity-based induction exhibited by children to category-based induction exhibited by adults, suggesting that category-based induction and requisite conceptual knowledge could be a product of feedback-based learning. While presenting a learning account of category-based induction, these findings seriously challenge the contention of the naïve theory position that category-based induction has to be based on *a priori* assumptions.

Conclusion

Overall, results of the three reported experiments represent novel findings indicating that (a) early in development people spontaneously perform similarity-based rather than category-based induction; (b) there is a gradual transition from similarity-based to category-based induction; and (c) category-based induction is a product of learning. These results support the similarity-based account of young children's induction, while presenting challenges to the naïve theory approach.

Abstract

A necessary condition for correctly assessing causality is the absence of confounding causes. This paper reports a pair of experiments that investigate whether people are sensitive to confounding when they infer causation. Two stories were constructed, one in which two candidate causes perfectly covaried with each other (*confounded*), and another in which the two candidate causes occurred independently of each other (*unconfounded*). In the confounded story, both causes covaried perfectly with an outcome; in the unconfounded story, only one of the two candidates covaried with the outcome. If people control for alternative causes while they evaluate a candidate cause, then subjects in the confounded condition should indicate that it is impossible to determine causality for either candidate alone, whereas those in the unconfounded condition should be able to judge that one of the candidates is causal and the other not. If people are not sensitive to confounding, however, subjects in the confounded condition should attribute causality to both candidates, and their judgments for these candidates should be the same as those for the target causal candidate in the unconfounded condition. Two experiments were conducted respectively with children and adults: Children received one or the other story, while adults received both. Both children and adults distinguished between confounded and unconfounded candidate causes when making attributions of causality. Our results show that children are able to state the indeterminacy of confounded candidate causes at an age much earlier than previously documented.

Introduction

One view of how children learn is that they approach the world as scientists and form theories about the world using information about variation and covariation to establish causal connections (e.g. Gelman, 1996; Gopnik, Glymour, Sobel, Schulz, Kushnir, & Danks, 2004; Gopnik, Sobel, & Schulz, 2001). Further, they intervene upon the world in order to discover these relationships (Schulz, 2003). Although children may have misconceptions in their explanations, as when a child states that he thinks God made the sun out of gold and lit it with fire (Siegler, 1998), the presence of such misconceptions does not mean that children are unable to use the data present in the environment to form correct causal attributions. Given that adults have had many more experiences than children, we should not expect children's theories to be the same as adult's theories, especially for complex phenomena. What is important is whether the same process is utilized when determining causality. In particular, this paper seeks to examine whether both children and adults are sensitive to confounding when there are two candidate causes for a novel outcome.

In addition to the potential implications for improving science instruction, assessing children's sensitivity to confounding is also important for differentiating between two types of models of causal learning. The first type is instantiated in the *unconditional* ΔP model (Jenkins & Ward, 1965); the second type consists of models that tease apart the influence of a candidate cause from the influences of alternative causes (e.g., Cheng, 1997; Cheng & Novick, 1992; Glymour, 2001; Gopnik et al., 2004; Novick & Cheng, 2004; Pearl, 2000; Spirtes, Glymour, & Scheines, 2000; Tenenbaum & Griffiths, 2001).

Under the unconditional ΔP model, people contrast the frequency of e, an effect of interest, when c, a potential cause, is present, with the frequency of e when c is absent:

$$\Delta P = P(e|c) - P(e|\sim c)$$

If ΔP is equal or close to 0, then c is considered noncausal; if it is noticeably greater than 0, then c is thought to cause e, and if it is noticeably less than 0, c is thought to prevent e. The unconditional ΔP model implies that people ignore confounding and pool over all the information known about the candidate cause. Thus, if two candidate causes perfectly covary with each other and the effect, then both candidates will be judged as causal.

Under the alternative approach, a definite causal judgment can result from the above contrast only when alternative causes are controlled (i.e., they occur independently of the candidate cause). One simple variant of this approach is the *conditional* ΔP model: the same ΔP formula is applied to a focal set of events in which alternative causes occur independently of the candidate (Cheng & Novick, 1992). For example, if there is a situation in which there are two possible causes of an event, one way in which a person could determine the causality of the individual candidates would be to compare the frequency of e in the situation in which only one candidate is present to a situation in which no candidate is present, holding the other candidate constantly absent. If people utilize conditional ΔP, they would be unable to draw a definite causal conclusion when

there is confounding because no focal set of events could be formed.

Although unconditional ΔP has fallen into disfavor in the adult causal learning literature, previous studies of children suggest that they do not withhold judgments of causality in the presence of confounded variables (e.g., Kuhn, Amsel, & O'Loughlin, 1988). In other words, they seem to behave as predicted by the unconditional ΔP model. Our study focusses on young children. If the ability to reason causally is an unlearned fundamental human process, then it should be present at an age much earlier than indicated by prior research.

One study looking at third, sixth and ninth graders, as well as non-college young adults and undergraduate college students found that before the ninth grade, students were unlikely to state that there was insufficient evidence to determine causality when there is confounding (Kuhn, Amsel, & O'Loughlin, 1988). In fact, not a single subject suggested indeterminacy as the correct answer until the 9th grade. In one condition, 20 subjects in each age group was asked to determine the whether a feature of a ball (namely, texture) caused a ball to be bouncier in the presence of a perfectly confounded covariate (namely, color). None of the 3rd or 6th graders, one 9th grader, 2 non-college adults, and 5 college subjects proposed indeterminacy as the correct answer. But, these experiments involved causes for which the students were likely to have prior theories, and people interpret ambiguous data in ways that are consistent with their prior beliefs (Darley & Gross, 1983). Kuhn et al. (1988) do not indicate whether students who did not notice the indeterminacy were answering in a manner consistent with their prior theory. Also, because their studies focus on the coordination of theory and evidence, one of criteria used for assessing students' answers was their ability to justify their responses. But, if causal learning is an unconscious process, students might be sensitive to confounding, yet unable to justify their responses. In the present study, the task is made simpler, by presenting subjects with a novel effect, thereby reducing the relevance of prior causal beliefs, and by measuring subjects' causal attribution without asking for a justification.

Data from two pilot experiments are presented. Both experiments test whether people differentiate between confounded and unconfounded candidate causes. In one experiment, the subjects were undergraduates, while in the other the subjects were pre-school age children. In both experiments, participants were presented with two possible causes for a novel event, and were asked to determine the cause of that event. In one condition the two possible causes were independently occurring, while in the other condition the two candidate causes always occurred together. If people are sensitive to confounding they should be able to make a causal attribution in the first condition but not the second.

Methods

These experiments were designed to test whether people are sensitive to the independent occurrence of potential causes of an effect when making judgments of causality. The first experiment was conducted on adults. Even if adults are able to succeed in this task, however, their success might well be due to prior training. The second experiment was therefore conducted on children. Similar materials were used for both experiments.

The second experiment was actually conducted first. Because the data with the children was not very clean, in order to develop a better protocol the materials were piloted with adults. The small sample sizes in both experiments are due to the preliminary nature of the data. Also, the adult pilot was ended when the adult answers became consistent. Both experiments will be re-run with larger sample sizes using the final adult version of the stimuli**.** Below we describe the methods for both experiments before reporting the results.

Experiment 1

Participants 10 undergraduates at the University of California, Los Angles enrolled in an Introduction to Psychology Course participated in the study. Students received class credit for participating in the study and were recruited using an on-line bulletin board for this course.

Design This experiment had two conditions and utilized a within-subjects design. In one condition, the two possible causes of an unusual event were perfectly correlated (confounded). In the other condition, the same two possible causes occurred independently of one another (unconfounded). Subjects were asked about the causality of the candidate causes in turn. The ordering of the stories, as well as the order in which the subject was asked about each candidate cause, was counterbalanced across subjects.

Materials Two passages of approximately the same length were constructed (one story was 668 words and the other was 681 words). Both passages tell the story of bunny rabbits that went to two different parties.

In both stories, the parties occur at the same time and on the same day. On the day of the party, the bunnies are randomly assigned to a party via a coin toss. Half of the bunnies ate candy before going to the party. At one of the parties the bunnies ate cake, while at the other party they did not. In the confounded condition all the bunnies who ate candy also ate cake, whereas in the unconfounded condition half of the bunnies who ate candy also ate cake, and vice versa. All the bunnies at the cake party grew new pink wings; none of the bunnies at the "no cake" party did. To avoid confusion between the two stories, in one story, the bunnies ate green grass candy and yellow cheesecake; in the other story the bunnies ate blue berry candy and orangey orange cake.

At the end of the story, participants were asked about the causality of each of the causal candidates in the story:

1) Does Yellow Cheese Cake/ Blue Berry Cake all by itself make bunnies grow new pink wings? Yes, No, or Impossible to tell?
2) Does Green Grass Candy/ Orangey Orange Candy all by itself make bunnies grow new pink wings? Yes, No, or Impossible to tell?

The text of the story was accompanied by illustrations. An appropriately colored wedge in the bunnies' stomachs represented the cake, and a candy shaped object in the bunnies' stomach represented the candy.

Because we were attempting to revise the stimuli in order to make the directions clearer for the children, the stimuli underwent slight modification across the 10 subjects. The conditions remained the same, but there were slight changes in wording and pictorial presentation across groups. The most significant wording change was that the story narrative was condensed, leaving only a concise explanation of the meaning of the symbols that represented the outcomes as well as the candidate causes. The most significant pictorial modifications occurred in the confounded condition. In the original stimuli, the bunnies were in two groups (the cake group and the no cake group), with the bunnies who ate candy evenly distributed throughout each group. In the final stimuli, the bunnies were arranged into four groups of bunnies that underwent each treatment (i.e., one group had cake and candy, one group had only candy, one group had only cake, and one group had neither cake nor candy). Both of these changes served to make the experiment easier for the subjects to understand and interpret.

The stories were shown as a power point presentation. The power point presentation was presented on a 15" computer screen.

Procedure Participants were randomly assigned to conditions that differed on the ordering of the stories and assessment questions. Participants were then told that they were going to hear a story about bunny rabbits in two little bunny towns. They were told that something interesting was going to happen to these bunny rabbits, and that it was their job to try to figure out what happened.

Participants looked at the illustrations on the screen as the experimenter read the story aloud. At the end of the story, participants were asked about the causality of each of the causal candidates in the story. The experimenter wrote down their answers on an answer sheet as they progressed through the story.

Experiment 2

Participants Sixteen pre-school children from the Bellagio daycare center at the University of California, Los Angeles participated in the study. Nine male and seven female children between the ages of 4;5 and 5;7, with a mean age of 4;11 participated in the study. One child was excluded from the analysis for answering incorrectly factual questions about the stories presented. The rest of the children answered all of these questions correctly (as explained later).

Design This experiment had the same two conditions as Experiment 1 but utilized a between-subjects design. The order in which children were asked about each candidate cause was counterbalanced across conditions.

Materials The stories presented to the children had the same content as the stories presented to the adults, with three differences. First, the children's protocols did not undergo significant changes. The initial adult protocols (with the distributed confounding variable and long narrative) are the same as the child protocol. Second, in both conditions, children saw green grass candy and yellow cheesecake. (This was possible because subjects only saw one story, which ruled out the possibility of carryover between stories.) The children's assessment procedure also differed from that of the adults.

Children were first asked for their spontaneous attribution. "Do you think that it is possible to figure out why the bunnies grew new pink wings?" If the child answered yes then the following questions were asked:

1) Why do you think these bunnies [pointing to those who went to the cake party] grew new pink wings?
2) Why do you think these bunnies [pointing to those who went to the no cake party] did not grow new pink wings? The ordering of these two questions was counterbalanced across conditions.

Because children sometimes did not give a free response, did not address both of the causal candidates, or did not address the causal candidates in their responses (e.g., "Bunnies grew wings because they wanted to"), additional probes were added, asking about each of the candidate causes separately. Children were told about statements that other children had made while reading this story. Children were asked whether they thought these statements were "definitely right, definitely wrong, or impossible to tell." The statements they were asked to judge were

1) GREEN GRASS candy all by itself makes bunnies grow pink wings.
2) YELLOW CHEESE CAKE all by itself makes bunnies grow pink wings.
3) YELLOW CHEESE CAKE and GREEN GRASS candy together make bunnies grow pink wings.

If the child had previously indicated that the yellow cheesecake was causal, they were not asked about the yellow cheesecake again (and the same for the other candidates).

Procedure Children were randomly assigned to the conditions. They were video taped during the session. In order to accustom children to the camera, they were first introduced to the camera and allowed to see themselves on the LCD screen. As with the adults, children were told that they would hear a story about bunny rabbits, and that it was their job to figure out what happened.

The children looked at the illustrations on the screen as the experimenter read the story aloud. At the end of the story, the children were asked four factual questions to assess whether they understood and remembered the content of the story. The experimenter pointed to a picture of the bunnies with the candy in their tummies and asked, "What did these bunnies eat?", the correct answer being "candy" (or cake and candy in the confounded condition). The experimenter then pointed to the bunnies without candy in their tummies and asked, "Did these bunnies eat candy?", the correct answer being "no". The experimenter then pointed to a picture of the bunnies at the cake party and asked, "What did these bunnies eat at the party?" (this question was omitted in the confounded condition if children answered cake and candy to the first question above), the correct answer being "cake". The experimenter then pointed to a picture of the bunnies at the no-cake party and asked, "Did these bunnies eat cake?" the correct answer being "no". Children who did not correctly answer all factual questions were excluded from the study.

Results

Experiment 1

Adult subjects were sensitive to confounding when they made causal judgments. The data are presented in Tables 1 and 2 below, with the number who answered correctly in bold font for each condition.

Table 1: Cake attributions for adults

	Causal Attribution		
Condition	Yes	No	Can't Tell
Confounded	0	0	**10**
Unconfounded	**8**	1	1

Table 2: Candy attributions for adults

	Causal Attribution		
	Yes	No	Can't Tell
Confounded	0	0	**10**
Unconfounded	0	**6**	4

Using McNemar's test for 2-related samples of categorical data, we see that the pattern of responses differed across conditions for both of the causal candidates. Subjects were more likely to say the cake was causal in the unconfounded condition than in the confounded condition, and conversely, more likely to say it was impossible to assess causality in the confounded condition than in the unconfounded condition ($p < 0.05$, exact statistic, binomial distribution used). Likewise, subjects were more likely to say that the candy was not causal in the unconfounded condition than in the confounded condition, and more likely to say it was impossible to tell in the confounded condition than in the unconfounded condition ($p < 0.05$, exact statistic, binomial distribution used). In fact, as can be seen in Table 1, for both cake and candy in the confounded condition, all subjects said that it was impossible to tell if either candidate was causal. In contrast, in the unconfounded condition, most subjects said that the cake was causal, and none said that the candy was causal.

The order of presentation of the conditions had no effect: Subjects were just as likely to give a correct response whether they received the confounded or unconfounded condition first (n.s.). We were unable to test the effect of the ordering of the questions on the two candidate causes because some information on the ordering was lost. There was no effect of candidate in either condition: subjects were just as likely to make the correct causal judgment for the candy as they were for the cake (n.s.).

Experiment 2

Children were also sensitive to confounding when they made causal judgments, but this data show more variability than the adult data.

Children were first categorized into one of five causal attribution categories: the cake is causal, the candy is causal, both causal (jointly or independently), it is impossible to tell, and other causal attribution (Table 3). Because the focus of this paper is on children's ability to determine whether there is sufficient evidence to attribute causality to an individual cause in the case of confounding, the answers were collapsed into two groups, either assigning causality to individual candidates or not assigning causality to individual candidates (Table 4). If children made a spontaneous causal attribution, this was taken as the value for the measure. If a child did not give a spontaneous response or gave an ambiguous answer, the value for this measure was taken from the child's answers to follow-up questions about each individual candidate.

Table 3: Children's causal responses

	Condition	
Child responses	Confounded	Unconfounded
Cake	0	**4**
Candy	0	0
Both	3	2
Can't Tell	**4**	1
Other	0	1

Table 4: Children's attributions to individual candidates

	Condition	
Causal Category	Confounded	Unconfounded
Individual Attribution	2	**7**
No Individual Attribution	**5**	1

In the confounded condition, 3 children said both candidates were causal and 4 said it was impossible to tell.

Children in this condition gave no other responses. All of these statements were spontaneous attributions, and their answers in the follow-up questioning were consistent with their spontaneous answers. If children in the "Both" category had meant that the candy and the cake together made the pink wings, but that it was not possible to judge either candidate by itself, this would have been a correct response. Given these children's pattern of responding, for two of the children it is not clear whether they meant the two were independently or conjunctively causal. To score conservatively, against sensitivity to confounding, we counted these as attributions to the individual candidates. The third child indicated that she thought the conjunctive answer was the best answer despite the fact that she answered yes to the probes asking about the causality of each candidate individually. This child was recoded as "no individual attribution" in Table 4.

In the unconfounded condition, 4 children said cake was causal, 2 children said they both were causal, one child gave an alternate attribution, and another said that it was impossible to establish causality. Five of these statements were spontaneous attributions, only one of which was consistent with follow-up questioning. Two children who were coded as making a causal cake-attribution initially began by giving unclear spontaneous responses.

Children were more consistent in their responses across question formats in the confounded condition than in the unconfounded condition (Fisher's exact test, $p < 0.05$).

Even with our small samples, given the scoring as we just explained, individual attribution (see Table 3) was more likely in the unconfounded condition than in the confounded condition (Fisher's exact test, $p < 0.05$). Moreover, the correct response was the modal response in each condition (Table 4). Even so, given our small sample size, in both the confounded and unconfounded conditions children's ability to make a correct causal attribution was not significantly different from chance (Fisher's exact test, n.s.).

Discussion

Like Kuhn et al. (1988), it is likely that this study underestimates children's causal reasoning abilities. The correctness of the children's causal attributions, when they occurred, where not impressive in this experiment. These results may seem at odds with recent literature suggesting that children are often able to make correct causal attributions at an early age (e.g., Gopnik et al., 2001). It is likely that the poor performance in Experiment 2 is due to an overly confusing experimental protocol, particularly the visual presentation of the stimuli. Because the confounding cause was distributed equally across both groups, it was difficult to visually isolate the correct focal set.

Because the stimuli used were different between the child and adult studies, it is impossible to tell what, if anything, developed from childhood to adulthood. Our results do not speak to whether adults are better at causal reasoning than children. But, it is clear that both adults and children can differentiate situations in which it is possible to make a causal determination from those in which it is impossible to make a causal determination.

One puzzling result is that the adults responded unanimously to the confounded condition but less clearly to the unconfounded condition, and seemed to be more confused about the candy. This difference between conditions, however, is likely due to confusion in the protocol. After the assessment, when subjects were asked to explain their answers, the two subjects in the unconfounded condition who did not answer that the cake was causal cited reasons of experimental control. For example, one subject answered, "The bunnies at one party could have drank something that the bunnies at the other party did not." When it was made clear that the bunnies were exactly the same, except for whether they had eaten cake or candy, both subjects gave the correct response. Similarly, the subjects who said "can't tell" for the candy in the unconfounded condition occurred in the earlier portion of the experiment, before the materials were finalized.

One might think that the unconfounded condition could use a simpler, less confusing, design. But, in order to compare the unconditional ΔP model with the conditional ΔP model regarding confounding, the unconfounded condition must present information on all four possible combinations of the two candidate causes: both candidate causes are present, neither is present, and only one or the other of the candidate causes is present. To form the appropriate focal set for each candidate cause, the subject could compare the outcome in a single candidate "cell" to the outcome in the no-candidate-cause cell. Alternatively, the subject could compare the outcome in the combined candidate cell to outcomes in each of the single candidate cause cells.

Let us consider two potential two-cell designs. In the simpler design, there is a single candidate cause. In one cell both the candidate cause and the effect are present, in the other cell neither the candidate cause nor the effect is present. In this case, if children attribute causality to the candidate cause, it could be due purely to association. Furthermore, if fewer children attribute causality in the confounded condition, it could be argued that that condition is simply more difficult because it involves two candidate causes rather than one.

In a more complex two-cell design, there are two candidate causes: In one cell candidate cause A is paired with the effect, in the other cell candidate cause B occurs without the effect. This situation is, in fact, confounded. There is a perfect (inverse) correlation between the occurrence of candidates A and B. The only appropriate focal set would compare the occurrence of the effect before and after the introduction of the candidate causes, essentially adding a no-candidate-cause cell. Even if temporal information is used, this type of design does not rule out the possibility of a third unobserved candidate systematically affecting both candidates as well as the effect. There would be a number of correct responses depending on the extraneous

assumptions made by the subjects regarding the influence of the unobserved candidate.

Conclusion

Both children and adults distinguish between confounded and unconfounded candidate causes when making causal inferences. All adults said that it was impossible to tell whether the cake or the candy alone caused the wings in the confounded condition. Because the subjects in the adult experiment were UCLA undergraduates and not less well-educated adults, and because the conditions used in this experiment were consistent with examples used in scientific methodology classes, it is possible that the adults have had prior training that allowed them to say that causal attribution was not possible when the causes were confounded. The same was not true of the children.

The child data suggests that children are able to state, at a much earlier age than documented by previous studies, that it is impossible to infer causality when two candidate causes perfectly covary. Children as young as 5 years old, less than half as old as previously believed, made such judgments. Moreover, these judgments were consistent across response formats.

Despite the variability in the data, and despite the fact that the children were presented with a version of the task that was more difficult than necessary, more children indicated that it was impossible make a causal judgment in the confounded condition than in the unconfounded condition. As predicted by the conditional ΔP model, children (and adults) are sensitive to confounding.

Abstract

Card sorts can be used to study the way human subjects organize conceptual knowledge. In this paper we define three measures of complexity of card sorts produced by human subjects. These measures are applied to a particular data set of subjects (students and experts) collected in a large, multi-institutional study where the concepts are taken from a first-year programming course. We show that certain of these measures are statistically significant in discriminating between students and experts and among students based on their performance levels.

Introduction

Card Sort [5] is a technique that seeks to elicit individual conceptual frameworks by giving a subject a collection of cards – each pre-printed, for example, with a word or phrase – and asking the subject to partition (*sort*) the cards into subsets based on the subject's own criteria. The subject is asked to repeat the process anew with different criteria until the subject can think of no additional sorts.

As part of a National Science Foundation (NSF) workshop (Grant DUE-0122560, awarded to the Institute of Technology at the University of Washington–Tacoma), workshop participants conducted a card sort study [4] on "first-competency" programmers: those who have typically completed a second-semester programming course for computer science majors. This study surveyed 243 student subjects and 33 "expert" subjects drawn from 22 institutions represented by the workshop participants. The "experts" were chosen for their proven programming maturity and experience. Both the student and expert subjects were given twenty-six cards used as stimuli. Each card was printed with a one-word programming-related term from the following table:

function	method	procedure
dependency	object	decomposition
abstraction	if-then-else	boolean
scope	list	recursion
choice	state	encapsulation
parameter	variable	constant
type	loop	expression
tree	thread	iteration
array	event	

The data set gathered by the workshop participants includes 1199 card sorts produced by 276 subjects.

A background questionnaire given to each card sort subject provided information on the subject's gender, age, and self-rating of familiarity with programming languages from a specified list (Java, C, C++, Ada, Scheme, Pascal, Visual Basic). At each participating institution, the institution's workshop participant ranked each of the institution's student card sort subjects on a scale from 1 to 5, with 1 representing low-performance and 5 representing high-performance.

The NSF workshop study addressed several questions, including the following:

- Do students and experts organize concepts differently?
- Are there differences between low- and high-performing students? similar to the differences between students and experts?
- Are there differences between male and female students? Between male and female experts?

In this paper, we describe how to compute numerical values that measure the "complexity" of the collection of all the sorts produced by a given card sort subject. These measures are based solely on how the subject partitions the cards into different categories and not on the names the subject gives to the categories nor on the criterion the subject used to sort the cards. We show that, for the NSF workshop study, certain of these measures can be used to distinguish (in a statistically significant sense) experts from novices and high-performing students from low-performing ones. We show that there are no significant differences between males and females.

The Measures

Following [1], we use the "edit distance" metric to define the distance between two card sorts. Specifically, if S_1 and S_2 are two partitions of the set of 26 cards into subsets, we define the *edit distance* $d(S_1, S_2)$ to be the minimum number of edit operations on S_1 (moving a card from one partition subset to another, possibly creating an empty subset and moving a card into it) that will transform it into the same set of subsets of S_2.

As shown in [1], the value of $d(S_1, S_2)$ can be computed using an algorithm for finding the maximum matching weight sum in a bipartite graph [3]: each subset in the partitions S_1 and S_2 is a node in the graph, and an edge between a subset in partition S_1 and a subset in partition S_2 has weight equal to the number of cards in

the intersection of the two subsets. If w is the maximum matching weight sum in this graph, the edit distance $d(S_1, S_2)$ is equal to $26 - w$.

The edit distance function d satisfies the usual properties of a metric except that two sorts S_1 and S_2 can have a zero edit distance without being the "same" sort from the point of view of the subject (the subject may have used different criteria to carry out the two sorts even though the resulting partitions are identical):

$d(S_1, S_2) >= 0$ for all S_1, S_2
$d(S, S) = 0$ for all S
$d(S_1, S_2) = d(S_2, S_1)$ for all S_1, S_2
$d(S_1, S_2) \leq d(S_1, S_3) + d(S_3, S_2)$ for all S_1, S_2, S_3

Definition. Suppose a card sort subject has produced k sorts represented by the sequence $X = (S_1, S_2, \quad S_k)$. Construct the complete graph where each node is a sort from the list X and where the edit distance metric d gives the weight of the edge between any two nodes (sorts) in the graph. The *minimum spanning tree (MST) measure* $\mu(X)$ of X is the sum of the weights of a minimum spanning tree of this graph.

This MST measure is based on all the sorts for a given subject. If a subject produces sorts that are largely similar, the pairwise edit distances will be relatively small. If one sort produced by the subject is quite distant from all the others, for example, this distance will appear only once in the minimum spanning tree. We regard the MST measure as evaluating the *complexity* of the collection of sorts produced by a subject. If a subject has produced a number of sorts that represent sort criteria having a high degree of "pairwise orthogonality", we would expect that two sorts produced by this subject would exhibit relatively small overlaps and thus a large edit distance. Consequently the MST measure of the sorts produced by the subject would be large. Observe that if a subject identifies two different sort criteria but produces sorts that are identical (the same number of piles and the same cards in the piles, up to permutation), the edit distance between these two sorts will be zero, which will contribute a zero term in the sum of the weights in the minimum spanning tree.

As an alternative to the MST measure, we considered the sum of *all* the pairwise edit distances between the sorts of a given subject. However, adding all the pairwise edit distances can result in a large value even if there is just one sort that is distant from several of the others. For example, consider two graphs representing two possible configurations of edit distances between four sorts, illustrated in Figure 1.

The sum of the edit distances in both of these graphs is 30. However, the MST measure of the left-hand graph is 10 while the MST measure of the right-hand graph is 14. (Minimum spanning trees for these graphs are illustrated with heavy lines for the edges.) We consider the right-hand graph in Figure 1 as having more "complexity" than the left-hand graph, and the MST measure captures this better than summing all the edit distances.

Definition. Another measure of card sort complexity is the number of sorts produced by a subject. Specifically,

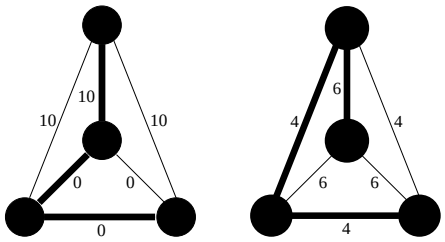

Figure 1: Example graphs

if the sorts produced by a subject are represented by the sequence $X = (S_1, S_2, \quad S_k)$, the *number of sorts (NSORT) measure* is k, and we define $n(X) = k$.

Since each new sort produced by a subject adds one edge to the minimum spanning tree used to compute the MST measure, the MST measure will normally increase as the number of sorts increases. We regard the NSORT measure as significantly less informative than the MST measure in taking into account card sort complexity for a given subject.

Note that if a subject produces just one sort, the underlying graph will have just one node and its spanning tree will have no edges, so the MST measure will be zero.

Definition. As $n(X)$ increases, we have remarked that $\mu(X)$ generally increases as well (see section). We define a measure that "factors out" the number of sorts as a contribution to the complexity of the set of sorts produced by a subject. The *normalized minimum spanning tree (NMST) measure* is

$$\nu(X) = \mu(X)/n(X)$$

.

Example

We illustrate our MST measure with two subjects in the study, both of whom produced three sorts. We will call them A and B (not their real names).

The sorts A_1, A_2, and A_3 produced by subject A have the following partitions:

Sort	Partitions
A_1	1,3,4,5,6,7,13,14,15,22,23
	2,8,9,10,11,12,16,17,18,19,20,21,24,25,26
A_2	1,3,4,6,7,10,13,14,15,18,23,26
	2,5,8,9,11,12,16,17,19,20,21,22,24,25
A_3	1,2,5,8,9,11,12,16,17,18,19,20,21,22,24,25
	3,4,6,7,10,13,14,15,23,26

For subject B, the sorts B_1, B_2, and B_3 are

Sort	Partitions
B_1	9,17,18,25
	1,3,5,8,12,13,20,26
	2,6,7,10,11,15,19,22
	4,14,16,21,23
	24
B_2	12,20
	18,25
	3,13,19
	5,10,15
	1,17
	8,9
	2,4,6,7,11,14,16,21,22,23,24,26
B_3	1,3,5,6,7,9,10,11,12,14,15,16,18,19,20,21,25,26
	2,4,8,13,17,22,23,24

The edit distances between the sorts for each of these subjects are given in the following tables:

Subject A

x	y	$d(x,y)$
A_1	A_2	5
A_1	A_3	5
A_2	A_3	2

Subject B

x	y	$d(x,y)$
B_1	B_2	15
B_1	B_3	18
B_2	B_3	18

The above tables give the pairwise edit distances between sorts for each subject, from which it is easy to determine the MST measures μ:

X	$\mu(X)$
A	7
B	33

Observe that the MST measure of subject B is much larger than that of subject A. Visually comparing the sorts produced by these two subjects, this is not surprising.

Comparison with number of sorts

The two subjects, A and B, were chosen because their MST measures were the smallest and largest among all subjects who produced exactly three sorts. Recalling that $n(X)$ represents the number of sorts produced by subject X, the following table gives the range of values of $\mu(X)$ for all values of $n(X)$ in the study. This table also includes the frequencies of subjects with the given number of sorts.

$n(X)$	**freq.**	**min** $\mu(X)$	**max** $\mu(X)$
1	2	0	0
2	30	3	19
3	63	7	33
4	67	13	46
5	40	20	58
6	33	23	69
7	17	30	66
8	12	32	77
9	5	45	72
10	3	35	72
11	2	64	98
13	1	50	50
14	1	79	79

This table shows that the MST measures $\mu(X)$ generally increase as the NSORT measures $n(X)$ increase and that for a given $n(X)$, there can be large variations among the values of $\mu(X)$.

Comparing Students to Experts

We expect that the greater experience and knowledge base of an expert will show up by experts producing larger NSORT values and that their sorts exhibit greater "orthogonality" (*i.e.*, larger pairwise edit distances) compared to non-experts, resulting in larger MST measures.

We use the nonparametric Wilcoxon two-sample test (also called the Wilcoxon-Mann-Whitney test) [2] to compare observations from two populations, with the null hypothesis being that the observations come from the same distribution. We use a one-sided test when a one-sided alternative hypothesis is supported by the observed data.

We will examine three measures to compare observations for students and experts: NSORT, MST, NMST.

NSORT measure

We first examine the numbers of sorts $n(X)$ produced by students and experts, with 243 student observations and 33 expert observations. The Wilcoxon two-sample test using numbers of sorts yields a z score of 1.33. Since the observed data suggests a one-sided alternative (the observed number of sorts produced experts is generally larger than the number of sorts produced by students), we reject the null hypothesis at the 10% level.

MST measure

We next examine the MST measures $\mu(X)$ produced by students and experts. The Wilcoxon two-sample test using MST measure observations yields a z score of 2.48, and we reject the null hypothesis with a one-sided alternative at the 1% level.

NMST measure

Since the MST measure more strongly distinguishes students from experts compared to the NSORT measure, we conjecture that the NMST measure $\nu(X)$ will factor out the less powerful number of sorts and produce a stronger difference between students and experts. Indeed, using the NMST measure observations yields a z score of 2.61, and we reject the null hypothesis at the 0.5% level.

Summary

The Wilcoxon-Mann-Whitney z scores for the three measures are given in the following table:

Students & Experts

measure	z	reject at
NSORT	1.33	10%
MST	2.48	1%
NMST	2.61	0.5%

Student Performance Levels

The researchers in this study were asked to give each student participant a performance ranking from 1 to 5, where 1 represents an assessment of low performance and 5 an assessment of high performance. Only 217 of the 243 students appear in the study ranking data, so we restricted our observations to this subset.

We used the nonparametric Mann-Kendall test (also called the *S-Test* in [2]) to test for randomness against a monotone trend. The "trend" is represented by an increase in student performance levels. Consider the MST measure, for example. If there is no trend (*i.e.*, a random trend) relating MST measure and performance level, then an MST measure for a lower-performing student would be just as likely to be larger than the MST measure for a higher-performing student as to be smaller. If there is a monotone, positive-going trend, then an MST measure for a lower-performing student would be less likely to be larger than the MST measure for a higher-performing student than to be smaller.

As with our comparison of students and experts, we again examined three measures: NSORT, MST, and NMST.

NSORT measure

Using NSORT measures to test for a monotone trend, the Mann-Kendall test produced a z score of 3.40, and we reject the null hypothesis at the 0.03% level.

MST measure

Using the MST measure μ, the Mann-Kendall test produced a z score of 3.21, and we reject the null hypothesis at the 0.06% level.

NMST Measure

Using the NMST measure ν, the Mann-Kendall test produced a z score of 0.37, which does *not* support rejecting the null hypothesis.

Summary and Analysis

The Mann-Kendall z scores for the three measures are given in the following table:

Monotone Trend

measure	z	reject at
NSORT	3.40	0.03%
MST	3.21	0.06%
NMST	0.37	not significant

These results show that differences among performance levels seem to correlate best with the numbers of sorts produced by the student subjects (as measured by $n(X)$) and not by the complexity of their sorts (as measured by $\nu(X)$). We suggest that better students are characterized as being more likely to take risks by producing a larger number of sorts, but that they do not have the depth of knowledge of an expert that would be necessary for their sorts to be highly orthogonal to one another.

Comparing high performing students to Experts

If high-performing students tend to have a larger number of sorts but with relatively little complexity, we predict that high-performing students will be similar to experts in numbers of sorts but that experts will have sorts that are measurably more complex. The Wilcoxon-Mann-Whitney z scores for the three measures are given in the following table:

High Performers & Experts

measure	z	reject at
NSORT	0.35	not significant
MST	0.66	not significant
NMST	1.83	5%

As predicted, the number of sorts for high performing students and experts are similar, but the NMST measure – which captures best the complexity of the sorts – statistically distinguishes experts from high performing students.

Comparing Females and Males

We conjecture that there are no differences between female (58) and male (184) subjects in our student populations. The Wilcoxon-Mann-Whitney z scores for the three measures are given in the following table:

Females & Males

measure	z	reject at
NSORT	0.34	not significant
MST	0.06	not significant
NMST	0.87	not significant

While the statistical results are not conclusive, the actual observations show that females in the study produced fewer sorts than their male counterparts, but the sorts they did produce were more complex. This is an area of interest for further study.

Since the data available to us did not include gender information on experts, we were unable to compare females and males among the experts.

Random sorts

We can expect a human to put cards into categories based on a sort criterion in a way that is very different from just throwing cards randomly into piles. On average, we would expect much larger edit distances between two random sorts than between two sorts produced by human subjects. In this section, we show that our MST and NMST measures distinguish human subjects from "random" subjects in a statistically significant way.

We first built a table giving the frequency distribution of the number of sorts for our human subjects. The fre-

quency data has already been given in a table in section .

For a given sort, we defined the sort *footprint* as the list of the sizes of each of the piles in the sort, in increasing order. (In mathematical terminology, this list is called a *partition*.) We then built a frequency distribution of all the sort footprints for the human subjects. The following table illustrates the distribution, displaying only part of the entire footprint data:

footprint	freq.
1 1 1 1 1 1 1 1 1 1 1 1 1 1 1 1 1 2 2 2 3	1
1 1 1 1 1 1 1 1 1 5 12	1
1 1 1 1 1 1 1 1 1 5 13	1
1 1 1 1 1 1 1 2 2 2 2 2 4 5	1
1 1 2 2 3 3 3 3 3 5	2
1 1 2 2 3 3 3 3 5 6	1
1 1 2 2 3 3 3 4 4 6	2
8 8 10	10
8 9 9	7
9 17	26

Using these frequency distributions, we generated 100 "subjects". For each generated subject, we randomly generated the number of sorts for the subject using the frequency distribution in section from our sample population. To generate a random sort for this subject, we randomly selected a sort footprint using the frequency distribution given in this section. Once we identified a randomly generated footprint, we randomly assigned cards to piles so that the sizes of the piles matched the selected footprint. In this way, the "subjects" we generated have a distribution of number of sorts similar to that of the human population, and each "subject" has a distribution of sort footprints similar to that of the human population.

Because the sorts for the generated "subjects" are randomly generated, we hypothesize that they will exhibit significant "complexity", in the sense that their pairwise edit distances will be large. Consequently, we expect that the randomly generated "subjects" will produce MST measures (both un-normalized and normalized) that are significantly larger than the human subjects.

After generating one such set of "subjects", we compared them to human subjects using the NSORT, MST, and NMST measures. The following table summarizes the results:

Human Subjects & Random Subjects

measure	z	reject at
NSORT	0.62	not significant
MST	11.07	off the charts
NMST	14.79	off the charts

Observe that the random population of subjects was generated in such a way that their distribution of number of sorts should be similar to the distribution of number of sorts from the human population. Consequently, we expect that the NSORT measures of these two populations should not be significantly different. Our statistics show that this is the case. However, the MST and NMST measures of human subjects are clearly different from those of the random subjects.

Conclusions

We conclude that our MST measure μ appropriately quantifies the combination of number of sorts and the complexity of these sorts for a subject. Subjects with larger MST values exhibit greater numbers of sorts with greater complexity. Since the MST measure, to some extent, includes a measure of the number of sorts of a subject, the NMST measure ν factors out the number of sorts, giving a value that distills the complexity of the sorts.

Comparing experts to students in the NSF workshop population, all the measures (NSORT, MST, and NMST) are significantly larger for experts compared to students. The NSORT measure is the least significant measure, and the NMST measure is the most significant.

Comparing students based on performance level, both the NSORT and MST measures have significant positive-going trends compared to performance level, but the NMST measure is not significant. This suggests that higher-performing students produce more sorts, but that because of their lack of experience (in this study, the student subjects were at the CS2 level), their sorts did not exhibit greater complexity. High-performing students and experts had similar NSORT measures, but the experts had significantly larger NMST measures, which gives further evidence to our observations about higher-performing students in the student population.

Comparing females to males in the student population, the three measures (NSORT, MST, and NMST) showed no significant differences. Examining the data, however, shows that the NSORT values appear to be smaller for females than males, but that the NMST values appear to be larger. This is an area that warrants further study.

We have shown that the MST and NMST measures of card sort complexity are statistically significant in discriminating between experts and non-experts. These measures may have broader applicability to other experiments requiring complexity measures.

Abstract

Hoekstra & Hyams (1998) claim that the overwhelming majority of Dutch children's Root Infinitives (RIs) are used to refer to modal (not realised) events, whereas in English speaking children, the temporal reference of RIs is free. Hoekstra & Hyams attribute this difference to qualitative differences in how temporal reference is carried by the Dutch infinitive and the English bare form. Ingram & Thompson (1996) advocate an input-driven account of this difference and suggest that the modal reading of German (and Dutch) RIs is caused by the fact that infinitive forms are predominantly used in modal contexts. This paper investigates whether an input-driven account can explain the differential reading of RIs in Dutch and English. To this end, corpora of English and Dutch Child Directed Speech were fed through MOSAIC, a computational model that has already been used to simulate the basic Optional Infinitive phenomenon. Infinitive forms in the input were tagged for modal or non-modal reference based on the sentential context in which they appeared. The output of the model was compared to the results of corpus studies and recent experimental data which call into question the strict distinction between Dutch and English advocated by Hoekstra & Hyams.

Root Infinitives in Child Language

A striking feature of the speech of children who are acquiring their native language, is that, in many languages, children go through a stage where they produce *Root Infinitives* (non-finite verb forms in contexts that require a finite verb form). Thus, English-speaking children may produce utterances such as (1), and Dutch children may produce utterances such as (2).

(1) Daddy drink coffee
(2) Papa koffie drinken (Daddy coffee drink-inf)

This phenomenon has been subject to considerable linguistic theorizing, as the fact that it occurs in several languages (including English, Dutch, Swedish, German and French) suggests the operation of invariant principles. A particularly influential Nativist theory has been provided by Wexler (1994). According to Wexler's *Optional Infinitive (OI) Hypothesis*, by the time children begin to produce multi-word speech, they have already correctly set all the basic inflectional and clause structure parameters of their language. They thus have adult-like knowledge of the word order and inflectional properties of the language they are learning. However, there is a stage of development (the Optional Infinitive stage), during which the abstract features of Tense (TNS) and Agreement (AGR) can be absent from the underlying representation of the sentence. This results in children initially using both finite and non-finite verb forms in contexts in which a finite form would be obligatory in the adult language. The great strength of the Optional Infinitive Hypothesis is that it explains the data from a wide variety of languages, as well as the relative sparseness of other errors. However, the theory also has some important weaknesses.

Firstly, the theory assumes a large amount of innate knowledge and ignores the possibility that the Optional Infinitive phenomenon may be understood as the result of an input-driven learning process without the need to assume large amounts of innate knowledge. Simulations with the MOSAIC model have already shown that a simple learning mechanism which is sensitive to the distributional characteristics of the input can give a close quantitative fit to the prevalence of the Root Infinitives in English and Dutch over a range of MLUs (Freudenthal, Pine & Gobet (2002a, 2003, in preparation).

Secondly, while the Optional Infinitive phenomenon occurs in several languages, cross-linguistic differences exist in the finer detail of the phenomenon that are problematic for Wexler's theory. One obvious way of explaining these differences is in terms of differences in the distributional characteristics of the language being learned. In this paper we assess the viability of such an explanation by simulating cross-linguistic differences in the fine detail of the OI-phenomenon in Dutch and English using MOSAIC. The central aim of this paper is therefore to investigate whether the same mechanism that captures one of the key similarities in the speech of children learning different languages can also capture differences in the way

that this phenomenon patterns as a function of differences in the languages being learned, and hence can provide a unified account of patterns of cross-linguistic similarity and difference in children's early multi-word speech.

The Modal Reference of Root Infinitives

The majority of Root Infinitives that Dutch children produce carry a modal meaning: they tend to express desires and wishes, or relate to unrealized events. Hoekstra & Hyams (1998) have dubbed this the *Modal Reference Effect*. The type of verbs that occur as Root Infinitives also differs from inflected verbs. Dutch speaking children appear to use Root Infinitives when referring to actions rather than static situations. This has been called the *Eventivity Constraint*. Wijnen (1996), analysed the speech of four Dutch children, and found that 95% of the children's Root Infinitives contained eventive verbs, and 85% of the Root Infinitives had a modal reference, thus confirming the Modal Reference Effect and Eventivity Constraint. According to Hoekstra & Hyams, the Modal Reference Effect and Eventivity Constraint do not hold for English. They present data based on an (unpublished) paper by Ud Deen (1997), who found that only 13% of English Root Infinitives carry a modal meaning. Ud Deen also found that, while the majority of English Root Infinitives are eventive in nature, this effect is less pronounced than it is in Dutch, with 75% of English RIs containing eventive verbs. Hoekstra & Hyams explain this cross-linguistic difference by referring to differences between the English and Dutch infinitive form. The English infinitive, they claim, is not a true infinitive, but a 'bare form'. Dutch has a true infinitive as it has an infinitival morpheme. This infinitival morpheme is thought to carry an *irrealis* feature which is responsible for the modal reference. This, they argue, is evident from the analysis of the following utterances:

3. I see John cross the street*
4. I saw John cross the street
5. I see John crossing the street

Utterance (3) is ungrammatical in English, because the English bare form denotes 'not only the processual part of the event, but includes the completion of that event' (Hoekstra & Hyams 1998, p. 105). A correct description of an ongoing event in English would therefore require the use of the past tense as in (4), or the progressive as in (5). Sentence 6 makes it clear that this constraint does not operate in Dutch: an ongoing event may be described using a present tense construction. Apparently, the Dutch infinitive does not signal completion of the event.

6. Ik zie/zag Jan de straat oversteken
   I see/saw John the street cross-INF
   I see/saw John cross the street.

This difference between the English and Dutch infinitival form also explains the difference with respect to the eventivity of Root Infinitives, as, according to Hoekstra & Hyams it is the modal reading of Dutch Root Infinitives that forces the selection of an eventive verb. Since English Root Infinitives are not exclusively modal, they can occur with stative as well as eventive verbs.

Problems with Hoekstra & Hyams' Account

While the Hoekstra & Hyams' account explains the differential reading of Dutch and English Root Infinitives, it predicts that the proportion of modal readings of RIs in Dutch and English is radically different. Theoretically, all RIs in languages with an infinitival morpheme should be modal, while the reference of English RIs is free. The proportion of modal RIs in Dutch and German appears to be considerably lower than 1.00 however. Wijnen (1996) reports a proportion of .85 averaged over 4 children, and Ingram & Thompson (1996) report a proportion of .55 using a strict criterion and .79 using a lenient criterion.

Ingram & Thompson also suggest that the modal reading of RIs in German (and Dutch), is caused by the fact that infinitive forms in adult German and Dutch are typically used in conjunction with a modal, as in (7) and (8). Since Dutch-speaking children predominantly hear infinitive forms in modal contexts in the input, they come to associate these forms with the modal reading and use them predominantly to express desires.

7. Ik ga morgen werken (I go-FIN Tomorrow work-INF)
8. Wil je spelen? (Want-FIN you play-INF)

The proportion of modal Root Infinitives in English may also be considerably higher than the .13 that was found in a corpus study by Ud Deen. An inherent weakness of corpus studies is that the modal/nonmodal reading of an utterance is assigned on the basis of the context in which it is produced. However, since the corpora are transcripts of spontaneous speech, the information required to discriminate between modal and non-modal readings is often lacking. For this reason, Blom, Krikhaar & Wijnen (2001) conducted an experiment in which children produced descriptions of modal and non-modal events. In the experiment, the majority of Dutch children's Root Infinitives (68%) were used to describe modal events. For the English children this was 44%. While this difference was significant and in the expected direction, this finding is problematic for Hoekstra & Hyams, as it suggests that the difference between Dutch and English is not a qualitative difference, but a graded, quantitative one which may well be related to the distributional characteristics of the language rather than differences in infinitival morphology.

In this paper, MOSAIC will be used to investigate the source of the differential reading of Dutch and English Root Infinitives. MOSAIC has a number of characteristics that make it a suitable candidate for such an investigation.

Firstly, the model has already been shown to successfully simulate the developmental change in the prevalence of Root Infinitives in Dutch and English (Freudenthal, Pine & Gobet 2002a, 2003, in preparation), as well as phenomena related to Subject Omission in English (Freudenthal, Pine & Gobet 2002b). The model's success in simulating the finer detail of the OI phenomenon therefore provides a strong test

of an input-driven account of the OI phenomenon. Secondly, the model learns off Child Directed Speech. The use of Child Directed Speech ensures a realistic frequency distribution, so that differences in the surface characteristics of a language are reflected in the input in a quantitatively realistic way. This is of particular importance as the practice of using artificially created input sets (which is common in simulations of phenomena in child speech) may lead the researcher to misrepresent the distributional characteristics responsible for the phenomenon under investigation.

Thirdly, MOSAIC uses no built-in linguistic knowledge. Whatever representations it builds up during learning are a result of the interaction between its learning mechanism and the distribution of the input it sees. This last characteristic is important because Hoekstra & Hyams' explanation of the differential reading of RIs is dependent on the assumption that the child knows that the infinitival morpheme implies a modal interpretation (rather than learning the association through exposure to the input). MOSAIC will be described below, followed by the details of the simulation.

Simulating Language Acquisition in MOSAIC

Whilst the version used for the simulations discussed here has changed from the earlier simulations, the main theoretical underpinning of the model remains the same. The basic tenet of the model is that the learning of language is a performance-limited process which is heavily weighted towards the most recent elements in the speech stream (i.e., which has an utterance final bias). Several authors have argued that children are better at learning material that occurs towards the end of the utterance (Naigles & Hoff-Ginsberg, 1998; Shady & Gerken, 1999; Wijnen et al. 2001).

MOSAIC learns from orthographically coded input, with whole words being the unit of analysis. The model is a simple discrimination net (an n-ary tree) which is headed by a root node. At the start of learning the discrimination net consists of just the root node. More nodes (encoding words or phrases) are added as the model is shown more utterances. An important requirement for nodes to be added is that whatever follows the word to be encoded in the input, must already have been encoded in the model. That is, the model will only learn a new word, when it has already encoded the rest of the utterance. This results in the model building up its representation of the utterances it is shown by starting at the end of the utterance, and slowly working its way to the beginning.

If the model were to see the utterance *I go home* three times, it would on its first pass encode the fact it has seen the word *home* at the end of an utterance. On the second pass, it would encode the sequence *go home*. After a third pass, it would have encoded the whole utterance. Figure one gives a graphical representation of the model at this stage.

The fact that MOSAIC builds its representation of an utterance by starting at the end of the utterance is the major mechanism responsible for its simulation of the development of Root Infinitives in Dutch. Early in Dutch children's development, 80-90% percent of their utterances containing verbs are Root Infinitives. This drops to 10-20% later in development (Wijnen et al, 2001). Early in training, the model encodes many utterance final phrases. Since the infinitive takes sentence-final position (as can be seen in examples 7 and 8), the model produces many utterances with only non-finite verb forms. As the model encodes longer and longer phrases, these Root Infinitives are slowly replaced by auxiliary/modal plus infinitive constructions.

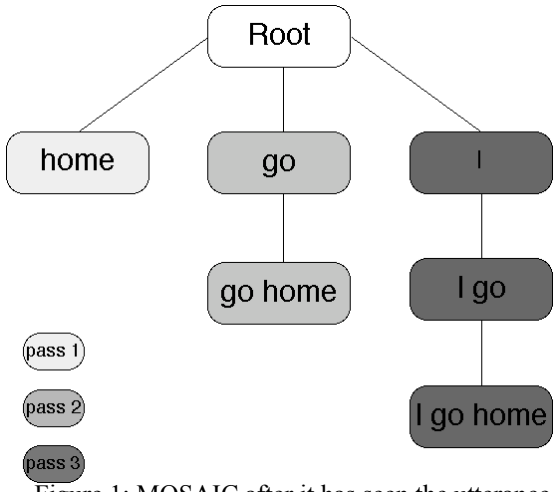

Figure 1: MOSAIC after it has seen the utterance *I go home* three times.

In the example illustrated in Figure 1, a (sentence final) word is encoded after one exposure. In fact, MOSAIC actually learns much more slowly than this, and the input corpus is fed through the model several times, so output of increasing average length can be generated after consecutive exposures to the input corpus. The probability of creating a node in MOSAIC is given by the following formula:

$$NCP = \left(\frac{1}{1 + e^{m - u/c}} \right)^{\sqrt{d}}$$

where: NCP = Node Creation Probability

m = a constant, set to 20 for these simulations.
c = corpus size.
u = total number of utterances seen.
d = distance to the end of the utterance.

The formula results in a basic sigmoid curve. The formula contains the size of the corpus and total number of utterances seen. The size of the corpus is included because the size of the available input corpora differs considerably (13,000 to 30,000 utterances for the corpora used in these simulations). The use of the term (m – u/c) ensures that after n presentations of the complete input corpus the Node Creation Probability is identical for corpora of different sizes. The 'distance to the end of the utterance' in the exponent causes material that occurs near the beginning of the utterance to have a lower likelihood of being encoded than material that occurs near the end. This effect decreases as the model sees more input.

Production of Novel Utterances

Utterance production in MOSAIC involves outputting all the utterances the model has encoded. However, the output that MOSAIC produces consists of more than the input it has seen. MOSAIC has a mechanism for linking words or phrases that have occurred in similar contexts. When the overlap between two words is sufficiently high (more than 10% of both the words that preceded and followed the target words are the same), the two words get linked. Two words that are linked can be substituted for each other when the model produces output. This mechanism allows MOSAIC to produce utterances that were not present in the input. Redington, Chater & Finch (1998), and Mintz (2003), have shown that similar mechanisms based on co-occurrence statistics can be quite effective in grouping words that are of the same syntactic category.

The model also includes a chunking mechanism, which results in frequent multi-word phrases being treated as one unit. Since the chunking mechanism does not play an important role in these simulations, it is not discussed any further in this paper.

The Simulations

In order to distinguish modal from non-modal Root Infinitives in the output of the model, infinitive verb forms in the input were tagged to reflect the context in which they occurred. In order to do this, all utterances in the input were (automatically) searched for words denoting a modal or not-realised context. These words constituted the standard modals, as well as some other words denoting a not-realised context, including *want* and *go*. The utterances containing a word denoting a modal context were then searched for words that matched an infinitive form. If such a word was found, it was tagged for having occurred in a modal context (by adding –MOD to the verb).

For both languages, two input corpora (available through the CHILDES data base (MacWhinney 2000)) were selected. For Dutch, these were the corpora of Matthijs (Simulation1) and Peter (Simulation2). For English the corpora of Anne (Simulation1) and Becky (Simulation2) were selected. The size of the corpora was approximately 13,000 utterances for Dutch, and 30,000 utterances for the English input. Since the input corpora consist of Child Directed Speech, the distributional characteristics are representative of the language that children hear. Each input corpus was fed through the model iteratively until the output reached a Mean Length of Utterance (MLU) of approximately 2.5. At this stage, all the utterances the model could produce were generated. The full output consisted of approximately 7,500 utterances for the Dutch corpora, and 15,000 for the English corpora. Next, all utterances in which all verbs matched the infinitive form were selected. The proportion of these utterances that had the infinitive form tagged for a modal context (i.e. had been learnt off a modal context) was then calculated. Table 1 gives the results for the English and Dutch simulations. For both Dutch simulations the proportion of modal infinitives is larger than it is for English. For all four possible comparisons of Dutch against English simulations, the difference was statistically significant ($\chi 2(1) > 12.00$ $p < .001$).

Table 1: Proportion of modal infinitives and total number of infinitives for Dutch and English simulations.

	Dutch	English
Simulation1	.70 (1447)	.47 (1577)
Simulation2	.54 (1474)	.48 (2581)

While these values are very close to those reported by Blom et al., this analysis ignores the complication that (especially in English) it is difficult to unambiguously identify the infinitive. In the English present tense, only the third singular differs from the infinitive. A true Root Infinitive can therefore only be identified in a third singular context (since many of the forms resembling the infinitive may actually be correctly inflected finites).

A second analysis was therefore performed on the subset of utterances that had a third singular subject (e.g. *He go/Hij gaan*). While the Dutch data could be restricted to all singulars rather than just third singular, it was considered preferable to use the same restriction for both languages. The results of these analyses are shown in Table 2.

Table 2: Proportion of modal infinitives and total number of infinitives for Dutch and English simulations, third singular context only.

	Dutch	English
Simulation1	.66 (104)	.43 (89)
Simulation2	.58 (102)	.42 (118)

Again, the proportion of modal RIs is larger in the Dutch simulations than it is in the English simulations (For all four possible comparisons, $\chi 2(1) > 4.30$, $p < .05$). Thus, MOSAIC clearly captures the difference between the two languages, suggesting that the differential reading of Root Infinitives in English and Dutch is related to the surface characteristics of the languages.

Having established that MOSAIC simulates the differential reading of RIs, we can now assess whether MOSAIC simulates the difference in verb types that occur in Root Infinitives. Hoekstra & Hyams cite a paper by Wijnen (1996) who found that 95% of Dutch Root Infinitives contained eventive verbs. In English, Ud Deen (1997), found that only 75% of Root Infinitives contained eventive verbs. While a direct comparison between these numbers is difficult as Wijnen and Ud Deen used a different set of verbs, stative verbs do appear to be used more often in English than in Dutch Root Infinitives. In order to perform a more controlled analysis, all Root Infinitives in Table 2 were coded for whether the main verb denoted an event or not. As can be seen in Table 3, MOSAIC does simulate the effect, though only three out of four differences are

statistically significant ($\chi2(1) > 6.20$, $p < .02$). The value of .92 for Dutch (simulation2) was not significantly different from .87 (English, simulation2). Inspection of the non-eventive verbs in simulation2 for Dutch revealed that 5 out of the 8 instances consisted of the verb *zien* (see), which was linked to the verb *kijken* (look), and was thus substituted in production. It thus appears that the generativity mechanism may have inflated the proportion of non-eventive Root Infinitives for this simulation.

Table 3: Proportion of Root Infinitives (third singular context only) that have an eventive main verb.

	Dutch	English
Simulation1	.98	.80
Simulation2	.92	.87

What causes the Modal Reference Effect?

The fact that MOSAIC simulates the difference between Dutch and English for both the modal reading of Root Infinitives and the eventivity of the main verb, suggests that these effects are related to differences in the surface characteristics of the two languages. In order to understand what these relevant surface characteristics might be, it is useful to examine more closely in what contexts third singular subjects are followed by a form resembling the infinitive. In both Dutch and English, the majority of the contexts are likely to be questions. English and Dutch differ however, in the way questions are formed. Whereas Dutch uses inversion to transform a declarative into a question, in English, the auxiliary *do* is inserted, resulting in phrases such as *Does he go*. While the auxiliary *do* patterns like a modal, it does not carry a modal or not-realised meaning. In English, a third singular subject followed by an infinitive form can therefore occur in both a non-modal (*Does he go*), and a modal context (*Can he go*). In Dutch, a third singular followed by an infinitive form can occur in double verb constructions such as *Kan hij fietsen* (Can he cycle-inf), or *Ik zie Jan lopen* (I see John walk-inf). The first of these is modal, but the second is not. Root Infinitives in the input are a further source of third singular plus infinitive contexts. In some situations (for example elliptical answers to questions) Root Infinitives are allowed in Dutch. In the two languages, the third singular is thus followed by the infinitive in different contexts. If a child learns Root Infinitives off the input, it is likely to produce them in the context in which they are most frequently encountered. One way of directly testing such an input-driven account of Root Infinitives is to search the input for occasions where a third singular is followed by an infinitive form, and noting whether the context is modal or not. Table 4 presents the results of such an analysis (using the most frequent third singular subjects that were present in the Root Infinitives of the model's output). Table 4 shows that in Dutch third singular plus infinitive constructions occur in a modal context more often than they do in English (again all four differences are statistically significant $\chi2(1) > 6.2$, $p < .02$).

Table 4: Proportion of modal contexts for third singulars followed by infinitive in English and Dutch input corpora.

	Dutch	English
Input1	.77 (113)	.37 (212)
Input2	.56 (140)	.41 (153)

Also of interest now is the question of what the non-modal contexts are in which these constructions occur. In English a large majority (90%) of these non-modal contexts do turn out to be 'do-questions'. Thus, while third-singular plus infinitive constructions can occur in modal as well as non-modal contexts, the dummy modal *do* alone makes up close to 40% of these contexts. In the Dutch input, non-modal contexts are limited in number, and largely confined to Root Infinitives (though a few double verb constructions do occur). The majority of non-modal Root Infinitives therefore appear to be learned off double-verb constructions in English and off Root Infinitives in Dutch.

Turning to the eventive-stative distinction it now also becomes apparent why Root Infinitives are more likely to contain statives in English. In English, stative verbs such as *want* or *need* frequently occur in utterances like *Does he want it*. In Dutch such an utterance does not carry the inflection on the dummy modal, but on the inverted main verb (*Wil hij dat; Wants he that*). As a result, statives in Dutch only occur as infinitives in very infrequent double verb constructions such as *Dat zou hij willen (That would he want*) The higher proportion of statives in English Root Infinitives can therefore also be explained in terms of the use of the dummy modal *do* in the input.

Conclusions

While Wexler's Optional Infinitive Hypothesis can explain the cross-linguistic occurrence of Root Infinitives, additional assumptions are required the explain the cross-linguistic differences in the fine detail of the phenomenon. Hoekstra & Hyams (1998), explain some of this fine detail (the differential temporal reference of Dutch and English children's Root Infinitives) by referring to qualitative differences between the languages. Specifically, they argue that the English infinitive is a bare form rather than a true infinitive. They argue that the English bare form does not carry the *irrealis* feature, which signals the modal reading of the infinitive. They therefore postulate qualitative differences in the fine detail of infinitival morphology between the two languages. Since children are thought to know the full grammar, English-speaking children will use Root Infinitives both in modal and non-modal contexts, and Dutch children should use Root Infinitives overwhelmingly in modal contexts. Experimental work by Blom et al. has shown however, that the difference is not as large as predicted by Hoekstra & Hyams, suggesting that it is a graded quantitative, rather than a qualitative difference.

In this paper MOSAIC was used to investigate whether the difference between Dutch and English could be related

to the surface characteristics of the two languages. The fact that MOSAIC has already been used to simulate the developmental patterning in the prevalence of Root Infinitives (relative to simple and compound finites) in English and Dutch lends credence to the basic mechanism for producing Root Infinitives that MOSAIC employs. While MOSAIC is clearly insufficient as a full model of the language acquisition process, it is a valuable tool for exploring how an utterance final learning bias can interact with the distributional properties of the input to produce the phenomena apparent in children.

MOSAIC clearly simulates the difference between English and Dutch in terms of the modal reading as well as the eventive/stative nature of the verbs in Root Infinitives. The fact that both phenomena can be explained by the use of the dummy modal 'do' (which patterns like a modal without ascribing modal meaning) shows that subtle differences in the distributional characteristics of languages can have quite profound effects on the patterning of child data. As these effects can be quite difficult to predict a priori, computational modelling can be an invaluable tool for investigating the complex relations between input characteristics and child speech.

The analyses reported here also underscore the importance of using realistic input when simulating child speech, as some effects are only likely to be simulated when realistic input is used. While dummy *do* is only one of many modals in English, it accounts for 40% of the third singular + infinitive contexts. However, *do* is also responsible for the occurrence of eventive RIs. Since these occur at a maximum rate of 20% in these simulations, an underestimation of the incidence of *do* in artificial input would likely result in failure of the model to simulate the effect. This is even more apparent when one realises that third singular plus infinitive contexts are largely restricted to questions; it seems unlikely that without prior knowledge of the importance of questions a researcher constructing artificial input would include 'do-questions' at a sufficient rate to simulate these effects.

The fact that the interaction between the learning mechanism and the distributional characteristics of the input can produce the different levels of modal Root Infinitives in the two languages strongly suggests that the observed phenomenon is related to surface characteristics (the contexts in which infinitives occur), rather than to differences in the infinitival morphology between the languages. Since MOSAIC does not have any knowledge of infinitival morphology (in fact does not employ any built in linguistic knowledge), these results clearly show that the Modal Reference Effect can be explained without assuming that children know the full grammar of their language, or the fine detail of infinitival morphology.

Extending the Computational Abilities of the Procedural Learning Mechanism in ACT-R

Wai-Tat Fu (wfu@cmu.edu)
John R. Anderson (ja+@cmu.edu)
Department of Psychology, Carnegie Mellon University
Pittsburgh, PA 15213, USA

Abstract

The existing procedural learning mechanism in ACT-R (Anderson & Lebiere, 1998) has been successful in explaining a wide range of adaptive choice behavior. However, the existing mechanism is inherently limited to learning from binary feedback (i.e. whether a reward is received or not). It is thus difficult to capture choice behavior that is sensitive to both the probabilities of receiving a reward and the reward magnitudes. By modifying the temporal difference learning algorithm (Sutton & Barto, 1998), a new procedural learning mechanism is implemented that generalizes and extends the computational abilities of the current mechanism. Models using the new mechanism were fit to three sets of human data collected from experiments of probability learning and decision making tasks. The new procedural learning mechanism fit the data at least as well as the existing mechanism, and is able to fit data that are problematic for the existing mechanism. This paper also shows how the principle of reinforcement learning can be implemented in a production system like ACT-R.

Introduction

Human choice behavior is often studied under various probability learning situations. In a typical probability learning situation, participants are asked to select one of the many options available, and feedback on whether the choice is correct or not is given after the selection. There are usually two main manipulations in a probability learning task: (1) the probabilities for each of the options being correct, and (2) the magnitudes of reward (usually monetary) received when the correct option is selected. One robust result is that people tend to choose the options a proportion of time equal to their probabilities of being correct – a phenomenon often called "probability matching" (e.g. Friedman et al., 1964). However, when the reward magnitudes are varied, the observed choice probabilities are sometimes larger or smaller than the outcome probabilities (e.g. Myers, Fort, Katz, & Suydam, 1963). These studies show consistently that people are sensitive to both outcome probabilities and reward magnitudes in making choices.

One limitation of the current ACT-R procedural learning mechanism (Lovett, 1998) is that it requires a pre-specification of correct and incorrect responses. Besides, feedback received is limited to a binary function (i.e. whether a reward is received or not). Apparently, a simple binary function may not be sufficient to represent the feedback from the environment. For example, imagine a situation in which there are several possible treatments for a particular disease and a physician has to choose a treatment that has the highest expected effectiveness. One may have to evaluate the effectiveness of each treatment through case-by-case feedback. For example, consider the case where the probabilities of effectiveness of three treatments 1, 2, and 3 are as shown in Figure 1. Since the effectiveness of each treatment follows a continuous distribution, a simple binary feedback function is obviously insufficient to represent the information received from the feedback.

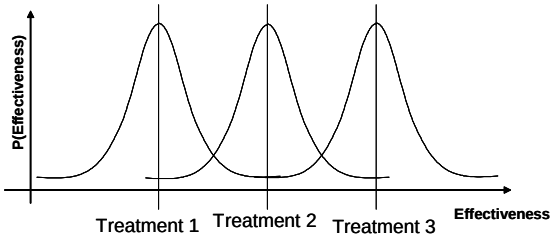

Figure 1. Probability of effectiveness of three treatments.

Another motivation for extending the current mechanism comes from recent findings of the functional role of dopaminergic signals in basal ganglia during procedural learning. Research shows that learning is driven by the deviation between the expected and actual reward (Schultz et al., 1995; Schultz, Dayan, & Montague, 1997). In other words, the reward magnitude is often processed as a scalar quantity – depending on whether the magnitude of the actual reward is higher or lower than expected, a positive or negative reinforcement signal is generated respectively. The pre-specification of correct and incorrect responses is therefore inconsistent with the current understanding of the procedural learning mechanism in basal ganglia.

The ACT-R 5.0 architecture

Figure 2 shows the basic architecture of the ACT-R 5.0 system. The core of the system is a set of production rules that represents procedural memory. Production rules coordinate actions in each of the separate modules. The modules communicate to each other through its buffer, which holds information necessary for the interaction between the system and the external world. Anderson, Qin, Sohn, Stenger, and Carter (2003) showed that the activity in these buffers match well to the activities in certain cortical areas (see Figure 2). The basal ganglia are hypothesized to implement production rules in ACT-R, which match and act on patterns of activity in the buffers. This is consistent with a typical ACT-R cycle in which production rules are matched to the pattern of activity in the buffers, a production is selected and fired, and the contents in the buffers updated. In ACT-R, when there is more than one production matching the pattern of buffer activity, the system selects a production based on a conflict resolution mechanism. The basis of the conflict resolution mechanism is the computation of expected utility, which captures the

effectiveness and efficiency of the production in accomplishing the goals of the system.

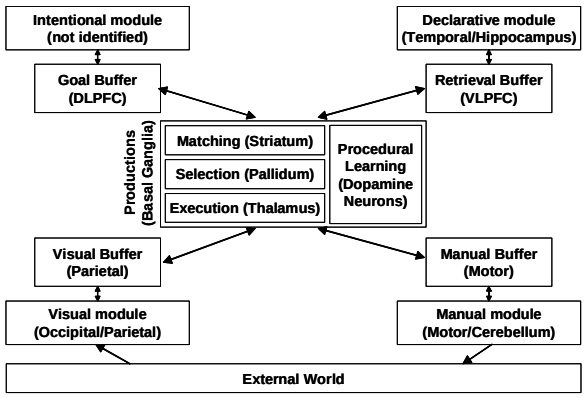

Figure 2. The ACT-R 5.0 architecture.

To adapt to the environment, the system must learn from the consequences of its actions so that when the same conditions are met in the future, a better choice of productions can be made. Procedural learning updates the expected utility of a production from the consequences of firing the production, and the dopamine systems in basal ganglia are believed to be involved in the learning process. Specifically, procedural learning appears to be coded by dopaminergic signals from the ventral tegmental area (VTA) and substatntia nigra to the striatum in basal ganglia (Schultz, et al., 1995; Schultz, et al., 1997), and different patterns are either reinforced or penalized according to the dopaminergic signals. Previous studies (Ljungberg, Apicella, & Schultz, 1992; Mirenowicz, Schultz, 1994) show that the activation of dopamine neurons depends entirely on the difference between the predicted and actual rewards. Once an unpredicted reward is perceived, response in dopamine neurons is transferred to the earlier reward-predicting stimulus. Inversely, when a predicted reward fails to occur, dopamine neurons are depressed in their activity at exactly the time when the reward would have occurred (Schultz, Apicella, Ljungberg, 1993). It therefore appears that dopamine signals do not simply report the occurrence of rewards. Rather, outputs from dopamine neurons appear to code for a deviation or error between the actual reward received and predictions or expectations of the reward. In other words, dopamine neurons seem to be feature detectors of the "goodness" of environmental events relative to the learned expectations about those events.

The current procedural learning mechanism

During each cycle of ACT-R, productions that match the contents of the buffer will be put into a conflict set. The productions in the conflict set are ordered in terms of their expected utility and ACT-R considers them according to that ordering. The expected utility of a production is defined as E = PG-C, where P is the estimated probability that the goal will be achieved if that production is chosen, G is the value of the goal, and C is the estimated cost of achieving the goal if that production is chosen (see Table 1). Procedural learning updates the value of P and C according to the following equations:

$$P = \frac{successes}{successes + failures} \qquad C = \frac{efforts}{successes + failures},$$ where

successes and *failures* are the number of times the production has succeeded or failed to accomplish the current goal respectively (i.e. a reward or penalty), and *efforts* is the total amount of time taken over all past uses of the production rule, successful or failed. These quantities start out with initial values that are updated with experience. For example, if for production n the initial *successes* equals 1, *failures* equals 1, and *efforts* equals 0.5, when a pre-specified *success* is encountered 0.1 second after k has fired, P will change from 0.5 to 0.67 (=2/(2+1)), C will change from 0.25 to 0.2 (=(0.5+0.1)/(2+1)). If G equals 20, then the expected utility (E=PG-C) will increase from 9.75 (=0.5*20-0.25) to 13.13 (=0.67*20-0.2). The successful experience has thus acted as a reward and reinforced production n by increasing its expected utility, and as a consequence, n will be more likely to be selected in the future..

Table 1. A list of free parameters and their definitions.

Parameters	Definition (Old mechanism)
G	Value of the goal (measured in seconds)
successes/ failures	Initial number of times the production has led to a success/failure state before the model starts
efforts	Total amount of time taken over all past uses of the production, successful or failed.
Parameters	**Definition (New mechanism)**
r_n	The actual reward received
K	The discount factor ($0 < K \leq 1$). Future rewards are discounted by 1/(1+KD), where D is the time between the firing of the current and the next production.
a	The learning rate.
D_{n+1}	The time between the consecutive firing of production n and n+1

Although the existing mechanism was able to match to human choice behavior, there are aspects in which the mechanism can be improved. First, in the existing mechanism, learning of P requires pre-specification of successful or failure states and the expected utility will increase or decrease respectively when the state is reached. The use of success and failure states may not be sufficient in situations where a continuous feedback function is required. From a practical perspective, pre-specification of success and failure states could be difficult especially in complex tasks, in which some states are often considered "more successful" than others. One way to improve the current mechanism is to learn from a scalar reward value. Being able to assign a scalar reward value to a production therefore allows more flexible pre-specification of the reward structure of the environment and allows the model to adapt to the environment accordingly. Second, the existing

procedural learning mechanism will change the expected utilities of productions only when the actual outcome is experienced, which requires keeping track of the whole sequence of previous productions that leads to the outcome. This could be computationally expensive especially when the number of productions is large. It is therefore desirable to have a mechanism that learns from local information before the outcomes are known.

The new procedural learning mechanism

In the artificial intelligence community, algorithms have been developed to allow agents to learn in different environments (Sutton & Barto, 1998). One established algorithm is the Temporal Difference (TD) algorithm, which was originally inspired by behavioral data on how animals learn prediction (Sutton & Barto, 1981). Research showed that the TD algorithm is well suited to explain the functional role of dopaminergic signals (e.g. Houk, et al., 1995; Holroyd & Coles, 2002, O'Reilly, 2003). The TD algorithm is designed to learn to estimate future rewards based on experience, and has a built-in credit assignment mechanism that reinforces the predicting stimuli.

In its simplest form, the new mechanism can be represented as $U'(n) = U(n) + aTD(n)$, where $U'(n)$ is the updated value of the expected utility $U(n)$ of production n after an ACT-R cycle, a is the learning rate, and $TD(n)$ is the temporal difference error. $TD(n)$ calculates the difference between the actual and expected rewards, i.e. $TD(n) = R(n) - U(n)$. The basic learning mechanism is therefore similar to the learning rule of Rescola and Wagner (1972) (e.g. see Sutton & Barto, 1981). The measure of future rewards has to take into account long-term as well as short-term consequences. It is plausible to weigh immediate primary reinforcement more strongly than delayed primary reinforcement. We chose to use the hyperbolic function to discount delayed reinforcement (the justification of using the hyperbolic function is beyond the scope of this paper, but see Lowenstein & Prelec, 1991; Mazur, 2001). A good estimate of the total future rewards is therefore $R(n) \approx r_n + U(n+1)/(1+KD_{n+1})$, where r_n is the immediate reward received for production n, $U(n+1)$ is the expected utility of the production that fires after production n, K is the discount parameter, and D_{n+1} is the time lag between the times when production n and production n+1 fire. To implement the mechanism in ACT-R, the basic algorithm has to be modified to take both the reward and cost into account and translate them into a single dimension[1] – i.e. the reinforcement will be the difference between the reward and cost (i.e. the net reward). In other words, the estimate becomes $R(n) \approx r_n - C_n + U(n+1)/(1+KD_{n+1})$, where C_n is the cost of firing production n. Putting the estimate of R(n) back to the equation for $U'(n)$, we have:

$$U'(n) = U(n) + a[r_n - C_n + U(n+1)/(1+KD_{n+1}) - U(n)]$$

One can see that when the estimate is perfectly accurate, $TD(n) = 0$, or $U(n) = r_n - C_n + U(n+1)/(1+KD_{n+1})$ and learning will stop. The value of TD(n) can therefore be considered the prediction error (as encoded by dopaminergic signals), and the mechanism learns by reducing this prediction error. It can easily be seen that once a primary reward is received, the expected utility of the productions that lead to the reward will be credited with a discounted reward, and discounting is heavier the farther away the production is from the reward.

The new mechanism updates the expected utility based on the difference between the predicted and actual net reward. There are two main differences between the new and existing mechanisms. In the new mechanism, the reward is a scalar quantity, and the amount of change is determined by the difference between the predicted and actual reward, which is consistent with the functional role of dopaminergic signals. This characteristic allows the new mechanism to extend its learning capabilities beyond a binary function as in the existing mechanism. Second, in the existing mechanism, learning requires keeping track of a long sequence of productions that lead to the reward. However, in the new mechanism, only the expected utility of the next production is required. The reinforcement signal will eventually propagate back to the productions that lead to the reward.

Testing the new mechanism

The goal of this paper is to show the limitations of the existing mechanism and how the new mechanism is able to extend the learning capabilities of ACT-R. However, owing to space limitation, we are unable to show all properties of mechanism. For example, none of the data sets in this paper was sensitive to the discount parameter K, so we fixed it at 1.0 and just varied the value of r_n to fit the data[2]. The learning rate a was also fixed at 0.1. We first used the new mechanism to fit two data sets from the probability learning tasks by Friedman et al. (1964) and Myers et al. (1963). Since these two sets of data were also modeled well by the existing mechanism (Lovett, 1998), we were able to compare the results of the two mechanisms and show that the use of TD error to drive the learning process is at least as effective as the existing mechanism. Finally, we used the new mechanism to fit the data from a decision making task studied by Busemeyer and Myung (1992), which we believe were problematic for the existing mechanism.

Probability matching behavior

In Friedman et al., participants completed more than 1,000 choice trials over the course of three days. For each trial, a signal light was illuminated, participants pressed one of the two buttons, and then one of the two outcome lights was

[1] ACT-R takes the agnostic economist's position of simply assuming these map onto some internal values without deeply inquiring why.

[2] Since the delay D is a constant for all data sets, it can be shown that the parameter K is absorbed into the value or r_n.

illuminated. Task instructions encouraged participants to try to guess the correct outcome for each trial. The study extended the standard probability learning paradigm by changing the two buttons' success probabilities across 48-trial blocks during the experiment. Specifically, for the odd-numbered blocks 1-17, the probabilities of success of the buttons (p and 1-p) were 0.5. For the even-numbered blocks 2-16, p took on the values from 0.1, to 0.9 in a random order. We focus on the analysis of the even-numbered blocks, as they show how people adapted to the outcomes with experience.

Table 2. Observed and predicted choice proportions from the experiment by Friedman et al. (1964). Predicted scores are in parentheses. Each block has 12 trials.

	Probabilities			
P	Block 1	Block 2	Block 3	Block 4
0.1	0.34 (0.37)	0.23 (0.24)	0.18 (0.17)	0.15 (0.13)
0.2	0.37 (0.41)	0.26 (0.26)	0.29 (0.23)	0.31 (0.23)
0.3	0.49 (0.49)	0.41 (0.41)	0.44 (0.34)	0.35 (0.33)
0.4	0.46 (0.53)	0.44 (0.50)	0.38 (0.43)	0.38 (0.38)
0.6	0.56 (0.59)	0.51 (0.59)	0.52 (0.55)	0.52 (0.57)
0.7	0.50 (0.56)	0.53 (0.64)	0.58 (0.72)	0.62 (0.75)
0.8	0.50 (0.51)	0.76 (0.71)	0.74 (0.77)	0.73 (0.78)
0.9	0.66 (0.62)	0.78 (0.79)	0.78 (0.81)	0.79 (0.81)

Table 2 shows the observed and predicted proportion of choices in the experiment by Friedman et al. Participants in general exhibited probability matching behavior. Across the four 12-trial subblock, participants chose the correct buttons in roughly 50% of the trials in the first block and approached the corresponding p values in each block. The predicted proportions were generated by the model, which had two critical productions, *Choose-Right-Button* and *Choose-Left-Button*, and the expected utilities of these productions were learned according to the new mechanism. The exact sequence of outcomes as reported in Friedman et al. was presented to the model. A reward of 3 is obtained when the correct button was chosen (i.e. r_n=3). The initial expected utilities of the two productions were set to 0. The fit was good, R^2 = 0.97, MSE = 0.003, which was similar to the model based on existing procedural learning mechanism. We conclude that the new mechanism can represent the learning mechanism at least as well as the existing mechanism with the same number of free parameters.

Overmatching behavior

Myers et al. performed another probability learning experiment, but they also varied the amount of monetary reward that participants would receive for each correct response. Participants would either receive no reward or penalty, ±1¢, or ±10¢ for each correct and incorrect responses. The probabilities that one of the alternatives was correct were p=0.6, p=0.7, and p=0.8. Table 3 shows the choice proportions for the participants in each of the conditions. When there was no reward, participants seemed to be exhibiting probability matching behavior. However, when there was a monetary reward, participants seemed to be "overmatching". From the data, it also appears that the higher the reward, the more the choice proportion exceeds the matching probability.

Table 3. Observed and predicted choice proportions from the experiment by Myers et al. (1963). Predicted scores are in parentheses.

Reward	Probabilities		
(cents)	p = 0.6	p = 0.7	p = 0.8
0	0.624 (0.612)	0.753 (0.750)	0.869 (0.829)
1	0.653 (0.676)	0.871 (0.834)	0.925 (0.938)
10	0.714 (0.711)	0.866 (0.836)	0.951 (0.944)

Since the task is basically the same as in Friedman et al., we used the same model to fit the data. We used the same set of parameters to fit the data in the no reward conditions (i.e. reward = 3). We chose the reward parameters (reward=±4.97 and ±5.7 for the ±1¢ and ±10¢ conditions respectively[3]) in the reward conditions to maximize the fit, and obtained R^2 of 0.98 and MSE of 0.0008, which is similar to the fit obtained by the existing procedural learning mechanism. However, we had only two free parameters in this model, compared to three free parameters in the model reported in Lovett (1998). In addition, the new mechanism provides a more natural interpretation of the overmatching behavior – when the reward was large, learning increases the expected utilities of the successful productions to higher values (since the deviation was larger). As a consequence, the model exhibited overmatching behavior. On the other hand, Lovett (1998) manipulated the architectural parameter G to fit the data, which seems awkward, as G is not supposed to be directly under strategic control.

Learning from normally distributed rewards

Busemeyer and Myung (1992) conducted an experiment in which participants were told to select one of the three treatment strategies for patients suffering from a common set of symptom patterns. Feedback on the effectiveness produced by the treatment was given after each selection. For the sake of convenience, the treatment with the highest expected effectiveness is called Treatment 3, and the next less effective treatment is called Treatment 2, and so on (see Figure 1). The effectiveness produced by each treatment was normally distributed with equal standard deviation, but the mean payoffs are different (as explained below). Participants had to evaluate each treatment based on trial-by-trial feedback. Participants were told to maximize the sum of the treatment effects over training and they were paid 4¢ per point. The means of the normal distributions are m-d, m and m+d for Treatment 1, 2, and 3 respectively. The two independent variables were mean difference (d) (i.e. the

[3] Since the reward values used in the model reflect subjective values, they do not necessarily follow a linear relationship with the external reward values.

separation of the distributions in Figure 1) and standard deviation (s) (which affects the amount of overlap in Figure 1). The exact values of d and s are shown in Table 4. Each participant was given 9 blocks (50 trials per block) of training in each condition. The model received the same amount of training as the participants.

From Table 4, we can see that as the mean difference increased, the observed choice proportions of the optimal treatment increased. As the standard deviation increased, the observed choice proportions of the best treatment decreased except when the mean difference was 3.0. The results showed that participants adapted their choice by learning the expected effectiveness of treatments. The results also showed that the more distinguishable the distributions were (larger mean difference or smaller standard deviation), the more likely the participants would choose the best treatment.

Table 4. Observed and predicted choice proportions of the optimal treatment from the experiment by Busemeyer & Myung (1992). Predicted scores are in parentheses.

Standard deviation (s)	Mean difference (d)		
	2.0	2.5	3.0
3.0	0.69 (0.74)	0.84 (0.79)	0.85 (0.84)
4.5	0.69 (0.72)	0.72 (0.76)	0.84 (0.80)
6.0	0.65 (0.68)	0.63 (0.69)	0.86 (0.83)

To model the data, we built three productions that chose each of the treatments. The initial expected utility of each production was set to 0. For each trial, the rewards obtained by the model were simulated by drawing a sample from the normal distribution that represents the effectiveness of the treatment chosen by the model. The value of r was chosen to be 1.76 to best fit the data. We obtained a fit of R^2=0.94, RMSE=0.007. The good fit to the data show that the new learning mechanism was able to build up the expected effectiveness of the treatments from trial-by-trial feedback, and was able to exhibit similar sensitivity to the differences of the distributions as participants. Since the effectiveness was sampled from a normal distribution, it is difficult to pre-specify which treatment was successful. It is therefore difficult to use the existing learning mechanism to model these data. In the new mechanism, however, whenever the actual reward was higher than the expected utility of the production, the production will be reinforced; otherwise the production will be penalized. With the same amount of experience (50 trials), the expected utilities of the production were able to reflect the actual expected effectiveness of the treatments.

Summary

We have fit a new procedural learning mechanism of ACT-R to three separate sets of data with all parameters held constant except the reward magnitudes the models received after each trial. In the first two cases, the new mechanism did at least as well as the existing mechanism in capturing the observed choice proportions in different settings. In the last case, we showed that the new mechanism fits data that are problematic for the existing mechanism. The new mechanism learned to probability match the true probabilities of outcomes by reducing the difference between the expected and actual reward. As the difference diminished, the change in the prediction decreased. When the reward was large, learning increases the expected utilities of the successful productions to higher values (since the deviation was larger). As a consequence, the chance of selecting the option that had the higher probability of being correct increased – i.e. the model exhibited overmatching behavior.

Although the first two sets of data can be modeled by the existing learning mechanism, the new mechanism provided a more natural explanation to the results. In the final set of data, we showed how the new mechanism generalizes and extends the computational abilities of the existing mechanism. The mechanism was able to learn the expected effectiveness of each treatment based on trial-by-trial feedback, without the need to pre-specify whether the productions had led to successful or failure states.

Discussion

We have presented a new procedural learning mechanism in ACT-R. The use of the deviation between the expected and actual reward values in the new learning mechanism is consistent with the current understanding of the functional role of VTA dopamine neurons in basal ganglia. We showed that the new mechanism generalizes and extends the computational abilities of the existing procedural learning mechanism. Specifically, the new mechanism is not limited to learning from binary feedback functions. Rather, the new mechanism is able learn from continuous reward functions with similar sensitivity to the variations in the reward distributions. The current paper also showed how the reinforcement learning mechanism observed in basal ganglia can be implemented in production systems such as ACT-R.

In practice, the current mechanism allows the use of a scalar reward parameter without the need to pre-specify success or failure states in a task. This pre-specification could be difficult especially in complex tasks in which a state could sometimes be good or bad depending on one's experience with the task, as experience may change one's expectation of different states. In addition, although the existing mechanism can adapt to different magnitudes of reward, the change of the architectural parameter G (in E=PG-C) to fit the data may not be easy in complex tasks that has many subgoals, especially when some subgoals may be considered "more successful" than the others.

Owing to space limitations, we are not able to show all properties of the mechanism. In fact, we have only tested the mechanism in single-choice tasks, which did not depend critically on the credit assignment mechanism. The discounting of future rewards therefore did not affect performance of the models in all three tasks that we have presented. However, we believe the discounting mechanism

is more plausible than the existing mechanism, in which immediate and future rewards are weighted equally.

In all three data sets, the model had the same amount of experiences as the participants and reached the same level of asymptotic performance. In the first data set, we also showed that the performance of the model in each of the four subblocks matched the participants well, suggesting that the learning rate of the mechanism is comparable to that of the participants. However, it is possible that the reinforcement learning mechanism could be slow for more complex tasks. It could be problematic, for example, when a primary reward is received after a long sequence production firings. Since only one production is updated during each ACT-R cycle, the primary reward may take several cycles to propagate back to the production where the critical decision is made. It is not clear how people learn in such situations. It is possible that they rely on direct instruction to point out such contingencies rather than counting on a automatic learning mechanism. It does not seem that the mechanisms behind the dopamine reward system are capable of spanning unbounded lengths of time in a way that would lead to rapid convergence.

Qualitative and Quantitative Effects of Surprise: (Mis)estimates, Rationales, and Feedback-Induced Preference Changes While Considering Abortion

Abstract

The Numerically Driven Inferencing (NDI) paradigm, and one of its methods, EPIC (Estimate, Prefer, Incorporate, and Change), are used to study both one's estimates and the effects of numeric feedback on one's personal policies (herein, about abortion). Both quantitatively and qualitatively, 92 undergraduates offered estimates and preferences for the legal U.S. abortion rate, explaining and justifying them. After receiving the (usually, quite surprising) true rate as feedback, they provided another (typically changed) preference-and-rationale. Results show that people vastly underestimated the abortion rate, and largely advocated decreases in it—both pre- and post-feedback. Feedback caused most of those who initially wanted no change in the abortion rate both to abandon the status quo and change preference-justifications; after feedback, two thirds of these students preferred a rate decrease, while the rest preferred an *increase*. Although many researchers hold that belief revision and conceptual change are quite difficult to elicit, these and other results show dramatic effects of simple base rate feedback on policy evaluation. Our findings highlight the importance of having and using data when reasoning about society-engaging topics such as abortion rates. This experiment represents a new way to study numerically-based reasoning that includes the subjective natures of our personal beliefs and social lives.

Please answer this question: "As a percentage of the current U.S. population, what is its *legal* immigration rate?" Does a typical response of 10% (Ranney, Cheng, Garcia de Osuna & Nelson, 2001) sound right? The true value is about *thirty-fold* less—only 0.3%. Does (or ought) this datum alter your immigration preference—your personal policy—some? Common sense may suggest that beliefs, decisions, and rationales will (or should) change with new information, but literatures from science learning to attitude change (e.g., from evolution or inertia to executions or diversity; Ranney et al., 2001), suggest that people are often unmoved by new data. Classical economics even suggests that preferences are exogenous (e.g., from estimates; Lurie & Ranney, 2003).

The Theory of Explanatory Coherence and its models (e.g., ECHO) describe a set of principles that guide belief evaluation and revision. Two such principles are that we (a) weigh evidence more strongly than conjecture, and (b) accept propositions explained more parsimoniously (Ranney & Thagard, 1988; Read & Marcus-Newhall, 1993; Schank & Ranney, 1991; Thagard, 1989). True base rates, then, would seem to represent parsimonious evidence (relative to a host of instances or anecdotes) and thus be (1) weighted heavily in one's reasoning about an issue and (2) evaluated as quite acceptable. The present paper explores aspects of this general hypothesis about (especially surprising) minimalist interventions—for instance, that a single, germane, critical number may foster conceptual change.

Some studies have noted that learning related base rate values (seeds) affects one's estimates (e.g., about spatial judgments or populations; Brown & Siegler, 1996; Brown, 2002, etc.). While intuitions about real world quantities are often incorrect (Brown, 2002), exposure to base rates increases the accuracy of one's estimates on closely related topics, and the benefits of such exposure can have lasting effects even months later (Brown & Siegler, 1996). Little is known, though, about the effects of base rate queries and feedback on preference/policy formation and change, so we suggest three "ifs." 1) If intuitions about real world numbers are often flawed, then they are likely being used to create anomalous or skewed personal policies among people. 2) If feedback can correct these intuitions, such feedback might affect individuals' policies. 3) If people are generally biased toward evidence (and they are; e.g., Schank & Ranney, 1991), then giving them factual, numeric feedback—say, the U.S. abortion rate, our main example—should affect conceptions and interpretations about the abortion rate, and thus affect both personal policies on abortion and the explanations supplied when justifying their policies. Among other questions, we seek to answer the following: Can supplying factual, numeric information about abortion markedly change one's abortion policy? Does receiving the actual rate as feedback affect the *Points of View* (POVs) by which people reason about abortion? Most such POVs (see below), involve moral or ideological reasoning aspects; religion plays a role, as well. (Space constraints prohibit reviewing the vast abortion literature here, e.g., Bernas & Stein, 2001, and we seek to focus on more paradigm-relevant aspects, in any case.)

We explore and measure phenomena of these sorts using a novel paradigm, Numerically Driven Inferencing (NDI; Ranney et al, 2001), and one of NDI's central empirical methods: EPIC (Estimate, Preference, Incorporate, and Change; cf. Lurie & Ranney, 2003, who introduced PEIC and IC as complementary methods). Such analytic frames allow us to study both estimates of, and dynamically changing preferences about, base rates (e.g., Munnich, Ranney, Nelson, Garcia de Osuna & Brazil, 2003). NDI also represents an emerging coherentist framework in which numbers are the "tips of the iceberg" of a person's thinking about a network of (magnitude-relevant) evidential and hypothetical propositions. A prime aspect of NDI's paradigmatic novelty is in its elicitation of what people *prefer* a quantity to be; it is further unique in its analysis of

[1] The order of the first two authors is alphabetical. *For J. Nelson's address, substitute in "Department of Psychology, 3510 Tolman Hall."

how such individuals' *policies* (as base-rate relative preferences) evolve in the face of numeric information. Using EPIC to study abortion numeracy, we asked each individual to *Estimate* the current legal abortion rate—per one million live births—and then offer a *Preference* (and thus a *policy,* relative to one's estimate) for what each would want the current rate to be (had one the power to change the rate), and give reasons for both numbers. They then received feedback (the actual abortion rate), which they *Incorporated* into their knowledge of the abortion issue. Students then provided a second preference and explanation; by contrasting their former and new preferences, estimates, and reasons, we can note *Changes* in preferences and policies that resulted from the feedback. Essentially, then, EPIC has four queries, about a rate X that has a value Y: (1) What is X's value? (2) What *should* X's value be? (3) X's value is actually Y, so (4) *Now*, what should X's value be?

Method

Participants, Design, Materials, and Procedure

Psychology pool undergraduates (N = 92) participated, as part of their course requirement. (The "N" will often be somewhat fewer in our Results, due to occasional missing data points.) The experiment used a pre- and post-feedback repeated measure, within a 2X2 factorial between-group design, although the two independent variables (Ranney et al., 2001) are tangential to the present issues and so omitted here, due to space constraints. Responses included numeric (continuous) estimates and preferences, written explanations of the estimates and preferences, and Likert ratings about: (a) general preference about a rate change, (b) familiarity with the topic, and (c) how much one cared about the topic.

This paper examines only one topic from a set of 16 (usually less emotion-laden) randomized topics: the U.S. legal abortion rate (which we defined for students—and represents the vast majority of abortions). Each person was first asked to estimate the current rate—per one million live births—and to explain the bases of that estimate. Next, each was asked how low and high the true abortion rate would have to be to be surprising, and to rate the confidence that the rate would fall in one's "non-surprise interval." Students were then each asked to give a numeric preference for the abortion rate, had one the power to change it, and to explain the preference. Then, they rated, on a 5-point Likert scale, how familiar they were with the topic of abortion rates, and how much they cared about the topic (with both ratings in contrast to the average American). As another measure of rate preference, on a 1-5 scale, students were also asked whether they generally preferred (1) a big decrease, (2) a decrease, (3) neither an increase nor a decrease, (4) an increase, or (5) a big increase. After this, feedback was provided—the then-current abortion rate—an often-shocking 335,000 per million live births (gleaned from independent federal agencies, e.g., the CDC & NIH; nb. the rate has since dropped some). Each was then asked to consider the feedback and again give a numeric preference, and to explain that final preference. Finally, the students were again asked both to rate how much they cared about the topic and to offer a 5-point general preference rating. (Our lab has since replicated this abortion item's results, and has noted the effects both of varying how the rate is framed––e.g., with respect to a million *fertile women*, Munnich et al., 2003—and of omitting a numeric referent.)

Coding Scheme for Written Justifications

As part of NDI's methodology, the written justifications for abortion preferences (before and after feedback) were coded qualitatively using verbal analysis methods. We developed a 14-category coding scheme by extracting major patterns from elicited explanations, and then coded *all* justifications with the scheme. A student's explanation could fit up to three of the 14 coding categories, with many requiring more than one code. Inter-rater reliability for coding the reasons was 90% among three coders. For ease of discussion, the 14 categories were grouped into six broader categories called *Points of View* (POVs) by which people justified their personal abortion rate preferences. These POVs are: (1) preferring a utopian world in which abortions are essentially unnecessary or moot; (2) that the abortion rate should reflect the greater good for society; (3) that abortions should always be allowed/legal, regardless of circumstance; (4) that abortions should only be allowed in some circumstances; (5) that abortions should never be allowed (e.g., illegal) under any circumstances; and (6) other/no explanation.[2]

Results

Findings are reported following the EPIC procedure: Estimates and Preference (EP), then Incorporation (feedback) and Change (IC). We also focus analysis on (a) written, post-preference, justifications, (b) correlations between preferences and some Likert ratings, and (c), two especially interesting subsets of participants: those who wanted a rate of zero abortions, and those who notably changed the direction of their preferences after feedback. (Space limits do not permit us to report all, or even all statistically significant, findings; cf. Ranney et al., 2001.)

[2] POVs (1-6) map onto the *original* 14 (a-n) code categories as follows. POV-1: (a) "perfect world" in which *all* pregnancies are desired or yield loving adoptions, (b) "birth control," with perfect contraception preventing *all* unwanted pregnancies, and (c) "responsibility" by *full* abstinence or pregnancy-completion. (I.e., a-c respondents wish abortions need never be considered.) POV-2: (d) abortions needed to optimize social benefit (e.g., economics, improved life-quality for all, and crime reduction). (POVs 3-5 concern availability or legality.) POV-3: (e) "better for mother or unborn child," as some wish to reserve abortion as perhaps better for the mother (e.g., her health) and/or fetus's predicted life, (f) "basic 'pro-choice' position," as some didn't expand on being pro-choice, (g) "women's right," with which they may choose abortion, and (h) "status quo," such that the abortion rate ought not change. (In categories e-h above, rationales include notions that abortions ought *always* be available.) POV-4: (i) "not for contraception," by which some decried abortions-as-birth-control, and (j) "emergency only," with abortions only allowed in extreme cases (e.g., after rape or to save a mother's life). POV-5: (k) "murder/loss of life," in which the fetus's loss of life is deplored, and/or abortion is seen as murder, and (l) the "basic con position," as some didn't expand on being anti-abortion. (Codes k-l reflect being *fully* anti-abortion.) POV-6: (m) a comment/rationale that was not captured by prior codes (e.g., "Why are you asking me this?") or (n) no explanation.

Estimates and Initial Preference/Policy

Participants greatly underestimated the abortion rate. The median *estimate* was 5,000 abortions per million live births (M=50,479; S.D. = 148,469), much less than the true—and often evocative—rate of 335,000. (Due to high variance, we focus more on median estimates, as they usually inform more than do means.) In general, students' initial numeric *preferences* differed from what they thought the true rate to be (i.e., there was, overall, a significant difference between one's estimate and initial preference; t(88)=-2.62, p=.01). The median initial preference was only 100 abortions per million live births (M = 19,381; S.D. = 110,372), or 4,900 less than the median *estimate*—that is, a policy advocating a 98% (or fifty-fold) decrease. Thus, most people (62.2%) preferred rate decreases, relative to their estimates. Counter-intuitively, ratings of familiarity and caring about the topic did *not* significantly correlate with estimate accuracies, indicative of rather modest metacognition.

Recall that we also elicited initial *general* preference ratings (from 1-5) for the abortion rate. These ratings tended to favor decreasing the abortion rate (M= 2.07), and were negatively correlated with initial caring ratings (r(90)=-.32, p=.002). The initial numeric preferences of those who wanted a *general* decrease (a "1" or a "2" rating) differed significantly (F(1,86) = 4.33; p = .04) from preferences of those who did not. The median initial preference was zero for those initially wanting a (Likert scale) decrease in abortions (n=56, M= 1,337.32; S.D.= 3,577). The median initial preference was 2,000 abortions per million live births for those who initially preferred either (a) an increase, or (b) neither an increase or a decrease on the Likert scale (n=34, M= 50,001; S.D.=178,723). Before feedback, the majority (62%) chose either "prefer big decrease" or "prefer decrease" for the abortion rate, prior to feedback, mirroring the numeric preferences. Only two participants wanted an "increase," and none preferred a "big increase." The rest (35.6%) preferred "neither an increase nor a decrease." As expected, given the great tendency to underestimate, initial preferences were negatively correlated with later being surprised by the feedback (r(89)= -.25, p=.02).

Of the 67 explanations by those who initially preferred a decrease in abortion (relative to their estimate), the bulk of them fell into three POVs: 26 explanations held that abortions should never be allowed, 24 referred to a utopian world in which abortions are unnecessary or moot, and 10 asserted that abortions should only be allowed in some circumstances. For example, one decrease-preferring participant (with Estimate: 100,000; Initial Preference: 0) wrote, "It would be great if every baby was cherished enough to be allowed to live." Another person preferring a decrease (Est: 1,000; Init. Pref: 10) stated, "Because I don't believe women should end a child's life unless it affected their own physical health." People preferring a rate equal to their estimates most often indicated that abortions should always be allowed (17 of 29 explanations); the remaining justifications were from all other POVs except that for the "Other/no explanation" (see Table 1). For example, one of these status-quo students (Est: 800; Init. Pref: 800) stated, "[I prefer] as many as necessary to not have unwanted children. I believe people have the right to have an abortion if they cannot have the child for personal reasons." All three people whose preferences exceeded their estimates indicated that abortions ought always be allowed. For example, one (Est: 20,000; Init. Pref: 1,000,000) stated, "People should choose whether or not they can bring a kid to the world."

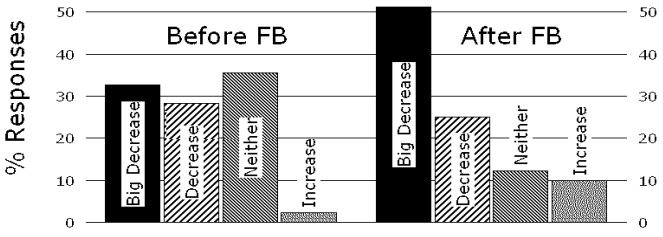

Figure 1: Distributions of general preference ratings (Likert; 1-4 out of 1-5), before and after feedback.

Incorporation (of Feedback) & Preference Change

After feedback, the median numeric preference *increased* to 1,000 abortions per one million live births (M = 108,178; S.D.= 174,688). However, that median is a larger 99.7% decrease-policy from the true abortion rate of 335,000. (Recall that the median initial preference called for a 98% decrease-policy in the rate, relative to their estimates.) Final numeric preferences still significantly differed from the feedback value (t(88)=-12.25, p<.001), and represented a non-proportionate shift in policy (p < .001 via a Wilcoxon Signed Rank test). Mirroring this policy shift toward a greater decrease (percentage-wise) in abortions, the mean Likert rating for general preference dropped from 2.1 (out of 5) to 1.8 after feedback (t(89)=3.39, p=.001). After feedback, 51.1% preferred a "big decrease," dramatically up from 32.6% (and 25.0% preferred a "decrease," down slightly from 28.3%). This movement is evident in Figure 1, which contrasts the distribution of initial Likert ratings for general preferences before and after feedback. Those who initially chose "neither an increase nor a decrease" most notably changed Likert ratings for general preferences; after feedback, 66% of them (21 of 32) "moved off the status-quo fence," with five coming to prefer a "big decrease," nine a "decrease," and the other seven dramatically diverging to prefer an "increase." In Figure 1, this scattering is seen in the shrinking of the "Neither" bar and the growth of both the "Big Decrease" bar and—more surprisingly—the "Increase" bar. (Note that no one in this study ever preferred a "Big Increase.") This striking bifurcation of most of the (initially) status-quo group is qualitatively analyzed below.

Mean care ratings (from 1 to 5: "not at all" to "much more than average"), increased significantly after feedback, from 3.29 to 3.51 (t(90)=-2.89, p=.005). Numeric and (Likert) general preference measures concurred, because after feedback, numeric preferences continued to differ between those wanting either a "decrease" or "big decrease" and those who did not (M= 1,337 and 50,001, respectively F(1,87) = 445.8; p<.001). Interestingly, both before and after feedback, "care" ratings were negatively correlated with general-preference Likert ratings (respectively, r(90)= -.32, p=.002; r(90)= -.21, p=.047). That is, those "caring" more about abortion preferred more of a decrease in its rate.

Table 1 shows the effect of feedback (i.e., pre- vs. post-) on the percentage of each POV mentioned, within the four

Table 1: Percent usage of POVs, from pre-feedback to post-feedback, by general/Likert preference rating.

	Big Decrease (1)		*Decrease (2)*		*Neither (3)*		*Increase (4)*

Abortions should always be allowed	5.7	1.8	9.4	0	58.6	81.8*	100	50*
Totals (i.e., each column sums to 100%)	*100*	*100*	*100*	*100*	*100*	*100*	*100*	*100*

levels of general preference Likert ratings that people used. Five notable distributional changes are marked by asterisks (*s). One such change (from 2.9% to 24.6*%) represents the finding that, before feedback, only *one* of 35 "big decrease" justifications was coded as "Abortions should be allowed only in some circumstances," but *14* of 57 "big decrease" justifications were so coded after feedback.

As a rather orthogonal analysis from those above, the following set of subsections examine three sets of participants and how they were differentially affected by feedback: those preferring zero abortions (both before and after feedback), those changing their basic position on the abortion rate, and the remaining participants.

Zero Preference Participants Of all students, 34.8% initially wanted zero abortions. After feedback, 84.2% of the 34.8% still preferred zero abortions. Initially, such people typically used a utopian world POV (50%), or a POV that abortions should never be allowed (41%). Feedback spurred only a non-significant drop in the use of a utopian world POV (42%), concomitant with a non-significant rise in the view that abortions should never be allowed (44%). Preferring zero abortions before feedback was correlated with initial caring ratings ($r(88)=.24$, $p=.025$); there was *no* correlation, though, between preferring zero abortions *after* feedback and *final* caring ratings ($r(88)=.06$; $p=.60$).

Participants Who Changed Away from "Status Quo" Of 89 respondents, 24% changed their policy direction—and *all* of these 21 were those who initially preferred neither an increase nor a decrease in abortions on the Likert scale, yet preferred either an increase or a decrease after feedback. We refer to these as "semi-flips," as no one *fully* flipped sides (e.g., from "increase" to "decrease" or vice versa). Of the "semi-flippers," 14 shifted to preferring a "decrease" (11 of whom were "technically surprised" by the feedback, in that 335,000 fell outside of their non-surprise intervals). Remarkably, given that almost everyone underestimated the rate (mostly by vast amounts), the other seven changed to wanting an *increase* in the abortion rate (e.g., by concluding that numerically unwarranted taboos due to media-skewed rate perceptions may be *inhibiting* abortions); indeed, six of the seven were technically surprised by the high feedback. For all semi-flippers, as per above, the initial (Likert) general preference was "3" (i.e., "neither an increase nor a decrease"). The post-feedback mean general preference for the semi-flippers dropped to 2.43, but this aggregates a drop to 1.64 for "decreasers-come-lately" (DCLs) and a rise to 4.00 for "*increasers*-come-lately" (ICLs).

Table 2 shows the POV distributions for the 21 semi-flippers, pre- and post-feedback, which significantly differed ($\chi^2(5,N=105)=11.88$, $p=.036$). Pre-feedback, most of their rationales indicated that abortions should *always* be allowed (12 out of the 21 people, with the other nine being grounded in all other POVs). Post-feedback, the POVs these students used depended *entirely* on whether one had semi-flipped to prefer an abortion-rate increase or a decrease. (Note: there were 22 instances, post-feedback, as one person used two POVs.) This feedback-driven bifurcation was total, as shown in Table 2's last two columns; note the complete lack of overlap, post-feedback, between the first two POVs (rows) and the next three (i.e., excluding "other/no explanation"). After feedback, four of the seven ICLs justified their preferences with "abortions should always be allowed," while the other three justified with "abortions should reflect the greater societal good." (One used both.) However, DCLs didn't use either of these two POVs to justify preferences: Instead, the greatest number of

Table 2: POV changes for semi-flip participants/POV-instances (pre- vs. post-feedback; 21 people vs. 22 POV instances), by general preference/Likert ratings (ICL = "increaser-come-lately;" DCL = "decreaser-come-lately").

	Pre-Feedback (out of 21 semi-flippers)	Post-Feedback (of 22 POVs)	
Point of View (POV) Justification (Note: the order has changed from Table 1)	Neither an Increase nor Decrease	Increase	Decrease or Big Decrease
Abortions should always be allowed	12 *(8 became DCLs; 4 became ICLs)*	**5**	0
Abortion rate ought depend on the greater good	2 *(both became ICLs)*	**3**	0
Utopian world where aborting a non-issue	2 *(both became DCLs)*	0	**8**
Abortions should never be allowed	1 *(who became a DCL)*	0	**3**
Allow abortions only in some circumstances	1 *(who became a DCL)*	0	**3**
(Other / No Explanation)	3 *(2 became DCLs; 1 became ICL)*	0	0

their post-feedback instances involved the utopian POV (eight of 14 instances); the remainder of these participants' explanations included the POVs that either abortions should never be allowed (three of 12 instances) or should be allowed only in some circumstances (three of 12 instances).

Thus, most semi-flippers initially wrote that abortions ought always be allowed, yet not one DCL wrote that belief after feedback. Further, semi-flippers were so polarized after feedback that there was no overlap at all between the POVs of the ICLS and the DCLs. For example, one initially-status-quo participant who first both estimated and preferred a rate of 20,000 (per million live births) wrote, "I think it is a good number." After feedback, the same person changed views, preferring an increase in the abortion rate to 500,000, stating: "I think there are too many kids being [born] into this country, especially since a lot...are being raised by teen/bad/druggie parents." In contrast, a semi-flipper who changed to prefer a *decrease* in the abortion rate post-feedback, at first both estimated and preferred a rate of 800, stating, "[I prefer] as many as necessary to not have unwanted children. I believe people have the right to have an abortion if they cannot have the child for personal reasons." Post-datum, this person wanted a rate of 200,000 (again, a decrease from the feedback's 335,000), stating, "A lot of these probably happen because women/men aren't taking the right precautions and with education or birth control. I think this number could start to decrease. But I do believe women have the right to abortions, but not the right to use abortions as a birth control method."

Remaining ("Non-Zero, Non-Semi-Flip") Participants
The distributional shift in POVs was also significant for the rest of the people (χ^2 (5, N=80)=139.24, p<.001)—those who preferred abortion rates above zero, but did not change the direction of their general preference (Likert) rating after feedback. Such people were neither semi-flippers nor those wanting zero abortions, and so represent a less extreme subgroup than those discussed above. It is instructive to note how the relative POV use changed for these intermediate "non-semi-flip/non-zero-preference" participants: Before feedback, the top three abortion POVs for these non-zero, non-semi-flip students were equally split (with 23.5% of instances apiece) among "allowed in some circumstances," "never allowed," and "always allowed." After feedback, though, the POV that abortions should be allowed in some circumstances represented 33.9% and the two absolute POVs that abortions should either *always* or *never* be allowed—made up 16.9% and 18.6% of the responses, respectively. The other POVs' percentages changed rather less (utopian world: 13.8→18.6; other/no explanation: 9.8→10.3; should depend on greater good: 5.9→1.7).

Discussion

Respondents largely estimated the legal U.S. abortion rate to be far lower than the true rate—seven times lower in mean, and 67 times lower in median. In fact, 79% of students were "technically surprised" by the feedback, such that the true abortion rate was not contained in their elicited non-surprise intervals. Thus, only 21% of our students captured the true value (335,000 legal abortions per million live births) in their non-surprise intervals—even though their mean confidence of doing so, just after offering their intervals, was 74%. Thus, participants were roughly 3.5 times less likely to capture the true rate than they anticipated.

The effect of the feedback on one's preference was likely due, in part, to its shocking magnitude. Results show that learning the true abortion rate clearly changed reasoning about abortions—with regard both to peoples' preferences and the points of view (POVs) by which they justified their policies. While the median person went from preferring 100 abortions per million live births to preferring 1,000, since the median estimate was 5,000 and the feedback was 335,000, students' new preferences represented a much more stringent relative abortion policy (from -98% to -99.7%). Indeed, the failure to capture the feedback value in one's non-surprise interval was significantly correlated with exhibiting a dramatic (i.e., non-proportionate) change in abortion policy (r(54)=.4; p<.01).

Overall relative policy preferences also became more fervently abortion-reducing (constrictive) on other metrics post-feedback. There was a significant overall drop in general Likert preference ratings for the abortion rate, after feedback. Indeed, almost 20% more of the students preferred a "big decrease" after learning the true rate (see Figure 1). The justifications also changed: Before feedback, 25.2% of the full set of explanations provided that abortions should always be allowed, while only 11.1% stated that abortions should be allowed in only some circumstances. After feedback, these frequencies were essentially reversed (13.5% vs. 20.2%). The only people who showed little shift in either their numeric preference or written justifications were those who preferred zero abortions—before and/or after feedback. Considering that these zero-preferring people (a strange-bedfellows group seeming to include utopian liberals and abolitionist conservatives; see Results) essentially held absolutist policies (for zero abortions), it is not surprising that the true rate did little to change that wish.

In both more quantum and qualitative senses, one of the most dramatic of the above results is that those who initially adopted a "status quo" policy usually changed their positions after seeing the generally surprising base rate feedback. Of the 32 respondents who first preferred neither an increase nor a decrease in the abortion rate, feedback caused 21 of them (66%) to take a directional position, thus becoming "semi-flip" participants. Base rate feedback also changed the POVs by which semi-flip people justified their preferences. While before feedback, most such students claimed that abortions should always be allowed, regardless of circumstances, these justifications shifted dramatically after feedback. The participants who changed to preferring decreasing the abortion rate no longer claimed that abortions should always be allowed, and instead largely justified their new preferences by preferring a utopian world in which abortions need never be considered, because either (a) all pregnancies would be wanted (or all unwanted pregnancies prevented), or (b) all unwanted babies would be readily adopted by loving homes. (This is consistent with "Wow! That's too many!" reactions.) Conversely, those semi-flippers who changed to prefer an *increase* after feedback used none of the justifications eventually used by those who

changed to prefer a decrease, and vice versa. Instead, these increasers-come-lately largely continued to claim that abortions should always be allowed, regardless of circumstances, or that the abortion rate should reflect the greater good for society. So, while semi-flip participants seemed rather homogenously like-minded before feedback, when it caused them to bifurcate into divergent positions (to prefer an increase or a decrease) there was no overlap in the types of justifications used. This is a dramatic effect, considering that the intervention is a single, albeit highly reliable, piece of information (i.e., 335,000:1,000,000).

Some Implications and Extensions

Our results show some of the effects of numerical feedback on personal preferences and policies regarding topics such as abortion—that is, topics for which the feedback is often surprising and quite far from individuals' estimates. More recent work from our laboratory observes this phenomenon in many realms, involving dozens of items and their rates—about incomes, inflation, executions, home ownership, etc.—and even SAT percentile use in college admissions. Lurie and Ranney (2003) are extending this work even further, into the arena of health-care research funding, and have proposed a general model that relates numeric estimates, preferences, feedback, and seeds.

One implication of this work is the need to improve citizens' thinking about critical base rates. For many of the topics our Reasoning With Numbers group employs, many people are clearly quite unaware of crucial numbers related to an issue (Ranney, et al., 2001), and they even have low metacognitive knowledge-awareness (e.g., no significant correlation, for abortion, between familiarity and accuracy). Therefore, our lab has carried out a variety of promising classroom-based experiments, from grades 5-12, to foster such metacognition (e.g., Munnich, Ranney, & Appel, 2004). Among other goals, our curricula are meant to improve students' abilities to (a) estimate (e.g., by disconfirming sub-par, early, estimate-hypotheses and bringing more knowledge and accountability to bear), (b) prefer (or justify what they prefer, e.g., by reflecting on more dimensions influencing one's wishes), (c) utilize feedback (e.g., by "letting go" of one's estimate), and (d) triangulate or "N-angulate" (e.g., by seeking relevant external information sources). Curricular assessments show broad numerical reasoning gains over control students (e.g., in estimation; Munnich, Ranney, & Appel, 2004).

Most people use information other than statistics (e.g., ethics, pragmatics, and conventions) to form their positions, and even use *misconceptions* of true statistics, at times. Still, the actual numbers, especially when surprising, can significantly affect how they think about the issue. Thus, NDI results contrast with views of scholars in diverse fields who suggest that learning, transfer, belief revision, and attitudinal (or conceptual) change are quite difficult to foster (Munnich, Ranney, & Appel, 2004; Munnich et al, 2003; Ranney et al., 2001). Incorporating numeric feedback—even just a single, critical, number—can often dramatically change how one views an issue and reasons about one's positions. Further, such changes clearly transcend the domain of numbers, in that there is much non-numeric reasoning that lies beneath the iceberg-tips of estimation and quantitative preference. NDI's methods (e.g., EPIC) represent new tools with which science may better probe the submerged prominences and embedded fissures of thought.

Does the Viewpoint Deviation Effect Diminish if Canonical Viewpoints are used for the Presentation of Dynamic Sequences?

Abstract

Two studies examine the visual presentation of dynamic sequences. Experiment 1 tests if there are canonical viewpoints, that are especially appropriate for presentation. Participants agreed that viewpoints with 90 degree deviation between axis of sight and axis of main movement in the sequence are better than other viewpoints. Experiment 2 examines if these canonical viewpoints weaken the perspective deviation effect in a recognition task according to their postulated information richness. A perspective deviation effect was found both for canonical and less canonical views, even if it was weaker for the canonical views.

Viewpoint Deviation and Canonicality

This paper deals with questions concerning the cognitive representation of visually presented dynamic sequences, specially the role of viewpoint. A first experimental series (Garsoffky, Schwan & Hesse, 2002) showed that the viewpoint from which one sees a dynamic sequence becomes part of the cognitive representation of that sequence and therefore influences later memory retrieval processes. This viewpoint deviation effect appeared in three experiments examining recognition memory for visually presented dynamic sequences (Garsoffky et al., 2002) and comprises the stable result, that cuttings from sequences are best recognized if they are presented in a viewpoint most similar to the viewpoint from which participants before saw the whole sequence. This means the cognitive representation of dynamic sequences is not uncoupled from the viewpoint from which one primarily saw the specific sequence and therefore influences later memory retrieval processes. The question now is, if this viewpoint deviation effect holds for all kinds of viewpoints or if the use of special viewpoints may reduce this effect. The following studies therefore ask, if various viewpoints differ in their qualification to present a sequence – i.e. if there exist so called canonical viewpoints that could by now only be shown for static objects (e.g. Palmer, Rosch & Chase, 1981) (Experiment 1), and further it will be investigated, if these canonical viewpoints have an influence on the viewpoint deviation effect found by Garsoffky et al. (2002) (Experiment 2).

The concept of canonicality in connection with visual viewpoints was firstly empirically investigated and defined by Palmer et al. (1981). They discuss the idea of canonical viewpoints from an information-processing approach, a categorization perspective, in terms of phenomenology, and with regard to the concept of affordances (Gibson, 1982) and they conclude, that canonical viewpoints compared to other viewpoints contain more information as well as information of high salience, are the most typical viewpoints of an object, are those viewpoints from which an object is most perceivable, and are especially qualified to present the affordance structure of an object.

Empirically canonical viewpoints are defined e.g. by asking participants to imagine an object and then to describe the viewpoint from which the imagination took place, or participants were asked from which viewpoint they would make a photo of an object, or participants had to choose between photos with varying viewpoints which photo in their opinion presented the object best (Blanz, Tarr & Bülthoff, 1999; Palmer et al., 1981). Evidence for canonical viewpoints is stated if there is high inter- and intraindividual agreement.

At least for static objects some conclusions about the nature of canonicality can be made that do not mutual exclude each other. (i) Functionality and familiarity: Especially objects of everyday life we often see from a specific viewpoint that corresponds with the functionality of that object, i.e. when interacting with that object we see the object from a specific, i.e. canonical viewpoint that allows optimal interaction (Blanz et al., 1999). (ii) Information richness: In some studies canonical viewpoints were discovered even for abstract or nonsense objects – a fact that can not be explained by familiarity or functionality (Cutzu & Edelman, 1994; Edelman & Bülthoff, 1992; Perrett &

Harries, 1988). It was concluded that canonical viewpoints present more information and especially more salient information of an object than other, less canonical viewpoints. They present a high number of visible surfaces of an object, important parts of an object are not covered, and they are stable against small variations of the viewpoint, i.e. the informational advances of that viewpoint remain the same even if the viewpoint is changed slightly (for a comprehensive list see Blanz et al., 1999). (iii) Discriminability: Cutzu and Edelman (1994) concluded from their findings using abstract objects, that because of limited cognitive capacity for every specific object only the diagnostically valuable attributes are stored, that help to distinguish this object from other objects. This means that it varies with changing contexts or tasks, which viewpoint is more canonical than other viewpoints.

This paper investigates if the usage of such high informative viewpoints, that allow optimal discrimination, leads to a more viewpoint independent cognitive representation of visually presented dynamic sequences. I.e. the question is if so called canonical viewpoints help to recognize sequences better even if they are presented from new viewpoints.

Experiment 1

In the first study it has to be determined if there exist canonical viewpoints not only for static objects but also for dynamic sequences and how they can be defined. The study picks up one classical way to examine the canonicality of different visual viewpoints (Palmer et al., 1981) – namely rating measures, i.e. participants judge the goodness of various viewpoints for presenting the dynamic sequence.

For dynamic sequences, there often is one main direction of movement, and it is supposed, that viewpoints are the more appropriate to present the sequence the more they allow the observer to understand this movement. Moreover it is assumed, that viewpoints deliver the more information according to this movement the more orthogonal they are to the main movement direction of the dynamic sequence. This is argued because viewpoints with the axis of sight parallel to the main movement direction cause perspective shortenings. So it is hypothesized, that viewers prefer viewpoints that are as much as possible orthogonal to the direction of the main movement and that viewers rate viewpoints worse if these viewpoints are more parallel to the main movement direction.

Method

Participants Six male and ten female students, from the University of Tübingen participated in this experiment. They were paid for their participation.

Apparatus Experimental procedures were controlled by a Microsoft computer and realized by a html-program. Film clips were presented on a black background in the left and the right half of a color monitor.

Stimulus materials and design Eleven dynamic sequences were programmed using xyZET (Härtel & Lüdke, 2000), a simulation program to teach physics in school. Each dynamic sequence consisted of four spheres (balls) with different colors, sizes, starting positions and velocities. All balls moved on parallel laps towards a kind of blue goal at one end of the rectangular space. So the sequences were similar to a kind of race, with the exception that the balls did not start at the same line and that not all of them reached the goal within the duration of the sequence. Each sequence was filmed from 5 different viewpoints: All viewpoints had the same height but differed according to the horizontal amount of deviation between the axis of sight realized by the camera perspective and the axis of movement direction of the balls; this amount of deviation could be either 0˚ (i.e. parallelism), 22.5˚, 45˚, 67.5˚ or 90˚ (i.e. orthogonality); see Figure 1. This resulted in 55 film clips (11 sequences by 5 viewpoints); three of these sequences, i.e. 15 film clips, were used for training, eight sequences, i.e. 40 film clips, in the experimental test. This variation resulted in a design with the variable "canonicality of presentation" (0˚ / 22.5˚ / 45˚ / 67.5˚ / 90˚; within-subjects).

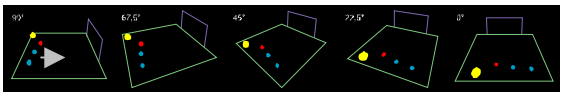

Figure 1: Visual presentations of the ball races used in experiment 1 with 0˚/22.5˚/45˚/67.5˚/90˚ amount of deviation between axis of ball movement (indicated by the little grey arrow) and axis of sight.

Procedure Participants were tested individually. The written instructions to the main part of the experiment – namely the rating of the film clip presentations at the computer - told them that they would see various dynamic sequences and that their task would be to rate the goodness of the viewpoint to present the dynamic sequence. It was explained, that the sequences were similar to races and that the relative positions of the objects to one another therefore is important when presenting the sequence. Further it was explained, that they always would see two film clips in succession presenting the same sequence but with different viewpoints and that they afterwards always should rate, which of the two film clips was the better presentation of that dynamic sequence by clicking with the mouse on one of two buttons (a button underneath the window of the film clip presented in the left half of the screen if they preferred this viewpoint or a button underneath the window of the film clip presented in the right half of the screen if they preferred that viewpoint). If participants had no more questions they were seated in front of the computer and a training phase started, which introduced some examples of the pair comparison task and trained to use the buttons. Data of the training phase were not analyzed.

When the film clip on the left side of the screen ended the last picture stayed in the window; after a short delay of one second the second film clip started on the right

side of the screen. At the end of the film clip also the last picture stayed on the screen. Now the participant had to made his or her rating by clicking one of two buttons. Then a short text note followed on the screen, inviting participants to click another button when they wanted to start the presentation of the next two film clips.

The order of the dynamic sequences was randomized as well as the order of viewpoint combinations. For each dynamic sequence there were 5 different viewpoints and each viewpoint was paired two times with each other viewpoint of this sequence: one time presented on the left half of the screen (i.e. the film clip they saw firstly) and one time presented on the right half of the screen (i.e. the film clip they saw secondly). So subjects in the experimental phase saw eight sequences, each in form of 20 pairs of film clips. All together subjects had to make 160 pair decisions; each specific viewpoint could reach a maximum of 64 preferences.

Results

Ratings For each participant it was counted, how often he or she favored a certain viewpoint compared to another viewpoint (number of "preferences"). An ANOVA with repeated measurement was performed, including the variable "canonicality of presentation" (0˚, 22.5˚, 45˚, 67.5˚ or 90˚; within-subjects). There was a significant main effect for this variable, F (4, 60) = 8.457, MSE = 227.802, $p < .01$ and also a significant linear contrast, F (1, 15) = 17.512, MSE = 397.233, $p < .05$. The viewpoints were rated better, the more the axis of camera sight deviated from the axis of sequence movement (0˚: 21.375 preferences; 22.5˚: 25.688 preferences; 45˚: 27.688 preferences; 67.5˚: 36.125 preferences; 90˚: 49.125 preferences). Single comparisons according to Scheffé revealed significant differences between 90˚ on the one hand and 0˚, 22.5˚ or 45˚ on the other hand.

Discussion

The results allow three statements: (i) In presentations of dynamic sequences specific viewpoints are preferred against other viewpoints. That means there are "canonical viewpoints" not only for static object presentations but also for sequences presenting dynamic movement. (ii) More than that it can be defined, which viewpoints are preferred, namely as predicted those viewpoints whose axes of sight are orthogonal to the axis of main movement in the sequences. (iii) Further it could be shown that viewpoints are rated worse the more they differ from this best, i.e. canonical viewpoint. The significant linear trend is a hint that canonicality – measured by preference judgements - is not an all-or-none concept.

Experiment 2

Experiment 2 now examines if there is a relation between the canonicality of viewpoints found in experiment 1 and the viewpoint deviation effect (Garsoffky et al., 2002). A recognition task is used and it is investigated if a thoughtful choice of viewpoint when presenting a dynamic sequence the first time (i.e. canonical viewpoints in the learning phase) can lower the effect of viewpoint deviation during recognizing cutouts of dynamic sequences (in the test phase). The rational for this question is the idea, that canonical viewpoints are information richer (Blanz et al., 1999; Cutzu & Edelman, 1994; Palmer et al., 1981), and that therefore it should be easier to recognize cutouts from a sequence even from deviating viewpoints, because one has more information about the sequence.

Method

Participants Eight male and twelve female, from the University of Linz, Austria participated in this experiment. Because the task was very difficult we tried to motivate the participants by informing them that the best three participants receive a gift coupon for a local cinema.

Apparatus The experimental procedures were controlled by an Apple computer (Power Macintosh 8100/80AV) and programmed using PsyScope (Cohen, MacWhinney, Flatt & Provost, 1993). Film clips and video stills were presented on a black background in the middle of a color monitor. Reaction times were measured by the computer internal clock, thereby resulting in an unsystematic measurement inaccuracy of 17 msec.

Stimulus materials and design Sixteen dynamic sequences were programmed, now using 3D canvas (amabilis.com) because this software offered more different colors than the simulation software used in experiment 1. Each of the sequences consisted of four balls with different colors, that moved on a rectangular plane in a linear parallel manner. The balls either moved towards a kind of goal or away from this goal and had different starting points. Further the balls moved with different and individually varying speed, i.e. they accelerated and decelerated – so again some kind of "races" resulted. Acceleration and deceleration was necessary to prevent that viewers could predict the end of the race after seeing only the first parts of the sequences by simply extrapolating the starting speed and position of each ball. Each sequence was filmed with a desktop camera from two different viewpoints (all camera viewpoints were 20˚ above the horizontal plane) – with 90˚ deviation between axis of ball movement and axis of camera sight (hypothesized to be the more canonical viewpoint) and with 0˚ deviation between the two axes (hypothesized to be the less canonical viewpoint). In the 90˚ condition the balls moved in 50% of the cases from the left to the right side and in 50% of the cases from the right to the left side to preclude that the 90˚ viewpoint simply is better, because it realizes the familiar reading direction. Accordingly in the 0˚ condition, the balls moved in 50% of the cases towards the observer and in 50% of the cases away from the observer (see Figures 2 and 3).

For each sequence 5 points of time that were evenly distributed throughout the sequences were defined, to get enough measurement possibilities. For each of these

points of time video stills for the recognition test phase were produced. These video stills had varying viewpoints on the sequence: All viewpoints had the same camera height (20˚ above the horizontal plane) but differed according to their horizontal deviation compared to the viewpoints in the film clips. This deviation could be 0˚, 45˚ or 135˚. Keep in mind that 0˚ does mean two different things for the film clips (learning phase) and the video stills (test phase): We speak of film clips with a 0˚ viewpoint, if there is no deviation between axis of ball movement and axis of sight. In contrast a video still with 0˚ is a video still the viewpoint of which does not deviate from the formerly presented viewpoint in the film clip – may this be a viewpoint with 0˚ or 90˚ deviation between axis of sight and axis of ball movement.

These variations resulted in a design with the variables "canonicality" (high / low; within-subjects), and "viewpoint deviation" (0˚ / 45˚ / 135˚ deviation between the viewpoints in the learning and the test phase; within-subjects).

	balls moving towards the goal	balls moving away from the goal
90˚; from left to right		90˚; from right to left		0˚; towards observer		0˚; away from observer		
Figure 2: Movement directions of the balls in experiment 2 towards / away from the goal, from the left to the right / from the right to the left, towards / away from the viewer, and with 0˚/ 90˚ deviation between axis of ball movement and axis of sight.

Procedure Again all participants were tested individually and received written instructions to the main part of the experiment – namely a description of the kind of dynamic sequences and their recognition task. First they passed through a training phase, the data of which were not analyzed. The experimental phase encompassed 8 races, i.e. 8 blocks. Each block consisted of an initial learning phase followed by a test phase. In the learning phase participants saw a dynamic sequence twice from either a canonical (90˚) or a less canonical (0˚) viewpoint, i.e. they saw the same film clip two times in succession from the same viewpoint. One second later, they successively saw 15 video stills (five points of time of the sequence each presented from three different viewpoints) as well as 15 distractor video stills which used the same viewpoints but presented other sequences, i.e. the sequences showed the same balls (same colors) but the video stills stemmed from other races with the balls moving with other speeds. So to perform the recognition task participants had to decide, if a video still showed a moment of the race seen before in the film or another race by checking the relative positions of the balls to each other. The order of the video stills was randomized. Each video still stayed on the screen until the participant pressed one of two reaction keys (one marked with "j" for the german word "ja" which means "yes", and one marked with "n" for the german word "nein" which means "no"). After the participant had reacted to a video still there always was a short delay of one second before the next video still was presented. The order of blocks (i.e. the different sequences) was randomized and each sequence was presented in the learning phase to half of the participants from a canonical viewpoint and to the other half of participants from a less canonical viewpoint.

a)  b) 
Figure 3: Example pictures of the film clips used in experiment 2, arrows indicating direction of ball movement. a) shows balls moving towards the goal from the left to the right with 90˚ deviation between axis of ball movement and axis of sight. b) shows balls moving away from the goal towards the observer with 0˚ deviation between the two axes.

Results

Recognition accuracy For each participant his or her number of "hits" (the number of video stills correctly recognized as showing a moment from the ball sequence which he or she had previously seen) was determined. Across all participants and conditions a mean of 67.3 hits% resulted. Then an ANOVA with repeated measurement was performed, including the variables "canonicality" (high vs. low; within subjects), and "viewpoint deviation" (0˚, 45˚ or 135˚; within subjects). A significant main effect for "viewpoint deviation" was found ($F(2, 38) = 32.646$, MSE = 0,006571, $p < .01$) with 72.9 hits% at 0˚ viewpoint deviation between learning and test phase, 69.9 hits% at 45˚ viewpoint deviation and 59 hits% at 135˚ viewpoint deviation. Single comparisons according to Scheffé revealed significant differences between 0˚ and 135˚ viewpoint deviation as well as between 45˚ and 135˚ viewpoint deviation ($p < .01$). Accordingly, there was a significant linear effect of viewpoint deviation ($F(1, 19) = 52.432$,

MSE = 0.007386, p < .01), also indicating that recognition accuracy becomes worse the more the viewpoint used in the test phase differs from the initially presented viewpoint in the learning phase. In addition, the interaction (see Figure 4) between "viewpoint deviation" and "canonicality" became significant (F (2, 38) = 9.364, MSE = 0.004185, p < .01). Single comparisons revealed significant differences between high and low canonical viewpoints in the learning phase only if there was 0˚ viewpoint deviation (p < .01); further if the viewpoint in the learning phase was low canonical, there were significant differences between 0˚ (77.8 hits%) and 45˚ (71.5 hits%) viewpoint deviation (p < .05) as well as between 45˚ and 135˚ (57.7 hits%) (p < .01); but if the viewpoint in the learning phase was high canonical, there was no significant difference between 0˚ (68 hits%) and 45˚ (68.3 hits%) deviation, but only between 45˚ and 135˚ (60.3 hits%) deviation (p < .01). There were no more significant effects in this analysis of variance.

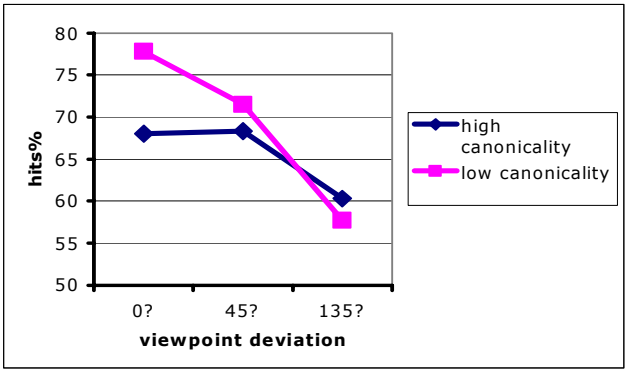

Figure 4: In experiment 2 for recognition accuracy there was a significant interaction between „viewpoint deviation“ and „canonicality“.

Recognition speed As a second dependent variable, reaction time was measured, i.e. the lapse of time from the beginning of each video still presentation until the participant pressed either the "j"- or the "n"-button. The following analysis only accounted for reaction times (RTs) to "hits" (i.e. correct "j"-reactions). Extreme RTs above 10 sec (i.e. more than 3 standard deviations above the overall mean) were excluded. This resulted in an exclusion of 1,16% of all RTs. To exclude outliers from analysis is a common method when dealing with reaction times (e.g. Cameron & Frieske, 1994; Diwadkar & McNamara, 1997; Eley, 1982; Hamm & McMullen, 1998; Lawson & Humphreys, 1996) because extremely slow responses indicate lapses of a participant´s attention on a particular trial. As the distribution of RTs was positively distorted, data were transformed by using natural logarithm, and analyzed in an ANOVA with the variables "canonicality" (high vs. low; within subjects), and "viewpoint deviation" (0°, 45° or 135°; within-subjects). For better vividness, the means reported in the text and figures are nontransformed RTs, despite the fact that the analysis of variance as well as the single comparisons were conducted using ln-transformed data. A significant effect was found for "viewpoint deviation" (F (2,38) = 12.194, MSE = 0.01284, p < .01). Applying single comparisons there were significant differences between 0° (2685 ms) and 45° (2944 ms) deviation (p < .01) as well as between 0° and 135° (3041 ms) deviation (p < .01). Accordingly also the linear trend for viewpoint deviation became significant (F (1, 19) = 16.387, MSE = 0.0179, p < .05). There were no more significant effects in this analysis of variance.

Discussion

In first line the results show once more (Garsoffky et al., 2002) a clear effect of viewpoint deviation: Recognition becomes worse the more the viewpoint from which one sees a cutout differs from the viewpoint from which one initially saw the sequence. This holds for recognition accuracy as well as for speed of recognition (see the two significant linear effects of viewpoint deviation). But the hypothesis that high canonical views in the learning phase weaken this viewpoint deviation effect receives only little support: On the one hand there is a significant interaction in recognition accuracy between canonicality and viewpoint deviation which shows that at least between 0° and 45° viewpoint deviation recognition accuracy does not become worse if in the learning phase a high canonical viewpoint is used. But on the other hand the use of a high canonical viewpoint in the learning phase does not weaken the viewpoint deviation effect between 45° and 135°. And at last there is no significant influence of canonicality on the viewpoint deviation effect for speed of recognition.

General Discussion

The results in the first place again support the stability and robustness of the viewpoint deviation effect for dynamic sequences (experiment 2): We used viewpoints that before (experiment 1) were rated as especially qualified to present critical aspects of visual dynamic sequences, namely the relative positions of the various balls to each other. I.e. these viewpoints were rated as being especially informative for this kind of dynamic event and therefore should allow to store in memory a maximum of discriminative information about the event. We hypothesized that if observers see dynamic sequences initially from these information rich "canonical" viewpoints, then the cognitive representations of the event should encompass more information and should therefore be more flexible if one has to rethink the event into other viewpoints – as demanded in the recognition task of experiment 2. But results show that the recognition performance still declines if the viewpoint presented during a later memory task differs from the viewpoint used in the initial learning phase, even if the observer initially saw the event from a canonical, information rich viewpoint. This means that the cognitive representation of a dynamic sequence still is viewpoint dependent, even if this viewpoint is especially information rich, i.e. delivers information about all or most important aspects of an event. This once more shows, that findings for static objects found by Biederman (Biederman, 1987; Biederman & Gerhardstein, 1993)

cannot simply be assigned to dynamic sequences: According to the geon structural description theory (Biederman, 1987) the cognitive representations of static objects are viewpoint independent, as long as these objects are shown from viewpoints that encompass the discriminative details of these objects, i.e. the so called "geons", and their relative positions to each other. Our findings contradict the applicability of this idea for dynamic sequences: Even using high discriminative viewpoints does not lead to a viewpoint independent cognitive representation; in fact the rethinking in other viewpoints still is critical for recognition performance. So our present findings rather point out, that findings with static objects or static arrangements of objects e.g. from Diwadkar and McNamara (1997), Shepard and Metzler (1971) and Tarr (1995) are more appropriate to predict memory processes of observers watching dynamic sequences, namely the formation of a viewpoint dependent cognitive representation (see the two significant effects of viewpoint deviation in experiment 2 for recognition accuracy and speed of recognition) and the occurrence of mental rotation processes (see the significant linear trend of viewpoint deviation in experiment 2) if new viewpoints are brought into play.

The Origins of Arbitrariness in Language

Michael Gasser (gasser@indiana.edu)
Computer Science Department; Lindley Hall 215
Indiana University; Bloomington, IN 47405 USA

Abstract

Human language exhibits mainly arbitrary relationships between the forms and meanings of words. Why would this be so? In this paper I argue that arbitrariness becomes necessary as the number of words increases. I also discuss the effectiveness of competitive learning for acquiring lexicons that are arbitrary in this sense. Finally, I consider some implications of this perspective for arbitrariness and iconicity in language acquisition.

A Language Design Task

Imagine you are inventing a language. It should associate signals ("forms") that can be produced and perceived by the users of the language with perceptual or motor categories ("meanings"). Assume that both forms and meanings are patterns of values across sets of dimensions and that you have been given the form and meaning dimensions. Assume further that the specific design task includes a set of meaning categories that need to get reliably conveyed. That is, given a particular pattern across the meaning dimensions, if it belongs to one of the given set of categories, a user who knows the language should be able to assign a form to it, that is, an appropriate pattern across the set of form dimensions. Similarly, given a pattern across the form dimensions, if it belongs to one of the set of form categories that you have built into your language, a user who knows the language should be able to assign a meaning to it. Furthermore, the form assigned to an input meaning should be the "right" form; that is, the form that gets output should pass the comprehension test in the reverse direction. Providing this form to a user who knows the language should result in an output meaning that is at least closer to the original meaning than to any of the other meaning categories. In the same fashion, the meaning assigned to an input form should pass the production test in the reverse direction.[1]

Your language is not hard-wired into a user; it must be learned through a series of presentations. A presentation consists of a pairing of a form and a meaning selected randomly from the set of possible form-meaning pairs that are built into the language, with a small amount of noise added to both the form and the meaning. Two constraints that you need to consider in your design are ease of learning and ease of storage. Each user has finite resources for learning and storage, and there is an advantage to languages that are learned with fewer presentations.

The main issue of concern in this paper is how the solution to a language design task of this type is constrained by the number of distinct meanings that are to be conveyed by the language. I will argue that there are advantages to languages with systematic relationships between forms and meanings and advantages to languages without such systematicity. I will then discuss how competitive learning fares at learning both types of languages. Finally I will discuss the implications for acquisition and evolution of human language.

Iconicity and Arbitrariness

How Iconicity Can Help

Learning the association between forms and meanings can be facilitated if there is a systematic relationship between the patterns. A simple example of such a relationship is a correlation between the values on a form dimension and a meaning dimension. There are two possibilities for where such a correlation might come from. One is for it to be based on a natural relationship between the two dimensions, for example, if they are the same dimension at a more abstract level. Such relationships are familiar in human language from onomatopoeia, in which form imitates meaning on one or more acoustic/auditory dimensions, for example, pitch. Examples of this type are more common in sign languages, where a movement of the hand in signing space may represent a physical movement of some object in meaning space.

A further possibility is for the relationship between the correlating dimensions to be completely arbitrary, or at least opaque to the users. In some sign languages, for example, American Sign Language and Japanese Sign Language, movement towards or away from the head represents the gain or loss of knowledge: learning, remembering, forgetting. But the motivation for the association between the form and meaning dimensions in this case would require that the user know that knowledge is in some sense in the head. Thus the relationship between the form and meaning dimensions in this case could be viewed as arbitrary by a particular learner, though the learner might still notice the systematicity of the rela-

[1] Note that in this sense, these simple languages deviate from human languages, which permit multiple forms for the same meaning and multiple meanings for the same form. But the constraint has to roughly hold for communication to get off the ground, and young children learning language seem to behave as though it does (Markman, 1989).

tionship, that is, that within this set of signs the head represents the location of knowledge.

These kinds of systematic relationships between form and meaning are referred to as **iconicity**. I'll return to the topic of iconicity and **arbitrariness**, the absence of iconicity, in human language later in the paper.

In an iconic language, there is less to learn than in a purely arbitrary language, so learning should be faster and require less storage. This is easily seen by imagining a language with five meanings to be conveyed and a single dimension each for form and meaning. An arbitrary language would require storing separately each of the five form-meaning pairs of values on this dimension, but a completely iconic language with a perfect correlation between the dimensions would only require a single value, a correlation of 1.0. This is illustrated in Figure 1.

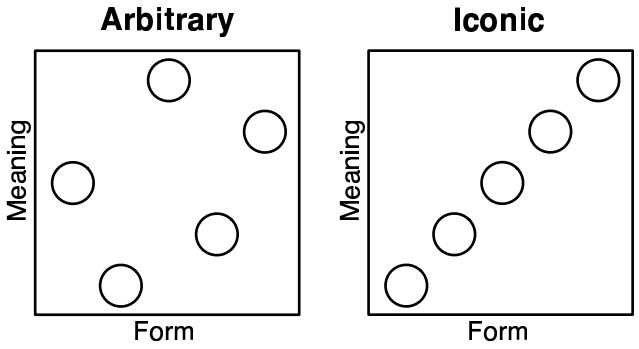

Figure 1: Arbitrariness and iconicity. Two simple languages, each with one form and one meaning dimension and five meanings to be conveyed. Noisy form-meaning pairs are indicated by circles in form-meaning space. In an arbitrary language, there is no correlation between form and meaning. In a perfectly iconic language, form and meaning correlate.

Iconicity can play a further role in the comprehension of the language. If an unknown or poorly learned form is presented in the presence of constraints on the possible meanings for the form, for example, if several candidate meanings are present, then iconicity can add further constraints. For example, if a user of a language knows that loudness in forms that refer to emotions tends to correlate with the strength of the emotion referred to, then for a particularly loud novel form, the user can eliminate candidate emotions that are mild.

How Iconicity Can Interfere

However, this advantage of iconicity should decline as the number of meanings to be associated with forms increases. Increasing the number of form-meaning pairs causes the average distance between these pairs in form-meaning space to decrease. Because of the noise that is part of form and meaning patterns, each form-meaning association occupies a region of the space. In other words, as the number of form-meaning pairs increases, the likelihood that the form regions for two different pairs share the same meaning (homophony) or that the meaning regions for two different pairs share the same form (ambiguity) increases. Obviously both sorts of overlap can interfere with communication; a noisy form pattern might get assigned to more than one meaning category, for example. They also interfere with learning; it will be more difficult to make the proper associations if forms or meanings are sometimes ambiguous.

Now consider how iconicity affects the likelihood of these sorts of overlap. Because iconicity constrains the possible form-meaning associations, it results in a narrowing of the space. This is illustrated in Figure 2. If we imagine the fixed set of meanings that are to be conveyed in the language as non-overlapping channels in the form-meaning space, then the possible forms for each can be viewed as circles (or hyperspheres in spaces of more dimensions) that can be slid back and forth in the channels, resulting in different languages. If we arrange two of these circles so that a portion of one is above a portion of another, we have the sort of overlap that represents ambiguity. There are obviously more ways to arrange the circles and avoid ambiguity in an arbitrary language like the one on the left than there are in a highly iconic language like the one on the right.

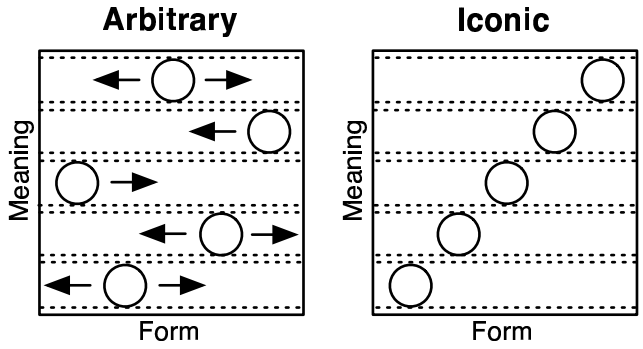

Figure 2: Arbitrariness, iconicity, and vocabulary size. For relatively large vocabularies, iconicity can interfere with communication because of the greater likelihood of overlap between form-meaning pairs. For a given vocabulary size, there are more ways to avoid ambiguity (and homophony) in an arbitrary than an iconic language.

A Simulation

For a learning algorithm that responds to regularities in the association between form and meaning, then, we should observe an interaction between vocabulary size and systematicity in the association (arbitrariness vs. iconicity), as measured by learning error.

To test this idea, I trained several feedforward connectionist networks to learn the associations from a set of meanings to a set of forms. The languages differed on two dimensions, vocabulary size and systematicity in the association. Both forms and meanings were represented by values along three dimensions, with ten possible values for each. Each dimension was represented by ten units, and each input and target value activated a gaussian pattern across the units so that there was the

possibility of some generalization from a value to values close to it.

The "small" languages contained 15 form-meaning pairs, while the "large" languages contained 100 form-meaning pairs. For "iconic" languages, each form-meaning pair coincided on two of the three dimensions, which were randomly selected for each pair. For example, a possible iconic form-meaning pair was: form {3, 2, 8}, meaning {3, 5, 8}. Note that for the iconic languages, there is thus a significant correlation across all three pairs of dimensions. For "arbitrary" languages, the values for each form-meaning pair were selected completely randomly. For each form-meaning pair, the network saw five separate presentations, one with the canonical pair, and four with noisy variations on this pair. For each of these variations, each dimension value was changed by 1 with a probability of 0.2.

Since these were feed-forward networks, they only learned the associations in one direction. Each network contained 30 meaning input units, 30 form output units, and 64 hidden units and was trained using back-propagation. Figure 3 shows the mean square error as training progressed. As can be seen, iconic languages have an early advantage because of the correlations that back-propagation can easily discover. For the small languages, this advantage holds throughout training. For the large languages, however, the network learning the arbitrary language eventually overtakes the one learning the iconic language, apparently because of the proximity of some of the form-meaning pairs to one another and the resulting confusion in the presence of noise.

Note that the potentially adverse effects of iconicity on learning depend crucially on the number of dimensions that are used to represent forms and meanings because the size of the form-meaning space increases with the number of dimensions. For a large enough number of dimensions, iconicity should be superior to arbitrariness, even for a relatively large vocabulary. In fact, if we increase the number of dimensions in the simulation from three to four, the long-term advantage of the arbitrary over the iconic language disappears.

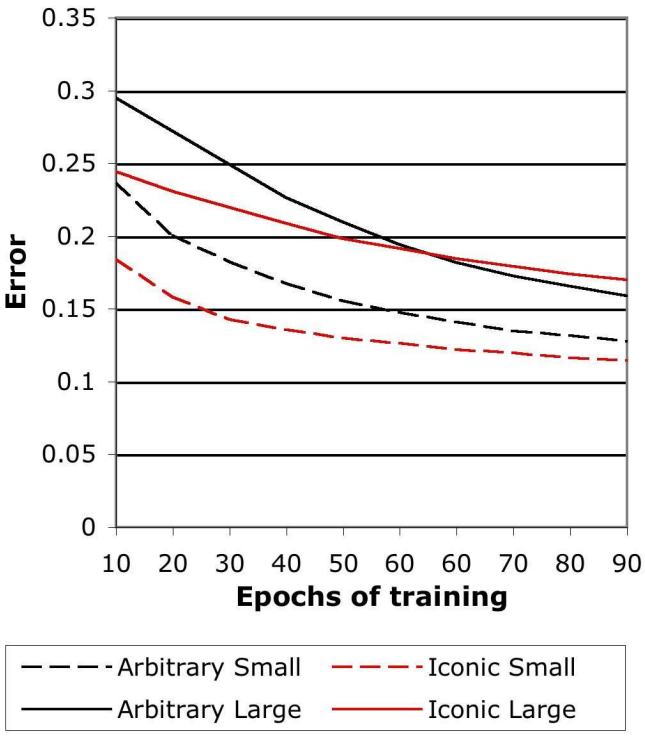

Figure 3: Learning of iconic and arbitrary languages by a feed-forward network. Root mean square error during training is shown for iconic and arbitrary languages consisting of 15 (small) and 100 (large) form-meaning pairs.

Arbitrariness and Competitive Learning

Learning Arbitrary Categories

Let us assume that the communicative demands of the users of the language require forms for a very large number of meanings and that the number of form and meaning dimensions available for representing forms and meanings is small enough that a mostly arbitrary language has a clear advantage over a mostly iconic one.

Now suppose we have some control over the kind of learner that is confronted with this large and mostly arbitrary language. What sort of learning mechanism would be best suited for this task? What matters most is that the different form-meaning pairs be kept distinct from one another. That is, each of these is in effect a separate category. (Since we are now dealing with categories of form-meaning association, it is time to start calling them "words.") Since in an arbitrary language there is little or no regularity to be found between the categories, an algorithm that focuses on within-category regularity, while it ignores between-category regularity, makes sense. Of course, the categories are not specified to the learner in advance; the learner neither knows how many form categories there are nor how many meaning categories there are. Thus the algorithm must be unsupervised.

Competitive learning (e.g., Grossberg, 1987) is such an algorithm (or family of algorithms). It seeks to cluster input patterns on the basis of similarity, and it is oblivious to any regularities that exist between the categories that it finds. It would seem to be well-suited to the task of learning words. But how does it respond to iconicity and arbitrariness?

A competitive learning network has an input layer and an output layer consisting of potential category units. The output layer either has a fixed number of units, representing an upper bound on the number of categories that can be learned, or, in a constructive competitive learning algorithm, the output layer adds new category units in response to error. In the simple version of competitive learning used here, for each input pattern the category unit whose weights best match the input pattern is treated as the "winner" for that pattern. It updates its input weights in the direction of the input pattern. The "losing" units also update their weights in the direction of the input, but with a much smaller step size.

A competitive learning network for the form-meaning

learning task has both form and meaning as inputs feeding into an output layer of category units. During training, an input pattern consisting of a form-meaning pair activates a winning unit, and the weights are updated. Ideally, a single category unit gets assigned to each form-meaning category; that is, each unit ends up representing a word. A single training presentation is illustrated in Figure 4A.

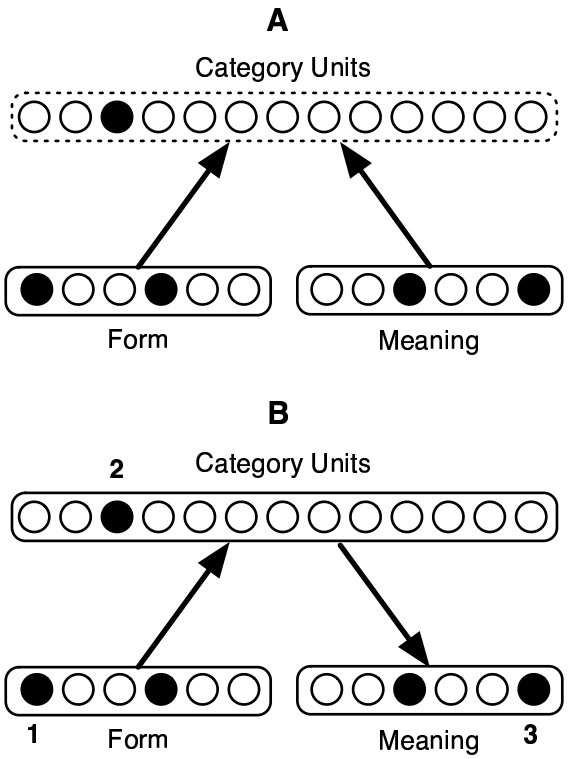

Figure 4: Competitive learning of form-meaning pairs. A. Training. An input pattern, consisting of both form and meaning patterns, is presented to the network, which selects a "winning" category unit, and updates its weights and, to a lesser extent, the weights of other units. In the constructive version of the algorithm used in the simulation, the category layer grows during training (indicated by the dashed border); it adds a new unit whenever error for an input pattern is above a threshold. B. Comprehension. An input pattern, consisting of a form pattern only, is fed to the network (1) and the winning category unit is activated (2). The active category unit activates a pattern on the meaning units (3).

Following training, the network can perform production or comprehension using the trained weights. For comprehension, a form pattern alone is input to the network, and a winning category unit is selected on this basis. This unit then activates the meaning units using the weights learned in the other direction. Production works in the opposite fashion, with meaning as input and form as output. Figure 4B shows how comprehension is implemented.

A Simulation

To test whether competitive learning could elucidate both the advantages and disadvantages of iconicity, I trained a competitive learning network of the type described above on both a completely arbitrary language and a maximally iconic language, in which all form dimensions correlated with meaning dimensions. There were four meaning and four form dimensions and 100 form-meaning pairs in the language. In addition to the form and meaning input layers, the network had a growable layer of category units. At each input presentation, a new category unit was added with a probability based on the error for the input pattern (the distance of the winning category unit from the input). Separate identical networks were trained for 50 epochs on the two kinds of languages. Figure 5 shows the results for several kinds of tests following training.

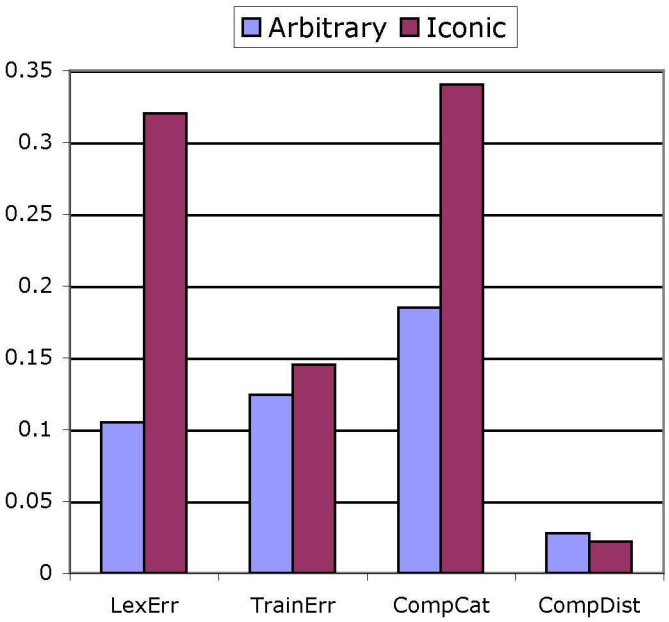

Figure 5: Competitive learning of arbitrary and iconic languages. Results are shown for the proportion of words that are not assigned distinct category units ("LexErr"); the final error on training patterns, that is, the average distance of input patterns from winning category units ("TrainErr"); the proportion of words in comprehension tests for which the meaning output was closer to a meaning category other than the intended one ("CompCat"); and the average distance of the meaning output in comprehension tests from the intended meaning ("CompDist").

The first two columns show tests directly related to the degree to which the networks mastered the languages. The first column shows what proportion of the 100 words became associated with distinct category units during training. Any category unit that ends up representing more than one word will obviously interfere with comprehension or production. For the iconic language there are more units doing double duty because of the greater similarity between the words. The second column shows another measure of learning, the average distance between an input pattern and the category unit that wins

when it is presented following training. The smaller this number, the more successful the network has been in handling all of the words. Again the network trained on the arbitrary language out-performs that trained on the iconic language.

The third and fourth columns represents tests of comprehension of forms, one for each of the words in the training set. There are two ways to test comprehension. One determines whether the meaning that is output is closer to the intended meaning (the one actually associated with the form in the language) than to any other. The result for this test appears in the third column. Again the arbitrary language has an advantage. A second way to test comprehension measures the distance between the meaning that is output and the intended meaning. The result for this test appears in the fourth column. Here the iconic language has a small advantage, one that holds over a range of parameter settings. This can be explained by considering what happens when a noisy or poorly learned form is presented to a network that has learned the iconic language. Even if the category unit that wins for this input is not the appropriate one, that is, the one that would yield the intended meaning, the meaning that is output will not be far off. Somewhat surprisingly, then, even though the iconic language is less well learned, it is more easily comprehended in this sense.

Human Language

What does all of this have to do with human language? Since at least the work of de Saussure (1983), it has been recognized that the association between form and meaning in human language is largely arbitrary. However, in Saussure's work and in other influential work by scholars such as Peirce (1998), iconicity and arbitrariness seem never to have been spelled out clearly enough to admit to any sort of rigorous test. They have always boiled down to "motivation" or "resemblance" or their absence.

The discussion above provides both a formalization of iconicity and arbitrariness and an account of why human language might have a strong tendency to be arbitrary. For whatever reason, we need to distinguish tens of thousands of categories of objects, attributes, states, and events, and the associations between these categories and the forms that convey them in a language need to be stored in a brain and to be learned through presentations that do not make explicit what the categories are. Under these circumstances, the arbitrariness of the form-meaning association helps keep words separate during learning.

Another implication of the discussion above is that word learning and word access in humans is a competitive process, that words are categories. This isn't a novel idea at all. In fact models of word recognition (e.g., Norris et al., 2000) and word access in language production (e.g., Levelt et al., 1999) that are not competitive are the exception. And the fact that competitive learning results in localized representations of words is compatible with the idea that words are the origin of symbolic behavior (Vygotsky, 1978).

But this brings up more questions. First, what about iconicity in human language? It is well-known that, far from being non-existent, iconicity actually thrives in some corners of language (Hinton, Nichols, & Ohala, 1994). It is a property of so-called expressive words, which make up an entire grammatical category in a wide range of languages, including Japanese, Korean, and many languages spoken in Africa, South Asia, Southeast Asia, and the Americas. It is also much more common in sign languages (Taub, 2001) than in spoken languages.

Given what I have claimed, we would expect iconicity in circumstances where the number of words is unusually small or in circumstances where the space of possible distinguishable forms is unusually large. The number of words is small early in first language acquisition, and there is some evidence that in at least one language with a large category of iconic words, Japanese, these words are relatively common in speech to children and they are easier for children to map onto meanings than arbitrary forms are (Yoshida, 2003). That is, they seem to play the role in comprehension that is suggested by the discussion above. Another situation in which a vocabulary is very small is experiments in which which adults have to communicate with one another without speaking. Not surprisingly, subjects in such experiments create highly iconic gestures to represent categories of objects and relations (Oda & Gasser, 2003).

However, expressives survive into the adult language for speakers of languages like Japanese, Tamil, and Zulu. One possible explanation is that these categories are more or less self-contained, existing in a sense in their own space. They tend to be characterized by particular formal properties such as reduplication, and they tend to convey particular categories of meanings such as movements, sounds, and textures. Perhaps expressives fail to interfere with other words because learners place them in a category all by themselves.

But what of sign languages? Although there is no evidence yet that the iconicity of sign languages helps young children pick up the meanings of words, there is lots of anecdotal evidence that adults learn sign languages relatively rapidly, presumably because of the iconicity. But how can we account for the pervasiveness of iconicity in the vocabularies (not to mention the grammars) of these languages? Although there is an apparent tendency towards somewhat less iconicity as these languages change, there is no evidence that the iconicity is disappearing (Taub, 2001). Of course it is possible that sign languages are more iconic than spoken languages because there are more ways to be iconic in the spatial than in the acoustic domain. But that does not explain how all of the iconicity can be tolerated, how the words keep from overlapping in the sense I have discussed. One possibility suggested by the account I've sketched is that the space itself is larger, that the number of dimensions along which signs vary or the number of distinguishable values along these dimensions is greater than it is for spoken word forms. This seems worth investigating.

Finally, how would competitive learning deal with a

language, or a subset of a language, that exhibited some iconicity, along with the more normal arbitrariness? The competitive network discussed above is doomed to being thrown off by the iconicity. Although it might, in the short run, perform better on a comprehension task, as happened in the simulation above, in the long run, it needs to be able to keep words separate from one another. However, there is nothing about competitive learning that restricts it to a single layer of category units. A more flexible network in fact is one that allows for different degrees of granularity in how the clustering of inputs takes place. This is achieved with layers with different numbers of category units or, for constructive networks, with different thresholds for the creation of new category units. The competition among units to classify inputs is only within, not between the layers. Such a network is shown in Figure 6. A network like this was trained on a set of 100 words, again with four form and four meaning dimensions, in which either the first form and first meaning dimension correlated or the second form and second meaning dimension correlated. The other two dimensions of form and meaning were uncorrelated. The larger category layer learned the set of words as before (note that the behavior of this layer is completely unrelated to the behavior of the other), while the smaller layer divided the patterns into two clusters. A comprehension task in a network like this relies on two winning category units, rather than one. That is, it can combine the correlational information embodied in the weights to the smaller layer with the arbitrary associations embodied in the weights to the larger layer.

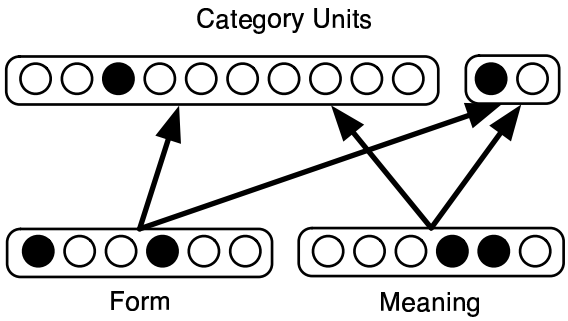

Figure 6: Competitive learning with multiple layers of category units. The number of category units (or the threshold for the creation of new units) in a layer governs the number of categories that it discovers.

Conclusions

Since iconicity seems to make so much sense and since humans are so good at imitation, it might seem surprising that human languages exhibit such overwhelming arbitrariness in the form-meaning relationships that define words. I have tried to show in this paper how the sheer number of concepts we feel the need to talk about inhibits us from making use of this strategy. It's crucial that words be kept separate, and it's easier to do this if there's little or no sense to how forms relate to meanings. This arbitrariness in turn favors algorithms that categorize form-meaning pairings, in short, algorithms that learn words. On this view, words are the local representations that result from the competitive learning of mainly arbitrary form-meaning associations.

But if this is so, how did it or how does it get that way? Did the advantage of being a competitive learner of form-meaning pairings cause our ancestors to evolve this approach to language? Or is this a mechanism that develops in children as they are exposed to a system that mostly fails to be iconic? Investigating the first possibility using evolutionary algorithms and investigating the second through the modeling of early word learning in children are future directions for this project.

On the Nature of Cognitive Representations and on the Cognitive Role of Manipulations. A Case Study: Surgery

Alberto Gatti (gatti3@unisi.it)
Department of Philosophy and Social Sciences, University of Siena
Via Roma 47, 53100 Siena, Italy

Abstract

The main point of discussion of the present article is the nature of representations, their formal structure and their origin and the cognitive role that manipulations of the environment can have. After having briefly reviewed the perspective expressed by the physical symbol system hypothesis, I take into account surgery as a case study that points out how many manipulative actions performed upon the environment have a cognitive relevance and the importance that the interaction with the environment can have in generating the representations used in cognitive processes and in giving them a formal structure. In the last part of the article I propose a model, that I call *Double Representation Approach*, which tries to give an explanation of the nature itself of representations, of the way they work in the cognitive processes and of certain important human cognitive behaviors.

Physical Symbol System Hypothesis

When first attempts were made to understand human cognition, one of the concepts that emerged as central was that of representation. A classical paradigm in which the notion of representation grew up was the hypothesis that an agent capable of intelligent action must be a physical symbol system (Newell, 1980; Newell & Simon, 1976).

A physical symbol system is a sort of device that contains symbols and symbol structures in memory and can perform processes upon these symbol structures. In more detail, according to the physical symbol system hypothesis, a physical symbol system and, thus, cognition performs three functional processes that occur sequentially and that are controlled by a central information processor. The three functional processes are the following: 1) a symbolic representation of the environment is constructed by means of a perceptual process performed by a perception subsystem; 2) the symbolic representation that has been constructed is delivered to the central processor, which processes it in order to extract information and to be able to select a symbolic expression that stands for an action; 3) an action subsystem decodes the symbolic description of the action and converts it into a concrete action in the environment.

It is important to understand what the terms "symbol" and "physical" mean. According to the classical definition given by Newell (1980), a symbol is an entity that stands for another entity. This kind of relation is called *designation* and its definition, with Newell's words, is:

> *Designation*: An entity X designates an entity Y relative to a process P, if, when P takes X as input, its behavior depends on Y. (Newell, 1980, p. 156).

Thus, a symbol is a syntactic element of a code and can be connected to other symbols to form symbol structures.

The term "physical" refers to the need for a physical implementation of a symbolic system in order for it to actually function and to actually operates upon and affect or be affected by the environment.

Following these definitions, we can distinguish three levels of organization in which a cognitive system can be divided: the semantic level, the symbol level and the physical level (Pylyshyn, 1989). At the semantic level, we have the content of knowledge and the goals that a system entertains. At the symbol level, the semantic content of the previous level is encoded by symbolic expressions. Finally, the physical level is constituted by the physical realization of the entire symbol system; in the case of humans, this level is represented by the biological level.

The postulation of a cognitive mechanism that works by means of symbols and symbol structures strictly implies the assumption that cognition takes place by means of internal representations and Newell (1980) considers "representation" as "simply another term to refer to a structure that designates" (Newell, 1980, p. 176):

> X *represents* Y if X designates aspects of Y, i.e., if there exist symbol processes that can take X as input and behave as if they had access to some aspects of Y. (Newell, 1980, p. 176).

Thus, according to the classical symbolic perspective, the central notion is that of representation. Now what we have to pay attention to and to focus on are two characteristics that Fodor and Pylyshyn (1988) indicate as the ones that identify classical symbolic models. Such characteristics are the *combinatorial syntax and semantics of mental representations* and the *structure sensitivity of processes*.

Let us begin with the first concept. Classical symbolic theories distinguish between structurally atomic and structurally molecular representations; structurally molecular representations are constituted by other representations that can be either atomic or molecular and the semantic content of a molecular representation is a function of the semantic contents of its syntactic constituents. According to this perspective, a *Language of Thought* (Fodor, 1975) is postulated, with syntactic components and structural relations between these components.

The second point is the structure sensitivity of processes. What this assumption means is that the principles by which mental representations are manipulated rely only on the structural properties of symbolic representations. More precisely, the formal, syntactic structure of a representation specifies the role of the representation within an inference and can cause the inferential process without reference to

the semantic content. Hence, the mental operations upon symbolic representations are activated only by the form of the representations.

So far, I have tried to delineate the main features of the classical physical symbol system hypothesis. In the following section, by means of a case study applied to the field of surgery, I want to question some aspects that emerge from the physical symbol system hypothesis.

A Case Study: Surgery

The arguments and claims that will be presented in the following two subsections emerge from a case study on surgery that I am conducting in the field in order to analyze the cognitive processes that go on in the work of surgeon. In particular, this study is devoted to analyze which kinds of representations are used in surgery, what the role of physical manipulations is, whether they have a cognitive relevance and how the distribution is of the cognitive processes involved in surgery.

In the following two subsections I want to point out two important cognitive elements: 1) the physical gestures involved in the processes of perception of data from the environment and 2) the formal structure and the origin of the representations used in cognitive processes. I will use surgery as a reference case and I will try to point out some relevant differences with respect to the classical physical symbol system hypothesis. In the first subsection I will take into account the case of a generic objective examination of the abdomen. In the second subsection, I will consider a specific surgical operation: inguinal hernia.

Objective Examination

The first step in the process that brings to a surgical operation is the examination that the surgeon conducts on the patient who feels specific symptoms. After a brief discussion to reconstruct the history of the patient, the surgeon begins what is called objective examination. Objective examination is a process of gathering of diagnostic data from the patient's body which is guided by the four evaluation principles of medical semeiology: inspection, auscultation, palpation, percussion (DeGowin & DeGowin, 1976; Swartz, 2002). In this subsection I take into account the case of a generic abdominal examination. This kind of examination is constituted by a series of evaluation acts that the surgeon accomplishes on the patient's abdomen by means either of external instruments or of parts of the body of the surgeon herself. In addition, this examination involves the cooperation of the patient, who is sometimes asked to make specific actions in interaction with the examination acts of the surgeon.

A generic abdominal examination can be schematized as in the following table 1.

Table 1: Abdominal objective examination.

	Evaluation action	**Means**	**End**
1	Inspection of the abdomen as a whole	Eyes	To evaluate how the aspect and the shape of the abdomen are
2	Inspection of the abdomen after having asked the patient to profoundly breathe	Eyes	To evaluate whether the abdomen moves
3	Auscultation of the abdominal wall before stimulating it with palpation	Stethoscope	To evaluate if there exists an intestinal peristalsis and how it is
4	Superficial palpation of the abdomen	Hands	To evaluate if there are signs of resistance to the abdominal wall that are linked to pathological situations
5	Deep palpation of the abdomen	Hands	To catch the aspects that the various parts of the abdomen can exhibit and that are linked to the contained bowels: -Consistence -Tension -Existence of masses
6	Auscultation of the abdominal wall after the stimulation by means of palpation	Stethoscope	-To evaluate whether, after having touched and moved the abdominal wall, an increase or decrease of the intestinal peristalsis has occurred -To evaluate if there is liquid out of the intestinal loops

The most important element that we can observe in the objective examination and that emerges from the scheme above is the following one: the surgeon uses specific per-

ceptive actions in order to catch and gather specific diagnostic data from the body of the patient. The data that the surgeon gathers are diagnostic signs that suggest a particular diagnosis or several different diagnoses and that help the surgeon in her abductive inference toward a final diagnostic hypothesis (Magnani, 2001). As diagnostic clues, the signs collected by the surgeon can be viewed, from a cognitive point of view, as representations that carry information.

The main feature of these representations is that they are constituted by structured sensations that the surgeon receives in response to her own structured perceptive actions. Therefore, two important aspects emerge: 1) the representations which are the diagnostic signs collected by the surgeon are sensations that the surgeon receives from the environment (the patient's body); 2) such representations are elicited and constructed by perceptive actions by means of which the surgeon interacts with the patient's body. These two points are important because they open the possibility to think of representations and cognitive processes in a new way which is different from the classical symbolic perspective.

According to the physical symbol system perspective, the representations that are used in cognitive processes are symbolic configurations that are inside the head of the cognitive agent. These representations are completely internal and are constituted by the symbols of a single language with a specific syntax. The case of medical examination seen above seems to lead to a more embodied perspective. It seems plausible to state that the representations on which the surgeon relies during an objective examination have, as formal structure, the one constituted by the sensations themselves that the surgeon receives. This formal structure can vary across a great range and, hence, is not the single one of the symbols of a single symbolic language.

Embodiment is also present at the level of cognitive processes. The physical symbol system perspective does not seem to give importance to the perceptive process as a moment in which not only data are simply perceived from the environment, but the environment is inspected and manipulated in specific ways in order to elicit more information. The perceptive actions that the surgeon performs during an objective examination have a strong epistemic value (Kirsh & Maglio, 1994), because they are devoted to examine the patient's body in specific ways so as to obtain specific information. These structured actions structure the sensations that the surgeon receives, that is, they structure her own representations.

A Surgical Operation: Inguinal Hernia

In this subsection I take into account a particular surgical operation as a case to point out some relevant aspects about the formal structure and the origin of the representations used by a cognitive agent. The surgical operation that I consider is the one of inguinal hernia in a male patient (Rutkow & Robbins, 1995; Shwartz, Spencer, Galloway, Tom Shires, Daly & Fisher, 1998; Trabucco & Trabucco, 1998). Inguinal hernia occurs when anatomical elements that are naturally contained in the abdomen enter the inguinal canal. Table 2 shows a schematic description of the main steps of an inguinal hernia operation in a male patient.

Table 2: Main steps of an inguinal hernia surgical operation

1	Incision of the cutis at the level of the inguinal canal
2	Incision of the fascia of the external oblique muscle to have access to the inguinal canal
3	Isolation of the spermatic cord
4	Isolation of the hernial sac
5	Rearrangement of the hernial sac into the abdomen
6	Hernioplasty at the level of the posterior wall of the inguinal canal
7	Suture of the fascia of the external oblique muscle previously cut
8	Suture of the cutis

One of the most relevant aspects of the inguinal hernia operation is that this operation requires a precise knowledge of the anatomy in order to recognize and carefully isolate the various anatomical structures that are found in the inguinal canal in an anatomical situation which has been altered by the hernia itself.

The main cognitive process which is involved in this surgical operation is, thus, the process of recognition. I define recognition as a matching process in which the real situation with which an agent has actually to do matches the salient features of an already defined internal representation that the agent entertains and that represents that identical situation or an analogous situation. Thus, in the case of surgery, a mechanism of recognition of an anatomical structure occurs when the anatomical configuration that the surgeon is confronting matches the internal representation that the surgeon entertains for that anatomical area.

Now, the first contact that a surgeon has with the external aspect of the anatomical structures of the human body is in the study of the illustrative anatomical tables on the anatomy books. This is the first moment in which the surgeon takes an anatomical representation that comes from outside and tries to memorize it, i. e., to bring it inside. I call this process internalization of an external representation. But every surgeon states that there is a difference between the book anatomy and the actual anatomical structures encountered in a real body, especially in those cases in which the anatomy has been altered by the pathological event, as it is in the case of the inguinal hernia. For this reason every surgeon states that recognizing the anatomical structures is a fact of experience.

Experience is a concept that deserves to be analyzed from a cognitive point of view. I have said above that the surgeon internalizes the anatomical representations that she studies on the anatomy books and that there is often a mismatching between these representations and the anatomical structures encountered in a real situation. Therefore, in order for the surgeon to be able to recognize anatomical structures in an actual situation, the book representations of the anatomy that the surgeon entertained must change in order to be in accordance with the anatomical structures actually encountered. Through the direct contact with the real anatomical elements, a process of change and adaptation of the previously internalized representations occurs. This is another

process of internalization, but more complex and slower than the previous one and slightly different from it.

This new process of internalization of external representations occurs by means of the repeated observation of many cases similar to each other and it is similar to a process of abstraction, in which, however, the final abstract representation is constituted by elements that have their deep origin in the experienced external elements. I use for this process the name of experience and I define experience as the process of internalization of external representations and of progressive change and adjustment, through the contact with the environment, of the internalized representations during which such representations acquire a configuration that conveys precise information in an unambiguous way and that can fit several different particular situations.

Also in the case of experienced surgeons there can be situations in which it is difficult to recognize the anatomical structures. This happens when there is such a situation in the operating field that a gap is created between internalized representations of the surgeon and actual configuration. It is in these circumstances that we can see again the cognitive role that manipulations can play. When anatomical data are confused and, therefore, the mechanism of recognition is made difficult, surgeons often make use of manipulations in order to find known anatomical reference elements. These manipulations are devoted to fill the gap between actual situation and internalized representations and, thus, they have an important cognitive relevance. The surgeon, for example, in front of a situation in which she cannot see an anatomical structure that she can usually see, almost always uses her hands to touch in certain areas in order to find anatomical reference elements that she expects on the basis of one of her internalized representations.

In this example is evident the cognitive role played by the manipulation, which examines the internal parts of a human body to construct an embodied representation which be in accordance with the internalized representation of the surgeon herself. At the same time, if the internalized representation of the surgeon is visual, in this example the surgeon is bringing into coordination two different representations of the same information, a visual representation and a tactile representation and this can be taken as an evidence that demonstrates that human cognitive agents are able to handle and, in fact, handle different representational codes and not a single one.

The case of surgery seems to push toward cognitive hypotheses that give the environment and the manipulations that humans perform upon it a predominant role as to the process of generation of the representations used in cognitive processes and as to their formal structures.

Double Representation Approach

In the previous section I have presented a case study and I have advanced some hypotheses about the origin and the formal structure of representations. In the present section I propose a model that tries to explain in a more detailed and more schematic way the nature and origin of representations and some critical cognitive behaviors that we can observe in human beings.

The classical view within cognitive science drew a distinction between what was called functional architecture and what was called anatomical architecture (Pylyshyn, 1989). The anatomical architecture can be considered as the implementational basis on which the functional architecture is realized. The functional architecture, instead, has to do with the algorithms that the mind uses when it carries out cognitive processes. The classical view concentrated its attention especially on the functional architecture and, in some cases, even argued that the physical level can be considered as a matter of implementational details. The functional architecture was described as the place of symbolic processes in which internal symbolic representations was processed. The symbols had an arbitrary relationship with their referents and formed symbolic structures which had a combinatorial syntax and semantics.

I want to revise the distinction anatomical architecture versus functional architecture and take into account the relationships that can take place between anatomical and functional architecture. To do so, I propose an approach that I call *Double Representation Approach*. Such approach locates two different representations as the components of any cognitive process that takes place in the interaction between human agent and environment. The idea is as follows:

1) **First-Level Representation**: this is the *pattern of neural activation* that arises as the result of the interaction between body and environment. This is the representation at the anatomical level and this is not the representation that human agents directly use in their cognitive processes.
2) **Second-Level Representation**: this is the thing for which the pattern of activation stands and this thing is the *sensation* that emerges from the encounter between our receptors and the structures of the environment and that is shaped by the structure itself of the environment. This is the representation at the functional level and this is the representation used by human agents in their cognitive processes.

The First-Level Representation is called representation because it is a pattern that has an analogical relationship with the structure of the environment and, thus, can be considered as an analogical representation of the environment. The Second-Level Representation could be considered as the "face" that we think the world has; in a certain sense it could be considered as the world itself. This assertion comes from the consideration that the world is always given to us through our sensorial perception, which can be considered, at last, as the only possible representation in which we can receive the physical world and the representation which is closest to the physical world. This means that the Second-Level Representation, even though it cannot be defined exactly as the world itself, has a strict relationship with the world. Now, I call representation the Second-Level Representation because the structured configurations of the environment are used in cognitive processes because of their carrying specific information, their representing such information. Therefore, the representations are the form of cognitively relevant information, they embody this information.

Now I want to explain in more detail what consequences the Double Representation Approach has on the way we can account for the way human agents reason. The First-Level Representation has a twofold influence on the way humans reason, the first one is direct, the second one is indirect and is mediated by the Second-Level Representation. We propose the following scheme:

1) The First-Level Representation, as a pattern of neural activation, can be assumed to influence the basic mechanism that underlies any cognitive process, regardless of the specific kind of representation used and of the specific algorithm followed. This basic mechanism can be assumed to be the one constituted by the construction of a pattern of elements and the fixation of this pattern.
2) Thanks to the analogical relationship between the patterns of neural activation (First-Level Representations) and the structures of the environment, the Second-Level Representations which we entertain reflect the structures of the environment. Therefore, human agents use representations that have several different formal structures each of which influences in a different way the reasoning process.

The Double Representation Approach can provide an account not only of the representations that originate in a direct contact between agent and environment, but also of those representations that human agents generate internally in the absence of the environment in order to solve a problem, represent a goal and so forth. The representations that originate in the contact between agent and environment take, at the first level, the form of patterns of neural activation and patterns of neural activation, after adequate training, tend to become stabilized structures and to fix. At this stage the patterns of neural activation no longer need a direct stimulus from the environment for their construction and fixation. In a certain sense they can be viewed as fixed internal records of external structures that can exist also in the absence of such external structures. These patterns of neural activation that constitute the First-Level Representations always keep record of the experience that generated them and, thus, always carry the Second-Level Representation associated to them, even if in a different form, the form of memory and not the form of a vivid sensorial experience. Now, the human agent, via neural mechanisms, can retrieve these Second-Level Representations and use them as internal representations or use parts of them to construct new internal representations very different from the ones stored in memory.

In the case of human beings, whose neural growth, according to the studies in neural constructivism (Clark, 2003; Quartz & Sejnowski, 1997), seems to be strongly environment-dependent, if we assume a strong relationship between neural mechanisms and cognitive processes, we are brought to the conclusion that the representations used in cognitive processes have a deep origin in the experience lived in the environment.

At least three conclusions can be drawn from the discussion above. First, as I have already said, the analogical relationship between First-Level Representations and environment causes the representations that human agents use in cognitive processes, that is, the Second-Level Representations, to be able to have various formal structures, we could say various types of syntax and not a single one. The Double Representation Approach tries to provide an explanation of the mechanisms that would occur in those cases in which it seems evident that humans are handling various types of representations.

Second, the Double Representation Approach seems to explain why human agents accomplish both computations of a "connectionist" type, such as pattern completion or image recognition and computations that use a combinatorial syntax and semantics, such as the ones exhibited in language usage. The First-Level Representation is generated as a pattern of neural activation and, if we assume, as I do, a more direct relation between neural basis and mechanism of reasoning, the mechanisms of connectionist creation of the neural pattern that constitutes the First-Level Representation could sometimes influence in a direct manner the mechanisms of reasoning carried out by means of the Second-Level Representation. This would explain the computations of a connectionist type. But, on the other hand, the First-Level Representation, in virtue of its connectionist character itself, has an analogical relationship with the environment and gives rise to structured sensations, that is, Second-Level Representations, that reflect the structures of the environment. Therefore, the cognitive agent can exploit all the syntactic structures that it finds in the environment and, most important, can follow the computations suggested by these structures. Now, among the syntactic structures that an agent can encounter there are the combinatorial ones and this would explain the combinatorial computations we experience.

Third, the fact that the Second-Level Representation is directly connected to the First-Level Representation and, thus, emerges from the interaction between body and environment points out the importance of the manipulative actions at the cognitive level. We can say that, in many cases, it is the actions of manipulation of the environment that create a specific representation that embodies specific information. In this sense, the Double Representation Approach could give an explanation to all those actions that human beings seem to perform not for achieving a physical goal, but for gathering specific information.

Conclusion

In this article I have first reviewed the classical physical symbol system hypotesis and I have concentrated on the fact that, according to this classical perspective, the representations that humans use in their cognitive processes would be internal symbolic structures of a single language with a specific syntax.

Subsequently, I have taken into account surgery as a case study to point out that the manipulations that humans use to perceive the environment may have a specific cognitive value and that the interaction with the environment plays a direct role in generating the formal structure of the representations used by human cognitive agents in their cognitive processes. The hypothesis that seems to emerge is that hu-

man agents use not a single representational code, but representations that can have multiple formal structures.

Finally, I have tried to construct a model that was able to explain in a more detailed way such hypothesis about the use of representations of multiple formal structures and that was able to provide an embryonic hypothesis about the way human cognition works.

Abstract

Event Related Potentials (ERPs) were recorded from 20 young subjects to auditory target stimuli while they were performing three different tasks, using an odd-ball paradigm; 1. Tones: Subjects were instructed to respond to a 2kHz tone, and ignore a 1kHz tone. 2. Phonological: Subjects were instructed to respond only to words that had a specific ending ("f"). 3. Semantic: Subjects were instructed to respond to words that belonged to a specific category (name of alphabetic letters). EEG was recorded from 19 electrode sites. Peak amplitude of the early component (N100) did not differ significantly across the three tasks, while peak latency differed significantly across stimuli. In contrast, the later endogenous component (P300) was stimulus- and task-dependent. P300 latency differed significantly across stimuli and tasks; 327 ms to target tones; 668 ms to the phonological targets; and 706 ms to target words in the semantic task. P300 amplitude was significantly larger to tones than to linguistic stimuli. P300 peak amplitude recorded from electrode sites over the left hemisphere to the tonal target stimuli did not differ significantly from that recorded over the right hemisphere. In contrast, P300 amplitude recorded to both the phonological and semantic targets was significantly larger over the left hemisphere than over the right hemisphere. The present results can aid in our understanding of how humans process linguistic stimuli. These findings emphasize the importance of using similar experimental protocols for a broad comparison of the ERP response to a variety of stimuli and tasks.

Introduction

The process of auditory speech perception requires the use of sensory information in conjunction with linguistic knowledge. Event related potential recordings which have been increasingly used in the research of human cognitive processes, can provide information on the patterns of cortical activity that underlie different modes of processing various kinds of auditory and linguistic information.

The use of P300 for auditory presented tonal stimuli is well known. Studies have compared the ERP responses to tonal stimuli to vowels (Tiitinen et al 1999), syllables (Kayser et al 2001) or words (Lovrich et al 1988) and reported prolongation of latency as well as decrease in amplitude. These differences reflect the involvement of different processes in tonal and speech stimuli.

Using tonal stimuli Polich (1997)) reported an asymmetry in P300 amplitude with right hemisphere dominance specifically at the frontal and central electrode sites. They interpreted the data as reflecting the allocation of attention. Other researchers (Bruder et al 1999, Breier et al 1999) did not observe any laterality effect. Using speech stimuli a left hemisphere advantage was observed for phonemes, syllables (Kayser et al 2001, Alho et al 1998) and word stimuli (Breier et al 1999).

Studies have examined ERP morphology and topography using linguistic stimuli (Novick et al 1985, Henkin et al 2002). There seems to be an agreement among researchers that while phonological processing is characterized by a left hemisphere advantage, semantic processing is less localized, since it involves the activation of distributed networks in the brain (Lovrich et al 1988, Thierry et al 1998, Angrilli et al 2000).

In the present study, we used the oddball paradigm to generate a clear P300 component. We suggest that this paradigm, and specifically the P300 component, is appropriate to compare the ERP to a variety of target stimuli that lie along a continuum of auditory processing, from basic sensory discrimination of auditory features (tones) to cognitive language processing (e.g. phonology and semantics).

Methods

Subjects:

Twenty University students ranging in age from 20-26, mean age 22.5 (10 male and 10 female) participated in the study as part of their course requirement. Written informed consent was obtained, and the Bar Ilan University Ethic committee approved all experiments.

All subjects reported they were right handed, native Hebrew speakers, healthy and had no history of neurological or psychiatric disease. All passed a hearing screening test

performed in a quiet room using the Madsen OB 822 audiometer.

Stimuli:

Three different auditory tasks were tested using the oddball paradigm. One task consisted of tonal stimuli, and the other two tasks consisted of speech stimuli:

Tones: Subjects were instructed to respond to a 2kHz pure tone target and ignore the standard 1kHz tone. The tone duration was 50ms with rise/fall time of 10ms, and an interstimulus interval (onset to onset) of 2 sec.

Speech stimuli: High frequency Hebrew monosyllabic short words were chosen as stimuli. The duration of word stimuli ranged between 450-500ms. The same initial phonemes were used for both targets and nontargets so that discrimination between the targets and nontargets was only possible if the subject attended to the last phoneme. For example: If the target was “kaf” (alphabetic letter), the nontargets were “kal” (easy) or “kar” (cold). In a series of pilot experiments, we attempted to record ERPs using 11different target stimuli. The waveform in the expected P300 window was extremely spread with no clear peak. Consequently, in the present experiment we used three different targets and twelve nontarget stimuli to generate a clear P300 (See figure 1).

Two linguistic tasks were included in the experiment:
Phonological: Subjects were instructed to respond only to words that had a specific ending ("f").
Semantic: Subjects were instructed to respond to words from a specific category (name of Alphabetic letter).

The exact same target and nontarget words were used in the two speech tasks so that we could compare the behavioral and ERP responses to the same target stimuli in the two different linguistic tasks.

The oddball paradigm was programmed on a PC with the Audio task editor, Orgil medical equipment. In all experimental tasks conducted, a total of 180-195 stimuli were presented, thus the probability that a stimulus would be a target was 0.2. Stimuli were presented binaurally at 60 dBSL.

Procedure:

During the experiment subjects were instructed to fixate on a point located 1.5meters distant on the wall facing them, while keeping eye movement, blinks and general body movement to a minimum.

Subjects were instructed to press a button when detecting the target stimuli. A practice run was used to ensure that all individuals understood the task. Presentation order of the different conditions was counterbalanced across subjects. The entire session (of all 11 tasks not all reported here) lasted not longer than 3.5 hours.

The recording system:

The electroencephalogram (EEG) was recorded from 19 sites on the scalp according to the International 10-20 system referenced to back of neck. A ground electrode was placed on the right mastoid. An additional electrode placed below the right eye recorded electrooculogram (EOG) to monitor eye movement. The impedance measured for each electrode was lower than 7k ohm. The EEG program used to collect the data was Ceegraph IV Digital EEG system Biologic Corp. Raw data was continuously recorded with a band pass filter at 0.1-100Hz, sampling rate was 256Hz. Signals were amplified and digitized on line with a 4ms step.

All data underwent analysis using BPM Orgil medical equipment. Recordings were first segmented into epochs that were time locked to the stimuli and extended from 200ms pre-stimulus to 1800ms post-stimulus. Behavioral reaction time and accuracy were measured. The data were referenced to a common 100 ms pre-stimulus base line. Trials containing eye blinks or movements, excessive muscle activity artifacts were corrected or rejected. If more than 15 of the 35-40 sweeps of a given target were rejected for any reason, then all of the data in that condition for that subject was rejected. Thus, each ERP was based on a minimum of 20-25 sweeps.

Recordings to the target were averaged separately from recordings to the standard stimuli. The responses to standards preceding the targets were averaged and used as the comparison. ERPs were originally analyzed for correct response only. Because there were no differences between the averaged ERPs for correctly detected targets and those for all targets, further analysis was based on the later.

In a collateral behavioral experiment eight young naive subjects were instructed to write down exactly what they heard. Target words were cut and segmented in 25 ms intervals from 200ms to 500ms. All the segments were rearranged and randomly presented. The earliest cut off point where at least six subjects recognized the word correctly was defined as the point of identification for that word (e.g. "taf" was identified at 300ms). The results indicated that although the length of the words in the present experiment ranged from 450-500ms, all the words were correctly identified within the range of 275-350ms after word onset. ERP recording analysis were time-locked both to stimulus onset, and also to the point of identification based on the behavioral judgments. Using averaging to behavioral point of identification rather than to the onset of stimuli showed no significant difference in P300 peak latency and amplitude.

The measurements:

Behavioral measures of reaction time and performance accuracy were recorded as well as electrophysiologic

measures. ERP's were quantified in terms of peak latencies and peak amplitudes of the maximum negative or positive values within specific time windows. The time window for the different components was determined by visual inspection of the grand averages over all subjects. N100 was identified as the most negative point between 50 and 180ms post-stimulus. P300 peak amplitude was identified as the maximum positive point between 250 and 450ms for tones and 550 to 900ms for the speech stimuli.

Statistical analysis

Latency and amplitude values as well as behavioral measures were subjected to repeated measures analysis of variance (ANOVA) with 3 levels of task as well as 6 levels of electrode site as within subject factors. The level of significance was set to $p<0.05$.

Correlation tests were preformed between tasks, between behavioral and electrophysiological components.

Results:

Behavioral results:

The accuracy and reaction time data were analyzed (each separately) by a one-way analysis of variance (ANOVA) with task as a repeated variable. Accuracy measured as percent of target detection was not significantly affected by task. Task had a significant effect on reaction times to target stimuli ($F[2,36]=109.426$, $p<0.001$). Post hoc analysis revealed that the response to the target tones was always shorter than to the target speech stimuli ($p<0.001$), with no significant differences in RT within the speech stimuli (Table 1).

Table 1: Behavioral results of accuracy and reaction time averaged from all 20 subjects.

		tone	phonology	semantic
Accuracy (%)	Mean SD	93.74 8.04	93.94 9.87	90.1 11.82
Reaction time (ms)	Mean SD	459.95 87.46	829.67 92.27	869.3 98.72

Electrophysiological results:

Latency: Latency values (N100 and P300) were analyzed separately by a repeated measure analysis of variance (ANOVA) with 3 levels of task as a within subject factor. Both N100 and P300 latencies showed a significant main effect of task (N100 $F[2,38]=12.35$, $p<0.001$; P300 $F[2,38]=217.561$, $p<0.001$) (Table 2). Post Hoc analysis showed that N100 latency to the target in the tonal task was significantly shorter than to targets in both speech tasks ($p<0.001$). However, there were no significant differences in N100 latency to targets in the phonological task versus targets in the semantic task. Post hoc analysis revealed that P300 peak latency was significantly shortest to tonal stimuli ($p<0.001$), and within the speech stimuli, P300 latency to targets in the semantic task was significantly longer than to the targets in the phonological task ($p<0.044$) (Figure 1).

There were no significant correlations between any of the behavioral and electrophysiological measurements.

Table 2: N100 and P300 latency results averaged from all 20 subjects

		tone	phonology	semantic
N100 latency (ms)	Mean SD	91.48 29.14	129.48 25.51	124.4 22.53
P300 latency (ms)	Mean SD	327.5 18.76	668.71 78.4	705.58 74.34

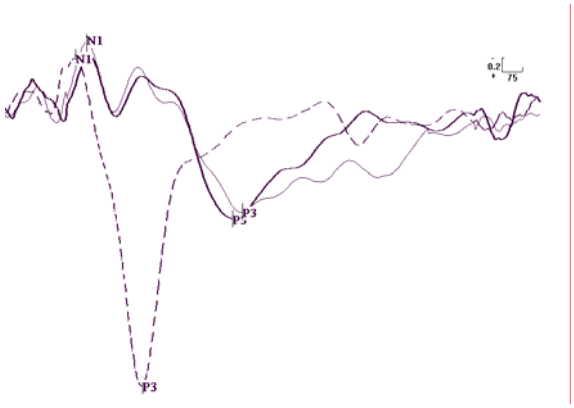

Figure 1: Grand average from all 20 subjects for the 3 tasks recorded at the Pz electrode. As can be seen, N100 latency was shorter for the tonal targets (dashed line) than the phonological (thick) and semantic (thin) targets. The P300 was shortest in latency and had larger amplitude to tonal targets as compared to speech targets.

Amplitude and Topography: A general repeated measure ANOVA with 5 levels for electrode site (frontal, central, parietal, occipital and temporal) revealed P300 amplitude was largest in parietal electrodes (Main effect of electrode site $F[4,76]=9.023$, $p<.001$). Further statistical analyses were performed on selected sets of scalp sites. On the basis of the observed distributions, the statistical analysis of ERP was limited to the central and parietal electrode sites (C4, Cz, C3, P3, Pz, P4).

Peak amplitude of N100 and P300 were analyzed separately by a two-way repeated measures analysis of variance (ANOVA) with 6 levels of electrode site and 3 levels of task as within subject factors.

N100: N100 amplitude showed a main effect of electrode site ($F[5,92]=144.194$, $p<0.001$) and did not show any significant effect of task. Post hoc analysis indicated that N100 peak amplitude was largest over the central electrode sites ($p<0.001$).

The degree of hemispheric asymmetry was computed by subtracting N100 peak amplitude recorded over the right hemisphere from that recorded over the left hemisphere (see Bellis et al 2000 for use of a similar index). As seen in

Figure 2 there was no significant difference in N100 amplitude recorded from the electrode sites over the left hemisphere (c3, p3) as compared to the electrode sites over the right hemisphere (c4, p4), for targets in either tonal, phonology or semantic tasks.

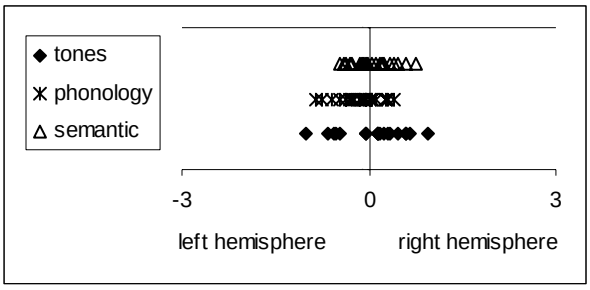

Figure 2: Degree of hemispheric symmetry in N100 amplitude. Results indicate responses were essentially symmetrical across all tasks.

P300: P300 peak amplitude was significantly affected by two of the variables, task and electrode site ($F[2,38]=21.08$, $p<0.001$; $F[5,95]=61.256$, $p<0.001$ respectively) as well as a two-way interaction of task X electrode site ($F[10,195]=3.021$, $p<0.001$). Post hoc analyses showed that the largest P300 amplitude was recorded over the parietal sites ($p<0.001$), and when comparing the tasks the largest P300 amplitude was recorded to targets in the tonal task ($p<0.001$).

P300 amplitude to targets in the tonal task were distributed symmetrically over the electrode sites. There was no significant difference in P300 amplitude recorded to tonal targets from the electrode site over the left hemisphere as compared to the comparable electrode site over the right hemisphere. In contrast, for both the phonological and semantic speech tasks, P300 amplitudes recorded from the parietal electrode site (p3) over the left hemisphere was significantly larger than P300 amplitude recorded from the parietal electrode site (p4) over the right hemisphere (phonology $t[18]=2.551$ $p<0.02$; semantics $t[18]=4.392$ $p<0.001$). (Figure 3).

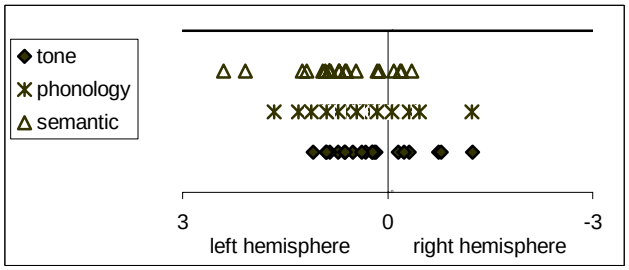

Figure 3: Degree of asymmetry for P300 amplitude. While for the tonal stimuli responses were essentially symmetrical, a significant degree of asymmetry can be seen for both speech stimuli, most pronounced in the semantic task, favoring the left hemisphere.

At the central electrode sites the distribution of P300 was symmetrical.

Discussion

Behavioral

The average accuracy scores for the 3 tasks ranged between 90-94% (Table 1). The high level of accuracy may have caused a ceiling effect and resulted in the inability to differentiate among the three tasks (Henkin et al 2002). In contrast, RT was sensitive to the different tasks. RT to targets in the tonal task was significantly shorter than to the targets in the two speech tasks. Although we did not find significant differences in RT to the targets in the phonological task versus targets in the semantic task, earlier studies did report such a difference (Novick et al 1985, Henkin et al 2002). The present study differs from the two earlier studies in that the construction of the targets in both the phonological and semantic tasks was such that subjects could not differentiate targets from nontargets unless they attended to the last phoneme. This may have presented a more difficult task than either of the earlier studies whose stimulus construction allowed for discrimination of targets from nontargets at an earlier stage of stimulus processing.

N100

The largest N100 peak amplitude was recorded over the central electrode sites. There were no significant differences between N100 recorded to targets and to nontargets in any of the tasks. Furthermore, there was a significant correlation between N100 to target and non-target in each of the tasks. These findings support the hypothesis that N100 represents obligatory primary sensory processing dependant upon the arrival of any stimuli at the auditory cortex, but does not by itself indicate any sort of discrimination or any of the task requirements (Martin et al 1999).

The N100 latency to the tonal stimuli was always shorter than to the speech stimuli, but there were no significant differences in N100 latency between the two speech stimuli. Similar results were previously reported (Wunderlich and Cone-Wesson 2001). Since N100 is an exogenous wave, it is sensitive to changes in the basic physical characteristics of the stimuli.

P300

As noted above, the P300 paradigm was chosen as the experimental technique so that the same electrophysiological components might be compared across a variety of stimuli and tasks.

In the present study P300 latency showed significant differences between the responses to tones and to the speech stimuli (327ms versus 668-706ms). The increase in latency for speech stimuli compared to tonal stimuli was reported previously (Tiitinen et al 1999, Kayser et al 1998). We

tested the hypothesis that the difference in P300 peak latency to tonal targets as compared to speech targets was due to the specific construction of the speech stimuli which required attention to the last phoneme before discrimination was possible. Subjects could only discriminate the target from the nontargets after hearing the last phoneme of the word while they could theoretically begin the process of discriminating the tone target from the tone nontargets beginning with stimulus onset. Furthermore, the duration of the tonal stimuli was 50ms, while the duration of the speech stimuli ranged between 450-500ms. This would mean that the difference in P300 peak latency to targets in the tonal task versus targets in the speech tasks should be directly related to the duration of the speech stimuli necessary to discriminate the words (Woodward et al 1990). In an adjunct experiment, we found that the average word identification point ranged between 275-350ms after word onset. Note the additional amount of time required for identification of speech stimuli (approximately 325ms) coincides with the time difference between P300 latency of tones (327ms) and P300 latency of speech stimuli (668-706ms).

Alternatively, it is possible that processing speech stimuli takes longer than processing tones. Therefore, the difference in P300 peak latency to tone targets versus speech targets also included the differences in processing time to the two types of stimuli (Bentin et al 1999).

The present findings can be related to the ongoing debate concerning the identity of the late ERP potential recorded to speech stimuli within the 500-750 ms time window, the "identity" thesis. Coulson et al (1998) argued that ERPs recorded in complex cognitive tasks are basically identical to (or are just modifications of) waves found in simpler conditions. Particularly, the P600 component of the scalp recorded event-related brain potential related to syntactic violation processing is just a delayed P300 similar to that recorded in simple oddball tasks (both are sensitive to probability manipulations and are similar in their respective scalp distribution). Kotchoubey and Lang (2001) used a paradigm in which subjects discriminated infrequent targets from frequent standards based on a semantic feature (e.g. animals versus other common nouns), this paradigm elicited a positive parietal wave in the 600 ms window frame. They argued that the P600 is an oddball delayed P300 component elicited in a semantic oddball experiment to more complex stimuli.

The alternative view states that there exist specific ERP waves manifesting brain mechanisms of language processing (Osterhout et al 1994, Frisch et al 2003). The late positive wave P600 recorded in response to syntactically anomalous words manifests specific brain mechanisms of syntactic processing.

Comparison between speech tasks: P300 latency to target stimuli in the phonology word tasks was significantly shorter than to targets in the semantic tasks. Similar results have been reported (Novick et al 1985, Cobianchi and Giaquinto 1997)

Topographical distribution

Tones: In our study both N100 and P300 peak amplitude in the tonal task were distributed symmetrically over the two hemispheres. These results are similar to previous reports using pure tones (Breier et al 1999) as well as complex tones (Bruder et al 1999, Kayser et al 2001).

Speech tasks: In the present study, While N100 peak amplitude distribution was symmetrical over the two hemispheres, P300 peak amplitude to the targets in the two speech tasks, was significantly larger when recorded from the parietal electrode over the left hemisphere (p3) as compared to the right hemisphere (p4). Similar results were reported in other studies using phonemes, syllables (Kayser et al 2001, Alho et al 1998) and words (Breier et al 1999). It is important to note that the change from hemispheric symmetry in tonal stimuli to hemispheric asymmetry in speech stimuli was found only for the P300 component and not for the N100 component (compare Fig 2 and 3). This dissociation of the two ERP components further emphasizes their different electrophysiological representations and may point to a dynamic change of hemispheric interaction in the processing of speech stimuli over time.

Phonology vs. semantics: A number of imaging and ERP studies have concluded that while phonological processing is more confined to regions of the left hemisphere, the semantic processing is less localized, since it involves the activation of distributed networks in the brain. (Ferlazzo et al 1993, Cobianchi and Giaquinto 1997, Thierry et al 1998, Angrilli et al 2000, Connolly et al 2001). For example, imaging studies demonstrated that phonological processes are related to Broca's area and the left inferior frontal gyrus (Demonet et al 1992, Becker at al 1999). However, during lexical-semantic tasks there is a wider cortical distribution of activation, not confined only to the left temporal and inferior frontal areas (Zatorre et al 1992, Kareken et al 2000, Zahn et al 2000). In the present study we found hemispheric asymmetry favoring the left hemisphere to targets in both the phonological and semantic tasks and did not find a significant difference in the hemispheric asymmetry of P300 peak amplitude favoring either the targets in the phonological or semantic tasks. These results are in line with several imaging studies (Poldrack et al 1999, Johnson et al 2001) that point to a greater activation of left hemisphere neural systems for both semantic and phonological tasks.

Abstract

People's ability to recall and use prior experience when faced with current problems is surprisingly limited. We suggest that one reason is that information is often encoded in a situation-specific manner, so that subsequent remindings are limited to situations that are similar to the original both in content and in context. *Analogical encoding*—the explicit comparison of two partially understood situations—can foster the discovery of common principles and allow transfer to new structurally similar situations. This paper addresses two new questions: (1) whether comparison can also improve people's ability to retrieve examples from long term memory; and (2) whether simply providing the common principle would suffice to promote transfer. The results show (1) that not only does comparing examples facilitate transfer *forward* to a new problem, it can also facilitate transfer *backwards* to retrieve an example from memory; and (2) providing a common principle is not sufficient: comparison is still beneficial.

Introduction

The ability to transfer relational knowledge across contexts is of central importance in human cognition. (Gentner, 2003). Yet people do not acquire relational abstractions effortlessly (Chi, Feltovitch & Glaser, 1981; Chase & Simon, 1973), nor do they always apply them when they would be helpful (Gick & Holyoak, 1980). Drawing analogies during learning can address both of these challenges (Catrambone & Holyoak, 1989; Gentner, Loewenstein & Thompson, 2003). We will also examine another role of analogy in learning. Our findings indicate that comparing two structurally similar examples (analogical encoding) not only facilitates transfer to *future* structurally similar cases, but also the retrieval of *prior* structurally similar examples from memory.

An important means of learning is analogical transfer—the use of a prior familiar situation (the base) to solve a novel situation (the target) by mapping the solution from the base problem to the target problem. This kind of transfer has been shown to occur in reasoning and problem-solving (Bassok, 1990; Novick, 1988; Reed, 1987; Ross, 1987). Research on analogical transfer also reveals an Achilles' heel. When people succeed in accessing appropriate prior examples to inform current problems, they perform well (e.g., Pirolli & Andersen, 1985). The importance of prior cases in current reasoning has been argued persuasively in the case-based reasoning literature (Kolodner, 1993; Schank & Riesbeck, 1981). However, people often fail to access prior cases that would be useful, even when they can be shown to have retained the material in memory (Gentner, Rattermann & Forbus, 1993; Gick & Holyoak, 1980). Indeed, people are often unable to solve a problem after having just solved an analogous problem (see Reeves & Weisberg, 1994 for a review).

One way to promote structural transfer is by comparing two initial examples (Gick & Holyoak, 1983). This process capitalizes on the fact that comparison between two exemplars tends to make common relational structure more salient (Gentner & Markman, 1997). We call this *analogical encoding*, to emphasize that one can compare two partly understood examples to derive a common interpretation (Kurtz, Miao & Gentner, 2001). As Gick & Holyoak (1983) demonstrated, comparing two initial examples can facilitate deriving a schema, which in turn facilitates transfer to a structurally-similar problem (Catrambone & Holyoak, 1989). In contrast, people learning from a single case tend to encode it in a context-specific manner, with the result that later remindings are often based on more obvious surface aspects (Gentner & Rattermann, 1991).

We are investigating analogical transfer in the domain of negotiation (Loewenstein, Thompson & Gentner, 2003; Thompson, Gentner & Loewenstein, 2000). Negotiation is a particularly apt arena, for several reasons. Negotiation principles must be applied across many different contexts, making transferability essential. Further, the learning must be applied in real time, often in stressful, competitive situations with the potential for considerable gain or loss. Finally, our participants are highly motivated; they are studying negotiation with a direct interest in raising their job effectiveness.

In a typical negotiation situation, there is a set of issues in which two parties have different preferences, and to which they assign different levels of importance. The goal is to achieve an agreement, with each participant trying to optimize their gain. The negotiation principle we focus on

here is the idea of constructing contingent contracts: agreements whose terms depend on the outcome of a future event (Bazerman & Gillespie, 1999). These contracts allow people to reach agreement despite differences in opinion. Despite their usefulness, untrained negotiators tend not to form contingent contracts. Instead, most negotiators form inefficient compromises (Thompson & Hastie, 1990).

In our studies, the basic method is as follows. We provide highly motivated students (typically MBA students or executives) with materials to prepare for a face-to-face negotiation. Before negotiating, all participants read two brief cases that illustrate a negotiation principle (e.g., a contingent contract) that would be advantageous to use in their face-to-face negotiation. Half the participants (the comparison group) are told to compare the two cases and write out their commonalities; the other half (the separate-cases group) is told to read each case and write out what is important about it. Participants are then paired with someone in the same condition to conduct the negotiation, which is set in a different context than the study cases. We have found that participants who compared the two cases are two to three times as likely to use the negotiation strategy in their subsequent face-to-face negotiations as those who analyzed the same cases one at a time (e.g., Thompson, Gentner and Loewenstein, 2000).

Comparing analogous cases promotes *forward transfer*. That is, it increases the likelihood that the common principle will be retrieved when an analogous situation occurs in the future. One route that has been proposed for this increased transfer may be that schema-abstraction leads to increased matching (Ross, 1989). This possibility follows directly from the assumptions of schema-abstraction. Comparison invites an alignment and re-representation of examples, yielding a common representation that is less context-specific than the initial ones (Gick & Holyoak, 1983; Loewenstein, Thompson & Gentner, 1999). Because this new representation has more general relational representations and fewer potentially conflicting object matches than the initial cases, the match with subsequent cases will be better, making remindings more likely (Forbus et al, 1995; Ross, 1989). However, there is another possible reason for the increase in forward transfer, namely, *learning-to-encode*. Having derived a common representation, people may encode future cases in the domain in a similar manner. (Medin & Ross, 1989). The learning-to-encode account predicts that future cases are likely to match the schema that resulted from the comparison, because they will be encoded in the same way.

Using retrieval to clarify the transfer process. Although most researchers have assumed that both increased matching and learning-to-encode are part of the story, the forward-transfer improvement could be explained solely by learning-to-encode. However, the learning-to-encode account cannot predict any effect on retrieval of cases acquired prior to the schema abstraction. Thus, if learning-to-encode is the main reason for improved transfer, then the effects of comparison should be unidirectional: better learning today will help performance tomorrow, but will be of little help in retrieving examples that were learned yesterday. In contrast, if schema abstraction per se is an important force here, then we will see bi-directional effects: abstracting a schema should aid in retrieval whether it is forwards or backwards.

Experiment 1

In Experiment 1, we tested whether analogical encoding facilitates *both* forward transfer and backwards retrieval. If so, this would suggest a degree of symmetry in the memory retrieval process. That is, it would suggest that an abstract relational structure is better retrieved by future cases and also serves as a better probe for prior cases than a specific case.

We gave all participants two analogous examples. We asked half to compare them, and half to study the examples one at a time. Next, to test whether comparison aids memory *retrieval,* we asked people to recall an example from their own experience that illustrated the same principle as the initial examples. Finally, to test for *transfer*, we asked whether people would use the principle to form better agreements in a subsequent face-to-face negotiation (as in our prior studies).

Our participants were management consultants in a negotiation training program. Given the amount of money and time devoted to this training, there is no question that they were highly motivated to learn. They should also be professionally predisposed to value learning and generalization.

Method

Participants A total of 124 participants aged approximately 25 to 45 years, all full-time professional management consultants working at the same organization, participated through a negotiation training seminar. There were 64 in the comparison condition and 60 in the separate cases condition.

Materials and procedure. Participants read role materials to prepare to be either the buyer or seller in a negotiation role-playing scenario. Just prior to engaging in the role play, participants received a training packet. The first page concerned details about their upcoming negotiation. The next pages contained two cases exemplifying the contingent contract principle. The Comparison group read both cases and then was asked "What is going on in these negotiations? Think about the similarities between these two cases. What are the key parallels in the two negotiations? Please describe the solution and say how successful you think it is." The Separate case group received the following question after each case: "What is going on in this negotiation? Please describe the solution and say how successful you think it is."

For both groups, the next page of the training packet asked participants to recall an example like those they had just read: "Please think of an example, preferably from your own experience, that embodies the same principle as that on

the previous page." We then asked participants to state the source of their examples. Participants were not limited as to time and typically spent 45-60 minutes on these three pages (an indication of their motivation to learn). We saw no time-on-task differences by condition. Then they were paired with someone from the same condition to negotiate. The negotiation case was set in a different context than the training cases, and was designed to afford creating a mutually beneficial contingent contract.

Scoring The negotiated agreements were scored by blind raters as to whether they contained a contingent contract (which was, by design, the optimal solution to the negotiation dilemma). Coders also rated the quality of the participants' initial responses concerning the two cases—that is, the degree to which the contingent contract schema was described—using a 3-point scale: 0 = no elements of the schema were present, 1 = some elements, and 2 = all elements. They also rated whether participants linked the case and principle in any way (as a manipulation check on the condition difference). Finally, coders also rated whether the examples participants recalled were contingent contracts, using the same scale as above, and categorized the source domains in which participants' examples were set. Overall, there was high agreement (87%); disagreements were resolved through discussion.

Results

As predicted, the comparison group was superior to the separate cases group on all three measures: schema quality, likelihood of transfer, and quality of remindings. Making comparisons led to grasping the contingency contract schema from the original examples, which in turn facilitated both linking it to prior examples in memory and using it in a new negotiation situation.

Schema understanding Comparison participants (M = 1.45) articulated the schema better than Separate case participants (M = 0.98), $t(122) = 2.97$, $p < .01$. Another striking finding was that fewer than one in five Separate cases participants linked the two cases in any way, despite the fact that they occurred contiguously and were analogous.

Transfer In their face-to-face negotiations, Comparison participants (69%) were nearly twice as likely to make contingent agreements than Separate case participants (33%), $?^2$ (1, N=62) = 4.22, $p < .05$. As in our previous research, this suggests that comparison facilitates transfer.

Remindings Participants in the Comparison condition (M = 1.25) retrieved better examples of contingency agreements than did participants in the Separate cases condition (M = 0.82), $t(122) = 2.65$, $p < .01$. This suggests that comparison aided people's understanding of the initial cases, thereby better guiding participants' retrievals.

Participants retrieved examples from their own business experience or that of a colleague, and less frequently drew upon examples from the popular press. The examples were mainly from the business domain (as expected—they were in a business training classroom), with the remainder being daily life examples such as betting on sports teams, uncertainty about the weather affecting a vacation activity, arranging a home mortgage, and so forth.

One source of participants' examples had a name within their organization—*value billing*. Value billing is a particular type of contingent contract wherein a consulting firm bills clients a low base fee, with a generous bonus structure based on the outcome of the work. Given that every participant probably knew about value billing, it is striking that most of those who used this example were in the Comparison condition.

Cross-measure associations As expected, schema understanding predicted retrieval performance. The association between articulating the schema and retrieving a match was reliable, ?2 (1, N=124) = 8.68, p < .01. In the transfer measure there was only a modest trend for the sum of a pair's schema ratings to be associated with their transfer ?2 (1, N=62) = 1.70, $p = .19$. However, "high performance pairs" (pairs in which at least one person articulated the schema and retrieved a matching example, and the pair formed a contingent contract—i.e., transferred) were marginally more likely to be in the Comparison condition (47%) than the Separate cases condition (23%), ?2 (1, N=62) = 3.75, $p = .05$.

Distinguishing retrieval from invention. To conclude that there is a comparison advantage for retrieval, it is important to assess whether participants were simply fabricating examples rather than retrieving them. That is, the retrieval advantage for the comparison group could stem simply from their using the derived schema to invent examples, rather than from recalling them. But in this case, we should see the highest proportion of structurally correct "retrievals" from participants who failed to state a source. In fact, the 32 people who did not state the source produced the *lowest* proportion of structural remindings (31%). The proportion was higher for those who stated non-verifiable sources (45%), and highest for those whose source was verifiable (and verified) (68%). The opposite would have been expected on the 'fabricating' account, and hence it seems reasonable to take the participants at their word.

Discussion

Comparing cases yielded consistent advantages for schema abstraction, retrieving a matching example from memory, and transferring to solve a new problem. Although our participants were consultants whose jobs depend on their ability to apply their knowledge in new situations, and who spent considerable time with the training materials, we saw little spontaneous comparison across examples in the group not explicitly told to compare. Nonetheless, a brief instruction to compare was sufficient to advance the

performance of their peers across all three measures of learning.

Another striking pattern is that despite the participants' considerable experience in the business world, over half of them did not recall any examples that were contingent contracts (or structural analogs). In fact, 11% failed to write down any case at all. Our results underscore that (1) transferring from analogous examples can be challenging even for sophisticated and motivated learners (Novick, 1988) (2) analogical encoding can dramatically increase transfer; (3) the benefits of analogical encoding derive in part from inducing a clearer schema for the common principle (Catrambone & Holyoak, 1989; Gick & Holyoak, 1983) and (4) analogical encoding can lead to increased retrieval of prior analogous examples.

Finally, the fact that analogical encoding aids in memory retrieval indicates that the effect of schema abstraction in memory access is bidirectional. The representations that resulted from comparison were *both* more readily retrieved by future analogs than were the separate cases and more effective as probes for prior analogs stored in memory. Thus, although we suspect that the transfer benefits of comparison derive in part from learning-to-encode—i.e., from encoding future examples in a structurally clear manner consistent with the schema—our results indicate that ease of matching must also play a role. The relatively abstract schemas that result from analogical encoding match better with prior examples just as they do with future examples.

Why not just give them the principle? The results of this study and prior work on analogical encoding lead naturally to a further question. If the advantage of mutual alignment is simply that comparing the two examples leads learners to derive the principle, then would learners not fare even better if the principle—in this case, the contingent contract principle—were simply given to them explicitly? We examine this directly in Experiment 2.

Experiment 2

In Experiment 2 we asked Masters of Business Administration (MBA) students to read a case and an abstract principle. If analyzing the principle and elaborating upon it is sufficient for transfer, we should find high rates of transfer in all groups. However, if principles need to be grounded in examples to be comprehensible and generalizable, then those asked to compare the case and principle should show a transfer advantage relative to those who study the example independently of the principle.

Method

Participants A total of 106 MBA students participated in the study, resulting in 27 pairs in the Comparison condition, and 26 pairs in the Separate condition.

Materials and Procedure The materials and procedure were similar to Experiment 1. The training packet did not ask for memory retrievals, and instead of two cases presented people with one case and an abstract description of contingent contracts. Participants in the comparison group were asked to compare the case and principle and specify commonalities, and then describe implications for negotiation. Those in the separate group were asked to read the case and the abstract principle separately, and were asked after each to state its implications for negotiation. Both groups received case and principle on consecutive pages. Participants then engaged in the negotiation with someone else in the same condition.

Scoring As before, coders rated the quality of the contingent contract schemas. They also rated whether participants had paraphrased the case in their responses, whether their responses contained generic advice about negotiation that was unrelated to contingent contracts, and whether they linked the case and principle in any way. They agreed on 93% of their judgments, and disagreements were resolved through discussion.

Results

In their initial descriptions, Comparison participants were more likely than Separate cases participants to articulate the full schema (74% versus 56%) and they less often failed to articulate any of the schema (12% versus 35%), $?^2$ (N=97, 2) = 7.36, $p < .05$. In their face-to-face negotiations, participants who compared the case and principle (44%) were over twice as likely to form contingent contracts as were participants who analyzed the case and principle separately (19%), $?^2$ (N=53, 1) = 3.87, $p < .05$.

The additional ratings of people's individual responses to the training materials showed a further surprising and consistent pattern. Despite the fact that all participants had read and discussed the case and the principle on consecutive pages, almost none of the Separate participants noticed the link between them. Thus, the Separate participants did not appear to notice that the principle was the general statement of what the case exemplified. Comparison participants (88%) were also more likely than Separate participants (34/47, or 71%) to paraphrase the case as they discussed it, $?^2$ (N=97, 1) = 4.24, $p < .05$. Participants in the Separate cases condition were also more likely to give general panaceas as advice (e.g., "it helps to have a good relationship when you're negotiating" or "you want to reach win-win deals") (77%) than comparison participants (31%), $?^2$ (N=97, 1) = 21.06, $p < .001$.

Discussion

Our results lead to something of a paradox. We find that learners who derive a schema through analogical encoding—either by comparing cases, or by comparing a principle with an example—can readily transfer the schema to new cases. Yet learners who are explicitly given the same schema—even along with an example case—cannot. Why? Can we say anything more specific that that "active learning is good"? We suspect that abstract principles are ineffective

because they are less well understood than specific cases (Forbus & Gentner, 1986; Regehr & Brooks, 1993). Indeed, in our study, some people had difficulty re-stating the principles. This is partly because learners may fail to understand the specific terms used, or how they are meant to combine. This is consistent with Ross & Kilbane's (1997) finding that if given an example followed by a principle, people remember the example but forget the principle. Another difficulty in understanding principles is that there are typically many different interpretations of a given relational abstraction. Thus, people may encode the principle in ways that are incompatible with the later example. The joint interpretation of an example and a principle helps overcome these limitations. People better understand the principle if they apply it to an example.

General Discussion

These studies show three learning advantages of analogical encoding. First, drawing comparisons facilitates acquiring an abstract schema. As Experiment 2 showed, it can do so better than studying a statement of the abstraction itself. Second, both studies replicated prior research showing that comparison facilitates applying derived abstractions to solve new problems. Third, analogical encoding of two current cases—that is, analogical encoding of a *probe*—leads to a retrieval advantage in accessing structurally matching cases from long-term memory. Our findings suggest that the second and third of these stem from the first: that it is the possession of clear schemas that facilitates both transfer and retrieval.

Implications for learning and transfer. Our findings have several implications for complex learning. On the dark side, the results of Experiment 1 suggest limitations on even experts' analogical thinking. Over half the participants failed to recall *any* structurally similar example from their own experience, despite the fact that they had considerable experience including specific experience in a particular kind of contingent contract (value billing) that would have qualified nicely. Prior studies suggest that people show more relational transfer in domains that are familiar or in which they possess expertise (Blanchette & Dunbar, 2001; Dunbar, 2001; Novick, 1988). However, as our results show, even for experts relational retrieval can be problematic.

A second rather gloomy finding is the failure of our (highly motivated) participants to spontaneously compare the two cases (Experiment 1) or the case and principle (Experiment 2). Here, as in our prior studies, participants in the Separate cases group almost never noticed the link between the two, despite the fact that they were on consecutive pages. The huge advantage found for the Comparison group, which did compare the two, makes this failure to notice the link all the more telling. It raises the question of how many potentially illuminating comparisons are missed in the course of learning. On the positive side, the relational fluency shown by the Comparison group offers a relatively simple technique whereby learners and educators can improve their understanding and gain relational insight.

Implications for memory retrieval. That analogical encoding can facilitate retrieval is consistent with the point that the match between a specific case and a general abstraction (which has few or no concrete features and therefore few mismatches) is better than the match between two specific cases (unless, of course, the cases are closely similar, with many matches and few mismatches) (Tversky, 1977). Further, it indicates that this advantage holds whether the schema is in the memory bank (as in prior studies of analogical transfer) or in the probe position.

The retrieval effect suggests that people can use a well-articulated principle to retrieve prior examples and reinterpret them as examples of this new abstract structure. This implies a clear mechanism by which reflection can reorganize knowledge. A major question in both child development and the field of expertise is whether and how people's existing knowledge changes as they understand a domain in new depth. To the extent that abstractions can call forth matching cases from memory, the learner may gain a richer understanding of the new abstraction and a re-representation of the prior example in light of the new abstraction. This suggests a means by which new knowledge can connect to existing knowledge and can reorganize that knowledge along more expert lines.

One encouraging implication of our findings is that examples people learn prior to understanding key abstract principles in a domain are not necessarily lost or wasted. Given the increasing demands for adults to learn, this is encouraging news. Teachers can capitalize on people's prior knowledge by encouraging people to recall familiar examples of new principles. We may well rely on learned cases every bit as much as researchers on analogy, categorization and case-based reasoning suggest, but we nonetheless may benefit considerably from interventions in how we encode them.

In conclusion, analogical encoding appears to be a powerful starting point for learning. The resulting understandings may radiate both backwards and forwards.

Recognition effects and noncompensatory decision making strategies

Abstract

Oppenheimer (2003) challenged the empirical evidence for the recognition heuristic by pointing to the possibility that existing demonstrations may have confounded recognition with a person's existing knowledge. In two experiments we remove the possibility of such a confound by independently manipulating recognition in a way similar to the "overnight fame" paradigm of Jacoby, Kelly, Brown and Jasechko (1989). We found evidence for a recognition effect, but neither compensatory nor noncompensatory decision making strategies seem to be able to completely explain our results. We discuss what modification to these strategies may be necessary.

Introduction

Gigerenzer and Todd (1999) proposed that when people make decisions, rather than using all possible information that they could, they use "fast and frugal" heuristics selected from an adaptive toolbox. Gigerenzer and Goldstein (1996) showed that such heuristics can lead to decisions as good or better at achieving the organisms goals as more resource intensive strategies. This *adaptive rationality* approach challenges the traditional approaches to rationality (see Chater, Oaksford, Nakisa, & Redington, 2003).

Goldstein and Gigerenzer (2002) proposed that the toolbox includes the recognition heuristic, which can be applied "If one of two objects is recognized and the other is not, then infer that the recognized object has the higher value with respect to the criterion." (p.76) In this sense it is an example of one-reason decision making, though it can also act as a subroutine in heuristics that use information beyond recognition, such as the *Take the Best* heuristic (Gigerenzer & Goldstein, 1996). Such heuristics embody Simon's (1956) concept of *bounded rationality*, which suggests organisms seek enough information for a good decision rather than spending resources on obtaining all relevant information.

However it is apparent from attempts to gather evidence for or against the recognition heuristic that there are some conceptual disagreements. In this paper we present our understanding of the heuristic and its relationship to other concepts of how recognition cues are used, and we present a new methodology for examining recognition as a process.

Previous studies

As evidence for people's use of the recognition heuristic, Goldstein and Gigerenzer (1999, 2002) showed that which German cities Americans recognized affected their choices for which of a pair of German cities was larger. However Oppenheimer (2003) challenged this empirical evidence for the recognition heuristic by suggested that because Goldstein and Gigerenzer used the 30 largest German cities, recognition was confounded with actual city size. Thus recognition itself may be irrelevant as a cue or combined with other cues. Such confounds exist in all their demonstrations because they state that the heuristic should only be found to be used when recognition has a correlation with the correct answer via an ecological valid mediator.

To remove this confound Oppenheimer (2003) presented a cities pairs task, in which recognition could not have a valid correlation because one city was fictional, and thus there was no correct answer. Furthermore the real cities, with which the fictional cities were paired, were either small or famous for reasons unrelated to size. Two studies tested the hypothesis that when subjects were presented with a city they recognized and one they did not, then preference for the recognized city would not be above chance (specifically, he tested if more than 50% of participants chose the recognized city). Both studies found that significantly fewer than 50% of participants chose the recognized cities.

Oppenheimer (2003) suggests that Goldstein and Gigerenzer's (2002) evidence showing that greater than 50% of subjects choose the city they recognized is consistent with them using the recognition heuristic. However because other cues may be confounded with recognition, these results are also consistent with strategies that combine cues together. For examples these other cues could be combined in tallying strategies, weighted additive models, or regression models and produce results consistent with the recognition heuristic. Oppenheimer claims that by demonstrating that cues that should be associated with recognition (cues indicating small in his experiments, those indicating big in Goldstein & Gigerenzer) influences the extent to which subjects chose the recognized city, he has shown that there is no evidence for the recognition heuristic. This interpretation of the data is disputable, partly because exactly what question this data addresses is arguable.

Distinguishing related questions

Experiments on the recognition heuristic have addressed three questions that are related but not necessarily the same:

1) Are there recognition effects on choice? Demonstrating this requires showing that people's choices are influenced by recognizing one option and not the other. This question generates a testable prediction that Oppenheimer's (2003)

data addresses: that subjects should prefer the recognized city at a rate greater than chance. He finds no evidence for this, and claims that Goldstein and Gigerenzer's (2002) evidence for it was due to confounds. However this question is not equivalent to the second.

2) Do people use the recognition heuristic? Oppenheimer (2003) states that "The recognition heuristic posits that individuals will use no information aside from mere recognition to make city size estimations." Goldstein and Gigerenzer almost certainly disagree with this statement. Gigerenzer and Todd (1999, p.32) state that different heuristics may be applied to a choice between two options, and which is applied depends on the person's knowledge. The recognition heuristic is most likely applied when the decider has no information except recognition. *When* it is applied then only recognition information should be used, but there is no claim in Goldstein and Gigerenzer (2002) that the recognition heuristic is always applied. Their own data show that the recognition heuristic is not always applied. Gigerenzer and Todd (1999, p. 32-33) briefly consider the question of how heuristics are selected and suggest that task and available cues determine it. Although their concept of a "toolbox" of heuristics implies that selection is critical, a valid criticism may be that how this is done is an under-developed aspect of their approach. In this they are not unusual as Falk and Konold (1997, p. 305) point out that it hard to make predictions regarding the representatives heuristic because "there is no established procedure for deducing how it will be implemented in a specific task."

3) Is recognition used in a noncompensatory way? Goldstein and Gigerenzer (2002) propose that the recognition heuristic is a noncompensatory algorithm, as are other algorithms proposed by Gigerenzer and Todd (1999). A prototypical noncompensatory algorithms is a lexicographic strategy (see Payne, Bettman, & Johnson, 1993). Cues are arranged in a hierarchy based on validity then starting from the top, one cue at a time is considered until one is found that discriminates between the options. In contrast, a compensatory strategy (such as linear regression or multi-additive models) integrates all cues in making a choice, although they may be given different weightings. A flow diagram of a noncompensatory algorithm in which recognition is the first cue considered is given by Gigerenzer and Goldstein (1996, Figure 2). The stopping rule for such an algorithm is the first cue considered that distinguishes between options. Characteristic of such algorithms is that a decision made on the basis of a higher cue cannot be reversed by cues lower in the order Goldstein and Gigerenzer (p. 82). The recognition heursitc is a special case of a noncompenstory strategy, so recognition need not be the first cue considered in noncompensatory strategies. Gigerenzer and Goldstein and Gigerenzer and Todd discuss various noncompensatory algorithms.

Possibly Oppenheimer's (2003) most interesting claim is that his data showing that people chose the recognized city less than 50% of the time shows that recognition is not used in a noncompensatory way. It is worth examining his arguments for this claim. He argues that if people are only sometimes using the recognition heuristics, then the problematic question of how they decide which heuristic to use is raised. If the task determines it then why was a recognition effect in Goldstein and Gigerenzer's (2002) paired-city task, but not Oppenheimer's (2003)? If the cues presented in the task determine which algorithm is used, then all cues have to be considered, undermining the efficiency of the "one-reason" decision making. Thus it is not as "frugal" in terms of processing and information as Goldstein and Gigerenzer claim.

If more than one cue is available then implicit in the claim that cues are ordered in a hierarchy is that cues must be considered at some level. The defining characteristic of a noncompensatory algorithm seems to be how the cues are combined at the decision point. In compensatory algorithms all available cues are integrated requiring some form of trade-off between those that favor different options, whereas in noncompensatory algorithms at the point of decision only one cue is considered and there are no trade-offs. Whether this means that noncompensatory algorithms are inherently more "frugal" than compensatory algorithms depends on what sort of assumptions are made about cue ordering or cue trade-off processes.

If competing subjective cue validities determine the order in which cues are considered by noncompensatory algorithms, then it would be predicted that the nature of the cues available in addition to recognition would influence the extent to which recognition determined the choice between two options. Thus Oppenheimer's (2003) evidence that other cues may moderate the impact of differential recognition on a choice does not in itself show that recognition is used in a compensatory algorithm.

In both Goldstein and Gigerenzer (2002) and Oppenheimer (2003) recognition was confounded with other information. To more effectively test how recognition is used requires a way to manipulate recognition free of any confounds.

Manipulating recognition

In existing studies of the heuristic, recognition has always been a pseudo-independent variable; that is, the studies have not manipulated recognition but instead examined the impact of what subjects recognized due to life experience.

We manipulated recognition by pursuing Goldstein and Gigerenzer's (2002) suggestion that recognition might be induced in a way analogous to the "overnight fame" effect found by Jacoby, Kelly, Brown and Jasechko (1989). Jacoby, et al. presented participants with a list of unfamiliar names that were included on a later list of names to which participants were asked to respond: famous or nonfamous? They were more likely to choose as famous the arbitrary names from the initial list. We used a similar methodology with small German cities to examine if induced recognition could affect the choice of which of two cities was larger.

To induce recognition we gave participants one of two *induction lists* consisting of eight German cities or towns (Zwickau, Leverkusen, Regensburg, Offenbach, Ulm, Stralsund, Coburg, Dormagen; or, Bochum, Gelsenkirchen, Darmstadt, Krefeld, Schweinfurt, Goslar, Lingen, Iserlohn) plus three irrelevant small cities. Participants were asked to count the number of syllables they thought each city name

contained. We conducted a pilot experiment to confirm that these induction lists could induce recognition. Eight members of the Michigan State University participant pool were given one of the induction lists, and nine the other list. After spending 30 minutes on unrelated tasks, participants were presented with a list of 20 small German cities, including the 16 from the two induction lists. For each city they were asked if they remembered seeing the city on the list they were given earlier. They recognized more cities from their own induction list (M = 85%) than from the list they had not been given (M = 11%), $t(32) = 18.62$, $p < .001$. Therefore the pilot experiment supported our assumption that presenting the syllable list would induce later recognition.

Aims of the experiments

In two experiments using induced recognition we examined recognition effects and how other cues may moderate any effect. This allowed us to address two of the three questions we outlined regarding recognition

1) Are there recognition effects on choice? Oppenheimer (2003) claims that the Goldstein and Gigerenzer's (2002) results are flawed because of confounds, but his experiments intentionally introduce another confound. To clearly establish whether there are recognition effects in the cities-pairs task requires a version with no confounds.

2) Do people use the recognition heuristic? The answer to this question is clearly "not all the time". A more reasonable question is what factors influence the degree to which people use the recognition heuristic? However no one has specified these factors well enough to examine this.

3) Is recognition used in a noncompensatory way? Addressing this question requires examining how other cues moderate the effect of recognition. Goldstein and Gigerenzer (2002) found that adding other cues did not affect the size of the recognition effect, whereas Oppenheimer found that they did. However in neither experiment were cues systematically manipulated within a single experiment. In our experiments we varied the amount of other cues available in order to address how information moderates recognition effects and thus throw light on the issue of whether recognition is used in a compensatory or noncompensatory way.

Experiment 1

In Experiment 1 we induced in Americans recognition of small German cities from an induction list of eight, then presented them with each of these cities paired with one from the alternative list of eight cities. We predicted that participants would be more likely to select the induced city in the pair. We also manipulated giving a positive (has a major league soccer team) or a neutral (the state the city was in) cue to the size of one city in the pair, either the induced or noninduced city. The least amount of extra cues was none, the next least neutral only, the next positive only, and the most extra cues received was both neutral and positive. If recognition is a compensatory cue, then the more information presented, the smaller the effect of recognition should be.

Method

Participants

A total of 256 members of the Michigan State University participant pool participated for partial course credit.

Materials

The two induction lists were the same as those described for the pilot experiment. For the *city-size task*, the eight cities from one induction list were paired with the eight from the other. Thus for each pair, one city was induced (i.e., appeared on the participant's induction list) and one was noninduced (i.e., appeared on the list the participant did not see). For each pair, participants chose which city they thought was larger. To obscure the purpose of the task, Oppenheimer (2003) included some pairs with obvious answers. Similarly we added three pairs containing a well-known large city (Berlin, Frankfurt, Munich).

With each city pair extra cues could appear, though cues were always independent of reality allowing us to freely manipulate information. (No participants pointed out that the information was incorrect.) There were four cue conditions. For the two *cue-none* pairs it was stated for both cities that there was no information available regarding whether it had a soccer team or which state it was in (Germany consists of 16 states). For the two *cue-neutral* pairs soccer team status was said to be unknown but a state was given for one city. For the two *cue-positive* pairs state was said to be unknown but one city was said to have a soccer team. For the two *cue-all* pairs for one city a state was given and it was said to have a soccer team, whereas this information was said to be unknown for the other city. Eight pairs for each participant were necessary because for four pairs the cue conditions were applied to the induced city, and for the other four pairs the cue conditions were applied to the noninduced city.

Note that Goldstein and Gigerenzer (2002) also conducted an experiment in which a city having a major soccer team was used as an extra cue to city size. They taught participants that having a team was indicative of being a large city, but found that it did not appear to alter the effect of recognition based on a between experiments comparison. We did not teach participants about this relationship but instead relied on participants generalizing from their likely awareness that the major American professional sports teams are rarely in small cities.

The same cities were always paired but each pair appeared equally often in each cue and induced condition. Cues appeared in two possible orders (maximum information to none, or vice-versa), and the cities appeared in two different orders. Thus there were 16 versions of the city-size task (four cue by two cue-order by two city-order conditions) that appeared equally often with each induction list.

Procedure

Participants were first given one of the two induction lists and told that their task was to write down the number of syllables in each city name as best they could. They then

spent 30 minutes doing unrelated tasks until they were given one version of the city-size task and asked to choose which city in each pair they thought was larger. After completing this task they were given a questionnaire that asked them: 1) Does the last task you completed relate to any of the previous tasks? 2) Were your responses to the last task you completed affected by any of the previous tasks? For each question they had to answer "yes" or "no" and to explain their answer. These questions were used to determine if participants were explicitly connecting together the induction and city size tasks. Participants who said the syllable task affected them when choosing cities were replaced in the design. This was to protect against the possibility that participants might just select cities because they thought they were supposed to select cities from the induction list. Fewer than 10% of participants were replaced and subsequent analyses found no evidence that the replaced subjects responded differently.

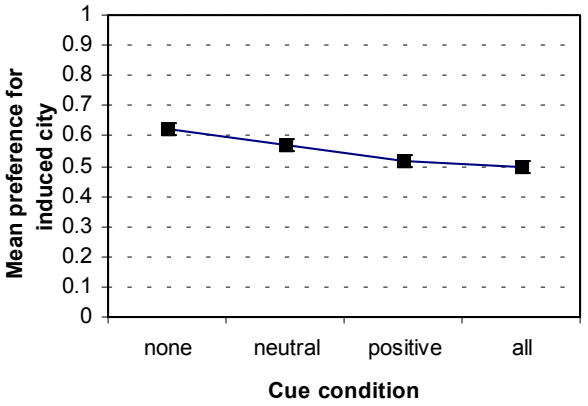

Figure 1: Mean preference for the induced city for each cue level (Bars represent one standard error). Above .50 represent preference towards induced cities.

Results

Figure 1 indicates mean preferences for the induced cities for each cue level. To calculate preferences we examined the two city pairs in each of the cue conditions. If a participant chose the induced city in both pairs (i.e., the pair in which cues were given for the induced city and the pair in which cues were given for the noninduced city) they were assigned 1.0, if they chose the induced city once and the noninduced once then they were assigned 0.5, if they chose the noninduced city both times then they were assigned 0.0. Thus mean preferences range from 0.0 to 1.0. Preferences above .50 indicate a bias towards induced cities, whereas below .50 indicates a bias towards noninduced cities.

Participants had preferences for the induced city above .50 for the cue-none (.62, $t[255] = 5.72$, $p < .001$) and cue-neutral (.57, $t[255] = 3.78$, $p < .001$) conditions, but not for the cue-positive (.52, $t[255] = 1.14$, $p = .258$) or cue-both conditions (.50, $t[255] = -0.14$, $p = .887$). Ordering the four cue condition in terms of amount of extras information given (none, neutral, positive, all) produced a significant linear trend, $t(765) = 5.38$, $p < .001$. Separately calculating the proportion of participants choosing the city for which cues were given, but ignoring whether this was the induced or noninduced city, we found a strong effect of how much information participants were given (cue-none .50; cue-neutral .58; cue-positive .79; cue-all .84), $F(3, 576) = 62.8$, $p < .001$.

Of the 256 participants, 44 indicated that they thought the city size task related to the syllable task, but they were not eliminated from the sample because they said that the syllable task did not affected their responses. However it is possible that effects were driven by just these participants who explicitly remembered the syllable task. Analyzing separately these 44 participants and the other 212, we found the same pattern of results for both groups as we found for the whole sample.

Discussion

When recognition was not confounded with any other information and it was the only cue available, then the city likely to be recognized was selected more than chance. The 62% selection rate for the cue-none condition was not as high as Goldstein and Gigerenzer (2002) report but there could be several reasons for this. First, we did not test which cities participants recognized and thus we did not only analyze pairs for which only one city was recognized, as Goldstein and Gigerenzer and Oppenheimer (2003) did. Based on the recognition pilot data, it could be estimated that this condition would apply for only 77% of our pairs. (To avoid any possible biases, we analyzed all pairs.) Second, our induction procedure may produce recognition that is relatively weak and uncertain compared to that based on experience. Goldstein and Gigerenzer treat recognition as a binary, all-or-none distinction; however creating this distinction is not without error. As the work on eyewitness testimony has amply shown (Wells & Loftus, 1984), recognition and can be uncertain and it may be hard for a person to decide if they recognize something. This may be especially true for foreign, hard to pronounce words briefly experienced once. Our induction procedure allowed us to manipulate recognition, but it may produce recognition with a different character to that in the previous experiments.

The results also showed that the presence of other cues can moderate the influence of recognition. Oppenheimer (2003) suggested that any evidence of such moderation is evidence against noncompensatory decision making of the type Goldstein and Gigerenzer (2002) described. However evidence that one cue moderates the mean effect of another cue does not establish that individuals are integrating cues as in compensatory multi-cue strategies. Our data may be consistent with Goldstein and Gigerenzer's approach in which only one cue is applied at a time but cues form a hierarchy based on validity. When recognition is uncertain other information may easily be seen as more valid.

Of course there is no true validity for either recognition or other information in this experiment, as relaxing that constraint is what allows us to freely manipulate these factors. We are assuming that participants come to the experiment with cue validities, thus it is not surprising if there may be individual differences in how they assign

validity. There may also be individual differences in strategy selection (Fasolo, Miscuraca, & McClelland, 2003).

Experiment 2

One way of investigating how recognition is combined (or not) with other cues is to equalize the amount of extra information given for each city in a pair. Different compensatory decision strategies differ in the way in which they combine cues, but the impact of a cue in these strategies is greatest when that cue differentiates between options. Thus cues that provide equivalent information for both choices should have no impact on decision making. Therefore the moderating effects of extra cues on recognition should largely disappear.

As Gigerenzer and Goldstein (1996) describe noncompensatory algorithms, cues should continue to be considered until one is found that differentiates the options. This stopping rule implies that only differential cues could moderate the effect of recognition because even if a nondifferential cue is higher in the validity hierarchy, it can have no impact on the final decision. Thus a noncompensatory strategy also predicts that when extra cues are not differential then the moderating effect of those cues on the impact of recognition should disappear.

Experiment 2 varied the same cues as in Experiment 1, but instead of giving cues about just one of the two cities, we gave equivalent cues for both. Thus the extra cues never distinguished the two cities, allowing us to test if undifferentiating information still moderated the recognition effect. Both compensatory and noncompensatory approaches make the same prediction: Whatever recognition effect is found for the cue-none condition, the same recognition effect should be found for other cue conditions. If this prediction is violated and cue condition still moderates the recognition effect, then it can point to modifications necessary to these approaches.

Method

Participants

A total of 128 members of the Michigan State University participant pool participated for partial course credit.

Materials and procedure

The exact same procedures and induction lists were used as in Experiment 1. The city-size task was identical except that equivalent cues were given for *both* members of the eight pairs. Thus for the two pairs in the *cue-all* condition a state was given for both cities and both cities were said to have a major league soccer team. For the two pairs in the *cue-positive* condition it was stated that both cities had soccer teams and that the states were not known. For the two pairs in the *cue-neutral* condition a state was given for both cities and it was stated that whether or not these cities had a soccer team was unknown. For the two pairs in the *cue-none* condition it was stated that neither piece of information was known. Thus the design of Experiment 2 was simpler than Experiment 1 but eight pairs were still given. We again counterbalanced the four cue conditions across the city pairs, used two orders of presentation, and two city-orders, which yielded sixteen version of the city task. Each version was presented equally often with each induction list.

Results & Discussion

Figure 2 presents the mean proportions of participants in each information condition who selected the induced city. In the *cue-none* condition the rate of choosing the induced city (.63) was significantly above .50, $t(127) = 4.29$, $p < .001$, but this was not the case for the *cue-all* condition (.54), $t(127) = 1.37$, $p = .175$. Proportions above 50% were almost statistically significant for both the *cue-neutral* (.56), $t(127) = 1.78$, $p = .075$, and *cue-positive* (.56) conditions, $t(127) = 1.91$, $p = .058$. Thus this experiment again found a clear effect of induced recognition when no prior knowledge could be confounded with recognition, especially when no new information about the cities was given.

Overall, there was a significant linear trend for cue condition on the proportions of induced cities selected, $t(381) = 2.15$, $p = .033$. Just as in Experiment 1, giving participants other cues reduced the impact of recognition. However it appears that the volume of information was critical, as this information did not differentiate the options.

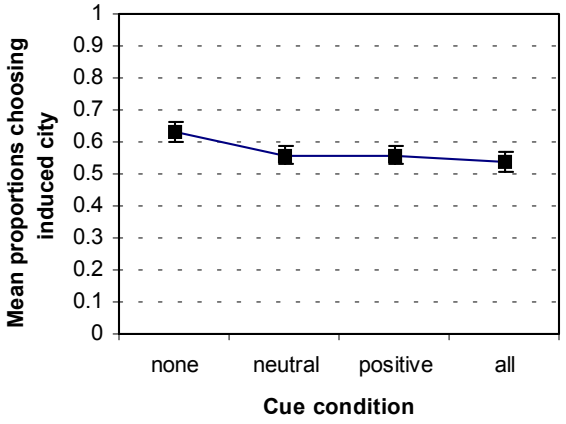

Figure 2: Mean proportions of participant in each cue condition choosing the induced city rather than the noninduced city (Bars represent one standard error). Above .50 indicates a preference for the induced city.

General Discussion

Our results show that recognition effects of the type Goldstein and Gigerenzer (2002) found are not only due to recognition being confounded with other cues. When recognition was unconfounded and was the only available cue the city more likely to be recognized was selected at a rate above chance.

Using within experiment manipulations our results supported Oppenheimer's (2003) finding that the presence of other cues could moderate a recognition effect. However

the results of Experiment 1 are consistent with recognition being part of either compensatory or noncompensatory strategies, as long as recognition is not always the most valid cue. In contrast, the results of Experiment 2 are consistent with the predictions of neither type of strategy, as nondifferential cues should have no impact on decision making. What assumptions would need to be added to these approaches in order for them to explain these results?

Whatever function a compensatory strategy applies to options, the same function would be applied to both cities in a pair. Thus providing the same cue for both cities should just add a constant to the evaluation of both cities. Thus the difference between evaluations will not change. One way to deal with the evidence from Experiment 2 would be to make the total amount of information part of the integration process. Perhaps there is a Weber function for comparing options like there is for comparing perceptual stimuli. This would represent a revision to current compensatory strategies that would yield testable predictions.

Nondifferential cues should be ignored by noncompensatory strategies. However, they could have an impact if the algorithm had a stopping rule that may stop evaluating cues before one is found that differentiates. It seems consistent with bounded rationality that sometimes the evaluation is made by an organism that there is little value in continuing looking for discriminating information. Thus as each nondifferentiating cue is examined there may be a nonzero probability that the organism will decide to stop. If the extra cues may be placed higher in the validity hierarchy than recognition (as Experiment 1 may suggest) then such a stopping rule could lead nondifferential cues to moderate the utilization of differential recognition.

Such a stopping rule might take into account the anticipated cost of evaluating information. This may be particular relevant in our paradigm as the type of uncertain recognition we might have induced may have a cost. Anderson's ACT-R framework emphasizes the cost of any remembering (Anderson, Lebiere, & Lovett, 1998). Recognition is not necessarily more accurate than recall (Tulving & Thomson, 1973), and it may be inaccurate and uncertain (Wells & Loftus, 1984). Thus even a single nondifferential cue may reduce the impact of recognition if it can be higher in the cue hierarchy.

Experiments that examine recognition free of confounds are useful for understanding this heuristic as a processes rather than just a phenomenon, and the importance of doing this in general was pointed to by Gigerenzer (1996). Both the compensatory and noncompensatory approaches to how multiple cues affect decision-making seem under-specified, and thus unable to explain the results of Experiment 2. The paradigm we introduced here has promise for furthering the understanding of heuristics utilizing recognition and the process by which recognition affects choices.

Abstract

We study how Extraversion and Neuroticism influence people's language production in interpersonal interactive situations. A priming study used confederate priming methodology to investigate syntactic priming behaviour. We expected that Extravert sociability would be related to the strength of priming effects, although Neurotic emotionality might also have an effect. Results indicate that Extraversion has no effect, but Neuroticism does have an effect. We discuss possible reasons and suggest further experimentation to investigate this finding. Implications and applications of this work are outlined.

Personality and interaction

Individuals differ in the way they speak and write. Some of those differences are systematic, and can be attributed to apparently deeper differences, such as personality traits, like Extraversion and Neuroticism (or Emotional Stability). Level of Extraversion is intuitively related to sociability and communication, and this is expressed through interpersonal behaviour. However, level of Neuroticism appears to be more related to anxiety and inward focus, and thus having greater influence on solo behavior. In the past, it has been found that both these personality traits do significantly influence an individual's language production behaviour in a variety of contexts (Pennebaker and King, 1999; Dewaele and Furnham, 1999). Recent work has investigated e-mail text, and suggested that even in that genre, there are characteristic sequences of words associated with each end (High or Low) of both dimensions (Extravert or Neurotic) (Gill and Oberlander, 2002, 2003b).

The majority of work on the relations between personality and language production has studied monologue only. Yet most everyday language occurs in the context of interpersonal interaction. So here, we aim to investigate the role of personality upon language use in a dialogue setting.

Studies of conversational behaviour have demonstrated that individuals align with their interlocutors on a number of levels (Pickering and Garrod, in press). The phenomena have been examined from both social and cognitive perspectives. On the social side, a key focus of interest is cooperation and audience design. On the cognitive side, a key focus is coordination and interpersonal priming.

For example, sociolinguistic studies have shown that speakers adopt accent or dialectal variation or a level of lexical density appropriate to their audience. This variation operates at phonological, lexical, and syntactic levels (Labov, 1972; Coupland, 1980; Bell, 1984; Bradac and Wisegarver, 1984). Audience design is regarded as a relatively conscious process over which the speaker has a certain amount of control. It may be a result of co-operativity, affiliation, or willingness to take another's perspective (Haywood, Pickering, and Branigan, 2003).

By contrast, from a cognitive perspective, coordination is viewed as an artifact of the underlying language production mechanisms. For example, it has been argued that references from the comprehension system are recycled to provide output for the production system (Pickering and Garrod, in press). Alignment is found at the lexical level (Brennan and Clark, 1996; Branigan, Pickering, and Cleland, 2000), the conceptual level (Garrod and Doherty, 1987), and the syntactic level (Pickering and Branigan, 1998). Unlike cooperation, such coordination is considered to be largely subconscious.

Coordination therefore provides a more direct insight into underlying processing abilities, and is less prone to outside influence. In approaching the study of personality in dialogue, we therefore use an interpersonal priming paradigm. At the outset, our question is very general: Can differences in interpersonal priming be attributed to personality?

To make this question more specific—and to attempt to answer it—the rest of this paper is structured as follows. First, we introduce a little more background on personality theory. Then, we frame a possible explanation of recent findings on the relations between Extraversion, Neuroticism and language production; this leads to two hypotheses concerning the possible relation between personality and interpersonal priming. We then present the priming experiment which tested these hypotheses. The results were somewhat unexpected, and we conclude by discussing their implications.

Overview

There are a number of approaches to personality (Matthews and Deary, 1998). Two of the most prominent trait theories are the five factor model (Costa and McCrae, 1992), and Eysenck's three-factor PEN model (Eysenck, Eysenck, and Barrett, 1985; Eysenck and Eysenck, 1991). These agree that two main factors are Extraversion (sociability) and Neuroticism (emotional stability). The Five Factor Model sees three further dimensions: Conscientiousness, Agreeableness and Openness; PEN arguably conflates these into one dimension, Psychoticism (tough mindedness). In what follows, we focus on the first two dimensions, common to both models.

The traits can be summarised thus: A typical Extravert tends to be sociable, needs people to talk to, craves excitement, takes chances, is easy-going, and optimistic. By contrast, a typical Introvert (Low Extravert) is quiet, retiring, reserved, plans ahead, and dislikes excitement; A typical High Neurotic tends to be an anxious, worrying, moody individual. A typical Low Neurotic tends be calm, even-tempered and relaxed (Eysenck and Eysenck, 1991).

Personality and language

Work on personality and language behaviour has studied a range of features. For instance, Extraverts are regarded as talking louder (Scherer, 1978), demonstrating a higher speech rate (Siegman, 1987), and they show less hesitation, but make a higher proportion of semantic errors (Dewaele and Furnham, 2000). At a grammatical level, Extraverts use greater proportions of pronouns, adverbs, verbs (Cope, 1969), which contrasts with the more explicit language of the Introverts and their increased use of nouns, modifiers and prepositions (Dewaele and Furnham, 2000). Additionally, Extraverts demonstrate lower lexical richness in formal situations (Dewaele and Furnham, 2000), whilst analysis of informal e-mail communication has shown highly Neurotic language to be more repetitious (Gill, 2003; Gill and Oberlander, 2003b). At a more content-oriented level, Pennebaker and King (1999), using the Linguistic Inquiry and Word Count text analysis program, showed that broad psychological language categories are related to dimensions of personality variation. For example, they found that when writing about thoughts and feelings, high Neurotics use more negative emotion words and fewer positive emotion words.

However, our interest here is on interaction: dialogue and conversation. Studies using speech act coding have found that Introverts used more hedges and problem talk, namely expressing qualification, and dissatisfaction with one's own activities, while Extraverts expressed more pleasure talk, agreement, and compliments, with content focusing more on extracurricular activities (Thorne, 1987). Extraverts have also been shown to use more self-referent statements, and initiate more laughter (Gifford and Hine, 1994). Gifford and Hine also found that Extraverts talk more, with other studies finding that they use a greater total number of words (Campbell and Rushton, 1978; Carment, Miles, and Cervin, 1965). As would be expected, Extraverts show greater desire to initiate interactions (McCroskey and Richmond, 1990), even in computer-mediated communication (Yellen, Winniford, and Sanford, 1995). Also, Dewaele (2002) finds that in L3 English production, Extraversion (and also Psychoticism) showed a strong negative relationship to communicative anxiety, whilst Neuroticism showed a positive relationship.

Studies investigating hemispheric asymmetry provide a further perspective on this area, for example, Davidson (2001) proposes the relationship between Extraversion and positive affect with approach behaviours, and Neuroticism and negative affect and withrawal behaviours. In the following hypotheses, we explore the implications of personality, affect and approach/withdrawal on priming behaviour.

Hypotheses for interpersonal priming

The likelihood of priming may be affected by the tendency to approach or the tendency to withdraw—or by both.

If Extraversion is associated with approach behaviours, it is natural to expect that higher Extraversion will lead to "more approach", and that this might mean that an individual will coordinate more with their interlocutor. Furthermore, the Extravert's higher drive to gain or retain the conversational floor will mean that less effort can be directed towards detailed language planning. Hence, if their partner has made a lexical or syntactic choice, the High Extravert is likely to re-use that choice, rather than explicitly planning a new one (cf. Gill and Oberlander, 2003a).

If Neuroticism is associated with withdrawal behaviours, it could well be that high levels of this trait result in "more withdrawal" and lower engagement with the interlocutor. Furthermore, the inward (worrying) focus of a High Neurotic might mean that more resources are devoted to inner thought, and fewer to interaction with the environment. Thus, we might expect that such an individual will coordinate less with their interlocutor.

Thus, there is a clear prediction for Extraversion, and a slightly more complex picture for Neuroticism. Of course, it could be that neither Extraversion nor Neuroticism have any effect on coordination or priming.

Method

In syntactic priming, a particular syntactic structure is more likely to be produced given prior exposure to the same structure (Schenkein, 1980). This

phenomenon has been replicated under experimental conditions when speakers say, hear, or read sentences (e.g., Bock, 1986; Pickering and Branigan, 1998; Corley and Scheepers, 2002). Bock and colleagues found that people tended to repeat the active or passive form of a sentence they had just read in describing an unrelated picture (Bock, 1986; Bock, Loebell, and Morey, 1992). In this study we employ the confederate priming method (Pickering and Branigan, 1998): The subject of the experiment takes part in a dialogue game along with a confederate of the experimenter. The game involves matching and describing pictures. Both participants apparently have the same two tasks: to describe a set of pictures so that the other participant can match them, and to verify whether the descriptions that they hear match the picture that they see. However, the confederate's descriptions are scripted.

Participants

Forty University of Edinburgh students who were self-declared native speakers of English were paid to participate in this study. Personality information derived from the NEO-PI questionnaire is as follows: Extraversion M = 51.75 (SD = 12.82), and Neuroticism M = 54.18 (SD = 12.72).

Materials and Design

We prepared two sets of pictures depicting actions. Each set included 12 pictures depicting transitive actions involving an agent and a patient. The entities depicted were chosen to be easily recognisable and nameable. There were two pictures for each of 12 transitive verbs (*bite, chase, dust, hit, kick, lift, poke, pull, push, shoot, touch, weigh*). These 24 pictures comprised the set of targets. The remaining 120 pictures in each set depicted intransitive actions. There were several pictures for each of 20 intransitive verbs. These comprised the filler pictures.

The appropriate verb was printed under each action. Each set of pictures depicted the same range of entities and actions. However, the pairing of entities with actions was different.

We term one set the Subject's Description Set and the other set the Confederate's Description Set. We created ordered pairs of prime and target pictures by pairing each description of a transitive action from the Confederate's Description Set (the prime) with a picture depicting a transitive action from the Subject's Description Set (the target picture).

Half of the prime sentences were assigned active descriptions of the form 'the X verbing the Y', and half were assigned passive descriptions of the form 'the Y being verbed by the X'. An experimental item was defined as the confederate's scripted description of a prime picture plus the subject's target picture paired with it. There were thus two versions of each item: active confederate description and passive confederate description.

We constructed four lists containing 24 experimental items and 120 subject fillers. The confederate fillers were randomly distributed in the remaining gaps. The entities depicted in the target picture were not present in the immediately preceding block (prime plus subject fillers and confederate fillers). The verb also differed between prime and target. Each picture was assigned to either the match or the mismatch condition for the matching task. For the latter, we assigned another picture depicting a different entity doing the same action (thus using the same verb) was assigned. Each list contained 12 experimental items with active prime descriptions and 12 with passive prime descriptions. Exactly one version of each item appeared in each list. Hence, Prime Type (active vs. passive) was manipulated within subjects and items. The dependent measure was the proportion of descriptions of target pictures produced with a passive structure.

Procedure

The Subject's Description Set was presented to the subject via a computer program.The order of the pictures was randomised for each subject, with between four and eight filler items intervening between each experimental item. A divider prevented the subject from seeing the confederate or his computer screen. The experimenter told the subject and the confederate that the experiment was investigating how well people communicate when they cannot see each other. Their tasks were alternately to describe the pictures to the other participant, and to match their picture to the other participant's descriptions. When it was the subject's turn to match, the confederate would see a sentence appear on his screen which he would read aloud and then press space bar, at which point a picture would appear on the subject's screen. The subject was instructed to say "yes" or "no" (or ask for repetition) and to press the Z key for "no" and the M key for "yes" according to whether the picture matched or mismatched the description. When it was the subject's turn to describe, a picture would appear on the subject's screen and the confederate would say "yes" or "no" (or ask for repetition) and press the Z key or the M key according to whether the picture on his screen matched or mismatched the description. Throughout the session, the experimenter and confederate acted as if the confederate was a genuine subject (e.g., the confederate asked questions about the task). Before the experiment, there was a practice session with two filler items each, after which the subject could ask for clarification if necessary. The confederate also gave the first description. Hence the confederate's description of a prime always immediately preceded the subject's description of a target. Both dialogue participants wore a lapel microphone. The experimental session was recorded on audio tape and subsequently transcribed.

Table 1: Proportion of Passive target responses after active and passive primes and degree of priming

Group	Nos.	PP	AP	Priming
Low E	8	.1363	.0300	10.6
Mid E	27	.2015	.0270	17.5
High E	5	.1500	.0480	10.0
Low N	5	.1160	.0480	6.8
Mid N	28	.2271	.0261	20.1
High N	7	.0486	.0343	1.4
Total	40	.1820	.0302	15.2

We coded the first response that the subject produced; 3 target responses that described the agent as the patient and the patient as the agent were excluded. We coded the remaining target 957 responses as passive if the patient was described as being verbed by the agent and as active if the agent of the action was described as verbing the patient.

An analysis of variance (ANOVA) was conducted, with prime type (active vs. passive) as a within subjects factor and Neuroticism (Low [> -1 s.d. of the mean], Mid [< 1 s.d. of the mean], High [$> +1$ s.d. of the mean]) as a between subjects factor.

Results

Proportions of passive target responses following passive and active primes are reported in Table 1; these are described by personality type of participant, and also for the group overall. Here we can see that in both cases the Mid groups appear to show greater priming. However the High and Low Neurotic groups appear to show even lower levels of priming than for Extraversion.

Turning now to our analysis of variance, and here the ANOVA revealed a significant effect of prime type (active vs. passive) on the proportion of passive forms used (F_1 (1,37) = 6.63; $p < 0.05$; F_2 (1,23) = 97.01; $p < 0.05$).

A significant interaction was found between Neuroticism (Low, Mid or High) and prime type (F_1 (1,37) = 3.68; $p < 0.05$). Post-hoc Tukey tests revealed that both the High N and Low N groups primed significantly less than the Mid N group ($p < 0.05$). No interaction was found between Extraversion and prime (F_1 (1,37) = 0.60; $p > 0.1$).

Discussion

We found a reliable effect of syntactic priming of active and passive structures in a dialogue task. This confirms our expectations and replicates previous syntactic priming found in dialogue (e.g., Pickering and Branigan, 1998) and with active vs. passive forms (e.g., Bock, 1986).

Additionally, our results demonstrate that Neuroticism is related to the degree of syntactic priming for passive constructions; Extraversion is not. We now relate these results to our hypotheses. For Extraversion, we proposed that higher levels of Extraversion would lead to an increase in priming. Here we found that the Mid group primed more, however this result was not significantly different to that of the Low and High groups. In this case we therefore accept the null hypothesis that Extraversion is not related to levels of priming. For Neuroticism, we find that the Low and High groups primed significantly less than the Mid group. Comparing this result directly with our Neuroticism hypothesis creates a tension: We proposed that the High group would less likely to prime due to an inward focus and thus withdrawal from their partner. To address these findings, we therefore reframe our Neuroticism hypothesis as follows: as before, we claim that the High group are less likely to prime due to inward focus, but that the Low group are also less likely to prime, since they are less concerned with monitoring themselves in relation to their interlocutor. In this case—as in our results—the extreme High and Low levels of the trait have an inhibitory effect on priming, and the Mid trait levels represent a facilitating effect.

We acknowledge that such explanation is relatively speculative, and further experimentation will be required to test this hypothesis. For example, the NEO-PI questionnaire divides Neuroticism into 6 facets: anxiety, angry hostility, depression, self-consciousness, impulsivity, vulnerability. It may be that these may relate more specifically to withdrawal or threat-monitoring, in which case these could be related to the priming information. However, we expect that a larger experimental population would be required for such work. For Extraversion, no significant pattern emerges, however we propose that the extremes are similarly inhibited by over- or under-other-directedness.

Turning now the significance of our findings, and they have several important implications. At a theoretical level, they provide more data about personality behaviour in dialogue contexts, which extend previous research using monologue data. Additionally this can better inform our understanding of personality in relation to models of language production.

Our results also contribute to the dialogue and priming literature which, for example, acknowledge that individuals often behave differently, but that systematic variation has mainly been examined in sociological terms. Here we have presented data which shows real and important differences between individuals in conversational behaviour, and highlights the potential role of personality in priming experimentation, more generally.

Finally, our findings can be used to directly inform dynamic computer interface technology, which could allow linguistic alignment in a realistic way. For example, Nass, Moon, Fogg, and Reeves (1995) have shown that computer users viewed their ma-

chine more favourably when it mirrored their personality. On the basis of work reported here, we are closer to being able to represent personality at the conversational, interactive level. We therefore anticipate that this will lead to more convincing artificial agents and intelligent dynamic computer interfaces.

These findings also nicely complement those presented by Branigan, Pickering, Pearson, McLean, and Nass (2003), in which computer users syntactic align with a pre-programmed computer interface, whether they believed this to be another person or an 'unintelligent computer'. Therefore, if such an 'unintelligent computer' was to project personality, we may expect it to vary its degree of priming—in addition to its lexicon—depending upon the sort of personality *it* may wish to project.

Conclusion

We have used experimental priming data to investigate the influence of personality on interpersonal language behaviour. Proposing hypotheses which suggested both Extraversion and Neuroticism influence linguistic coordination, here we found that the less interpersonal trait—Neuroticism—surprisingly influenced priming, whilst Extraversion did not. Given our finding that priming is facilitated by moderate Neuroticism, but inhibited by more extreme levels, we explain this in terms of withdrawal by building upon a previously proposed model of personality and language production. Issues regarding the significance and potential implications of this study are also discussed.

Abstract

Enhanced behavioral performance mediated by multisensory stimuli has been shown using a variety of measures, including response times, orientation behavior and even simple stimulus detection. In the particular case of the study of saccadic response to unimodal or bimodal stimuli, Corneil et al. (2002) were able to show that the bimodal visual-auditory saccades benefited from the accuracy of visual saccades at saccadic response time (SRTs) typical of auditory saccades. However, there has been little evidence of multisensory mediated improvement in stimulus localization. Recently, Hairston et al. (2003) shows improvement in visual-auditory localization performance (variability) for induced myopia while no benefit was reported for normal vision. Using a similar experimental design, taking into account two space dimensions, azimuth vs. elevation, we examined the ability of human subjects to localize visual, auditory and combined visual-auditory targets for stimuli considered optimal for the given task. The results showed significant improvement in bimodal localization when compared with the more accurate modality, visual, as measured with multi criterion data (precision, dispersion and orientation of the response patterns). Furthermore, the 2D analysis of combined visual-auditory target localization performance, for azimuth and elevation response components, underlines the role of the auditory system in the determination of the response characteristics. The data suggested that visual-auditory localization performance benefited from the "*best of the two worlds*" (Corneil et al., 2002), in that it was improved only in the horizontal plane, and restricted to the response criterion where audition is more reliable than vision.

Introduction

The literature dealing with intersensory perception first dealt with the phenomena of sensory illusions, the most well known being the ventriloquism effect (Howard and Templeton, 1966) and the McGurk effect (McGurk and McDonald, 1976). Both these "on-line" effects result from discrepancies, either spatial and/or temporal between the two unimodal components of the stimulation. The much more ecological situation, in which visual and auditory signals are synergetic, i.e. in terms of spatial and temporal congruence, has been rarely investigated systematically in a localization task. Furthermore, to our knowledge, taking into consideration the two dimensions (azimuth and elevation) of the observer's perceptive field for a multimodal localization task was never explored. In addition, the simultaneous presentation of spatially congruent visual and auditory cues was mostly studied considering detection of a target (Frasinetti et al., 2002), orientation toward a target (Stein et al., 1988, 1989) or reduction in response latencies (Hugues et al., 1994; Frens et al., 1995, Colonius & Arndt, 2001) rather than purely localization capability. When shown, increase in precision of the localization was restricted to the analysis of an angular value, expressing the stimulus-response discrepancy in polar coordinates. The purpose of this experiment was to evaluate multisensory integration in a two-dimensional localization task and qualify the nature of a cross modal benefit that could be obtained when the spatial information in the two modalities was convergent. We suggested a separate analysis of the localization performance for the azimuth and elevation components of the response, as a function of target double pole coordinate system in which the origin coincides with the center of the head. This procedure should reveal the contribution of the auditory modality into the bimodal localization performance, given the initial differences in coding the position of an auditory target in azimuth (Interaural Time and Level differences) and in elevation (monaural spectral shape cues). Indeed, as a consequence of this specific coding, auditory resolution differs in the horizontal and the vertical dimension while the visual resolution, associated to a retinotopic coding, is isotropic in space. The investigation of criterion we assumed to be relevant for the task was performed. Centering, precision, dispersion and orientation of the responses were successively examined to determine a potential benefit and the modal contribution of a bimodal visual-auditory target presentation.

Materials and methods

Participants

Ten adults, aged 22 to 50 years, took part in the experiment. They all had a minimum of 20/20 visual acuity (if need be, corrected). Their audiometric capacities were also normal, with age related variations. All were naïve regarding the setup configuration (number and positions of the auditory sources).

Experimental setup

The participant sat in darkness in the center of an acoustically transparent semi-cylindrical vertical screen, 120 cm in radius and 145 cm high, with the head maintained by a chin-rest, as shown in Figure 1. A Liquid Crystal Display Philips Hopper SV10 video-projector was hung above and behind the observer, 245 cm from the screen, providing a 80° horizontal x 60° vertical green light field of view of 1.5 cd.m^{-2} average luminance (Fig. 1). The color green (coordinates of the 1931 CIE system x = 0.267; y = 0.640) was used for the background and for the visual stimulus, and made it possible to obtain a maximum signal to noise contrast and maximum background homogeneity, given the characteristics of the optic device. A PC (Pentium III 300 MHz) equipped with a 128 SoundBlaster sound card and a Matrox G400 (32MB) video card generated the stimuli. It was connected to the video-projector on the one hand, and to the loudspeakers via an audio switch and its Velleman K8000 control module, on the other hand. Thirty five 10-cm-diameter loudspeakers (Fostex FE103 Sigma) were laid out behind the screen in a 7 x 5 matrix, with a 10° step. The speaker positions were defined in a two-dimensional polar coordinate system with the origin at the straight-ahead fixation position. Eccentricity in the perceptive field was referred in relation to this coordinate system. The speakers were positioned at azimuths 0°, ±10°, ±20°, ±30° and elevations 0°, ±10°, ±20° (Figure 2).

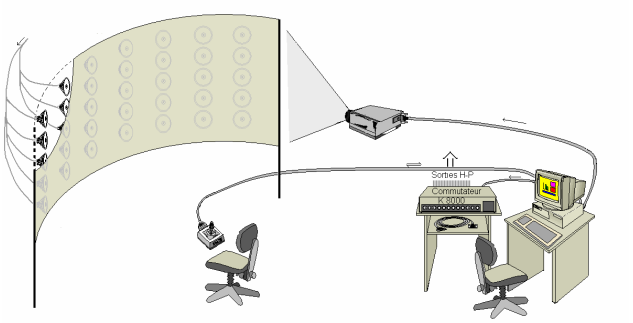

Figure 1: The experimental setup.

Visual stimuli consisted of a spot of light (100ms, 20 cd.m^{-2}), subtending a 1° of visual angle and auditory stimuli consisted of a pink noise burst (broadband noise, constant intensity per octave), 100ms duration (20ms fade-in and fade-out), at 49dB as measured at the subject's ear or hearing position, against a 38dB background noise (precision integrating sound level meter Brüel and Kjaer Model 2230). The device allows the precise superimposition of the visual and auditory stimulation for a combined presentation to the target, where the spot of light is exactly located at the center of the loudspeaker's cone. To perform localization judgments, participants used a track-ball, allowing for movements along all directions. Figure 2 describes the succession of the events in trial.

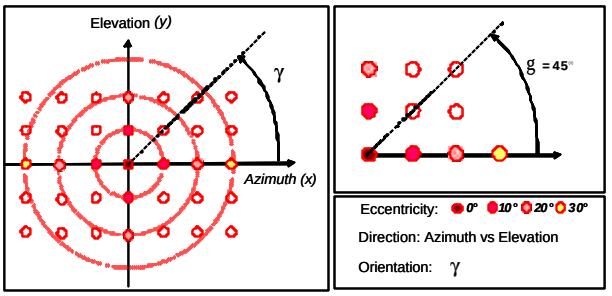

Figure 2: Definition of the independent variables used in the analyses and characterizing the target position. *Eccentricity* refers to the distance of the target from the center of the 2D perceptive field, *Direction* allow transforming target and response *Orientation* (?) in a two components position (azimuth and elevation).

1. At the beginning of each trial, a fixation cross was presented at the center of the screen, at (0°, 0°) coordinates, for 500 to 1500 ms for acquisition.
2. At the extinction of the cross, the visual, auditory or bimodal visual- auditory stimulus was presented randomly at one of the 35 positions during 100ms. The picture illustrates a - 20° to 0° visual stimuli.

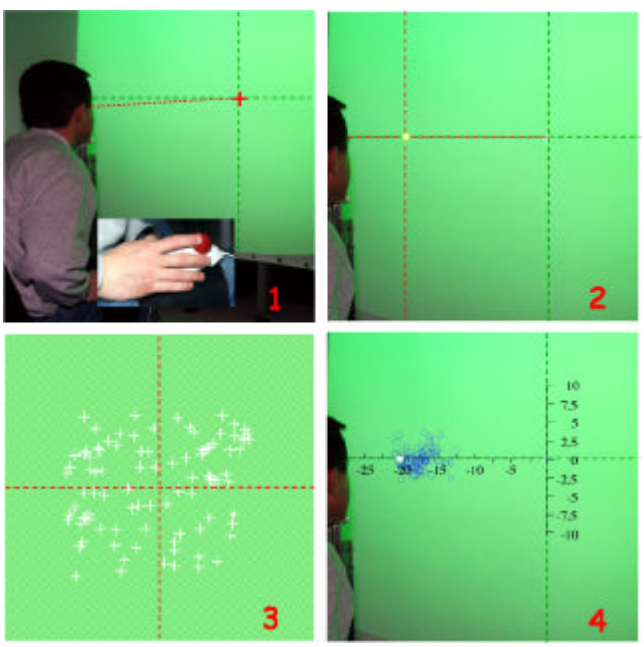

Figure 3: The experimental paradigm. 1. Presentation of a fixation cross at the center of the screen. 2. A visual stimulus at (-20°, 0° coordinates). 3. All the possible cursor position for the -20°, 0° target position. 4. Each dot stem from an individual localization response.

3. After the target disappears, a response cursor, associated to the further manipulation of the track-ball, appears randomly inside a 20° imaginary circle whose center is the position of the target with a minimum of 2.5° distance from it in both axes (azimuth and elevation).

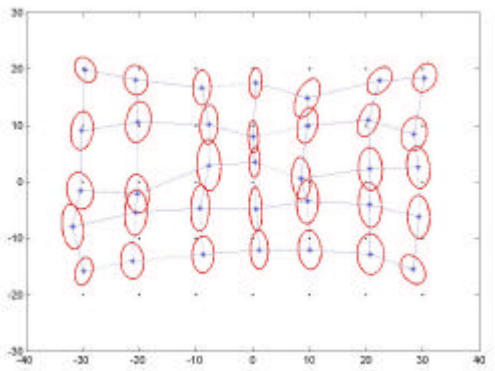
Subjects were instructed to localize the target as accurately as possible while pointing this cursor towards the perceived location of the target, the temporal constraint being secondary. The picture 4 illustrates the response distribution of the 10 subjects and 10 repetitions for the given location of the visual stimulation. The experiment consisted of 6 experimental sessions with 10 repetitions of each stimulus combination (3 stimulus conditions [Visual, auditory, bimodal] at 35 locations [7 azimuth values, 5 elevation values] presented in pseudo-random order) for a total of 175 trials per session, with a 1.5s inter-trial interval.
Prior to testing, 20 practice trials were performed to make the participant familiar with the task and the manipulation of the track-ball. The session lasted about 30 min. and a minimum 24-hour delay was observed between two sessions.

Data analysis

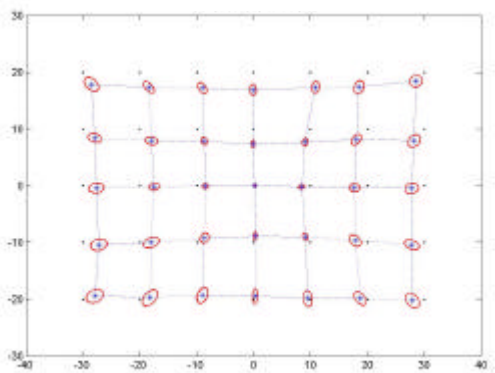
Localization errors were calculated as the difference, in degrees, between the localization judgment and the actual target location. Taking into consideration the azimuth and elevation components of the response, *centering* and *precision* of the responses were calculated from the raw data. *Centering* refers to the mean response, which the sign denotes a tendency to overshoot (positive values associated to errors eccentric to the target in reference to the reference coordinates) or undershoot (negative values associated to errors central to the target). *Precision* evaluate the amount of discrepancy (absolute value) from target to designation. The distribution of the response patterns were computed using a procedure of regression analysis for obtaining the regression slope that determines the major *orientation* of the response distribution. Estimation of the maximum and minimum variance of the distribution along the slope axis and the perpendicular one, respectively noted *b* and *a*, were used for *dispersion* analysis. By extension, in reference with Hofman et Van Opstal (Hofman et Van Opstal, 1998), a characterization of the response patterns under a geometrical approximation, i.e. ellipses, did allow a better comparison within and between modalities than the traditional methods using a two-dimensional discontinuous space analysis (Oldfield et Parker, 1984). In this way, the analysis of dispersion and orientation of the patterns would provide complementary data to those obtained with the use of the horizontal and vertical axis of the 2D coordinate system. To analyze the data, multiple 2-way within subjects ANOVAs were performed according to the specific hypothesis: Statistical comparisons were structured to examine the main effect of target modality (visual, auditory, combined visual-auditory) and target location (eccentricity range [0°, 10°, 20° and 30°] and direction [azimuth versus elevation]) as well as the possible interaction between the variables.

Results

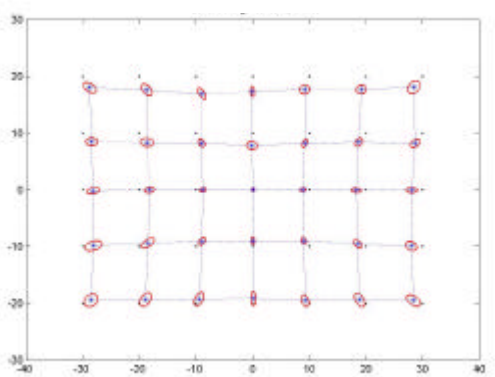
The results only consider here the comparison of response localization between modalities while a preliminary work was performed on unimodal data to ensure the validity of the results. We shall now successively describe the data using the four variables mentioned in section Data Analysis.



Auditory condition



Visual condition



Combined visual-auditory condition

Figure 4: Responses patterns as approximated by ellipses for the 3 conditions and the 35 target positions.

Precision of the responses

A short look at the approximated data for each condition of presentation of the target for the 35 positions tested (Figure 4) underlines the specificity of the auditory system in terms of localization capability and the relative similar localization behavior between the visual and the bimodal conditions.

Table 1: Precision of localization between conditions

Modality	Azimuth		Elevation		A/E	$F_{1,3486}$	*P*
	Error	SD	Error	SD			
Auditory	**2,96°**	**±2,6°**	**6,15°**	**±4,94°**	**A<E**	**1159**	**<0,0001**
Visual	**1,87°**	**±1,7°**	**1,86°**	**±1,63°**	**A=E**	**0,119**	**0,7304**
Bimodal	**1,53°**	**±1,5°**	**1,62°**	**±1,49°**	**A<E**	**7,7**	**0,0055**

A more detailed analysis of mean of errors confirmed this first impression. A repeated measures ANOVA showed that the effect of modality condition is significant in azimuth ($F_{2,336}$=87.2; p<.0001) and in elevation ($F_{2,336}$=23.316 p<.0001). The much more interesting result concerned the significant improvement in bimodal localization compared to the visual one in azimuth, (Scheffe test, p=0.0302) but interestingly, not in elevation (Scheffe test, p=0.8355). When looking at the within-modality variations between error in azimuth and error in elevation, expressed by the Azimuth/Elevation precision relationship (A/E in table 1), it appears that the gain obtained in the bimodal condition follows the difference in precision of the auditory condition (with statistically significant values). This result is an argument for audition playing a structuring role in intersensory processing for a spatial task.

Centering of the responses

One of the most well known characteristics of the auditory system is concerned with the differences in accuracy between azimuth and elevation, in relation to the differences in the initial information extraction process in the two directions of space (Oldfield & Parker, 1986; Hofman & Van Opstal, 1998). As a consequence, there is a strong response bias in the elevation responses, with a central compression of the auditory space related to a systematic undershoot of target eccentricity in this direction. No observable or statistical improvement in centering was obtained between the visual and the combined audio-visual conditions. On the other hand, the localization of an auditory target in azimuth is much less biased by eccentricity than for the visual and bimodal conditions, as illustrated in Figure 5. In this direction, the reduction of error is at the maximum when the direction of the visual and the auditory biases are in opposition of signs. When the sign of the bias is identical, no visible effect is observed. A statistical comparison between the visual and bimodal results fails to show any improvement, probably due to the arithmetic mean performed on data expressed in polar coordinates. Despite the lack of significance, the results did again suggest that the contribution of the auditory modality did enhance performance.

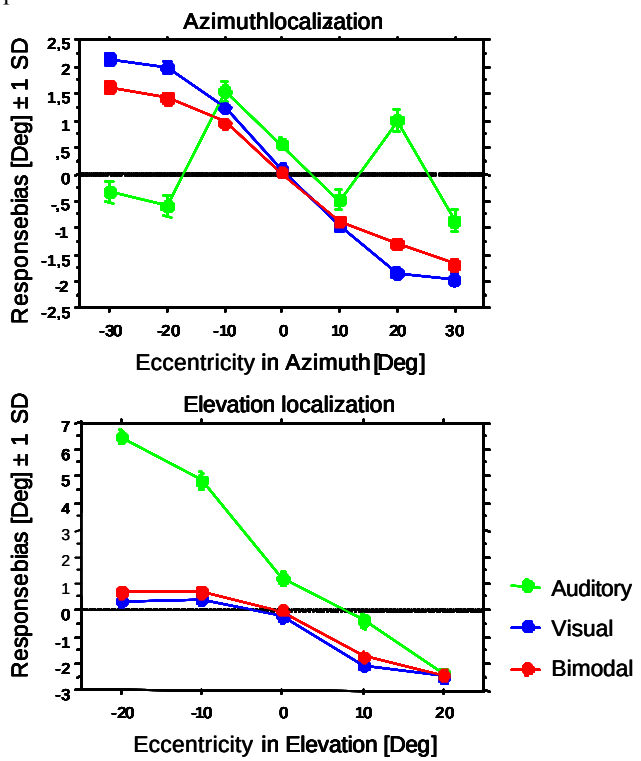


Figure 5: Centering of the responses for azimuth and elevation components of the localization responses. Improvement in performance is only visible in the horizontal plane.

Dispersion of the responses

The diverse responses are compared on the two characteristic axis of the responses patterns, *a* and *b* (Cf. Data analysis).

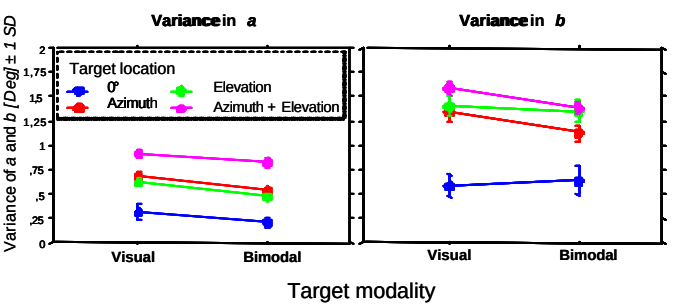

Figure 6: left: Decrease in variance in a between the visual and bimodal condition for all target locations. Right: Decrease in variance in b between the visual and bimodal condition for the targets that didn't belong to the median sagittal plane (0° and Elevation).

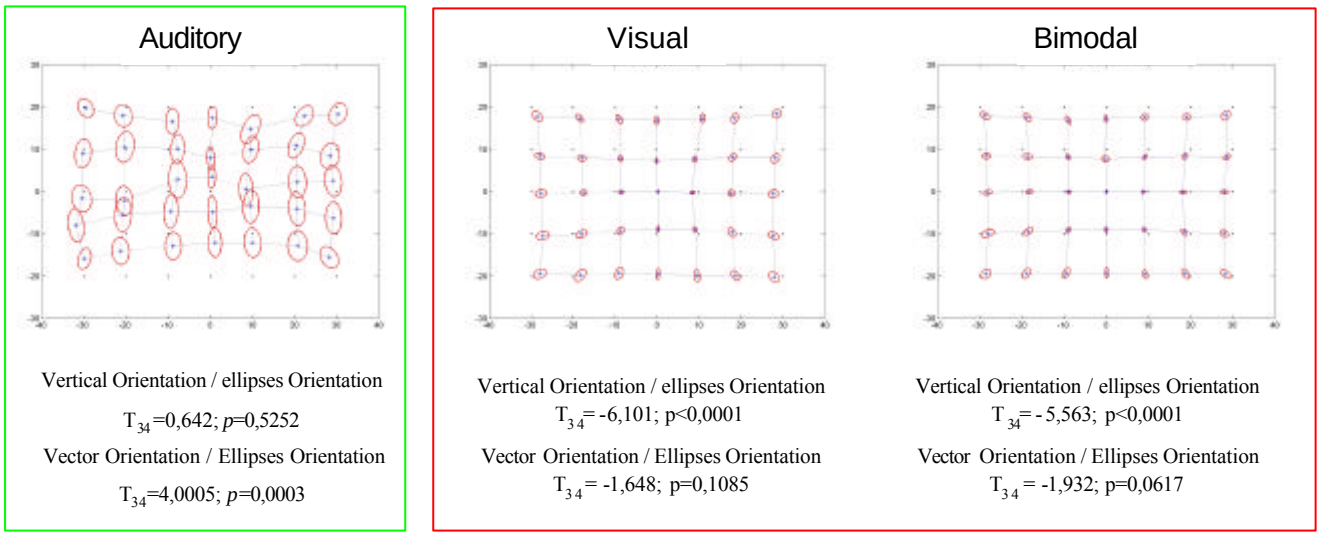

Figure 8: Orientation of the responses in relation with target location in the 2D perceptive field. In the auditory condition, the response patterns are vertically oriented (90°-180° axis) while visual and bimodal response patterns exhibit a vector distribution with the ellipses oriented centrifugally (toward the center of the perceptive field).

The minimum variance axis, *a*, diverges significantly according to the modality condition for target presentation (repeated measures ANOVA: ($F_{2,338}$=43.055 p<.0001), with the comparison of visual and bimodal conditions being also significant ($F_{1,169}$=23.356 p<.0001). Similar results are obtained for the *b* axis, with a slightly different behavior in relation to target location, expressed by the belonging or not to a specific plane (0°, Azimuth, Elevation, or combined eccentricity in Azimuth and Elevation). Indeed, only the targets that are not located on the median sagittal plane (0°and Elevation only) did benefit of a significant variance reduction (Figure 6).

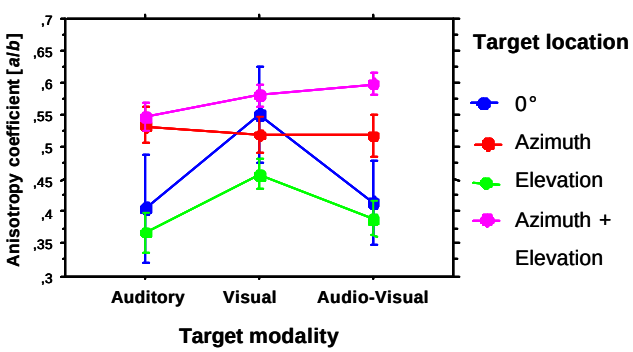

Figure 7: Anisotropy coefficient variations according to target modality and location in the 2D perceptive field. Note that the coefficient varies in the same way for auditory and bimodal conditions.

We also calculated an anisotropy coefficient, corresponding to the *a*/*b* ratio (a "1" value corresponding to an homogeneous distribution along the two axis), and looked at the variations of this coefficient according to the target location in space. It can be seen in Figure 7 that the value of the coefficient follows the same variations in the auditory and the combined visual-auditory condition. Once again, these data pointed out the role of the auditory modality into the multimodal spatial perception, not only in performance improvement, but also in representation structuring.

Orientation of the responses

At this point, we shall remember that the orientation of the responses distributions are determined by the slope of the regression analysis computed for the 35 tested target positions and the 3 modalities. In each condition, the calculated orientation is compared to two models of sensory coding: an auditory coding using a Cartesian coordinates system on one hand, and a vector coding, which can reflect a saccadic component in the response, on the other hand. The data shown in Figure 8allow mentioning that auditory response patterns are vertically oriented while visual and bimodal response patterns exhibit a vector distribution with the ellipses oriented centrifugally. These observations could reflect a possible different role of the saccadic system according to the target modality and the presence vs. absence of visual information in the perceptive field.

Discussion

This study investigated the localization performance to visual, auditory, and bimodal stimuli distributed throughout the 2D perceptive field. The result of the current study illustrates a significant multisensory

enhancement of localization performance in precision and dispersion. Through a quantitative approach, the data allowed to parameterize the different dimensions which describe the perceptive field of an ideal observer and to attest to the relative contribution of each sensory modality into the bimodal perception. The results argue for an integrative process applying for synergetic presentations of visual and auditory stimuli, and cues considered as well suited for the given task. For all that, our result did not refute the very ecological principle of the "inverse effectiveness rule" (Stein & Meredith, 1993). They just underline the structuring role of the auditory system only when it is more reliable than the visual system, what can be shown only by the comparison in performance for the two directional components (azimuth and elevation) of the response. It is a strong argument to say that sensory integration in a localization (spatial) task rests on a tendency to optimization. Looking at the data obtained by Corneil et al. (2002), showing that bimodal visual-auditory saccades were at least as accurate as visual saccades, but also generated at saccadic response times (SRTs) shorter typical of auditory saccades, our result also go in the way of a very similar neural process applying. This tendency to optimize shall be considered as an economic and ecological process that drove the Central Nervous System (CNS) to use the sensory systems in relation with the specific contribution they can have. In the case of a localization task (spatial task), and given the reliability of each sensory system, we demonstrated an improvement in centering and a part correction of the variance attributed to audition, an increase in precision and possibly in structure of representation for vision.

Expressions Related to Knowledge and Belief in Children's Speech

Andrew S. Gordon (gordon@ict.usc.edu) and Anish Nair (anair@usc.edu)
Institute for Creative Technologies, University of Southern California
13274 Fiji Way, Marina del Rey, CA 90292 USA

Abstract

Children develop certain abilities related to Theory of Mind reasoning, particularly concerning the False-belief Task, between the ages of 3 and 5. This paper investigates whether there is a corresponding change in the frequency of linguistic expressions related to knowledge and belief produced by children around these ages. Automated corpus analysis techniques are used to tag each expression related to knowledge and belief in a large corpus of transcripts of speech from normally developing English-learning children. Results indicate that the frequency of expressions related to knowledge and belief increases steadily from the beginning of children's language production. Tracking of individual concepts related to knowledge and belief indicates that there are no clear qualitative changes in the set of concepts that are expressed by children of different ages. The implications for the relationship between language and the development of Theory of Mind reasoning abilities in children are discussed.

A Developing Theory of Mind

Among the most interesting of human cognitive abilities are those concerning how we understand and reason about the minds of others. The term *Theory of Mind* is used pervasively throughout the cognitive sciences to refer to the set of abilities that enable people to reflect introspectively on their own reasoning, to empathize with other people by imagining what it would be like to be in their position, and to generate reasonable expectations and inferences about mental states and processes.

Within the research area of developmental psychology, Theory of Mind has been studied as a set of cognitive abilities that progressively emerge in children. A standard experimental instrument for studying children's Theory of Mind abilities is the false-belief task. In a standard version of this task (Wimmer & Perner, 1983), the child is introduced to two characters, Maxi and his mother. Maxi places an object of interest into a cupboard, and then leaves the scene. While he is away, his mother removes the object from the cupboard and places it in a drawer. The child is then asked to predict where Maxi will look for the object when he returns to the scene. Success on this task has been criticized as neither entirely dependent on Theory of Mind abilities nor broadly representative of them (Bloom & German, 2000), however its utility has been in reliably demonstrating a developmental shift. Wellman et al. (2001) analyzed 178 separate studies that employed a version of this task, finding that 3-year-olds will consistently fail this task on the majority of trials by indicating that Maxi will look for the object in the location to which his mother has moved it. 4-year-olds will succeed on half the trials, while 5-year-olds will succeed on the majority of trials. Call & Tomasello (1999) demonstrate that these results are consistent across verbal and non-verbal versions of this task.

Children's developing performance on the false-belief task is particularly interesting when couched within the larger debate concerning *maturation* and*. conceptual change* in cognitive development. Like every other cognitive ability that emerges in childhood, performance on Theory of Mind tasks is likely due to a complex combination of maturing innate abilities and knowledge learned through experience. Still, understanding the relative importance of these two factors may have some utility in evaluating two types of cognitive process models that have been proposed to account for human Theory of Mind abilities.

First, *Theory Theory* hypothesizes that Theory of Mind abilities are computed by prediction and explanation mechanisms by employing representation-level knowledge about mental attitudes (Gopnik & Meltzoff, 1997; Nichols & Stich, 2002). Second, *Simulation Theory* argues that Theory of Mind abilities are computed by imagining that you are in the place of the other person, then inferring their mental states by monitoring the processing that is done by your own cognitive abilities (Goldman, 2000). With respect to the development of Theory of Mind abilities in children, each of these theories would emphasize different things as most important. Theory Theorists would argue that the acquisition of mental models of commonsense psychology would play the most important role, a view consistent with a conceptual change model of development (e.g. Bartsch & Wellman, 1995). In contrast, Simulation Theorists would look instead for a maturational change that enabled children to take the perspective of other people or in the monitoring of one's own mental state, a view consistent with a modularity model of development (e.g. Scholl & Leslie, 2001).

One approach to investigating this issue is to look for evidence of the acquisition of mental models of commonsense psychology in the language that children use in everyday conversation. The contemporary view of natural language understanding and generation presupposes that the meaning of verbal expressions are representational in nature, and that these underlying representations are the same ones that would be manipulated for the purposes of inference (e.g. explanation and prediction). By tracking the production of children's speech that references commonsense psychology concepts, we can look for some correlation between linguistic competency with commonsense psychology concepts and emerging Theory of Mind abilities.

In this paper, we explore the progressive use of expressions that reference commonsense psychology concepts in children's language. The approach that we take in this investigation is to employ automated corpus analysis techniques developed within the computational linguistics research community, where the aim is to construct computer programs to reliably recognize every possible way of expressing a concept within a given language. In using automated corpus analysis techniques, we were able to quickly analyze each of the datasets within the CHILDES linguistic corpus (MacWhinney, 2000) that contained transcriptions of normally developing, monolingual English-learning children.

The specific interest that we had in conducting this research concerned the acquisition of a linguistic competency for concepts related to knowledge and beliefs, as they are the most relevant to the false-belief task described earlier. By examining the correspondences between these linguistic competencies and the ages in which children acquire cognitive competencies in Theory of Mind tasks, our aim is to provide an additional point of evidence that can be used in arguing for or against the competing models of the cognitive processes that underlie these abilities.

The Theory of Mind in Language

The Theory of Mind in Language project at the University of Southern California is an effort aimed at developing a large-scale lexical-semantic resource for the automated annotation of commonsense psychological concepts expressed in English text. This resource is being authored as a set of local grammars, encoded as finite-state transducers that can be applied to large text corpora for concept-level tagging and markup. Associated with each unique concept tag in the resource is a local grammar that has been hand-authored with the aim of recognizing every possible way that the concept could be expressed in the English language. The application of these local grammars to text documents produces an annotated text, where each English expression that is recognized as referencing a commonsense psychological concept is tagged. The following paragraph (from William Makepeace Thackeray's 1848 novel, *Vanity Fair*) provides an example of the output of the application of this lexical-semantic resource.

> Perhaps [*partially-justified-proposition*] she had mentioned the fact [*proposition*] already to Rebecca, but that young lady did not appear to [*partially-justified-proposition*] have remembered it [*memory-retrieval*]; indeed, vowed and protested that she expected [*add-expectation*] to see a number of Amelia's nephews and nieces. She was quite disappointed [*disappointment-emotion*] that Mr. Sedley was not married; she was sure [*justified-proposition*] Amelia had said he was, and she doted so on [*liking-emotion*] little children.

The tag set that is being used in this lexical-semantic resource was developed first through the large-scale analysis of strategies, defined as the abstract structural commonalities that exist between analogous planning cases (Gordon, 2002). 635 concepts resulting from this analysis (grouped into 30 representational areas) were related to a Theory of Mind, which constitutes the broadest cognitive science specification of a representational Theory of Mind to date. Gordon & Hobbs (2003) describe how this tag set is modified through the process of examining the breadth of English language expressions that are related to a given representational area, among the 30 in the complete set. Gordon et al. (2003) describes the process of constructing local grammars for each of the concepts in the revised tag set, encoded as finite-state transducers, and describes an evaluation to determine the effectiveness of this approach at automatically recognizing every English expression that refers to the concept tag in written text.

One of the 30 representational areas described in this previous work, Managing Knowledge, specifically deals

Managing knowledge (37 concepts)

He's got a logical mind (*managing-knowledge-ability*). She's very gullible (*bias-toward-belief*). He's skeptical by nature (*bias-toward-disbelief*). It is the truth (*true*). That is completely false (*false*). We need to know whether it is true or false (*truth-value*). His claim was bizarre (*proposition*). I believe what you are saying (*belief*). I didn't know about that (unknown). I used to think like you do (*revealed-incorrect-belief*). The assumption was widespread (*assumption*). There is no reason to think that (*unjustified-proposition*). There is some evidence you are right (*partially-justified-proposition*). The fact is well established (*justified-proposition*). As a rule, students are generally bright (*inference*). The conclusion could not be otherwise (*consequence*). What was the reason for your suspicion (*justification*)? That isn't a good reason (*poor-justification*). Your argument is circular (*circular-justification*). One of these things must be false (*contradiction*). His wisdom is vast (*knowledge*). He knew all about history (*knowledge-domain*). I know something about plumbing (*partial-knowledge-domain*). He's got a lot of real-world experience (*world-knowledge*). He understands the theory behind it (*world-model-knowledge*). That is just common sense (*shared-knowledge*). I'm willing to believe that (*add-belief*). I stopped believing it after a while (*remove-belief*). I assumed you were coming (*add-assumption*). You can't make that assumption here (*remove-assumption*). Let's see what follows from that (*check-inferences*). Disregard the consequences of the assumption (*ignore-inference*). I tried not to think about it (*suppress-inferences*). I concluded that one of them must be wrong (*realize-contradiction*). I realized he must have been there (*realize*). I can't think straight (*knowledge-management-failure*). It just confirms what I knew all along (*reaffirm-belief*).

Figure 1. Example expressions for 37 concepts related to Managing Knowledge.

with the concepts surrounding knowledge and belief, including assumptions, contradictions, justifications, logical consequences, truth, falsehood, and the mental processes associated with these commonsense psychological entities. Gordon et al. (2003) describe 37 concept tags associated with this area, which is presented here in Figure 1. The evaluation described in this previous work indicated that the lexical-semantic resources associated with this specific subset of the tag set was effective at identifying 83.92% of the expressions associated with these tags in English written text (recall score), and that 92.15% of the tagged expressions would be judged as appropriate by a human rater (precision score).

References in the CHILDES Corpus

As a corpus of analysis, we utilized the CHILDES database of children's speech (MacWhinney, 2000), a collection of transcripts from a wide variety of psycholinguistic studies conducted largely in the 1980s. Specifically, we analyzed the transcripts from the 42 research studies that contributed data of normally developing monolingual English-learning children.

To facilitate the analysis of this dataset according to the age of the children, individual files were generated containing only the transcripts of speech produced by a single child for each of the transcript files (a total of 3001 individual files). The total number of words in each file was calculated and the age of the child (in months) was recorded. There were 3,347,340 words transcribed in these files from children ranging in age from 11 to 87 months.

Figure 2 presents a histogram of the number of words in the files associated with each age of the children. The notable spike that appears in this figure is due to a large dataset that exists within the CHILDES database contributed from a study by Hall et al. (1984). The groups of children are collectively identified only as being between the ages of 54 and 60 months without differentiation, so all of this dataset was used for evidence at the low end of this range. More significantly, Figure 2 reveals that comparatively little data exists within the CHILDES corpus of normally developing monolingual English-learning children after the age of 5 years (60 months). Although the available data should allow for the observation of some interesting trends throughout the age range of the corpus, some caution is necessary when drawing strong conclusions about children older than 60 months.

In order to enable comparisons between children and adults, each of the analyses were also conducted on the CALLHOME American English Speech data collected and transcribed by the Linguistic Data Consortium (1997). The CALLHOME database consists of transcripts of 120 unscripted telephone conversations (302,083 words) between native speakers of English, where the callers average 38.875 years in age (σ=16.14).

Given these text corpora, two sets of analysis were conducted. Both of these analyses involved the use of tag frequency as data points. To compute tag frequency, the local grammars described in the previous section were applied to a corpus in order to find every expression within the corpus that should be tagged with the concept associated with each local grammar. The number of tagged expressions was then divided by the number of words that were searched to compute each frequency data point. In the first analysis, the frequency of all expressions of the 37 concepts related to knowledge and belief were tabulated for each of the datasets. In the second analysis, the frequencies of expressions related to each individual concept (of the 37 total) were tabulated.

No attempt was made to filter the results of the application of the local grammars to improve precision, and no evaluation was conducted to estimate the recall rate on these corpora. However, after reviewing the resulting tags we believe that the precision and recall scores obtained on these corpora are only marginally less than was achieved in the evaluation of written text tagging conducted by Gordon et al. (2003) using the same set of local grammars.

Frequency of all expressions related to knowledge

The first analysis that we conducted was to apply all of the local grammars for the 37 concepts related to knowledge and belief to each of the data files corresponding to children of different ages. In all, there were 18,283 tags produced

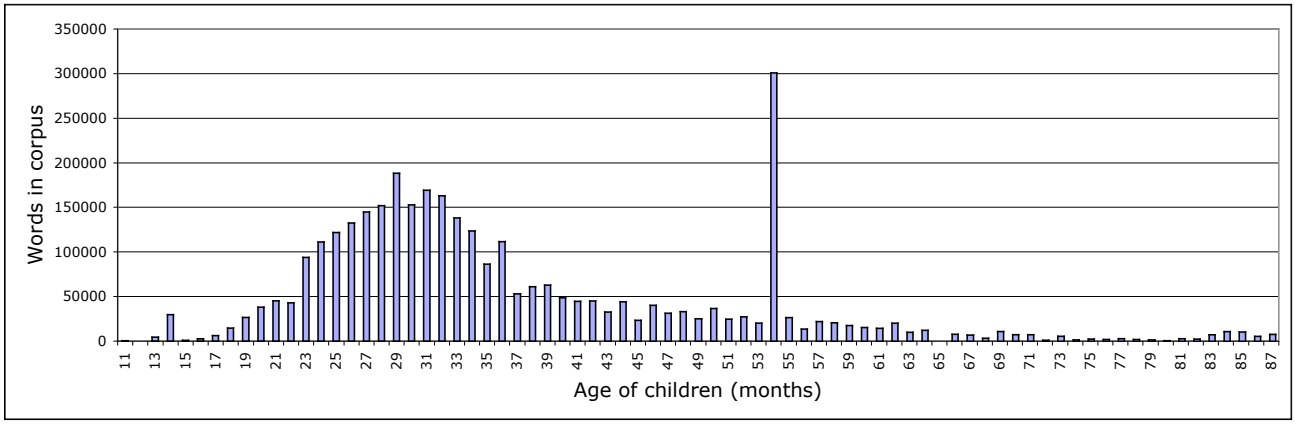

Figure 2. Number of words in corpus by age of children in months

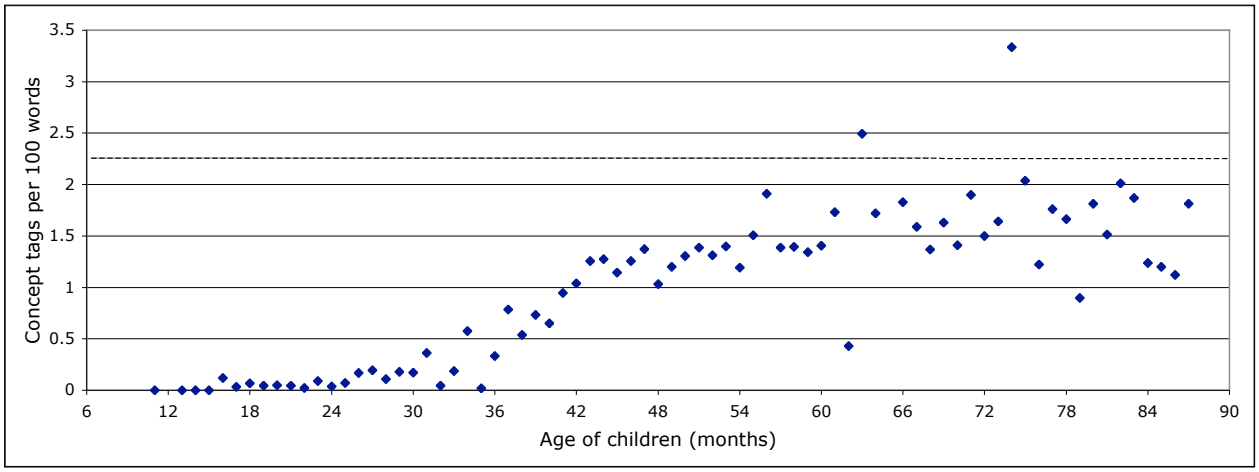

Figure 3. Frequency of all expressions related to knowledge and belief by age of children

through the application of these local grammars, with only 19 of the 37 tags appearing in the data. Nearly half of these tags were for the concept of a justified proposition (9113 tags), while the remaining half was dominated by tags to the concepts of belief (3150 tags), contradictions (3485 tags), and partially-justified propositions (1483 tags).

Applying the full set of local grammars to the CALLHOME data set produced 6775 tags, yielding a frequency of 2.24 reference per 100 words of speech. 21 of the 37 tags were assigned to this data, with the highest frequencies going to the concepts of justified proposition (3172 tags), contradiction (1551 tags), belief (1000 tags), and partially-justified proposition (493 tags).

Figure 3 presents a graph of the frequency per 100 words of speech for all expressions related to the concepts of knowledge and belief based on the age of the children (in months) of the analyzed data. As a point of comparison, the frequency for the CALLHOME data (2.24) is also indicated on the graph as a dashed horizontal line. The data on the graph can be described by the linear function $y=0.0281x - 0.3914$, where the correlation statistic (r^2) is 0.7021.

The results indicate that expressions related to knowledge and belief do not appear at the beginning of children's speech production, but increase in frequency in a strongly linear manner from 30 months (2.5 years) until 48 months (4 years), when the frequencies of these expressions are roughly half of what is observed in adult conversational speech.

Frequency of expressions of individual concepts

In the second analysis, we individually applied each of the 19 local grammars that produced at least one tag in the corpus to each of the transcript data for children of different ages. The primary purpose of this analysis was to track the relative increase in frequency for each concept over the developmental period where a change in Theory of Mind abilities is evident (between 36 and 60 months of age).

	Total tags	24 mo.	30 mo.	36 mo.	42 mo.	48 mo.	54 mo.	60 mo.	CallHome

Figure 4. Frequency of expressions of individual concepts related to knowledge and belief (tags per 10,000 words)

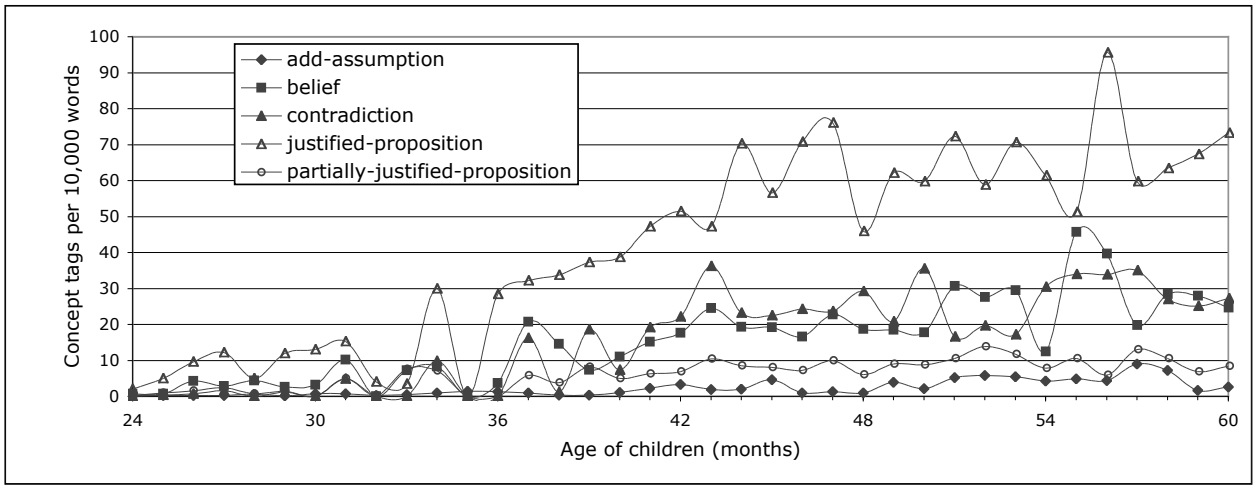

Figure 5. Frequency of expressions of the 5 most frequent individual concepts by age of children

Figure 4 presents a chart of the results of this analysis. Each concept is listed with the total number of tags assigned in the corpus and frequencies of occurrence within the data sets for 24, 30, 36, 42, 48, 54, and 60 month-old children, along with the CALLHOME frequency for the concept. Figure 5 further describes the results of this analysis by charting the growth in frequency of expressions related to the 5 most frequent concepts tagged in the corpus (add-assumption, belief, contradiction, justified-proposition, and partially-justified-proposition) between the ages of 24 and 60 months.

The results indicate that the increases in overall frequency of expressions related to knowledge and belief can be attributed to a steady increase in expressions related to a handful of concepts, particularly the concepts of belief, contradiction, and justified-propositions. This steady increase begins at 24 months and continuing past 48 months, when the frequencies of these expressions are roughly half of what is observed in adult conversational speech evidenced by the CALLHOME corpus. There is no evidence of any qualitative change in the sorts of concepts related to knowledge and belief that are expressed by children of different ages.

Discussion

The overall purpose of this study was to determine the relationship between a linguistic competency in the production of expressions related to knowledge and belief and children's developing Theory of Mind abilities, particularly during the age range where children acquire competency on the false-belief task (between 3 and 5 years in age). In this section, we will consider the results of our analysis with respect to this purpose.

First, there is no evidence to suggest a qualitative change in the *frequencies* that children express concepts related to knowledge and belief between the ages of 3 and 5. Looking first only at the frequency of all expressions related to knowledge and belief we see that children between the ages of 3 and 5 are continuing a steady increase in frequency that started at the beginning of their speech production. The sparse data that we have for children older than 60 months suggests that this gradual increase begins to level off after this point. If we had seen a non-linear shift in the frequencies of expression between 3 and 5, then an argument could have been made relating linguistic competency to Theory of Mind abilities. Finding no such shift, one could reasonably infer that the developing linguistic competencies that children have for expressions related to knowledge and belief are unrelated to their reasoning abilities in Theory of Mind tasks.

Second, there is no evidence to suggest a qualitative change in the *concepts* that children express related to knowledge and belief between the ages of 3 and 5. Looking at the individual frequencies for each of the 19 concept tags that were assigned to the corpus we see that the handful of concepts that account for the vast majority of tags increase in frequency at a constant rate from the very beginning of children's speech production. Very few expressions appear in this data related to other concepts that appear with slightly higher frequencies in adult discourse, and there is no evidence that linguistic competency is acquired for these concepts during this period of time either. If we had seen a change in the concepts that were being expressed between 3 and 5, then a different argument could have been made relating linguistic competency to Theory of Mind abilities. Finding no such change one could again reasonably infer a lack of a direct relationship between language-use and acquired reasoning abilities.

Together these two points argue against a strong relationship between linguistic competencies for expressions related to knowledge and belief and children's developing Theory of Mind abilities. This argument is particularly important in evaluating cognitive models that assume that Theory of Mind abilities and language abilities are enabled by representational mental models of the same type. If we assume that the sophistication of children's representational theories of knowledge and belief is closely related to the way that children express these concepts in language, then

there is little evidence to suggest that these representational theories change at all between ages of 3 and 5, when competency on the false-belief task develops. Accepting this assumption, the evidence in this paper would argue against any strong *conceptual change* account of Theory of Mind abilities where competency on the false-belief task is due solely to the acquisition of more sophisticated representational mental models. This evidence would argue instead for a *maturational* account, where competency on the false-belief task can be attributed to the development of new cognitive abilities for taking the perspective of other people or in the monitoring of one's own mental state between the ages of 3 and 5. One strong counterargument that could be made against this line of reasoning concerns the differences in the linguistic competencies between language production and language understanding. In analyzing transcript data consisting of words uttered by children, this study can make no claims regarding the linguistic competency that these children might have for *understanding* expressions related to knowledge and belief during the relevant periods of development.

Conclusions

The availability of large corpora of transcripts of children's speech production has afforded researchers the opportunity to investigate a wide variety of issues related to language acquisition. This paper has demonstrated that specific issues related to the acquisition Theory of Mind abilities can also be addressed using these corpora. By employing automated techniques for the tagging of expressions related to commonsense psychology we have been able to efficiently analyze data sets that are larger than could have been reasonably tackled given limited resources.

The specific interest of this paper was to determine if there was evidence for change in the linguistic competency in expressions related to knowledge and belief during developmental periods associated with acquired competency in the false-belief task (between 3 and 5 years of age). By using automated corpus analysis techniques, expressions related to knowledge and belief were identified across all datasets within the CHILDES corpus containing speech from normally developing monolingual English-learning children. By charting the frequencies of these expressions at different ages, it is evident that children steadily increase the frequency of expressions related to knowledge and belief at a constant rate from the beginning of their speech production. By tracking the production of expressions related to individual concepts, no qualitative changes in the conceptual content of these expressions over time is evident. These results argue against a strong relationship between linguistic competencies for expressions related to knowledge and belief and children's developing Theory of Mind abilities.

Strategy Constancy Amidst Implementation Differences: Interaction-Intensive Versus Memory-Intensive Adaptations To Information Access In Decision-Making

Abstract

Over the last two decades attempts to quantify decision-making have established that, under a wide range of conditions, people trade-off effectiveness for efficiency in the strategies they adopt. However, as interesting, significant, and influential as this research has been, its scope is limited by three factors; the coarseness of how effort was measured, the confounding of the costs of steps in the decision-making algorithm with the costs of steps in a given task environment, and the static nature of the decision tasks studied. In the current study, we embedded a decision-making task in a dynamic task environment and varied the cost required for the information access step. Across three conditions, small changes in the cost of interactive behavior led to changes in the strategy adopted for decision-making as well as to differences in how a step in the same strategy was implemented.

Introduction

In the 80's and 90's, Payne, Bettman, and Johnson (1993) showed that decision-makers trade-off efficiency of their decision making strategy for the effort it requires. They attempted to quantify the cognitive effort of decision making by counting the number of steps that different strategies required for the same decision. The conclusion of this work was that people adapt to a wide variety of conditions to find a strategy that is about as accurate as it needs to be for as little cognitive effort as possible.

As interesting, significant, and influential as Payne, et al.'s work was, its scope was limited by three factors; the coarseness of how effort was measured, the confounding of the costs of steps in the decision-making algorithm with the costs of steps in a given task environment, and the static nature of the decision tasks studied.

First, the *elementary information processes* (EIPs) that Payne et al. used to count steps were neither elementary or steps. By today's standards EIPs such as "reading value, comparing two values or storing a result in long-term memory" (Todd & Benbasat, 2000) would be analyzed as a series of more fundamental cognitive, perceptual, and action operations. Furthermore, the count of steps was not based on an analysis of the decision-making process executed by a human, but stemmed from task analyses of the minimum number of steps a perfect agent would require to execute the algorithm. The step count did not consider the mis-steps or re-steps taken by a boundedly rational agent as they skipped a step or forgot an intermediary product, and then backed up and redid a number of steps to recover.

Second is the confounding of the costs of a step in the decision-making algorithm with the costs associated with how a step is implemented in a given task environment. Research has shown that the organization, form, and sequence of information influences strategy selection (for example, Fennema & Kleinmuntz, 1995; Kleinmuntz & Schkade, 1993; Schkade & Kleinmuntz, 1994). Other research has looked at how individual differences in working memory capacity interact with interface design to affect performance on decision-making tasks (Lohse, 1997). Other studies have looked at how the design of decision aids may have unintended consequences for the decision strategies that people adopt (Adelman, Miller, & Yeo, 2001; Benbasat & Todd, 1996; Rose & Wolfe, 2000; Todd & Benbasat, 1994, 1999, 2000). At least one study has investigated how the cost of information access affects strategy selection (Lohse & Johnson, 1996).

The third limit on the scope of Payne, et al.'s pioneering work is that the decision-making tasks they used were static, not dynamic. Although time constraints were sometimes introduced (Payne, Bettman, & Luce, 1996), these were extrinsic, not intrinsic to the decision-making task. For example, subjects were told to work quickly, timed, or rewarded for fast performance. Such extrinsic time pressure differs from tasks where the information, options, and criteria for decision-making change over time (Adelman, Bresnick, Black, Marvin, & Sak, 1996) or in which an early step in decision-making may result in changes to the task environment (Ehret, Gray, & Kirschenbaum, 2000). Hastie (2001) has characterized these dynamic situations as entailing a series of "linked decisions in a dynamic, temporally extended future" and has marked understanding this type of decision making as one of his 16 challenges for decision-making research in the 21st century.

The current paper reports empirical data from the first of a planned series of experimental and modeling efforts to extend the scope of decision-making research. In the study reported here, decision-making was embedded as an integral part of a dynamic classification task. Subjects' goal was to score as high as possible on the classification task while maximizing performance on the decision-making task. This initial study focuses on the ways in which varying the cost of interactive behavior affects the decision-making process. Specifically, across three between-subject conditions, we introduced modest differences in the cost of information access and studied how these differences affected the mix of cognitive, perceptual, and action operations for acquiring and comparing information.

Method

Subjects

Forty undergraduate students participated for approximately five hours each. Seven failed to complete the study. Subjects were either given course credit or were paid $5.00 per hour of participation and a $5.00 per hour completion bonus. Subjects were run individually.

Task

The experimental task was a preferential choice decision-making task embedded in the Argus Prime simulated radar-operator task environment (Schoelles & Gray, 2001a). Argus Prime is a complex but tractable simulated task environment (Gray, 2002) that we have used in a variety of studies (see, e.g., Gray & Schoelles, 2003; Schoelles, 2002; Schoelles & Gray, 2001b).

Classification Task. For the classification task, the subject must assess the threat value of each target in each sector of a radar screen (depicted in Figure 1). The screen represents an airborne radar console with ownship at the bottom. Arcs divide the screen into four sectors; each sector is fifty miles wide. The task is dynamic since the targets have a speed and course. A session is scenario driven; that is, the initial time of appearance, range, bearing, course, speed, and altitude of each target are read from an experimenter-generated file. The scenario can contain events that change a target's speed, course, or altitude. New targets can appear at any time during the scenario.

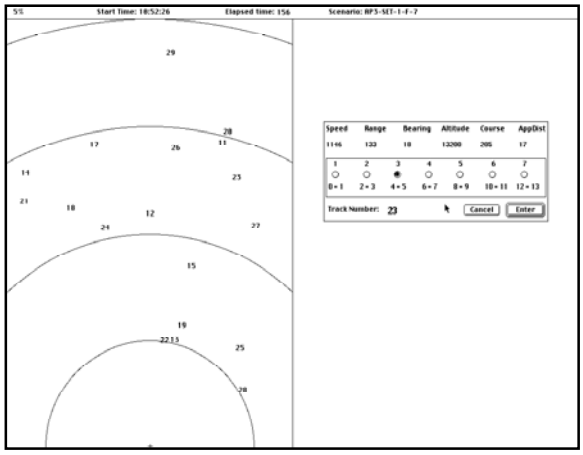

Figure 1: Argus Prime Radar Screen (left) and Information/Decision Window (upper right).

The subject selects (i.e., hooks) a target by moving the cursor to its icon (i.e., track number) and clicking. When a target has been hooked, an information window appears (on the upper-right of the display) that contains the track number of the target hooked and the current value of target attributes such as speed, bearing, altitude, and course. The subject's task is to combine these values, using an algorithm that we have taught them, and to map the result onto a 7–point threat value scale (at the bottom of the information window).

Targets must be classified once for each sector that they enter. If a target leaves a sector before the subject can classify it, it is considered incorrectly classified and a score of zero is assigned. A running score that indicates percentage of targets correctly classified is shown in the upper-left of the display. For this study, each Argus Prime scenario lasted 12-min. During this period a subject had the opportunity to calculate the threat value of between 70 and 90 targets.

The Decision–Making Task (DMT). The decision-making task (DMT) was added to Argus Prime for this study. As discussed in the Procedure section, subjects were introduced to the DMT after an hour of training and a second hour of practice on the classification task.

Each scenario proceeded until the subject had classified 8 targets. At this point, a DMT presented the subject with 4 or 6 targets for which he or she had already calculated the threat value. All groups were given the identification number for each of the DMT alternatives in a *target-column* that appeared in the lower right of the display (this area is blank in Figure 1). The subject's task was to determine which target had the highest threat value and select that target by clicking on its number in the target-column. The DMT ended and the classification task resumed when the subject clicked the CHOOSE button located below the target-column.

On making a correct choice, feedback was given via a simulated explosion, the chosen aircraft was removed from the radar screen, and the overall percent score for decision-making on that scenario was increased. If the participant chose the incorrect target, the participant's overall percent score for that scenario was reduced. A running average of DMT performance was presented to the right of the classification score. After classifying or re-classifying 8 more aircraft, another DMT was presented. This sequence continued until the end of each scenario.

Procedure

Subjects were randomly assigned to one of three DMT conditions: Table, 0-Second Lockout (0-Lock), or 2-Second Lockout (2-Lock). We were most interested in differences between the two lockout conditions, with the Table condition providing a measure of how high decision-making performance could be in this task environment under near optimal conditions.

As in other Argus Prime studies, subjects were trained for 1-hr on the Argus Prime classification task. They then practiced this task during their second hour by performing four scenarios in which the classification task was the only task. After the fourth scenario, subjects were given a short break and were then instructed on the DMT task. Training on the DMT took approximately 10-min. During the last 8 scenarios (5 through 12), subjects continued doing the classification task while being interrupted to perform the DMT.

The more time spent on the DMT, the more likely it would be that a target would cross a sector boundary

without being classified. Such unclassified targets were assigned a score of zero. Hence, time on the DMT decreased time available for classification. This, in turn, placed pressure on the subjects to perform the DMT quickly.

The three between-subject conditions differed in their cost of information access. As it was unclear to us how demanding the DMT would be in the Argus Prime task environment, the Table condition provided near minimum access costs. For this condition the numeric threat value for each target was listed in the target-column next to the target's identification number. Subjects simply scanned the target-column for the highest threat value (a 1–7 scale).

In contrast, to obtain a threat value, the 0-Lock and 2-Lock groups had to locate the target on the radar screen and move the cursor to it. Similar to a "tool-tip", the threat value then appeared next to the target. For 0-Lock, the threat value appeared as soon as the cursor moved to the target. For 2-Lock, the threat value appeared after a 2-s delay.

Results

Our focus is on process measures; namely, how the cost of information access affects the combination of cognitive, perceptual, and action operators required to implement the information access step in decision-making. For these comparisons, we focus on the two lockout conditions as we have not yet analyzed the eye movement data required to infer process in the Table condition. However, before discussing the process measures we look at outcome measures for both classification and decision-making. For these outcome measures, the Table condition provides a baseline against which to compare the effect of increased access costs on outcome.

Classification

All subjects received four practice scenarios of Argus Prime with the classification task only, followed by 8 scenarios where performance on the classification task was interrupted by the decision-making task.

An analysis of variance (ANOVA) that looked at classification performance over blocks of scenarios (scenarios 1–4, 5–8, and 9–12) yielded a significant main effect of block, F (2, 30) = 3.1, p = 0.0597, MSE = 2313. Performance improved from a mean of 56% during practice to 66% in the first four DMT scenarios to 72% in the final four DMT scenarios (see Figure 2).

All conditions were treated the same through the initial training and initial four practice scenarios. Hence, performance on the four practice scenarios provides an opportunity to determine whether the subjects in the three conditions were of roughly equal ability (as per the assumption of random assignment of subjects to condition). A second ANOVA was conducted on scenarios 1–4. As judged by the classification scores there were no differences among the three groups (F < 1). Any difference in classification performance during the 8 DMT scenarios will be regarded as due to the DMT manipulation.

A third ANOVA focused on classification performance during the 8 DMT scenarios (scenarios 5 through 12). Classification scores varied significantly between conditions [F (2, 30) = 7.0, p = 0.003, MSE = 3118.9], Table = 79%, 0-Lock = 64%, and 2-Lock = 65%. Planned comparisons showed that this difference was localized in the Table versus 0- and 2-Lock comparison (p = .0008) with no difference between 0-Lock and 2-Lock (F < 1). Performance increased from scenario 5–8 to 9–12 [F (1, 30) = 33.6, p = .0001, MSE = 1167] but this effect did not interact with DMT condition (p = 0.12).

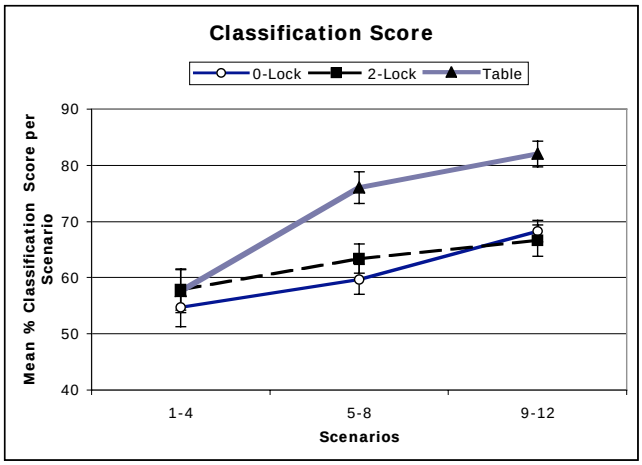

Figure 2: Classification Score across Practice scenarios (1–4) and DMT scenarios (5–8 and 9–12). (Error bars show the standard error.)

Summary of Classification Performance. The three groups were equal in their classification performance during practice (scenarios 1–4) and each continued to improve through the first and then second set of DMT scenarios (5–8 and 9–12). However, once the DMT began, the two lockout conditions performed lower on the classification task than the Table condition. As discussed below, the Table condition spent much less time on the DMT than did the lockout conditions. Hence, we believe the difference in classification performance is simply attributable to the difference in time spent by the three groups on the classification task.

Decision-Making Task (DMT)

Outcome Measures. Although performance on the decision-making task was uniformly high (see Figure 3), there was a significant difference between conditions [F (2, 30) = 10.4, p = .0004, MSE = 0.05] with Table being almost perfect (0.98) followed by 0-Lock (0.94) and then by 2-Lock (0.91). Planned comparisons showed the difference between Table and the two lockout conditions to be significant (p = .0003) and the difference between 0-Lock versus 2-Lock to be marginally significant (p = .064). The influence of number of choices (DMT-4 versus DMT-6) was also significant [F (1, 20) = 14.25, p = .0007, MSE = .043]. The interaction of number of choices with condition

was marginally significant, F (2, 20) = 2.71, p = .08, MSE = .008.

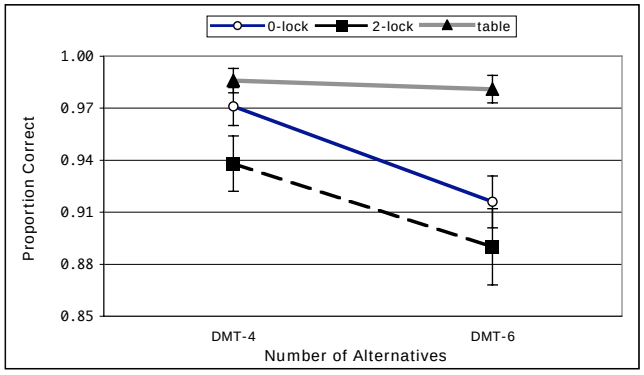

Figure 3: Proportion Correct Choices in Decision Making Task by Number of Alternatives (DMT-4 and DMT-6) and Interface Condition. (Error bars show the standard error.)

A second outcome measure is the time per DMT. This measure yields a significant effect of condition [F (2, 30) = 27.45, p = .0001, MSE = 4953] with Table spending a mere 2.7-s per DMT, 0-Lock spending 16.5-s and 2-Lock spending 23.6-s per DMT. The effect of number of targets per DMT was significant (p = .0005); however, this effect is constrained by a significant interaction of condition by DMT number [F (2, 30) = 3.21, p = 0.054, MSE = 83.8]. This interaction reflects the near asymptotic performance of Table in both DMT-4 (2.6-s) and DMT-6 (2.7-s) whereas both of the Lock groups showed a healthy increase in time from DMT-4 to DMT-6 (14.2 to 18.8 for 0-Lock and 20.8 to 26.3 for 2-Lock).

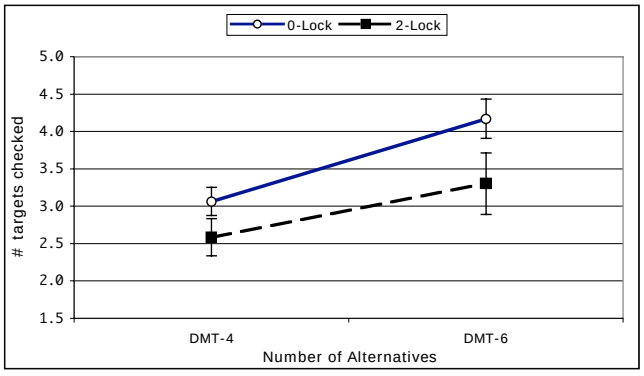

Figure 4: Number of different targets checked per DMT for 0-Lock and 2-Lock. (Error bars show the standard error.)

Of course the 2-Lock condition was locked out for 2-s for each check they made. To determine the contribution of lockout time to the difference between 0-Lock and 2-Lock we subtracted 2-s for each check or recheck made by 2-Lock. With this adjustment, time per 0-Lock versus 2-Lock was no longer significant (F < 1), leaving only a significant main effect of DMT target number [F (1, 20) = 15.45, p = .0008, MSE = 397].

Process Measures. Our first process measure is total number of targets that were checked at least once per DMT. Clearly, if subjects were doing a thorough job this number would be 4 for DMT-4 and 6 for DMT-6. Although we do not have this information for the Table condition, we do have it for the two lockout conditions (see Figure 4) and it is not surprising to find a significant main effect of number of alternatives [F (1, 20) = 33.87, p = .0001, MSE = 18.34] with DMT-4 checking an average of 2.82 targets versus 3.74 for DMT-6. However, this absolute increase masks a relative decrease as DMT-4 checked 72% of their targets versus 62% for DMT-6.

More interesting for our purposes is the difference in number checked across the two lockout conditions. Although 0-Lock checked slightly more targets than 2-Lock (3.62 versus 2.94) this difference was not significant (p = .24). No other comparisons were significant.

Our second measure of process is the number of rechecks per DMT. If a threat value was checked once, how likely was it to be rechecked? As the proportion correct and number checked varied between DMT-4 and DMT-6, we were somewhat surprised that the number of rechecks was constant (F < 1). It is somewhat less surprising that more rechecks were done for 0-Lock than for 2-Lock [F (1, 20) = 44.63, p = .0001, MSE = 4.57]. However, it does surprise us that the 2-Lock condition made almost no rechecks (see Figure 5). None of the interactions were significant (F < 1).

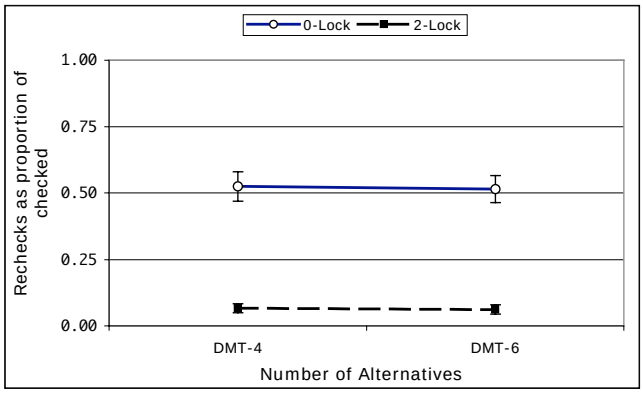

Figure 5: Rechecks as a proportion of those checked at least once. (Error bars show the standard error.)

Our third process measure is the time per check or recheck. We know from Figure 4 that 0-Lock performed more checks per DMT than 2-Lock. However, after subtracting 2-s for each check, the analysis of time per DMT showed that 0-Lock spent as much time per DMT as did 2-Lock. Hence, the time per check must be greater for 2-Lock than 0-Lock. We tested this conjecture in our final process analysis.

Time per check or recheck (after subtracting 2-s for each check made by 2-Lock) yielded a significant difference between lockout conditions [F (1, 20) = 7.98, p = 0.01, MSE = 374]. Even after subtracting 2-s per check, 2-Lock spent over twice as much time per check as 0-Lock (7.2-s versus 3.1-s). Interestingly enough, no other comparisons were significant—neither number of alternatives (DMT-4 versus DMT-6, F < 1) nor any interactions.

Discussion of Results

The Classification results suggest that the three between-

subject conditions (Table, 0-Lock, and 2-Lock) were equivalent as measured by their performance during the four practice scenarios. Performance on classification increased across the eight scenarios in the decision making part of the study. This increase suggests that subjects were still taking the classification task very seriously.

The classification score differences between conditions during scenarios 5-12 appear to reflect the differences in time spent on the decision-making task. As the Table condition spent < 3-s per DMT compared to 16-s for 0-Lock and 24-s for 2-Lock they had more time to devote to the classification task. (Although there were significant differences between groups on the mean number of DMTs per scenario, these differences were small – Table = 3.4, 0-Lock = 2.9, and 2-Lock = 2.7 DMTs per scenario.)

All groups did well on the decision-making task though the Table group did the best. Table also spent much less time per decision than did the other two groups. The time to locate and move the mouse to the screen position of the target contributed to time spent per check by each of the Lock groups. However, although the search and movement costs were similar for 0-Lock and 2-Lock, the 0-Lock group made more rechecks than did the 2-Lock and this difference was constant across DMT-4 and DMT-6. Likewise, after subtracting time for the 2-s lockout, time per check was over twice as great for 2-Lock than for 0-Lock. What factors can explain these patterns?

Discussion

The current study addresses three limits to traditional research on the tradeoff of effectiveness for efficiency in decision-making. First, rather than counting the steps required for an expert agent to execute a decision-making algorithm, we counted the actual steps taken by human subjects during the process of decision-making and measured the duration of those steps. This approach provides better evidence for what people actually do when they make a decision and exposes important intermediary steps not captured by the traditional approach. For example, the current data reveals that the 0-Lock group performs many rechecks of threat value during decision-making. The necessity to check a step more than once implies that the requirement to hold the currently highest threat value in memory while searching for another target is an important sub-step that is affected by memory limits.

Second, by varying the interface design of the decision-making task, we have begun to disentangle the cost of a step in a decision-making algorithm from the cost due to how a step is implemented in a given task environment. It is obvious that the 0-Lock and 2-Lock conditions required more visual search and more motor movement than did the Table condition. In addition, the necessity to search for the next target while holding the currently highest threat value and its target identification number in memory adds a significant cognitive cost to the lockout conditions as compared to the Table.

Of great interest to us is that the additional 2-s per check imposed on the 2-Lock condition seems responsible for the vast differences in process and the slight differences in outcome between lockout conditions. 0-Lock rechecked more targets per decision-making trial while spending half as long on each check or recheck than did 2-Lock. Although there was nothing preventing subjects in the lockout conditions from rechecking the same number of targets or spending the same amount of time per check and recheck, they differed on both of these measures. Apparently differences in lockout costs led the two groups of subjects to adopt two different solutions to the problem of comparing a new threat value to the currently highest threat value. Encoding of location is a fairly automatic outcome of locating a target on a screen (Ehret, 2002). For 0-Lock, after a target had been found once, the cost of reacquiring that target was relatively low. This low reacquisition cost led 0-Lock to adopt a strategy of minimum memory encoding (as judged by the time spent per check) and more reliance on rechecks. For the 2-Lock group, the 2-s lockout did not simply add a delay in the time to access threat value, it also added 2-s to the retention interval for previously encoded threat values as well as for previously encoded target locations. As time for retrieving an item from memory varies with its activation level, we interpret the additional time per check of 2-Lock over 0-Lock as reflecting additional time spent retrieving old information from memory as well as a longer encoding time in anticipation of a longer retention interval.

Third, our experiment helps to move decision-making studies from static to more dynamic paradigms. Time spent on the decision-making task took time away from performing the classification task. Subjects had spent the first two hours of the study learning and practicing the classification task. During the last three hours we encouraged them to continue working hard on classification and to attempt to improve their performance. The data indicate that all groups improved their classification performance throughout the 8 decision-making scenarios.

The pressure to do well on the classification task apparently led subjects in the lockout conditions to satisfice on the decision-making task. As reported earlier, only 72% of the DMT-4 targets and 62% of the DMT-6 targets were checked on any given decision-making trial.

Summary & Conclusions

The study shows that small changes in the cost of interactive behavior may lead to changes in the strategy adopted for decision-making as well as to differences in how a step in the same strategy is implemented. The low cost of scanning the target-column for threat values led the Table condition to use all of the data to achieve near perfect performance in decision-making. In contrast, the lockout conditions satisficed by using less than 100% of the target data.

Although the two lockout conditions did not differ in the amount of information accessed, the differences in lockout time led each group of subjects to implement the information access step in very different ways. The 0-Lock

group adopted an interaction-intensive procedure that made good use of perceptual–motor operations to minimize memory load. In contrast, the 2-Lock group adopted a memory-intensive procedure that maximized memory load and minimized lockout time per alternative. The different procedures adopted by the different groups reflect an adaptation of cognition, perception, and action to the cost structure or soft constraints (Gray & Fu, 2004) of the task environment.

Functional Interactions Affect Object Detection in Non-Scene Displays

Abstract

Two experiments suggest that functional relations influence the processing of visual stimuli. Experiment 1 demonstrated that participants are more accurate to detect targets engaged in functional interactions with related items than when they are simply surrounded by those items. Experiment 2 demonstrated that the accuracy of visual search in a non-scene display is affected when distractor items can be grouped functionally versus when distractor items are simply semantically related to each other. Overall, these data suggest that functional relations between objects affect the allocation of visual attention and by consequence, the processing of natural scenes and other structured visual stimuli.

Introduction

An important aspect of semantic knowledge about objects concerns function. The very identity of an object often hinges upon its intended use. The experiments presented here explore the possibility that participants performing object search tasks may be sensitive to functional relations among the objects being searched. This work is based on the idea that natural scenes are mentally represented in terms of the functional groups they comprise (Green & Hummel, 2004). For example, a coffee shop may be defined as a place where it is possible to make, buy, sell, and drink coffee. The objects associated with these activities (a table and chair in certain arrangement suggest dining) form the basic units of the scene definition.

While scene categories are difficult to define in terms of the objects present (the same objects may form different types of scenes by virtue of different arrangements), or in terms of the spatial layout only (the identities and meanings of objects have bearing on scene categorization), a function-based scene representation may provide a consistent, flexible, and useful definition (see Green & Hummel, 2004, for a more thorough discussion).

In both experiments presented here, the presence of functional relations (the presence of meaningful structure) in the stimulus was expected to improve performance: In Experiment 1, we expected the processing of a target object in a functional relation to be facilitated (relative to a target adjacent to the same objects, but not interacting with any of them). In Experiment 2, we expected that functionally meaningful relations would effectively unitize pairs of distractor objects, making search more efficient than when such objects must be rejected one by one.

Experiment 1

Experiment 1 investigated whether functional interactions would affect observers' ability to detect and locate target objects in non-scene displays. The experiment required observers to indicate whether a named target object was present in a masked, briefly-presented array of twelve line-drawn objects. We manipulated whether the search array contained a distractor object semantically associated to the named target, and whether the target and associated distractor (if both were present) were interacting.

In general, the addition of an associated distractor object to a search array impairs performance in visual search. Moores, Laiti, & Chelazzi (2003) found that when participants searched for a target, distractor objects semantically associated with the target had the effect of reducing accuracy and increasing latency relative to when distractors were not associated with the target.

In the current experiment, we expected a similar result. Overall performance should be lower when an associated distractor object is present in the search array relative to when no associated distractor is present (though Auckland, Cave, & Donnelly, 2004, find evidence for the opposite effect). However, it remains unclear whether such effects interact with relational information in guiding visual search. Specifically, there is reason to believe that the introduction of functional interactions between targets and associated distractors will modulate the impairment caused by target-distractor associations, to some degree.

Riddoch, Humphreys, Edwards, Baker, & Willson (2003) found that functional interactions facilitated the processing of the interacting objects. Their subjects were parietal patients who showed extinction when trying to report the names of two simultaneously-presented objects. When objects were presented together but were not interacting, the patients could reliably report the name of one object, but not both. When the objects were positioned to interact, patients showed increased ability to accurately report the name of the second object. This suggests that functional relations may in fact play a special role in the processing of visual stimuli.

Experiment 1 brought together the two results mentioned above, combining semantic associations between targets and distractors with functional interactions between targets and distractors in a single experiment. Based on the results of Moores, et al. (2003) and Riddoch, et al. (2003)

we expected that introducing a semantically associated distractor to a search array would impair target detection, but that this effect would be reduced when the target interacted with the associated distractor.

Method and Materials

Stimuli All materials were presented on a Macintosh iMac personal computer running the SuperLab application. Stimuli were composed of black and white line drawings (some taken from Snodgrass & Vanderwart (1980), others created specifically for this work) that depicted everyday objects.

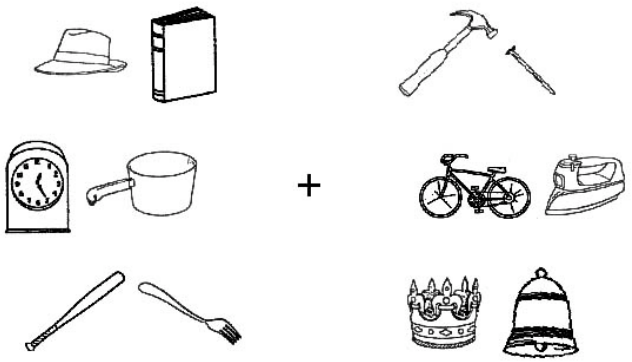

Figure 1: Typical stimulus from Experiment 1. Here the target (hammer) is interacting with a related distractor item (nail).

All search arrays employed the same basic layout (see Figure 1). A fixation cross was centered in the stimulus array. Twelve objects (each approximately 2.3° visual angle in width/height) were arranged around the fixation cross in two concentric circles. The inner circle had a radius of approximately 4.5° visual angle, and the outer circle had a radius of approximately 7.9° visual angle. Six objects were centered on the inner circle, with objects located at 45°, 90°, 135°, 225°, 270° and 315° from vertical. The six remaining objects were centered on the outer circle. Objects on the outer circle were placed horizontally in line with objects on the inner circle. In this way, the twelve objects made up six pairs. This layout placed paired objects closer to each other than to any other object in the array.

/\Critically, we manipulated the presence and position of a related distractor item in the search display. On target-present trials, the target could appear with no semantically-related distractors (the *target-only* condition), with a semantically-related distractor in a location not adjacent to the target (*non-adjacent*), paired with, but not interacting with the target (*adjacent*), or paired with and interacting with the target (*interacting*). Catch trials were presented in which the related distractor was present without the target (*distractor-only*), and in which neither the related distractor nor the target were present (*none*).

Each participant completed 24 randomly-ordered trials, with each trial using a different target object. Each participant saw one of 24 counterbalanced sets of stimuli. Across counterbalancing sets, every target object appeared in every condition equally often.

Participants Participants were 40 undergraduate psychology students at the University of California, Los Angeles. Participants took part in the experiment as part of a research requirement for a psychology course.

Procedure Participants were instructed to look for named target objects and indicate (a) whether the target object was present and if so, (b) its location in the search display. The participant was given a description of how each trial would proceed and what responses were required. The participant viewed a single practice trial, with the experimenter providing a verbal description of what was happening at each step and how the participant should respond. The experimenter emphasized that accuracy was important in all responses, but that the speed of response mattered only during the detection task.

Each trial proceeded as follows: First, a word naming the target object appeared in the center of the computer screen in black 24-point Arial font and remained on the screen until the participant pressed a key. Then, a fixation cross appeared in the center of the screen. After 750ms, the fixation cross was replaced by a search array. The search array was visible for 250ms and was subsequently masked until response or until the trial timed out (2500ms after search array onset).

The participant indicated whether or not the target object was present in the search array by making a key press (yes or no) as quickly and accurately as possible. After response, the participant was presented with an labeled layout of the search array and was asked to indicate the location of the target object appeared (or to verify that the target object did not appear) by pressing a letter on the keyboard. This response was not speeded. A 1000ms inter-trial interval during which the computer screen was blank preceded the next trial.

Results

Accuracy and response time (RT) data were analyzed using within-subjects ANOVAs. Trials upon which detection RT exceeded 2500ms were counted as errors. Error trials were excluded from all RT analyses.

Detection Accuracy Accuracy data (***d'***) from the detection task are presented in Table 1. The main effect of stimulus condition on detection accuracy only approached significance ($F(3,117) = 1.927$, $MSE = 0.621$, $p = 0.129$). However, planned comparison indicated that mean ***d'*** in the Interacting condition was significantly higher than mean ***d'*** in the Adjacent condition ($t(39) = 3.242$, $SE = 0.126$, $p = 0.002$). This comparison is the most revealing with respect to the effect of functional interactions, as the only difference

between the Interacting and Adjacent conditions is the orientation of the associated distractor object. Of the four conditions, only the Interacting condition produced performance significantly different than chance ($t(39) = 1.895$, SE = 0.168, $p = 0.0325$ one-tailed).

Detection Response Time RT data are presented in Table 1. Mean RT on the detection task did not vary across conditions ($F(3,111) = 0.537$, MSE = 48600, $p = 0.658$). No pair-wise comparisons yielded significant differences.

Table 1: Summary of response time and accuracy data from Experiment 1.

Condition	Detection d'	Detection RT	Localization accuracy
Interacting	0.319 (SE = 0.168)	1340 ms (55)	0.558 (0.048)
Adjacent	-0.091 (0.174)	1388 (61)	0.488 (0.062)
Non-Adjacent	0.024 (0.188)	1398 (54)	0.431 (0.057)
Target Only	0.078 (0.141)	1362 (57)	0.502 (0.061)

Localization Accuracy Accuracy data for the localization task are presented in Table 1. As a measure of localization accuracy, we report the probability that the correct location would be chosen given that a target was present and the observer attempted to localize the target. That is, we excluded target-absent trials, and trials where the observer made a localization response indicating that the target did not appear in the search array.

There was no main effect of stimulus condition on localization accuracy ($F(3,105) = 0.911$, MSE = 0.108, $p = 0.439$). No pair-wise comparisons were significant.

Discussion

Though weak, these results do suggest that functional relations influence the processing of objects in non-scene displays. This effect obtained even though the task did not require participants to use (or even notice) the functional relations in the stimuli. Indeed, it may be argued that functional information is not useful in this task. Only one sixth of the trials each participant saw contained a meaningful functional relation between the target and related distractor item. One would not expect the pattern of results observed were the processing of functional relations effortful.

If functional information influences the allocation of visual attention during simple search tasks, then it seems plausible that the guidance of visual attention during search of natural, structured scenes is also influenced by such information. Heuristics about what kinds of objects should appear together in scene could help the visual system to efficiently deploy attention, and facilitate the processing of scene-consistent stimuli. The finding that functional relations affect the processing of simple visual stimuli also suggests that visual representations may include abstract, functional information.

Experiment 2

Experiment 1 suggests that functional relations do influence the processing of visual stimuli during a search task. The presence of a functional relation involving the target object and an associated distractor object increased detection accuracy relative to when an associated distractor was adjacent to, but not interacting with the target. That result does little to discriminate between the possibility that interacting objects are processed more efficiently than other objects and the possibility that functional interactions capture visual attention.

Experiment 2 sought to decide between these explanations. In this experiment, distractor objects engaged in functional interactions, and the number of functional groupings in the search array was varied parametrically. If functional groups capture attention, then one would expect the addition of interacting distractor pairs to impair performance, performance suffering increasingly as more interacting pairs are added. On the other hand, if objects engaged in functional relations are processed more efficiently than objects not engaged in functional interactions, then one would expect performance to improve as more interactions are introduced to distractor objects. Search time in non-scene displays is a function of the number of distractor items present (Biederman, et al., 1988). If functionally interacting objects form perceptual groups, then adding interactions among distractors while holding the total number of display objects constant should effectively reduce the number of perceptual units that must be searched. As a result, displays with more interactions should yield superior search performance.

Method and Materials

Stimuli All materials were presented on a Macintosh iMac personal computer running the SuperLab application. Stimuli were composed of a subset of the black and white line drawings used in Experiment 1.

The experimental trials were divided into four conditions: zero functional interactions (the *0i* condition), one interaction (*1i*), two interactions (*2i*), or three interactions (*3i*). In addition to the four experimental conditions, two control conditions were run to provide baseline search performance measures. All search arrays in the four experimental conditions employed the same basic layout (see Figure 2). A fixation cross was centered in the stimulus array. Eight objects (each approx. 2.3° visual angle in width/height) were arranged around the fixation cross in two concentric circles. The inner circle had a radius of approximately 4.5° visual angle, and the outer circle had a radius of approximately 7.9° visual angle. Four objects

were centered on the inner circle, located at 45°, 135°, 225°, and 315° from vertical. The four remaining objects were centered on the outer circle. Each object on the outer circle was placed horizontally in line with an object on the inner circle. In this way, the eight objects made up four pairs. As before, objects within a pair were closer to each other than to any other object in the array.

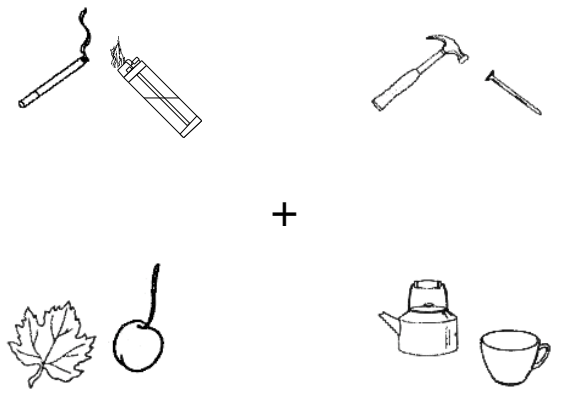

Figure 2: Typical stimulus from Experiment 2. Here, the target (leaf) is accompanied by seven distractor objects, of which four are engaged in interactions (lighter-cigarette, hammer-nail). The other distractor pair (kettle-cup) is related but not interacting. This is an example of a *2i* stimulus.

The identity and orientation of distractor items in the search display were manipulated. In each array, one distractor object was paired with the target object (or a lure). The remaining six distractor objects were organized into three pairs. The distractor objects in each pair were semantically associated and capable of entering into a functional interaction. In this experiment, participants performed trials in which there were zero, one, two, or three of these distractor pairs were actually arranged to interact.

In the control-five object condition (the *5c* condition), the target (or lure) was accompanied by four distractor objects that were unrelated to the target, and unrelated to each other, for a total of five objects in each array. In the control-eight object condition (*8c*), there were seven distractor objects unrelated to the target and each other, for a total of eight objects in each search array. Objects in the *8c* condition were arranged in accordance with the layout depicted in Figure 2. Objects in the *5c* condition occupied five of the eight positions (randomly selected) in the standard search array for this experiment.

Each participant completed 228 randomly-ordered trials. Each participant saw every target object in every condition, but no one target appeared with the same distractor objects in more than one array.

Participants 40 undergraduate psychology students at the University of California, Los Angeles participated in the experiment as part of a research requirement for a psychology course.

Procedure The procedure in Experiment 2 was identical to that of Experiment 1. On each trial participants viewed a target label and a briefly-presented search array which was masked. Participants made a speeded response indicating the presence or absence of the target object, and then a non-speeded location response. Instructions were identical to those in Experiment 1.

Results

Response time (RT) and accuracy data were analyzed using within-subjects ANOVAs. Trials on which detection RT exceeded 2500ms were counted as errors. Error trials of all types were excluded from all RT analyses.

Detection Accuracy Accuracy data (***d'***) are presented in Table 2. There was a main effect of stimulus condition (including control conditions) ($F(5,195) = 4.750$, MSE = 0.17, $p < 0.001$). There was also a significant effect of condition among the four experimental conditions (*0i*, *1i*, *2i*, and *3i*) ($F(3,117) = 3.485$, MSE = 0.164, $p=0.018$). Detection accuracy was significantly higher in the *5c* condition than in the *8c* condition ($F(1,36) = 4.152$, $p = 0.04$).

Planned comparisons indicated that accuracy in the *1i* condition was significantly worse than in the *0i*, and *3i* conditions, but not the *2i* condition. The *0i*, *2i*, and *3i* conditions were not significantly different than each other.

Trend analysis indicated that there was a significant increasing linear trend in detection accuracy across the *1i*, *2i*, and *3i* conditions ($F(1,39) = 8.684$, MSE = 0.169, $p = 0.005$). In addition, there was a significant quadratic trend across the *0i*, *1i*, *2i*, and *3i* conditions ($F(1,39) = 6.085$, MSE = 0.151, $p = 0.018$).

Detection Response Time RT data are presented in Table 2. There was no significant difference in RT across the six experimental conditions, ($F(5,200) = 1.199$, $p=0.311$).

No pairwise contrasts were significant, but participants were marginally faster to accurately respond in the *5c* condition, than in the *8c* condition ($F(1,40) = 3.137$, $p = 0.084$).

Localization Accuracy Accuracy data for the localization task are presented in Table 2. As in Experiment 1, we report the probability that the correct location would be chosen given that the target was present and the observer attempted to localize the target.

There was a significant main effect of stimulus condition on localization accuracy ($F(5,195) = 38.649$, MSE = 0.006, $p < 0.001$). There was also a main effect of stimulus condition across the *0i*, *1i*, *2i*, and *3i* conditions ($F(3,117) = 3.522$, MSE = 0.005, $p = 0.017$). Post-hoc analysis indicated that localization was significantly more accurate in the *3i* condition than in the *0i* condition, and that a

significant linear trend existed across the *0i*, *1i*, *2i*, and *3i* conditions ($F(3,117) = 9.597$, $MSE = 0.005$, $p = 0.004$).

Table 2. Summary of Reaction Time and Accuracy Data for the Detection Task in Experiment 2.

Condition	Detection RT	Detection d'	Localization accuracy
0i	812 ms (SE = 30)	1.40 (.092)	0.845 (.019)
1i	822 (34)	1.17 (.099)	0.880 (.019)
2i	833 (34)	1.36 (.115)	0.872 (.017)
3i	820 (32)	1.44 (.093)	0.899 (.014)
5c	810 (32)	1.61 (.102)	0.676 (.014)
8c	831 (32)	1.42 (.100)	0.825 (.018)

Discussion

The results of Experiment 2 suggest several possibilities. If the only meaningful difference among the four experimental conditions is the decrease in accuracy observed in the *1i* condition, then the data support an attention-capture account. Specifically, if the presence of a single functional group among distractors impairs performance, then it is possible that the participant's attention was drawn to the functional interaction (which never contained the target) and so the actual target was detected less often. One could explain the disappearance of this effect in the *2i* and *3i* conditions if the ability of a functional group to capture attention is dependent on its uniqueness in the display. Adding multiple functional interactions among distractors may "wash out" such an effect by bringing the average salience of the display elements closer to the maximum salience of any one element (i.e., the salience of a functionally interacting pair is farther from the mean salience of the display when one interaction is present than when multiple interactions are present). This explanation is somewhat unsatisfying, and the trend analyses performed suggest a more interesting alternative.

There was a significant linear trend among the *1i*, *2i*, and *3i* conditions, and a significant quadratic trend among those and the *0i* condition. The shape of these data suggest that the addition of functional interactions among distractor objects did not strictly hurt performance (as predicted by an attention-capture account), nor did the introduction of interactions strictly improve performance (as predicted by a grouping account). It seems possible that functional groups do capture attention, but that they also facilitate the processing of the objects they comprise. The drop in performance from the *0i* to *1i* conditions would indicate that the increase in search efficiency resulting from the inclusion of a single interacting pair of distractors did not outweigh the cost incurred by that pair's tendency to capture attention. However, as more interacting distractor pairs were added, the accumulated gains from more efficient processing of interacting objects improved overall performance. Performance in the *3i* condition was only numerically superior to that in the *0i* condition, but if the linear trend across the *1i* to *3i* conditions is extrapolated, then one can imagine that the continued addition of functional interactions among distractor would produce performance reliably exceeding that in the *0i* condition. In fact, in the extreme case, imagine searching for a random object among a disorganized array of distractors versus searching for the same object among distractors organized into a coherent scene. Both intuition and empirical evidence suggest that search will be more efficient in the latter case (Loftus & Mackworth, 1978; Hollingworth & Henderson, 2000).

Finally, localization accuracy data from Experiment 2 suggest that the extraction of spatial information about objects in a stimulus is more efficient when that stimulus includes functional relations between objects. Notably, it was organization of non-target objects that led to this advantage. In Experiment 1, a similar (but unreliable) advantage was observed for localization of target objects that engaged in functional interactions.

Conclusions and Future Directions

The current work was motivated by the idea that natural scenes are mentally represented in terms of the functional groups they comprise (Green & Hummel, 2004). Experiment 1 suggested that objects are more easily detected or identified when they were interacting with related distractors as compared to when they were not interacting with related distractors, or when no related distractors were present. Experiment 2 showed an interesting non-monotonic pattern associated with the introduction of functional interactions to the display. The addition of a single interaction seemed to impair detection, while performance improved with addition of subsequent interactions.

The data from Experiments 1 and 2 suggest that functional interactions may have two effects on visual search: 1) single functional groups may capture attention; 2) objects in functional groups may be processed more efficiently than objects not engaged in interactions.

Existing data from eye movement studies are not consistent with the first claim. A number of studies (De Graef et al, 1990; Henderson et al., 1999; Loftus & Mackworth, 1978) suggest that visual information (e.g., local contrast, spatial frequency, color) is the main determinant of fixations early in natural scene viewing. Evidence indicates that during natural viewing, scene-consistent objects are fixated more rapidly than inconsistent objects, but that this type of semantic information only mediates eye movements after the first several fixations on a scene (De Graef et al., 1990). In short, semantic

information does not seem to influence early fixations, playing a role only later in visual scanning. This suggests that functional groups (which include abstract semantic information) should not capture attention.

Alternatively, the data from these experiments may be explained as an effect of familiarity with canonical arrangements of objects. Because people are routinely exposed to objects arranged in functionally meaningful ways, some other non-attentional influence may be involved. Specifically, the existence mental symbols that represent entire familiar functional groupings may influence the preattentive grouping of a visual stimulus array and lead to faster processing of the objects therein. The existence of perceptual groupings based on functional information (which were not considered in those studies) might affect early attentional guidance in way that is not easily understood if one is looking for effects of semantic consistency only.

Empirical and computational work have been used to study the effects of perceptual grouping on visual search with basic perceptual stimuli (e.g., colored shapes, oriented lines). Some models of search account for effects of perceptual grouping better (and more naturally) than others. For example, the Spatial and Object Search (SOS) model (Grossberg, Mignolla, & Ross, 1994) places perceptual grouping processes at the center of visual search operations. Grouping processes take place pre-attentively in the SOS model, an assumption consistent with a number of empirical results (e.g., Humphreys, et al., 1989).

An important aspect of the SOS model with respect to the functional grouping hypothesis is that its perceptual grouping mechanisms are linked to spatially-invariant representations of objects. SOS allows knowledge about objects to influence perceptual grouping (presumably, so that objects form perceptual units, instead of collections of object parts or features). An extension of SOS might employ representations above the level of objects (e.g. representations of functional groups) to make contact with grouping processes as well. A preattentive grouping mechanism linked to representations of functional groups might yield effects like those observed in Experiments 1 and 2.

Whether functional groups are perceptual groups remains to be established, but the results of Experiments 1 and 2 suggest that familiar functional relations (interactions between objects in a visual scene) may be an important component of visual processing. Current work addresses the possibility that functional groups are in fact perceptual objects.

A Multiple-Trace Memory Model Exhibiting Realistic Retrieval Dynamics

Collin Green (cbgreen@ucla.edu)
Aniket Kittur (nkittur@ucla.edu)
Department of Psychology, 1285 Franz Hall

Abstract

A process model of human memory dynamics is proposed as an implementation of Kittur, Green, & Bjork's (2004) mathematical model. Both models are based on an ideal information processing approach, in which an item's accessibility is based on the predicted future need of that item. The proposed model is an adaptation of the multiple-trace architecture of Hintzman's MINERVA2 model (Hintzman 1984; 1986; 1988). We present simulations of complex spacing and practice dynamics encompassing the mechanics of Bjork and Bjork's (1992) New Theory of Disuse, which accounts for diverse phenomena such as massed vs. spaced practice and spontaneous recovery. In addition, we show how the model explains and simulates time-dependent serial position effects (such as the shift from recency to primacy with delay and time-invariant recency effects). The model's potential as a tool for exploring the relationship between the content of items in memory and more general memory dynamics is also discussed.

Memory as a System for Predicting Need

Kittur, Green, & Bjork (2004) described a mathematical model of memory dynamics inspired by Bayesian statistics. The model is driven by the assumption that memory approximates an ideal information processor, keeping memory items accessible to the degree that they are likely to be needed in the future (see Anderson, 1989 for further rationale on this approach). The predicted future need for an item is computed by the model based on the pattern of past retrievals for that item and the time since it was last retrieved. This is best illustrated by analogy.

Imagine that Book A has been checked out of a library once a month for the past year. Book B, on the other hand, has been checked out every week for the last month but never prior to that. If the librarian was forced to choose which of the two books should be kept readily available, the best choice would change over time. Initially, the librarian would probably keep Book B more readily retrievable as it has been needed frequently in the recent past (possibly, an instructor has assigned reading from this book for a class project); however, after a month has passed with neither book being required, the librarian would likely decide that Book A should be more accessible, given its history of being required at regular, if infrequent, intervals.

The Kittur, Green, & Bjork (2004) model functions in a similar way. It calculates the probability that an item will be needed given three key pieces of information: the average interval between past retrievals; the number of times the item was retrieved in the past; and the time since it was last retrieved. The use of these elements allows for a distinction between item accessibility and item storage, a key insight of the New Theory of Disuse (NTD) (Bjork & Bjork, 1992). The model was inspired by and provides a potential algorithmic basis for the NTD and the complex memory dynamics it explains.

The New Theory of Disuse

The NTD accounts for a variety of effects in the human memory literature. The NTD includes the following assumptions about memory (see Bjork & Bjork, 1992):

1)Memory items are associated with two distinct "strengths": a *storage strength* (SS) and a *retrieval strength* (RS). SS indicates how well-learned an item is (that is, the accumulated history of an item is reflected in its SS). RS, on the other hand, indicates how readily accessible an item is for retrieval. RS alone determines the probability that an item will be successfully recalled from memory. SS does not directly influence memory performance, but has important implications for memory dynamics over time[1].

2)SS does not decrease. SS grows during study or retrieval events as a decelerating function of the current SS. That is, all else being equal, items with low SS benefit from study or retrieval events more than items with high SS. The total storage strength across all items in memory is therefore unbounded. Changes in SS are dependent on both RS and SS. An item gains SS as a decelerating function of its current SS, and as a decelerating function of its current RS.

3)RS increases and decreases. As with SS, an item gains RS as a result of study or retrieval events. When the item is not being studied or retrieved, such as when other items are being attended, RS decreases. As a result, gains in RS for one item necessarily result in a loss of RS for the other (unstudied) items in memory, though these are not necessarily changes of the same magnitude. Changes in RS are dependent on both RS and SS: Gain in RS due to a retrieval or study event is a decelerating function of current RS, and an increasing function of current SS. Conversely, RS loss in is faster the larger the current RS is, and slower with larger SS.

4)Generally, retrieval events are more potent than study events. Increments in both SS and RS are larger when an item is retrieved versus when it is studied.

[1] The two-strength theory espoused by NTD and implemented in MNEM is an important difference between it and other related need-based models, such as Anderson's ACT-R (1989). We are currently exploring testable differences between the models.

The postulation of two separate strengths whose magnitudes influence each other is at the core of NTD's account of retrieval and memory dynamics.

The MNEM Model

Many models of human memory employ a strategy that assumes each item stored in memory is represented by a single memory trace. For example, the studied item "horse" would be instantiated as a single mental symbol, and further exposure to "horse" would serve to strengthen or heighten the activation (or gain—i.e. sensitivity to excitation) of that symbol. However, such models struggle with the problem that no two exposures to an item are identical: the spatial, temporal, or subjective context of encoding is variable. Additionally, changes in attention or effort may occur during different exposures to an item and attributes of a stimulus that are important at one point may be more or less important at some point in the future. Multiple trace models of memory are better suited to deal with variable encoding, in that they do not assume that all encodings of an item are linked to a single representation. Such models also do not assume a mechanism for reconciling variable encodings with unitary representation.

MNEM (*M*emory *N*eed *E*xpectation *M*odel), like MINERVA2 and other multiple trace models, works on the assumption that every instance of encoding lays down a new memory trace in the long-term store. If a single stimulus is encoded on multiple occasions (studied and re-studied), then MNEM creates and stores separate traces for each encoding event. Because of random information loss during encoding events (see below), recording new traces for every instance produces variability in the Long Term Memory (LTM) representations of a repeated item. This variability occurs in addition to any variability introduced by context, environment or attention, which may also be introduced to the model.

Representation

The representations upon which MNEM operates are simple, and are adapted from Hintzman's (1984) MINERVA2 model. Each trace in MNEM is an ordered vector of size *n*, with each element taking on the values of -1, 0, or +1. The elements can be thought of as corresponding to specific feature dimensions (e.g. "redness", "roundness", "chair-ness", etc.), with values indicating the absence of a specific feature (-1), the presence of the feature (+1), or a lack of information about the feature (0). The format is open to other interpretations, of course.

Consideration of the history of a memory item depends on the ability to examine past encodings of that item. It is unlikely, however, that any two memory traces are actually identical. That is, identifying instances of trace *T* is simple when literal copies of *T* are stored in several LTM locations, but it is more likely that LTM traces containing the same information are encoded with different contexts, or with different features emphasized. Instead of a single strengthened trace *T*, or many literal copies of *T*, we may store several traces similar to *T*: *T'*, *T"*, etc. As such, it is necessary to resolve some ambiguity about *which* traces in LTM should be counted as instances of a single item.

MNEM uses a specific similarity metric to evaluate the similarity of two memory traces. Borrowing again from the MINERVA2 model, the similarity of an LTM trace *T* to some probe trace *P* is calculated as follows:

$$S(P,T) = \left(\frac{1}{N_R}\right)\sum_{j=1}^{n} P(j)T(j), \qquad (1)$$

where *n* is the number of elements in the trace and N_R indicates the number of relevant features in the pair of traces. Relevant features are defined as features for which at least one of the two traces contains a non-zero value; in other words, if neither trace contains any information about the presence or absence of a feature, then the feature is not counted as relevant. This similarity function approximates a dot product calculated on the feature sets of the two traces, *T* and *P*.

This representational format is admittedly simplistic, though one advantage of this simplicity is that it requires few assumptions. In fact, the MNEM model requires only two key properties of its representations: they must be amenable to *some* systematic similarity metric, and they must be combinable in a systematic way.[2]

Any representational format that meets these requirements is compatible with the MNEM model. This flexibility makes it amenable to incorporation into diverse cognitive architectures, where other components of the system might necessarily place more serious constraints on the representational format. (As an example, as ordered one-dimensional vectors may be too limiting for representing relational structures, an alternative and appropriate format could be used provided it satisfies the above requirements). That human memory traces satisfy these constraints is a common (if sometimes implicit) assumption among cognitive scientists. The ability to judge the degree to which two stimuli are similar is fundamental to human cognition. Schema abstraction, generalization, and conceptual blending are psychological phenomena that may involve the combination of two or more stimuli to form a composite or abstraction.

Architecture

Like MINERVA2, MNEM has two components: a working memory (WM) and a LTM. WM consists of a buffer that holds a single trace. All inputs to and outputs from LTM are buffered by WM. Traces that are in WM may be encoded into LTM, and information retrieved from LTM is brought into WM.[3]

[2] The second requirement is not important for simulating retrieval dynamics, but will be critical in future work when the model is used to generate content from a set of memory traces.

[3] The authors have not attempted to model WM except in the sense that it is a buffer between the world and LTM. In MNEM, multiple traces are not maintained simultaneously, and no attention is required for WM trace maintenance. WM traces may be overwrit-

LTM is simply a collection of memory traces that have been encoded from WM. The current model imposes no (theoretical) limit on the capacity of (the number of traces in) LTM. Each LTM trace is associated with an index. The indices are assigned in the order with traces are encoded into LTM, so that traces encoded earlier have lower indices. The authors consider this equivalent to incorporating spatio-temporal tags on memory traces. Extensions of MNEM may attempt to use a subtler form of spatio-temporal tagging.[4]

Operations

Encoding The encoding operation of the model is relatively simple, and amounts to little more than copying a WM trace into LTM. As discussed, MNEM assumes that variability exists in encoding process (i.e. information is randomly lost during encoding).

The accuracy of encoding depends on a learning rate parameter (L) which indicates the independent probability that any trace feature will be properly encoded (where $0 < L \leq 1$). For example, when $L = 0.7$, seven out of ten features in a trace are accurately copied into the LTM trace (on average). The features that are not properly encoded result in gaps in LTM information (zeros are written into the LTM trace where 1 or -1 existed in the WM trace). During the encoding process, information is only lost, not distorted: a 1 in the WM trace is never erroneously encoded as a -1 in the LTM trace, nor vice versa. This encoding procedure is taken directly from MINERVA2.

Every encoding event yields a new LTM trace, regardless of whether the content of the new trace is redundant with existing LTM traces. The similarity of traces is not considered during the encoding process.

Retrieval Calculating RS for an item is also relatively straightforward. The main complication arises from determining which LTM traces should be considered in the RS calculation when variability exists among different encodings of an item. To address this problem, MNEM "marks" the traces in LTM whose similarity to the probe item exceeds a set criterion. (This criterion similarity, C_s, is a parameter of the model). For example, if C_s is set to 0.75, then only traces for which $S(P,T) \geq 0.75$ will be marked for inclusion in the RS calculation. Once LTM traces are marked, the mean retention interval between them is calculated:

$$\overline{RI(P)} = \frac{1}{(N_m - 1)} \sum_{i=2}^{N_m} [index(M_i) - index(M_{i-1})], \quad (2)$$

where P is the item for which RS is being calculated, M_i is the i^{th} marked LTM trace, and N_m is the total number of marked LTM traces.[5] The *index()* operator simply indicates that the model is using the LTM index for a trace and not the trace itself.

This mean interval is multiplied by the number, or "base rate", of similar instances in LTM. The base rate (*BR(P)*) is equal to the number of marked traces in LTM:

$$BR(P) = N_m. \quad (3)$$

The product of the mean retrieval interval and the base rate[6] is divided by the size of the current retrieval interval, which is the number of time steps that have elapsed since the last marked item was encoded:

$$CI(P) = index(P) - index(M_{\max}), \quad (4)$$

where $index(M_{max})$ indicates the index of the timestep during which a marked trace was most recently encoded. Also, *index(P)*, the time index for the encoding of the current item, is simply set to the index of the current timestep (which is equal to the number of traces in LTM plus one: $N_{ltm} + 1$).

In summary, RS can be characterized thus:

$$RS(P) = \frac{\overline{RI(P)} * BR(P)}{CI(P)}. \quad (5)$$

That is, the accessibility of an item P, is equal to the product of the average retention interval between instances like P in LTM and the number of such instances, divided by the interval that has elapsed since the last instance of P occurred.[7]

In order to compare forgetting curves, it is necessary to normalize *RS(P)*. This is accomplished by finding the ratio of logarithm of *RS(P)* to the maximum value that *RS(P)* obtains for an item (immediate recall).[8] (Because the log may be negative, we add one to both numerator and denominator for convenience). In all simulations, this ratio is reported as RS. That is:

$$RS_{reported}(P) = \frac{\log(RS(P) + 1)}{\log(RS_{\max}(P) + 1)}. \quad (6)$$

---

ten, but this is the only way that information is "lost" from MNEM's WM.

[4] The authors are currently exploring the incorporation of a context vector into encoded representations, or giving individual traces an activation value which would be initialized to some maximum at encoding, and would decay over time. In the latter strategy, the activation value would represent a trace's "age" for purposes of calculating RS. The RS calculation would consider the difference between the activations of two traces. This approach remains untested, but seems promising in that the decay function would likely be non-linear, decelerating as it approaches zero. This being the case, two traces equally displaced in absolute time would become less discriminable with age.

[5] When only a single trace in LTM is marked, the average retention interval is defaulted to a value of 1.

[6] This product is the closest analog to SS in MNEM: $SS(P) = \overline{RI(P)} * BR(P)$. Note that unlike RS, SS is strictly increasing with additional study, and is not subject to decay. SS influences changes in RS, most importantly by retarding the loss of RS over time (see Figure 3).

[7] This definition of RS is at the core of the Kittur, Green, and Bjork (2004) model, which exhibits the same memory dynamics in a single-trace architecture.

[8] See Pavlik & Anderson (2003) for rationale on scaling forgetting using the maximum (current) activation of a trace.

The result of normalization is that immediate recall yields a reported RS of 1, and any delay in recall produces an RS between 0 and 1. This allows for comparison of forgetting curves in terms of probability of recall.

Trace Composition The formation of composite traces from a set of LTM traces is also important in this model. We have specified how one may calculate the RS of a specific item in LTM, but retrieving useful information from the LTM store is another matter entirely. MINERVA2 includes a mechanism that uses similarity to weight traces in LTM, and forms a composite "echo" by averaging these weighted traces. MNEM employs a similar strategy, but instead of *all* traces in LTM, only those that exceed the similarity criterion are weighted and averaged. While this is an important aspect of the model, and may allow simulation of important memory phenomena (e.g. encoding specificity, context effects, etc.) the details of this operation are not directly relevant to the retrieval dynamics discussed here, and we will leave them for another time.

Simulation Results

The NTD was conceived to "post-dict" a number of memory effects. In the previous discussion of that theory, behavioral correlates of RS and SS were noted. MNEM implements the same relationships between RS and SS and its performance is similar to that of humans on a variety of memory tasks.

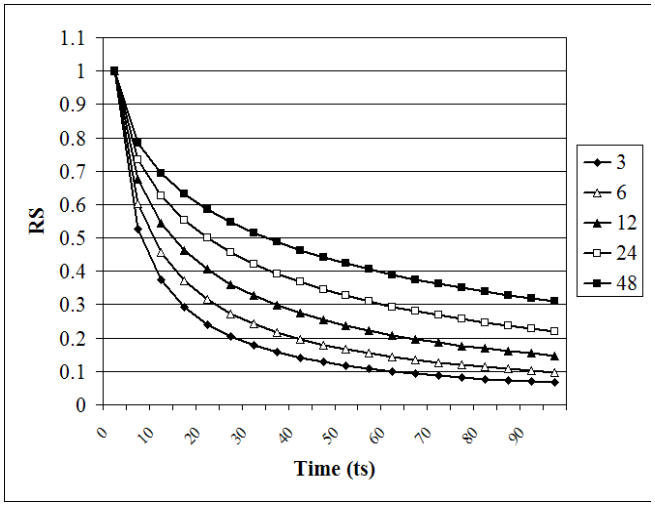

Figure 1: Forgetting curves for items studied three times each, with inter-item intervals of 3, 6, 12, 24, or 48 timesteps.

Forgetting Over Time

MNEM displays forgetting curves that closely resemble those of human subjects. Behavioral data suggest that the probability of recalling a once-studied item declines as a function of the retention interval. More specifically, access to an item declines as a function of intervening experience (Thorndike, 1914; McGeoch, 1932; Bjork & Bjork, 1992).

NTD postulates that probability of recall is linked to RS only, but that changes in RS are mediated by SS. The particular rate of forgetting for an item is influenced by the frequency of exposure to an item (Melton, 1967; Krueger, 1929), as well as the interval between exposures (Peterson, Hillner, & Saltzman, 1962; Whitten & Bjork, 1977). MNEM captures the general shape of forgetting curves, and simulates frequency and spacing effects observed in human data.

In simulation, a single item *A* is studied according to various schedules. At various delays, the RS of *A* is calculated, which indicates the probability that it would be recalled at that interval since last study. To simulate the passage of time without study or retrieval events, a randomly generated memory trace is encoded into LTM on each timestep.[9] Note that in simulation, the calculation of RS does not affect the state of LTM.

The simulated practice schedules vary in the number of exposures of *A*, as well as in the spacing of exposures. Forgetting curves generated by MNEM for items studied with equal frequency, but different inter-item intervals are shown in Figure 1. Figure 2 shows forgetting curves for items studied at equal intervals, but with different frequencies.

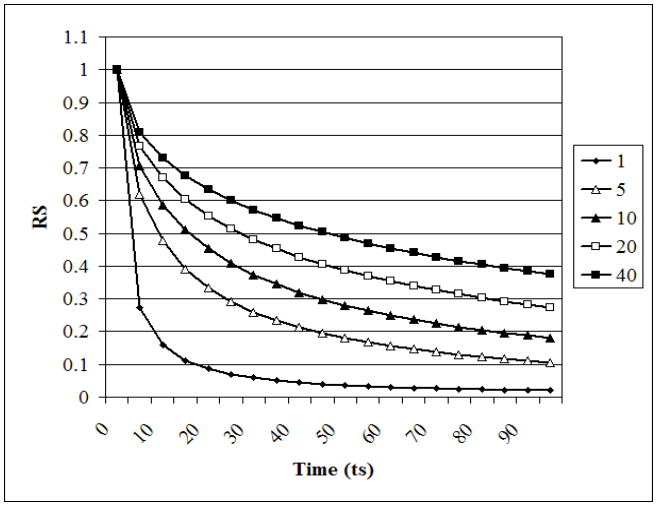

Figure 2: Forgetting curves for items studied with equal spacing (3 timesteps between exposures) and frequencies of 1, 5, 10, 20, or 40 exposures.

Spacing and frequency effects are important aspects of human memory in that they give rise to more complicated phenomena. For example, in some circumstances an old habit may be replaced with a new behavior, only to re-emerge at a later time, a phenomenon known as spontaneous recovery (Estes, 1955; Koppenaal, 1963).

[9] It is worthwhile to note that the noise introduced to the LTM system is relatively unconstrained. In fact, the same method that generates the "studied" trace for these simulations is used to generate the "noise" traces that are interpolated between the study event and the sampling of RS.

NTD and the MNEM model account yield spontaneous recovery as a natural consequence of different forgetting rates. Simulation data in Figure 3 show spontaneous recovery. Item *A* represents an old response that has been learned over a long period of time. Item *B* is a new response intended to replace *A*. As *B* is acquired, *A*'s RS decays substantially. However, we observe that *A* gains an advantage after a certain delay. If *B* is not practiced, the larger SS of item *A* yields a shallower forgetting curve. The decay of RS is slower for trace *A* than for trace *B* and the curves cross over. The older habit will remain more accessible thereafter.

Primacy & Recency

Primacy and recency are well-known memory phenomena. When a list is studied, items that appeared early in the study list are more recallable than items near the middle of the list. Primacy effects have been attributed to covert rehearsal between study presentations (Glenberg et al., 1980). Effectively, subjects create extra study opportunities in the gaps between item exposures.

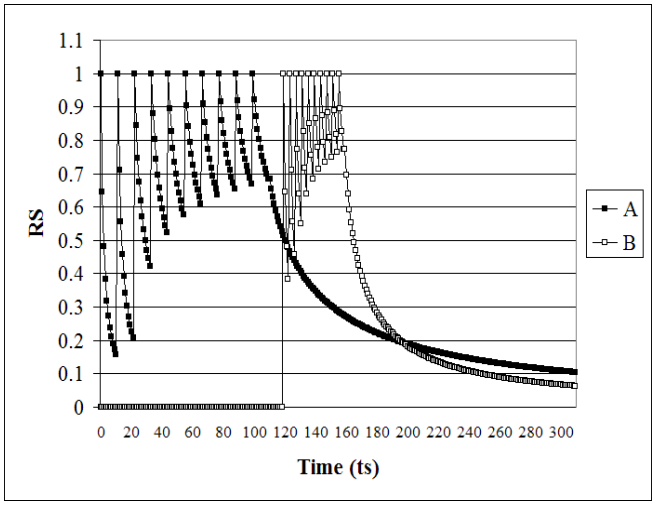

Figure 3: Spontaneous recovery of response *A* occurs after learning response *B*. This is due to a larger increase in response *A*'s SS at reminding, owing to a lower RS at that time.

Similarly, items presented near the end of the list are also recalled better than mid-list items. Recency results from the relatively short retention interval between study and test. Prior work has demonstrated that there is a shift from recency to primacy over increasing retention intervals (Craik, 1970; Knoedler, Hellwig, & Neath, 1999). The MNEM model shows similar behavior.

In simulation, a list of 20 items is studied, with five timesteps between study events. Between trials, the simulated subject is assumed to perform covert rehearsal on some of the items presented so far, in order, for the duration of the interval. This strategy lasts for a limited number of presentations (three, in this simulation), at which point the simulated subject is assumed to become overwhelmed by the number of items and therefore abandons the covert rehearsal strategy. Beyond this point, inter-trial intervals are filled with random traces, as in previous simulations.[10]

At the end of the study phase, the RS for each of the 20 items is calculated at five different retrieval intervals. The serial position curves that result are shown in Figure 4. Three features are notable: the prominence of recency effects in immediate recall; the presence of primacy in all serial position curves; the shift of recency to primacy as the dominant pattern in the data as the retention interval grows.

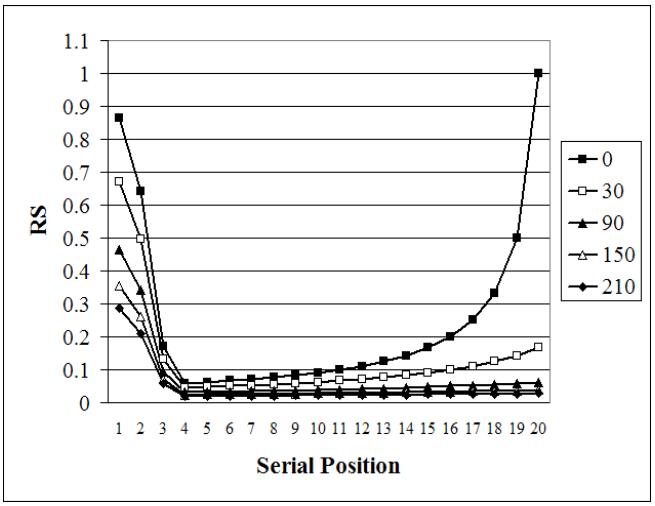

Figure 4: Serial position curves at delays of 0, 30, 90, 150, and 210 timesteps. Note the rapid decay of recency effects relative to the slower decay of primacy.

The recency effects observed in simulation share a subtle property with human behavioral data: time-invariance. Some data from humans suggest that the magnitudes of recency effects follow a ratio rule (Glenberg et al, 1980; 1983; Bjork & Whitten, 1974). This phenomenon was described mathematically by Bjork & Whitten (1974). Specifically, recency effects scale with the log of the ratio of mean presentation interval divided by the current retention interval:

$$recency \propto \log\left(\frac{\overline{RI(P)}}{CI(P)}\right) \quad (7)$$

This behaviorally-derived ratio rule is inherent in the MNEM model (see Kittur, Green & Bjork, 2004). Figure 5 shows serial position curves for various ratios of mean retentional interval to current retention interval.

Conclusions and Future Directions

The model described here shows memory dynamics that are consistent with human behavioral data. Forgetting curves, spacing and frequency effects, and serial position curves are generated in simulation by following the assump-

[10] Glenberg, et al., (1980) observed that primacy effects were eliminated when participants were prevented from performing cumulative rehearsal on early list items.

tions of NTD, and allowing items to accumulate independent SS and RS.

The relative simplicity of this model (and its more general mathematical formulation in Kittur, Green, & Bjork, 2004), makes it a useful tool for exploring subtle issues in memory and generating concrete experimental predictions. There is potential to extend our understanding of retrieval dynamics to a greater diversity of memory phenomena by manipulating the content of the memory traces used in simulation. For example, MNEM provides a natural platform for exploring the influence of inter-item associations on memory dynamics. In addition, MNEM may prove to be informative on issues surrounding schema abstraction, categorization, and other arenas where knowledge content is an issue. Context, encoding specificity, and variability effects may also be amenable to analysis with this model in the future.

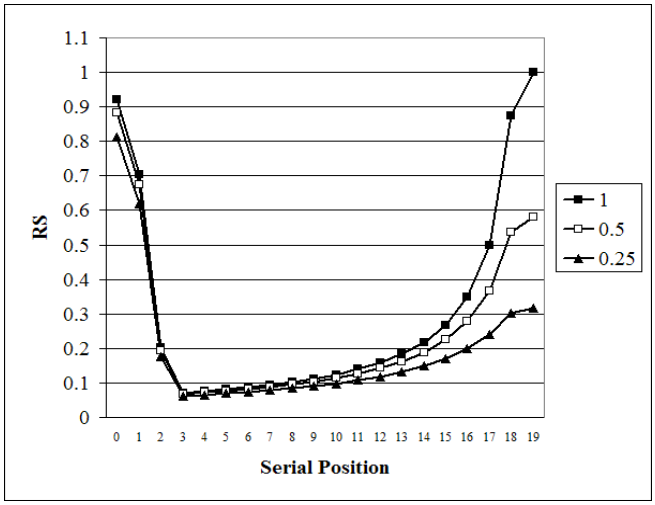

Figure 5: The magnitude of recency effects in MNEM scale with the ratio of mean retention interval to current retention interval. Serial position curves are shown for spacing to retention interval ratios of 1, 0.5, and 0.25.

Abstract

We argue that human judgments about hidden causal structure can be explained as the operation of domain-general statistical inference over causal models constructed using domain knowledge. We present Bayesian models of causal induction in two previous experiments and a new study. Hypothetical causal models are generated by theories expressing two essential aspects of abstract knowledge about causal mechanisms: which causal relations are plausible, and what functional form they take.

Everyday reasoning draws on notions that go far beyond the observable world, just as modern science draws upon theoretical constructs beyond the limits of measurement. The richness of our naive theories is a direct result of our ability to postulate hidden causal structure. This capacity to reason about unobserved causes forms an essential part of cognition from early in life, whether we are reasoning about the forces involved in physical systems (e.g., Shultz, 1982), the mental states of others (e.g., Perner, 1991), or the essential properties of natural kinds (e.g., Gelman & Wellman, 1991).

The central role of hidden causes in naive theories makes the question of how people infer hidden causal structure fundamental to understanding human reasoning. Psychological research has shown that people can infer the existence of hidden causes from otherwise unexplained events (Ahn & Luhmann, 2003), and determine hidden causal structure from very little data (Kushnir, Gopnik, Schulz, & Danks, 2003). This work has parallels in computer science, where the development of a formalism for reasoning about causality – causal graphical models – has led to algorithms that use patterns of dependency to identify causal relationships (Pearl, 2000; Spirtes, Glymour, & Scheines, 1993). It has recently been proposed, chiefly by Gopnik, Glymour, and their colleagues (Glymour, 2001; Gopnik, Glymour, Sobel, Schulz, Kushnir, & Danks, 2004), that these algorithms may also explain how people infer causal structure.

A fundamental issue in explaining how people infer causal relationships is accounting for the interaction between abstract causal knowledge and statistical inference. The classic debate between approaches that emphasize cause-effect covariation and those that emphasize mechanism knowledge (e.g., Newsome, 2003) turns on this issue. Causal graphical models provide a language in which the problem of causal induction can be formally expressed. However, conventional algorithms for inducing causal structure (e.g., Pearl, 2000; Spirtes et al., 1993) do not provide a satisfying account of either the roles of causal knowledge or statistical inference, or their interaction. These algorithms use tests of statistical independence to establish constraints that must be satisfied by causal structures consistent with the observed data. No knowledge of how causal mechanisms operate, or the functional form of relationships between cause and effect, enters into the inference process. As we argue below, such knowledge is necessary to explain how people are able to infer causal structure from very small samples, and to infer hidden causes from purely observational data. Constraint-based methods are also unable to explain people's graded sensitivity to the strength of evidence for a causal structure, because they reason deductively from constraints to consistent structures.

We will present a rational account of human inference, Theory-Based Causal Induction, which emphasizes the interaction between causal knowledge and statistical learning. Causal knowledge appears in the form of causal theories, specifying the principles by which causal relationships operate in a given domain. These theories are used to generate hypothesis spaces of causal models – some with hidden causes, some without – that can be evaluated by domain-general statistical inference. We will use this framework to develop models of people's inferences about hidden causes in two physical systems: a mechanical system called the stick-ball machine (Kushnir et al., 2003), and a dynamical system involving an explosive compound called Nitro X.

Theory-based causal induction

Our account of causal induction builds on causal graphical models, extending the formalism to incorporate the abstract knowledge about causal mechanism that plays an essential role in human inferences. We will briefly introduce causal graphical models, consider how prior knowledge influences causal induction, and describe how we formalize the contribution of causal theories.

Causal graphical models

Graphical models represent the dependency structure of a joint probability distribution using a graph in which nodes are variables and edges indicate dependence. The graphical structure supports efficient computation of the probabilities of events involving these variables. In a *causal* graphical model the edges indicate causal dependencies, with the direction of the arrow indicating the direction of causation, and they support inferences about the effects of interventions (Pearl, 2000). An intervention is an event in which a variable is forced to hold a value, independent of any other variables on which it might depend. Intervention on a variable A is denoted do(A). Probabilistic inference on a modifified graph, in which incoming edges to A are removed, can be used to assess the consequences of intervening on A.

The structure of a causal graphical model implies a pattern of dependency among variables under observation and intervention. Conventional algorithms for inferring causal structure use standard statistical tests, such as Pearson's χ^2 test, to find the pattern of dependencies among variables, and then deductively identify the structure(s) consistent with that pattern (e.g., Spirtes et al., 1993). These "constraint-based" algorithms can also exploit the results of interventions, and often require both observations and interventions in order to identify the hidden causal structure. Gopnik, Glymour, and colleagues have suggested that this kind of constraint-based reasoning may underlie human causal induction (Glymour, 2001; Gopnik et al., 2004; Kushnir et al., 2003).

The role of causal theories

Constraint-based algorithms for causal induction make relatively little use of prior knowledge. While particular causal relationships can be ruled out a priori, there is no way to represent the belief that one structure may be more likely than another. Furthermore, the use of statistical tests like χ^2 makes only weak assumptions about the form of causal relationships: these tests simply assess dependency, regardless of whether a relationship is positive or negative, deterministic or probabilistic, strong or weak.

Several researchers (e.g., Shultz, 1982) have argued that knowledge of causal mechanism plays a central role in human causal induction. Mechanism knowledge is usually cited in arguments against statistical causal induction, but we view it as critical to explaining how statistical inferences about causal structure are possible from sparse data. Knowledge about causal mechanisms provides two kinds of restrictions on possible causal models: restrictions on which relationships are plausible, and restrictions on the functional form of those relationships. Restrictions on plausibility might indicate that one causal structure is more likely than another, while restrictions on functional form might indicate that a particular relationship should be positive and strong.

These restrictions have important implications for causal induction algorithms. If all structures are possible, both observations and interventions are typically required to identify hidden causes, and without strong assumptions about the functional form of causal relationships, samples must be relatively large. With limitations on the set of possible causal structures and expectations about functional form, however, it is possible to make causal inferences from just observations and from small samples – important properties of human causal induction.

Using causal theories in causal induction

The causal mechanism knowledge that is relevant for statistical causal inference may be quite abstract, and may also vary across domains. Much of this knowledge may be represented in intuitive domain theories. In contrast to Gopnik et al. (2004), who suggest that causal graphical models are the primary substrate for intuitive theories, we emphasize the role of intuitive theories at a more abstract level, providing restrictions on the set of causal models under consideration. Such restrictions cannot be represented as part of a causal graphical model: causal graphical models express the relations that hold among a finite set of propositions, while causal theories involve statements about all relations that could hold among entities in a given domain.

Formally, we view causal theories as *hypothesis space generators*: a theory is a set of principles that can be used to generate a hypothesis space of causal models, which are compared via Bayesian inference. The principles that comprise a theory specify which relations are plausible and the functional form of those relations. These principles articulate how causal relationships operate in a given domain, but need not identify the mechanisms underlying such relationships: all that is necessary for causal induction is the possibility that some mechanism exists, and expectations about the functional form associated with that mechanism. This vague and abstract mechanism knowledge is consistent with the finding that people's understanding of causal mechanism is surprisingly shallow (Rozenblit & Keil, 2002).

In the remainder of the paper, we will demonstrate how Theory-Based Causal Induction can be used to explain human inferences about hidden causes in physical systems. Different systems require different causal theories. We will examine inferences in a mechanical system, the stick-ball machine (Kushnir et al., 2003), and in a dynamical system, Nitro X, which we explore in a new experiment. When reasoning about these systems, people infer hidden causal structure from very few observations, and are sensitive to graded degrees of evidence.

The stick-ball machine

Kushnir et al. (2003) conducted two experiments in which participants had to infer the causal structure

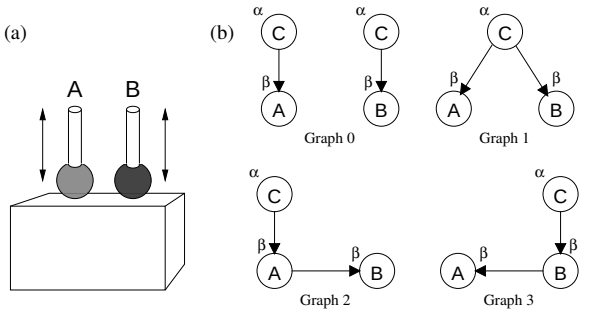

Figure 1: (a) A stick-ball machine. (b) Graphs indicating potential causal structures for the stick-ball machine. Nodes A and B correspond to the two balls, nodes marked C are hidden causes.

of a physical system, the "stick-ball machine", consisting of two colored balls (A and B) mounted on sticks which could move up and down on a box (see Figure 1(a)). The mechanical apparatus moving the balls was concealed, keeping the actual causal relationship unknown. In both experiments, all participants were familiarized with the machine, and told that if one ball caused the other to move it did so "almost always". This probabilistic causal relation was demonstrated by showing the two balls move together four times, an event we denote $4AB$, and A moving alone twice, $2A\bar{B}$. There were three test conditions in Experiment 1, seen by all participants. In the *common unobserved cause* condition, participants saw $4AB$, and four trials in which the experimenter intervened, twice moving A with no effect on B, $2\bar{B}|\text{do}(A)$, and twice moving B with no effect on A, $2\bar{A}|\text{do}(B)$. In the *independent unobserved cause* condition, participants saw $2A\bar{B}$, $2\bar{A}B$, $1AB$, $2\bar{A}|\text{do}(B)$, and $2\bar{B}|\text{do}(A)$. In the *one observed cause* condition, participants saw $4B|\text{do}(A)$ and $2\bar{B}|\text{do}(A)$. Experiment 2 replicated the *common unobserved cause* condition, and compared this with a *pointing control* condition in which interventions were replaced with observations ($4AB$, $2\bar{A}B$, $2A\bar{B}$). The order of conditions and trials within conditions was randomized across participants. In each condition, participants identified the underlying causal structure by indicating graphs similar to those shown in Figure 1(b). The results of both experiments are combined in Figure 2. One causal structure was chosen by the majority of people in each condition – Graph 1 in the *common unobserved cause* condition, Graph 0 in the *independent unobserved causes* condition, Graph 2 in the *one observed cause* condition, and Graph 0 in the *pointing control*.

The results of these experiments provide two challenges to constraint-based accounts. First, people are able to make inferences from small samples – in many cases, far less data than might be required for all relevant χ^2 tests to yield results consistent with the appropriate causal structure. Second, people's

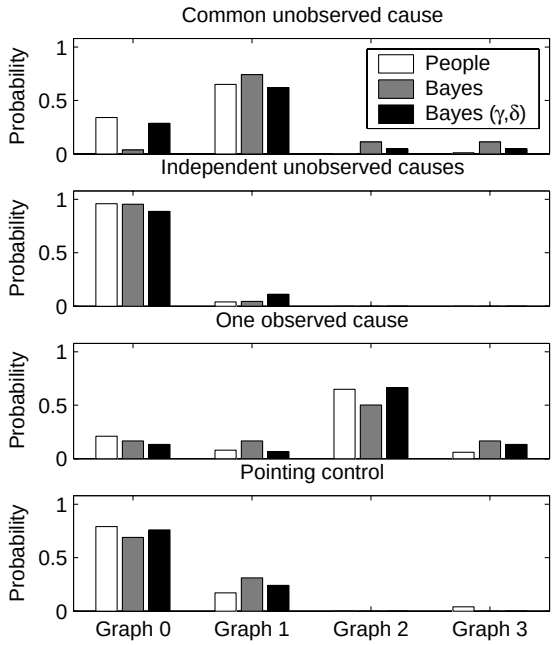

Figure 2: Results of Kushnir et al. (2003), shown with predictions of Bayesian models.

judgments reflect a sensitivity to graded degrees of evidence: in the *independent unobserved causes* condition, over 95% of participants chose Graph 1, while only 60-80% of people chose the most popular structure in the other conditions. This was not simply a consequence of a preference for Graph 0 – the same structure was less popular in the *pointing control* condition, suggesting that there is a difference in the evidence that the data provide for Graph 0 in these two conditions. Constraint-based algorithms are not sensitive to graded degrees of evidence: a causal structure is either consistent or inconsistent with the pattern of dependencies in a dataset.

A theory-based account

Our model of the stick ball machine uses a physical theory that contains three principles:

1. Balls never move without a cause.
2. A hidden cause moves with probability α.
3. A moving cause moves its effect with probability β.

If we add the restrictions that every ball has a single cause and hidden causes never have causes (but can move themselves, per Principle 2), we obtain the four structures shown in Figure 1(b). The principles of the physical theory place strong constraints on the functional form of the causal relationships identified in this structure, allowing us to compute the probability of events involving A and B for each graphical structure, as shown in Table 1.

Given a dataset D, we compute a posterior probability distribution over these structures, $P(\text{Graph } i|D)$, combining prior probabilities,

Table 1: Event probabilities for causal structures

Event	Graph 0	Graph 1	Graph 2
AB	$(\alpha\beta)^2$	$\alpha\beta^2$	$\alpha\beta^2$
$\bar{A}B$	$\alpha\beta(1-\alpha\beta)$	$\alpha\beta(1-\beta)$	0
$A\bar{B}$	$\alpha\beta(1-\alpha\beta)$	$\alpha\beta(1-\beta)$	$\alpha\beta(1-\beta)$
$\bar{A}\bar{B}$	$(1-\alpha\beta)^2$	$1-2\alpha\beta+\alpha\beta^2$	$1-\alpha\beta$
$A\|\text{do}(B)$	$\alpha\beta$	$\alpha\beta$	$\alpha\beta$
$B\|\text{do}(A)$	$\alpha\beta$	$\alpha\beta$	β

Note: Probabilities for Graph 3 are the same as those for Graph 2, exchanging the roles of A and B.

$P(\text{Graph } i)$, with the probability of the observed data under each structure, $P(D|\text{Graph } i)$, using Bayes' rule:

$$P(\text{Graph } i|D) \propto P(D|\text{Graph } i)P(\text{Graph } i)$$

$P(D|\text{Graph } i)$ is the product of the probabilities of the individual events making up D, which can be obtained from Table 1.

If we assume a uniform prior for $P(\text{Graph } i)$, the causal theory leaves two parameters unspecified: α, the probability of a hidden cause moving on a given trial, and β, the probability that a moving cause moves its effect. We set β empirically, via a small experiment. We showed 10 participants a computer simulation of the stick-ball machine, and reproduced the familiarization trials used by Kushnir et al. (2003): participants were told that when A causes B, it makes it move "almost always", and were shown that A moved B on four of six trials. We then asked them how often they expected A would move B. The mean and median response was that A would move B on 75% of trials, so we used $\beta = 0.75$.

Figure 2 shows the predictions of the Bayesian model with $\alpha = 0.47$. The model gave a correlation of $r = 0.94$ with the data, and correctly predicted the most common response in each condition. The model also admits graded degrees of evidence, with the observations and interventions in the *independent unobserved causes* condition providing stronger evidence for Graph 0 than the observations in the *pointing control*. The model departs from people's judgments in one case, failing to predict the minority preference for Graph 0 in the *common unobserved cause* condition. This disparity could have many explanations, such as a default preference for independence between objects, or differences in the salience of different data types and causal structure. For instance, interventions may be weighted higher than observations by a factor of γ, and hidden common causes may receive only a fraction $1/\delta$ of the prior probability accorded to other structures. Figure 2 shows an almost-perfect fit ($r = 0.99$) for such a model, Bayes (γ,δ), with $\gamma = 4, \delta = 2, \alpha = 0.4$. Further experiments will be necessary to determine whether these sorts of psychological variables play a role in the process of causal induction.

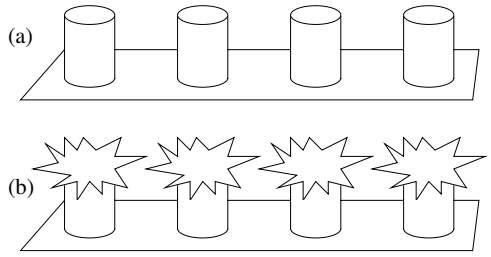

Figure 3: (a) Four cans of the extremely unstable compound Nitro X. (b) A simultaneous explosion.

Nitro X

To provide a further demonstration of the importance of graded degrees of evidence and the ability to infer hidden causes from very little data, we conducted an experiment that tested people's ability to infer the causal structure of a dynamical physical system. Our experiment presents a more severe inductive challenge than the tasks considered by Kushnir et al. (2003), as it requires inferring a hidden common cause from just a single observation, with no verbal cues that such a structure might exist. In the experiment, we introduced people to a novel substance, Nitro X, and illustrated its dynamics: cans of Nitro X could spontaneously explode, and could detonate one another after a time delay that was a linear function of spatial separation, as would be expected from the slow propagation of pressure waves. We then presented them with the *simultaneous* explosion of several cans, without the delays characteristic of pressure waves propagating from one can to the next. We expected that people would see this suspicious coincidence as evidence for some kind of hidden common cause, such as an external force shaking the table. We varied the number of cans, m, to see whether the magnitude of the coincidence had an effect on people's inference to a hidden cause.

Method

Participants Participants were 64 members of the MIT Brain and Cognitive Sciences subject pool, split evenly over four conditions ($m = 2, 3, 4, 6$).

Stimuli The stimuli were pictures of cans sitting on a table, presented on a computer screen. A new set of cans was shown on each trial, and by the end of the trial all cans on the screen had exploded, demonstrated by cartoon explosion graphics like those shown in Figure 3.

Procedure The experiment consisted of three familiarization trials and five test trials. The familiarization trials introduced the participants to Nitro X. In the first trial, participants were told that Nitro X is very unstable, and this was demonstrated by the experimenter tapping a can and the can exploding. In the second trial, participants saw two cans of Nitro X, the experimenter tapped one can,

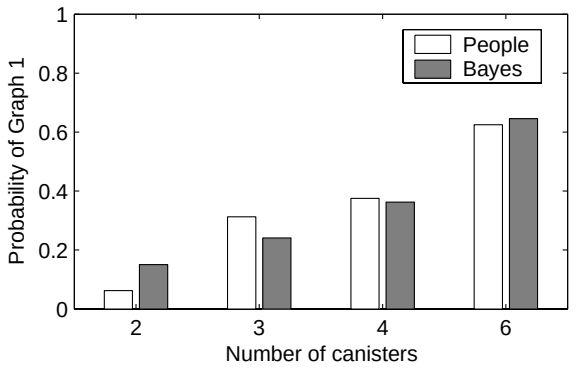

Figure 4: Results of the Nitro X experiment.

which exploded, and the can next to it exploded shortly afterwards. On the third trial, participants were again reminded about the instability of Nitro X, and saw a single can explode without any action by the experimenter, after waiting for a few seconds.

The first two test trials were identical for all four conditions, and both involved four cans exploding in a causal chain, with a delay between successive explosions. In the third test trial, the number of cans in the display was varied, $m = 2, 3, 4$ or 6, depending on condition. After a brief delay, all of the cans exploded simultaneously. The last two test trials allowed the participants to interact with Nitro X by tapping, and will not be discussed further here.

After each test trial, participants were given a sheet of questions for each test trial. These sheets gave three options:

1. The first can exploded spontaneously. That explosion caused the other cans to explode, in a chain reaction.
2. Each can exploded spontaneously, all on its own. There was no causal connection between them.
3. Neither of the above is a likely explanation. Please write a plausible alternative here.

The order of the first two options was counterbalanced, but the third option was always last.

Results and Discussion

For all trials, two rates examined the written responses of participants choosing the third option above, and were in 100% agreement in classifying all such responses as indicating a hidden cause. Over 95% of participants correctly identified the causal chain in the first two trials. The proportion of participants identifying a hidden cause on the third trial, with the simultaneous explosion, is shown in Figure 4. There was a statistically significant effect of m, $\chi^2(3) = 11.36$, $p < 0.01$. The number of cans influenced whether people inferred hidden causal stucture, with most people seeing two cans as independent but six as causally related.

Constraint-based algorithms cannot explain our results. If we imagine that time is broken into discrete intervals, and a can either explodes or does not explode in each interval, then we can construct a contingency table for each pair of cans. Statistical significance tests will identify pairwise dependencies among all cans that explode simultaneously, provided appropriate numbers of non-explosion trials are included. The existence of a hidden common cause is consistent with such a pattern of dependency. However, as a result of reasoning deductively from this pattern, the evidence for such a structure does not increase with m: a hidden common cause is merely consistent with the pattern for all $m > 2$.

This experiment also illustrates that people are willing to infer hidden causal structure from very small samples – just one datapoint – and from observations alone. Constraint-based algorithms cannot solve this problem: while a hidden common cause is consistent with the observed pattern of dependency, causal structures in which the cans influence one another cannot be ruled out without intervention information. People do not consider this possibility because they have learned that the mechanism by which cans influence one another has a time delay. Further situations in which the temporal properties of causal relationships influence causal induction are described by Hagmayer and Waldmann (2002).

A theory-based account

The results of the Nitro X experiment are easy to model: any increasing function of the number of cans would be sufficient. Our goal in modeling these data is to illustrate how Theory-Based Causal Induction extends to a system with non-trivial dynamics and different causal mechanisms, and to show that inferences to hidden causes from the smallest possible sample – a single observation – can have a physically plausible and statistically rational explanation.

We model the explosion times of cans by assuming that at each infinitesimal moment, there is a certain probability that the can will explode. This assumption means that the explosion time of each can follows a Poisson process, with a "rate parameter" determining the probability of explosion at each moment. We set the rates using the following principles:

1. A can explodes spontaneously at rate α.
2. A hidden cause becomes active at rate γ.
3. At the moment a hidden cause is active, a can influenced by that cause explodes at rate $\alpha + \beta$.

A complete theory of Nitro X would need to include further principles stating the functional form of the causal relationship between cans, encoding the fact that this relationship involves a time delay. We have omitted these principles because they do not directly affect the inference to a hidden cause when all explosions are simultaneous.

This theory generates a large number of possible causal structures, with hidden causes influencing various subsets of the cans. We will focus on the two structures shown in Figure 5: Graph 0, in which all

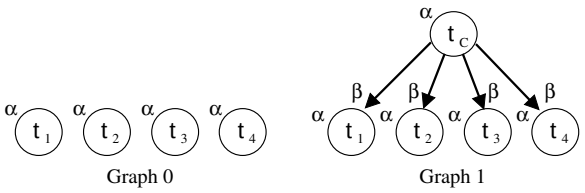

Figure 5: Graphs indicating potential causal structures for the Nitro X experiment.

cans explode spontaneously, is the "null hypothesis" for any inference concerning hidden causes, while Graph 1, in which all cans are also influenced by a hidden cause, gives the highest probability to a simultaneous explosion. These structures are defined on variables representing the time at which cans explode, $t_1, \ldots, t_m$, and the time the hidden cause becomes active, t_C. The inference to a hidden common cause is modeled by computing the posterior probability $P(\text{Graph } 1|T)$, where $T = \{t_1, \ldots, t_m\}$. In a simultaneous explosion, all t_i take the same value, t.

It follows from the theory outlined above that for Graph 0, each t_i is an independent Poisson process with rate α, which gives $P(T|\text{Graph } 0) = \alpha^m \exp\{-m\alpha t\}$. For Graph 1, t_C follows a Poisson process with rate γ. Conditioned on t_C, each t_i is a Poisson process with rate α, except at the moment when the hidden cause becomes active, at which point the rate is $\alpha + \beta$. Computing $P(T|\text{Graph } 1)$ requires integrating over all values of t_C, which we approximate by choosing t_C to maximize $P(T|t_C)$:

$$\begin{aligned} P(T|\text{Graph } 1) &= \int_0^\infty P(T|t_C)P(t_C)\, dt_C \\ &\approx \gamma(\alpha+\beta)^m \exp\{-m\alpha t - \gamma t\} \end{aligned}$$

Applying Bayes' rule, it follows[1] that $P(\text{Graph } 1|T)$ is a sigmoid function of m,

$$P(\text{Graph } 1|T) = \frac{1}{1+\exp\{-gm-b\}}$$

for $g = \log\frac{\alpha+\beta}{\alpha}$ and $b = \log\frac{P(\text{Graph } 1)}{P(\text{Graph } 0)} + \log\gamma - \gamma t$.

The model predicts that increasing m should increase $P(\text{Graph } 1|T)$ for any positive values of α and β, as this results in a positive gain, g. The theory involves four parameters: α, β, γ, and $P(\text{Graph } 0)$. Since these four parameters are not identifiable – multiple sets of parameter values are consistent with the same sigmoid function – we set the parameters of the sigmoid g and b. Using $g = 0.58$ and $b = -2.90$ gives $r = 0.958$, and the predictions shown in Figure 4. These parameters indicate $\beta = 0.79\alpha$ and an initial preference for Graph 0.

Our theory-based approach explains why the number of cans involved in a simultaneous explosion should influence the evidence for a hidden cause, but is clearly not the only model compatible with these data. However, our analysis exposes the rational basis for human judgments, and makes further intuitive predictions that we are in the process of testing. For example, the $-\gamma t$ term in the expression for b indicates that, all other things being equal, decreasing the time before a simultaneous explosion increases the evidence for a hidden cause.

Conclusion

Explaining human causal induction requires supplementing the formal methods developed in computer science with the causal domain knowledge that people possess. We have shown that using physical theories to inform rational statistical inference makes it possible to explain how people infer hidden causal structure from such limited data. We anticipate that the same framework, using appropriately modified causal theories, can shed light on inferences about hidden causes in other domains.

Evidence of Muddy Knowledge in Reaching for the Stars: Creating Novel Endings for Event Sequences

Belfield, Dublin 4, Ireland

Abstract

This experiment examines people's ability to invent creative outcomes to simple event sequences. We report a study where participants are given everyday event descriptions and asked to describe either a predictable outcome (Predictable group) or a creative outcome (Creative group). Following the Creative Cognition approach (Finke, Ward & Smith, 1992), we expected that though those instructed to be creative might generate novel and interesting outcomes, they would also be bound by their knowledge of the outcomes that typically occur. The results support this prediction, in that while the Creative group manifested more inventive variability in their outcomes relative to the Predictable group, their proposed outcomes still overlapped in part with those of the Predictable group. These results show that although creativity may take people beyond their knowledge, they can never fully break free from that knowledge.

Introduction

Creativity is like reaching for the stars with your feet firmly stuck in the mud of everyday life. While the creative act takes us beyond what an individual or a society has thought before, it seems to be inextricably constrained by what is known already (see e.g., Boden, 1995; Finke, Ward & Smith, 1992; Perkins, 1981; Sternberg, 1999). In science, new theories come from reactions to old paradigms, but still work from the same methodologies and findings of previous decades. In the arts, similar reactions to the conventions of a previous age occur, though often themes and materials remain the same. In this paper, we examine this interplay between creativity and the constraints placed on it by prior knowledge by studying people's generation of novel outcomes to conventional event sequences. We often need to imagine unconventional or novel outcomes to typical happenings (e.g., in launching a new product or assessing the impact of new technologies). Yet, we know of little work which examines people's creativity in such situations.

The idea that creativity is often constrained by prior knowledge has been strongly and convincingly argued for in Finke et al.'s (1992) Creative Cognition Approach and their 'Geneplore model'. This approach has been supported by several appropriate empirical demonstrations. For example, Ward (1994) asked participants to imagine and then draw creatures that live on a distant planet very unlike earth. This simple creative task revealed that converse to the instructions, almost all the participants produced animals very like the ones living on this planet, in that they exhibited features such as bilateral symmetry, external organs (e.g. eyes, ears) and appendages (e.g. legs, tails). Ward concluded that the participants were constrained by their experience of real world animals and could not deviate easily from such prototypes. This type of influence from background knowledge has been subsequently demonstrated in studies on the generation of novel product names (Rubin, Stoltzfus & Wall, 1991), ideas for traffic improvement (Marsh, Landau & Hicks, 1997), and even the generation of non-words (Marsh, Ward & Landau, 1999). Haught & Johnson-Laird (2003) have reported similar findings in a task where people were asked to come up with a creative sentence incorporating two or three specific nouns. They found that people were quite restricted in their output; for example, the words 'lion' 'strawberry' and 'harp' tended to result in similar sentences, such as "The lion was playing the harp while eating the strawberry". In Ward's (1994) view, these "structured imagination" effects occur because, when faced with a problem whose solution requires creativity, people tend to take the path of least resistance by retrieving domain specific information or an existing solution (whether this is an experimenter provided example or self-generated from previous knowledge) and then attempt to modify the old construct in some novel way.

In the present study, we look at the constraint placed by background knowledge in a task that deals with novel sentence generation involving script-like scenarios (Bower, Black & Turner, 1979; Schank & Abelson, 1977). In our task, people are presented with typical event sequences that have incomplete, but predictable, endings (see Appendix). These scenarios either involve conventional events that proceed uninterrupted (e.g. "Matthew had wanted to quit his job for months. One day he walked into his boss's office…"), or events that are interrupted by some surprising event or state (e.g. "The cup of coffee was balanced on the arm of the chair. Suddenly, Richard sneezed….). In both cases, the main manipulation was to ask people to come up with a creative outcome to the sequence. In the remainder of this paper, we detail this study and sketch the properties of a computational model that might capture the effects found.

Proposing Creative Outcomes to Events

Following the Creative Cognition Approach, we expected that our creative-ending generation task would manifest the constraining influence of prior, background knowledge in our participants. In the experiment, there were two main groups, the Predictable and Creative groups. Both groups were given the same set of event sequence materials

(divided into Unfolding and Surprise scenarios). However, the Predictable group was asked to "think of a typical ending to the scenario…", whereas the Creative group was asked to "think of a creative ending to the scenario…". Thus the design was a 2 x 2 one, with Group being a between-participants variable (Predictable or Creative) and Scenario being a within-participants variable (Unfolding or Surprise).

The main prediction was that the Creative group would generate many of the same outcomes as the Predictable group, as they would be constrained by their background knowledge of the typical endings of these events. However, we thought that something additional would also be included in these endings, giving them an added novel twist. So, in the specific measures we used, we expected more elaborate endings in the Creative group (i.e., more propositions generated), but we also expected that some of these propositions would overlap with those produced by the Predictable group (i.e., propositions reflecting a common ending). To put it another way, the Predictable group's endings should strongly overlap with those generated by the Creative group.

We had no apriori grounds for expecting a difference between the Unfolding and Surprise scenarios, though they do appear to be distinct categories. In the Unfolding scenarios the sequence of actions proceeds unchecked in a predictable way. In the Surprise scenarios one state or sequence of actions is cut across by another sequence of actions. Interestingly though, in the Surprise scenarios the interrupting sequence is also predictable, it's a "typical surprise" (e.g., a poorly balanced object being knocked).

Experiment

Method

Participants Thirty native English-speaking undergraduate psychology students from University College Dublin volunteered for this experiment.

Materials Twenty-four scenarios involving typical everyday event sequences (see Appendix). All scenarios had two sentences and required a third to complete the sequence. The 24 materials consisted of three types of sequences: 8 Unfolding items, 8 Surprise items and 8 filler items. The Unfolding items described two events/states in a typical sequence with a predictable outcome (e.g. "Cathy saw the cake in the window. She hadn't had lunch that day…"). The Surprise items described one event/state that was interrupted by another event/state leading to a predictable outcome (e.g., "The little boy played by the edge of the pond. Suddenly he slipped on some moss…").

Design In the 2 x 2 (Group x Scenario) design, participants were randomly assigned to one of two between-participant groups, Predictable (N=15) and Creative (N=15). All participants received the same 24 scenarios, which were presented in a different random order to each participant.

Procedure Each participant was given a booklet containing all the materials, the first page of which included instructions. The items were presented so that only one scenario appeared on each page (one sentence per line with a prompt stating 'your ending:' in the space below each scenario). Participants in the Predictable group were given the instructions to "think of a typical ending to the scenario", whilst those in the Creative group were asked to "think of a creative ending" to be written as a concluding sentence. In the Creative group participants were also asked to describe a "creative turn of events, not just the use of creative language" so as to avoid a misinterpretation of the instructions. An earlier pilot showed that without this instruction, some people just produced purple-prose versions of typical endings rather than truly novel endings.

Scoring Participants' responses in completing the presented sentences were firstly rated for level of *creativity*. Then the responses were analysed into propositions. As a further measure of creativity, we wished to examine the *diversity* and *richness* of responses made, but we also examined the *commonalities* between responses to determine if there was any overlap across the different conditions.

To measure *creativity*, following Haught & Johnson-Laird's (2003) procedure, two judges independently rated each sentence (blind to condition) on a 7-point scale, with a score of 1 denoting a highly uncreative sentence and a score of 7 denoting an extremely creative sentence.

To measure *diversity*, for each item we categorised the distinct propositions used in people's endings. So for example, for the "Cathy looked at the cake in the shop window. She hadn't had lunch that day…" item, there were three distinct classes of responses given as endings:

(1) Cathy gets the cake.
(2) Cathy decides not to get the cake for some reason (e.g., diet).
(3) Cathy was hungry.

To measure the *richness* of the responses, we scored the endings produced for their word length and the number of different events mentioned in them. This measure was used because, even though people were asked to provide just one sentence, in many cases multiple events/states were included in the responses. So for example, in the cake-seeing scenario, the response "But she knew she was on a diet so decided to wait until she got back to her office, and then ate something less fattening", was classed as having *three* events/states:

(1) Attribute of being on a diet (a state).
(2) Cathy went back to office (event 1).
(3) She ate something less fattening (event 2).

To measure *commonality*, we noted the most common response, i.e. the frequency of occurrence of a given response across a given group. In the cake-seeing scenario the most common event was "Cathy gets the cake" which received 11 counts in the Predictable group and 9 in the Creative group.

For each of these measures, two raters independently scored the materials. The inter-rater reliability was uniformly high on each; for example, in the diversity measure a random sample of ratings showed 94.99% inter-rater reliability in categorising the different responses.

Table 1: Sample responses from two scenarios

"Katie searched everywhere for her little kitten. Then she heard a miaow from the bin"

Predictable	*N*	*Creative*	*N*
Katie opened bin	11	Katie opened bin	4
An explanation that kitten was in bin	3	An explanation that kitten was in bin	4
Kitten walked out of bin	1	Katie found whole cluster of kittens	1
		Katie found wrong kitten	1
		Kitten was being carried away	1
		Katie couldn't understand how kitten was in bin	1
		Bin collector came	1
		Katie was relieved	1
		Katie was disappointed	1

"The cup of coffee was balanced on the arm of the chair. Suddenly Richard sneezed"

Predictable	*N*	*Creative*	*N*
Cup of coffee fell	13	Cup of coffee fell	7
Richard saved cup from falling	1	Richard saved cup from falling	1
Richard's snot went into coffee	1	Richard's snot went into coffee	3
		Chair propelled backwards	1
		Friend got shock and dropped her cup of hot chocolate	1
		Spaceship flew out of nose	1
		A gust of wind went through the window	1

Results & Discussion

To summarise, analysis of the results showed that, though the Creative group produced more creative, diverse and richer responses than the Predictable group, they also could not avoid the commonly occurring events that were invited by the scenario. These results demonstrate that in generating novel outcomes, people are restricted by their background knowledge. Table 1 illustrates samples of the responses made by participants in two scenarios in the experiment.

Creativity of Responses All of the responses were rated blind-to-condition by two judges independently on a 7-point scale. The judges' ratings were reliably correlated (Pearson's $r = 0.748$, $p < 0.01$). A 2 x 2 ANOVA on these ratings for the Group (between-participants) and Scenario (within-participants) variables revealed a main effect of Group, Materials and a reliable interaction, $F(1,478) = 4.65$, $p < 0.05$, $MSe = 6.01$. As expected, responses from the Creative group ($M = 3.523$) were rated as being more creative than those of the Predictable group ($M = 2.245$), $F(1,478) = 188.82$, $p < 0.01$, $MSe = 397.84$. It was also found that the Unfolding materials were rated as more creative ($M = 2.96$) than the Surprise materials ($M = 2.80$), $F(1, 478) = 4.897$, $p < 0.05$, $MSe = 6.338$. This finding suggests that such unfolding events promote greater creative products. This was an unexpected result. It may indicate that it is harder to break the inevitability of the outcome to a surprise scenario because its outcome is much more highly determined. However, we should exercise some care in making sweeping conclusions about this difference, as it is not reflected in any of the other measures. The reliable interaction showed that the most creative condition was the Creative-Unfolding one ($M = 3.68$), followed by the Creative-Surprise ($M = 3.36$), Predictable-Unfolding ($M = 2.24$) and Predictable-Surprise ($M = 2.23$) conditions respectively.

Diversity of Responses Overall, one would expect a greater diversity of responses in the Creative group versus the Predictable group. This is exactly what we found (see Figure 1). A 2 x 2 ANOVA on the diversity scores revealed a reliable main effect of Group, with the Creative group generating more classes of responses ($M = 6.37$) than the Predictable group ($M = 3.5$), $F(1, 14) = 34.6$, $p < 0.01$, $MSe = 66.13$. There was no reliable effect of Scenario and no reliable interaction. An indication of the greater diversity in Creative responses can be seen in Table 1 where both scenarios show more diversity in the Creative condition.

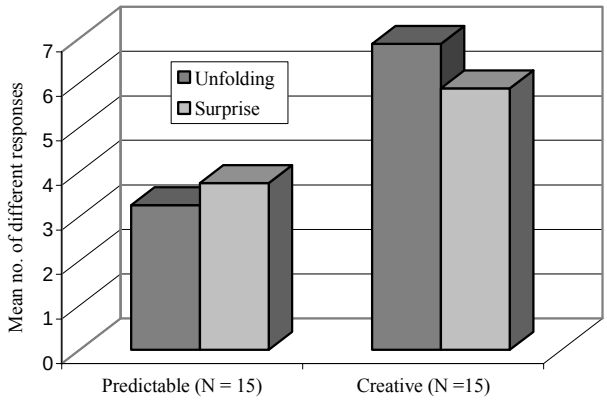

Figure 1: Diversity - the mean number of different responses generated for each condition

Richness of Responses Another index of creativity is the elaborateness or richness of the endings generated. In general, one would expect a greater richness in the responses made by the Creative group than by the Predictable group. Like Haught & Johnson-Laird (2003) we tapped this dimension by examining the average sentence length of people's endings. In addition to this we calculated the mean number of different events in each response.

A 2 x 2 ANOVA again revealed a main effect of Group but no other reliable effects. The Creative group was more likely to provide longer responses ($M = 12.5$ words) than the Predictable group ($M = 9.24$ words), $F(1, 233) = 35.071$, $p < 0.01$, $MSe = 1220.29$. An example of a Predictable response for the first scenario in Table 1 was "She reached in and pulled the kitten out" (word count = 8), a creative response for the same scenario was "She pulled a white kitten from the bin, her kitten was black so she put the white kitten back and carried on looking" (word count = 23).

A 2 x 2 ANOVA on the mean number of different events in the ending showed a comparable pattern; a reliable main effect of Group, but no other effects. The Creative group was more likely to include additional events per ending (M = 1.8) than the Predictable group (M = 1.46), $F(1,233)$ = 19.583, $p < 0.01$, MSe =13.86. Using the example above, the predictable response was classed as having one event and the creative was classed as having three events.

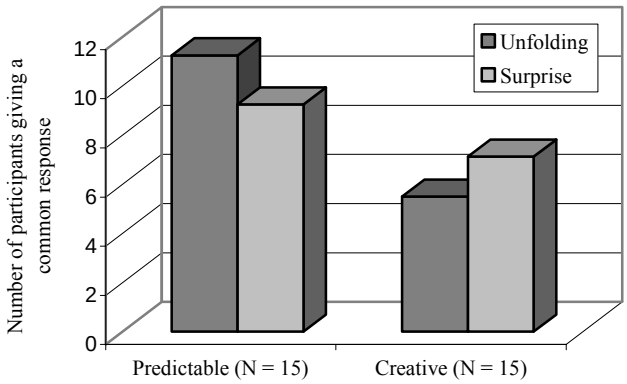

Figure 2: Commonality – count of most common response for each scenario across conditions

Commonality of Responses The above measures show the generativity of the Creative group at work relative to the Predictable one, but they do not reveal the constraints we expected from background knowledge based on Ward's (1994) proposals. If this constraint is in evidence we should see that, in spite of the clear differences in the creativity of responses, there should be certain commonalities between the Creative and Predictable groups too. Specifically, we should see many of the Creative group using the same, inevitable events as some part of their endings. As Figure 2 illustrates, this is exactly what we found. In an analysis of the most commonly produced response, we observed that while those in the Predictable condition (M = 10.25) were more likely to produce the common event, those in the Creative condition (M = 6.313) also produced this same event to a high degree, $F(1, 14) = 31.042$, $p < 0.01$, MSe = 124.03). Again an example of this can be seen in the second scenario in Table 1: the most common response for all participants is that the "cup of coffee fell", which received high counts in both conditions.

General Discussion

The aim of this study was to explore how creative instructions would influence an individual's completion of a common event sequence. The Creative Cognition approach argues that background knowledge can play a constraining role in the creative process, a proposal that is confirmed by the present results. More specifically this experiment has shown that the expectations we have about certain events in the world have a profound influence on our thought processes. We found that although responses of the Creative group were more creative, rich and diverse than those in the Predictable group, certain elements of the endings provided by both groups overlapped considerably. Thus, it appears that whilst creativity in essence involves some degree of variability and unpredictability, it is firmly rooted in our background knowledge of events. In the remainder of this section, we discuss the relationship of these results to the literature on comprehension, and how they might be modeled computationally.

Consistency With Theories of Comprehension

Graesser Singer & Trabasso (1994) stress that knowledge of goals, actions and events are deeply embedded in our perceptual and social experience. As we interact with the environment, we have a strong tendency to interpret event sequences as causal seqeunces, and a similar process occurs in comprehension by means of *inferences* (Kintsch, 1998; Zwaan, 1999). For example, Duffy (1986) observed that when reading, we continually form expectations about future events, so as to develop a causal chain of narrative. The 'Situation Model' of comprehension holds that we construct a detailed mental representation of people, objects, locations, events and actions described in a text (e.g. Zwaan, 1999). Consequently, when reading the scenarios of the present experiment, it was difficult for participants to avoid making rapid, almost automatic inferences about the mental states of the characters and/or the events that would typically occur. In the scenario where Cathy sees the cake for example, it can easily be inferred that Cathy is hungry and that she would like to eat the cake. It could be hypothesised that in this task, the participants naturally link the two sentences together, and in order to provide a coherent ending, they must fit their response with the depicted events so that it is easily understandable and 'makes sense' when read. It is this fundamental knowledge constraint that often overrides instructions to be creative.

Possible Computational Models

Connell & Keane (2002, 2003, in press) have developed a computational model of plausibility judgements for event sequences that is consistent with the above general theory of comprehension. At present, this model takes some event description and finds alternative possible inferential paths to link the events described, this elaborated representation then being scored to assess the plausibility of the description. As such, this Plausibility Analysis Model (PAM) is one possible candidate model that could be extended to deal with the present findings. Such an extension would have to rely on two significant changes: (i) the generation of further possible events to a given sequence based on background knowledge and then (ii) the application of some set of selection heuristics to rank order these possible outcomes for their novelty. As a first pass, such rules could just favour less likely outcomes; that is, outcomes that could possibly occur but that are not strongly supported by prior experience. Obviously such an extension would invite new predictions about the relationship between plausibility and creativity too.

Concluding Comments

The present paper reports a novel study of people's ability to generate creative endings to sentences describing commonplace event sequences. This work connects several areas that have previously been quite separate; namely creativity, sentence comprehension and plausibility. The convergence of these three areas presents a real opportunity for understanding this type of creativity in a new and computationally well-specified way. In short, we should be able to characterise the mud of everyday knowledge, exactly how it glues us to the ground and, yet, the exact nature of the way in which we reach for the stars.

Appendix: Materials Used in the Study

Unfolding Scenarios

1 Cathy looked at the cake in the shop window. She hadn't had lunch that day.
2 The dog saw the bone in kitchen bin. He wagged his tail in anticipation.
3 Thomas the cat felt bored. He noticed the dangling tablecloth.
4 Katie searched everywhere for her little kitten. Then she heard a miaow from the bin.
5 James wanted to read the paper. He stopped at the shop on his way home from work.
6 Robert hated his old car. He decided to call the bank.
7 Matthew had wanted to quit his job for months. One day he walked into his boss's office.
8 Jim felt very cold. He got some coal and firelighters.

Surprise Scenarios:

1 John and Pat were kicking a football on the street. A speedy car sharply turned the corner.
2 Michael's shopping bags were bursting with groceries. He felt one of the handles begin to break.
3 The cup of coffee was balanced on the arm of the chair. Suddenly, Richard sneezed.
4 The yacht sailed on as the crew slept. A rocky reef lay directly ahead.
5 Paul was crossing a busy road. Unexpectedly his mobile phone rang.
6 Peter and Sally ate lunch in the small restaurant. They didn't realise that the meat wasn't properly defrosted.
7 The little boy played at the edge of the pond. Suddenly, he slipped on some moss.
8 The sheep were grazing in the field. Suddenly, a wolf approached the flock.

Task Complexity and Difficulty in Two Computer-Simulated Problems: Cross-cultural Similarities and Differences

Abstract

Complex problems have often been described along certain dimensions, e.g. complexity, transparency, and dynamics. However, problem descriptions of the researcher and problem-characteristics perceived by the participant might differ. This study investigates subjective task complexity and its relationship to complex problem solving performance. Research questions are: Do problem perceptions differ a) between different complex problems? b) between cultures? and c) between participants' performance? Two hundred eighty three students from the US, Brazil, and India participated in this study. Participants played the two computer simulations, Fire and Coldstore, and filled out a problem-characteristics questionnaire after each simulation. Factor analysis revealed two factors; one labeled "Task Complexity", the other "Task Difficulty". Results indicate a) that Fire was perceived as more complex and more difficult than Coldstore in the Brazilian and US sample. The Indian sample perceived both problems as equally complex and difficult; b) a significant main effect of culture was found in Fire and Coldstore regarding Complexity; c) a significant main effect of performance was found for Task Difficulty in Fire and Coldstore, but not for Task Complexity. Cultural variables that could explain the results, such as uncertainty avoidance and differences in computer experience, are presented. Results are further discussed under a theoretical and applied perspective.

Complex Problem Solving and Culture

The study of complex problem solving has increased in the last decades especially in Europe (Frensch & Funke, 1995). Computer simulations of complex problems have been widely used to study human problem solving behavior (Brehmer & Dörner, 1993). The researchers were motivated to incorporate into their simulations characteristics common to real life situations, e.g. complexity, transparency, and dynamics (Dörner, 1996). A problems' complexity is derived from the inclusion of many interdependent variables. Complex problems are nontransparent in that the problem solver initially does not know or understand the nature of the hidden variables in the problem situation. The situations change dynamically with and without the actions of the problem solver. One might derive that the more complex, the more non-transparent, and the more dynamic a problem objectively is, the more difficult it is. However, the described problem characteristics are not objective descriptions of complex problems, but are dependent on the knowledge and experience of the problem solver. Individuals differ in experiences regarding problem-related knowledge and strategic knowledge. The complexity, transparency, and dynamics of a situation interpreted subjectively might be completely different. Therefore, both the problem's specific characteristics and the experience of the problem solver will influence the subjective interpretation of the problem. This interpretation is a crucial aspect of the problem solving process and thus, one might expect individual differences.

Knowledge and experience of the problem solver is strongly influenced by one's cultural environment and several studies have shown how problem solving differs between cultures (Cole, Gay, Glick, & Sharp, 1971; Güss, 2002; Strohschneider & Güss, 1999). Culture is a broad term that can be defined in many ways (Kroeber & Kluckhon, 1963). Under a psychological perspective it can refer to implicit and explicit shared knowledge that is transmitted from generation to generation (Smith & Bond, 1998). This knowledge is helpful for a specific group to adapt to specific conditions of the environment. Cross cultural differences in problem solving strategies validate that the people's knowledge base is strongly influenced and shaped by their cultural environment. In essence, the more interesting questions is why and how problem solving strategies are influenced by culture.

One aspect of this implicit knowledge are values that direct behavior, one such value is called *uncertainty avoidance*. A problem is by definition an uncertain situation as the problem solver does not know how to reach a goal state. Uncertainty avoidance refers to "the extent to which the members of a culture feel threatened by uncertain or unknown situations" (Hofstede, 2001, p. 161). Our expectation is that values of uncertainty avoidance influence the initial perception of a problem. For example Hofstede (2001) studied uncertainty avoidance in 53 countries. In his study, India and the United States showed weak uncertainty avoidance, whereas Brazil showed high uncertainty avoidance.

This study investigates the following questions: Do participants perceive different problems in different ways, i.e. is one problem regarded as more complex than another problem? Do perceived problem-characteristics differ between cultural groups? If so, can differences in uncertainty avoidance explain differences in problem perception? Might it be that those problems are created and described with a bias from a western point of view?

Method

Participants

Participants in this study were 283 students from three countries. In India (n=96), participants came from the University of Kerala in Thiruvananthapuram, and from Loyola College, Kerala. In Brazil (n=86), participants were from the universities of Gama Filho, Rio de Janeiro and Faculdade Roy Barbosa, Salvador da Bahia. In the United States (n=101), students were from Northern Illinois University and University of North Florida. Participants received either course credit or were paid for their participation. Students were from the schools of arts and sciences, social sciences, and business. None of the participants had taken part in other complex problem experiments prior to this study. Seventy percent of the participants were majors in psychology. One hundred seventy-six participants were female, and 107 participants were male. Their ages ranged between 18 and 38 years. The average age in the US sample was 22.6 years, in the Indian sample 23.8 years, and in the Brazilian sample 22.0. The mean ages in the three cultural samples were not significantly different. Samples were comparable according to course or major and gender. Data were collected in group sessions (2 hours) and individual sessions where Fire and Coldstore simulations were administered (2 hours).

Materials: Fire, Coldstore, and Problem-characteristics-questionnaire

Participants played two computer simulations, called "Fire" (Gerdes, Dörner, & Pfeiffer, 1993) and "Coldstore" (Reichert & Dörner, 1988). Instructions to each simulation were provided and test games were played before the actual simulation started. After each simulation, a questionnaire regarding simulation characteristics was completed. Instructions and questionnaires were translated from English in translation-backtranslation procedures into Brazilian Portuguese with the help of bilingual Brazilians. The material was presented in Brazilian Portuguese in Brazil and in English in the US and in India. Indian participants, as bilinguals, had no difficulties in answering the Likert-scale questions. The questionnaires consist of identical items and are labeled Fire-characteristics-questionnaire (FCQ) and Coldstore-characteristics-questionnaire (CCQ). This questionnaire is a modification of the one originally developed by Schaub (2001). It consists of 24 items which participants rate on a 7-point Likert scale regarding complexity, transparency, and dynamics. Examples of questions related to complexity are "I find the game complex" and "There are many variables in this simulation". Examples of questions related to transparency are "Not everything is visible that you would like to see" and "The game developments were quite surprising". Examples of questions related to dynamics are "The simulation is dynamic with many changes", "Changes occur often without my intervention".

In the Fire simulation, the participant assumes the role of a fire fighting commander and has to try to protect three towns and the forest from approaching fires. In Coldstore, the participant takes the role of a supervisor in a grocery store with a coldstorage unit. The automatic temperature device has broken down and the participant has to manually control the temperature until the cooling trucks arrive. The goal is to keep the temperature stable at an optimal temperature in order to keep products from freezing or spoiling. Each simulation lasts about 12 minutes.

A comparison of the simulation characteristics of Fire and Coldstore shows that Fire is more complex and more dynamic, yet both are similarly non-transparent. On the screen of the Fire simulation, the participant sees the forest, three cities, fire fighting trucks, helicopters, water dikes, and stone area. In Coldstore, the participant sees the control wheel, the actual temperature, and the target temperature on the screen. Fire is not just more complex regarding stimuli on the screen, but also regarding possible actions. Fire offers 4 main (and a few other) command options for 3 helicopters and 9 fire fighting trucks at any time. These commands can be given to individual units or several units at the same time. At any given time, a person has the choice of a minimum of 4 x (12!) = 312 alternatives. (In fact, the participant has still some additional options). On the other hand, the participant can also just wait and watch what happens. Coldstore offers the participant only one option, a control wheel which the participant clicks with the cursor to regulate the temperature.

Although both simulations can be described as highly dynamic and changing in a non-linear way, Fire is significantly more dynamic than Coldstore. Fires break out at certain times in the simulation, in different locations. Wind strength, wind direction, and interventions of the participant all influence how the fire spreads. Subjectively, participants experience time pressure. In Coldstore, the development of the temperature changes but with delayed effects.

Both simulations can be described as moderately non-transparent. In Fire, participants see the fire, and see wind direction and strength. However, many participants have problems operating the commands. Even if participants have played a test game and have read the instructions, many don't understand the impact of the consequences and long-term effects of some of the commands. In Coldstore, transparency is related to delayed feedback. Participants have the impression, and are often surprised, that the temperature does not immediately react to changes on the control wheel. For many participants, the reasons behind the temperature fluctuations are hard to understand. Analysis of participants' questionnaire responses will show if Fire is indeed described as more complex, more dynamic, and similarly non-transparent as Coldstore. Data analysis will

reveal a universal or a culture-relative perception of problem characteristics.

Initially, the reliability of the two game characteristics-questionnaires (FCQ, CCQ) was studied. Exploratory factor analysis was conducted to investigate the underlying theoretical structure of the instruments, and measurement equivalence was studied with item analysis. Data regarding participants' subjective evaluation of simulation characteristics was then compared between the three cultural groups and related to performance in the two simulations.

Results

In cross-cultural comparisons, data must be analyzed for equivalence before any meaningful cross-cultural comparisons can be made. Cronbach's alpha was used to assess the instrument's reliability. The Cronbach's alpha coefficients of 13 complexity items were .632, .552, and .802 for the Indian, Brazilian, and US samples respectively. The internal consistency for complexity items is adequate for the US sample, but not for the Indian and Brazilian samples. The Cronbach's alpha coefficients of the 7 transparency items and 4 dynamics items in all three cultural samples were relatively low, i.e. between .242 and .551. This was the case for the Fire- and the Coldstore-characteristics-questionnaire (FCQ and CCQ). The Cronbach's alpha coefficients for all 24 items in Fire were .762, .691, and .827, for India, Brazil, and the US, and indicate a one-dimensional construct. Further investigation of the measurement's structure using exploratory factor analysis was conducted for the overall sample and for each cultural group. Results indicated two main factors (overall and in each cultural sample). The first factor "Task Complexity" refers to items indicating complexity, transparency, and dynamics. The second factor "Task Difficulty" refers to the subjective impression of the participant on the situation. To compare the factor structure and loadings between the different cultural groups, the coefficient of congruence (MacCallum, Widaman, Zhang, & Hong, 1999) was calculated. Results indicate a similar factor structure in all the cultural samples in both simulations. In a next step, item analysis was conducted following van de Vijver and Leung (1997) approach. Items showing cultural bias were excluded from further analysis.

Items of Factor 1 and Factor 2 are significantly correlated in both simulations (Fire-complexity and Fire-difficulty, r = .189**; Coldstore-complexity and Coldstore-difficulty, r = .178**. Moreover, items of Factor 1 in both simulations are significantly correlated (Fire-complexity and Coldstore-complexity, r = .361**) and items of Factor 2 in both simulations are significantly correlated (Fire-difficulty and Coldstore-difficulty, r = .130*). Factor 1 in one simulation and Factor 2 in the other simulation are not significantly correlated. Cronbach's alpha coefficients for the new scales "Task Complexity" and "Task Difficulty" were calculated for the cultural subgroups and for the overall sample. The Cronbach's alpha coefficients ranged between .606 and .833 in the two Fire item subscales and between .648 and .795 in the two Coldstore item subscales. These reliability measures can be considered satisfactory considering the small number of items in each scale.

Task Complexity and Task Difficulty in the US, Brazilian, and Indian Samples

In a next step, Fire and Coldstore were compared regarding Complexity and Difficulty. Results showed that Fire was perceived as more complex and more difficult than Coldstore (see Figure 1). Lower mean scores indicate high complexity and high difficulty. Dividing the overall score of 18 by 7 (7 items), gives an average of 2.6 on a scale from 1 to 7. This means that overall, the Fire simulation was considered quite complex and quite difficult [Complexity: M_F = 17.59, SD_F = 6.43; M_C = 22.97, SD_C = 8.80; $F(1, 551)$ = -67.36, $p < .001$, $\eta^2 = .11$] and [Difficulty: M_F = 18.57, SD_F = 5.98; M_C = 21.74, SD_C = 6.96; $F(1, 557) = 33.25$, $p < .001$, $\eta^2 = .056$].

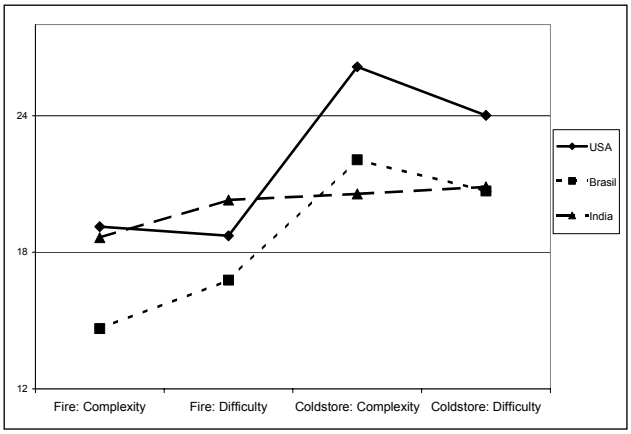

Figure 1: Mean values of US, Brazilian, and Indian participants in Complexity and Difficulty in Fire and Coldstore (Complexity and Difficulty scores are inverted).

In a next step, Complexity and Difficulty in Fire and Coldstore were compared among the three cultural groups using ANOVAs. Scheffe post-hoc tests were calculated to compare differences in the mean values between the three cultures. Comparisons of mean values between cultures in Fire showed that the US and Indian samples had significantly higher average scores regarding Complexity and Difficulty than the Brazilian sample. Brazilian participants perceived the Fire simulation as more complex and difficult (low scores indicate higher complexity). US participants perceived Coldstore as significantly less complex and less difficult. Interestingly, Indian participants' ratings in Coldstore did not differ significantly from their ratings in Fire. These findings show how participants from different cultures view problems quite differently. In the following parts, we will analyze Complexity and Difficulty in relation to task performance.

Fire: Task Complexity and Difficulty in Relation to Actual Task Performance

The performance variable in Fire was the percentage of protected forest at the end of the simulation. Among all the participants, the percentage of protected forest ranged from 41.97% to 97.45% (M = 63.91%, SD = 19.36). The overall scores were distributed in percentile ranks: 25th percentile at 46.61%, 50th percentile at 52.92%, and 75th percentile at

83.01%. Every participant was assigned a score from 1 to 4 according to his or her performance, with higher scores indicating higher performance. Separate two-way ANOVAs were calculated with the two independent variables culture (3 levels) and performance score (4 levels). Dependent variables were Complexity and Difficulty.

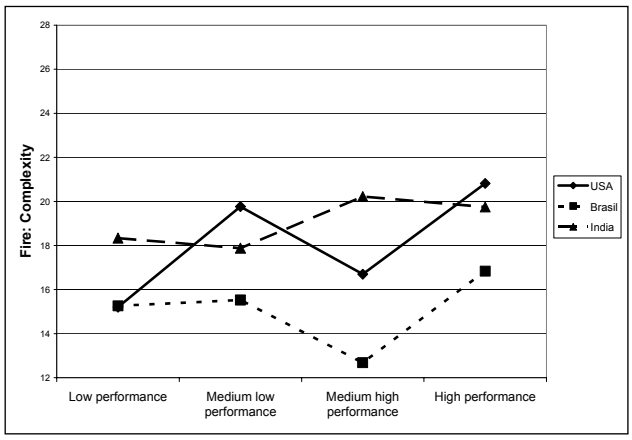

Figure 2: Mean Complexity values of US, Brazilian, and Indian participants according to performance in Fire (Complexity scores are inverted).

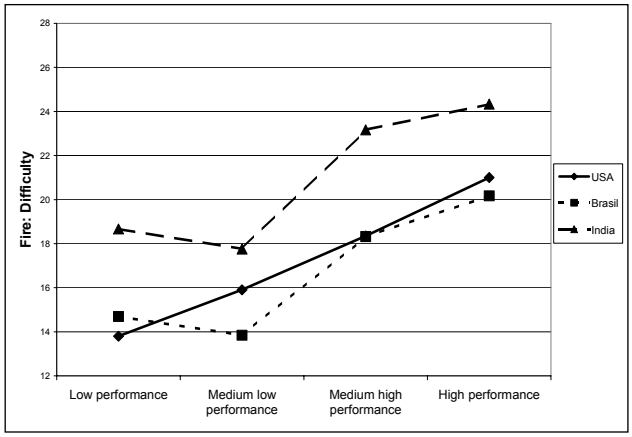

Figure 3: Mean Difficulty values of US, Brazilian, and Indian participants according to performance in Fire (Difficulty scores are inverted).

Regarding the Fire simulation, a significant main effect of culture was found in both Complexity, $F(2, 260) = 8.66$, $p < .001$, $\eta^2 = .065$, and Difficulty, $F(2, 260) = 14.11$, $p < .001$, $\eta^2 = .10$ (see Figures 2 and 3). Post-hoc Scheffe tests showed, that Brazilian participants rated the Fire simulation as significantly more complex and more difficult than US and Indian participants. A significant main effect of performance was found for Difficulty, $F(3, 259) = 17.69$, $p < .001$, $\eta^2 = .175$, but not Complexity. Those who performed better tended to rate the Fire simulation as less difficult. However, regardless of their actual performance on the Fire task, the Fire simulation was viewed with similar complexity. Regarding complexity, interaction effects between performance and culture were not significant.

Coldstore: Task Complexity and Difficulty in Relation to Actual Task Performance

In Coldstore, the sum of the absolute deviations (SAD) from the target temperature was the performance criterion. The minimum of SAD was 134.82, the maximum 1360.85 (M = 632.99, SD = 263.71, N = 288). The overall SAD scores were distributed in percentile ranks: 25th percentile at 434.80, 50th percentile at 667.41, and 75th percentile at 826.29. The SAD was recoded into values of 1 to 4 according to performance, with higher scores indicating the least deviations, and thereby better performance.

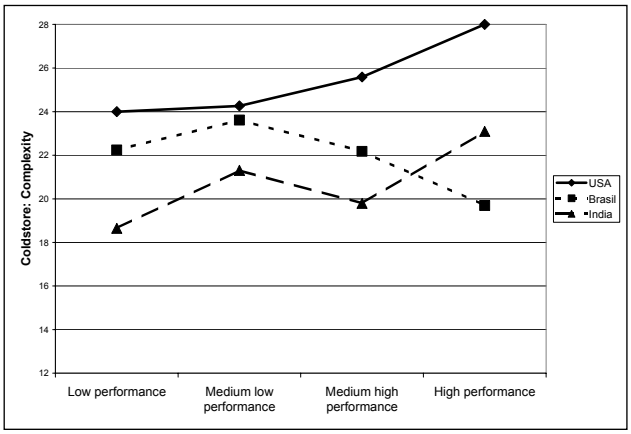

Figure 4: Mean Complexity values of US, Brazilian, and Indian participants according to performance in Coldstore (Complexity scores are inverted).

Separate ANOVAs were calculated with the independent variables, culture (3 levels) and performance score (4 levels). Dependent variables were Complexity and Difficulty. Again, a high score stands for low complexity and low difficulty (inverted, e.g. "I find the game complex" 1-Yes, 7 -No).

In the Coldstore simulation, a significant main effect of culture was found for Complexity, $F(2, 258) = 6.64$, $p = .002$, $\eta^2 = .051$, but not for Difficulty (see Figures 4 and 5). US participants found the Coldstore simulation less complex compared to Brazilian and Indian participants. A significant main effect of performance was only found for Difficulty, $F(3, 257) = 3.391$, $p = .019$, $\eta^2 = .039$ but not for Complexity. As post hoc Scheffe tests reveal, the American participants rated the simulation's complexity as well as the simulation's difficulty significantly lower than the Brazilian and Indian participants. No significant differences between the Brazilian and Indian samples were found.

As evident in Figure 5, the Difficulty scores in Coldstore are relatively similar among the low, medium low, and medium high performance groups with an unusual pattern in the American sample. Only high performing participants viewed the simulation as less difficult. This means that participants who performed well in Coldstore (group 4), rated the simulation as less difficult than those who did not

perform as well. We found this trend in the American and Brazilian samples, but not in the Indian sample. The interaction effect between performance and culture was significant for Difficulty, $F(6, 254) = 2.585$, $p = .019$, $\eta^2 = .059$.

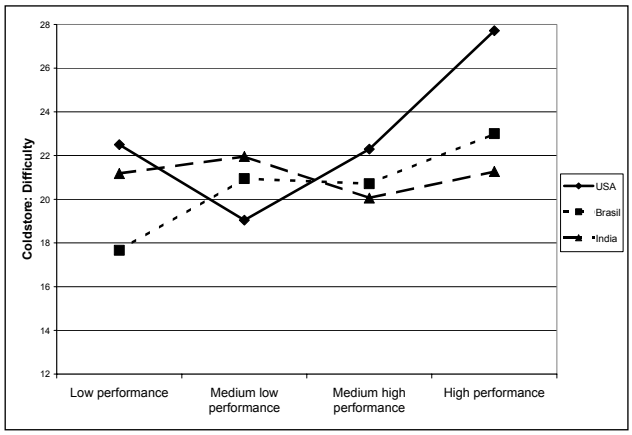

Figure 5: Mean Difficulty values of US, Brazilian, and Indian participants according to performance in Coldstore (Difficulty scores are inverted).

Discussion

In this study, we asked whether problem-characteristics-perceptions differ between complex problems, between cultures, and between performance levels. These questions were studied by administering the simulations Fire and Coldstore and the problem-characteristics-questionnaires to US, Brazilian, and Indian participants. The questionnaires assessed Task Complexity and Task Difficulty. Overall and as expected, Fire was perceived as more complex and more difficult than Coldstore.

In both simulations, no differences were found regarding participants' perception of Task Complexity in relation to performance. Regardless of whether a participant performed in the low, medium or high level, the perception of the simulations' complexity was relatively similar. However, Task Difficulty in both simulations was dependent on performance levels. Participants who performed better regarded the simulations as less difficult compared to those who performed less well. The participant's perception of the task, whether difficult or easy, is related to their actual performance.

This study showed that task complexity and difficulty assessment is an essential step if one wants to compare performance in specific problems. If these simulations are administered in an applied setting or in training programs, it is important to know how the characteristics of these simulations are perceived.

Data analysis also revealed interesting cross-cultural differences. Brazilian participants, compared to Indian and US participants, found the Fire simulation more complex. US Americans, compared to Brazilian and Indian participants, found Coldstore less complex and less difficult. Brazilian and US participants found Fire more complex and difficult compared to Coldstore. However, Indian participants found Fire and Coldstore equally complex and difficult.

There are several possible explanations for these cross-cultural differences. One most plausible reason for the differences among the three cultures is uncertainty avoidance. We expect that low scores in uncertainty avoidance will result in low ratings of complexity and difficulty. In our study, we assessed uncertainty avoidance with the same three questions Hofstede used, but applied them to the school context instead of the work context. In Hofstede's study (2001), India and the United States showed weak uncertainty avoidance scores, whereas Brazil showed high uncertainty avoidance. Surprisingly in our samples, India showed the strongest uncertainty avoidance, Brazil the least uncertainty avoidance, and the US scores were between the Indian and Brazilian ones. The differences between the countries were statistically significant. The different results of our study and Hofstede's study might be related to the samples. Whereas Hofstede's samples consisted of IBM managers, our samples consisted of students. Our participants were also significantly younger and Hofstede has shown significant correlations between age and uncertainty avoidance. A final reason for the different results might be related to changes in cultures. Most of Hofstede's data were collected between 1967 and 1972, i.e. more than 30 years ago and having undergone significant political, economic, and societal development. India, for example, underwent many economic and political changes, especially since the opening of its borders in the 1990s to the world market.

Data analysis revealed that differences in uncertainty avoidance cannot explain cultural differences in problem perception. Brazilian participants, for example, had the lowest uncertainty avoidance scores but the highest Complexity and Difficulty scores in Fire.

A seemingly obvious influence on Complexity and Difficulty scores may be attributed to differences in computer experiences, familiarity with such computer simulations, and motivation to play and succeed in the simulations. However, current results show that although these variables were assessed, none of them can explain the cross-cultural differences in Complexity and Difficulty. The correlations between these variables and task Complexity and Difficulty were not statistically significant.

Why do Brazilian participants compared to US and Indian participants find Fire more complex and difficult? Brazilians perception of Fire as more complex and difficult might be related to the Brazilian time-orientation (Milosevic, 2002). Cross-cultural studies show lower punctuality in Brazil compared to the US (Levine, West, & Reis, 1980) and a more impulsive present-orientation in Brazil (Strohschneider & Güss, 1998). Dealing with a highly dynamic situation like Fire puts the participant under time pressure. Thus, Brazilians with a culture of less strict time orientation may regard the situation as complex and difficult, since their focus is mostly on the immediate, current situation and not on actions in a course of time.

Another question related to the results is why Indian participants view Complexity and Difficulty of Fire and Coldstore similar and Brazilian and US participants view

Fire more complex and difficult than Coldstore. Some studies describe on a general level Western thought as analytic and Eastern thought as holistic (Nisbett, Peng, Choi, & Norenzayan, 2001). A more detailed look at this dichotomy in empirical studies about thinking patterns might reveal more detailed intra- and cross-cultural variations on this general theme. It might be that Brazilian and US participants pay more attention to the details and characteristics of the problems. In a current study (Glencross & Güss, 2004) we find that Indian participants inquire less about problem situations and show more optimism regarding successful planning than US participants. Indians seem to accept the situations as they are, without asking many questions. We find this acceptance of the problem also in other cross-cultural studies between India and Germany (Güss, 2000; Strohschneider & Güss, 1999). These findings could explain why Fire and Coldstore are perceived similarly by the Indian participants.

To summarize, this study stresses the importance of cross-cultural research in the field of cognition. This study showed how perception of task complexity and difficulty can differ between participants of different cultures. For further research, these problem-characteristics-perceptions could be related to strategies that participants use to deal with the complexity and difficulty of the task. It is likely that individuals use different strategies to deal with different perceptions of task complexity and difficulty. The perception of problem characteristics is often the start of the problem solving process, and one can expect and be amazed by the interesting and relevant cross-cultural differences during the next problem solving stages.

Acknowledgements

This research would not have been possible without the support of friends and colleagues in Germany, the US, Brazil, and India. We would like to thank especially Prof. Dietrich Dörner in Germany for providing the two simulations; Prof. Charles Miller in Illinois; Prof. Cristina Ferreira, Prof. Cilio Ziviani, Prof. Nadia, and Dr. Miguel Cal in Brazil; Prof. Krishna Prasaad Sreedhar, Dr. S. Raju, Dr. Ajay Kesavan, and Mr. Ibrahim Syed in India, and the many students who participated.

This research would also not be possible without funding. This study is based on work supported by the National Science Foundation under Grant 0218203 from 2002 to 2005 with the title "Cultural influences on dynamic decision making".

Abstract

This paper presents a model of human spatial orientation, using a task that involves locating targets on a map of the space. The model uses a hierarchical solution process that was reported by many of the participants in an empirical study. It encodes the location of the target in the visual scene by identifying a cluster of objects that contains the target and then encoding the position of the target within that cluster. By applying this description of the target's location to the representation on the map of the space, the model is able to correctly identify the target. Using this general strategy, it reproduces all of the major trends in the empirical data.

Introduction

The relative ease with which people are able to navigate through familiar and unfamiliar environments is a human ability that is not well understood. This process requires the integration of multiple sources of information, since immediate visual perception rarely provides a complete representation of a space. To make informed decisions, generally additional information is necessary. When the space is familiar, this information may be available in memory (e.g., a cognitive map). In other cases, however, people often use external maps of a space to facilitate their decision-making.

When external maps are used in conjunction with visual perception to make spatial judgments, one source of difficulty is the difference in how spatial information is represented in the two views of the space. In visual perception, spatial information is available in egocentric terms (e.g., Klatzky, 1998). That is, the locations of objects in the space are encoded in terms of their distance from the viewer and their bearing relative to the viewer. So, the viewer serves as the origin and the direction the viewer is facing defines the orientation. In contrast, external maps identify the orientation and origin within an allocentric frame of reference. These representations are commonly oriented according to cardinal directions, with north at the top.

When the frames of reference in two representations of a space are different, they must be brought into correspondence before they can be used together to facilitate decision-making (Levine, Jankovic, and Palij, 1982). This process requires the ability to identify a common point in both views of the space, along with another piece of information (a second point or a reference direction) to align the orientations. Once this is done, information can be shared between the two views to provide more complete information about the space. Orientation tasks require individuals to establish correspondence between two views of a space. Often, participants are shown a target in one view of a space and are asked to locate it in the other view. Research has shown that the difficulty of this kind of task depends on a number of factors, including the location of the target object and the difference in the orientations (misalignment) between the two views of the space (e.g., Easton and Sholl, 1995; Hintzman, O'Dell, and Arndt, 1981; Rieser, 1989).

The cognitive model that is presented here illustrates a perspective for understanding how the results obtained in studies of orientation tasks arise. The model was developed in the context of the ACT-R architecture. The remainder of this paper presents a brief description of the empirical work on which the model is based, followed by a description of the model and its performance.

Experiment

Participants were shown 2 views of a space containing 10 objects. On the left was a visual scene showing the 10 objects, one of which was highlighted to identify it as the target. On the right side was a map of the space, indicating the locations of the 10 objects as well as the viewer's position. Participants were asked to click on the object on the map that corresponded to the target that was indicated in the visual scene. Figure 1 shows a sample trial.

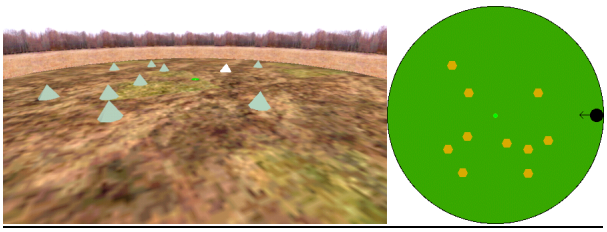

Figure 1: Sample trial for the orientation task.

Method

The spaces were created using the Unreal Tournament game engine (2001), which allows users to create their own 3-D worlds. The 10 objects in the space for each trial were placed in clusters, which were centered around one of 8 positions in the space. In each trial there were four clusters, containing one, two, three, and four objects. The positioning of the clusters was such that on some trials, there were two clusters directly in front of the viewer (one nearby and one farther away), a cluster on the left, and a cluster on the right. In the other trials, there were two clusters on each side of the space relative to the viewer, one nearby and the other farther away. The sample trial in Figure 1 shows the latter case. The configurations and locations of the clusters (in terms of the number of objects in each one) relative to the viewer were counterbalanced. This design resulted in spaces where the objects were not arranged in a well-defined pattern, making it less likely that participants would use strategies that have been described for similar tasks in the past (Gunzelmann and Anderson, 2002).

This experiment varied several factors to closely examine how they impact human performance on orientation tasks. First, the target was located in one of the clusters on each trial. As a result, the target could have been positioned in any of eight general locations relative to the viewer on a given trial. In addition, the target was located in a cluster that contained from one to four objects. So, the target was located in the vicinity of zero to three nearby distractors. Finally, this experiment involved a manipulation of the degree of misalignment between the two views of the space. The two perspectives were either aligned, misaligned by 90 degrees (clockwise or counterclockwise), or misaligned by 180 degrees (maximally misaligned).

There were 20 participants in the experiment. Ten participants completed one half of the possible trials in the experiment, while the other ten completed the other half. When they finished the experiment, participants completed a version of the Vandenberg and Kuse Mental Rotations Test, an assessment that measures spatial ability (Vandenberg and Kuse, 1978). Participants were ranked based upon their scores on this task. Using these rankings, participants were matched between the two conditions and their data were combined to create "meta-participants". The data from these meta-subjects were used in the analyses described here, although the general conclusions remain the same if the data from the two conditions are analyzed independently. Finally, the experiment utilized a drop-out procedure, such that if a participant made an error, the trial was repeated later in the experiment. More complete details concerning the methodology are available in Gunzelmann and Anderson (submitted).

Results

Response times and accuracy were recorded for each trial in the experiment. Overall, accuracy was quite high (96%), and the pattern of errors was quite similar to the response time data (r=.83). This suggests that the results were not due to a speed-accuracy trade-off. As a result of the high degree of accuracy, the data presented here consider the response times for correct responses that participants produced as they performed the experiment.

There are a number of important findings in this experiment, which are summarized in Figures 2, 3, and 4 below. First, in terms of misalignment, the data correspond well with previous research (Figures 2 and 4). As the misalignment between the two views increases, response times increase as well, $F_1(3,27)=38.62$, $p<.001$. Next, the local distractors placed around the target also had an impact on performance (Figures 2 and 3). These data show that as more local distractors were present, participants took longer to identify the correct object on the map, $F_1(3,27)=60.67$, $p<.001$. The magnitude of this effect, however, depended on the degree of misalignment between the two views (Figure 2). Specifically, the impact of the number of local distractors increased as misalignment between the two views increased, $F_1(9,81)=8.79$, $p<.001$.

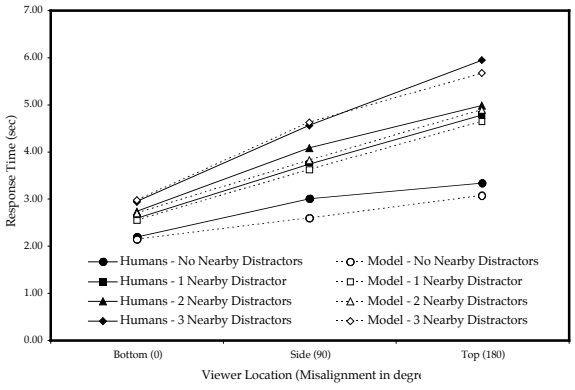

Figure 2: Response times (sec) as a function of misalignment and the number of distractors nearby to the target.

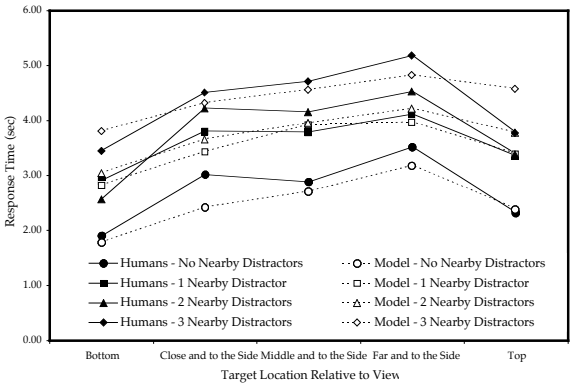

Figure 3: Response times (sec) as a function of the target's location relative to the viewer and the number of distractors nearby to the target.

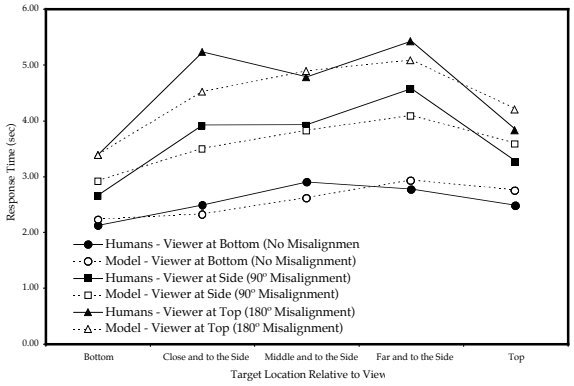

Figure 4: Response times (sec) as a function of the target's location relative to the viewer and the misalignment between the two views.

The impact of the target's location relative to the viewer is shown in Figures 3 and 4. The overall effect was significant, $F_1(7,63)=11.39$, $p<.002$. This result contains two major components. Firstly, response times were fastest when the target was located more directly in front of the viewer (the first and last points on each line in Figures 3 and 4). Secondly, difficulty tended to increase as the target was located farther from the viewer on one side of the visual scene or the other (the remaining points in Figures 3 and 4). Importantly, these trends were produced regardless of the number of distractors that were located near to the target (Figure 3), and this interaction was not significant, $F1(21,189)=1.79$, $p>.15$. In contrast the target's location did have an influence on the impact of misalignment (Figure 4). This result shows that the impact of misalignment was diminished when the target was in line with the viewpoint (the first and last points on each line in Figure 4). This interaction was significant in these data, $F1(21,189)=3.78$, $p<.02$.

In addition to the response time data, retrospective verbal reports from participants provided evidence about how they did the task. In general, participants indicated that they engaged in a two-step process to find the answer. The first step involved identifying a cluster of objects that contained the target so that the cluster could be found on the map. Once the cluster was identified, participants determined which of the objects in the cluster was the correct response.

Discussion

The results of this experiment highlighted several factors that contribute to difficulty in orientation tasks. First, misalignment between the two views of the space impacted difficulty similarly to the results of previous studies (e.g., Gunzelmann and Anderson, 2002; Hintzman, et al., 1981; Rieser, 1989; Shepard and Hurwitz, 1984). Also, the findings show that the location of the target relative to the viewer within a space influences how difficult it will be to locate it on a map. Unlike previous research, this result is demonstrated without using a highly organized configuration of objects in the space. As the target was positioned farther from the viewer, and when the target was less directly in front of the viewer, difficulty increased. These findings suggest that participants were using the viewer's location in the space as a key reference feature to help them determine the location of the target. Response times were faster when the target was in a location that could be encoded more easily with respect to the viewer's position in the space.

This experiment also showed that difficulty increased as more objects were located in the vicinity of the target, a factor that previous research has not addressed. This result suggests that participants were considering only a portion of the space when trying to locate the target, since the total number of objects was the same for all trials. In addition, this effect did not vary as a function of the particular location of the target. This outcome suggests that the location of the cluster does not impact how the target's location within that cluster was encoded.

The hierarchical solution process reported by participants illustrates how they were able to limit their search to a subset of the items in the space and shows why more local distractors would result in longer response times. The presence of more objects near to the target requires more, or more complex, transformations to bring the information in the two views into correspondence, which should take more time (e.g., Bethell-Fox and Shepard, 1988). It appears that one can view the process of solving these tasks as developing a description of the target's location, which then has to be transformed to apply to the map. This description could be verbal, or could involve the creation of a mental image.

ACT-R Model

ACT-R is a general theory of cognition that has been implemented as a running simulation (Anderson and Lebiere, 1998). It operates as a production system with several core assumptions related to its operation. First, there is a division between declarative and procedural knowledge. Declarative memory contains information in the form of chunks, while procedural knowledge is composed of productions, which contain information about transforming one state into another. The latest version of ACT-R is composed of a set of modules for perceptual, motor, and cognitive aspects of human performance. Information is processed independently within these modules, allowing them to operate in parallel. There are buffers associated with each of the modules that essentially represent working memory. The contents of these buffers are what drive the production system. Productions match against the contents of the buffers, and it is only the contents of those buffers that can be directly accessed. It is at the level of production selection and execution that the system operates in a serial manner.

Because ACT-R includes perceptual and motor modules, it is able to interact with experimental software under realistic constraints. Although the perceptual module currently is not sophisticated enough to parse the visual scene shown in Figure 1, it does contribute important timing information to the model's performance. The motor module adds additional constraints to the mouse movements and clicks that the model executes. The parameters that control these aspects of ACT-R's behavior are based on largely on the EPIC theory (Kieras and Meyer, 1997). At a general level, the model was implemented within this architecture to perform the task based on the two-step process described by the participants in their verbal reports. There are, however, a number of details that are important to the model's performance as it goes through this general process. These are described next.

Model Design

The model begins each trial by locating the target in the visual scene. Once this location has been identified, the model finds other objects that are in the vicinity of the target. It counts those objects, and encodes the overall location of the cluster as being in the left, right, or central portion of the visual scene. Then, to encode the location of the target in the cluster, the model revisits the items in the cluster, and encodes the target's position relative to the near-far and left-right axes. So, the model develops a representation of the target's location in the visual scene that would be something like "the leftmost object in the cluster of two on the right of the visual scene." This is the target's position in the sample trial in Figure 1.

With a representation of the target's location in the visual scene, the model shifts its attention to the map of the space, beginning by locating the viewer's position, which is indicated. The next step is to find the correct cluster. If the cluster was encoded as being in the middle of the visual scene, the model searches straight out from the viewer's location to find it. However, when the cluster was positioned to one side or the other, spatial updating is required when the two views are misaligned so that the correct portion of the map is searched. This updating consists of a remapping of "left" and "right" to the corresponding directions on the map relative to the viewer's orientation. For instance, in the sample trial in Figure 1, the right portion of the visual scene corresponds to the top half of the map.

The updating process is a source of difficulty which requires extra time. In addition, when the two views of space are maximally misaligned (the viewer is at the top of the map), the updated values for the map directly conflict with the egocentric values. This adds a second source of difficulty to the updating process, which adds additional time to its execution. Once the values are updated, the model is able to search the appropriate portion of the map for the correct cluster. To perform this search, the model begins near to the viewer's location and searches outward until it finds an object that is in a cluster of the appropriate size.

Once the first step of finding the appropriate cluster is completed, the model needs to determine which of the objects within the cluster on the map is the target. Like the cluster location, the encoding of the target's position is based in the egocentric coordinate system from the visual scene. So, when the two views are misaligned, updates to this information are needed to match the rotated coordinate system of the map. These updates are similar to those described above. Misalignment is one source of difficulty, while direct conflict between the two reference frames is another.

One detail of this process requires some explanation. In the model, the amount of updating done in the second step depends on the number of objects in the cluster. When there are no nearby distractors, this step is skipped. In this case, when the "cluster of one" is found, the model is immediately able to respond by clicking on that object. In cases where there are 2 or 3 objects in the cluster, there is a simple encoding of the target's position within the cluster that requires only one axis. With 2 objects, the target is always on the left or on the right, and is also always the closest or farthest object in the cluster. When the cluster has three objects, the target can also be the one in the middle on each of the axes. In the model, this possibility is represented by having the model update only one of the axes in order to locate the target within the cluster.

When the cluster has 4 objects, the encoding necessarily becomes more complex. This is represented

by having the model update both axes when the cluster has four objects in it. Once again, there is the potential for direct conflict between the two frames of reference in these updates, which adds to the difficulty of this operation. The basic idea is that the complexity of the description needed to encode the target's location increases as the number of objects in the cluster increases. As a result, the difficulty of transforming this description so that it applies appropriately to the map increases as well. This notion is supported by past research, which has demonstrated that more complex figures take longer for individuals to mentally rotate (Bethell-Fox and Shepard, 1988).

The model's performance is modulated by several parameters. First, as noted above ACT-R's perceptual mechanisms are not currently sophisticated enough to process a raw image like the one shown in Figure 1. Thus, as a simplification, the model is presented with a 2-D, egocentrially-oriented representation of the visual scene, which essentially is another map. So, the model implicitly embodies the assumption that participants extract a 2-D representation from the visual scene as they encode the information from it. A constant of .25 seconds was added to the model on each trial to represent the cost of extracting such information from the visual scene.

The second parameter in the model was the retrieval time, which was set to .11 seconds. As the model does the task, it requires some declarative information (mostly related to directional information). Each time a chunk is retrieved from declarative memory, it takes .11 seconds. However, most of the model's performance is driven by the information on the screen, so this parameter does not play a large role in determining the model's predictions.

The only other parameter that was manipulated in the model controls how long it takes to perform the operations needed to update the directions (left, right, up, and down) that it uses to locate the target on the map. The parameter was set so that each of the updates requires .60 seconds. This value applies to each operation that is necessary, and is also applied when direct conflict arises between the allocentric frame of reference and the original egocentric reference frame. This means that if one axis needs to be updated, it will take .60 seconds. If two axes need to be updated, it will take 1.20 seconds. However, if in addition to the update there is direct conflict between the two frames of reference, these updates take 1.20 and 1.80 seconds respectively. These costs apply to the updates needed to locate the cluster and to identify the target within the cluster. When an update is needed to identify the portion of the map where the cluster is located, it involves updating a single axis (left-right). When the cluster has been located and the search begins for the target, the update involves one axis when there are one or two nearby distractors, and two axes when there are three nearby distractors. Each of these updates may or may not involve direct conflict that needs to be resolved in addition to the update. All of the other parameters in the model were given their default ACT-R values.

Model Performance

The model captures all of the major trends in the data. First, the model reproduces the misalignment effect (Figures 2 and 4). As the misalignment between the two views increases, the model takes longer to respond. In the model, this effect comes from the costs of updating the frame of reference to find the cluster on the map and to find the target within the cluster. In addition, the costs associated with the second update depend on the size of the cluster, producing the interaction between misalignment and the number of nearby distractors shown in Figure 2. As the number of nearby distractors increases, the impact of misalignment increases. This illustrates the idea that it is more difficult to update the descriptions of the target locations when those descriptions are more complex. In the model, it is the extra cost associated with the spatial updating process as more nearby distractors are present that produces this interaction. The mechanisms in the model capture the effect of both misalignment and the number of distractors well, with an overall correlation of .992 for the data shown in Figure 2 (RMSD=.187 seconds).

The model makes predictions about the difficulty of the task based upon the target's location in the visual scene as well. These data are shown in Figures 3 and 4, along with the empirical results. The model produces a good qualitative fit to the data, although the particular values are a little off in some instances. The model's predictions arise because it begins its search for the cluster on the map from the viewer's position, moving outward until it locates an object in the cluster. Thus, when the target is farther from the viewer, it takes the model longer to locate an object in the cluster. In addition, the model produces an interaction between target location and misalignment (Figure 4). The effect of misalignment is smaller when the target is directly in front of the viewer (bottom and top target locations) because no spatial updating is necessary to find the cluster. As noted above, the same effect appears in the empirical data, and the model captures the effect well (r=.954, RMSD=.325 seconds for the data in Figure 4).

Finally, there is no interaction in the model between the number of nearby distractors and the location of the target in the visual scene (Figure 3). This corresponds to the empirical results as well (r=.910, RMSD=.351). The result is because of the two-step process, reported by participants, that the model uses to do the task. The target's location within the cluster is encoded without regard to the location of the cluster. So, the impact of the target's location results from the search for the

cluster. Similarly, the number of nearby distractors only impacts the solution process after the cluster has been located, when the correct target must be identified.

Conclusions

Overall, the model produces data that are in line with the performance of the human participants, which lends support to the conclusion that they were using the strategy they reported to do the task. The model produces all of the major trends, in most cases with data that are very close to the data from the human participants. In the model, misalignment impacts both the search for the cluster and the search for the target within the cluster. In contrast, the location of the target only influences the search for the cluster, both in terms of its distance from the viewer and whether or not it is in line with the viewer's position. The interaction of target location with misalignment in the model arises because no spatial updating is needed when the target is directly in front of the viewer. Finally, the number of nearby distractors only impacts the search for the target within the cluster, interacting with misalignment because of the different amounts of spatial updating required based on the number of objects in the cluster. Note that the location of the target does not interact with the number of nearby distractors, suggesting that they affect different aspects of the solution process. The performance of the model supports the conclusion that similar processes are being used by the participants.

In conclusion, this model provides a framework for understanding human performance on spatial tasks. It's most important characteristics relate to the hierarchical encoding of the target's location in the visual scene. This encoding allows the model to limit its search to a portion of the map, ignoring many of the objects in the space. In addition, the model's performance assumes that the two steps in the solution process are independent. As a result spatial updating that is performed for step 1 does not carry over to the execution of step 2. This contributes to the large effect of misalignment on the model's performance. Finally, the model also indicates that perceptual-motor aspects of performance are important factors in this kind of task. The time needed to execute shifts of visual attention contribute to many of the effects described here, especially the impact of the target's location and the impact of the number of local distractors. These issues deserve careful attention in future research.

Abstract

The causal impact of an observable cause can only be estimated if assumptions are made about the presence and impact of possible additional unobservable causes. Current theories of causal reasoning make different assumptions about hidden causes. Some views assume that hidden causes are always present, others that they are independent of the observed causes. In two experiments we assessed people's assumptions about the occurrence and statistical relations involving a hidden cause. In the experiments, participants either only observed a cause or actively manipulated it. We assessed participants' assumption online after each learning trial and at the end of the learning phase. The results show an interesting dissociation. Whereas there was a tendency to assume negative correlation in the online judgments, the final judgments tended more in the direction of an independence assumption. It could also be shown that the judgments were generally coherent with the learning data. These results are consistent with normative theories that drop independence as the default assumption.

Introduction

Most events are causally influenced by more than a single cause. Unfortunately, very often these other causes are unknown or cannot be easily observed. Therefore we often have to rely on the observed statistical relationship between cause and effect when assessing causal strength. For example, whenever a new influenza virus invades East Asia, health representatives try to estimate its health risks, well aware of the fact that many other factors determine whether a patient will die or not. The question of how to assess causal strength when there are hidden causes has challenged normative theories of causality and psychological theories of causal reasoning for some time. A number of different accounts have been proposed analyzing how the causal impact of an observed factor can be accurately estimated if certain assumptions are made about potential hidden causes. In this report we will first give a brief overview of how two current theories of causal reasoning handle hidden causes. In the second part of the report we will present two experiments in which we assessed the assumptions of learners about the impact and probability of hidden causes. In the final section we will discuss potential theoretical implications of these findings.

Theoretical Accounts of Hidden Causes

We are going to focus on a simple causal structure consisting of a single observable cause C and one possible hidden cause A both influencing a joint observable effect E. The two observable events C and E are statistically related. Cause C is neither sufficient nor necessary for the effect, $P(e|c)<1$ and $P(e|\sim c)>0$. How can the causal impact of the observed and - if possible - the impact of the hidden cause be assessed in such a situation?

Associative Theories and the Constant-Background Assumption

Associative theories, such as the Rescorla-Wagner theory (Rescorla & Wagner, 1972), would model this task as learning about the association between a cue representing the observed cause and an outcome representing the effect. Along with the cause cue a second background (or context) cue would be part of the model. This background cue is assumed to be always present and to represent all other factors that might also generate the outcome. Thus, the background cue would play the role of representing the hidden cause A in the outlined causal model. According to the Rescorla-Wagner rule, only weights of cues that are present in a certain trial are being updated. Therefore the permanently present background cue will generally compete with the cause cue in cases in which the cause cue is present. If the outcome is also present the associative weights of both cues will be raised, if the outcome is absent, the weights will be lowered. However, in cases in which the cause cue is absent, only the weight of the background cue will be altered. At the asymptote of learning the associative weight of the observed cause will equal the contingency (i.e., $\Delta P=P(e|c)-P(e|\sim c)$) of the cause cue and the outcome. The associative weight of the background cue will correspond to the probability of the outcome in the absence of the cause cue. Thus, the more often the outcome (=effect) occurs on its own, the higher the associative weight of the background cue will be.

Power PC Theory and the Independence Assumption

Cheng's (1997) Power PC analysis of the causal impact of a single cause can be viewed as a special case of a causal Bayes net in which two causes independently influence a joint common effect (Glymour, 2001, Tenenbaum & Griffiths, 2003). The theory states that the occurrence of the effect E is a consequence of the causal powers of the observed cause C and a hidden cause A (p_c and p_a), and of their base rates $P(c)$ and $P(a)$. Formally the probability of the effect equals the sum of the base rates of the two causes multiplied by their causal power minus the intersection of the causes multiplied by both causal powers:

$P(e) = P(c) \cdot p_c + P(a) \cdot p_a - P(c) \cdot P(a) \cdot p_c \cdot p_a$.

Therefore the probability of the effect E given that the observed cause C has occurred is

$P(e|c) = p_c + P(a|c) \cdot p_a - P(a|c) \cdot p_c \cdot p_a$ [1],

and the probability of the effect given that the observed cause is absent is

$P(e|\sim c) = P(a|\sim c) \cdot p_a$ [2].

Equations [1] and [2] offer an account for hidden causes irrespective of whether they are dependent or independent of the observed cause C. However, if they happen to covary, the power of the causes cannot directly be estimated by the observable data because there are four unknown parameters to be estimated by two observable conditional probabilities. Therefore Power PC theory makes the assumption that the observed and the hidden causes are independent, $P(a|c) = P(a|\sim c) = P(a)$. Based on this assumption the causal power of the observable cause can be calculated by

$p_i = (P(e|c) - P(e|\sim c)) / (1-P(e|\sim c))$.

The independence assumption of Power PC theory implies that the probability of the hidden cause stays the same regardless of whether the observed cause has occurred or not. If this assumption holds, Equation [2] defines lower boundaries for the base rate and the causal strength of the hidden cause. The causal power of the hidden cause and its base rate have to be at least as big as the probability of the effect in the absence of the observed cause, $p_a \geq P(e|\sim c)$ and $P(a) \geq P(e|\sim c)$. Equation [2] also defines a coherence criterion for estimates about hidden causes. In order to be compatible with the observed data, the estimates must honor this equation.

It is important to note that even if independence is not assumed, Equations [1] and [2] still hold and have implications for the unobservable cause. The power of the hidden cause and its probability in the absence of the observed cause are still determined by Equation [2]. Therefore estimates for both values should be constrained by $P(e|\sim c)$. Moreover, Equation [1] provides constraints for the admissible probabilities of the hidden cause in the presence of the observable one. However, this constraint is fairly complex and does not provide the same straightforward implications as Equation [2].

Summary

Both theories consider hidden causes. Associative theories assume that a hidden cause (i.e., the constant background) is always present. In contrast, Power PC and other causal Bayes net theories assume that the hidden cause is independent of the observed cause and that its probability is constrained by the data. The probability of the effect in the absence of the cause marks its lower boundary. These theories also permit to model statistical dependence between the observed and the hidden causes.

Both theoretical accounts agree that $P(e|\sim c)$ is to a certain degree indicative of the causal strength of the hidden cause. But whereas associative theories generally regard this probability as a valid indicator, Power PC and other causal Bayes net theories view this conditional probability as a lower boundary of the causal impact of the hidden cause.

Experiments

The following two experiments explore what assumptions participants make about the presence and impact of a hidden cause in a trial-by-trial learning task, and whether these assumptions conform to the predictions of any of the discussed theoretical models. Thus far very little research has been conducted about naïve participants' assumptions about hidden causes. An exception is a study by Luhmann and Ahn (2003). They found that participants judged the impact of a hidden cause to be higher if $P(e|\sim c)$ was 0.5 than if it was zero. The experiments presented in this report will go beyond these findings. In addition to causal strength estimates, we collected assessments of the probability of the hidden cause using different kinds of measures. We also varied the learning conditions.

In both experiments participants learned about the causal relation between an observable cause and a single effect. Additionally participants were told that there was one other possible but unobservable cause of the effect. The statistical relation between the observable cause and the effect was manipulated in the two experiments while either keeping the contingency (Experiment 1) or the causal power (Experiment 2) constant. In Experiment 1 participants could only passively observe the cause, which occurred at its natural base rate, in Experiment 2 participants were allowed to manipulate the cause. A number of dependent variables were collected to assess participants' estimates of the probability of the hidden cause and the impact of both the observed and the unobserved causes. Participants were asked to guess the presence of the hidden cause on each trial during learning, and they were asked to give summary estimates after learning was completed. In one condition ("prediction before effect") participants were first informed about the presence or absence of the cause in each trial, and then they were asked to guess the presence of the hidden cause without receiving feedback about this alternative cause. Finally they were informed whether the effect has occurred at this particular trial or not. Predictions of the hidden cause prior to effect information can only be guesses based on observed frequencies of the effect in past trials. Based on normative theories (e.g., Power PC theory) we expected participants to generate independence between the causes. In the second condition ("prediction after effect") participants received information about the presence of both the cause and the effect and then had to predict the hidden cause. As before no feedback was provided about the hidden cause. In this situation participants had complete information about the cause

and the effect which should allow them to make more informed guesses about the hidden cause, especially if the observed cause is absent: If in this case the effect is present, participants should conclude that the hidden cause is also present. However if the effect is absent, they should have the intuition that the hidden cause is absent. Predictions based on the presence of the observed cause are more difficult. If in this case the effect is absent, participants should infer that the hidden cause is more likely to be absent than present; if the effect is present the hidden cause should also be given a higher probability of being absent. Based on the theories outlined above, we expected that participants in both conditions would generate independence between the causes in their trial-by-trial predictions. A third control condition left out the trial-by-trial predictions. In this condition participants rated the causal strength of the observed and the hidden cause as well as the probability of the hidden cause in the presence and in the absence of the observed cause after the learning phase. Again we expected participants to rate the causes to be independent. We also expected that the strength ratings for the observed cause would be based on causal power, and that the ratings for the hidden cause would be influenced by $P(e|\sim c)$.

Experiment 1

With Experiment 1 we pursued two goals. The first was to investigate whether participants would assume independence between the observable and unobservable cause. The second goal was to find out whether the power estimates for the unobservable cause would be influenced by the probability of the effect in the absence of the observed cause. Participants were given the task to assess the causal relation between a fictitious microbe ("colorophages") and the discoloration of certain flowers. In addition they were told that there was only one other possible cause of the effect, an infection with another fictitious microbe ("mamococcus"), which was currently not observable. Participants were then directed to a stack of index cards providing information about individual flowers. The front side of each index card showed whether the flower was infected by colorophages or not, and the backside informed about whether the flower was discolored or not. Then participants were instructed about the specific learning procedure in their condition. The learning conditions were manipulated as a between-subjects factor. In Condition 1 ("prediction before effect") participants were first shown the front side of the card, then they had to guess whether the flower was also infected by the other microbe, and finally the card was turned around by the experimenter revealing whether the flower was in fact discolored or not. In contrast, in Condition 2 ("prediction after effect") the card was first turned around and then the participant made her guess about the hidden cause. Guesses were recorded without giving feedback. In the third, control condition cards were simply shown and turned around by the experimenter.

As a second factor the statistical relation between the observed microbe and discoloration was manipulated. Three different data sets consisting of 20 cases each were constructed. Table 1 summarizes the statistical properties of the three data sets. As the table shows, the contingency ΔP was constant across the data sets, whereas both $P(e|\sim c)$ and causal power were rising. All three data sets were shown to every participant in a within-subjects design. Different data sets were introduced as data from different species of flowers. It was pointed out to participants that the effectiveness of the microbes might vary depending on the species. The order of the presented data sets was counterbalanced.

Table 1: Statistical properties of data sets shown in Experiment 1

	Data Set 1	Data Set 2	Data Set 3
$P(c)$	0.50	0.50	0.50
$P(e\|c)$	0.60	0.80	1.00
$P(e\|\sim c)$	0.10	0.30	0.50
ΔP	0.50	0.50	0.50
Power p_c	0.56	0.71	1.00

After each learning phase participants were asked to rate the causal influence of the observed and the hidden cause on a scale ranging from 0 ("no impact") to 100 ("deterministic impact"). Participants were also asked to estimate how many of ten flowers that were infected with the observed microbe were also infected with the other microbe, and how many of ten flowers that were not infected with the observed microbe were instead infected with the other microbe. No feedback was provided about these assessments.

36 students from the University of Göttingen were randomly assigned to one of the learning conditions. Figure 1 shows the mean ratings of the impact of the observed and the hidden causes.

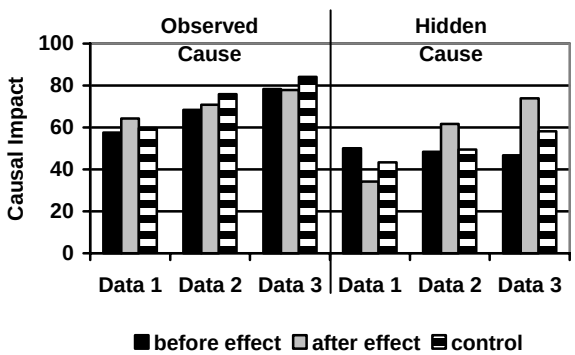

Figure 1: Mean ratings of causal impact for the observed cause (left) and the unobserved cause (right) in Exp. 1.

An analysis of variance revealed a significant increase in impact ratings for the observed cause, $F(2,66)=12.7$, $MSE=296.6$, $p<.01$, supporting the predictions of Power PC theory. The same analysis for the hidden cause resulted also in a significant main effect of the factor data set, $F(2,66)=4.92$, $MSE=408.1$, $p<.05$, which indicates that with increasing $P(e|\sim c)$ participants tended to assume a stronger impact of the hidden cause. This result is in accordance with the predictions of all theoretical accounts. However, the interaction between data sets and learning condition also

turned out to be significant, $F(4,66)=4.55$, $MSE=408.1$, $p<.05$. The observed increase was strongest in the 'prediction after effect' condition followed by the control condition. This interaction might be due to the learning procedure. In the 'prediction after effect' condition participants were sensitized to the possible presence and impact of the hidden cause more than in the other two conditions. Being informed about the occurrence of the effect in the absence of the observable cause is a strong cue pointing to the presence of the hidden cause.

Table 2 shows the results concerning participants' assumptions about the dependence between the causes. The online predictions of the hidden cause in the presence and absence of the target cause were transformed into conditional frequencies, and combined into subjective contingencies, $\Delta P = P(a|i) - P(a|\sim i)$. On the left side of Table 2 the generated contingencies underlying online predictions are listed, the right hand side shows the corresponding contingencies based on the final probability ratings.

Table 2: Mean estimates of dependence between observed and unobserved cause. Numbers indicate contingencies (possible range:-100 to +100).

	Generated Dependence			Estimated Dependence		
	Data Set 1	Data Set 2	Data Set 3	Data Set 1	Data Set 2	Data Set 3
Before Eff.	33.3	8.3	-21.7	30.0	5.8	-3.3
After Eff.	17.0	17.5	-28.8	0.8	0.0	-22.6
Control	-	-	-	14.4	5.8	-4.2

An analysis of variance of the generated contingencies yielded a significant trend from positive to negative assessments which proved independent of learning condition, $F(2,44)=22.1$, $MSE=749.8$, $p<.01$. The estimated contingencies showed a similar trend, $F(2,66)=4.2$, $MSE=753.9$, $p<.05$. The mean contingencies in the different data sets varied slightly across learning conditions, $F(2,33)=2.8$, $MSE=1646.4$, $p<.10$. The generated contingencies were significantly above zero if $P(e|\sim c)$ was zero, and significantly below zero if $P(e|\sim c)$ was 0.5. The estimated contingencies showed a similar but only marginally significant pattern. Thus, there was a hint of a dissociation between online and post hoc assessments which will be followed up in Experiment 2.

These results do not conform to the theoretical assumptions of the discussed theories. Participants did not assume that the hidden cause was always present or that the two causes were independent.

A closer analysis of the conditional probabilities revealed that the negative trend was due to an increase in the generated and estimated probability of the hidden cause in the absence of the observed cause, whereas the subjective probability of the hidden cause in the presence of the observed cause remained relatively stable. This pattern is in part consistent with the analysis outlined in the introduction, $P(a|\sim c)$ seems directly constrained by $P(e|\sim c)$. In contrast, the constraint for $P(a|c)$ is more complex, which may be the reason why participants had more difficulties honoring it.

Even if participants' answers did not conform to the independence assumption, their answers still might be coherent with the observed data. Both Power PC theory and Bayesian models can model dependence between observed and hidden causes. Although precise power estimates might be impossible, the data still yields constraints on plausible estimates. The most important constraint is that the product of the causal power (or strength) of the hidden cause and the probability of the hidden cause in the absence of the observed cause must equal the probability of the effect in the absence of the observed cause. To find out whether participants honor this constraint we used their ratings to recalculate the probability of the effect when cause C was absent:

$P(e|\sim c)_{rec}$ = Rating Impact $A \cdot$ Rating $P(a|\sim c)$.

The results are shown in Figure 2. It can be seen that the recalculated probabilities in the 'prediction after effect' condition were surprisingly close to the actually observed probabilities. In contrast, the recalculated probabilities in the other two conditions were inaccurate. Apparently, participants had to be sensitized by the learning procedure to the presence and impact of the hidden cause to be able to derive coherent estimates. Learning that the effect is present in the absence of the target cause apparently provided the necessary information to make educated guesses about the hidden cause. Without this information the guesses showed some systematicity but did not conform very well to the observed data.

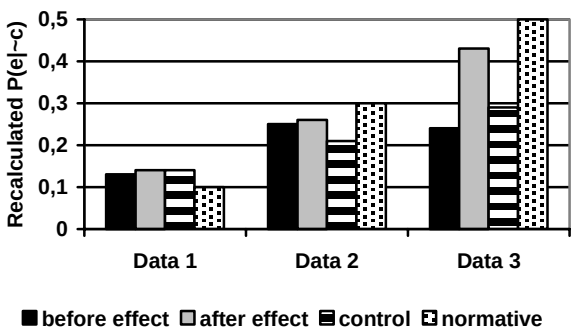

Figure 2: Mean recalculated probabilities of the effect in the absence of the observed cause (Experiment 1).

Experiment 2

In Experiment 1 we used a scenario in which the observable cause could only be passively observed. Therefore a dependence of the observed and unobserved cause was possible and maybe for some participants plausible. In Experiment 2 we allowed participants to arbitrarily manipulate the observable cause. Since these random interventions cannot be based on the presence or absence of the hidden cause, they should make the independence between the alternative causes more salient than in the observation context. Thus, we expected that participants would now assume the causes to be independent in all conditions of the present experiment.

Participants were instructed to imagine being a captain on a pirate ship firing his battery at a fortress. A second ship, which cannot be seen, was also firing at the fortress. Participants had a certain number of shells available and had to decide on each trial whether to fire or not. This procedure ensured that all participants saw the same data despite the fact that they set the cause themselves. The three learning conditions of Experiment 1 were used again. Participants had to guess whether the other ship currently fires either before they were informed about the occurrence of an explosion in the fortress ("prediction before effect"), or they had to predict the other ship's action after they had learned whether the fortress was hit ("prediction after effect"). In a third, control condition no predictions were requested.

Three data sets consisting of 60 cases each were constructed. Table 3 shows the statistical properties of the data. In contrast to Experiment 1 the contingency between the observed cause and the effect decreased across the data sets, whereas the causal power remained stable. Participants learned about all the three data sets with order being counterbalanced.

Table 3: Data shown in Experiment 2

	Data Set 1	Data Set 2	Data Set 3
$P(c)$	0.50	0.50	0.50
$P(e\|c)$	0.70	0.80	0.90
$P(e\|\sim c)$	0.00	0.33	0.67
ΔP	0.70	0.47	0.23
Power p_c	0.70	0.70	0.70

60 students from the University of Göttingen were randomly assigned to one of the three learning conditions. The same dependent variables as in Experiment 1 were collected.

Figure 3 shows the results for the estimates of the causal impact of the observed and the hidden cause.

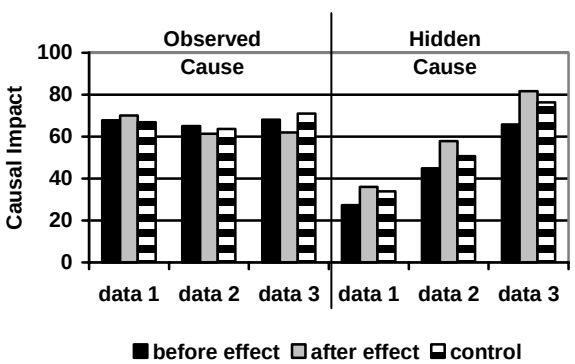

Figure 3: Mean ratings of causal impact for the observed cause (left) and the unobserved cause (right) in Experiment 2.

An analysis of variance of the impact ratings for the observed cause yielded no significant effects, which is in line with the predictions of Power PC theory. As in Experiment 1 the estimated impact of the hidden cause rose significantly across the data sets, $F(2,114)=65.7$, $MSE=408.2$, $p<.01$. This finding is consistent with the predictions of all discussed theories. There was also a significant difference between learning conditions, $F(2,57)=4.06$, $MSE=591.8$, $p<.05$. Participants in the 'prediction after effect' condition rated the impact of the hidden cause to be higher than in the other two conditions. This results points in the same direction as the results of Experiment 1 indicating that predictions with effect information may have sensitized participants to the role of the hidden cause.

Table 4: Mean estimates of dependence between observed and unobserved causes. The numbers express contingencies.

	Generated Dependence			Estimated Dependence		
	Data Set 1	Data Set 2	Data Set 3	Data Set 1	Data Set 2	Data Set 3
Before Eff.	-23.8	-33.2	-29.2	-4.1	8.2	-8.2
After Eff.	-3.9	-20.4	-35.4	12.8	-10.8	-1.0
Control	-	-	-	9.5	9.2	-6.0

Table 4 shows the results concerning the assumed dependence between the two causes. Although the random interventions were expected to increase the salience of independence, participants generated a negative dependence between the two causes which rose across the data sets, $F(2,76)=6.97$, $MSE=510.1$, $p<.01$. The interaction also turned out to be significant, $F(2,76)=3.57$, $MSE=510.1$, $p<.05$. The negative ratings decreased more strongly when participants had received effect information than in the contrasting condition ("prediction before effect"). As in Experiment 1 this trend can be traced to an increase in the generated probability of the hidden cause in the absence of the observed cause. In contrast, the estimated dependencies did not statistically differ. The results are consistent with an independence assumption. Thus, in this experiment there was a clear dissociation between online and posthoc judgments.

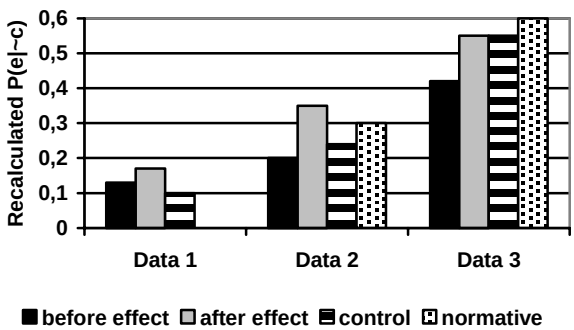

Figure 4: Mean recalculated probabilities of the effect in the absence of the observed cause (Experiment 2).

Figure 4 is based on an analysis of the coherence of the estimates with the constraints from the learning data (using the same method as in Experiment1). It can again be seen that participants honored the normative constraints.

Conclusions

All current theories of causal reasoning consider hidden causes that may also influence observable effects. In most theories independence between the observable cause and the hidden cause is the default assumption, which is a precondition for giving precise estimates for the causal strength of the observed cause-effect relation. Whereas associative theories create independence by assuming constant presence of alternative causes, Power PC theory and Bayesian models are more flexible. Typically these models assume a varying independent hidden cause. However, these theories can also model situations violating the independence assumption by providing bounds for consistent estimates. All theoretical accounts agree that the impact of the hidden cause has to be at least as high as $P(e|\sim c)$. We found evidence in both experiments that participants honored this constraint. Moreover, our analyses showed that participants' judgments about the probability and impact of the hidden cause were in most conditions coherent with the data.

Furthermore, we assessed participants' assumptions about the statistical relation between the observed and the hidden causes. In Experiment 1 learners passively observed the causal relations. In this experiment participants expressed that the causes were positively correlated when $P(e|\sim c)$ was low but they assumed a negative correlation when $P(e|\sim c)$ was high. The generated and estimated probabilities suggest that participants may have assumed that $P(e|\sim c)$ is an indicator of the probability of the hidden cause in the absence of the observed cause ($P(a|\sim c)$) and an indicator of the impact of the hidden cause (p_a) but that $P(e|c)$ conveys little information about the probability of the hidden cause conditional upon the presence of the observed cause ($P(a|c)$). As a consequence participants only adapted their guesses about $P(a|\sim c)$ to the observed $P(e|\sim c)$ while sticking with the initial assumption about $P(a|c)$ irrespective of $P(e|c)$.

In Experiment 2 we increased the salience and plausibility of independence between the alternative causes by letting participants randomly manipulate the observable cause. And indeed the final estimates expressed the assumption of independence. However, surprisingly participants generated a negative correlation in their trial-by-trial predictions. Using the explanation we gave for Experiment 1, this pattern implies that the initial assumption of $P(a|c)$ was at a relatively low level. People may find it unlikely that two independent actions are performed simultaneously by coincidence. In addition participants may erroneously overapply the 'principle of explaining away' (Pearl, 1988) in this task. This principle states that it is generally true that alternative independent causes are less likely in the subset of events in which the cause and effect are present as compared to the whole set of events in which only the effect has occurred. However, in the overall set of events causes should still exhibit independence regardless of the order in which the causal events are experienced. Another related possible explanation might be that people are reluctant to consider overdetermination of effects. Since one cause suffices to explain the effect, assuming a second hidden cause is not necessary. Intuition tells us that one cause is enough for the presence of an effect. It is interesting to see that this intuition seems particularly strong when participants consider single trials of cause-effect patterns. In this situation learners have to decide whether one or two causes generated the effect. Looking back at the learning set at the end of the learning phase seems to decrease the salience of these possible cases of overdetermination, which may be the reason for the interesting dissociation between the tendency to assume negative correlations in online judgments but independence in the summary judgments at the end.

Theoretical Implications

Our results contradict the assumption of associative theories that learners assume constant presence of alternative, hidden causes. The results also indicate that independence of varying causes is not the general default assumption. The online predictions revealed a tendency to assume correlations between alternative causes. Both Power PC theory and causal Bayes nets allow modeling this assumption. Although causal power may in these cases not always be numerically identifiable, these theories can provide constraints for plausible estimates. Future research will have to explore the boundary conditions and the generality of people's assumption across different tasks. The observed dissociations in the present studies indicate that a simple account may be unlikely.

Abstract

Visual search in an important aspect of many tasks, but it is not well understood how many aspects of layout design affect visual search. This research investigates, with reaction time and eye movement data, the effect of local density on the visual search of structured layouts of words. Layouts were all-sparse, all-dense, or mixed. Participants found targets in sparse groups faster even after numerosity effects were factored out, and searched sparse groups before dense groups. Participants made slightly more fixations per word in sparse groups, but these were much shorter fixations. Perhaps most interesting, roughly halfway through searching each mixed layout, participants appeared to switch search strategies with respect to the number of fixations per group of words and fixation duration. When dense groups were searched early in a trial, search strategies were more similar to search strategies in the all-sparse layouts. When searched later in a trial, search strategies were more similar to search strategies of all-dense groups. When combining densities in a layout, it may be beneficial to place important information in sparse groups.

Introduction

It is through visual search that people locate the content and controls for many tasks. Yet, it is not well understood how many layout design practices affect visual search. A large body of basic research on visual search exists in psychology (for example, Greene & Rayner, 2001; Hayhoe, Lachter, & Moeller, 1992; Shen, Reingold, & Pomplun, 2000; Treisman, 1998). Many phenomena have been observed and many theories have been proposed to explain them. However, there has been comparably little research on how to apply basic psychological phenomena in a practical setting. A good applied theory of visual search is needed.

Previous research has investigated the extent to which theories from basic research apply to more ecologically valid tasks in human-computer interaction. One such line of research investigated the visual search of hierarchical layouts with experimentation and cognitive modeling (Hornof, 2001, in press; Hornof & Halverson, 2003). In these experiments, participants searched for a precued target item in labeled or unlabeled layouts. In the labeled layouts, groups had headings and the participant was precued with the target group heading as well as the target item. In the unlabeled layouts, the groups had no headings. It was found that a useful visual hierarchy motivated fundamentally different search strategies. That is, when useful group headings are present, people will first search the headings and then the group content.

The current study extends the work in Hornof (2001) and Hornof and Halverson (2003) by investigating the visual search of more complex non-hierarchical layouts. The purpose of this research is to (a) further inform the development of a predictive tool for evaluation of visual layouts, and (b) contribute to the theories of applied visual search in human-computer interaction.

Varying the density of text and objects is one common design practice used to establish grouping and hierarchy in visual displays (Mullet & Sano, 1995). This paper reports a study that investigates the effect of varying local density on visual search strategies of two-dimensional menu-like lists of words.

The density of items in a display is one factor that has been shown in effective field of view (EFV) studies to affect the number of items that can be perceived in a single fixation. EFV, also referred to as the useful field of view or perceptual span, is the region from which the visual perceptual system processes information in a single fixation. There have been many studies on EFV for various tasks (for example, Bertera & Rayner, 2000; Mackworth, 1976; Rayner & Fisher, 1987; Reingold, Charness, Pomplun, & Stampe, 2001). These studies have found a limited region in the visual field that is sufficient for normal perception of static scenes. This region can be centered on the point of fixation or can be asymmetric with respect to the point of fixation. In addition, these studies have found that the EFV varies in size by type of stimuli, type of task, and task difficulty.

Bertera and Rayner (2000) varied the spacing (density) between a fixed number of randomly placed characters in a search task. They found that search time decreased and the estimated number of letters processed per fixation increased as the density increased. Mackworth (1976) showed similar results in a study in which participants searched for a square among uniformly distributed circles on a scrolling vertical strip. Ojanpää, Näsänen, and Kojo (2002) studied the effect of spacing on the visual search of word lists, and found that as the vertical spacing between words increased (i.e. as density decreased), search time also increased. In general, research examining the interaction between EFV and density has found that the visual search of more dense stimuli is faster per object, with the decrease in the number

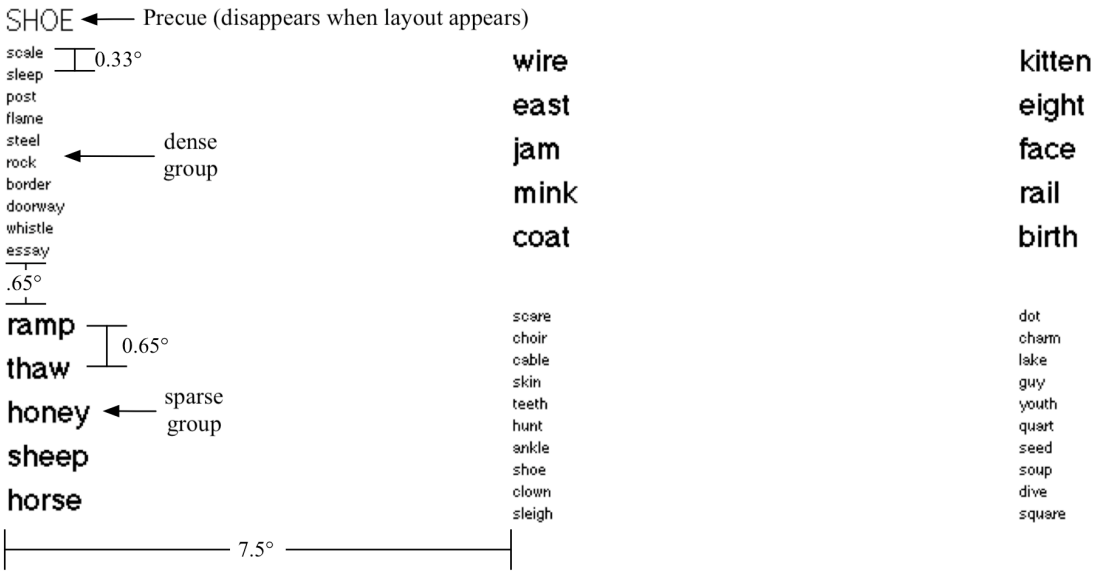

Figure 1: A mixed-density layout. All angle measurements are in degrees of visual angle.

of fixations required to find the target being the largest factor.

Density may be measured as *overall density* or *local density*. Overall density is the number of items per degree of visual angle over an entire layout. Local density is the number of items per degree of visual angle within a visually distinct group.

Besides affecting the search time and number of items inspected per fixation, local density may also affect the *order* of inspection. Several studies have found that visual attention is drawn to "more informative" stimuli (for example, Berlyne, 1958; Mackworth & Morandi, 1967). "More informative" is often defined as regions having greater contour in pictorial stimuli. For example, with geometric shapes, angles are considered more informative than straight lines. Yet, it is not readily known how to predict *a priori* which of two stimuli are more informative. One plausible factor of "informativeness" is local density. It may be that regions with a higher local density are more informative since they are more likely to contain more angles.

The following hypotheses were tested in this study:

H1: The search time per word is greater in sparse layouts than in dense layouts.

H2: Dense regions will be searched before sparse regions.

The following experiment builds on previous research by investigating the extent to which previous findings hold in tasks that are more ecologically valid than those used in Bertera and Rayner (2000) and Mackworth (1976). While these previous studies are very informative, the stimuli are single characters or simple shapes. It is unclear whether the same phenomena will be seen with stimuli in which the items are more complex, such as words, or when density changes within a visual layout. One spatial property – local density – was manipulated in this study.

Method

Participants

Twenty-four people, 10 female and 14 male, ranging in age from 18 to 55 years of age (mean = 24.5) from the University of Oregon and surrounding communities participated in the experiment. The participants were screened as follows: 18 years of age and older; experienced using graphical user interfaces (such as Microsoft Windows or Macintosh); no learning disability; normal use of both hands; and normal or corrected-to-normal vision. Participants were paid $10, plus a bonus that ranged from $0 to $4.54 based on their performance.

Apparatus

Visual stimuli were presented on a ViewSonic VE170 LCD display set to 1280 by 1024 resolution at a distance of 61 cm that resulted in 40 pixels per degree of visual angle. The experimental software ran on a 733Mhz Apple Power Macintosh G4 running OS X 10.2.6. The mouse was an Apple optical Pro Mouse, and the mouse tracking speed was set to the fourth highest in the mouse control panel.

Eye movements were recorded using an LC Technologies Eyegaze System, a 60 Hz pupil-center/corneal-reflection eye tracker. A chinrest was used to maintain a consistent eye-to-screen distance.

Stimuli

Figure 1 shows a sample layout from one mixed-density trial. All trials contained six groups of left-justified,

vertically-listed black words on a white background. The groups were arranged in three columns and two rows. Columns were 7.5 degrees of visual angle from left edge to left edge. Rows were separated by 0.65 degrees of visual angle.

There were two types of groups with different local densities: *Sparse* groups contained five words of 18 point Helvetica font with 0.65 degrees of vertical angle between the centers of adjacent words (0.45° for word height, and 0.2° for blank space). *Dense* groups contained 10 words of 9 point Helvetica font with 0.33 degrees of vertical angle between the centers of adjacent words (0.23° for word height, and 0.1° for blank space). Both types of groups subtended the same vertical visual angle.

There were three types of layouts: *sparse*, *dense*, and *mixed-density*. Sparse layouts contained six sparse groups. Dense layouts contained six dense groups. Mixed-density layouts contained three sparse groups and three dense groups. The arrangement of the groups in the mixed-density layouts was randomly determined for each trial. Sparse and dense layouts were identical to the mixed-density layout, with the exception of group densities.

This experiment was designed, in part, to determine the effect of combining multiple local densities in a single layout. Combining multiple local densities necessitated maintaining the number, size (in degrees of visual angle), and spacing of groups between layouts. Therefore, text size and number of words per group were varied to produce different local densities. Text size often covaries with local density in real-world tasks.

The words used in each trial were selected randomly from a list of 765 nouns generated from the MRC Psycholinguistic Database (Wilson, 1988). No word appeared more than once per trial. The words in the list were selected as follows: three to eight letters, two to four phonemes, above-average printed familiarity, and above-average imagability. Five names of colors and thirteen emotionally charged words were removed.

The target word was randomly chosen from the list of words used in each trial. The participant was precued with the target word before each layout appeared. The precue appeared at the same location every time, directly above the top left word in the layout, in 14 point Geneva font.

Procedure

Each trial proceeded as follows: The participant studied the precue; clicked on the precue to make the precue disappear and the layout appear; found the target word; moved the cursor to the target word; and clicked on it.

The trials were blocked by layout type. Each block contained 30 trials, preceded by five practice trials. The blocks were fully counterbalanced.

At the start of each experiment, the eye tracker was calibrated to the user. The calibration procedure required the participant to fixate a series of nine points until the average error between the predicted point of gaze and the actual location of the points fell below an error threshold (approximately 6.35 mm). During the execution of the experiment, an objective measure of the eye tracker's calibration was taken during each trial as described in Hornof and Halverson (2002). In short, if the calibration had deteriorated below a threshold (2.13 cm), a calibration was automatically initiated before the next trial. In addition, the trial in which the error was found was not analyzed, and a new trial was added to the block.

To separate visual search time from mouse pointing time, the point completion deadline was used (Hornof, 2001). In short, participants were instructed to not move the mouse until the target was found. Once the mouse was moved more than five pixels in any direction, they had a small amount of time (determined by Fitts' law) to click on the target. If this time was exceeded, a buzzer sounded and the trial was recorded as an error. The trial in which the error occurred was not analyzed, and a new trial was added to the block.

Results

Since dense groups contained more words, the following analyses were conducted after normalizing for the number of words per layout. This was accomplished by dividing the search time and number of fixations per trial by half of the number of words in the layout.[1] Table 1 shows the mean search time per word, the mean number of fixations per word, and the mean fixation duration for each layout type. The mean search time per word, mean fixations per word, and mean fixation duration for each of the twenty-four

[1] Measures were divided by half based on the assumption that participants, on average, searched half of the items. This assumption is not consequential for analysis purposes.

Table 1: Search time per word, fixations per word, and fixation duration for sparse, mixed-density, and dense layouts.

	Search Time per Word (ms)		Fixations per Word		Fixation Duration (ms)	
Layout	Mean	SD	Mean	SD	Mean	SD
Sparse	208.25	49.10	.69	.16	250.44	33.21
Mixed	253.58	61.78	.70	.14	306.97	48.81
Dense	265.11	54.52	.62	.14	369.65	67.89

n=24

participants were analyzed using repeated-measures ANOVAs. Eye movements that started before the precue was clicked and after the target was clicked are excluded from all eye movement analysis. An alpha level of .05 was used for all statistical tests.

Participants spent, on average, less time per word in layouts with fewer dense groups, $F(2,46) = 13.94$, $p < .01$. Post-hoc analysis showed that the search time was faster in the sparse than in the mixed layouts ($p < .05$) or dense layouts ($p < .05$); but not different between the mixed and dense layouts ($p > .05$). Participants made slightly fewer fixations per word in layouts with more dense groups, $F(2,46) = 3.25$, $p = .05$. Post-hoc analysis showed that participants used fewer fixations per word in the dense layouts than in the mixed layouts ($p = .01$). Conversely, participants' fixations were longer in layouts with more dense groups, $F(2.46) = 61.82$, $p < .01$. Post-hoc analysis showed that participants made longer fixations in the dense layouts than in the mixed layouts ($p < .05$) and longer fixations in the mixed layouts than in the sparse layouts ($p < .05$).

The search time per trial was analyzed by layout uniformity (all one density vs. mixed density) and target group density. Figure 2 shows the results. Locating a target in dense groups took longer than sparse groups, $F(1, 23) = 83.87$, $p < .01$. The mean search time for all-sparse and all-dense was no different than the mean search time for mixed-density layouts, $F(1,23) = 1.03$, $p = .32$. However, there was an interaction between layout uniformity and target group density, $F(1,23) = 16.87$, $p < .01$. In other words, when the target was in a sparse group, participants found the target faster in all-sparse layouts than in mixed layouts; when the target was in a dense group, participants found the target faster in mixed-density layouts than in all-dense layouts. Further, in mixed density layouts, participants found the target faster when it was in a sparse group, ($p < .01$).

Group visitation data were also analyzed. A group was visited if one or more contiguous fixations fell within 1 degree of visual angle of the group. Group revisits were not included in the analysis presented here. The order of group visitation in mixed density layouts was tested by comparing the percentage of visitations to sparse or dense groups for the first through sixth group visit, regardless of the position of each group in the layout. The results are shown in Figure 3. The data show that participants tended to visit sparse groups before dense groups, $\chi^2(5, N = 24) = 500.04$, $p < .01$.

The mean number of fixations per group and mean fixation duration per group were analyzed. Group revisits were not included in the analysis presented here because it was assumed that the participants' behavior may differ within groups already visited. Additionally, the final groups visited were not included because it was assumed that the participants' behavior may differ within the group in which the target was found. Repeated-measures ANOVAs were conducted to test the effects of group density, layout type (all one density or mixed density), and order of group visit. Figure 4 shows the number of fixations per group as a function of the order in which groups were visited, regardless of the group position in the layout. Each layout type is plotted separately. Mixed layouts are further separated by the visits to dense versus sparse groups. Figure 5 is similar to Figure 4, but shows the mean fixation duration.

The overall number of fixations in all-dense and all-sparse layouts was no different than in mixed-density layouts, $F(1,9) = 2.69$, $p = .14$. The fixations in mixed density layouts are longer than in other layouts, $F(1,9) = 11.22$, $p < .01$. Participants used more fixations per group in dense groups than in sparse groups, $F(1,9) = 112.30$, $p < .01$. Fixation durations were longer in dense groups than in sparse groups, $F(1,9) = 139.36$, $p < .01$.

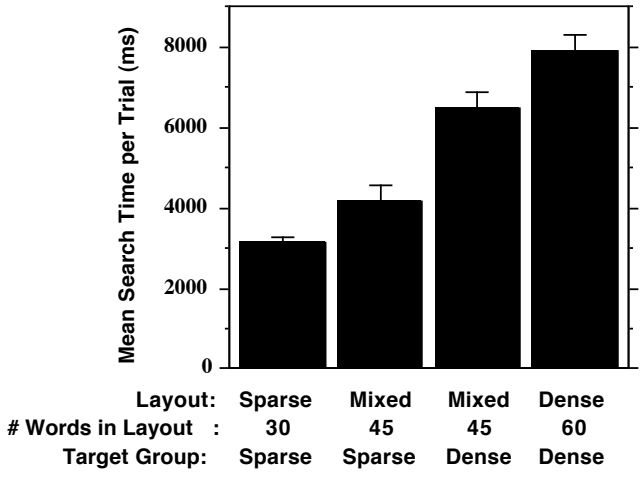

Figure 2: Search time for trials in which the layout was sparse, mixed-density, or dense, and the target was in either a sparse or dense group. Error bars indicate ±1 standard error.

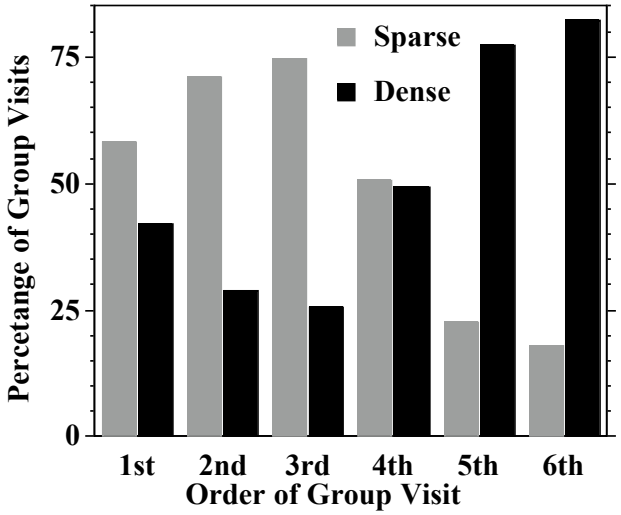

Figure 3: The percentage of visits in mixed density layouts that were to sparse or dense groups, as a function of the order in which groups were visited.

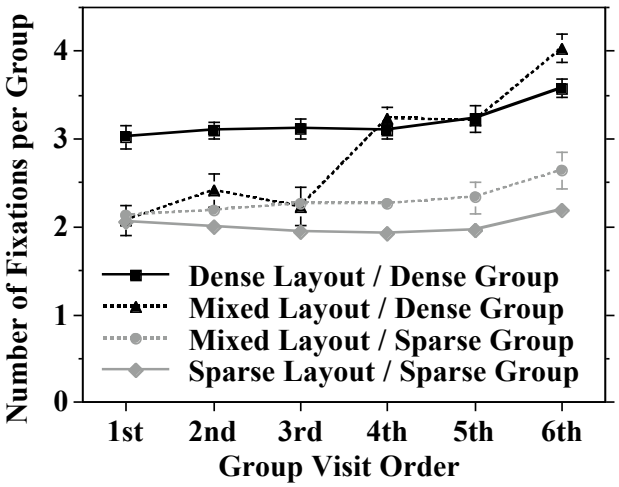

Figure 4: Mean number of fixations per group as a function of layout, the density of the group currently visited, and order of the visit. Error bars indicate ±1 standard error.

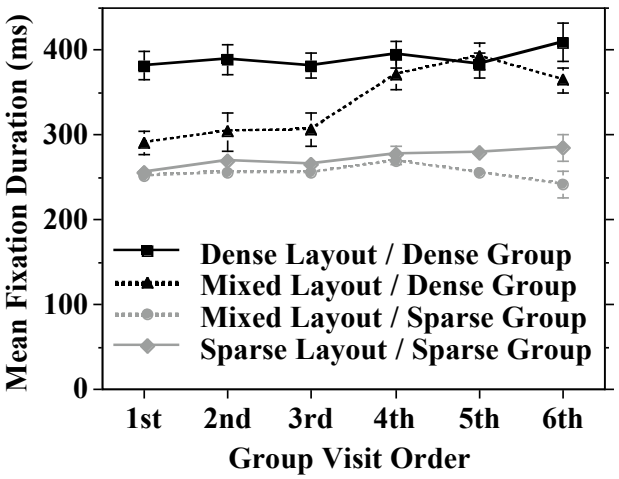

Figure 5: Mean fixation duration by group as a function of layout, the density of the group currently visited, and the order of visit. Error bars indicate ±1 standard error.

Participants used more fixations per group as search progressed, $F(5,45) = 8.14$, $p < .01$. Contrast analysis revealed that the sixth group visited received more fixations than all other groups (all p's < .05), but there were no differences between any other orderings (all p's > .05). Fixation durations tended to be longer for groups visited later than for groups visited earlier, $F(5,45) = 4.89$, $p < .01$. The following interactions were also found in the fixations per group data: The difference between the number of fixations in sparse and dense groups was greater in uniform density layouts than in mixed density layouts, $F(1,9) = 5.20$, $p = .05$. As search progressed (i.e. from left to right in Figure 4), the number of fixations increased faster in mixed-density layouts than in all-dense and all-sparse layouts, $F(5,45) = 6.7$, $p < .01$. The number of fixations increased faster in dense groups than in sparse groups, $F(5,45) = 5.05$, $p < .01$.

Discussion

The data counter the study's first hypothesis – that the search time per word is greater for sparse layouts than for dense layouts. The search time data reported here demonstrate that people actually spent *less* time per word searching sparse layouts. Participants adopted a more efficient eye movement strategy that used slightly more, but much shorter, fixations in the sparse groups. This result is contrary to the search time results found by Bertera and Rayner (2000) and Ojanpää, et al. (2002) in which the search time decreased as the density increased. This discrepancy may be due to the way in which density is manipulated. In the previous studies, the spacing between items was varied. This could result in a need for more saccades, as both Rayner (2000) and Ojanpää, et al. (2002) found, to move the EFV over the next group of unprocessed stimuli. In the current study, the size of words (i.e. font size) was varied. The smaller words were more tightly packed, which could have made it more difficult for people to fixate directly on the desired words, requiring more saccades as found in this study. It may be that although various factors affect local density, they do not all affect visual search of those densities in the same way.

The data also counter this study's second hypothesis – that participants will search dense groups first. A preference for search order as a function of group density was found. However, it was in the opposite direction than predicted. The search time data show that when the target was in a sparse group, the mean search time was much closer to that of the sparse layouts, and that when the target was in a dense group, the mean search time was much closer to that of the dense layouts. If one density were consistently searched before the other, then we would expect the search time for targets located in groups of a preferred density to be lower than the search time for targets located in the other groups, which is what we observed. The data suggest that the participants tended to search the sparse groups first. This preference was confirmed with analysis of the eye movements in the mixed layouts. As is seen in Figure 3, participants tended to look at sparse groups first.

While the first group visited was quite often a dense group, as seen in Figure 3, this is expected as the top-left group in the layout was equally likely to be either sparse or dense and 89% of all initial fixations were to that group. These are likely *anticipatory fixations*, as predicted and observed by Hornof and Halverson (2003).

A trend that emerged from the data analysis is evidence of a shift in search strategy between the third and fourth group visited in mixed layouts, right around the time that participants tended to switch from sparse groups to dense groups. When a dense group was one of the first three groups visited, the participants tended to search the dense groups in the same manner as sparse groups, with fewer and shorter fixations. Yet, when the participants searched

through the all-dense layouts, all-sparse layouts, or sparse groups in the mixed-density layouts, no significant changes in oculomotor programming were found at any point during the search. This suggests that the participants started searching mixed-density layouts with a more eager approach, adopting the search strategy used for the preferred sparse-density groups; then, as the search progressed and the target had not been found, participants reverted to a different strategy for dense groups.

Conclusion

This research investigates the effect of local density on visual search of structured, two-dimensional layouts. It is shown that sparse groups of words are searched faster and, when presented with dense groups, sparse groups are searched earlier than dense groups. This lends support to the practice of displaying important information in less dense groups.

Further, at least in the mixed density task, people appear to apply local search strategies used for sparse groups to all groups, regardless of density, early in the task. At some point in the unfolding of their visual search, approximately halfway through, the participants made a global strategy shift towards a more thorough search of dense groups. This suggests that care should be taken when combining densities in a visual layout. Performance in a mixed density task cannot be predicted by assuming people will search regions of a given density the same as they will in a layout of uniform density. Additional research will determine how these findings generalize to a variety of mixed-density layouts.

Abstract

The present study investigated changes in both the sender's and the receiver's linguistic style across truthful and deceptive dyadic communication. A computer-based analysis of 242 transcripts revealed that senders used more words overall, increased references to others, and used more sense-based descriptions (e.g., seeing, touching) when lying as compared to telling the truth. Receivers naïve to the deception manipulation produced more words and sense terms, and asked more questions with shorter sentences when they were being lied to than when they were being told the truth. These findings are discussed in terms of their implications for linguistic style matching.

Introduction

Maxims such as "honesty is the best policy" and "let the truth be told" reinforce the notion that telling the truth is the best way to communicate. When telling everyday lies, then, deceivers must be careful to assume a position of sincerity in order to make their partners believe them and avoid being viewed in a negative light. In fact, this feat might not be very difficult to accomplish. Previous research suggests that it is quite difficult to catch a liar as deception detection rates in many experiments are not much better than chance (Vrij, 2000).

In general, there are three methods for trying to detect deceit. The first method focuses on vocalic and physical nonverbal behaviors (e.g., movements, smiles, voice pitch, speech rate, stuttering, and eye gaze) (Vrij, 2000). The second method involves measuring physiological responses with various technologies, such as polygraph machines (Vrij, Edward, Roberts, & Bull, 2000).

The third method is concerned with the content of what is said (e.g., verbal behavior, as well as a study of linguistic properties of liars' texts). For example, previous research suggests that liars tend to make less sense and tell less plausible stories (e.g., making discrepant and ambivalent statements), among other verbal characteristics (for review, see DePaulo, Lindsay, Malone, Mulenbruck, Charlton, & Cooper, 2003).

The present study employs automated linguistic analysis, in which a computer program is used to analyze the linguistic properties of texts, to examine the verbal content of deceptive and truthful conversations. As Pennebaker, Mehl, and Niederhoffer (2003) note, words used in daily interactions reveal both psychological and social aspects of peoples' worlds. Certain words and parts of speech can be markers of emotional, psychological, and cognitive states. Given that deceiving others likely involves changes in emotional or psychological states, linguistic cues detected using automated techniques may indicate lying in conversation.

Linguistic Indicators of Deception

A review of the relatively small literature concerned with automated linguistic analyses of deception indicates that, to date, at least four main types of linguistic cues have been associated with deception: 1) word counts 2) pronoun usage, 3) words pertaining to feelings and the senses, and 4) exclusive terms (Burgoon, Buller, Floyd, & Grandpre, 1996; Burgoon, Bliar, Qin, & Nunamaker, 2003; Newman, Pennebaker, Berry, & Richards, 2003; Pennebaker et al., 2003).

Consider first differences in word counts across deceitful and truthful messages. Previous studies have found that senders offer fewer details when lying than when telling the truth (Burgoon et al., 2003; DePaulo et al., 2003; Vrij, 2000). Senders may offer fewer details because they are less familiar with what they are discussing, or because they are trying to avoid providing details that may be inconsistent

with their fabrication. As such, senders may be expected that deceptive interactions would be characterized by fewer words on the part of the sender.

With regard to pronoun usage, Newman et al. (2003) observed that individuals consistently used first person singular pronouns less frequently when lying than when telling the truth. Using first person pronoun words such as "I," "me,"or "my" involves taking ownership of a statement, and deceivers may refrain from using these first person pronouns due to either a lack of personal experience or a desire to dissociate themselves from the lie being told. The findings regarding the use of second and third person pronouns are less consistent. Some studies have found that liars are less likely to use second and third person pronouns (Newman et al., 2003) while other studies have found that liars in fact use more second and third person pronouns (Ickes, Reidhead, & Patterson, 1986). According to Ickes et al. (1986), senders who are careful about constructing deceptive messages will exhibit an increased other-focus and therefore a higher use of second and third person pronouns. Finally, DePaulo et al. (2003) also found that liars are more likely to use third person pronouns in their deceptive interactions.

Research examining verbal cues associated with feelings and sense terms (e.g., see, touch, listen, etc.) suggests that deceivers tended to use more expressiveness, which includes both negative and positive forms of emotion, compared to truth-tellers (Burgoon et al., 2003). In addition, senders may be more likely to use sense words in an effort to create a detailed story to avoid eliciting skepticism from the deceiver (Burgoon et al., 2000).

Finally, previous research also suggests that liars use fewer exclusive words than truth-tellers (Newman et al., 2003). Exclusive words include prepositions and conjunctions such as "but," "except," "without," and "exclude." These words require a deceiver to discuss what is in a category and what is not. As such, deceivers may find it a more complex task to invent what was done versus what was not done (Newman et al., 2003).

Deception, Conversation and the Receiver

Although the literature on automated approaches to linguistic analysis of deception suggests that word counts, pronouns, feeling words, and exclusion words may predict deception, previous research is limited in two important ways. First, previous research has been limited primarily to analyses of deception in the context of monologues rather than in conversational contexts. For example, Newman et al. (2003) conducted five studies in which participants discussed a given topic by writing about it, talking about it to a video camera, or by typing their views on it. In these cases, only the liar's behavior was analyzed because there was no target of those lies present during the studies. Given that most lies tend to occur during conversations with others (DePaulo, Kashy, Kirkendol, & Epstein, 1996), and given the fact that language use in conversation differs in important ways from language use in monologues (Clark, 1996; Schober & Clark, 1989), the focus of previous research on monologue-based deception may limit its applicability to everyday conversation.

A second, and related, weakness is that previous research on linguistic predictors of deception has focused almost exclusively on the sender (i.e., the teller of the deception or the truth). For example, Newman et al. (2003) examined only a sender's handwriting, videotapes, and typed transcripts. In no case were the reactions of receivers (i.e., the targets of deceptive messages) studied. However, in conversations there is a reciprocal exchange between senders and receivers that can have important effects on deceptive behavior (Burgoon et al., 1996; Burgoon, Buller, & Floyd, 2001). As such, it may be important to look at both parties when examining interactions. If senders alter their behavior in systematic ways when lying versus when they are telling the truth, as previous research suggests, then an important question that remains to be addressed is whether receivers will also behave differently when lied to than when they are told the truth.

One possible outcome is that receivers will engage in linguistic style matching, which refers to the degree to which two people in conversation adjust their own speaking behavior, or style, to match their partners' behavior (Niederhoffer & Pennebaker, 2002). The observation that people vary their words on a turn-by-turn level when in conversations with others is assumed to reflect the coordination processes inherent in natural conversations (Grice, 1989; Niederhoffer & Pennebaker, 2002). Indeed, participants in conversations have been known to exhibit similar types of concurrent behaviors (both vocal and nonvocal), kinesics, proxemics, facial expressions, and word usage, regardless of topic content (Niederhoffer & Pennebaker, 2002).

If, as linguistic style matching suggests, people in conversation adjust their linguistic behavior to that of their partners, then any differences in linguistic behavior by senders across deceptive and truthful communication should also be observed in the receiver's behavior. That is, receiver's behavior should mirror the behavior of the sender in terms of word usage and linguistic variables across deceptive and truthful communication. If receivers engage in linguistic style matching during deceptive interactions, then receivers, like senders, should produce fewer words, fewer first person pronouns, more second and third pronouns, more exclusive words and negations, and more words pertaining to the senses.

Finally, there may also be receiver activities that do not simply match those of the sender. For example, if a receiver becomes suspicious of the sender's truthfulness, the receiver may probe their partner more frequently, perhaps by asking additional questions.

The present study examined the linguistic styles of senders and received engaged in truthful and deceitful conversations. The conversations were conducted in a text-based, computer-mediated setting, in which participants exchanged synchronous messages. A computer-mediated

communication setting was used in the present study for several reasons. The first is that the transcripts were created automatically as the participants interacted. The second is that, because the interaction was entirely text-based, all of the information exchanged by the participants during their interaction was captured in the transcripts (Hancock, in press).

Methods

Participants (n = 66) were upper-level students at a northeastern American university, and they participated for credit in various courses. Participants were randomly paired to form 33 same-sex, unacquainted dyads (15 male and 18 female).

Participants were recruited for a "study of how unacquainted individuals communicate about various conversation topics." Upon reporting to the laboratory, participants were led separately to remote rooms where they completed an initial set of forms, including informed consent.

The general procedure was adapted from Burgoon et al. (2001). All participants were told that they would be having a conversation with an unknown partner. They were instructed that they would discuss 5 topics, which were then provided to the participants on a sheet of paper. The first topic was always "When I am in a large group, I…" This initial topic was designed to allow the participants to become comfortable interacting with their partner, and was not included in any analyses. After this topic, participants began a discussion of the four experimental topics which included: "Discuss the most significant person in your life", "Talk about a mistake you made recently", "Describe the most unpleasant job you have ever had to do" and "Talk about responsibility." There was no time limit and participants were asked to discuss each topic until they had exhausted it and understood each other's responses.

One of the two participants was randomly assigned to the role of sender, and the other to the role of receiver. Senders were asked to sometimes deceive their partners. In particular, they were instructed "to NOT tell 'the truth, the whole truth, and nothing but the truth'" (Burgoon et al., 2001) on two topics, and to be truthful on the other two topics. The two topics in which the whole truth was not to be told were marked with an asterisk on the sheet of paper given to the sender.

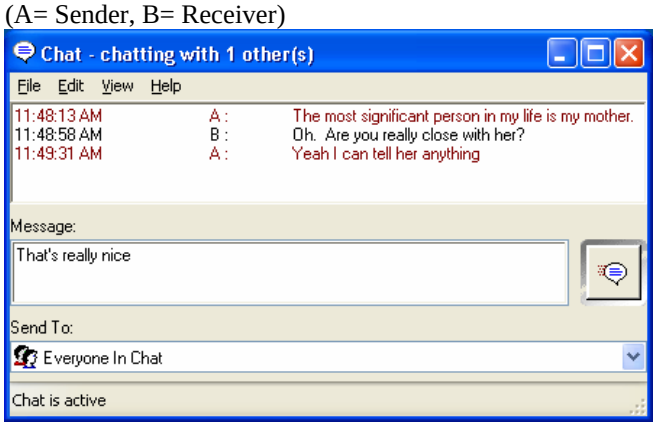
Examples of lies were given to the senders, and it was emphasized that the senders should try to produce lies that were fairly substantial (e.g., saying that they went on a vacation when in fact they did not) rather than small lies (e.g., saying that they went on a vacation from August 4th to the 10th when they actually went from August 5th to the 11th). Senders had approximately five minutes to plan their stories. Receivers were blind to the deception manipulation and were told that they were going to have a conversation with another person and that their role was to keep the conversation going. The same list of topics in the same order was given to the receivers but without any asterisks marking topics.

The sequence in which the topics were discussed, and the order in which the sender lied, was counterbalanced across 16 orders. After the initial ice-breaking topics, senders were instructed to lie on either the next two topics or on the last two topics. Half of the senders followed a truth-first, deception-second order. The remainder followed a reverse order. Because topics followed a diagram-balanced Latin square order within truth and within deception, all topics appeared within a given time period.

Participants discussed the topics in a text-based, computer-mediated setting and performed the task at isolated computer terminals. Participants used one of two desktop computer stations while the experimenter monitored and recorded the interaction from a third station. Once participants were seated at their terminals, the experimenter briefly demonstrated the use of the computer interface, Netmeeting, in which participants typed their message in a private composition window and hit enter to send their message to a shared chat window (see Figure 1). Message transmission was virtually instantaneous.

Once participants finished the discussion task, they were asked to complete a series of questionnaires based on their conversation. The data from these questionnaires are not reported here. After completing the post-interaction questionnaires, each member of the dyad was brought to a common room, and introduced to his or her partner and they were fully debriefed.

Figure 1. Screenshot of the Netmeeting Interface (A= Sender, B= Receiver)



Automated Linguistic Analyses

Both sender and receiver transcripts were converted into separate text files separated by topic. Each dyad produced eight different transcript files: two deception discussions and two truthful discussions for each sender, and two deception discussions and two truthful discussions for each receiver, which produced a total of 264 transcripts.

All transcripts were analyzed using the Linguistic Inquiry and Word Count (LIWC) program (Pennebaker, Francis, & Booth, 2001). This text analysis program was used to create empirically derived statistical profiles of deceptive and truthful communications (Pennebaker et al., 2003), and it

Table 1. Means and (Standard Errors) of the linguistic output variables by role and truth condition.

	Sender		Receiver	
	Lie M (SE)	Truth M (SE)	Lie M (SE)	Truth M (SE)
Word Count	156.11 (17.07)	125.08 (11.20)	157.36 (16.56)	119.61 (10.96)
Words / sentence	10.20 (.97)	9.03 (.53)	8.21 (.42)	9.07 (.59)
1st Person Pronouns	8.01 (.35)	8.52 (.34)	8.08 (.45)	8.92 (.41)
2nd Person Pronouns	2.41 (.31)	2.82 (.32)	2.64 (.32)	2.25 (.22)
3rd Person Pronouns	3.30 (.33)	2.46 (.18)	2.57 (.31)	2.43 (.27)
Negations	2.19 (.21)	1.77 (.16)	2.27 (.19)	2.20 (.21)
Senses	2.47 (.16)	2.09 (.19)	2.49 (.18)	2.18 (.22)
Exclusive Words	4.01 (.27)	4.18 (.32)	3.63 (.22)	3.86 (.31)
Questions	15.88 (2.27)	16.39 (2.32)	15.33 (1.53)	10.84 (1.34)

Note: all statistics represent the percentage of total words in the transcript, with the exception of Word Count, Word per Sentence and Questions variables, which represent absolute totals.

has been used in studies to predict outcome measures like social judgments, personality, psychological adjustment, and health. LIWC analyzes transcripts on a word-by-word basis, including punctuation, and compares words against a file of words divided into 74 linguistic dimensions. For the purposes of this study, only variables relevant to the hypotheses or of potential interest to deception were included, which left 8 variables within the four categories mentioned above: word counts; pronouns; emotion words and words pertaining to the senses; and exclusive words and negations. In addition, question frequency was also analyzed.

LIWC produces the percentage of each variable type by dividing the frequency of the observed variable by the total number of words in the sample. Word counts were not reported as percentages, but as frequency totals.

Results

A 2 (discussion type: truthful vs. deceptive) x 2 (role: sender vs. receiver) repeated measure type General Linear Model (GLM) procedure was conducted on each dependent variable. Table 1 contains the descriptive statistics for each variable.

Overall, more words were produced during deceptive discussions than during truthful discussions F (1,32) = 7.11, $p < .05$. The increase in word count for deception was equivalent for both senders and receivers, F (1,32) < 1, *ns*, and no interaction was observed, F (1,32) < 1, *ns*, suggesting that both senders and receivers used more words when the sender was lying than when the sender was telling the truth.

An analysis of the number of words used per sentence revealed no main effect of discussion type or role. However, a significant interaction between discussion type and role was observed, F (1,32) = 4.07, $p < .05$. Simple effects analyses conducted at each level of discussion type revealed that during truthful discussion senders and receivers produced the same number of words per sentence, F (1,32) < 1, *ns*. In contrast, during deceitful discussion, receivers used marginally fewer words per sentence than senders, F (1,32) = 3.81, $p = .06$. Considered together, these data suggest that receivers used shorter utterances when being lied to than when they were being told the truth, while senders used the same number of words per sentence regardless of discussion type.

The next set of analyses examined pronoun usage. No significant effects were observed for first person pronouns (e.g., "I," "we," "self"). Similarly, no effects were observed for the usage of second person pronouns (e.g., "you"). An analysis of third person pronouns referring to others (e.g., "he," "she," "they"), however, revealed a main effect of role, F (1,32) = 4.68, $p < .05$. Senders used third person pronouns more frequently than receivers. In addition, senders were significantly more likely to discuss others when lying as compared to when they were telling the truth, F (1,32) = 4.57, $p < .05$.

With regard to the production of exclusive words and negations, no reliable effects were observed. Regardless of discussion type, senders and receivers produced the same number of exclusive words and negations.

The next analyses examined the use of words that pertained to the senses (e.g., "see," "touch," "listen"). Participants used significantly more sense words during deceptive conversations than during truthful ones, F(1,32) = 5.34, $p < .05$. No effect of role was observed, F(1,32) < 1, *n.s.*, nor did role interact with discussion type, F(1,32) < 1, *n.s.*

The last analysis was concerned with the number of questions asked during the interactions. A main effect of discussion type was observed, $F(1,32) = 4.02$, $p < .05$. More questions were observed during deceptive discussions than during truthful discussions. This main effect, however, was qualified by a marginally reliable interaction between discussion type and role, $F(1,32) = 3.24$, $p = .08$. Simple effects analyses conducted at each level of role revealed that while senders asked the same number of questions across deceptive and truthful discussion types, $F(1,32) < 1$, *ns.* , receivers asked more questions during deceptive discussions than truthful ones, $F(1,15) = 9.58$, $p < .01$. Considered together, these data suggest that receivers were more likely to ask questions when they were being lied to than when they were being told the truth

Discussion

The primary objective of the present study was to examine the linguistic behaviors of both senders and receivers during dyadic communication that involved both deceptive and truthful discussions. The first question of interest was determining whether the senders' linguistic behavior changed when the sender was being deceptive relative to when the sender was being truthful. The data suggest that, overall, when senders were lying to their partners, they 1) produced more words, 2) used more "other" pronouns (e.g., "he," "she," "they"), and 3) used more terms that described the senses (e.g., "see," "hear," "feel") than when they were telling the truth.

In general, this linguistic profile is consistent with previous research suggesting that senders attempt to construct a more cohesive and detailed story in order to seem believable (Burgoon et al., 1996). For example, the increased number of words observed in the deceptive discussions may reflect the senders' attempts to convey a more complete story when attempting to deceive. Similarly, senders may have increased their use of sense words to enhance the believability of the deception (e.g., "He *saw* her do it."). Finally, the use of other-focused pronouns during deceptive discussions reveals the senders' attempts to shift the focus away from themselves (DePaulo et al., 2003; Ickes, 1986).

The present data, however, differs with previous research in several important respects. For example, previous research suggests that liars tend to use fewer words than truth tellers (Burgoon et al., 2003; DePaulo et al., 2003; Vrij, 2000). Why, then, did senders in the present study produce more words during deceptive discussions than during truthful discussions? One possibility is that the senders in the present study were engaged in conversation with a partner, whereas previous research has focused primarily on deception in monologue formats (e.g., Newman et al., 2003). It is possible, for instance, that senders engaged in conversation used more words in an effort to convince suspicious or skeptical receivers (e.g., Burgoon et al., 2001). Indeed, receivers in the present study asked more questions when they were being lied to than when they were telling the truth (see below), which may have required senders to use more words to address the additional questions.

Similarly, previous linguistic analyses of deception suggest that senders use more negative emotion terms (e.g., Newman et al., 2003; Vrij, 2003). This difference is perhaps not surprising given the differences in discussion topics between the present study and the Newman et al. (2003) study. As noted above, Newman et al. asked participants to lie or tell the truth about highly emotional topics, such as abortion, which may have been more likely to elicit strong emotional verbal content than the more mundane topics employed in the present study (e.g., "Talk about a mistake you made recently.").

The second question of interest was whether the linguistic style of the receivers changed systematically according to whether or not their partners were lying. The data suggest that, in fact, receivers' linguistic profile changed across deceptive and truthful discussion topics. In particular, when being lied to, receivers 1) used more words, in shorter sentences, 2) used more sense words, and 3) asked more questions than when they were being lied to. These observations are particularly striking given the fact that receivers were blind to the deception manipulation.

These data provide relatively robust support for the linguistic style matching model (Niederhoffer & Pennebaker, 2002). First, receivers matched changes in the sender's total word production and use of sense words. Second, like the senders, receivers' use of emotion words and exclusion words did not change across deceptive and truthful conditions. Considered together, the present data suggest that receivers engaged in linguistic style matching.

There were, however, a number of linguistic variables on which receivers and senders diverged. While senders used more other pronouns when lying than when telling the truth, the receivers' use of other pronouns did not differ across discussion types. This observation may reveal the unique motivation of senders to distance themselves from their deception. Perhaps more importantly is the observation that receivers asked more questions and used fewer words per sentence when they were being lied to than when they were being told the truth. These surprising data suggest that the receivers were skeptical of the senders during deceptive conversations. Because senders did not produce more questions when they were being deceptive, the change in the receivers' question-asking behavior does not simply reflect linguistic style-matching. Instead, these data suggest that although receivers were not explicitly aware that their partner was lying to them (i.e., they were blind to the deception manipulation), they were implicitly aware that they were being lied to.

An important limitation of the present study, however, is that participants interacted in a text-based computer-mediated environment. An important question is how these verbal behaviors we observed in text-based conversations will be altered when nonverbal channels of communication are available. While additional research will be required to address this question, communication via the Internet is becoming increasingly ubiquitous. Indeed, millions of people use text-based forms of communication on a daily basis, and previous research suggests that people do tell lies during computer-mediated interactions, such as Email and Instant Messaging, although not as frequently as they do over the phone or in face-to-face contexts (Hancock, Thom-Santelli, & Ritchie, 2004). As such, the present data provide important insights into interpersonal deception in this new communication domain.

Finally, there may not necessarily be a classification of specific words to predict deception, as previous research by Pennebaker et al. (2003) and Newman et al. (2003) may suggest, but deception may be more reliably predicted by looking at the methods of constructing lies. The present research advances our understanding of how linguistic behavior changes according to the truthfulness of the discussion. Lies that take place during conversation tend to include more words, more other-directed pronouns, and more sense words than truths. Equally important, if a receiver is being lied to by someone who fits this linguistic profile, he or she may be more likely to use more overall words and sense terms, and to ask more questions.

Acknowledgments

The authors are grateful to Yufen Chen and Judith Yellin for their assistance in data collection, and to Joseph Walther and Geri Gay for their comments on earlier drafts of the manuscripts.

The transfer of logically general scientific reasoning skills

Anthony M. Harrison (anh23@pitt.edu)

Pittsburgh, PA 15260 USA

Abstract

Extending the paradigm introduced by Schraagen (1993), two near-expert groups and novices completed two scientific discovery tasks, one from each of the experts' domains. In this way, both groups designed simulated experiments from within and outside of their domain. The role of domain familiarity on the application of general scientific reasoning skills is explored by contrasting the performance of the experts in their domain to that in the unfamiliar domain. Results indicate that at the graduate level, near-experts are able to apply general scientific reasoning skills across dissimilar domains, while novices still have difficulty with the transfer.

Introduction

How common are scientific reasoning skills across different domains of practice? Schraagen (1993) as well as Schunn and Anderson (1999) address this issue in their experiments. Both studies relied on the same basic paradigm: two groups of expert researchers and one group of novices were asked to design and conduct a series of experiments in a scientific discovery task. One of the expert groups was familiar with the domain that the task was drawn from (e.g. cognitive psychologists working on a memory experiment), whereas the other was less familiar with the domain, but still from the same general field (e.g. social psychology). The scientific reasoning skills (e.g. experimental design, hypothesis generation, and data evaluation) exhibited by both expert groups were similar and mapped cleanly onto those mentioned in the literature (e.g. Klahr & Dunbar, 1988; Dunbar, 1993; Chinn & Malhotra, 1999). The novices showed a similar pattern of failures as those found by other researchers focusing on non-scientists (e.g. Kuhn, Schauble & Garcia-Mila, 1992; Klahr, Fay & Dunbar, 1993; Zajchowski & Martin, 1993).

Almost all studies that have focused on non-scientists have found remarkably poor performance (see Detterman, 1992 for a review) on scientific reasoning skills. Fortunately, those that have studied practicing scientists in their own domain have found just the opposite (e.g. Dunbar, 1997). Why is it that expert scientists do so well outside of their domain of expertise, yet novices do so poorly? Schunn and Anderson (1999), as well as Schraagen (1993), report that the differences found between the practicing scientists and the novices could not be accounted for by general reasoning ability differences. This leaves two alternative explanations: context of the problem influencing the transfer of the skills, and scientific training itself.

While the studies conducted by Schraagen (1993) and Schunn and Anderson (1999) seem to point towards the influence of scientific training, there is a problem with interpreting it in that way. Both of these studies utilized highly similar groups of experts (all were experimental psychologists of some sort). The similarity of the domains of expertise might be confounding the influence of context on transfer. While the experiments were designed such that the task would be unfamiliar to one of the expert groups, it is likely that they were familiar enough to provide sufficient context cues to trigger the use of the appropriate scientific strategies. The novices, however, would not have had the cues to signal which strategies would be appropriate. If the studies had utilized more dissimilar experts this would not have been an issue. As it is, the transfer context remains a confounding factor.

Voss et al. (1986) provide some support for the transfer hypothesis. Their studies looking at the problem solving of novices and dissimilar experts found that the quality of the reasoning was dependent upon the match of the task to the expert's domain. They report chemists' reasoning being roughly equivalent to that of the novices when attempting to solve political science problems, while the political scientists exhibited a higher quality of reasoning on the same tasks. However, while the Schraagen and Schunn & Anderson studies utilized science-based domains that were overly similar, the Voss, et al. study utilized a non-science-based domain. This makes comparisons across the studies problematic.

The difficulty of transferring skills from one context to another has long been a recognized problem (e.g. Thorndike & Woodworth, 1901; Singley & Anderson, 1989; Detterman, 1992). Singley and Anderson propose that transfer can only occur between two situations for identical elements. This transfer then depends on how the elements were encoded. If researchers only use scientific reasoning skills when faced with problems in their domain, it is possible that they will be coded in a manner that is specific to that context. It would therefore be unlikely that they would use the strategies when those context cues were absent. So in this situation, the

superficial elements of the unfamiliar task mask the relevance of using scientific skills. Unless there is a more abstract understanding of these skills (more general encoding), they will fail to be used in other scientific reasoning contexts.

Much like the experiments of Schraagen (1993) and Schunn and Anderson (1999), this study was designed to explore the differences in scientific reasoning in novices, task experts (at experimentation in general) and domain experts (in the problem domain). The core difference is that instead of using a single task, there are two isomorphic discovery tasks from different scientific domains. Each of the expert groups is a domain expert in one of the two tasks, making each group task experts for both and domain experts for only one. This design allows us to look specifically at the influence of domain familiarity on the transfer of scientific reasoning. Should domain familiarity play a key role in the transfer of the scientific reasoning skills, we would expect the skills to only manifest themselves when the experts are within their natural domain. When working in the unfamiliar domain, their performance would be more like that of the novices. If, however, they are able to recognize the deeper scientific structure of the unfamiliar problem, then their performance should be better than that of the novices and qualitatively equivalent to that seen in their natural domain.

Methods

Participants were recruited from two major universities: 33 undergraduates, 16 from one university, and 17 from the other. The graduate samples were each drawn from a different university (due to enrollment). 11 biology graduate students and 17 industrial/organizational psychology students were recruited, all had completed at least two years of study. Participants were paid for their participation.

Participants were asked to complete two isomorphic experiment-based exploration tasks: they were to determine how each of six task relevant independent variables (IV) affects the outcome of the dependent variable (DV). For example, the biology task had participants design experiments to determine how each variable (water temperature, turbidity, dissolved oxygen, pH, fecal and phosphorus contents) influenced the growth of a certain bacteria that was responsible for the development of open sores on fish. The industrial psychology task had participants design experiments to determine the role of manager characteristics (e.g. technical, critical reasoning, writing skills) on the objectivity of employee appraisals.

Experiments were designed and conducted in a computer simulated laboratory where participants were able to manipulate each IV in question; run and view experiments; take notes on hypotheses, experiments, and outcomes; as well as assign conclusions as to the influences of the IVs on the DV. No data analysis or graphing tools were provided. Each task was self-paced, allowing participants to conduct as many experiments as they needed in order to draw their conclusions. The simulated experiment lab was built with Java™ allowing the recording of all user actions for playback[1].

The task domains were selected based on graduate enrollment in the domains across two universities. Experts in the domains (instructors and researchers) were recruited during the design of the tasks to maximize the external validity of the tasks. The tasks, from microbiology and industrial/organization psychology, were based on experiments found in the literature. The IVs' qualitative effects on the DVs were maintained for 4 of the 6 variables. Two IVs from each task were modified so that they would produce anomalous results. One was anomalous from a theoretical perspective (TA), which was merely an inversion of the qualitative trend. The second was data anomalous (DA) in that a 20% subset of the variable's range produced extreme values. The anomalous variables were added to test the sensitivity of the participants to data anomalies (e.g. Chinn & Brewer, 1993).

Results

The critical comparisons in this study are two orthogonal comparisons: the experts vs. novices (graduates and undergraduates), as well as between the two groups of experts. The expert analyses are between the experts within their domain and outside their domain (domain and task experts respectively). The In-Domain group consists of the biology graduates working on the biology task and the psychology graduates solving the psychology task. The Out-Domain group consists of the same participants, merely performing the opposite task. Unless otherwise noted, all tests are repeated measure ANOVAs with the two tasks as the repeated factor. Specific statistical measures are reported in table 1; significance is assumed at $p<0.05$. Task presentation was counter-balanced, and there were no significant effects of task order on any of the reported measures.

Experimental Design Measures

Participants spent on average 43 minutes on each of the two tasks. While the graduate students spent a little longer on each task (approx. 47 minutes) than the novices (approx. 39 minutes), the differences were nonsignificant. Likewise, the number of experiments designed and conducted in each task did not differ significantly either between the novices and the experts (37 and 47

[1] The experiment can be downloaded from the author's website http://simon.lrdc.pitt.edu/~harrison/

respectively) or within the In-Domain and Out-Domain groups (48 and 45 respectively).

The next design measure considered the breadth of the experimental space that the participants searched (Klahr & Dunbar, 1988). Each IV that they could manipulate had a fixed range, which were divided into five equally-sized bins. For each unique experiment that manipulated a given variable, the total number of bins visited was computed. The more complete the variable range covered, the more informative the results will be with respect to that variable on the whole.

As expected, the novices covered a significantly smaller range than the graduates (see figure 1). However, there were no differences between the In-Domain experts (e.g. biology graduate students performing the biology task, and vice versa) and the Out-Domain experts (e.g. psychology students performing the biology task).

Looking at the breadth of search for the two anomalous variables yielded similar findings. The novices searched a much narrower space for the theory anomalous and data anomalous variables. Likewise, there were no significant differences between the domain and task experts.

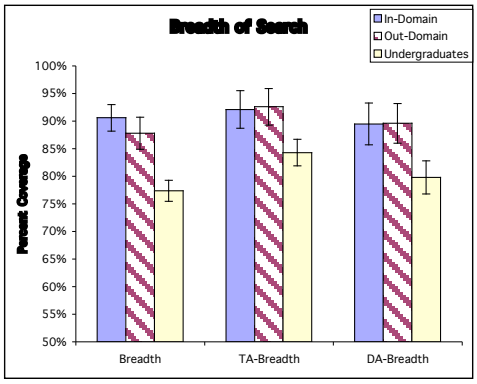

Figure 1. Breadth of experimental space search for all, theory anomalous (TA), and data anomalous (DA) variables.

Another design measure looked at the conservativeness of the experimental designs. With the lack of any data analysis tools, maximizing the interpretability of each simulated experiment was very important. Participants conducted experiments one at a time. The only way to draw conclusions was to compare outcomes of successive experiments. If the comparisons were confounded (multiple IV manipulations), accurate conclusions would be very difficult to draw. Two versions of a VOTAT (vary one thing at a time) score were computed for each task (Tschirgi, 1980). The local VOTAT was computed by averaging the number of variables manipulated in one experiment when compared to the immediately previous experiment. The global VOTAT was computed between the current experiment and the most similar previous experiment (regardless of when it occurred). Since there were no significant differences between the two measures across groups and tasks, the two were combined into an average composite. The novices consistently manipulated multiple variables per experiment, averaging 1.42 changes per experiment, which was significantly more than the graduate sample's 1.23. There were no differences between the experts within or outside their domains.

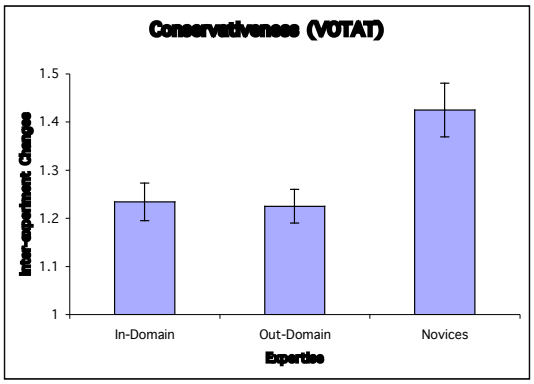

Figure 2. Average number of variables manipulated per experiment. One change at a time yields optimal interpretability in this scenario.

Note-taking

It is hard to argue against the importance of meta-processing skills in scientific reasoning. For this study, we chose to look at the note taking behavior of the participants. This is analogous to practice of scientists keeping a detailed lab notebook (Dunbar, 1997). The first measure is merely one of length, how much note taking is going on. Novices took very few notes (if any), which is in stark contrast to the experts who took significantly longer notes. For the experts, there were no differences in note-taking length when in or out of their natural domain.

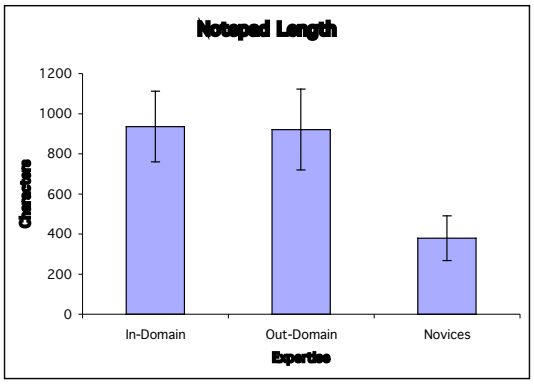

Figure 3. Length of notes (in characters) taken during experiment. Significant difference between novices and experts, none between the experts.

Knowing how much note taking was occurring lead us next to ask how they were utilized. A simple three-category scheme was developed a priori. Notes could be categorized as non-existent (including uninterpretable and

irrelevant notes), effects tracking (documenting variable values and experiment outcomes, effectively duplicating the provided experiment log), or hypothesis tracking (documenting hypotheses, suspected relationships, etc.). As can be seen in figure 4, all groups did an equal amount of effects tracking. The significant differences were in the amount of hypothesis tracking that the experts did.

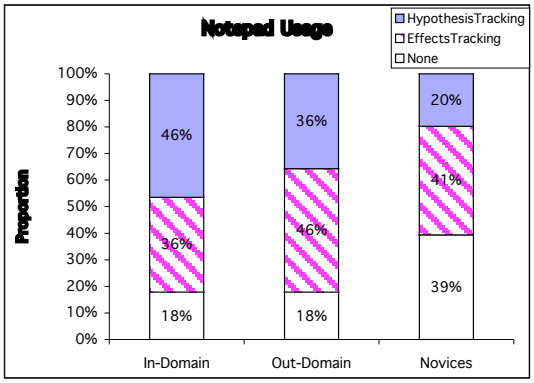

Figure 4. Type of notepad usage. Significant difference between novices and experts, $\chi^2(2,N=61)=5.9$, $p<0.05$. No significant differences between expert groups.

Data Interpretation

The final set of measures where designed to assess the participants' ability to interpret the data and draw conclusions regarding the relationships between the independent variables and the outcome measure. Participants were asked to write out their conclusions for each variable including the qualitative trend, critical values, magnitude, and any "strange" properties. One point was awarded for each property that was correct. Averaging across each of the variables yielded an overall interpretation accuracy score. Making it conditional on the breadth of the experiment space that was searched further refined each variable's score. For instance, any conclusions about critical values would be erroneous if they had not explored the variable range within which the values occurred. The left most graphs in figure 5 show both the raw and the conditional overall interpretation accuracy scores. Once more the novices scored lower than the experts with no significant differences between experts in or out of their domains. The differences between the raw and conditional scores were nonsignificant; participants did not appear to be drawing conclusions beyond what was possible given the data collected.

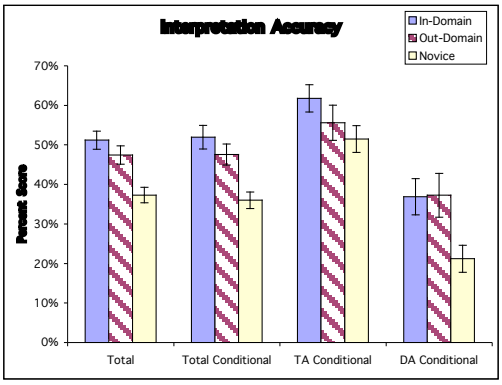

Figure 5. Interpretation accuracy scores, conditional on breadth of search.

The conditional accuracy scores for the anomalous variables were also examined (right half of figure 5). For the theoretically anomalous (TA) variables there were no differences among the three groups. The difference between In- and Out-Domain participants for the TA variable would likely be magnified if established domain experts had been used instead of the graduate students. There was a significant difference between novices and experts for the data anomalous (DA) variables, but this is directly attributable to the differences in the breadth of search for the data anomalous variables (see figure 1).

IQ Surrogates

Since this study had to be conducted across multiple universities, one of the first concerns was general IQ differences between the sampled populations. Using SAT and GRE scores as IQ surrogates, simple ANOVAs were computed. There were no significant differences within the novice undergraduate samples across the two universities, allowing the collapsing of the two groups. There were significant differences between the graduate samples (one from each university) and the novices. The post-hoc LSD showed no differences between the two graduate samples. Figure 6 shows the average combined SAT/GRE scores of the three groups. Further more, regression models were run on all the key dependent measures to test for IQ effects. None of the models approached even marginal significance: higher IQ participants did not perform better than the lower IQ participants. This data suggests that the IQ confound cannot account for the expertise effects found.

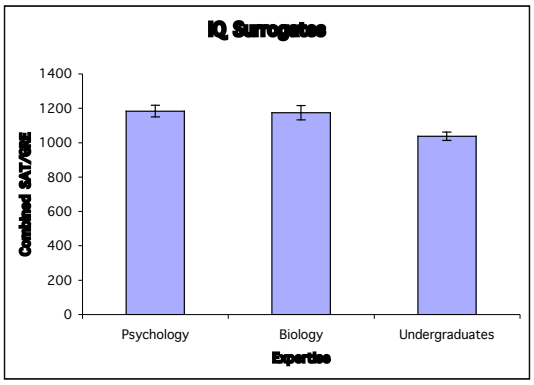

Figure 6. Combined SAT/GRE scores as IQ surrogates. No significant effects due to IQ.

Measure	Undergraduates v. Graduates (p-value)	In-Domain v. Out-Domain (p-value)
Breadth of search		
Overall	0.002	0.429
Theory	0.04	0.894
Data	0.02	0.987
VOTAT	0.02	0.86
Note length	0.001	0.93
Note usage†	0.05	0.875
Data interpretation		
Overall	0.00	0.234
Theory	0.41	0.301
Data	0.03	0.952
IQ surrogates††	0.000	0.34

Table 1. Significance of the planned comparisons. All measures are repeated measure ANOVAs with the tasks as the repeated factor, except for † Note usage (Chi-squared) and the †† IQ surrogate (standard ANOVA).

Discussion

Across the board expert groups performed significantly better than the novices, both inside and out of their domains. Additionally, there were no significant differences between the experts in or out of their natural domains. The findings mirror those of Schunn and Anderson (1999) and Schraagen (1993), even with the use of graduate students as opposed to established and practicing experts. Regardless of the domain, experts used the same general strategies in solving the discovery problems. Had the Out-Domain performance been significantly different from the In-Domain performance, bringing it closer to that of the novices, we could conclude that domain familiarity was influencing the transfer of the scientific reasoning skills.

The only major divergence from the former studies was the lack of a difference between the experts when it came time to draw conclusions from the data collected. While data interpretation per se has nothing to do with a particular domain, both Schraagen (1993) and Schunn and Anderson (1999) found qualitative differences between their task and domain experts. Both expert groups in this study performed equally poorly (but still significantly better than the novices). However, this could have been due to the fact that these tasks produced more data than those in other studies and lacked any analysis tools, such as graphs or tables (a common criticism leveled by the graduate students during the debriefing questionnaire).

Another difference in this study was the inclusion of anomalous variables (both theoretical and data based). Given that anomalies often draw the attention of scientists (Dunbar, 1997; Chinn & Brewer, 1993), it was interesting to see how sensitive the two expert groups were to them. One might expect that upon detection of an anomaly, that participants would search that section of the experimental space more thoroughly. Unfortunately, this is not seen for any of the expert groups (see figure 1). There are no reliably significant differences between the search patterns in terms of breadth or VOTAT (data not shown). This is not to say that the experts did not notice the anomalies; they just didn't exploit them in their experiments, in contrast to the findings of Dunbar (1997) and Tricket, et al (2001). This difference is likely due to the use of graduate students as opposed to established researchers.

Summary

Much like the studies of Schunn and Anderson (1999) and Schraagen (1993), we were interested in exploring the generality of scientific reasoning skills. Both studies concluded that while the quality of the reasoning was domain specific, the processes used were general. As was seen in these studies there are strong differences between the experimental skills exhibited by novices and the experts, or in this case, the developing experts. These differences cannot be attributed to a simple variable such as differences in intelligence. What's more is that the two expert groups behaved qualitatively the same whether they are working in their familiar domain or in a novel one. They were able to transfer the appropriate skills based on the deeper scientific structure and were not negatively influenced by the unfamiliar domain. The bidirectional transfer across a wider context difference is more evident in this study because of the utilization of genuinely dissimilar target domains, as opposed to the psychological domains used by Schunn & Anderson and Schraagen or the chemistry and (non-scientific) political-science domains used in the Voss, et al (1986) studies.

Abstract

It has been well established that collaborative learning is more effective in producing learning gains than individuals working alone. The present study investigates three potential mechanisms responsible for learning from collaborative problem solving: other-directed explaining, co-construction, and self-directed explaining. College undergraduates were trained to criterion on the first four chapters of a popular physics textbook. They were then asked to collaboratively solve three physics problems. Preliminary evidence suggests that other-directed explaining was effective in half of the cases, whereas co-construction led to proportionally more generated knowledge. Self-directed explaining was particularly effective for the individual generating the solution; however, there was only a modest gain for the partner who listened to the explanations. The relative impact of these three mechanisms is compared.

Introduction

Collaboration is a ubiquitous part of life and can be found in scientists' laboratories, the business world, the military, and the classroom. Given its usefulness in the real world, peer collaboration has become an important instructional intervention. The literature evaluating the effectiveness of peer collaboration has generally produced positive results (Dillenbourg, Baker, Blaye, & O'Malley, 1995); however, it is far from being an educational panacea (Barron, 2003). The open question remains, "Why is collaboration effective?" Prior research implicates three potential mechanisms responsible for learning during collaboration: other-directed explaining (Ploetzner, Dillenbourg, Praier, & Traum, 1999; Roscoe, 2003), co-construction (Damon, 1984; Rafal, 1996), and self-directed explaining (Chi, Bassok, Lewis, Reimann, & Glaser, 1989; Chi, DeLeeuw, Chiu, & LaVancher, 1994). The goal of the present study is to investigate the relative contributions of all three mechanisms to individual learning.

The first mechanism, other-directed explaining, occurs when one peer instructs or explains to another partner how to solve a problem. Other-directed explaining may benefit only the speaker, but not the listener because the speaker is the one actively engaged in conveying the to-be-learned material (Chi, Siler, Jeong, Yamauchi, & Hausmann, 2001; Webb, Troper, & Fall, 1995). However, because both partners have opportunities to explain to their partners, it is conceivable that other-directed explaining is a mechanism that accounts for learning during collaboration.

The second hypothesized mechanism for successful learning from collaborative problem solving is co-construction. Co-construction is defined as the joint construction of knowledge. The process of constructing knowledge may proceed in a variety of ways, but the most natural is for peers to either elaborate or critically evaluate their partners' contributions.

Elaborative co-construction is the generation of knowledge by extending the ideas of one's partner (Tao & Gunstone, 1999) and has been shown to be an effective dialog pattern (Hogan, Nastasi, & Pressley, 1999; van Boxtel, van der Linden, & Kanselaar, 2000). Similarly, knowledge might be constructed through the critical discussion of ideas. Critical co-construction occurs when interacting peers critically evaluate each other's ideas. Support for this particular type of interaction comes from the literature on argumentation. Schwartz, Neuman, and Biezuner (2000) found dyads that successfully solved fraction problems were most likely to engage in argumentation.

Co-construction and other-directed explaining are likely candidates to explain the potential successes of learning from collaborative problem solving. However, there is another potentially overlooked mechanism, which is to learn from listening to someone self-explain (i.e., self-directed explaining). Learning from another person's explaining is analogous to learning from a worked-out example; however, in a collaborative problem-solving context, the source of the worked-out example is not a textbook, but a peer. When a dyad is faced with solving a problem, it is natural for one person to begin solving, while the other listens to the ensuing solution attempt (Shirouzu, Miyake, & Masukawa, 2002). The speaker may be talking out loud while solving a problem while her partner listens. This is a form of self-directed explaining. As has been shown in prior research, self-explaining is an effective learning strategy (Chi et al., 1989). What is unclear, however, is if a partner can benefit from listening to self-directed explaining. One goal of the present study is to provide initial evidence for the utility of self-directed explaining (or self-explaining with an audience).

The structure for the remainder of the paper is as follows. First, we will provide a brief description of the study, which

will then be followed by evidence for the three hypothesized mechanisms discussed above: other-directed explaining, co-construction, and self-directed explaining. The final section will compare the relative impact on learning from the three mechanisms.

Method

Participants

Students were recruited via advertisements placed in a university newspaper. The study used a between-subjects design with a total of ten undergraduate pairs (n=20) participating in the experimental group (i.e., Collaboration condition) and a total of ten (n=10) undergraduates in the control group (i.e., Text-only condition). Upon completion of the experiment, participants were paid for their time. To control for prior knowledge, eligible participants were required to have taken only one high school physics course.

Materials

The domain chosen for the present study was kinematics. Some of the topics covered were vector addition and subtraction, average and instantaneous velocity and acceleration, and an emphasis on Newton's second and third laws. The material was taken from the first five chapters of a popular physics textbook (Halliday & Resnick, 1981).

Measures Four mastery tests were developed to assess participants' understanding of each of the first four chapters. Participants were required to solve 80% of the problems correctly before advancing to the next chapter. After the first four chapters were learned to mastery, participants read the fifth chapter on force. The test administered after the participants had read the fifth chapter served as the pretest to the learning intervention.

The pretest consisted of three problems. The three problems were decomposed into a total of nine solution steps. Each solution step was then labeled with a concept from physics. For example, Problem 1 asks the individual to find the acceleration of two boxes in contact. To correctly solve the problem, the two boxes should be conceptualized as a *compound body*. To demonstrate an understanding of the compound body concept, the solver is required to sum the masses. The labeled solution steps will henceforth be called "concepts" (see Appendix for the mapping between problems, concepts, and the groups that were assigned to each problem). There were a total of nine different physics concepts across all three problems.

The text was available to the participants during the mastery tests, the pretest, and during the instructional phase, but it was not available during the posttest. The reason for making the text available during the pretest, but not the posttest, was to provide the most stringent test for learning, in the sense that we did not want our participants' inability to remember details of formulas to hinder their performance.

During the collaboration session, each pair was asked to solve three physics problems. For the present paper, only 18 of the 30 problems were analyzed.[1] Nine groups solved the first problem, which contained 4 different concepts; 5 groups solved the second problem, which contained 3 different concepts; and 4 groups solved the third problem, which was composed of 2 different concepts. Henceforth, there were 59 concepts assessed across the three problems and ten groups.

Finally, a posttest measured the amount of material learned during the instructional phase (administered M=5.0; SD=3.6 days after the collaboration session). The posttest contained three problems, which were isomorphic to the pretest and collaborative problems (i.e., the same nine concepts were tested on the posttest).

Procedure

All of the participants were asked to study each of the first four chapters individually in the way that they found natural. Participants solved the problems on the mastery tests either while they read the text or after they were finished. When the participants were confident in their solutions, they submitted their answers to the experimenter, who then immediately scored their performance. If the student correctly answered 80% or more of the questions, then he or she was permitted to advance to the next chapter. If the criterion was not met, then the student was shown which problems were incorrect and encouraged to read the text and correct the mistakes. This cycle of reading and testing continued for the first four chapters until criterion performance was met. On average, students spent a total of 6.5 hours to reach mastery of the four chapters.

The pretest was administered after the students read chapter five. Once they were finished with the pretest, an instructional phase was scheduled. For the Collaborative condition, the pretest was not scored immediately, so that the participants were not paired on the basis of their pretest scores. Dyads were formed under the constraints that they finished the background material relatively close in time, and they were the same gender.

During collaboration, the dyads solved three force problems. They were encouraged to use their partners as a resource and to work together to understand and solve the problems. The entire text (chapters 1-5) was available to the dyads during the collaboration session. The Text-only group solved the same problems, but did so individually with the text available. After the instructional phase, the posttest was individually administered.

The sessions were recorded (both audio and video) and later transcribed. The transcription was based on the audiotapes of the dialogues, using information from the video for interpretations when necessary.

[1] A subset was used because the performance data for the present study comes from a larger study in which all of the items were relevant.

Analyses and Results

Coding scheme

The first coding step was to segment the transcribed protocols. The segments were taken at the level of problem-solving episodes (i.e., several turns dedicated to a single concept). The boundaries of a problem-solving episode began with a proposed equation, and ended with either the final solution of the equation or the abandonment of a solution path altogether. Across all groups and problems, there were a total of 87 problem-solving episodes.

Episodes were then coded as other-directed explaining (ODE), self-directed explaining (SDE), or co-construction. Other-directed explaining occurred when a more-knowledgeable partner explained a concept to a less-knowledgeable partner. Pretest performance for each participant determined his or her knowledgeability status for each concept. Because each problem was composed of several concepts, the individual's status could change from one problem-solving episode to the next, depending on his or her pretest performance.

When the less-knowledgeable peer explained a concept during a problem-solving episode, either to a more-knowledgeable or equally knowledgeable partner, then the episode was coded as self-directed explaining. Again, pretest performance was used to determine knowledgeability.

Finally, when both partners were being generative in the conversation by adding significant and relevant contributions, the episode was coded as co-constructed. Co-constructed episodes were further decomposed into elaborative and critical co-construction, which will be defined shortly.

Once the problem-solving episodes were coded in terms of the conversational elements, the content (i.e., the physics concepts) was also coded. The content was then linked to the episode analysis, which allowed us to track the impact of dialog on posttest performance. For example, if a more-knowledgeable peer explains how to solve the compound body concept to her less-knowledgeable partner, then that episode was coded as "other-directed explaining *about* the compound body." To measure the learning effect of other-directed explaining on the listener, we then looked at her posttest performance on the compound body concept. Because some problems involved multiple solution attempts, only the final problem-solving episode was linked to the posttest concepts (N=59).

Collaborative problem solving resulted in learning gains

Did the individuals learn from the collaborative problem-solving session? To answer this question, we calculated gain scores for each individual, which controlled for pretest knowledge: $g = (post - pre)/(100\% - pre)$ (Crouch & Mazur, 2001). Thus, the gain scores reflect the increase (or decrease) in learning per concept, per person. Overall, there was an average net gain of 26% (while controlling for pretest knowledge), which was significantly different from zero (p=0.002).

Evidence that individuals learned from collaborative problem solving can also be found in the analysis of the control (Text-only) group. The gain from pre- to posttest for the Collaboration group was significantly greater than zero, while the gain for the Text-only group was not ($F(1,9)=0.756$, p=0.41) even through the two groups did not differ at pretest.[2] This suggests that the learning gains are due to the activities the dyads engaged in during collaborative problem solving, which is presented in the next three sections.

Other-directed explaining during collaborative problem solving

As stated in the Coding Scheme section, both the content and episode were coded together to give us a sense of the impact of other-directed explaining on learning. Table 1 contains an excerpt of one student explaining her reasoning to another. The example begins with Beth asking Abby[3] to elaborate on a previous line of reasoning. There are two features to note in this example. First, Abby's style is definitely instructional. Her intent is to explain, as clearly as she can, how to solve the problem (see Appendix problem 1.ii.). Second, Beth does not contribute much to the conversation, but merely indicates that she is attending to Abby's explanation with her use of continuers.

Table 1: Example of other-directed explaining

Beth:	So like 14 newtons would be the net force acting on B?
Abby:	No, this-the overall force is ten,
Beth:	Mm-hmm.
Abby:	but if you split it, if-if-both of the blocks, as we know, are accelerating at two meters per second. If they're in contact then they have to be accelerating at the same, rate.
Beth:	Mm-hmm.
Abby	And, because, by Newton's second law F-F [pause] equals mass times acceleration. And we know the acceleration,
Beth:	Mm-hmm.
Abby:	of each block and we know the mass of each block. So you can calculate the force-the force of each block. Or the force acting on each block.

Of the 59 final problem-solving episodes, there were a total of 11 other-directed explaining episodes (11/59=19%). On posttest, the listener (i.e., the less-knowledgeable peer) correctly used 5 concepts that they had previously used incorrectly on pretest. The data are summarized in the left segment of Figure 1. The black bars represent the

[2] The data for the Text-only and Collaboration comparisons is taken from the full pretest and posttest (see footnote 1).

[3] All names are pseudonyms.

percentage of the corpus dedicated to a particular dialog type, while the grey bars represent the gain scores of the listeners (controlling for pretest knowledge). While a gain of 5 concepts is encouraging, especially given that the text was unavailable during the posttest, the probability of learning from listening to other-directed explaining is low (5/11=45%). This is not entirely surprising, given the finding that receiving elaborated help does not always lead to learning gains (Webb, 1989).

It is also informative to measure the performance of the more-knowledgeable speaker. Figure 2 suggests that the speaker (ODE), who knew the concepts on pretest, maintained 82% of her knowledge by correctly demonstrating her knowledge of the concepts on the posttest (see white bars in Fig. 2).

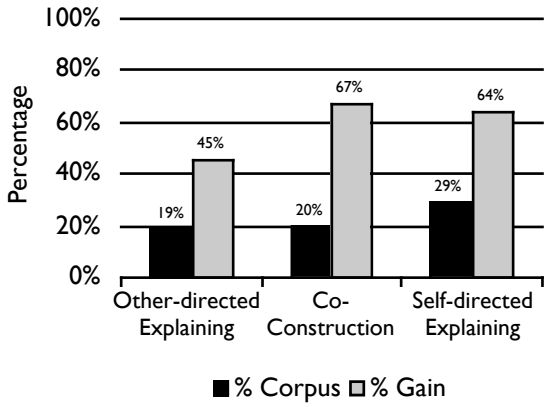

Figure 1: Gain scores associated with the absolute frequency for each dialog pattern.

Partners co-construct answers during collaboration

As stated in the introduction, co-construction is a hypothesized mechanism that has been proposed to account for learning from collaborative problem solving. A problem-solving episode was coded as co-construction when both partners were actively constructing new knowledge. The co-constructed solutions were further categorized as elaborative and critical co-construction. Elaborative co-construction was defined as one partner adding a significant contribution to the discourse that develops another person's idea. Here is an example of elaborative co-construction (Problem 2.ii.):

Table 3: Example of elaborative co-construction

Ron: It's the weight of the crate, which is ten, times gravity right? [R writes 10kg(9.8m/s^2)="] So it's, 98N, plus the five [R writes "98N+5"]-oh no, cause we don't know what it is yet, really. Well I mean, it's-
Ben: Mg-Mg is the force exerted by the block, on the Earth.
Ron: Mg, that's,
Ben: Weight.
Ron: Mass times gravity, right?
Ben: Mm-hmm.

Episodes were coded as critical co-construction when they contained conflicts between the two partners (Druyan, 2001). The difference between partners' solutions led to a discussion where each attempted to convince the other how to solve the problem.

The following protocol excerpt is taken from Jill and Sara solving the compound body problem (see Appendix, Problem 1.i.). The question is difficult because it requires the solvers to represent the blocks as a single body; neither student demonstrated an understanding of this on the pretest. Sara believes the question implies that the acceleration should be found separately for each block, but Jill makes a case for the compound body. The conflict is between treating the blocks separately or jointly. Here is their argument:

Table 2: Example of critical co-construction

Sara: Yeah. It's just-it didn't say? I thought it said each of them. [Reads: **Find the acceleration of the blocks.**] To me that says find the acceleration of each block. You know like, since they're two different kilograms.
Jill: It's going to be, the same though.
Jill: Because like, if we, go like this [pushes a book and pencil], and I do this, they're both moving at the same acceleration.
Sara: [Talks to Experimenter: 4 turns]
Sara: Because if you-well you can get a different acceleration by breaking it up though.
Jill: Oh wait. You know what? The acceleration will be the same for both of them. Acceleration is the same for both of them. Force acting on block B, is different from force acting on block A.
Sara: Ok. Because their mass, is different.
Jill: Yeah. Because-yeah.

The frequency of co-constructive episodes is summarized in Figure 1 (see the middle bars). Two results are of particular interest. First, the amount of co-construction is similar to the frequency of the other-directed explaining episodes. More importantly, however, is the proportion of co-construction episodes that led to learning. Of the 12 episodes where the solution was jointly constructed, 8 of them led to the correct application on posttest (8/12=67%). Although co-construction was a relatively rare conversational pattern (12/59=20%), the reported frequency replicates prior estimates from a different domain (McGregor & Chi, 2002). Furthermore, the knowledge produced during collaboration was useful to both the individuals, which suggests the viability of group-to-individual transfer. That co-construction lead to a high proportion of learned concepts further supports the constructivist perspective that being active, as opposed to merely listening to a didactic explanation, is important for learning (Chi et al., 2001; Webb et al., 1995).

Co-construction was further decomposed into elaborative and critical co-constructive episodes. Of the 12 instances of co-construction, 5 were elaborative (5/12=42%) and 7 were

critical (7/12=58%). Elaborative led to a gain of 3 concepts (3/5=60%), whereas critical co-construction led to the correct application of 5 concepts on posttest (5/7=71%). Because of the small numbers, it is difficult to tell if elaborative or critical co-construction was more effective in subsequent learning. Follow-up research needs to be done to gain a better understanding of what drives learning from co-construction.

Learning occurs from self-directed explaining for speakers and listeners

Prior research has shown that good students spontaneously self-explain while learning from worked-out examples (Chi et al., 1989). Subsequent research has shown that prompting students to self-explain can lead to learning gains, above and beyond those who spontaneously self-explain (Chi et al., 1994).

Figure 1 suggests that self-directed explaining (SDE) also operates in a collaborative problem-solving context. The frequency of self-directed explaining is high relative to the other conversational patterns (i.e., other-directed explaining and co-construction). We observed 17 episodes of self-directed explaining, which accounts for 29% of the corpus. In terms of the average gain, self-directed explaining episodes lead to a 64% increase (see Fig. 1).

The effects of self-directed explaining can be further differentiated into the gain observed by the speaker and listener. In the present context, the listener is also trying to learn the material; therefore, she has a stake in the problem-solving process. Instead of being a passive recipient, the collaborative partner listens to and could potentially monitor the ensuing self-explanation.

As expected, the gain was proportionally high for the speaker (71%; see Fig. 2). While self-explaining is effective for the explainer, the question becomes, does listening to a self-explanation benefit the listener? The answer to this question seems to be mixed. To a certain extent, listening to another person self-explain can produce learning. Specifically, there was a net gain of 5 concepts for the listeners (5/17=29%; see Fig. 2). Therefore, it appears that observing reasoning in action (i.e., being the listener) is about as effective as listening to other-directed explaining (ODE). Further coding is needed to gain a better understanding of what the listener is doing while listening to a partner self-explain. One might hypothesize that the listeners benefit only when engaged in a constructive activity, which has received some empirical support (Webb et al., 1995).

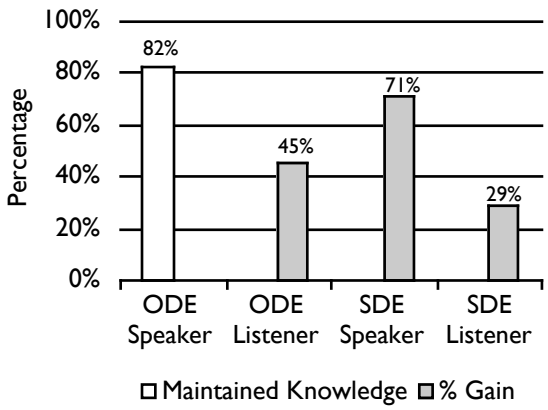

Figure 2: Gain scores as a function of dialog pattern and dominant speaker or listener.

Discussion

The primary goal of the present study was to demonstrate that several different mechanisms contribute to learning from collaborative problem solving. These three mechanisms were other-directed explaining, co-construction, and self-directed explaining. All of these mechanisms were associated with learning, but did so to different degrees. In terms of the overall proportion, self-directed explaining produced the strongest learning gains, with the caveat that the learning gains were greatest for the speakers. Other-directed explaining also lead to learning gains for the listener, but only to a limited extent. Several explanations given by the speaker during other-directed explaining did not translate into increased problem solving behaviors on posttest. Finally, co-construction, although relatively infrequent, led to increased problem-solving performance. Two-thirds of the co-constructed concepts were correctly used on the posttest.

A secondary goal of the present study was to demonstrate that multiple mechanisms operate within dyads. That is, one group may engage in other-directed explaining on a problem that one person understands (whereas the other does not). Then on the next problem, the same dyad may have to co-construct the solution because each individual has a different solution, and they must resolve their differences. Most research on collaborative problem solving measures the influence of one mechanism on learning in isolation of other potential explanations. The results from this study suggest that the pattern of communication is largely shaped by the background knowledge of the participants.

Finally, we attempted to show that self-explaining can take place in a collaborative context. While effective for the speaker, there was marginal utility for the listener. The effect was strongest when the speaker was engaging a partner with low pretest knowledge, but this effect needs to be substantiated by further research. The results from this study agree well with the idea that being constructive while solving problems leads to better learning and understanding.

The Adaptability of Language Specific Verb Lexicalization Biases

Abstract

Languages vary in how they encode motion events. For example, English motion verbs often encode the manner of the motion while Spanish motion verbs encode the path. Efficient verb learning has been argued to involve the acquisition of language specific lexicalization biases. When given a novel verb paired with a single motion event, English speakers interpret it as a manner verb, Spanish speakers as a path verb. The present study examines the nature and plasticity of this lexicalization bias. Do lexicalization biases result in a permanent alteration of the semantic interface? Or are these biases continually shaped through our experiences with word learning? English-speaking adults were taught 12 motion verbs. The composition of the set of verbs was varied from 100% manner to 100% path with 3 levels in between. Lexicalization biases were monitored by testing verb extension after the first ambiguous exemplar of each verb. We replicate the finding that English speakers have an initial manner bias. However, we find that this bias changes over time in response to the input: Participants who learned path verbs developed a path lexicalization bias. Experiment 2 replicates this result with a different syntactic frame.

Introduction

Children's early lexicons are curiously lopsided. Across a variety of linguistic environments, nouns dominate early vocabularies, while verbs are initially scarce (for a review see Gentner & Boroditsky, 2001). There are a number of explanations for initial noun dominance, which are by no means mutually exclusive. Verbs differ from nouns in the frequency with which they occur in isolation or in salient positions within the utterance and they also differ in the types of concepts that they encode and the types of entities that they pick out in the world. All of these factors have been argued to play a role in early noun dominance (Gleitman, 1990; Tardif, Shatz & Naigles, 1997; Caselli, Casadio & Bates, 1999; Snedeker & Gleitman, 2004).

Gentner and her colleagues have argued that nouns are prominent in the early lexicon because they typically denote physical objects which can be individuated (and presumably conceptualized) on the basis of the child's perceptual experience of the world (1982; Gentner & Boroditsky, 2001). Verbs, they argue are more difficult for novice language learners because perception does not package events into stable individuals. Instead languages decide how to conflate the conceptual components of events into lexical items. This results in greater cross-linguistic differences in the meanings of verbs than in the meanings of nouns. To learn verbs, they argue, children must first discover how their language chooses to package events. To the extent that lexicalization patterns are systematic within a language, children should be able to draw generalizations from known instances, developing lexicalization biases which allow the pace of verb learning to accelerate.

The parade case for systematic cross-linguistic variation in lexicalization is the conflation patterns that occur in verbs of motion (Talmy, 1975). A motion event consists of a thing that is moving (the figure), the location it is moving relative to (the ground), the manner in which it is moving and the path along which it moves. All languages have ways of expressing these elements, but how they do so varies. 'Manner' languages, such as English and Mandarin, typically pack manner of motion into the verb, leaving path for an optional prepositional phrase ("He ran into the store"). In contrast, 'path' languages, such as Spanish and Greek and typically encode path in the verb and fob off manner on an optional gerund ("Él entró en la tienda corriendo"). In English, path verbs are relatively scarce (Gutiérrez, 2001; Talmy 1975). This cross-linguistic difference in verb use shows up in distributional analyses and production studies with both children and adults (Aske, 1989; Jackendoff, 1990; Berman & Slobin, 1994).

This systematic difference in lexicalization patterns also results in differences in how the speakers of manner and path languages learn new motion verbs, consistent with the predictions of Gentner's relational relativity hypothesis (1982). When confronted with a novel verb used to describe a single motion event, English speaking adults and seven year olds will extend the word to other events with the same manner of motion but not to events that have the same path (Naigles & Terrazas, 1998; Hohenstein & Naigles, 2000). In contrast Spanish speaking adults and seven-year olds extend the verb to events that have the same path but not the same manner. Thus each group has developed a lexicalization bias that is consistent with the primary verb lexicalization pattern in their language.

While verb lexicalization biases clearly exist, we know little about how they might develop or how they are mentally represented. One intriguing hypothesis comes from the literature on the development of the shape bias in noun learning. Smith and colleagues have argued that the shape bias is a generalization based on the words that the child has previously acquired (Smith, Jones, Landau, Gershkoff-Stowe & Samuelson, 2002). Children, they

claim, are initially unbiased learners who acquire their first nouns by patiently waiting for the situational concomitants of word use to tease apart the many alternate hypotheses about how a word might be extended. In this way, they manage to acquire a sizeable number of nouns, many of which are well-organized by shape. They argue that the shape bias is simply a second-order generalization of these known words. This account is supported by two lines of evidence. First, in the studies of Smith and her colleagues children fail to show a systematic shape bias until they have acquired a substantial number of nouns (but see Waxman, 1999). Second, toddlers who are trained on shape-based categories develop a shape bias and show accelerated acquisition of nouns, while those who are trained on substance-based categories or given an unsystematic training set do not.

While Gentner makes no specific proposal for how verb lexicalization biases could be acquired, the mechanism laid out by Smith seems consistent with the relational relativity hypothesis. Children learn a number of verbs that follow a language specific lexicalization pattern and then form the expectation that verbs in the same semantic field will be extended in a parallel fashion. But what does this expectation consist of? There are at least three possible explanations for how cross-linguistic differences in word learning biases could be instantiated.

First, children's word learning experiences could permanently alter their conceptual systems resulting in a change in the repertoire of possible concepts or in their relative salience or stability. This is an unlikely explanation for the manner-path lexicalization bias. Speakers of the two languages show similar behavior on nonlinguistic memory and categorization tasks, suggesting that verb conflation patterns do not affect the accessibility of manner or path concepts (Papafragou, Massey & Gleitman, 2002). Furthermore, since both languages have ways of expressing both manner and path, the linguistic evidence itself radically limits the degree to which conceptual alteration can be invoked. Thus we have to look to changes in the semantic interface which maps between linguistic forms and concepts.[1]

Second, lexicalization biases could be permanent alterations in the semantic interface. The mappings between linguistic forms and concepts could be altered so that certain conceptual dimensions are unavailable as candidates for verb meanings, although they might be used in nonlinguistic tasks or even as meanings for other terms. This mechanism would be the semantic parallel of Werker's functional reorganization hypothesis for phonological development (1995). Finally, lexicalization biases may be more plastic mappings between linguistic forms and concepts which can modified as the child gains access to new information sources. Critically, if lexicalization biases are generalizations on the basis of known words, then they may be dynamically updated as children learn a larger and more varied set of verbs. To date there has been little work on the plasticity of the semantic interface between words and concepts. While several studies have examined the effects of age of acquisition on semantic processing of a second language, the results vary with the measures and contrasts that are studied (compare e.g., Weber-Fox and Neville, 1996 with Munnich, 2002). To the best of our knowledge no one has looked at the plasticity of lexicalization biases. Experiment 1 explores the possibility that manner lexicalization bias for motion verbs continues to be malleable into adulthood and is shaped by the set of verbs that a person learns. Experiment 2 replicates this finding when the verb is presented in a different syntactic context.

Experiment 1

Each participant learned twelve new motion verbs. For each novel verb, participants (1) saw a single ambiguous scene with a salient path and manner of motion, (2) were tested to determine their initial interpretation of the verb, (3) saw five additional instances of the new verb which disambiguated its meaning (e.g. five scenes with same manner but a novel path), and finally, (4) were tested again to ensure that they had learned the novel verb.

Critically, the proportion of path and manner verbs was varied across participants. Some participants learned only manner verbs, some learned only path verbs, and others received different proportions of both types. We predicted that our adult participants would have little difficulty learning either the manner or the path verbs. The critical measure was the participants' responses to the initial test trials, which followed the first ambiguous scene. Because a single verb-scene pair is consistent with either a manner or path interpretation, responses to this test sequence reveal the participants' verb lexicalization bias. Since our participants are English speakers, we expect that they will begin with an initial bias to interpret the novel verbs as encoding manner of motion. However, if these estimates of prior probability are updated in response to the verbs that the participant has learned, then responses on the initial test trials should change in response to novel verbs. Thus we predict that over the course of the experiment participants who learn path verbs will develop a path bias, while those who learn manner verbs will retain the manner bias. [2]

Methods

Participants 56 adult native English speakers participated in this study. Since our goal was to determine how previously learned verbs influence the interpretation of future verbs, we eliminated all participants who failed to

[1] We follow Jackendoff's (2002) suggestion that language specific semantics are most parsimoniously described as an interface between linguistic forms and conceptual representations, rather than as a separate level of representation, but nothing in our argument rests upon this distinction.

[2] Similar issues have been explored in artificial category learning studies. Critically, Kersten, Goldstone & Schaffert (1998) found that adults who learned manner event categories were more likely to focus on the manner feature of an ambiguous category. They used simple animated events with bug-like agents and no sentential context. These stimuli did not appear to engage participants' prior lexicalization biases: English speakers showed a strong initial path bias. Unlike the present work, the study did not examine generalization after a single ambiguous exemplar.

learn 5 or more of the verbs after viewing the disambiguating scenes. Sixteen participants were excluded for this reason.

Stimuli Participants saw short video clips of motion events. Each event depicted an actor moving in a salient manner and in a salient path with respect to some reference object (e.g., a woman walking tip-toe behind a large sign). Twelve manner and twelve path concepts were selected as target verb meanings. Some concepts corresponded to English verbs, some to English prepositions, and some had no monomorphemic English equivalent. The path verb meanings were: *around, between, down, up, in front of, along, in, diagonal to, over, across,* and *behind*. The manner verb meanings were: *crab-walk, crawl, twirl, flap-walk, hop on 1 foot, hop on 2 feet, march, run, skip, stoop-walk, tiptoe,* and *walk*.

Participants were presented with a block of questions and videos for each of 12 novel nonce verbs. Each block was identical in layout and was made up of 4 phases: an initial ambiguous scene, an initial bias test, training and a final test phase. An example test block for a manner verb is shown in Table 1 and an example for a path verb is shown in Table 2.

Table 1: Sample block for a novel manner verb.

Target Concept: Crab-Walk	Manner	Path
Ambiguous Scene	Crab-walk	Out
Initial Test: Manner	Crab-walk	Behind
Initial Test: Path	Skip	Out
Training One	Crab-walk	Front
Training Two	Crab-walk	In
Training Three	Crab-walk	Between
Training Four	Crab-walk	Across
Training Five	Crab-walk	Diagonal to
Final Test: Path	March	Out
Final Test: Manner	Crab-Walk	Between

Table 2: Sample block for novel path verb.

Target Concept: Out	Manner	Path
Ambiguous Scene	Crab-walk	Out
Initial Test: Manner	Crab-walk	Behind
Initial Test: Path	Skip	Out
Training One	Hop 2 Feet	Out
Training Two	Walk	Out
Training Three	Run	Out
Training Four	Stoop-walk	Out
Training Five	Dance	Out
Final Test: Path	March	Out
Final Test: Manner	Crab-Walk	Between

In the ambiguous scene, the participant saw a written sentence containing a new nonce verb (e.g. *"She is going to torg out the door."*) and a video which illustrates the sentence (e.g., a woman crab walking out of the door). The initial test consists of two clips which are presented sequentially. The participant is asked if clip is an instance of the new verb ("Is this torging?"). One test clip matches the manner of the ambiguous event but not the path; the other matches the path but not the manner. During the training phase, participants are presented with 5 video clips which disambiguate the meaning of the word. If the verb is being taught as a path verb, then all 5 clips will show the same path as the ambiguous training clip but vary in their manner. If the word is being taught as a manner verb, the reverse will be true. The final test parallels the initial test; one video matches the path of the ambiguous clip, the other matches it in manner. This test allows us to determine if the participant has succeeded in learning the verb.

Each manner verb was arbitrarily paired with a path verb. The paired verbs shared the same initial scene and the same test scenes (see Tables 1 & 2). Pairing the items in this way allowed us to examine how participants with different verb learning experiences responded to identical stimuli. The disambiguating videos were different for each member of a pair. Subjects were assigned to one of five conditions which differed in the proportion of the novel verbs that encoded path (0, .25, .50, .75 or 1). The 12 verb pairs were randomly ordered and half of the participants in each condition were tested with the blocks in reverse order.

Procedure Stimuli were presented on a computer which using custom software. The participants were told that they would be watching videos that would teach them new words and answering the questions about these words.

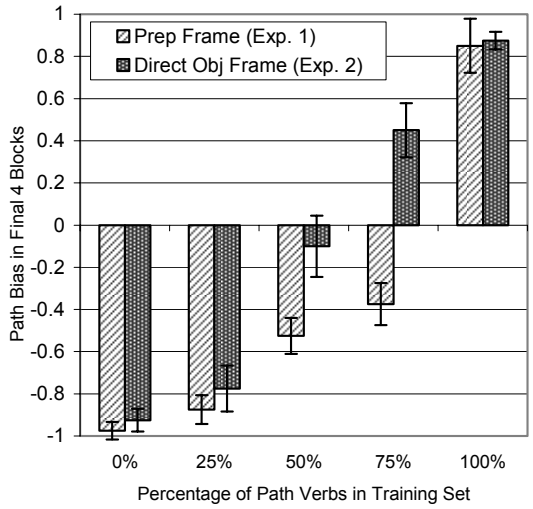

Figure 1: Path Bias on Final Blocks

Results

Responses to the final test questions were used to exclude participants who failed to learn the verbs. Our analyses focused entirely on participants responses in the initial test. To explore how bias changed over time we examined responses to the first four verb blocks and the last four verb blocks. The participants' responses were converted to path bias scores by taking the proportion of blocks where the subject extended the word to the path match and subtracting the proportion of blocks where they extended the word to

the manner match. This number would equal -1 for a perfect manner bias and 1 for a perfect path bias.

The ANOVA of the first four blocks revealed that these English speaking subjects entered the study with a strong manner bias (M = -.58, F (1,40) = 145.69, p < .001). 76% of the participants responded yes to a manner video while only 5% responded yes to a path video. However, there were also differences between the training condition demonstrating that the verbs in the training set were already beginning to shape participants interpretations of the initial ambiguous scenes (F(4,40) = 12.97, p < .001). This effect was driven by participants in the 100% Path Verbs Condition who had no systematic bias in these early blocks (M = .08).

In the final four blocks of the experiment, the initial bias trials are clearly shaped by the set of verbs that the participant has learned (see Figure 1, F(4,40) = 45.14, p < .001). Participants in the 100% Path Condition have developed a strong, consistent path bias in their interpretation of new verbs (M = .85). Those in the 0% and 25% Path Conditions show an equally clear manner bias (M = .98, M = .88). In the 50% and 75% Path Conditions participants flout the input, continuing to show a mild preference to interpret the new word as a manner verb.

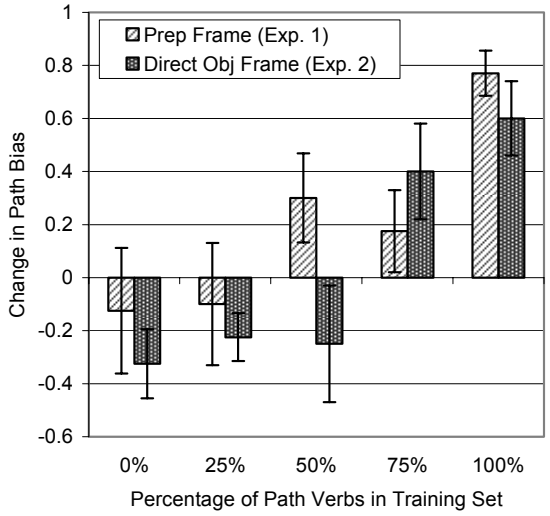

Figure 2: Change in Path Bias between the First 4 and Last 4 blocks.

To further explore how lexicalization biases changed over the course of the experiment, we directly compared the results of the first and final blocks. In Figure 2 this is graphed as the change in path bias. There was a substantial increase in path bias in the final trials (F(1,40) = 7.45, p < .009) and a reliable interaction between the time in the experiment and the Training Condition (F(4,40) = 4.75, p < .003). Participants in the 100%, 75% and 50% Conditions showed an increase in path bias, while participants in the 25% and 0% retained or strengthened their manner bias.

Experiment 2

In Experiment 1, the nonce verbs appeared with prepositional phrase arguments. In English, this syntactic frame is used more frequently with manner verbs, although it can be used colloquially with path verbs as well (e.g. *"She ran around the tree."* or *"She circled around the tree.")*. In English path verbs are often used in simple transitive frames (*"She circled the tree."*) and this usage is typically considered more proper. Naigles and Terrazas (1998) found that both English and Spanish speakers were more likely to interpret novel verbs as encoding manner when syntactic frames with semantically rich prepositions were used. If the participants assume that each component of the motion event is encoded in only one word of the sentence, they may be reluctant to conflate path in the verb when it is already marked in the preposition. In Experiment 2 we used simple transitive sentences to explore whether the syntactic context influenced participants' initial lexicalization biases or the changes in these biases in response to newly learned words.

Methods

Participants 52 English-speaking adults participated in this study. Responses from 2 participants were excluded because they failed to learn 5 or more target verbs.

Stimuli, Procedure and Coding Participants were tested on the same verbs sets as before (100%, 75%, 50%, 25% or 0% Path Verbs). The procedure was identical to Experiment 1 except that verbs were introduced with simple transitive frames. Thus *"He torged down the stairs"* became "*He torged the stairs."*

Results

When the novel words were presented in transitive frames, subjects showed only a weak bias in the first four verb blocks (M = -.14, F(4,40) = 3.56, p = .067) which may reflect the early effect of Training Condition on path bias (F(4,40) = 6.56, p < .001). Participants in the 0% Path Condition show a manner bias (M = -.60) while those in the 100% Condition have a path bias (M = .28). By the final four verb blocks, participants' initial interpretations of the new nonce verbs are essentially categorical and closely match the set of words that they have learned (F(4,40) = 60.17, p < .001). There is a reliable shift in bias between the first and final blocks, which interacts with Training Condition (F(4,40) = 21.56, p < .000). Participants who learned all path verbs showed an increase in path bias (M = .60) while participants who learned all manner verbs showed an increase in manner bias (M = -.33). A direct comparison of Experiments 1 and 2 demonstrates that syntactic frame influenced participants' performance on both the final and first 4 blocks. These differences are limited to the 50% and 75% Path conditions, conditions where subjects are given weak evidence for a lexicalization pattern which differs from the dominant pattern in English.

General Discussion

These experiments 1) replicate Naigles & Terrazas' findings that adult speakers of English have a bias to assume that novel verbs encode the manner of motion rather than the path; 2) demonstrate that this lexicalization bias remains

plastic into adulthood; and 3) demonstrate that this lexicalization bias can be influenced by the words that a person learns. English speaking adults who were taught new motion verbs developed lexicalization biases that matched the verbs in their training set. This pattern was observed regardless of whether the ground nominal was presented as the object of a preposition (consistent with a manner verb) or as the direct object of the verb (consistent with a path verb). In the remainder of the discussion we re-examine Gentner's relational relativity hypothesis in the light of these findings and discuss the development of verb lexicalization biases.

Reexamining Relational Relativity

Gentner's relational relativity hypothesis proposes that the acquisition of verbs is delayed because children must discover how their language packages and categorizes events (1982). Naigles and colleagues have extended this argument by suggesting that efficient verb learning requires the acquisition of language-specific semantic patterns, which we have called lexicalization biases (Naigles & Terrazas, 1998). The current study demonstrates that learners retain a remarkable degree of plasticity in lexicalization biases. They can not only learn verbs which violate the lexicalization pattern of their language; they can actually change their lexicalization biases to reflect the patterns in newly acquired words. These results suggest that verb lexicalization biases are not the result of permanent alterations in conceptual structure or unalterable changes in the semantic interface. Instead these biases appear to be plastic generalizations based on the words the learner has acquired. In essence a lexicalization bias results from a change in the prior probability of a class of hypotheses based on the prior success of hypotheses from that class.

The flexibility of these biases raises questions about the role that they play in potentiating early verb learning. If stable lexicalization patterns are required to repackage relational components into the individuated events, then why do adults have little difficulty in rapidly and spontaneously recombining these components? [3] We would argue that this ability is essential for learning the range of verbs that exist within any one language. While the variability of cross-linguistic encoding of events has received much attention, there is considerable variation in verbs that can be used to describe a single event within a language (Gleitman, 1990). For example, we can refer to an event in which a girl kicks a ball to her mother as *giving, passing, kicking, rolling, receiving, moving, crossing* or *contacting* depending on the components of meaning that we wish to include in the verb or the perspective that we are taking on the scene. In light of such variability, rigid lexicalization biases are likely to be counterproductive. Within language variation in lexicalization also seriously limits the role that these biases can play in constraining word learning, and thus limits the explanatory potential of the relational relativity hypothesis.

If language-specific semantic mappings cannot eliminate the ambiguity inherent in events, then how do children ever become rapid and efficient verb learners? We believe that two factors are at play. First, children may improve in their ability to make use of cross-situational observation. Much of the work in early word learning has focused on what children are able to learn from a single word-scene pair. In the case of nouns it may be possible to make a meaningful conjecture about the meaning of a word on the basis of a single referent. Many of children's early nouns label artifacts and natural kinds. Concepts of these kinds are organized in taxonomic hierarchies, which have multiple levels (animal, mammal, dog, poodle) and categories which are mutually exclusive at a given level (Markman, 1989). This conceptual structure helps bridge the gap between reference and meaning. Once the observer has correctly picked out the referent of an artifact or natural-kind term, then its meaning can be limited to concepts on the path from the individual exemplar up to the top of the hierarchical tree. If there is a conceptually or perceptually privileged basic level, then a single referent might provide enough information to map the word to the correct node of that tree (Rosch et al., 1976; Markman, 1989).

But in the case of verbs, cross-situational observation may be essential. There is little evidence that the concepts encoded in verbs form complex taxonomic hierarchies. Instead most observers have argued that states and events are grouped into semantic fields which are organized as a cross-cutting lattice of concepts rather than as mutually exclusive categories (Talmy, 1985; Behrend, 1995). Identifying a single referent event merely identifies a point in this multi-dimensional conceptual space but it does not tell the observer which dimension(s) of the event are encoded in the verb. Multiple exemplars, however, can be used to rule out the relevance of some dimensions and provide convergent evidence for the importance of others.

Second, children's verb learning also benefits from their increasingly sophisticated representations of the utterances in which new verbs appear. Initially children must learn the meanings of new words by observing the nonlinguistic contexts in which those words are used. This initial information source provides ample support for noun learning but provides inadequate information about meanings of many verbs (see e.g., Snedeker & Gleitman, 2004). More sophisticated learners can use the known words which co-occur with novel verbs to focus their attention on the relevant events. As the child gains knowledge about the syntax of her language, the structural environments in which the verb occurs can also provide increasingly fine-grained information about its meaning

[3] Perhaps that the manner-path distinction is the wrong place to search for stable lexicalization biases, since both manner and path languages have verbs of each type (Ashe, 1989). We challenge the reader to come up with a better example of a systematic lexicalization pattern which applies to a large number of verbs. The explanatory potential of the relational relativity hypothesis depends on the prevalence of this predictable variation.

Examining the Early Development of Verb Lexicalization Biases

Clearly the present experiments cannot rule out the possibility that young language learners have relatively inflexible language-specific lexicalization biases which serve as sharp constraints on children's hypotheses about verb meaning. Furthermore, even plastic and probabilistic biases could provide useful guidance for verb learning. Understanding the role of lexicalization biases in early verb learning clearly requires studying how these biases develop in young children. The limited information that we have about the development of the manner-path bias suggests that this bias may emerge quite late: Hohenstein and Naigles (2000) have found the 3 year old English speakers and Spanish speakers show no differences in their extension of novel motion verbs (both populations prefer to extend the words to events with the same manner of motion). The obvious explanation is that children this age simply lack the ability to derive lexicalization biases from the words they learn. But this seems unlikely in light of Smith and colleagues' finding (2002) that children under two can develop a shape-bias after learning just a handful of exemplars. The alternative explanation is that the verbs that 3-year-olds know simply don't support this generalization. In elicited production tasks English speaking adults show a clear preference for manner, however, speakers of path languages like Greek and Spanish often produce equal numbers of manner and path verbs when describing motion events (Papafragou et al., 2002; Naigles et al., 1998), suggesting that young Spanish speakers may have little evidence for a path lexicalization bias. To determine whether young children can form verb lexicalization biases in response to clear category structure, we are currently testing three- and five-year old children in a modified version of Experiment 1. Our preliminary findings (N = 9) suggest that five-year-olds will rapidly form a bias for the dimension which has been relevant on previous trials. Children who are given six path verbs select path as the relevant dimension on 67% of all trials, while those who are given manner verbs do so only 25% of the time ($p < .05$).

Acknowledgments

This work grew out of conversations with Sourabh Niyogi and Bob Berwick and we are grateful for their ideas, inspiration and assistance. We also thank Melanie Goetz, Liz Sepulveda, Natan Cliffer, Rob Speer, Mahvash Malik and Sylvia Yuan, for their assistance with filming and testing. This project was funded by a grant from the NSF (IIS-0218852) to the second author and Bob Berwick.

Scopal ambiguity preferences in German negated clauses

Abstract

When following a negated matrix clause, adverbial clauses (ACs) like "because it was paid very well" in (1) can be interpreted as residing within the scope of the negation (1b), or outside of it (1).

(1) a. Peter did not quit his job because it was paid very well
b. Peter did not quit his job because it was paid very badly.

Depending on the scope of the negative, the interpretation differs dramatically: Whereas Peter did in fact not quit his job in (1a), he did so in (1b), but for yet unknown reasons. It has been shown for English (see Frazier & Clifton, 1996), that there is a preference to interpret the adverbial clause outside of the scope of the negation so that (1b) appears fairly odd. This observation challenges recency based processing principles, such as late closure, since the high attachment (to IP) appears to be preferred over low attachment (to VP) (see figure 1). In this paper, we will present evidence on German equivalents of (1a,b), varying the order of the negative and the verb (Experiment I), the context in which the ambiguity appears (Experiment II), and the position of the adverbial in relation to the clause boundary where the negation of the main verb is restricted or even retracted (Experiment III). None of these variations reduced the preference substantially. Only an explicit alternative cause reduced it but even this variation did not eliminate the difficulty of the inside scope interpretation. We will argue that incremental interpretation as well as immediate attribution of prosodic structure determine the interpretation of the adverbial clause.

Introduction

Whereas the scope of quantifiers has been the subject of substantial research (e.g., Ioup, 1975, Johnson-Laird, 1969; Kurtzman & MacDonald, 1996; for an extensive discussion see Frazier, 1999) this is much less the case for the scope of negations. In this paper, we will look at sentences like (1) where an adverbial clause can be interpreted as either being within the scope of the negation in the matrix clause or outside of it. Structurally, the adverbial clause has to be attached to the VP if it is interpreted as residing within the scope of the negation whereas it has to be attached to IP if it is interpreted outside the scope of the negation.

Locality based principles of syntactic attachment as they are assumed in most theories of human sentence processing (e.g., Frazier, 1978; Gibson, 1991) predict a preference to attach the adverbial clause to VP, and thus a preference to interpret it inside of the scope of the negation.

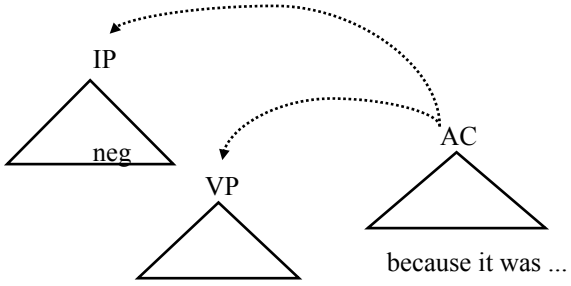

Figure 1

However, Frazier and Clifton (1996) found a clear preference for an interpretation of the AC outside of the negation scope. In their experiments, this preference does not show up in early stages of processing, but only in later off-line measures. In the framework of Construal Theory, the authors argue that only argument like or primary relations are attached to the phrase marker of the sentence immediately. Only primary relations are subject to syntactic attachment principles like Minimal Attachment or Recency. As a non-primary relation, the adverbial clause is only construed as part of the maximal projection of the preceding thematic domain (i.e. the IP). All kinds of factors (syntactic, semantic, pragmatic, or prosodic) jointly determine the final interpretation of the clause.

In this paper, we do not want to dispute the immediacy of the attachment or the interpretation of adverbial clauses. We are much more interested in the question of which factors are driving this final preference, and how general or universal it is. This means testing this preference in different constructions, in different environments, and across languages. Therefore, we have been looking at German versions of Frazier and Clifton's materials. In four experiments, we tried to find a way to override the interpretational preference, by putting the negation in focus position (Exp I), varying contextually given presuppositions (Exp II), and restricting the negation (Exp III). Since our main interest does not lie in the question of when these factors come into play, but only whether they do have an effect at all, in all of our experiments, we applied an off-line acceptability judgment task.

Experiment I

In Experiment I, we wanted to test whether the preference for high attachment of the adverbial clause which has

already been established for English can also be found in German. Additionally, we varied the position of the negation "nicht" (not). Since the clause final position in German is prosodically more dominant than clause internal positions, we assumed that an interpretation of the adverbial clause inside the scope of the negation might be more viable if it is clause final. As a control for lexical effects we included controls without negations.

Methods

Materials. Eighteen sentences were constructed, closely related to the materials from Frazier and Clifton (1996). Each sentence contained a main clause followed by a subclause beginning with "weil" (because). The comma preceding "weil" is obligatory in German for all possible interpretations. It cannot serve as a cue for the interpretation of the adverbial clause. In the main clause, a character was introduced as the subject in the default topic position. The pronoun in the because-clause was meant to refer to the subject of the main clause. This was the most plausible reading according to the intuitions of the experimenters and qualitative interviews after the experiment showed that subjects interpreted the pronouns exactly this way. Six versions of each sentence were constructed. In two, the negation preceded the clause-final participle (condition VP-internal, 2a,b). Two versions had the negation as the last word of the main clause (VP-final, 2c,d). Crossed with the position of the negation, the because-clause could either be plausibly interpreted as being inside of the scope of the negation or not. In order to control for potential plausibility differences in the adverbial clauses, we included two controls (2e,f) which only differed with respect to the adverbial clause, but did not have a negation in the matrix clause.

(2) a. neg. VP-internal, AC outside negation scope
Die Sekretärin hat nicht gekündigt, weil sie ein hohes Gehalt erhielt.
The secretary has not quit her job, because she got a high salary.
b. neg. VP-internal, AC in negation scope
Die Sekretärin hat nicht gekündigt, weil sie ein geringes Gehalt erhielt.
The secretary has not quit her job, because she got a low salary.
c. neg. VP-final, AC outside negation scope
Die Sekretärin kündigte nicht, weil sie ein hohes Gehalt erhielt.
The secretary did not quit her job, because she received a high salary.
d. neg. VP-final, AC in negation scope
Die Sekretärin kündigte nicht, weil sie ein geringes Gehalt erhielt.
The secretary did not quit her job, because she received a low salary.
e. no negation (control-a)
Die Sekretärin war unbeliebt, weil sie ein hohes Gehalt erhielt
The secretary wasn´t liked very much, because she received a high salary.
f. no negation (control-b)
Die Sekretärin war unbeliebt, weil sie ein geringes Gehalt erhielt.
The secretary wasn´t liked very much, because she received a low salary.

Six counterbalanced forms of the questionnaire were constructed. One sixth of the 18 experimental sentences appeared in each version in each form of the questionnaire, and across the six forms, each experimental sentence appeared once in each version. Each sentence was followed by a question concerning its acceptability. These 18 sentences were combined with 36 sentences of various forms varying in complexity (simple main clauses, simple embeddings and doubly nested embeddings) and plausbility (from fully plausible to fairly implausible according to the intuitions of the experimenters). One randomization was made of each form.

Participants. Eighteen participants, mostly undergraduate students from the University of Freiburg, judged the acceptability of sentences presented in a printed questionnaire. They either received course credits or they were paid for their participation. All subjects´ native language was German, none of them was bilingual.

Procedure. The rating technique used was magnitude estimation (ME, see Bard et al., 1996). Participants were instructed to provide a numeric score that indicates how much better (or worse) the current sentence was compared to a given reference sentence (Example: If the reference sentence was given the reference score of 100, judging a target sentence five times better would result in 500, judging it five times worse in 20). Judging the acceptability ratio of a sentence in this way results in a scale which is open-ended on both sides. It has been demonstrated that ME is therefore more sensitive than fixed rating-scales, especially for scores that would approach the ends of such rating scales (Bard, et al., 1996).

Each questionnaire began with a written instruction where the subject was made familiar with the task based on two examples. After that subjects were presented with a reference sentence for which they had to provide a reference score. All following sentences had to be judged in relation to the reference sentence.

Results

Individual judgments were individually standardized and logarithmized. Table 1 contains mean judgments in the six conditions.

Table 1: Acceptability judgments Experiment I

	neg. VP-internal	neg. VP-final	no negation
AC within scope of negation	-.64	-.79	.24
AC outside of scope of negation	.28	.31	.34

Judgments were submitted to a two-factorial MANOVA including the factors "negation" (VP-internal, VP-final, no negation) and "attachment" (IP, VP). There was a main effect of "negation" ($F1(2, 34) = 11.25$, $p < 0.001$; $F2(2,34) = 10.89$, $p < 0.001$), resulting from the fact that on average, sentences without negations were judged more acceptable than those containing negations (VP-internal: - 0,178, VP-final: - 0,240; no negation: 0,287). The main effect of "attachment" as well as the interaction "negation"*"attachment" reached significance as well ("attachment": $F1(1,17) = 51.29$, $p<0.001$; $F2(1,17) = 26.00$, $p < 0.001$; "negation"*"attachment": $F1(2,34) = 7.26$, $p <0.01$; $F2(2,34) = 8.64$, $p < 0.01$). Planned comparisons show that low attachment was judged less acceptable in sentences containing a VP-internal negation ($F1(1,17) = 26,47$, $p < 0.001$, $F2(1,17) = 16.20$, $p < 0.01$) as well as in sentences containing a VP-final negation ($F1(1,17) = 38.31$; $p < 0.001$; $F2(1,17) = 29.29$, $p < 0.001$), whereas there was no difference in acceptability between the control sentences ($F1(1,17) < 1$, ns; $F2(1,17) < 1$, ns).

Discussion

In Experiment I, we clearly replicated the findings Frazier & Clifton (1996) report for English. In German as in English it is harder to interpret the adverbial clause as residing within the scope of the negation. Varying the position of the negation, however, did not exert an influence on the acceptability of this interpretation. The clause-final focus on the negation is obviously not sufficient to render it more viable. In the second experiment we tried to put the negated sentences in contexts that were supposed to bias for either of the two interpretations.

Experiment II

For Experiment II, we constructed four different contexts for each sentence: A neutral context, leaving open whether or not the proposition stated in the following matrix clause holds or not (3), a context biasing an external scope reading (4), and two contexts biasing an internal scope reading, with one context explicitly stating that the proposition stated in the matrix clause should not be negated (5) and another one presupposing that e.g. the secretary actually quit her job (6).

(3) Neutral context
Jeder hat die Neuigkeiten über die Sekretärin gehört.
Die Sekretärin hat nicht gekündigt, weil sie ein (a) hohes / (b) geringes Gehalt erhielt.
Everybody heard the news about the secretary.
The secretary did not quit her job, because she got a (a) high / (b) low salary.
(4) Contextual bias: AC outside neg. scope
Jeder hat sich gefragt, ob die Sekretärin gekündigt hat.
Die Sekretärin hat nicht gekündigt, weil sie ein (a) hohes / (b) geringes Gehalt erhielt.
Everybody wondered, whether the secretary had quit her job.
The secretary did not quit her job, because she got a (a) high / (b) low salary.
(5) Contextual bias: AC within neg. scope (I)
Jeder hat gehört, dass die Sekretärin gekündigt hat.
Die Sekretärin hat nicht gekündigt, weil sie ein (a) hohes / (b) geringes Gehalt erhielt.
Everybody heard that the secretary had quit her job.
The secretary did not quit her job, because she got a (a) high / (b) low salary.
(6) Contextual bias: AC within neg. scope (II)
Jeder hat sich gefragt, warum die Sekretärin gekündigt hat.
Die Sekretärin hat nicht gekündigt, weil sie ein (a) hohes / (b) geringes Gehalt erhielt.
Everybody wondered, why the secretary had quit her job..
The secretary did not quit her job, because she got a (a) high / (b) low salary.

Methods

We applied the same technique as in the previous experiment. 24 subjects, all native German speakers and all students from the University of Freiburg participated in the experiment. Fillers varied along the full range from fully grammatical to ungrammatical, as well as from fully plausible to highly implausible.

Results

There was a reliable main effect of Scope: sentences for which the adverbial clause had to be interpreted inside the scope of the negation were judged less acceptable than their counterparts ($F1(1,23) = 26.25$, $p < 0.001$; $F2(1,15) = 53.4$, $p < 0.001$).

Table II: Acceptability judgments Experiment II

	Neutral Context	Scope external	Scope internal I	Scope internal II
AC inside scope of negation	-.54	-.38	-.16	-.44
AC outside scope of negation	.36	.26	.39	.52

No main effect of context was found ($F1(3, 69) < 1$, ns; $F2(3,45) = 1.23$, ns). Although explicitly stating the fact that

the proposition described in the matrix clause should not be negated rendered the sentences slightly more acceptable numerically, this did not result in an interaction between Context and Scope (F1(3,69) = 1,12, ns; F2(3,45) = 1.61, ns).

Discussion

In all contexts, even in those biasing the inside scope reading, interpreting the adverbial clause outside of the scope of the negation was judged more acceptable. Before we will discuss why this may be the case, we will extend the phenomenon by including a temporal adverb as a possible domain for the negation.

Experiment III

In Experiment III we presented the same ambiguous constructions as in the earlier experiments. However, we added two conditions with a temporal adverb between the negation and the adverbial clause. This has the effect that now, the adverbial clause in (7d) can easily be interpreted outside of the scope of the negation which is restricted by the temporal adverb (The secretary quit the job before yesterday because of the low salary.). The only viable interpretation for (7c), however is an interpretation of the adverbial clause inside the scope of the negation (The secretary actually quit the job yesterday, but not because she got a high salary, but e.g., because she didn't have another job offer before.). The prediction is that we should find the same preference for the outside scope reading in these constructions.

(7) a. AC outside of neg. scope, no restriction before clause boundary
Die Sekretärin kündigte nicht, weil sie ein hohes Gehalt erhielt.
The secretary did not quit her job, because she got a high salary.
b. AC within neg. scope, no restriction before clause boundary
Die Sekretärin kündigte nicht, weil sie ein geringes Gehalt erhielt.
The secretary did not quit her job, because she got a low salary.
c. AC inside of neg. scope, restriction before clause boundary
Die Sekretärin kündigte nicht erst gestern, weil sie ein hohes Gehalt erhielt.
The secretary did not quit her job only yesterday, because she got a high salary.
d. AC outside of neg. scope, restriction before clause boundary
Die Sekretärin kündigte nicht erst gestern, weil sie ein geringes Gehalt erhielt.
The secretary did not quit her job only yesterday, because she got a low salary.

Methods

As in the other experiments, subjects judged the acceptability of the sentences in relation to a reference sentence (Magnitude Estimations). The sixteen experimental sentences were randomly mixed with 48 filler sentences of varying acceptability (some ungrammatical, some highly implausible). Sixteen native German subjects, all students of the University of Freiburg, participated in the experiment.

Results

The sentences where we included a temporal modifier as a possible domain for the negation were generally more complex and judged less acceptable than the shorter versions 5F1(1,15) = 17.69, $p < 0.001$; F2(1,15) = 10.07; $p < 0.01$). More importantly though, the interpretation of the adverbial clause outside of the scope of the negation was clearly preferred in both, the shorter and the longer version (F1(1,15) = 45.10, $p < 0.001$; F2(1,15) = 156.00, $p < 0.001$). The difference between the inside and the outside scope reading was, however, somewhat stronger for sentences without a temporal adverb as indicated by a reliable interaction between the two experimental factors (F1(1,15) = 5.71, $p < 0.05$; F2(1,15) = 7.51; $p < 0.05$).

Table 3: Acceptability judgments Experiment II

	Restriction before clause boundary	No restriction before clause b.
AC within scope of negation	-.54	-.24
AC outside of scope of negation	-.05	.85

Discussion

Although the sentences including a temporal modifier were somewhat less acceptable than the shorter versions, they showed the same preference pattern. Interpretation of the adverbial clause inside the scope of the negation is always far less acceptable than its outside scope interpretation. The interaction between the domain of the scope of the negation and the presence of a temporal modifier can be explained by the fact that the sentences including a temporal adverb were generally semantically more complex. Assuming a preference for incremental interpretation (Konieczny, Hemforth, Scheepers, & Strube, 1997; Crocker, 1995), the negation in these conditions has to be revised (First the secretary did not quit her job, then she did, but not only yesterday.). This local revision is obviously less costly than a revision between clause boundaries as in (7b), but it may have reduced the difference between the final interpretation of (7c) and (7d).

Experiment IV

In our fourth experiment, we presented a continuation of the sentence, explicitly providing the alternative cause (8a).

(8) a. Die Sekretaerin hat nicht gekuendigt, weil sie ein geringes Gehalt erhielt, sondern weil sie ihre Arbeit langweilig fand.
The secretary did not quit her job because she got a low salary bur because she found her work boring.
b. Die Sekretaerin hat nicht gekuendigt, weil sie ein hohes Gehalt erhielt, obwohl sie ihre Arbeit langweilig fand.
The secretary did not quit her job because she got a high salary although she found her job boring.

In this Experiment we found, that although the difference is actually strongly reduced, interpreting the "because"-clause inside the scope of the negation still causes some difficulties (mean ME score: 0.09 for 8a, +0.45 for 8b, $F1(1,15) = 5.83$, $p < 0.05$; $F2(1,15) = 6.51$; $p < 0.05$).

General Discussion

A strong preference to interpret the adverbial outside of the negative was established, which turned out to be very stable across experiments. It is independent of the ordering of the verb and the negative (Experiment I).

It shows up even in very strong contexts biasing the inside scope reading where the secretary actually quit her job (Experiment II), and the same pattern can be established in constructions, where the negation can be interpreted as restricted by a temporal adverb (Experiment III). Finally, Experiment IV shows that the preference for interpreting the adverbial clause outside the scope of the negation is reduced but not eliminated by a continuation that provides an explicit alternative to the negated because clause.

Obviously, the interpretation of the adverbial clause inside of the scope of the negation is very hard even in a context biasing for this reading. The question is why this is the case. One possibility is that the short texts in (5) and (6) are still semantically incomplete, since we now know what is not the reason for the secretary quitting her job but not what the reason for doing so actually is. Since it may be assumed that negative information is not as well presented as positive information (Legrenz, Girotto, & Johnson-Laird, 2003)), mental models for texts like these may be insufficiently specified und thus less acceptable. The data presented for Experiment IV, on the other hand, suggest that this aspect actually plays a major role. However, it does not seem to tell the whole story, since even an explicitly given alternative does not render the inside scope reading as acceptable as the outside scope reading.

An further possibility lies in the interaction of semantic and prosodic information. Ronat (1984) presents the Prosodic Binding hypothesis for French, roughly stating that a prosodic boundary delimits the scope of a quantifier or a wh-phrase (see also the Scope Correspondence Principle (SPC) suggested by Hirotani, 2003, for Japanese). Note, that this is actually a principle of grammar, meant to constrain the interpretational domain of quantifiers.

Assuming that even during silent reading, a prosodic structure of a sentence is constructed (Implicit Prosody Hypothesis; Fodor, 1998), this may play a role in reading as well. Since there is a high probability for a prosodic boundary between the matrix clause and the adverbial clause, the AC cannot be interpreted inside the scope of the negation. The inside scope reading of the adverbial clause is actually only viable with a very marked prosodic contour. At least intuitively (as stated by several native German and English informants), the break before the adverbial clause in this marked prosodic contour is strongly reduced. Interestingly, this seems to be true even though there still has to be a comma in the German clauses. So the comma by itself cannot be the major factor. The remaining difficulty in interpreting "complete" models may thus result from the interaction of semantic and prosodic constraints. This will, however, be a question to be answered in future research (Bradley, Fodor, Fernandez, Hemforth, & Pynte, in prep).

Acknowledgments

This research has partly been sponsored by the German Research Foundation (He 2310/3). We want to thank Regine Becher, Christian Mönke, and Daniel Umber for their assistance in constructing the materials and running the experiments. We also want to thank the two anonymous reviewers for their helpful comments.

Abstract

Past research on children's categorizations has suggested that children use perceptual and conceptual knowledge to generalize object names. Especially, some researches suggested that the relation between ontological categories and linguistic categories is a critical cue to categorize objects. However, this mechanism has not been specified. This paper reports new insights to reveal children's categorizations based on the survey of adults' knowledge. We estimated the English and Japanese ontological spaces from data and used these results to simulate behavioral experiment of previous research. The results show a possibility that linguistic cues help children to attend specific perceptual properties.

Introduction

Categorization is a form of information compression, one solution to handle an almost infinite number of entities efficiently. Where do these categories come from and how do children know which words to map to which categories?

Quine (1960) pointed to the difficulty of word learning without prior category knowledge. If we hear a novel word in an unknown language, how do we infer its meaning ? For example, suppose we heard 'gavagai' while looking at a rabbit in a field. 'Gavagai' might mean *rabbit*, but it could also mean *rabbit's color* or an infinite variety of other possibilities. By Quine's analysis, word learning should be highly problematic for first language learners.

Constraints to acquire word meanings

Markman & Hutchinson (1984) among others proposed that children learn nouns easily because they do have prior knowledge about kinds of categories. Research over the past 20 years has indicated that this knowledge is considerable. Children know, for example, that animal categories are organized by multiple similarities, that artifact categories are organized by shape, and that substance categories are organized by material. Given a single thing of each of these kinds and told its name, children systematically generalize that name to new instances in ways specific to the kind of thing it is (Landau, Smith & Jones, 1988; Soja, Carey & Spelke, 1991, etc.) One hypothesis is that this knowledge is learned, that as children learn common nouns, they learn the correlations between properties specific to different kinds and the similarities relevant to categorizing those kinds - that things with eyes are classified by multiple similarities, things that are solid and rigid are classified by shape, and things that are nonsolid and nonrigid are classified by material (Jones & Smith, 2002; Yoshida & Smith, 2003). The learning hypothesis is plausible because children's differential categorizations of animates, objects and substances emerge only after they have learned some number of names for these different kinds (Samuelson & Smith 1999), The present paper provides a simulation model of how this might be learned.

Linguistic categories and ontological categories The fact that children distinguish animal, object, and substance categories in noun learning is also interesting because these ontological categories are often related to linguistic individuation, to how different languages quantify nouns. Most of the world's languages treat animates as countable discrete things. Others, like English, also treat inanimate objects as discrete and countable. Few (if any languages) individuate substances in these ways. (Lucy, 1992)

Some have suggested a deep relation between ontological categories and their learning how their language quantifies entities. For example, Quine (1960) hypothesized that children learning English learn to distinguish objects and substances by learning the count-mass distinction. In English, nouns such as "dog" and "cup" that label individuated things are count nouns and mandatorily take the plural if there are more than one instance; in contrast, nouns such as "sand" that label a substance are mass nouns and are not pluralized. Thus this linguistic distinction could teach children that there are two different kinds of categories.

Soja, Carey and Spelke (1991) criticized this idea, because their experiments indicated that 2-year-old children who do not use count-mass syntax nonetheless classify objects by shape and substances by material. Imai & Gentner (1997) reported supporting results in a study comparing English and Japanese speakers. Japanese makes no distinction comparable to the count-mass distinction in its quantification system. Yet Imai and Gentner found that both Japanese- and English-speaking children categorized objects by shape and substances by material.

A boundary shift Imai and Genter also found differences in the range of things treated as objects versus substances by speakers of the two languages. Speakers

of English treated complex and simple solids as objects categorized by shape and nonsolid forms as substances categorized by material. In contrast, Japanese speakers treated complex solids as objects classifiable by shape and treated simple solids and nonsolids as substances classifiable by material. Yoshida and Smith interpreted these results in terms a boundary shift, suggesting that count-mass syntax shifted the object boundary in English relative to that in Japanese so that it also included simple but solid shapes. If this interpretation is correct then linguistic contrasts such as count-mass syntax may play a role in the development of ontological categories.

Yoshida and Smith also predicted and found a corresponding boundary shift at the animate-inanimate boundary. They predicted this from an analysis of Japanese which distinguishes animates and inanimates in ways that English does not, through its quantification system and also via the verbs "iru" and "aru" which mean "exists". In locative constructions such as "There is," animates require the use of iru and inmates require the use of aru. Yoshida and Smith hypothesized that this distinction, like the count-mass distinction in English, would perturb the boundary between animates and objects. In support of this idea, they showed that the range of things treated as animates (and classified by multiple similarities) was broader for Japanese-speaking than English-speaking children.

The purpose of the simulations reported here is to explain the mechanism underlying the boundary shift. Following Yoshida and Smith, we propose that ontological categories are the product of learned correlations among the properties such as shape, material and color and also linguistic contrasts such as the count-mass distinction in English and the iru-aru distinction in Japanese.

Experiment 1

We measured statistical structure of common noun category via adult judgments. We studied the statistical structure of 48 nouns that name common categories typically known by 2 year olds (Fenson, Dale, Reznick, Bates, Thal & Pethick, 1994) [1]We did this in two steps. First, we asked adults to judge how a list of 16 adjectives taken from some studies using the Semantic Differential (the SD; Osgood, 1957) described category relevant properties such as shape, material, movement. Second, in vocabulary survey, we asked adults to rate how the 16 adjectives described the 48 noun categories.

Method

Participants In the adjective survey, we recruited 12 volunteers (from 23 to 25 years old) from Kyoto university. In the vocabulary survey, we recruited 104 students (from 18 to 22 years old) from Kyoto Koka women's university who received a class credit for participation.

Stimuli The stimuli consisted of (1) a list of category relevant perceptual properties: shape, material, color, texture, sound, temperature, flavor, movement, smell, and function, (2) 16 adjective pairs: dynamic-static, wet-dry, light-heavy, large-small, complex-simple, slow-quick, quiet-noisy, stable-unstable, cool-warm, natural-artificial, round-square, weak-strong, rough hewn-finely crafted, straight-curved, smooth-bumpy, hard-soft; and (3) 48 nouns commonly known by young children [2] (see also Table 1).

Adjective survey Participants were asked - 'How do you use these words (adjective pairs) to express familiar objects' perceptual features'. Participants made these judgments using an electronic file of the 16 (adjectives) by 10 (properties) cells. The ratings were on a 5 point scale (1: very inappropriate, 2: inappropriate, 3: neither, 4: appropriate, 5 :very appropriate).

Vocabulary survey Participants were presented with one noun at a time and asked to judge the applicability of the 16 adjective pairs on a 5 point scale. For example, if the adjective pair was big-small, participants would be asked the thing labeled by the noun very small, small, ambiguous, big and very big. Five different orders were used across subjects.

Analysis We used Principal Component Analysis (PCA) to analyze the vocabulary with mean linguistic-scale scores of the all participants. PCA is a popular method to compress information by the least loss of data variance.

We used the results to estimate the English and Japanese ontological spaces. We added 1-dimension syntactic cues which was close to ontological categories (Table 1) to raw data (16 dimensions), and analyzed the combined data (17 dimensions). In the English condition, we added count-mass syntax which was encoded as 1-0. In the Japanese condition, we added iru-aru syntax just as in the English condition. In the neutral condition, we added the value 0.5 for all objects. We decided these parameters of syntactic categories based on the dictionaries. We assumed that (1) our ontology space consists of perceptual and linguistic properties, and that (2) the most important factor of these space is the variance of the object's distribution. These assumptions are reasonable, because (1) our goal is to estimate children's ontology space in the context of generalizing novel names and (2) we name entities different labels based on not similar features but different properties.

Our another goal is to estimate perceptual weights in two language conditions. However, principal components consist of weights of linguistic scales, so we can not directly know which perceptual weights the ontology spaces have. Therefore we defined perceptual weights of principal components as the equation(1) to analyze perceptual weights in English and Japanese conditions.

$$W_{dp} = \mid \sum_{l} C_{dl} M_{lp} \mid \qquad (1)$$

[1]This form of the MCDI is a parental checklist of words designed to measure the productive vocabulary of children between 16 and 30 months of age.

[2]The 9 categories are 'animals', 'body parts', 'clothing', 'food and drink', 'furniture and rooms', 'outside things', 'small household items', 'toys', and 'vehicles'.

d is a dimension of principal components. l is a index of 16 linguistic scales of the SD (see also Method). p is the index of the 10 perceptual properties (see also Method). W_{dp} is the pth perceptual weight of dth principal component. C_{dl} is the loading of lth linguistic scales of dth principal component. M_{lp} is the estimated expressiveness of the pth perception of the lth linguistic scales. C_{d*} is a unit row vector and M_{*p} is a unit column vector, so W_{dp} is the absolute inner product of two vectors, or $\mid cos\theta \mid$ (θ is the angle of two vectors).

Results and Discussion

First three and six principal components respectively accounted for more than 70% and 90 % of the variability in the data.

Estimated ontological spaces The first two principal components of the vocabulary survey data were displayed as a 2-dimensional plot (Figure 1 is the result of neutral condition). In the neutral condition, we found animates and body parts in upper-right area, vehicles in upper-left area, furniture in lower-left area and substance in lower-right area. This distribution of entities leads us the following interpretation of the first two components. The first principal component axis can be interpreted as 'solidity', because solid and non-solid entities are located in the left and right sides, respectively. The second principal component axis can be interpreted as 'animacy', because dynamic and static entities are located in the upper and lower sides, respectively.

There were no clear boundaries in neutral 2-dimensional space, but we found global boundaries in the English and Japanese space. Furthermore, the English and Japanese spaces had a great difference. The English space also had 'solidity' axis as the first principal component, but the Japanese space had 'animacy' axis as the first principal component. Therefore, we analyzed these distributions of entities by clustering.

First three principal components (total 70% over) were enough to analyze global structure of results, so we analyzed this 3-dimensional data by hierarchical clustering(Figures 2 and 3).

The clustering of the neutral condition showed the clusters like MCDI classes, but did not show any global boundaries. On the other hand, the analyses of the English and Japanese conditions showed the global boundary (Figures 2 and 3). There were two global clusters categorized near by the root of the tree. One cluster mainly consisted of 'objects' category members, and another cluster mainly consisted of 'substance' category members. The second branch occurred in the object cluster. There was the 'animates' cluster near substance cluster in the part of objects cluster. That is why, English ontology space seemed defined by 'individuation' or 'solidity'.

In the Japanese condition, there were two global clusters that mainly consisted of 'animates' members and 'inanimates' members. Despite being inanimates, vehicles(e.g. 'airplane', 'car') and body parts(e.g. 'eye', 'hand') were near the animates members. There seemed an 'animacy' boundary in the Japanese ontological space because animates and dynamic objects make cluster and inanimates make another cluster.

Table 2: The estimated perceptual weights. In the Experiment 2, we used the normalized W_{dp} ($\sum_p^{10} W_{dp} = 1$).

	English	Japanese
shape	0.091	0.047
color	0.067	0.194
texture	0.086	0.09

Perceptual weights of the English and Japanese spaces We estimated perceptual weight in the English and Japanese ontological spaces. Tables 2 shows the results of the estimation.

Compared with the Japanese condition, the English condition showed higher weight on shape. Contrary to the English condition, the Japanese condition showed higher weights on color and texture.

Estimating ontological category One potential problem with the present experiment is that the perceptual ontological space was derived from only Japanese speaker's data.

We are currently collecting the English data. Preliminary results indicate that they are extremely similar to those of Japanese speakers. The Pearson's correlation of mean across participants are .79 in vocabulary survey and .80 in adjective survey. In this work, we have assumed that the adjective - noun ratings and the adjectives - properties ratings reflect the perceptual structure of the categories. It could be argued that these rating reflect instead how predicates and nouns co-occur in a language.

Sommers (1963) claimed that knowledge of ontological categories is intimately related to predicability, that is, to the knowledge of which predicates in a language can be combined with which nouns. For example, the predicate 'is asleep' distinguishes animals and non-animals. Furthermore, Keil (1979, 1981) showed that children's judgments of predicability, like those of adults, yield an

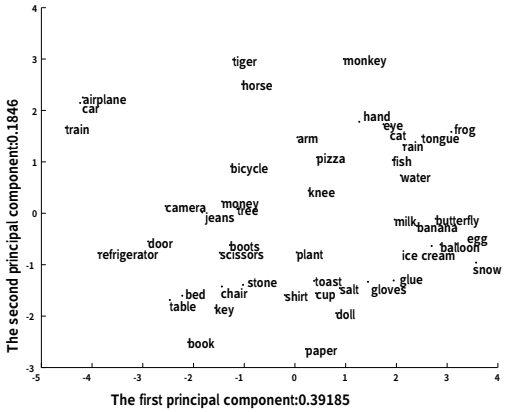

Figure 1: The first two principal components for the neutral condition. The first principal component (x axis) was interpreted as 'solidity' or 'size' of objects. The second principal component(y axis) was interpreted as 'animacy' or 'movement' of objects.

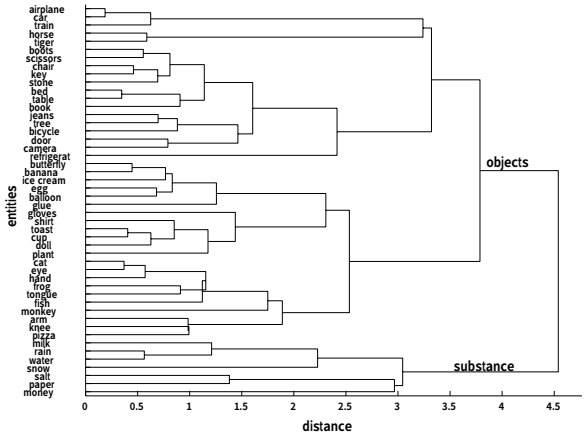

Figure 2: The result of cluster analysis for the English condition. We estimated 'objects' cluster and 'substance' cluster in superior hierarchy.

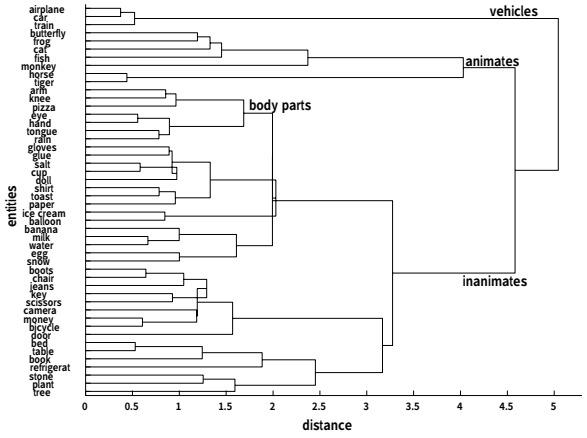

Figure 3: The result of cluster analysis for the Japanese condition. We estimated 'animates' cluster and 'inanimates' cluster in superior hierarchy.

ontological tree, though a less elaborate one than adults. The question of whether our judgments reflect the structure of categories in the world or relations among words is a difficult one. Given our preliminary results from English, if they do reflect relations among words-predicates and nouns,those relations are nearly identical in the two language, a fact one might want to explain by the regularities in the world.

Experiment 2

In Experiment 2 uses the results of Experiment 1 to simulate the boundary shift reported by Yoshida and Smith.

Experiment to be simulated The specific goal is to simulate Yoshida and Smith's second experiment which showed a boundary shift in the animate - inanimate boundary Japanese speakers relative to English speakers. The participants in Yoshida and Smith's experiment were 3-year-old English and Japanese monolingual children. The experimenters presented children with an ambiguous entity that could be seen as depictions of ether animates or inanimates and named it with a novel label (e.g. in Japanese 'Kore-wa teema dayo', in English 'This is a teema.'). Experimenters did not provide any cue such as "iru" or "aru" which might cue these as depictions of animates or inanimates Experimenters then presented children with test objects and asked them whether the test object had the same name Exemplars and test objects matched or did not match in three perceptual features (Table 3).

The results suggested that Japanese speakers treated these ambiguous forms as depictions of animates, extending the name to new instances by multiple similarities. In contrast, English speakers treated them as inanimates objects, extending the name to new instances by shape. Thus, Yoshida and Smith proposed that the Japanese speaking children included a wider range of kinds in the animate category relative to English speakers just as English speakers include a wider range of instances in the objects category than do Japanese speakers. The question for Experiment 2 is whether we can use the adult judgments in Experiment 1 to simulate these results.

Method

Following Yoshida and Smith's method, we assumed that objects categories are defined in terms of shape, color and texture, and that other nonstudied features will have no effect on the similarity of a test object to the exemplar.

We also assume that children's name extensions are based on the psychological distance between a test object and the exemplar. We defined the psychological distance between stimuli by the equation (3). Probability of 'yes' response which means two objects belong to the same category is defined by the equation (2).

$$P_{yes} = exp(-b\delta) \tag{2}$$

$$\delta = \Big(\sum_{i \subset perception} D_i w_{il} \mid (e_i - s_i)^m \mid \Big)^{\frac{1}{m}} \tag{3}$$

Table 3: Experimental conditions of Yoshida & Smith (2003). 'm' means feature match between exemplar and test object, and 'N' means non-match

condition	1	2	3	4	5	6
shape	m	m	m	m	N	N
texture	m	m	N	N	m	N
color	m	N	m	N	N	m
	S+T+C	S+T	S+C	S	T	C

$b > 0$ is the scaling parameter of the transfer between a distance and a yes-response ratio , and $m > 0$ is the metric parameter. $i \subset perception = \{shape(S), color(C), texture(T)\}$ means the population of the perceptual features. e_i represents the ith perceptual dimension of the exemplar, and it is a random value from 0 to 1. s_i represents the ith perceptual dimension of the test stimulus. s_i is a random value from 0 to 1 in case of feature non-match or the same value as the exemplar in case of feature match (see also Table 3). w_{il} is the value of ith perceptual weight of l ($l \subset \{English, Japanese\}$) participant(see also Table 2). D_is are the supplementary terms which represent ith perceptual bias common in English and Japanese. We added these terms to the model because the feature differences of stimuli were not controlled in the behavioral experiment. D_is represent the relative mean difference of perceptual features. The model have four free parameters (b, m, two D_is) ,because D_is are the ratios among three perceptual features.

Results and Discussion

We simulated the second experiment of Yoshida and Smith (Figure 4) by the computational model (Figure 5). We used Monte Carlo simulation to estimate optimal parameters. In the result, we estimated $b = 12$, $m = 0.8$, $(D_{shape}, D_{texture}, D_{color}) = (7, 1, 0.6)$ ($D_{texture} = 1$ is constant) and $R^2 = 0.916$ between the response patterns (12=2 (language of participants)×6 (feature controlled condition)) of simulation and those of behavior. When we did not add two parameters D_is, the fitness of the model was $R^2 = 0.683$. This suggested the methodological problem of estimation by the equation (2).

In the behavioral experiment, the English speakers categorized the stimuli based on their shape and the Japanese speakers categorized them based on their multiple features. These results suggested that the English speakers categorized ambiguous objects as inanimates whereas Japanese speakers categorize them as animates. Thus our model fitted the behavioral results well, and provides a simple account of the crosslinguistic difference.

General Discussion

Recent studies on early word acquisition have shown that some biases, such as shape bias, are not so universal, but dependent on context and language. For example, Children speaking English show stronger shape bias for inanimate objects than those speaking Japanese. These findings are explained by postulating children's linguistic, cultural and category knowledge influences boundaries between ontological categories.

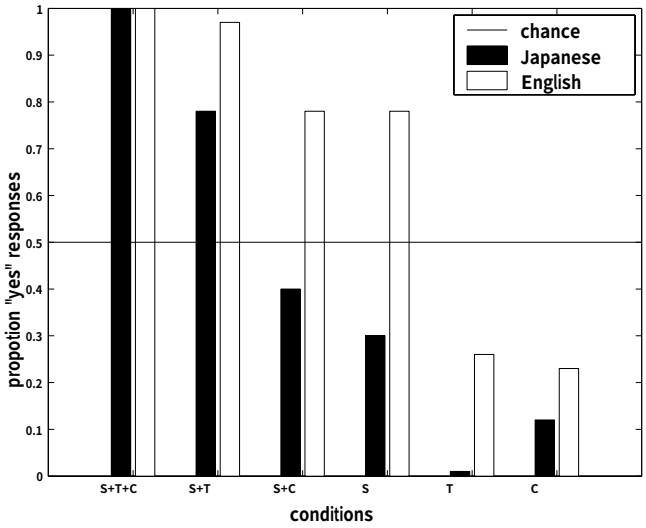

Figure 4: The behavioral data of Yoshida & Smith (2003). The English speakers categorize stimuli based on shape, while the Japanese speakers categorize them based on multiple features.

The present simulation offers a mechanism. The results of the simulation suggest that (1) ontological categories may not be a special nor given but an emergent property derived from multidimensional perceptual and linguistic features, and (2) crosslinguistic differences along this ontological continuum can be explained by a difference in the emergent variable due to different statistical structure of linguistic features. Specifically, we assumed that the emergent property can be extracted by information compression of the multidimensional feature space, such as PCA. To evaluate whether we can account for the behavioral findings, we conducted a survey to obtain the multidimensional feature space of objects, and a series of quantitative analyses to obtain the language specific ontological spaces. Without linguistic features, the compressed perceptual space spanned by two principal components was organized by objects' solidity or size. Thus, a solidity-dominant space can be derived from the perceptual feature space, but there was no principal component representing an "individuation continuum" from animates to objects to substances. More interestingly, addition of linguistic features made the ontological space more well-defined, and the estimated language-specific ontological spaces are quite consistent with previous findings. The estimated English ontological space was solidity-dominant and shape-weighted. This is consistent with Colunga & Smith (2000) and Samuelson (2002) showing that American children attended solidity of objects in object categorization. On the other hand, the estimated Japanese ontological space is animacy-dominant and color-and-texture-weighted, which is consistent with Yoshida & Smith (2001, 2003) showing that

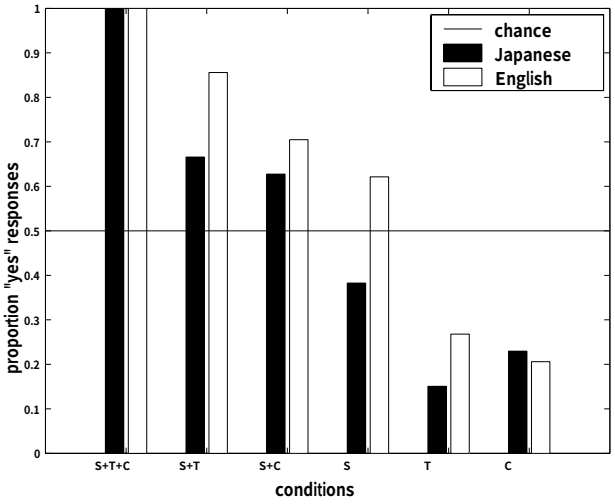

Figure 5: The result of simulation.
The coefficient of determination of 12 responses pattern (R^2) is 0.916

Japanese children attended multiple features of objects.

Furthermore, objects/substance boundary was clearer in the English space than the Japanese space. This results is consistent with Imai & Gentner (1997). In addition to qualitative matches with previous data, our theory make a good quantitative fit to the behavioral data of Yoshida & Smith (2003). With a simple computational model that categorization response is based on similarity derived from a distance on the ontological space, the behavioral data showing difference in shape bias for objects between English and Japanese speaking children with various different stimulus conditions could be simulated quite well.

Beyond the "boundary shift" Our account expands the boundary shift hypothesis in the following senses. First, our theory proposes an underlying mechanism of boundary shift in a quantitative fashion. Second, the individuation continuum is not a separate dimension, but a statistical property embedded in the multidimensional feature space. Ontological features such as animacy and solidity may be extracted from perceptual and linguistic features through statistical learning. This suggests a possibility that more abstract conceptual features are also formed by statistical learning of basic perceptual and linguistic features.

Perception as Prediction

Stephen A. Hockema (shockema@indiana.edu)

Abstract

Learning is often about prediction. This paper asks whether perception is also. The main idea is that perception is a stream and that perceivers learn the trajectory through which one moment in that stream turns into the next. A behavioral experiment with children is described that tests two hypotheses developed from this idea.. In the experiment, children briefly watch a transformation (e.g., a triangle increasing in size and/or saturation). If children learn the trajectory of change and if prediction is at the core of perception, then a subsequent statically presented object should trigger the perceptual system to anticipate the "next state". To test this, children were asked to make same/different judgments that should, by hypothesis, be interfered with by the learned trajectory. Children became less able to detect pairs that were the "same" when asked to make judgments about the dimension that they had seen varied. Furthermore, there was evidence that two dimensions could be made more integral by covarying them simultaneously. Both of these results were simulated with a simple connectionist model constructed to embody a predictive mechanism. Taken together, these results lend support to the idea that the perceptual system is designed to make predictions in time and that this architecture gives a "dynamic" aspect to perception.

Introduction

Perception is an interaction *in time* between a dynamic mind and a dynamic world. It is crucial to the understanding of this process that *both* sides of the relation are changing in time. This paper examines two key implications of this fact: 1) an element of *prediction* must be inherent in the perceptual process, and 2) the system should be *adaptable* to a changing environment.

There is ample evidence for the adaptability of the perceptual system in the short and long term. In the short term, the evidence shows up in the form of aftereffects and priming. For example, motion aftereffects (MAEs), illusions of motion (without displacement) that occur after viewing real motion in a certain direction for a short time, are considered to be perceptual adaptations that serve to keep the system in balance (Anstis, Verstraten, & Mather, 1998). In the long term, adaptation shows up as the perceptual learning of new psychological dimensions and features and the readjustment of the relative attention paid to existing dimensions (Goldstone, 1998). In brief, our perceptual systems constantly tune themselves to the environment.

Furthermore, our perceptual systems must also be tuned to *anticipate* the future. In the short term, the system must be able to predict, at a very low level, how our environment and the things in it change and appreciate which changes are normal and which are unexpected. Normal changes include regular transformations along dimensions, for example changes in position, size, orientation, luminance, pitch, and so on.

There is evidence for the predictive capabilities of the system in many everyday activities, like tracking moving objects behind occluders, navigation through crowds, simple eye-hand coordination, and in several related experimental phenomena where the system exhibits momentum when tracking predictable changes. For example, in the phenomenon known as representational momentum , subjects learn to anticipate the continuation of a transformation, for example an object moving across a computer screen. When the object suddenly disappears and subjects are probed about its nal position, there is evidence that the remembered position is shifted forward along the path of the trajectory (Freyd, 1992). This has been taken by some (e.g. Freyd, 1992; Hubbard, 1999) as evidence of a dynamic representation that continues to move forward after the real object has disappeared. However, the evidence is also consistent with the possibility that the trajectory of the object is being perceptually *predicted* and thus the perceived position of the object at any given instant in time is actually ahead of its actual position.[1] Such a view would be consistent with an explanation for several other perceptual illusions given recently by Changizi and Widders (2002) and Changizi, Nijhawan, Kanai, and Shimojo (2003).

This paper will present further empirical evidence of a perceptual adaptation that is triggered by predictable variation. A simulation of the experiments using a simple model of a predictive mechanism will then be presented as additional support for these ideas.

Experiment

If an adaptable, predictive mechanism is built into our low-level perceptual systems then it should be possible to prime the system to anticipate and perceive change as in the momentum effects, even when tested with static objects. If the primed change is along a dimension, this might disrupt the perception of the value for this dimension in a subsequently presented static object. If caused by an adaptable, predictive mechanism, this disruption would have two characteristics:

1. a perceptual *shift* in the direction of the primed change; and
2. less certainty about the precise value of the dimension.[2]

[1] Of course it is possible that both of these theories are operating.

[2] This is analogous to uncertainty principles in physics, although it also stems from the imperfection that will be inherent in any physical predictive mechanism, especially in circumstances where it has only had a brief exposure to the trajectory that it is trying to learn to predict.

This experiment deals with the second characteristic. It was designed to test the hypothesis that priming the perceptual system with bidirectional change along a dimension could lead to perceptual spreading along it. Such an effect should make it more difficult for perceivers to make accurate *comparisons* along this dimension subsequent to experiencing this priming. In particular, the spreading should increase the likelihood that perceivers will see two things that are actually the same as being different on the dimension.

In this experiment, this hypothesis was evaluated using a task where the dimensional change was expansion and contraction in size. Thus, it was expected that subjects would have more difficulty judging two shapes as being the same size after exposure to change along the size dimension than after being exposed to no change, or to change along an irrelevant dimension. In this experiment, color saturation was used as the control dimension. The participants were preschool-aged children under the assumption that the developing perceptual system is more sensitive to these priming effects.

The use of preschool children was also motivated by the desire to investigate the usefulness of a predictive mechanism to a developing perceptual system. Based on the simple idea that "things that change together go together", the hypothesis was formulated that if the perceptual system adapts to a coherent transformation along more than one dimension, these dimensions might become perceptually "fused", or more *integral* in the sense formalized by Garner and Felfoldy (1970).

Method

The experiment was a between-subjects design. Subjects were randomly assigned to one of four conditions. There were also four possible orderings of the test trials (see below). Subjects were randomly assigned to one of these four orders, which were counter-balanced across the four conditions.

Participants Thirty-two children from the Bloomington, IN area have participated. Children were all between 4 years and 4 years, 8 months of age. (Mean age was 4.3 years.)

Procedure The experiment was divided into three phases, all of which used a computer to present the stimuli.

In the first, "warm-up" phase, subjects were familiarized with the computer and trained to press the space bar whenever they were presented with a pair of shapes on the screen that were the same *size*. This phase was the same for all subjects, regardless of what condition they were in. The items presented included pictures of various common and colorful objects (e.g. balls, flags, hearts, etc). Across trials matching and mismatching objects and matching and mismatching sizes varied orthogonally so as to instruct the child as to the importance of attention to size only.

Subjects were presented with 32 warm-up comparisons, starting at a slow presentation rate and gradually increasing to 1.25 seconds per pair. Whenever a new pair appeared, the computer would emit a short beep. A different pitched beep would sound whenever the space bar was pressed. If an error was made (either the pair were the same size and the child failed to press the space bar, or the pair were different sizes and the child incorrectly pressed the space bar), the computer would emit a lower beep and the warm-up sequence would stop. The experimenter would then explain the mistake to the child, pointing out what they should have done, and then continue the sequence. If, after 32 trials, the child had not yet grasped the task, the training phase was repeated. If they still had not grasped the task after three passes, the subject's data was replaced.

In the second phase, the "priming" phase, all children were shown a simple video animation that lasted 80 seconds and consisted of 20 repetitions of a "transformation" of two shapes. The transformation that children saw depended on their condition assignment and will be described in the next section, however the instructions were identical for all four conditions. Children were told that they were playing a game in which they were supposed to press the space bar whenever the shapes "stop changing" and "begin to change back". The game was simply a ruse to help keep the children paying attention to the crucial animations.

The final phase of the experiment, the "test" phase, was similar to the training phase. Here subjects were again told to press the space bar as quickly as possible whenever they saw a pair of shapes that were the same size. In the test phase, the shapes being compared were either a pair of circles or a pair of squares. Half of the comparisons were the same size and half were different. The shapes were either both blue or both red, with their saturations varying as described in the next section. As in the warm-up phase, the computer emitted a beep whenever a new pair was displayed and a different pitched beep whenever the space bar was pressed. No feedback was provided during the test phase.

During the test phase, each pair was displayed for exactly 1.25 seconds. After being given the instructions, and prior to starting, subjects were warned that the speed would be fast and that they should get ready. There were 32 test stimuli in this phase, broken down into four sets of eight. After each set of eight, the computer would pause and the subject would be reminded of the instructions, and told to get ready again. Test trials were presented to subjects in one of four random orders. To ensure that children were still on task, any child that pressed the space bar on at least 20% or more than 80% of the test trials was replaced.

Materials The priming phase was designed to "teach" the perceptual system a predictable trajectory of change. There were four possible animations used corresponding with the four conditions. All animations showed the gradual transformation of a pair of side-by-side triangles. The left and right triangle always transformed identically and in synch with one another. The left triangle was always red and the right triangle was always blue. The four conditions were as follows:

1. Control: increasing and decreasing saturation;
2. Size-Only: increasing and decreasing size;
3. Correlated: both size and saturation increasing and decreasing: the bigger the triangles got, the more saturated, and the smaller they got, the less saturated;
4. Anti-correlated: both size and saturation increasing and decreasing: the bigger the triangles got, the less saturated, and the smaller they got, the more saturated.

Since *size* is at least one of the transformed dimensions in Conditions 2-4, the three conditions will collectively be referred to as the "Size-change" conditions. Conversely, since *saturation* is at least one of the transformed dimensions in Conditions 1, 3 and 4, these three conditions will be referred

to together as the Saturation-change conditions.

The minimum size (area) of the triangles in the three Size-change animations, as displayed on the monitor, was $1.83cm^2$ (base $1.63cm$, height $2.25cm$); the maximum size was $29.25cm^2$ (base $6.5cm$, height $9.0cm$). The minimum saturation in the Saturation-change animations was 0.1 on a scale of 0 to 1; the maximum was 1.0. For Condition 1, the size of the triangles remained constant at $29.25cm^2$. For Condition 2, the saturation of both triangles remained constant at 0.8. For the Size-change animations, the triangles always started and ended at their smallest point.

In the Testing phase, there were four different types of comparison possible. These were among shapes that were either big, medium or small in size (see Table 1) and high, medium or low in saturation (1.00, 0.45 and 0.20 respectively in the range of 0 1).

Table 1: Actual On-Screen Areas (in cm^2)

Term	Squares	Circles
Big	27.56	9.33
Medium	12.25	5.25
Small	4.86	2.33

The four types of comparison were as follows:

1. Identical: Pair being compared were identical in both size and saturation. There were four variations of this: big/high, big/low, small/high, small/low.

2. Saturation Different: Pair being compared were the same size, but differed in saturation. There were two variations of this: big/high compared to big/low and small/high compared to small/low.

3. Size Different: Pair being compared were the same saturation, but differed in size. There were four variations of this. In the rst two, the pair were both high saturation. In the second two, the pair were both low saturation. One of the shapes was always medium size and the other was always either small or big.

4. Both Different: Pair being compared were different both in size and saturation. In these pairs, the bigger shape always had the higher saturation. (This was done for reasons related to other experiments not reported here.) As in the Size Different comparisons, one of the shapes was always medium size and the other was always either small or big.

Results

Children's errors were classi ed by the type of comparison trial in which they occurred and the condition to which the subjects were assigned. There were two broad classes of errors: *Misses*, where the shapes were the same size yet the subject failed to press the space bar, and *False Alarms* where the shapes were different size and yet the subject incorrectly pressed the space bar.

Figure 1 shows the average number of Misses broken down by the four priming conditions and two types of relevant test trial (Identical trials on the left and Saturation Different trials on the right in each group). As can be seen, there were signi cantly more Misses in the Size-Change conditions as compared to the Control Condition ($p < .02$ for the Identical trials, $p < .002$ for the Saturation Different trials).

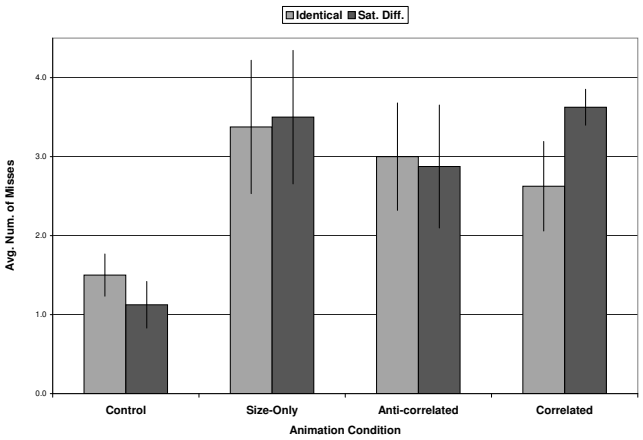

Figure 1: Average Misses for Same-Size trials

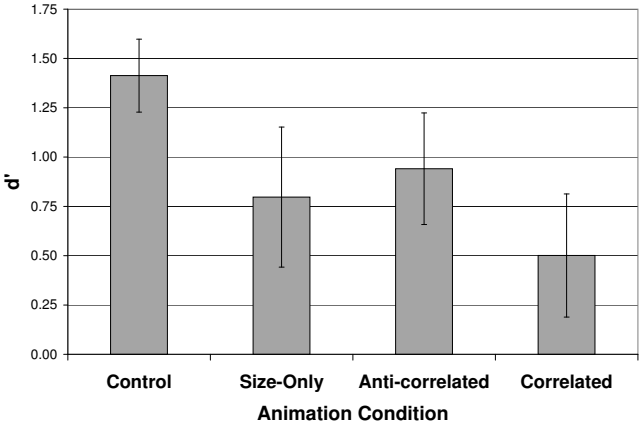

Figure 2: Average disciminibility

An analysis from the perspective of Signal Detection Theory (SDT) was also performed. Figure 2 shows the average d' (discriminability or sensitivity) for each of the four conditions.[3] As can be seen, the three Size-change conditions had a signi cantly lower average d' value ($p < .03$) than the Control Condition. (In this context, lower d' values mean that it is harder to distinguish Same Size shapes from Different Size shapes.) The three Size-change conditions also had a marginally signi cant ($p < .06$) higher average β value (criterion for pressing the space bar): they were less likely to respond Same Size in general. Also, the Correlated condition by itself also had a signi cantly lower d' ($p < .01$) and higher β ($p < .03$) than the Control condition.

Figure 3 shows the False Alarms, again broken down by the four conditions and two types of relevant test trial (Size Different trials on the left and Both Different trials on the right). Considering Figure 3, notice that the gap between the number of False Alarms in the Different Size, *Same* Saturation trials and the number of False Alarms in the Different Size, *Different* Saturation trials increased in the conditions where size and saturation were covaried (Correlated and Anti-correlated) over what it was in the conditions where they were varied in-

[3] For one subject in Condition 2, d' was infinite because the subject had a Hit Rate of 1.0. For this subject, d' was estimated using an adjusted Hit Rate of $15.5/16 = .9688$, yielding a d' of 3.01.

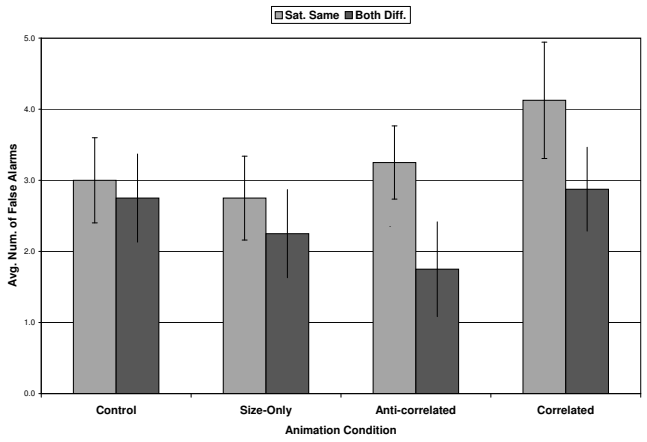

Figure 3: Average False Alarms for Different-Size trials

dependently. The graph shows the group averages and the error bars are the standard error of these means. For each subject, the difference between their number of False Alarms on the Different Size, Same Saturation trials and the Different Size, Different Saturation trials was computed. This difference was found to be signi cantly above zero in both the Correlated ($p < .006$) and Anti-correlated ($p < .028$) conditions. Comparing to the Control and Size-only Conditions, it can be seen that no such difference existed where the dimensions were varied independently during the priming event. When the within-subject difference scores of the two covaried conditions are compared to the difference scores of the two independent conditions, the covaried differences are signi cantly bigger ($p < .04$). Thus, differences in the irrelevant dimension of saturation had a larger effect on subjects' comparisons of size during test when size and saturation were covaried together during the priming event.

To see if the effect of the priming event looses its potency over time, the probability of error on any given test trial was correlated with how long after the priming phase it occurred. Table 2 shows the correlation coef cients between error frequency and trial. In no case was the correlation signi cant. Thus, performance did not change throughout the test phase.

Table 2: Correlation between trial number and error prob.

Condition	r
Control	$-.12$
Size-only	.12
Correlated	$-.17$
Anti-correlated	$-.29$

Discussion

The results appear to support the rst hypothesis of perceptual spreading. Priming with size transformations in the three Size-change conditions led to a decrease in the ability to detect shapes that were the same size in the Test phase. This is consistent with spreading (bidirectional propagation) along the size dimension due to the anticipation of change by the perceptual system. Such spreading apparently leads to dif - culties in comparison.

The speeded comparison task focusing on just size was chosen speci cally to induce errors it is known that children have dif culty ignoring variation on an irrelevant dimension to focus on just one dimension (Smith & Evans, 1989). The point of interest here was how the type of errors would be affected by the prior experience with a systematic trajectory of change. It is noteworthy that in the Control and Size-only conditions, performance was *not* signi cantly different for test comparisons where the saturation was different than it was for comparisons where the saturation was the same. Thus, size and saturation were fairly separable in these two conditions. The fact that the gap in the number of False Alarms widened in the two covaried conditions over the two independent conditions is taken as support for the second hypothesis: It appears that coherent, predictable change along both the size and saturation dimensions caused them to become more integral, such that saturation differences had signi cantly more of an effect on size comparisons. This nding has developmental implications, providing a possible account for how low-level *features* and *properties* that start out as perceptually distinct can congeal into perceptual *dimensions* when they are experienced as covarying in a predictable and coherent way. One thing that is very interesting about the present results is that it took only a relatively short exposure (80 seconds) to such regularity to produce this effect! Further, the effect appeared to decay slowly (not measurably) over the course of the experiment. Taken together, the quick adaptation and slow decay of the effect suggest that an interesting avenue of future research will be to explore the relationship between the amount of experience with certain types of transformation and the duration of the adaptation. This type of predictive learning of correlations may well be a potent part of the developmental process.

Signal Detection Theory: An Alternative Explanation
Signal Detection Theory (SDT) is a type of analysis that assumes that the system responsible for making decisions is inherently noisy, such that, for example in the case of this experiment, even when the shapes are obviously very different in size there is still a chance that the subject will respond Same Size . What makes SDT really useful here is that it provides a way of separating subjects' propensity to respond Same Size (their *bias* or *criterion*) from their ability to tell the difference between the Same Size test trials and the Different Size trials. The predicted perceptual spreading effect should result in a decrease in this second ability, not merely a change in bias. And, importantly, there was a signi cant difference in discriminability (d') triggered by experience with the Size-change transformations. Subjects had a harder time distinguishing between Same Size and Different Size test trials in these conditions, as the spreading hypothesis would predict.

The assumption of inherent noise that underlies SDT also provides another way to explain the data. It is possible that priming the system with changing size (dynamic priming), increased the internal noise in the perceptual system related to size judgements. (In SDT terms, this amounts to increasing the variance of both the signal absent and signal present distributions.) This would show up in the analysis as a decrease in d', as seen. This provides a potentially useful description at a different level of abstraction. Indeed, the uncertainty stemming from the proposed predictive mechanism

might provide a mechanistic explanation (at a lower level) for the increased noisiness.

Yet another possibility, and perhaps a simpler account of the present data than the adaptive prediction hypothesis, is that the dynamic priming of size increased the children's sensitivity to size differences, enabling them to make ner-grained distinctions of size. In this case, the inherent noisiness of the system would have more of an effect. Subjects would be more sensitive to very slight discrepancies in size caused by noise and would be less likely to respond Same Size in general (i.e., they would both Miss more and False Alarm less). This would show up in the analysis as a difference in their response bias, β.

The fact that there was a marginally signi cant increase in β in the three Size-change conditions means that this hypothesis cannot be ruled out here as a possibility.[4] It should be noted that this alternative only offers an explanation for the overall decrease in performance in the three Size-change conditions relative to the Control condition, but it does not address the effects related to increased Integrality. Nor does this bias-shift account explain the (more signi cant) shift in d', which indicates that subjects in the size-change conditions really did have more dif culty distinguishing the Same Size test trials from the Different Size trials. For this, an adaptive, prediction mechanism still seems to be reasonable.

A motion aftereffect? The analysis of the probability of error as a function of trial is interesting because it shows that the induced effect does not decay rapidly. If it were a typical motion aftereffect, 80 seconds of exposure to the animation motion might be expected to trigger on the order of 10 seconds of aftereffect, as motion aftereffects typically decay with the square root of the time exposed to the inducing motion (Anstis et al., 1998). Yet the error rate showed only a very slow decay, lasting over a minute.

Furthermore, the present effects are also set apart from typical motion aftereffects in that they occur after seeing *bidirectional* motion. Motion aftereffects typically occur in the opposite direction from the direction of inducing motion (Anstis et al., 1998). The theory behind this is that the visual system adapts to correct what it (mistakenly) takes to be drift in the neurons detecting motion in the inducing direction and lowers their weight relative to neurons sensitive to motion in the opposite direction. If this accurately re ects what really happens (in a MAE), then bidirectional motion should not produce the aftereffect because there will be no incentive for the visual system to suspect drift in the rst place, the opposing motions will cancel each other out.

Thus, it would appear that the effect observed in this experiment is a new and different type of perceptual adaptation that is related to traditional motion aftereffects, but underwritten by a potentially different mechanism.

Model Simulation

The basic principle of perceptual prediction was embodied in a connectionist model consisting of a simple recurrent network (Elman, 1990). Its task was to actively sample its sensory input and try to predict how it changes in time. By its nature, such a network allows for supervised learning in the sense that it can validate its predictions by what eventually happens. Thus, whenever the model encounters consistent, gradual, continuous variation (for which it cannot already account), it might actively train itself to predict this variation. The model was constructed such that its predictions could be fed back into its input units, enabling extrapolation in time and giving perception temporal extent .

There is not room in this paper to go into the details of the input representation and training procedure. Basically, a shape was represented by its values on the size and saturation saturation dimensions. There were three different training sequences corresponding to the four animation conditions in the experiment. (The Correlated and Anti-correlated conditions were equivalent in the model representations, so they were combined into a single simulation condition called Covaried .) For each pattern in a sequence, the network was trained to predict the next pattern. A small amount of noise was injected into this process.

Sixteen networks were trained and tested in each condition on the same sequences of test pairs that the children saw in the experiment. The model made *comparisons* as follows: Given two patterns to compare, one was chosen to go rst, passed through the network and the outputs were buffered. Then the other pattern was passed through the network and its outputs on the nine size units were compared to the buffered outputs of the rst pattern using a cosine distance metric. If they fell within 30 degrees of one another, the process was stopped. If not, the buffered outputs from the two patterns were then fed back in as inputs (keeping the same context layer activations).[5] This process repeated until either the output vectors eventually came within $\lambda = 30$ degrees of one another or 10 iterations had gone by. Whenever this process terminated, the following value was calculated:

$$\text{How Different} = \text{Iterations Required} + \frac{1 - cos(\theta)}{1 - cos(\lambda)}. \quad (1)$$

This equation gives an estimate on how different the two (*dynamic*) representations were from one another. The more iterations that were required, the more different the patterns were. θ is the nal angle between the two output vectors.

Finally, the model decided whether or not to say Same Size for the patterns based upon how different they were from one another. The likelihood of saying same was inversely proportional to the score computed by Equation 1. This was operationalized with:

$$\text{Say Same} = (rand < \exp(\frac{-\text{How Different}}{\beta})) \quad (2)$$

where *rand* was a random number uniformly distributed between 0 and 1, and β was a bias parameter that was set to 2 for this simulation.

Results and Discussion Figures 4 and 5 show the average Misses and False Alarms (respectively) over the simulation runs. These are comparable to Figures 1 and 3.

As can be seen, the basic trends that were present in the child data were also present in the model simulations. In particular, there were signi cantly more misses in the Size-change conditions as compared to the Control condition. Furthemore, the degree of integrality signi cantly increased in

[4] This has been taken up in other experiments not reported here.

[5] The prediction of dynamic spreading stems from this.

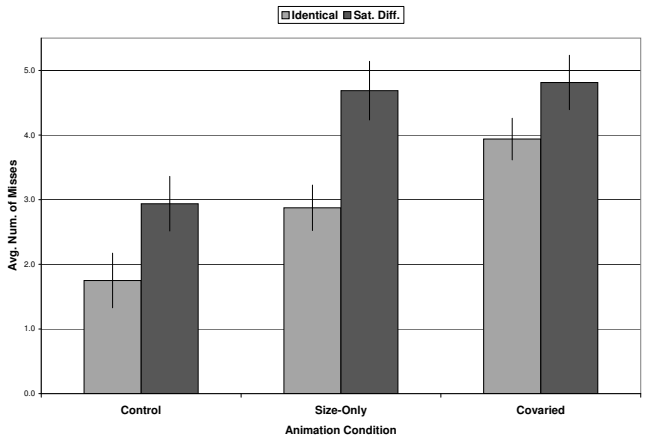

Figure 4: Misses from model simulation

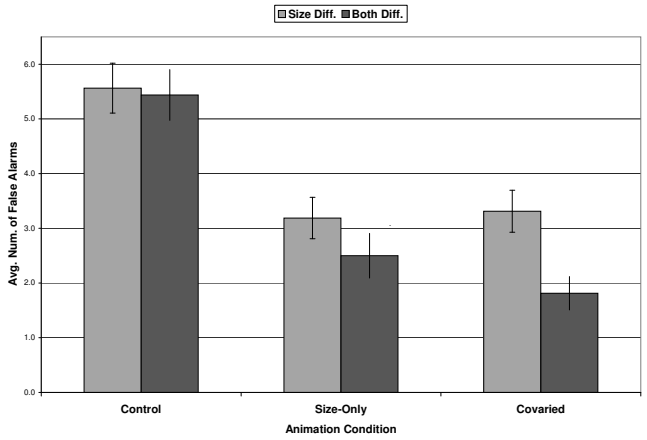

Figure 5: False Alarms from model simulation

the Covaried condition as seen in the increased False Alarm gap of Figure 5. This was due to the fact both the size and saturation dimensions shared the hidden layer and the network learned that each of these dimensions was a good cue to predict the next state of the other.

General Discussion

At the core of this paper is the idea that our perceptual systems are oriented around *transformations*. Transformations contain rich information about the structure of the world. Indeed, it is through this temporal structure that we perceive atemporal structure. (For example, movement is necessary for the detection of occluding edges.) Furthermore, perception itself is a process: it has temporal extent. There is never a single instant when we achieve a percept.[6] Moreover, given that the objects of our perception can be changing at the same time we are perceiving them, it behooves us to learn to anticipate their transformations.

The experiment presented herein was designed with this in mind. It provided evidence for a perceptual adaptation in response to brief experience with a predictable trajectory. It showed that there is a dynamic component involved in perception, even with *static* shapes that are *perceptually present*. It also showed that experience with coherent transformations might have developmental consequences, given that the adaptation caused two dimensions that were initially fairly separable to become more integral. The model simulation then tried to esh out one way a simple predictive mechanism could simultaneously explain both of these effects.

Taken together, these data support the idea that perceptual adaptations go beyond being temporary adjustments to unusual environments and can have important developmental consequences. Indeed, this is the real stuff of development. Long term effects are achieved as the accumulated result of many small tweaks to the system occurring on a situation-by-situation basis. Thus, understanding how the perceptual system can and does adjust in short time windows to speci c situations should be useful towards increasing our understanding of the type of lasting changes that the architecture can achieve. These results are admittedly only a rst step in that understanding, but they do indicate several directions for future work in this regard.

Abstract

An important study by Münte, Schiltz, and Kutas [Nature *395* (1998) 71-73] using ERPs (=Event-Related brain Potentials) suggested that sentences starting with the temporal connective *before* are more taxing for working memory than sentences starting with *after*, as evidenced by a slow negative shift for *before* sentences. According to Münte et al., *before* sentences present events out of the correct chronological order, as in *Before the author submitted the paper* [=second event], *the journal changed its policy* [=first event]. In order to come up with the correct discourse representation of the sentence, the correct chronological order has to be restored, leading to extra memory load. In the present experiments using a self-paced reading paradigm it will be shown that *before* sentences are not more difficult to process than *after* sentences, but that they are even read faster than *after* sentences. In addition, it is shown that *before* sentences in which events are presented in the *correct* chronological order, as in *The journal changed its policy* [=first event], *before the author submitted the paper* [=second event] are read more slowly than corresponding sentences with *after*. Implications for Münte et al.'s theory are discussed and objectives for future research are formulated.

Introduction

Readers do not wait with the interpretation of a sentence until they have received the final word. On the contrary, the process of understanding sentences occurs in a highly incremental fashion, approximately as each word is encountered (e.g., Altmann & Steedman, 1988). A striking illustration of this phenomenon is provided by Münte, Schiltz, and Kutas (1998). In a study using ERPs (=Event-Related brain Potentials), they showed that sentences starting with the temporal connective *before* were processed differently from sentences starting with *after*. Almost immediately after presentation of the temporal connective, the ERP waveforms for the *before* and the *after* sentences started to diverge, with the more negative values for the *before* sentences. Münte et al. argued that this negative shift reflected the additional discourse-level processing that is necessary to deal with sentences that present events out of their correct chronological order. Consider, for instance, sentence 1a, which is an example sentence of the materials used by Münte et al. (1998).

1a. Before the author submitted the paper, the journal changed its policy.

Here, the event of submitting a paper precedes the event of policy change in this specific *sentence*, but in *reality*, the policy change happened first, which can be described as `Before [Event2], [Event1].` In contrast, sentences starting with *after*, such as 1b, present the events in their correct chronological order, exactly as they purportedly happened in reality: first a submission, then change of policy, so: `After [Event1], [Event2].`

1b. After the author submitted the paper, the journal changed its policy.

As the size of the negative shift in the ERP waveforms turned out to be highly correlated with the individual working memory spans of the participants (the higher the memory span, the larger the effect), Münte et al. concluded that the problem with *before* sentences is really a working memory problem. In other words, it is claimed that when reading a sentence starting with *before*, readers immediately realize that the events that they are going to read about will have to be re-ordered at some stage to arrive at a coherent and valid semantic representation of the sentence. Thus, the temporal connective *before* may act as a kind of cognitive operator instructing the language processor to hold in memory the event reported on in the first clause, in order to enable the reconstruction of the events in their correct chronological order, presumably after the sentence has been read.

There are, however, a number of problems with this interpretation. First of all, there is no *a priori* reason to interpret a *negative* shift as evidence for processing difficulty or any other form of effortful (memory-related) processing. For instance, a well-known ERP component such as the 'P600' is a *positive* component (occurring about 600 ms post-onset of a critical stimulus), which can be evoked by a number of syntactic problems, such as ungrammatical sentences (Osterhout & Holcomb, 1992), correct sentences with an unpreferred syntactic structure

(Hagoort, Brown, & Groothusen, 1993), syntactically complex sentences (Kaan, Harris, Gibson, & Holcomb, 2000), and even in sentences with a correct syntactic structure that are semantically anomalous (Hoeks, Stowe, & Doedens, 2004). In other words, it cannot be excluded that for some reason or other the *after* sentences are the most difficult, and that this processing difficulty is reflected as a *positive* shift in the ERP signal.

But even if the negativity does indicate processing problems, and the *before* sentences are actually the most difficult, there is another reason why the interpretation of Münte et al might be wrong. For example, if we take a look at the data that Münte et al. provide on the participants with the high and the low working memory score, visual inspection of the waveforms suggests that the ERPs for the *before* sentences actually do not differ between the two working memory groups. Shouldn't these *before* sentences be extra taxing for the group with the smallest working memory capacity, as compared to the high working memory group? What we see instead is a difference between the groups for the *after* sentences, which are more *positive* for the group with the high working memory score. This is quite unexpected, given that the *after* sentences are relatively 'easy' and do not tax memory at all, at least much less than *before* sentences, as Münte et al. claim. In addition, there is only a very slight difference in the low working memory group between the the 'difficult' *before* sentences and 'easy' *after* sentences, which is also rather unexpected. It is not immediately clear how this pattern of results should be interpreted, but it is clear that it does not support Münte et al.'s hypotheses.

In the light of these problematic aspects it seems necessary that two specific issues regarding the processing of sentences with temporal connectives be resolved. First, it is very important to find out whether *before* sentences are more difficult than *after* sentences, or whether it is the other way around. Once this is known, we also know how to interpret the negative shift for *before* sentences reported by Münte et al. Indeed, we might be looking at a *positive* shift, if the *after* sentences turn out to be the most difficult. Secondly, if *before* sentences are more difficult than *after* sentences, we should be able to establish whether this is caused by the chronological order of the events described in the sentence or perhaps by other factors. In the present experiment we will focus on exactly those issues using a self-paced reading paradigm.

The first issue can be tackled rather straightforwardly: by measuring the time people take to read the sentence in either the *before* or the *after* version, we can establish which condition is the most difficult, as it will be read more slowly. The second issue is more complicated, but can be investigated in the following way. Consider sentence 2a, which is an example sentence from the present experiment (with English translation in brackets).

2a. Voordat Piet de sinas dronk, at Stefan de koekjes op.
(Before Piet drank the soft drink, Stefan ate the biscuits)

This sentence presents the events out of chronological order, as did sentence 1a. The 'drinking' event which is mentioned first, actually happened later than the 'eating' event. However, in a sentence such as 2b, the events are presented in their chronological order again.

2b. Stefan at de koekjes op, voordat Piet de sinas dronk.
(Stefan ate the biscuits, before Piet drank the soft drink)

Thus, sentence 2b should not be problematic at all, and be processed faster than a similar sentence with *after* in the second clause (e.g., Stefan ate the biscuits [event2], after Piet drank the soft drink [event1]).

Experiment 1

This experiment is a reading time experiment in which participants read sentences for comprehension and made semantic plausibility judgments after reading each sentence.

Method

Participants Forty native speakers of Dutch were paid for participating in this experiment (28 female; mean age 21 years, age range 18-30). All were currently receiving a university education.

Materials & Design For this experiment, 80 sets of sentences were constructed, each set consisting of eight versions of a given item. Experimental lists were constructed with 10 experimental items per condition, and no list containing more than one version of a given item. All 80 experimental sentences were plausible as determined by two expert raters. An equal number of implausible filler sentences (see sentence 4 below for an example) were added such that each list contain an equal number of plausible and implausible items. The purpose of the semantic plausibility test and the implausible fillers was to encourage deep semantic processing of the experimental sentences.

The order in which experimental and filler items appeared was determined semi-randomly and was the same for each list. Each list was presented to an equal number of participants (i.e., five) and each participant saw one list. Only the first four of the eight conditions belong to the present Experiment 1; the other four conditions were part of a related experiment that will be discussed below as Experiment 2. The experimental sentences for the first experiment appeared in the following forms:

3a. **Before (first clause), Incorrect order (E2 - E1)**
Before Piet drank the soft drink [E2], Stefan ate the biscuits [E1].

3b. **After (first clause), Correct order (E1 - E2)**
After Piet drank the soft drink [E1], Stefan ate the biscuits [E2].

3c. **Before (second clause), Correct order (E1 - E2)**
Stefan ate the biscuits [E1], before Piet drank the soft drink [E2].

3d. **After (second clause), Incorrect order (E2 - E1)**
Stefan ate the biscuits [E2], after Piet drank the soft drink [E1].

The filler sentences had exactly the same form as the experimental sentences (in exactly the same quantities) but were semantically implausible, as sentence 4.

4. Before the murder was committed, the police found the dead body.

A practice session consisting of 30 items preceded the actual experiment.

Procedure Participants were seated behind a computer screen in a sound-proof cabin. Each sentence was preceded by an asterisk indicating the start of a new sentence. Participants were instructed to use the 'b'-key on a keyboard before them to read the sentence clause-by-clause. That is, after the first key-press the asterisk disappeared and the first clause appeared (e.g., "Before Piet drank the soft drink,"); after the second press the first clause disappeared and the second clause appeared (e.g., "Stefan ate the biscuits."); at the next press the second clause disappeared and the question "Goed?" (="Correct?") appeared. Participants had to press the right SHIFT button to indicate that the sentence was semantically plausible, and the left SHIFT button if they felt it was not. Each response was followed by feedback on the correctness of the answer (i.e., "Correct!" / "Wrong!"). Participants were asked to read the sentences carefully and to respond as quickly as possible without compromising accuracy. After the feedback the asterisk reappeared. In all, the experiment took approximately 20 min.

Results

Analysis First, reading time data were screened for outliers. Reading times less than 200 or greater than 4000 ms were excluded. After that, all observations were excluded which deviated more than 2.5 *SD*s from either the participant or the item mean of each clause in each condition. Two analyses were performed: an *F1*-ANOVA on the condition means for each participant and an *F2*-ANOVA on the condition means for each item. The factors Temporal Connective (*before* vs. *after*), Connective Position (in first clause vs. in second clause), and Clause (first clause vs. second clause) were treated as within-participants and within-items factors. In the participant-based analyses, the factor List (i.e., grouping together participants that were presented with the same list) was also included in the analyses as a between-participant factor, and in the item-analyses the factor Itemgroup (i.e., grouping together items that appeared in the same condition in each list) was entered as a between-items factor. Both factors had 8 levels as there were 8 lists and 8 itemgroups (see design section above). In addition, accuracy percentages were calculated per condition. Mean reading times and accuracy are presented graphically in Figure 1.

Accuracy As can be seen in Figure 1, accuracy was high for each condition (overall accuracy 90 %). No significant interactions or main effects were found (all F-values < 1).

Reading Times The 3-way interaction between Temporal Connective x Connective Position x Clause was significant in the analysis on items (F2(1,72)=4.12; p<.05) and marginally significant in the participant analysis (F1(1,32)=3.23; p=.08). Post Hoc analyses showed that there was no significant difference between *before* and *after* sentences as far as the first clause is concerned (though reading times of first clauses containing *before* were numerically smaller than those of first clauses containing *after*). Much larger differences were found in the second clause. The second clause of sentences with *before* in the first clause was read significantly faster than of sentences with *after* in the first clause (p<.05). The opposite pattern, however, was found for the sentences with the temporal connective in the second clause: here, the *before* sentences were read more slowly than the *after* sentences, though this difference was only marginally significant (p=.09).

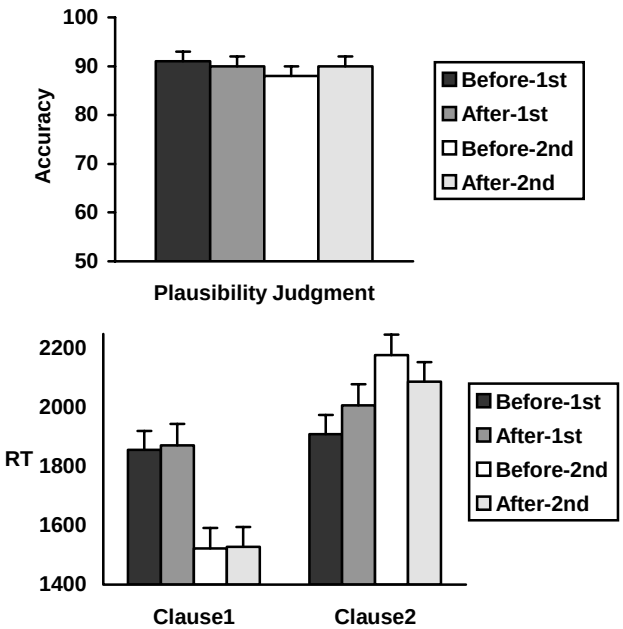

Figure 1. Accuracy (in percentages, upper panel) and Reading times (in ms, lower panel) for Experiment 1. "Before/After-1st"=temporal connective in first clause; "Before/After-2nd"= connective in second clause.

A number of other effects were significant, which should of course be interpreted with caution in the presence of the significant 3-way interaction. For instance, the 2-way interaction of Connective Position and Clause was significant (F1(1,32)=107.16; p<.0001; F2(1,72)=87.80; p<.0001), reflecting longer reading times for the clause in which the temporal connective was present (connective in first clause: first clause: 1865 ms, second clause: 1525 ms; connective in second clause: first clause: 1959 ms, second clause: 2138 ms). More interestingly, there was also an interaction between Connective Position and Temporal Connective (F1(1,32)=5.06; p<.05; F2(1,72)=4.80; p<.05), indicating that *before* sentences as a whole were read faster when the temporal connective appeared in the first clause (*before*: 1884 ms; *after*: 1940 ms) than when it appeared in the second clause (*before*: 1854 ms; *after*: 1808 ms). No other effects concerning Temporal Connective were significant (all F-values < 1). The factors Clause (Clause 1: 1695 ms; Clause 2: 2048 ms) and Connective Position (connective in first clause: 1912 ms; in second clause: 1831

ms) had significant main effects ($F1(1,32)=34.80$; $p<.0001$; $F2(1,72)=84.98$; $p<.0001$, and $F1(1,32)=10.08$; $p<.005$; $F2(1,72)=13.69$; $p<.0001$), respectively).

Discussion

This experiment yielded two important results. First, in the conditions where the temporal connective appeared in the first clause, there was no evidence at all for *before* sentences being more difficult than *after* sentences as expected on the basis of Münte et al.'s arguments (1998). Quite on the contrary, the first clause of *before* sentences was read numerically faster than the first clause of *after* sentences. More importantly, the second clause of *before* sentences was read *significantly faster* than that of *after* sentences, with an average advantage of 97 ms for the *before* sentences. This finding clearly indicates that *before* sentences are in fact easier to process than *after* sentences, contra Münte et al.'s predictions. So perhaps the slow negative shift for the *before* sentences is actually a slow *positive* shift for the more difficult *after* sentences.

The second important result comes from the conditions where the temporal connective was placed in the second clause. Here, we see no difference in reading times in the first clause, which is as one would expect given that there is no difference between the conditions yet, as the temporal connective only appears in the second clause. We do see substantial differences in the second clause, but in a direction opposite to Münte et al.'s predictions. Recall that the *before* sentences with the temporal connective in the second clause present the events in the correct chronological order (see sentence 3c), in contrast to sentences with *after* in the second clause (see sentence 3d). This should have solved the problems of increased memory load and thus have led to a processing advantage for the *before* sentences as compared to the *after* sentences. However, what we find is a 110 ms *dis*advantage for *before* sentences with the events in the 'correct' temporal order. This strongly suggests that presenting events out of chronological order does not lead to processing difficulty. It even seems that presenting events in the correct chronological order leads to an increase in processing difficulty.

Summarizing, this experiment showed, contrary to expectation, 1) that sentences starting with *before* are easier to process than sentences starting with *after*, and 2) that presenting events out of chronological order does not cause processing difficulty.

Experiment 2

Experiment 1 was intended to answer two straightforward questions about the processing of temporal connectives: 1) are *before* sentences more difficult than *after* sentences, and 2) is that the case because before sentences present events out of chronological order? We have seen that neither one was true. Experiment 2 was more exploratory, focussing on the possible interaction between *temporality*, or the chronological ordering of events, with the processing of *referential expressions* which is another important aspect in the construction of a coherent discourse representation (Garnham, 1999). The main issue here is whether temporal and referential processing draw on the same resources, or whether they are processed in parallel by independent mechanisms.

It is assumed that the use of referential elements such as pronouns (e.g., 'he' or 'she') in a sentence may increase the processing load during comprehension. When a pronoun is encountered, a search process needs to be initiated in order to find the intended *referent* for the pronoun (i.e., the person or thing that is referred to by the pronoun). It has been shown that this search process can be more costly than for instance having a proper name (e.g., *Stefan*) where no search process is necessary (Streb, Rösler, & Hennighausen, 1999).

In Experiment 2, the materials from Experiment 1 were used, except that in each sentence a pronoun was inserted, as in sentence 5a.

5a. Stefan at de koekjes op, voordat hij de sinas dronk.
(Stefan ate the biscuits, before he drank the soft drink)

In this sentence, the pronoun *he* appears in the second clause and is used *anaphorically*, that is, it refers back to an entity that is mentioned earlier (in this case *Stefan*). Although there is a pronoun present that might induce a search process, it does not seem likely that in this specific case this search process is in any way difficult. In fact, in a sentence such as 5a there is only one possible referent (i.e., *Stefan*) and the use of a proper name, permitting immediate identification of the referent, would even be sub-optimal (see e.g., Gordon, Grosz, & Gilliom, 1993, regarding a phenomenon called the 'repeated name penalty'). However, if the pronoun were to *precede* its referent, this might be taxing for working memory, or lead to other processing difficulty, because it will not be possible to fully process the clause that contains this pronoun before the referent is known. Consider 5b, for an example of such a sentence.

5b. Voordat hij de sinas dronk, at Stefan de koekjes op.
(Before he drank the soft drink, Stefan ate the biscuits)

In this sentence, the pronoun is used as a *cataphor*, or *backwards anaphor* (Garnham, 1999), and refers to an entity that will be mentioned later. Because the first clause cannot be fully interpreted as it lacks crucial information on whom the pronoun refers to, and because the reader does not know when this referent will be presented, it seems reasonable to assume that these sentences are difficult to process, as compared to sentences such as 5a. If this kind of effortful processing of cataphors is handled by the same mechanism that is responsible for temporal processing one would expect an interaction between these two factors. If, on the other hand, these two kinds of processes proceed in parallel and are carried out by independent systems, then there will be no interaction.

In summary then, Experiment 2 aims to clarify two things:

1) whether cataphoric constructions are more difficult to process than anaphoric ones, and

2) whether this difference in processing load has a (possibly differential) effect on how *before* and *after* sentences are handled. In other words, do temporal and referential processes interact?

Method

Participants, Design, & Procedure Participants, design and procedure are described in the method section of Experiment 1.

Materials Most aspects of the materials are described above in the materials section of Experiment 1, except for the conditions of the current experiment, which were the following:

6a. **Before (first clause), Incorrect order, cataphor**
Before he drank the soft drink [E2], Stefan ate the biscuits [E1].

6b. **After (first clause), Correct order, cataphor**
After he drank the soft drink [E1], Stefan ate the biscuits [E2].

6c. **Before (second clause), Correct order, anaphor**
Stefan ate the biscuits [E1], before he drank the soft drink [E2].

6d. **After (second clause), Incorrect order, anaphor**
Stefan ate the biscuits [E2], after he drank the soft drink [E1].

Note that a full factorial design is not possible, as sentences with a pronoun in the first clause and a connective in the second clause are ungrammatical when the pronoun is intended to refer to the entity mentioned in the second clause (as in: "$He_{(i)}$ drank the soft drink, before $Stefan_{(i)}$ ate the biscuits"). Instead, a reduced design was chosen that would enable us to answer some important questions regarding the interaction of temporal and referential processing.

Results

Analysis After screening for outliers (see Experiment 1), mean RTs and mean accuracy percentages in each condition were calculated for both participants and items. Figure 2 presents the mean reading times and accuracy for Experiment 2.

Accuracy As can be seen in Figure 2, accuracy was high for each condition (overall accuracy 87 %). The main effect of Temporal Connective was marginally significant in the participant-based analysis ($F1(1,32)=2.80$; p=.10), but not in the item-based analysis ($F2(1,72)=1.74$; p=.19), indicating a trend for slightly greater accuracy in the *before* sentences (89%) as compared to the *after* sentences (86%). There was no significant effect of Connective Position (F-values < 1).

Reading Times The 3-way interaction between Temporal Connective x Connective Position x Clause was not significant in the present experiment (both F-values < 1). The interaction of Temporal Connective and Clause was significant in both participant-based and item-based analyses (F1(1,32)=5.89; p<.05; F2(1,72)=8.95; p<.005). This interaction is caused by *before* sentences taking longer than *after* sentences in the first clause (i.e., 1558 vs. 1519 ms, respectively) with a reverse pattern for the second clause (i.e., *before*: 1917 ms vs. *after*: 1999 ms). None of these two separate contrasts were significant, however (p-values>.20). Perhaps more importantly, there was also a trend towards an interaction between Temporal Connective and Connective Position (F1(1,32)=3.07; p=.09; F2(1,72)=1.67; p=.20), suggestive of shorter times for *before* sentences as a whole when the temporal connective appears in the first clause (i.e., *before*: 1704 ms vs. *after*: 1762 ms), contrasting with the pattern of results when the temporal connective appears in the second clause (i.e., *before*: 1771 ms vs. *after*: 1756 ms).

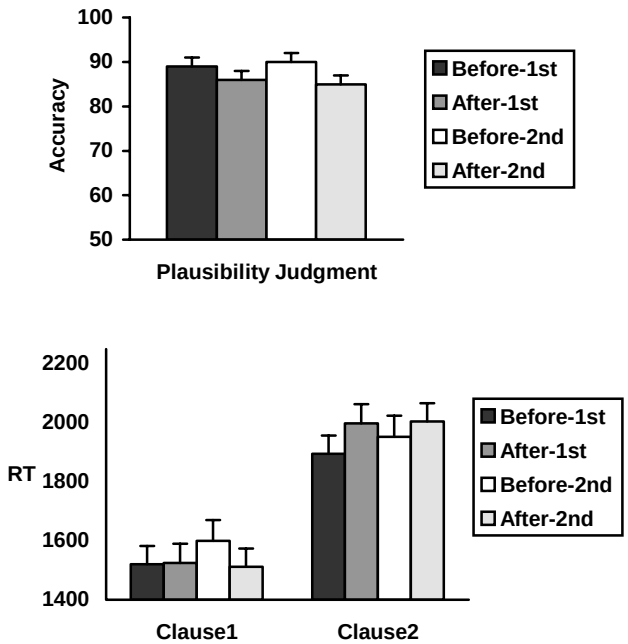

Figure 2. Accuracy (in percentages, upper panel) and Reading times (in ms, lower panel) for Experiment 2. "Before/After-1st"=temporal connective in first clause, pronoun is cataphor; "Before/After-2nd"=temporal connective in second clause, pronoun is anaphor.

As to the main effects, there was a marginally significant main effect of Connective Position (F1(1,32)=1.55; p=.22; F2(1,72)=3.06; p=.09), suggesting that sentences take longer to read when the temporal connective appears in the second clause than when it is present in the first clause (i.e., 1764 ms vs. 1733 ms). Finally, there was a significant main effect of Clause (F1(1,32)=56.37; p<.0001; F2(1,72)=195.57; p<.0001), reflecting the large difference in reading times between first clause (1539 ms) and second clause (1958 ms). There was no main effect of Temporal Connective (*before*: 1737 ms; *after*: 1759 ms; p-values >.30).

Discussion

The aim of this experiment was to establish whether cataphoric constructions were more difficult to process than anaphoric ones, and also whether any difference between them would affect the processing of temporal structure. Some tentative evidence for such an interaction seems to come from the finding that *before* sentences are faster than

after sentences when containing cataphors, but not when containing anaphors. However, this might very well be the result of an unfortunate 'blip' in the data, that is, the fact that reading times for the first clause differ between conditions that had identical first clauses (i.e., of sentences with the connective in the second clause). It is not unlikely either that the marginally significant main effect of Connective Position, another indication of a possible difference between cataphors and anaphors, is caused by just that spurious effect. So what can we say about cataphors and anaphors then?

What we can say about cataphors is that they do not seem to be hard to process. Perhaps the most striking difference between the present two experiments is the large reduction in first clause reading times when proper names / NPs (i.e., in Exp. 1) are replaced by cataphoric pronouns (i.e., in Exp. 2), indicating that inserting cataphoric pronouns makes sentences easier. However, because these clauses differ between experiments in the lexical material they contain, no strong conclusions can be drawn from this outcome. What is equally apparent, however, is that cataphors do not *create* a difference between *before* and *after* sentences: there is no difference at all in the first clause and only a slight difference in the second clause, which is numerically almost identical to the pattern of results in Experiment 1 (for sentences with the temporal connective in the first clause, see also Figure 1). As for anaphors, it seems clear that they do not cause processing difficulty either. On the contrary, they seem to make the processing of *before* sentences easier, if we compare the results of both experiments: In Experiment 1 *before* (with the correct order of events) was read more slowly than *after* (with the incorrect order of events) in the sentences with the connective in the second clause; in Experiment 2 this is (numerically at least) the other way around. In summary then, the outcome of this experiment strongly suggests that cataphors are not difficult to process, that anaphors are even easier, and that chronological order of events is not a factor of importance.

Conclusion & Future Directions

The present experiments have convincingly shown that *before* sentences are actually *easier* to process than *after* sentences. In addition, it has become clear that the chronological order of events does not strongly influence ease of sentence processing. Finally, as there was no strong evidence for an interaction between temporal and referential processing, it is still a bit unclear whether these two kinds of information are processed by the same or by different cognitive mechanisms.

When we try to understand the Münte et al. results in the light of the present findings, we must conclude that the slow potential difference building up while the sentence is read should not necessarily be interpreted as a negativity for the *before* sentences, but rather as a positivity for the *after* sentences. In addition, this slow wave difference does not seem to be related, or at least not directly, to presenting events in or out of their correct chronological order, nor with memory processes *per se* (recall that the low working memory group from Münte et al. did not show a difference between *before* and *after* sentences). This leaves us with a lot of new questions: why are *after* sentences more difficult to process than *before* sentences? and how should we then conceive of the relationship between working memory capacity and temporal processing, if it does not work as Münte et al. hypothesized? It is possible that connectives (and also pronouns) evoke certain processing strategies that do not tax memory, or only minimally. Hoeks and Stowe (2002), for instance, have speculated that *before* might activate a relatively cost-free 'temporal ordering frame' (maybe only available for individuals with high working memory capacity?) that allows for fast sentence integration, whereas *after* does not. More research focussing on these processing aspects of temporal connectives is definitely needed. But also research using language corpora in order to establish both form and function of different kinds of temporal expressions in text and communication.

Abstract

We describe the construction of statistical models that provide inferences about the probability that subjects will consider events to be memory landmarks. We review methods and report results of experiments probing the classification accuracy and receiver-operator characteristics of the models. Then, we discuss opportunities for integrating models of memory landmarks into computing applications, and present a prototype time-line oriented content browsing tool.

Introduction

Studies of memory support the assertion that people make use of special landmarks or anchor events for guiding recall (Shum, 1994; Smith, 1979; Smith, Glenberg & Bjork, 1978)) and for remembering relationships among events (Davies & Thomson, 1988; Huttenlocher & Prohaska, 1997). Such landmarks include both public and autobiographical events. More generally, there has been significant study and modeling of episodic memory, where memories are considered to be organized by *episodes* of significant events, including such information as the location of an event, attendees, and information about events that occurred before, during, and after each memorable event (Tulving, 1983; Tulving & Thomson, 1980). Memory has been shown to also depend on the reinstatement of not only item-specific contexts, but also on more general context capturing the situation surrounding events.

We believe that automated inferences about important memory landmarks could provide the basis for new kinds of personalized computer applications and services. Rather than focusing on specific machinery proposed as models for recall (*e.g.,* Malmberg, Steyvers, Stephens, *et al*.,. 2002;. Raaijmakers & Shiffrin, 2002; Shiffrin & Steyvers, 1997), we set out to investigate the feasibility of directly learning models of memory landmarks via supervised learning. We focus here on the construction, testing, and application of predictive models of memory landmarks, based on events drawn from users' online calendars.

We first review experiments with the construction of personalized models of memory landmarks. We describe how we construct models that can be used to infer the likelihood that events will serve as memory landmarks, reviewing the extraction of data from subjects' online calendars, the collection of assessments about landmarks with tools that enable subjects to label their calendar events, and the learning of models via Bayesian learning procedures. After reviewing the performance of the models, we describe, as a sample direction for the use of predictive models of memory landmarks in computing applications, a prototype, named MemoryLens Browser. MemoryLens Browser employs the inferences about landmarks in visualizations for browsing files and appointments. Finally, we review research directions aimed at enhancing coverage and discriminatory power of models of memory landmarks.

Accessing Events and Event Properties

We will focus on the construction of models of memory landmarks derived from users' online calendar information. Electronic encodings of calendars provide rich sources of data about events in users' lives. People who rely on electronic calendars, often encode multiple types of events in an online format. Such items include appointments, holidays, and periods of time marked to indicate such activities as travel and vacation. In large enterprises that rely on computer-based calendaring systems, appointments and events are typically formulated, accepted, displayed and managed via schemas capturing multiple properties of the events.

We developed a calendar event crawler that works with the Microsoft Outlook messaging and appointment management system. The crawler analyzes a user's online calendar to create a case library of events and properties associated with each event. The calendar crawler extracts approximately 30 properties for each event. Most of these properties are obtained directly from the online data and metadata stored for events. These properties include the *time of day* and *day of week* of events, *event duration*, *subject*, *location*, *organizer*, *number of invitees, relationships between the user and invitees*, the *role of the user* (*i.e.,* user was the organizer, a required invitee, or an optional invitee), *response status* of the user to appointment invitations (*i.e.,*

user responded *yes*, responded *tentative*, *no response*, or *no response request made*), whether the meeting is *recurrent* or *not recurrent*, whether the time is marked *as busy or free* on the user's calendar, and the nature of the *inviting email alias*—the alias used to send the meeting invitation.

In addition to properties in the database schema employed by Outlook, a subsystem of the crawler accesses the Microsoft Active Directory Service to identify organizational relationships among the user, the organizer, and the invitees, noting for example, whether the organizer and attendees are *organizational peers*, *direct reports*, *managers*, or *managers of the user's manager*.

Beyond the use of data from Outlook and Active Directory Services, we created several derived properties representing statistics about atypical situations, based on the intuition that rare contexts might be more memorable than common ones. In particular, we developed procedures for computing *atypical organizers, atypical attendees,* and *atypical locations.* We compute a measure of the rarity for these properties of events by considering the portion of all meetings over all events under consideration or for a fixed period of time (*e.g.,* events over a year) in which the property under consideration has the same value it has in the event at hand. For the studies reported here, we computed atypicality based on all events under consideration.

To compute the value of *location atypia* for events, we first compute the number of times each location has appeared in a user's calendar over a fixed period. The system then discretizes the *location atypia* variable into a set of states, capturing a range of percentiles, and the location atypia variable for each event acquires a particular value based on the rarity of the location associated with that event.

An analogous derivation is used for computing *organizer atypia* and *attendee atypia*. For these variables, all people attending all of the appointments for the fixed period under consideration are analyzed, and the portion of a subject's appointments attended or organized respectively by each attendee is noted. A meeting acquires the *organizer atypia* or *meeting atypia* value associated with the least frequent attendee or organizer of the meeting.

Building Models of Memory Landmarks

We recruited 5 participants from our organization for data collection and tagging. We asked the subjects to review a list of all of the appointments, holidays, and other annotations stored in their calendars that were extracted automatically by a calendar crawler, and to identify the subset of events that they viewed as serving as salient, memory landmarks. More specifically, we directed the subjects to do the following:

> *Please review the events on your calendar and identify those events that would serve as key memory landmarks on a timeline of events for such purposes as searching for files and appointments.*

Each subject downloaded software components and executed the event-collection program to crawl their calendars and to create a case library of labeled data. The cases typically spanned several years of presentations, trips, meetings, tasks, and holidays, and included several thousand items. We provided subjects with a memory-landmark assessment tool that lists events drawn from their online calendar within a scrollable window, ranked from most recent to most distant events. The tool provides fields, adjacent to each event, that subjects use to label items as landmark or non-landmark events.

We pursued the construction of predictive models of memory landmarks from the supervised training data. We elected to employ Bayesian-network learning methods so as to have the ability to visually inspect key probabilistic dependencies among variables and, in particular, to understand key variables and states of variables influencing the likelihood of events being called memory landmarks.

We partitioned the data into training and testing cases, with an 80/20 split; that is, we built the models for each individual using 80% of their labeled data and evaluated the learned model on the remaining 20% of the labeled data. We employed a Bayesian structure-search procedure, developed by Chickering, Heckerman & Meek (1997), to build Bayesian-network models for event landmarks for each subject The procedure employs a greedy search through a large space of dependency structures and computes, for each plausible dependency structure, an approximation for the likelihood of the data given the structure. A model score is computed as a function of this likelihood and a model-prior parameter that penalizes for complexity. The model with the highest score is selected.

We optimized the model-prior parameter by splitting the training set 80/20 into subtraining and subtesting data sets, respectively, and identifying a soft peak in the Bayesian score. This value of the parameter at the soft peak was used to build the model from the full training set.

We inspected the predictive models constructed for each subject, noting dependencies among key variables, the discriminatory power of variables, and classification accuracy of the models at predicting the data held out from the training procedure.

Figure 1 displays a Bayesian network built from the data from one of the participants in the study (subject S1), showing all of the variables and the dependencies among them. A sensitivity analysis demonstrated that key influencing variables in this model for discriminating whether an event is a memory landmark are the *Subject, Location string, Meeting sender, Meeting organizer, Attendees,* and whether the meeting is *Recurrent*.

We explored the strength of dependencies for variables in the model for each subject and found similar influences of key variables across subjects. For subjects in our study, *atypically long durations*, *non-recurrence of events*, a user *flagging a meeting as busy* or *out of office*, and *atypical locations* or *special locations* had significant influence on the inferred probability that events would be considered a landmark event. We found that meetings marked as *recurrent* meetings rarely served as memory landmarks.

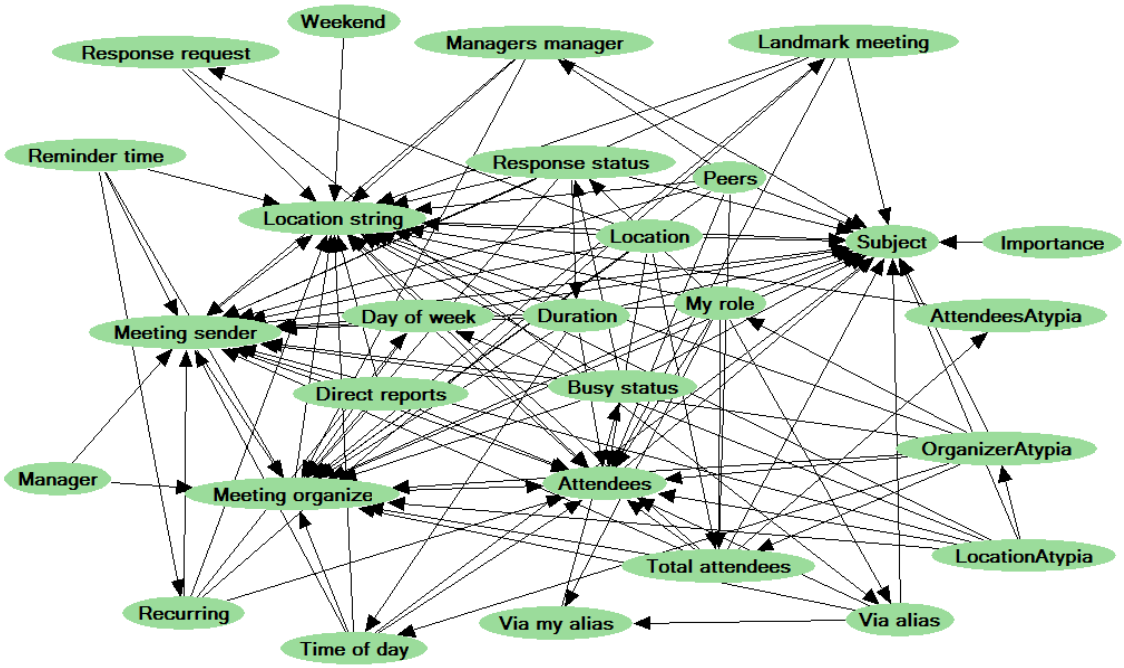

Figure 1: Bayesian network learned from online calendar data (subject S1) showing dependencies among event properties and likelihood that an event will be considered a memory landmark by a subject.

Table 1 shows the classification accuracies of the learned models of landmarks. For each test case, the values of the properties of the event are identified (or computed for derived properties) and then input to the model which provides a probability that the event is a memory landmark. That is, we compute *p*(*Event selected as a memory landmark*|*E*), given evidence *E*—the multiple properties of associated with each event on the subject's calendar. The models range in classification accuracies for the five subjects from 0.78 to 0.95.

In addition to looking at overall classification accuracies, we swept out receiver-operator (ROC) curves to visualize the relationship between false negatives and false positives at different thresholds for admitting events as memory landmarks. The false-positive rate is varied by changing the threshold of the probability score that is required for classifying an event as a memorable landmark, and the corresponding false negative rate is noted. The curves for the subjects in the study are displayed in Figure 2. We note that the ROC curves show a trend toward lower false positives and false negatives with increases in the size of the training sets.

The ROC curves are particularly important for understanding the value of employing such predictive models of memory landmarks in computing applications. As we shall explore in the next section, one class of computing applications centers on the use of a user-controlled threshold on the probability of events used to identify landmark events. In such uses of predictive models of landmarks, users may be given the ability to define, *e.g.,* via a slider control, the subset of all events that should be admitted, say, for displaying within a rendering of a timeline of events. Such timelines could provide useful "memory backbones" when searching for content in a large personal store. Models for inferring the likelihood that events will serve as memory landmarks promise to endow such computing applications with the ability to minimize clutter by limiting the revelation of events to those which are likely to be useful landmarks. Moving beyond basic timelines for searching for desktop content, applications include the use of the inferential models for constructing hierarchical views of events for browsing large quantities of time-based content, such as autobiographical corpora. We shall now explore a sample application we have constructed to investigate prospects for harnessing statistical models of memory landmarks.

Applications of Models of Memory Landmarks

To motivate ongoing work on the use of supervised and unsupervised machine learning to construct models of landmark events, we developed a prototype that demonstrates how such predictive models might be used. We have integrated components for learning and reasoning about memory landmarks into a prototype named *MemoryLens Browser.* The prototype is focused on providing users with a timeline of landmark events to assist them to find content across their computer store. We recently distributed the prototype to a limited group of users within our organization and are pursuing feedback about the system.

MemoryLens comes in the spirit of recent work on developing tools for assisting computer users to better locate information from their personal stores (Adar, Karger & Stein, 1999; Dumais, Cutrell, Sarin, Cadiz & Jancke, 2003). Ringel, Cutrell, Dumais & Horvitz, (2003) recently reported on results of a set of user studies that showed that memory

Table 1: Training data and classification accuracies for predictive models tested on hold-out data for five subjects.

	S1	S2	S3	S4	S5
Total events	3864	3740	2770	1743	1996
-Train	3091	2992	2216	1394	1596
-Test	773	748	554	349	400
Accuracy	0.87	0.94	0.95	0.88	0.78

landmarks can be used to help computer users find relevant results in searches across personal corpora. Significant decreases in the time required to identify search results was found when memory landmarks were used in comparison with the no-landmarks condition. That system employed informal, heuristic rules for selecting memory landmarks.

MemoryLens Browser allows users to train models of memory landmarks on a portion of events from their calendar; the prototype offers menu options which provide access to the training and modeling capabilities that we described earlier. Users invoke a personalization component that executes a crawl of their calendar. The prototype provides assessment and machine-learning tools, allowing users to identify a subset of events in their calendars as landmark events, and to build predictive models by invoking machine learning from the labeled data.

In use, the models constructed by users serve to infer the likelihood that each evemt drawm from the user's calendar will be considered a landmark, *p*(*Event will be viewed as a memory landmark*|*E*), given multiple evidential properties, *E*, extracted from unlabeled calendar items. These likelihoods are considered in the generation of a timeline of inferred landmarks adjacent to files gathered from across a user's file system. The files are positioned at places along the timeline in accordance with the times that they were created or last modified. An event-detail slider control provides users with a means of changing the threshold on the inferred likelihood of memory landmark that is required for displaying events. The slider control allows users to specify thresholds for admitting items for display with successively smaller inferred likelihoods. Only calendar items representing events that have a probability of being a landmark that is greater than a user-set threshold are displayed; as the slider is moved from "most memorable" to "least memorable," the required probability for display of events is lowered, thus bringing in greater numbers of events.

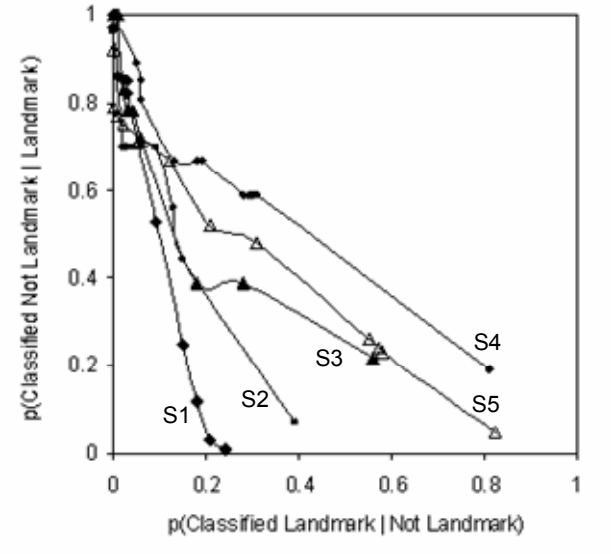

Figure 2: Receiver-operator curves showing the relationships of false negatives and false positives for five subjects at a range of thresholds on probabilities for admitting an event as a memory landmark.

A screenshot of the user interface of MemoryLens Browser is displayed in Figure 3. Thumbnails of file types are sorted in the right-hand column of the browser, in a traditional time-sorted view manner that computer users are familiar with. Within the left-hand column, a list of relevant dates associated with the files are displayed, including the year, month, and relevant days that files were created or modified. The middle column contains memory landmarks that have been assigned through inference a landmark probability exceeding a user-set threshold. The titles of memory landmarks are displayed in the appropriate temporal location, adjacent to the files.

Figure 3 shows three different screenshots of the graphical interface of MemoryLens, each representating a different setting of the probability threshold for the same span of time. Of the three snapshots, the view at the right is set to the highest probability threshold, thus revealing the fewest events. In this case, only the events representing two major conferences, for which the subject had to travel afar to attend, are displayed. As the threshold is lowered, a wedding, an editorial board meeting, a conference call, and a one-on-one meeting are included in the display. Further diminishing of the threshold for admitting events brings larger numbers of events into view. Beyond the use of thresholds for admitting versus excluding events from the landmarks column, the saturation of color of the text used to title events is faded as the probability of memory landmark diminishes—providing an additional cue about the likely value of using the event as a memory landmark.

We have been interested in probing the ability of models with the discriminatory performance represented by the family of ROC curves displayed in Figure 2, to construct useful time-line views. Such views should contain recognizable landmarks, while bypassing the clutter associated with showing a great number of events, and should allow users to work with such models in an exploratory, interactive manner (Horvitz, 1999) with tools embodied in MemoryLens' controls and display.

To relay a qualitative feel for the quality of timelines constructed with the use of the predictive models that we have generated, consider the ROC curve for a model of subject S1. The curve tells us that, at a probability threshold for accepting events as landmarks where ninety percent of the events on the timeline are correctly identified as

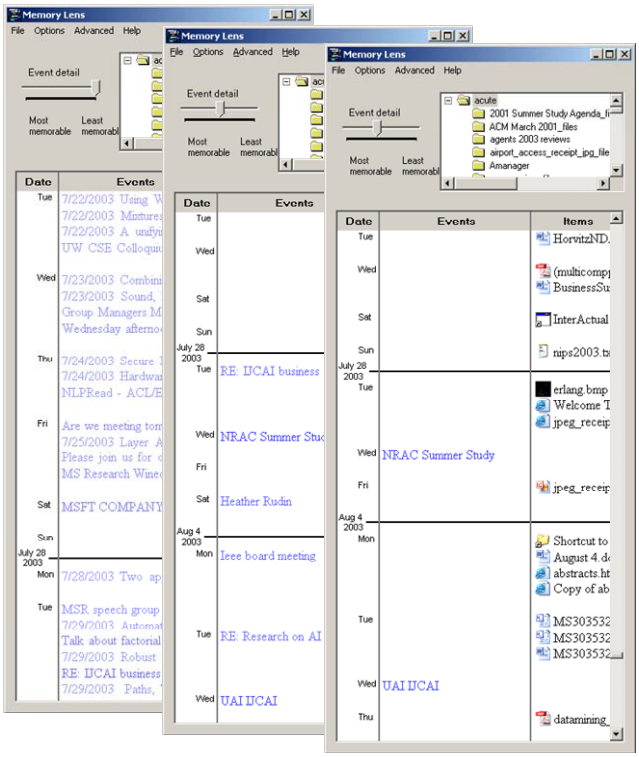

Figure 3: MemoryLens Browser with memory-landmark timeline displayed at three different settings of the threshold on the likelihood required for an event to be considered a memory landmark.

important landmarks, fifty percent of the important landmarks will not be displayed. Such precision and recall may be quite tolerable for navigating to target periods of time, given the overall density of landmarks for users; we found that subjects in our study typically showed 2-4 landmark events per week over the span of their assessments. A recall of half of these events would still tend to identify landmark events for every week.

Understanding the comprehensive value of providing users with selective views of landmark events on timelines will require detailed user studies of the use of specific prototypes and artifacts. We are interested in such studies of the value of specific designs built on predictive models of memory landmarks. Such studies would serve to enhance our understanding of the sensitivity of particular features and services to the performance of the predictive models.

Research Directions

We have focused in this paper on the construction and performance of predictive models that can be used to infer the probability that events drawn from online calendars will be considered memory landmarks by users. We provided, as a motivating example, a prototype application to highlight potential applications. Although we did not dwelled on comprehensive evaluations of the value of the use of memory landmarks in such prototypes, we are nonetheless interested in pursuing a deeper understanding of the value to users of rendering memory landmarks of different types and in different settings. We also seek to better understand the value of employing accurate predictive models of memory landmarks, based on a well-defined probabilistic semantics, versus using simple sets of heuristics to choose events for display.

In addition to pursuing a better understanding of the value of memory landmarks for users performing search and retrieval in computing applications, we are exploring several avenues of opportunity with refining and extending models of memory landmarks.

Generalization of Models. In one area of work, we seek an understanding of the accuracy of *inter-subject* predictions. Inter-subject classification accuracy probes the potential for using models constructed from one subject's training data, or a composite model built from multiple subjects, to predict hold-out data from other participants. Validating generalization across users would suggest that it is possible to field software applications that would require minimal personalization effort, via the use of pre-trained "seed" models. Such models would have a poor ability, without additional training, to consider highly personalized information such as variables containing specific text strings representing labels on meeting locations and subjects. This information tends to vary highly among the subjects.

Beyond Calendar Events. Events captured on users' calendars are convenient, but only a small subset of "events" users may wish to have captured, reasoned about, and harnessed in computing applications appear on a calendar. We are interested in building and refining predictive models for other items that could serve as additional memory landmarks or bolster event landmarks by providing richer context. As an example, we are pursuing, in a parallel project, the construction of predictive models that can identify the likelihood that images drawn from a large online personal photo library represent landmark events. To date, image analysis tools have been used in conjunction with several heuristics to select pictures when a user wishes to only review a subset of photos from a large library. Such methods include the use of a measure of the representativeness of each image to other images in the same session or event, based on such evidence as features derived from an analysis of color histograms (Platt, 2000).

In another realm, we are interested in learning from data predictive models that can automatically select the most important national and world developments, as captured by news events over time.

Beyond calendar-centric events, images, and news, online interactions, communications, and patterns of interactions with computer-based content may serve as memory landmarks. For example, particular email exchanges, or documents associated with clusters of items that have been reviewed or created in patterns of activity over time may provide an important source of events.

Taken together, multiple models of memory landmarks may be used in conjunction to build rich, multi-source timelines, providing views at different scales of time and for

different quantities of events, triaged by the likelihood that events will serve as memory landmarks.

New Classes of Evocative Features. We are also exploring the value of adding new observations features to the modeling of memory landmarks. For example, we are interested in the value of introducing a consideration of observations that assist with inferences about the likelihood that a meeting has been attended, given desktop activity over time and the sensed location of systems. Prior work has demonstrated the feasibility of performing relatively accurate inferences about the likelihood that a meeting has been or will be attended, based on an analysis of meeting properties, including activity monitored during meetings (Horvitz, Jacobs, & Hovel, 1999; Horvitz, Koch, Kadie & Jacobs, 2002; Mynatt & Tullio, 2001). Information about the likelihood of meeting attendance promises to have influence on the probability that the meeting will be viewed as a memory landmark. Other factors include capture and analysis of acoustical energy during meetings, and preparatory or follow-up activity associated with appointments.

Learning Models of Forgetting. Finally, we believe that there are opportunities for developing analogous statistical models of events and tasks that will be forgotten via supervised training. Recent longitudinal studies of office workers have identified classes of important events that are forgotten and have demonstrated the value of heuristics for ways to provide reminders about such events (Czerwinski & Horvitz, 2002). Beyond applications for people in good health, we see the feasibility of developing models for supporting people suffering with pathologies of memory associated with various forms of dementia.

Summary

We reviewed research highlighting prospects for developing and harnessing predictive models of events that will be viewed as landmarks. We focused in particular on the construction and evaluation of models that infer subsets of events drawn from subjects' calendars. After reviewing the classification and ROC curves associated with training sets obtained from five subjects, we discussed the potential to employ predictive models of memory landmarks in computing applications. We described as an example, the MemoryLens Browser prototype. Before concluding, we touched on several current research directions, including opportunities to perform additional studies to evaluate the value of displaying memory landmarks in search tasks, on seeking to define and understand the discriminatory power of additional evidential distinctions in building predictive models of landmarks, and developing models of landmark events for online images, news stories, and other items encountered or created by users in their daily lives that might be encoded as important landmarks in episodic memory.

Abstract

Why do people gesture when they speak? The reasons are not entirely clear. This paper tests two hypotheses about the role of gesture in speech production: the Lexical Access Hypothesis, which holds that gesturing aids in lexical access, and the Information Packaging Hypothesis, which holds that gesturing aids in conceptualization. Participants were asked to describe dot patterns that were either easy or difficult to conceptualize in terms of geometric shapes. Patterns that were more difficult to conceptualize elicited more gesture than the patterns that were easier to conceptualize. This result supports the Information Packaging Hypothesis.

Introduction

It is often said that a picture is worth a thousand words. In the case of speech production, it sometimes seems that creating pictures with our hands can help our audience understand what we are saying. However, despite the intuitive feeling that we gesture primarily to help our audience, some research suggests that gestures contribute little to an audience's understanding of a gesturer's speech (Krauss, Morrel-Samuels, & Colasante, 1991; Krauss, Dushay, Chen, & Rauscher, 1995; but see Kendon, 1994 for an alternative perspective). Speakers often produce representational gestures even when they know that their audience cannot see them, making it unlikely that their intended purpose is solely to help the audience (Alibali, Heath, & Myers, 2001).

This evidence that gesture does not help comprehension has led some investigators to propose that gesture has a more direct role in the speech production process, by facilitating the planning of speech. Specifically, gesture may play a role in speaking about ideas that are highly spatial or motoric in nature (Kita, 2002; Krauss & Hadar, 2001). It has been shown, for example, that gestures are more likely to coincide with words that are spatial and concrete (e.g., *spin, under,* or *cube*) than with words that are non-spatial and abstract (such as *evil*) (Krauss, 1998; Morsella & Krauss, in press; Rauscher, Krauss, & Chen, 1996). By actively engaging spatial-motoric ideas through gesture, it may become easier to speak about them.

Although gesture may be an overt manifestation of spatio-motoric thought, exactly how gesture may facilitate speech production is still the subject of some debate. The majority of research in this area has followed the speech production model proposed by Levelt (1989), which divides the speech production process into three broad stages: conceptualization, formulation, and articulation. During conceptualization, the prelinguistic thoughts of a speaker are generated and combined into propositional form. During formulation, these thoughts are translated into the appropriate linguistic units by searching through the mental lexicon and identifying the proper lemmas and lexical entries. During articulation, the motor plan for pronouncing the phonemes corresponding to the lexemes is created and executed. It seems unlikely that the production of representational gestures influences motor aspects of articulation, and, indeed, research has typically focused on the earlier stages of speech production (conceptualization and formulation) as the possible beneficiaries of gesture.

Work by Krauss and colleagues (Krauss, Chen, & Chawla, 1996) places the influence of gesture on speech as occurring primarily during the formulation stage. According to their view, referred to hereafter as the Lexical Access Hypothesis, gestures serve as a cross-modal prime to help speakers access specific items in the lexicon. In support of this view, a number of studies have shown that speakers produce more iconic gestures when the words of an utterance are more elusive (e.g. Hostetter & Hopkins, 2002; Morrel-Samuels & Krauss, 1992). For example, when speakers have time to verbally rehearse an utterance, they gesture less than when speaking completely extemporaneously (Chawla & Krauss, 1994). Similarly, speakers gesture more when describing ideas or shapes that are not readily named than when describing ideas or shapes that are easily named (Graham & Argyle, 1975; Morsella & Krauss, in press). Research with aphasic patients also suggests that gesture is involved in the formulation stage. Aphasic patients whose problems are primarily ones of lexical access use more gestures than age-matched controls (Hadar, Burstein, Krauss, & Soroker, 1998). Those whose problems are primarily not ones of lexical access produce fewer gestures than other types of aphasic patients (Hadar, Wenkert-Olenik, Krauss, & Soroker, 1998). Finally, prohibiting speakers from gesturing has been shown to negatively affect speech fluency, especially for speech that is spatial in nature (Rauscher et al, 1996).

Studies that induce tip-of-the-tongue states have yielded slightly less compelling and more contradictory findings about the facilitative effects of gesture on formulation.

Frick-Horbury and Guttentag (1998) found that preventing participants from gesturing increased retrieval failures, whereas Beattie and Coughlan (1998) found exactly the opposite pattern. Participants who were restricted from gesturing actually retrieved more words than those who were allowed to gesture in Beattie and Coughlan's study. In both studies, when participants actually produced gestures, they did not resolve their tip-of-the-tongue states more often than when they did not gesture. Thus, although gestures do tend to co-occur with speech that is spatial and with words that are difficult to find, the claim that gestures actually help the speaker to find the right words remains somewhat unwarranted at this time.

Because Levelt's (1989) speech production model is a stage model, each stage of the production process partly depends on input coming from the previous stage. Articulation cannot begin without at least a minimal amount of characteristic input from the formulator; a word cannot be uttered until it has been decided what word should be uttered. Likewise, formulation and lexical access depend on the output from the conceptualizer. The ideas and propositions that are to be expressed must be available before the correct lemma and lexical affiliate can be searched for and accessed. It would seem therefore that facilitation in the conceptualization process would translate into some facilitation at the lexical level as well. A concept that is clear in the speaker's mind is more readily lexicalized than a concept that is unclear and vague. Thus, the fact that gestures tend to co-occur with words that are spatial and somewhat elusive could also be explained as facilitation at the conceptual level. Gesture may help speakers to clarify or organize their ideas, and this may make the output of the conceptualizer more readily accessible to the formulator. Such a view of gesture is referred to as the Information Packaging Hypothesis (Kita, 2000). According to this hypothesis, gestures help speakers organize knowledge that is spatio-motoric in nature and put it into a verbalizable form. Gesture is thus a mode of thinking, an aid in translating spatio-motoric knowledge into linguistic output. By activating the appropriate bodily representations of spatio-motoric ideas, the ideas can be more fully realized.[1]

Evidence for the Information Packaging Hypothesis comes from studies that have attempted to manipulate the difficulty of conceptualization while holding constant the difficulty of lexical access. Alibali, Kita, and Young (2000) did this with children using a conservation task. They found that children used more representational gestures when they were asked to explain why two items (e.g. two balls of play dough) were different amounts than when they were asked simply to describe how the two items looked different. The words used by the children were highly similar across the two tasks; however, the explanation task required more complex conceptualization than did the description task. The authors argued that children used representational gestures more frequently in the explanation task because of the increased demands on the conceptualizer. Melinger and Kita (2001) found that adults were more likely to gesture in instances where there was a greater choice of what to say, despite the fact that the actual words being spoken in both situations were nearly identical. Again, the authors argued that gesture arises as a result of taxing the conceptualizer rather than the formulator.

Although these studies provide suggestive evidence for the Information Packaging Hypothesis, their conclusions are far from definitive. Although Alibali et al. (2000) found a significant difference in gesture production based on the difficulty of conceptualization, they did not find an especially strong effect. Also, because the study investigated gesture production in children, it may not be appropriate to generalize the findings to adult gesturers. Melinger and Kita's (2001) results suggest an effect in adults. However, they did not report statistical analysis of their data, so it is not clear whether the differences they describe are reliable.

The present experiment was designed to further distinguish between the Information Packaging Hypothesis and the Lexical Access Hypothesis. If gestures do indeed help speakers to conceptualize a spatial situation rather than just helping them to find the right words to describe that situation, then speakers should produce more gestures in a task where there are multiple conceptual options. Similarly, when the task provides only one conceptual option, speakers should produce fewer gestures. However, as long as the words that are ultimately used to describe the situation are the same, the Lexical Access Hypothesis would predict no difference in gesture production regardless of conceptual difficulty.

In order to manipulate conceptual difficulty without affecting difficulty of lexical access, it was necessary to find a task that would result in similar verbal output regardless of the level of conceptual difficulty. For this purpose, we designed a dot description task in which participants were asked to describe patterns of dots to a listener. Patterns of dots were created that could be conceptualized in a number of different ways; that is, a number of different geometric patterns could be imagined to be drawn through each dot pattern. For example, the pattern in Figure 1 could be conceptualized as two triangles, one rectangle with a triangle on top, a five-pointed star, three straight lines, or two parallelograms. This scenario (the dots-only condition) should be more conceptually difficult than a scenario in which the same dot patterns are displayed with lines drawn through them to guide conceptualization (the dots-plus-shapes condition). In both conditions, however, the goal of the participants is to describe only the dots; thus, the words ultimately used by participants should be similar regardless of the conceptual condition in which the dot pattern is presented.

[1] It should be noted that when gestures aid the conceptualizer, they may or may not also aid the formulator. A speaker who is having difficulty finding a particular word may use gesture as a way of clarifying the idea in his or her mind; this may or may not add enough additional information for the formulator to successfully access the lexical affiliate.

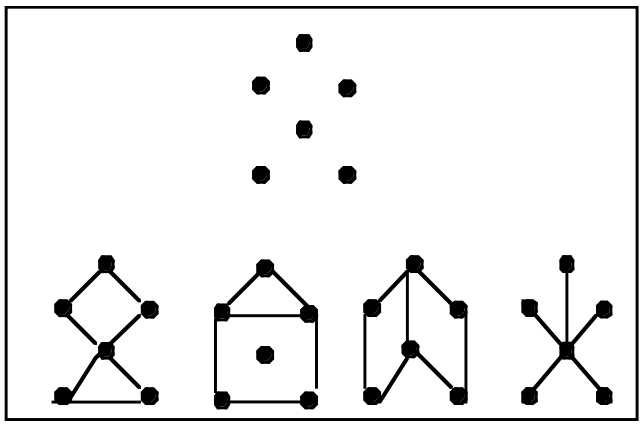

Figure 1: Sample Pattern (top) in Dots-Only Condition and 4 Possible Conceptualizations (bottom)

Method

Participants

Undergraduate students were recruited from the Psychology participant pool at the University of Wisconsin, Madison. A total of 63 individuals (32 males, 31 females) were screened for participation, and those who had not learned English in infancy were excluded. Additionally, one individual was not included because a wrist injury made it difficult for him to gesture. These eliminations resulted in a final sample of 48 individuals (24 males, 24 females) with a mean age of 19.4 yrs (SD = 1.75). Participants did not know that gesture was the focus of the study.

Stimuli

The stimuli were six dot patterns, each of which included 6 to 9 black dots on a white background. Each pattern was designed so that it did not represent the outline of any single geometric shape, but instead afforded a variety of different geometric shapes (see Figure 1). Patterns were created in AppleWorks 6 and loaded into PsyScope for experimental presentation in the conceptually difficult (dots-only) condition.

From each of these six dot patterns, the participants' natural responses in the dots-only condition were used to create patterns for the dots-plus-shapes condition. Each conceptualization provided by the participants in the dots-only condition was transposed onto the appropriate dot pattern by making lines through the dots to indicate the conceptualization pattern. These patterns were also made in AppleWorks 6 and loaded into PsyScope for experimental presentation in the conceptually easy (dots-plus-shapes) condition. All stimulus patterns in both conditions were presented on a Macintosh Powerbook G3 laptop with a 35-cm color screen.

Procedure

Participants were told that the focus of the study was their ability to remember dot patterns that are presented to them for a very short duration and to describe these patterns effectively to another participant. They were told that their descriptions would be audio-taped and played later for another participant who would try to recreate the pattern based on their descriptions. A hidden video camera was focused on the participant throughout the experiment providing a head-on view of the participant from the waist up, and their descriptions were never heard or seen by anyone other than the experimenters. Following their participation, each participant was debriefed regarding the true nature of the experiment and given the opportunity to have his or her videotape destroyed. All declined.

Each participant was brought individually into the testing room, which was divided by a wooden screen. On one side of the screen, a chair was placed in front of a small table (58.5 cm H x 71 cm W x 71 cm L) where the laptop computer was situated. The participant was told to sit in this chair and the experimenter knelt next to the computer and participant to give the instructions and practice trial for the experiment. During instruction, each participant was shown a sample dot pattern and told that patterns similar to it would appear on the computer screen for a very short duration. The participants were told that their task was to describe the pattern as clearly as possible so that the participant who would hear the description via audiotape would be able to successfully reproduce it. Furthermore, they were told that while the task was to get the listener to reconstruct the dots only, they should imagine the dot patterns in terms of geometric shapes and figures. Rather than saying, for example, that there is a dot at the top of the page and another dot about 2 cm below it with another dot directly to the left of that, they should describe the pattern as being a right triangle with dots on each corner with the right angle of the triangle facing toward the left.

Participants in both conditions received two sample patterns that were appropriate to their experimental condition (i.e., patterns shown to dots-only participants contained only dots while patterns shown to dots-plus-shapes participants showed dots with lines drawn to aid conceptualization). During the instructions and example presentations in both conditions, the experimenter produced some small, scripted gestures that were identical across conditions.

Following these instructions, participants in both conditions were asked to complete a practice trial while the experimenter was still present. The experimenter provided feedback as needed based on this practice trial to reemphasize the need to describe the pattern in terms of geometric shapes and to adequately describe the location of the dots within these shapes.

Because the purpose of this study was to manipulate conceptual difficulty without affecting lexical difficulty, measures were taken to assure that lexical access was as easy as possible for participants in both conditions. Following the examples and practice trial, all participants were presented with an alphabetical list of 16 words that

seemed likely to occur in descriptions of the patterns. This list included names of geometric shapes as well as spatial and relational prepositions. Each word was displayed in the center of the computer screen for 1200 ms, and participants were asked to pronounce each word out loud as it appeared on the screen. The goal was to have these 16 words primed and readily accessible to participants in both conditions.

After making sure that the participant understood all of the instructions, the experimenter pressed 'record' on the audio-recorder and went to the other side of the wooden screen, where she pretended to prepare for the next part of the experiment. On the experimenter's side of the screen, a table and chair were set up to face away from the participant so that in addition to vision being blocked by the wooden screen, the experimenter was not looking in the same general direction as the participant as he or she described the patterns. While it is difficult to ever definitively rule out the possibility that some gestures produced by the participants were intended for communicative illustration, the presence of the wooden screen, the relative positions of the experimenter and participant, and the participants' naivete regarding the hidden video camera make it highly unlikely that the participants perceived any direct visual audience for their descriptions. Thus the gestures produced by the speakers were most likely for purposes other than direct communicative illustration.

When the participant was ready to begin the first trial, he or she pressed a key on the laptop keyboard. At the beginning of each of the six trials in the experiment, a single black dot was displayed in the center of the computer screen for 2 s as a signal that the stimulus pattern was about to appear. The single dot was then replaced by one of the six dot patterns, which were presented to all participants in the same fixed order. The pattern remained on the screen for 3 s and was followed by a 1 s pause. After this brief pause, a short beep was heard which cued the participant that it was time to begin describing the pattern. When the participant was ready to proceed with the next pattern, pressing any key on the laptop keyboard prompted the beginning of the next trial.

Because it is crucial to the design of this study that the words used by participants in the dots-only condition closely match those used by participants in the dots-plus-shapes condition, each participant in the dots-plus-shapes condition was matched to a participant in the dots-only condition. The responses of the participant in the dots-only condition were used to create the stimuli shown to the matched participant in the dots-plus-shapes condition. Lines and shapes were drawn through each dot pattern to produce a replica of the conceptualization that was described by the dots-only participant. This was done in order to encourage the participants in the dots-plus-shapes condition to conceptualize the pattern in the same way as their dots-only counterpart, and consequently to use similar words to describe the pattern. Because this process necessitated that the stimuli be redesigned and the computer reprogrammed for each dots-plus-shapes participant, 8 participants were completed in the dots-only condition before the patterns were recreated for the dots-plus-shapes condition. Participants were then randomly matched to one of the dots-only participants with gender as the only criterion for pairing; males were always matched to males and females were always matched to females. This pairing procedure was then repeated for blocks of 8 individuals until the final sample of 24 gender-matched pairs (12 male and 12 female) was obtained.

Coding

The descriptions given by each participant were transcribed verbatim, and all iconic gestures were identified. Individual gestures were distinguished from one another by a change in hand shape or motion. For example, a motion straight across from left to right accompanying the words "the bottom line" was coded as one iconic gesture. If a similar movement occurred as the first motion of a sequence in which the hand moved diagonally upward and then diagonally downward without changing hand shape (to imply triangle), this entire sequence was coded as one iconic gesture.

The total number of gestures produced by each participant for each pattern was divided by the total number of words uttered during the participant's description of that pattern. This quotient was then multiplied by 100 to yield the iconic gesture rate per 100 words. Thus, each participant's gesture rate per 100 words was calculated for each of the six pattern descriptions.

Table 1: Frequency of Spatial Terms Used in Each Condition

Dots-Only	Spatial Word	Dots-Plus-Shapes
121	Line	148
116	Triangle	172
110	Top	122
100	Right	67
94	Bottom	124
90	Point	106
72	Middle	78
58	Parallelogram	89
58	Down	45
54	Left	40

Results

Analysis of Speech Produced

To address the question of whether conceptual difficulty affects gesture production separately from the effects of lexical difficulty, it is important that the lexical items being retrieved are similar across conditions. The 10 most commonly used spatial terms used by participants in the dots-only condition are shown in Table 1. Although there is some variation in the exact rank-order of the words, the correlation between the frequency of occurrence of each word in the two conditions is high and significant, $r(8) =$

0.833, $p < .001$, suggesting that the spatial words used by participants were similar in the two conditions.

Analysis of Gesture Production

The central question of interest in this experiment is whether or not frequency of gesture production is affected by difficulty of conceptualization. The Information Packaging Hypothesis predicts that gestures aid in conceptualization and should thus be used more frequently when conceptualization is more difficult. Alternatively, the Lexical Access Hypothesis predicts that so long as the accessibility of the lexical items being produced remains constant, gesture production should not be affected.

An inherent problem in analyses of gesture production between participants, however, is the fact that there is a large amount of individual variation in the amount of gesture produced by different individuals. Some individuals gesture a lot, while others gesture rarely or not at all. For example, in the current data set, two participants produced an average of more than 16 gestures per 100 words, while eleven others did not gesture at all. This large variation in gesture production between participants necessitates the presence of a very large difference between condition means before a significant effect can be detected. Because of this issue, we analyzed the data using items (i.e., dot patterns) rather than individuals as the unit of analysis. That is, rather than collapsing across patterns and comparing individuals in the two different conditions, data were collapsed across participants and gesture rates were compared for each of the six patterns.

A paired t-test revealed a significant effect of condition on iconic gesture rate ($t(5) = 2.84$, $p < .05$). Patterns in the dots-only condition elicited an average of 5.69 iconic gestures per 100 words ($SD = .81$) whereas the same patterns in the dots-plus-shapes condition elicited an average of 4.79 iconic gestures per 100 words ($SD = 0.26$) (see Figure 2). Thus, gesture rate varied as a function of difficulty of conceptualization, with more gestures produced in the condition with more difficult conceptualization. The distribution of high and low gesturers in each condition suggests that this effect was not driven solely by the presence of a few high gesturers in the dots-only condition.

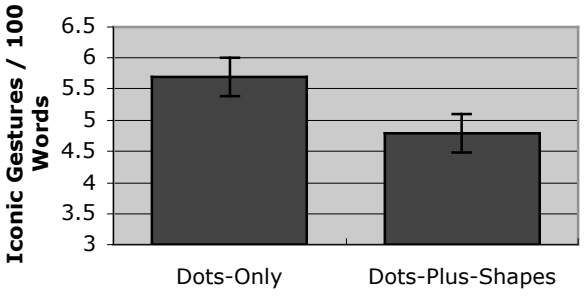

Figure 2: Average Rate of Iconic Gestures/100 Words Produced in Each of the Two Conditions

The dots-only condition included the four participants with the highest gesture rates, but also included four participants who did not gesture at all. The dots-plus-shapes condition also included participants at both extremes, with six who gestured more than 10 times per 100 words and seven who did not gesture at all.

Discussion

The Information Packaging Hypothesis (Kita, 2000) holds that gesture helps refine and organize spatio-motoric concepts so that they can be readily translated into verbalizable units. Alternatively, the Lexical Access Hypothesis holds that gesture primarily aids speech production by priming the appropriate items in the lexicon. The present experiment sought to distinguish between these two hypotheses by varying the conceptual difficulty of a task and observing the extent to which gestures are produced under the two levels of conceptual difficulty.

The difference in gesture rates in the two conditions supports the Information Packaging Hypothesis. Although the difference was small, participants gestured at a higher rate in the dots-only condition, in which they had to produce their own conceptualizations of the stimuli, than in the dots-plus-shapes condition, in which they had the conceptualizations given to them. This finding suggests that gesture does indeed occur not only when lexical access is more difficult, but also when the situation is more conceptually difficult. The present findings do not disprove the Lexical Access Hypothesis, but they do suggest that gesture can serve an earlier stage in the speech production process, above and beyond any benefits it may have at the lexical access stage.

This finding is consistent with current views about the embodied nature of cognition (e.g., Glenberg, 1997). Briefly stated, the central claim of embodied accounts of cognition is that the ways in which we are able to interact bodily with the world profoundly affect the way we think. From an embodied perspective, symbolic representations such as language are grounded or assigned meaning via their links to bodily experiences and actions. It has been shown, for example, that sentence comprehension is affected by how easy it is for the comprehender to mentally simulate him or herself actually performing the actions implied by the sentence (Chambers, Tanenhaus, Eberhard, Filip, & Carlson, 2002; Glenberg & Kaschak, 2002).

If we *understand* language in terms of how we can interact bodily with the world, it seems likely that this same embodied knowledge may also be integral to our ability to *produce* language. Indeed, the present work regarding the role of gesture in conceptualizing and formulating speech seems to point to a role for embodiment in language production. We suggest that the spontaneous gestures produced in the act of speaking are a manifestation of embodied knowledge. Borrowing a phrase from Schwartz (1998), who argued that gestures reflect "physically instantiated mental models", we suggest that gestures reflect *bodily* instantiated mental models. According to the

Information Packaging Hypothesis, such gestures enhance speakers' abilities to think and speak about those concepts. Thus, when speakers activate their embodied knowledge through gestures, they are better able to express that knowledge in the linear, symbolic system of language.

In conclusion, then, it may very well be that a picture is worth a thousand words; however, the pictures we make with our hands are not only worthwhile for our listeners, but also for ourselves.

Acknowledgments

We thank Arthur Glenberg, Charles Snowdon, and Maryellen MacDonald for their insightful comments on the design of this project.

Abstract

Cognitive Constraint Modeling (CCM) is an approach to reasoning about behavior that (1) provides a framework for investigating the hypothesis that skilled behavior is the optimal solution to a constraint satisfaction problem defined by objective, environmental, knowledge, and architectural constraints, (2) derives predictions of behavior from formal specifications of theory, (3) supports reasoning using both dependency-based and cascade-based ontologies for expressing temporal relationships between processes. A software tool that demonstrates the potential advantages of CCM is described. The tool, called CORE, can be used to partially automate the generation of behavioral predictions given a specification of the constraints. We explore the application of CORE to dual-task data previously modeled with EPIC and ACT-R.

Introduction

When people acquire a skill they are able to adapt their behavior so as to incrementally improve the value of some utility function. With practice, the scope for improvement attenuates and performance asymptotes. It may asymptote at a level that is consistent with constraints imposed by the environment or perhaps at a level determined by the knowledge that is brought to the task. The bounds may instead be imposed by the human cognitive architecture. More plausibly, the asymptote may be determined by a combination of constraints, including the stochastic and temporal profiles of the task environment *and* the human cognitive, perceptual, and motor systems. The approach to the asymptote is bounded by a multiplicity of constraints (Simon, 1992).

There has of course been much work aimed at modeling skilled behavior and its acquisition (e.g. Anderson and Lebiere, 1998; Meyer and Kieras, 1997; Taatgen and Anderson, 2003). The purpose of the current paper is to provide an initial demonstration of how models of skilled behavior can be generated by the formal derivation of behavior descriptions from multiple constraints, and in particular, how this approach supports reasoning about asymptotic bounds on skilled behavior. The specific objectives of the paper are:

(1) To introduce the hypothesis that skilled behavior is the optimal solution to a constraint satisfaction problem defined by architecture, task environment, and knowledge constraints.

(2) To introduce a formal modeling approach, called CCM, that directly supports reasoning about the optimal bounds on skilled behavior. By using deductive inference and constraint satisfaction algorithms, CCM computes the necessary consequences of the constraints imposed by the task environment, by strategic knowledge, and by the cognitive architecture. These constraints may determine, for example, which cognitive and environmental processes can execute in parallel and which have sequential dependencies.

(3) To specify two ontologies which provide alternative information processing vocabularies for the cognitive and task theory, and the resulting descriptions of behavior. The first is a straightforward formalization of temporal dependencies, implicit in existing work based on CPM-GOMS. The second is a richer ontology that permits specifying sets of communicating information processes, where both the processes, inter-process communication channels and buffers are subject to resource constraints. This framework has much in common with McClelland's cascade model (McClelland, 1979). Both ontologies are formally defined by a set of declarative axioms that are part of the model specification.

The paper has the following structure. We first introduce the background to our work on CCM and then describe a reasoning tool, called CORE (Constraint-based Optimal Reasoning Engine). We describe the application of CORE, using the temporal dependency axioms, to reasoning about a dual task experiment first reported by Schumacher, Lauber, Glass, Zubriggen, Gmeindl, Kieras, Meyer (1999) and subsequently modeled by Byrne and Anderson with ACT-R/PM (Byrne and Anderson, 2001). In doing so we show that CORE is flexible enough to support inference about the implications of both central and peripheral bottleneck theories of dual task performance. CORE requires 42 simple, universally quantified, declarative statements to

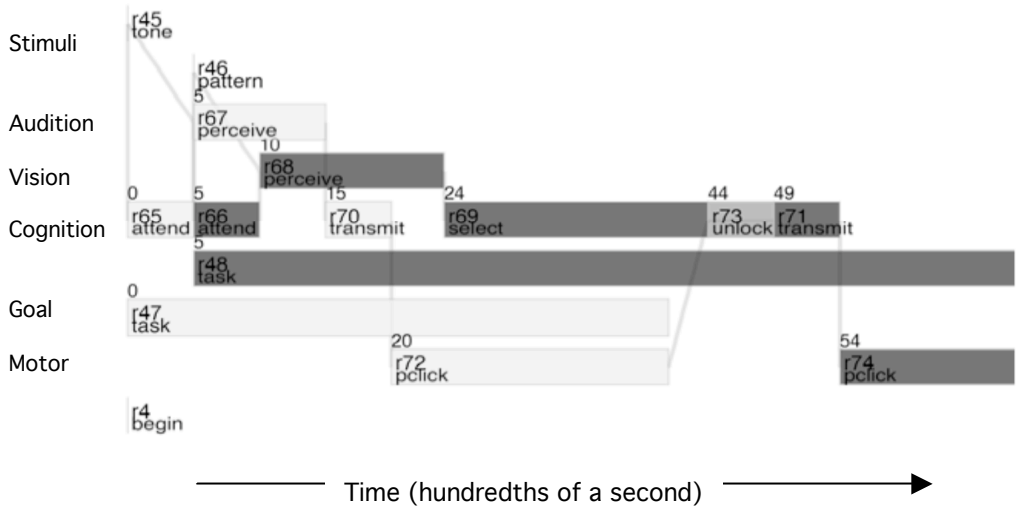

Figure 1: A CCM-d prediction of performance on Schumacher et al.'s (1999) Experiment 3 task.

specify the task, strategies, architecture, and axioms required to reason about the dual task. We also report that the optimal schedule for Schumacher et al.'s task suggests that participants may have been using a strategy not previously considered. Lastly, we introduce, and describe the benefits of, the cascade-based axioms.

Background

Predicting how long it will take people to perform a task is difficult, but important. It is difficult because human performance depends on a multiplicity of complex interacting constraints that derive from the environment, from human psychology, and from knowledge that people bring to the task. Skilled performance of a routine task usually involves the execution of a number of parallel but interdependent streams of activity: For example, one hand may move to a mouse; while the other finishes typing a word; and the eyes begin to fixate on a menu while the required menu label is retrieved from memory. Each of these processes takes a few hundred milliseconds, but together they form behaviors that take many seconds. Importantly, the details of how processes are scheduled, of how they are ordered, and of the implications of their inter-dependencies, has significant consequences for the overall time requirement.

There are a number of scientific and engineering tools that support the prediction of skilled performance time. Many of these tools share a common intellectual origin in the Model Human Processor (MHP: Card, Moran & Newell, 1983). Card et al. introduced the MHP as an engineering model in which human cognition was described as a set of communicating processors each of which had parameters (e.g. for cycle time) derived from human experimental psychology. More recent engineering tools, particularly CPM-GOMS (Gray, John, Atwood, 1993), have also utilized the processor and process framework. EPIC, a production system architecture that synthesizes more recent results in cognitive and perceptual psychology (Meyer and Kieras, 1997) was also influenced by the work of Card et al. (1983). Most recently, ACT-R/PM (Byrne and Anderson, 1998) extended the ACT-R architecture with a set of EPIC-like perceptual-motor modules.

The strength of these strands of work is evident in the range of experimental findings for which explanations can be offered; for the successful efforts at delivering scientifically validated tools to applied practitioners (e.g. Gray, John, Atwood, 1983); and for the rigor that is evident in the insistence that theory be expressed computationally (e.g. Byrne and Anderson, 2001; Meyer and Kieras, 1997). However, there are issues. Below we have listed three that were significant in motivating the work reported in this paper.

(1) It is difficult to inspect and modify architectural assumptions (Cooper and Shallice, 1995). Cognitive architectures embody architectural assumptions in underlying code, and are not easy to change. This would not be a problem if the details of an architectural theory were stable and comprehensive enough to be applied to a wide range of tasks. But in the forseeable future the modeler will find it valuable to easily manipulate and add architectural assumptions that are still under debate in the field.

(2) Model predictions can be a function of theoretically-irrelevant or implicit assumptions. Current approaches force modeling at certain fixed levels of abstraction. In general, computational cognitive architectures force computational completeness in order to incrementally simulate behavior. But one consequence is that modelers must specify the details of procedural knowledge and the representations used in long term and short-term memory, which may not be intended as theoretical commitments.

(3) It is difficult to predict the asymptotic bound on skilled behavior. Though learning architectures such as ACT-R/PM could in principle automatically asymptote to the appropriate skilled behavior, the mechanism is an open research problem and puts a robust learning theory on the critical path to efficiently modeling skilled behavior.

CORE: A tool to support reasoning about behavior

CORE takes as input a set of mathematically stated constraints on behavior and outputs a prediction. In this respect it shares some similarities to the work of Duke and Duce (1999). One of the formats for the output, a CPM-GOMS-like Pert chart, is illustrated in Figure 1. The prediction in the Figure is for a dual task behavior studied by Schumacher et al. (1999) and subsequently modeled in ACT-R/PM by Byrne and Anderson (2001). Each box represents a process. Task 1 (light gray processes) is to respond to a tone (high or low) with a left-finger key press, and task 2 (dark gray) is to respond to a pattern with a right-finger key press. In the Figure, time is represented on the horizontal access and each row represents a different resource or processor, perception at the top, through cognition and goal, to motor actions. The task processes represent the temporal extent of the representation of each task on the goal.

Following Card et al. (1983) constraints are described in terms of the temporal and resource properties of a distributed set of processors, each with its own processing capabilities. Each processor is defined in terms of a set of parameters and a defined set of processes. Each process has parameterized limits (min, max) on its duration. The duration of motor movements can be automatically determined by a calculation of Fitts's Law. The duration of cognitive and perceptual processes may be directly determined from the empirical literature (e.g. estimates of the time required to switch attention), or by functions that, for example, model hypotheses about the behavior of retrieval mechanisms.

The relationships between the processes represented in Figure 1 are an attempt to reproduce the assumptions adopted by Byrne and Anderson (2001). The processing sequence for each stimulus is: attend to the stimulus, perceive the stimulus, select a response, transmit a command to the motor system. The duration of the select process is determined by ACT-R/PM's retrieval function.

The lines between processes in Figure 1 represent temporal *dependencies*. A dependency is a type of constraint that specifies that one process must be scheduled after another has finished. While the particular prediction illustrated in Figure 1 has been constrained by dependencies, cognitive constraint modeling is not limited to dependency-based representation of theories. The constraints that specify the meaning of dependencies are the essence of a set of CCM axioms that we call CCM-d (CCM-dependency). CCM-d provides a formal specification of the CPM-GOMS modeling framework (Vera et al., 2004). (An alternative set of axioms, called CCM-c, for CCM-cascade, is described later in the current article.)

Representing a theory

Constraints on behavior are specified to CORE in terms of relationships between events in the environment, tasks, and psychological processes.

The semantics of the language for expressing statements is a subset of second-order predicate calculus. An entity is represented as a set of elements where each element is either an ordered pair, or a triple where the first element is '++'. For example, the following reads, there exists a cognitive process called initclick that must be scheduled after process U_j.

$$\exists P_i: \{ (isa,process)\ (name,initclick)\ (resource,cognition)\ (++,after,U_j) \} \subseteq P_i \qquad (1)$$

Each pair consists of an *attribute* and a *value*. A set must only contain a single element with a particular attribute (e.g. there must only be, at most, one pair that matches the pattern (name,_)). Each triple consists of the symbol '++', an attribute, and a value. For triples, there are no restrictions on the attribute or value. Triples support the expression of sets in which an attribute can have multiple values. The features in (1) are specified as a subset of P_i ($\subseteq$). Further features may complete the specification of this process.

Sets that represent processes, must have a start attribute and a duration attribute. This can be represented with the statement that all P_is that contain the pair (isa,process), must also contain a start time S_i and a duration D_i.

$$\forall P_i: \{ (isa,process) \} \subseteq P_i \rightarrow \{ (start,S_i), (duration,D_i) \} \subseteq P_i \qquad (2)$$

Relationships between the start times and durations of processes are represented with simple integer-arithmetic constraints. The following represents the assumption that a motor process is a necessary consequence of an initialization process, that a motor process cannot occur before its initialization process, and that the maximum temporal gap between the two processes is 300ms. This constraint must hold irrespective of the task.

$$\forall P_j: \{ (isa,process)\ (name,initclick)\ (start,S_j)\ (duration,D_j) \} \subseteq P_j \rightarrow \exists P_i: \{ (isa,process)\ (name,click)\ (start,S_i) \} \subseteq P_i \wedge S_j + D_j \leq S_i \wedge S_i - (S_j + D_j) \leq 300 \qquad (3)$$

Given a set of axioms, statements of this form can be used to represent theoretical assumptions about the task environment, about instruction taking, about the strategies that people deploy, and about the human cognitive architecture.

Crucially, universally quantified constraints specified in a predicate calculus are not production rules. The constraints may appear to possess a similar surface form to production rules but, in fact, the semantics are very different. Most importantly, unlike production rules, these declarative statements of theory are statements of what *must* be true irrespective of context. They are not elements of a

procedure that generates the description. The constraint must hold for every circumstance where its antecedent is met. The generation of a model with these constraints is entirely monotonic and the order of expansion can be (and often is) different to the predicted order of behavior.

Generating a prediction

Given constraints on behavior, CORE can be used to generate a prediction. This is a two-phase process.

Phase 1. CORE derives the necessary implications of the theory. For example, given a P_i (as defined in statement 1) above and rule (2), CORE would derive that the initclick process must have a start and duration:

$$\exists\, Pj: \{ (isa,process)\ (name,initclick)\ (resource,cognition)\ (++,source,U_i)\ (start,S_j)\ (duration,D_j) \} \subseteq P_j \quad (4)$$

Subsequently, with rule (3), CORE can derive that there must be a motor click process, with a start time and duration constrained by the given equations.

Arithmetic constraints on the start time, duration, and costs of a process are posted to a constraint store that is implemented in a Sicstus Prolog variant of Constraint Logic Programming for Finite Domains (CLP FD: Jaffar & Lassez, 1987). Much of the power that CORE provides is a direct consequence of CLP FD functionality (Vera et al., 2004). Importantly, the scheduling algorithms provided by CLP FD make it possible for an analyst using CORE to focus on the declarative specification of theory without worrying about the theory-irrelevant algorithms by which behavioral implications will be derived.

At the end of phase 1 the values of the start, duration, and other parameters, such as cost, are constrained by the posted equations, but their values are not yet uniquely determined.

Phase 2. Phase 2 involves making a prediction by finding a particular behavior that is consistent with the set of constraints, i.e. phase 2 must identify a consistent set of values for variables that were posted to the CLP FD constraint store (e.g. start time, duration, cost). This is achieved by calling a function that uses constraint satisfaction to achieve variable assignment. This function can be configured to use a range of scheduling algorithms. Two are particularly important for the purposes of reasoning about cognition: greedy scheduling and optimal scheduling.

Greedy scheduling. Scheduling proceeds with the tick of a clock. On each tick, a process is selected that can be scheduled immediately. The process is assigned the appropriate start time. Greedy scheduling can be used to model ACT-R/PM and EPIC. A greedy scheduling algorithm is not guaranteed to give an optimal schedule.

Optimal scheduling. Using CLP FD, a branch-and-bound algorithm can be used to generate a schedule with the greatest utility. We have used a utility function that is maximal when cost is minimized. Cost is defined as the sum of the total duration of the schedule and the durations of the buffers required to store information. As we illustrate below the ease with which CORE can be used to generate predictions of the optimal behavior, given the theoretical assumptions, is one of its key advantages.

Reasoning about dual task performance

In Schumacher et al.'s (1999) experiment (Experiment 3) participants were required to respond to a tone and a visual pattern with key presses that depended on whether the tone was high or low and whether the pattern contained a particular feature. The tone and the pattern were presented with a small gap of between 50 and 1000ms (Stimulus Onset Asynchrony). Participants were asked to prioritize the tone task. The tone task response times were, on average, unaffected by SOA. In contrast, the mean pattern task response time, at a short SOA (50ms), was less than the sum of the tone task and pattern response times at long SOAs (> 500ms). This finding has been taken as evidence that some elements of tone and pattern task were performed in parallel at short SOAs. Byrne and Anderson were interested in modeling Schumacher's data using ACT-R/PM in order to demonstrate that cognitive parallelism is not required to explain these results. They argued that the results can be modeled with either the EPIC or ACT-R/PM assumptions and that Schumacher's data provides evidence for strategic deferment of the pattern task response.

Specification and Inference

We demonstrate that the theoretical assumptions of Byrne and Anderson (2001) and separately of Schumacher et al. (1999) can be precisely expressed as a small set of predicate calculus constraints, and that CORE can be used to support reasoning about their behavioral consequences.

We used 42 universally quantified constraints to capture the theoretical assumptions underlying the architecture and strategies deployed in Byrne and Anderson's model (see www.cf.ac.uk/psych/howesa/ccm). Together with the CCM-d axioms, these constraints are a mathematically-complete specification of the theory underlying Figure 1. They capture constraints on the task environment, the strategy, the architecture, and in addition the axioms of CCM-d. (It would in fact be possible to use many fewer constraints but we attempted to write them in a way that was general enough to enable reuse.) We selected parameters to fit the performance time and ran the model with a greedy scheduling algorithm to check its performance. It produced the same pattern of results as reported by Schumacher and modeled by Byrne and Anderson (2001).

One of the constraints that is particularly important for the predictions made by Anderson and Byrne's model states that the duration of retrieval is sensitive to whether the retrieval request is issued when the tone task overlaps in time with the pattern task. This relies on an implementation of the ACT-R retrieval time function, *retrieval_time(B,S,T),* where B is the base level activation, S is the source activation, and T is the returned retrieval duration. The source activation is lower per task when there are multiple concurrent tasks.

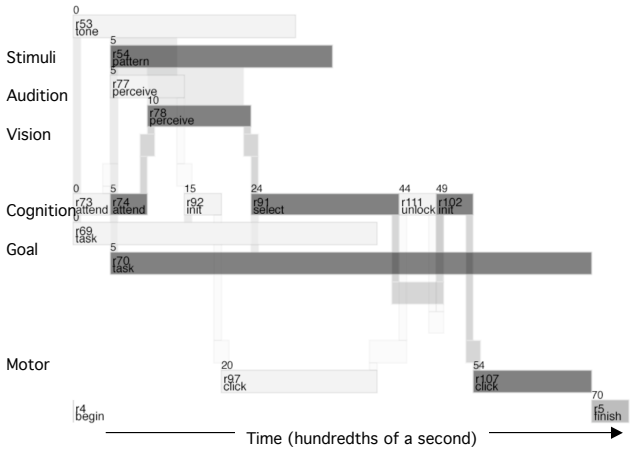

Figure 2: A CCM-c prediction of performance on Schumacher et al.'s (1999) experiment 3 task.

Subsequently, we modified the specification in order to remove the ACT-R/PM assumption that there is a central bottleneck on human cognition and permit EPIC-like concurrent cognitive processing. Only a handful of changes were required to make this alteration, demonstrating the claim that CORE facilitates reasoning about the consequence of different architectural assumptions. First, the tone task and pattern task cognitive processes were assigned to separate resource streams, and second, an unlock process was introduced and its duration adjusted to fit the data.

The fact that ACT-R and EPIC resource assumptions can be captured with such similar sets of constraints is unsurprising given their shared intellectual history (though it would be interesting to compare the Lisp code). In general, the space of theories that can be represented with CCM is determined by the requirement that theories are described in terms of processes, processors, the relationships between them, and by the axioms (CCM-d or CCM-c).

Skill and optimal constraint satisfaction

In order to explore the hypothesis that skilled behavior is the optimal solution to a constraint satisfaction problem, we switched from greedy scheduling to optimal scheduling (a parameter change in the input specification). CORE generated a novel prediction. In the behavior for a task with a 50ms SOA and a simple pattern, rather than choose to schedule the pattern selection process so that it was concurrent with the tone task, CORE chose a schedule in which selection (i.e. retrieval) is deferred until after the tone task has finished. The benefit is that by deferring selection, the overall time requirement is slightly reduced. This is because even though the selection process starts later (after the tone click in Figure 1) it has a much shorter duration (only 30ms compared to the 250ms). The resulting difference in the overall time cost of the schedules is marginal but the qualitative difference in the strategies is dramatic. The analysis exposes a necessary consequence of ACT-R's retrieval function and the assumption that people adapt strategies to reduce time cost.

The example illustrates the way in which CORE can facilitate the exposure of a logically required implication of a set of theoretical assumptions. Byrne and Anderson's ACT-R model does not make this prediction because it does not optimize over the total cost of the behavior. Optimal scheduling exposes the possibility that participants strategically defer retrieval so as not to incur the costs of concurrent processing.

Our analysis also raises a question about a fundamental assumption embedded in the ACT-R retrieval function: That retrieval time is not dynamically adjusted with changes in source activation occurring during retrieval. I.e. the sensitivity of the retrieval time function to source activation is limited to the value of the source activation at the time of the retrieval request. An alternative assumption would be that retrieval could take advantage of increases in source activation that occur after a retrieval request is made but before a chunk is delivered. With this alternative assumption, deferred retrieval in the Schumacher task would carry no advantage. Which assumption provides a better model of human retrieval is an empirical question that is not answered by Schumacher's data.

Cognition as cascading information processing

CORE is flexible enough to accept theory specifications expressed relative to a range of different sets of axioms. For the work reported above we used axioms that were based on the notion of a dependency (CCM-d). However, there are intrinsic limitations of dependency-based axioms (Vera et al., 2004) and we have therefore been working on the specification of a set of axioms that is based in part on the idea of a cascade as a mechanism for representing overlapping, communicating processes. Our formalization builds on McClelland's (1978) original cascade assumptions to explicitly include the declaration of resource-limited communication channels and buffers between processes.

Figure 2 illustrates a prediction derived by CORE using CCM-c axioms. The start times and durations of the processes are the same as in Figure 1. The difference between the figures is that the relationships between processes are expressed in terms of cascades. These capture the resource requirements and temporal constraints on the inter-process communication channels. The cascades are represented in Figure 1 as the lightest gray bars that run between the processes. One advantage of cascades is that they prevent cognitively implausible process orderings that would be legal using CCM-d. For example, the process ordering init(x), init(y), click(y), click(x) is legal in CCM-d but cognitively implausible because it assumes no cost to buffering information between the cognitive intention and the motor action.

Discussion

We have introduced a framework and a tool for making inferences about the implications of formally specified theories of skilled behavior. The tool uses a constraint logic-programming environment to support the inference of the

asymptotic bound on skilled behavior given a specification of the constraints on the task environment, on perception, on cognition, and on action.

Our investigations are at an early stage. We have so far explored the potential of dependency and cascade axioms on only a handful of tasks. In addition to the dual task described in the current paper we have also used CORE to generate predictions for a range of applied tasks including a call-center accounts advise task, and a laboratory version of an Automated Teller Machine.

Our aim in conducting this work was not to recast ACT-R/PM and EPIC in a formal language. The aim was to provide a tool that could assist in the prediction of the asymptotic bound on skilled behavior given constraints on, not only, objective and environment but also on strategies and architecture. We concur with Simon (1992) that an analysis of the optimal adaptation given all of these sources of constraint provides a more accurate estimation of behavior. While the extent to which we can achieve our aim is yet to be determined, we have presented arguments for the scientific merit of deductive inference in exploring the asymptotic bound on skilled behavior. We have shown that by deriving the optimal schedule of behavior for these constraints, logically implied but previously unexplored predictions of behavior can be exposed. The fact that a novel prediction was generated for a task that has been the subject of a number of published studes illustrates that the benefits of cognitive constraint modeling go beyond redescription of existing theory.

One potential concern is that if we were to write a set of constraints to capture the range of behaviors exhibited by, for example ACT-R, we would generate a set that was as large and formidable as ACT-R's Lisp code. Our response is twofold. First, we note that CCM is not a simple subset of ACT-R, it includes functionality, particularly optimization, that is not present in simulation architectures. Second, we point out, again, that our aim is not to recast ACT-R or EPIC in a formal language. More particularly, our aim, at present, is not to build a simulation architecture, rather it is to provide a tool for supporting reasoning about psychological theory. Much of the complexity of the ACT-R and EPIC implementations may be related to the simulation-based framework in which they are cast.

Our current work is aimed at further developing the generality of CORE. Most importantly, we need to take full advantage of the constraint satisfaction engine, CLP FD, that is used for the calculation of arithmetic parameters. In the present implementation of CORE, this engine is not used to reason about the symbolic inter-process constraints. We also need to work on using constraint satisfaction techniques that support reasoning about statistical distributions rather than just integer values.

In conclusion, we have introduced a constraint-based framework for reasoning about human behavior and argued for the utility of a specific tool called CORE. Our investigation suggests that partially automatic algorithms can be used to generate predictions of optimal human behavior from concise, theory-relevant, and readily modifiable, specifications of psychological theory.

Abstract

We describe a connectionist model designed to reflect some of the anatomy of the visual pathways, notably the precise division of the human fovea and its subsequent contralateral projection to the cortex. The model was trained on a realistically large-scale problem, mapping between Chinese orthography and phonology. This split-fovea model replicated the interaction between character regularity and frequency that has been found in Chinese phonetic compound naming tasks. It also provided cross-language support for the hemispheric desynchronization account of dyslexia. Finally, the model predicted different regularity effects between characters with different phonetic radical positions.

Introduction

Cognitive scientists aim to understand language processing universals. Seidenberg and McClelland's "triangle model" of the reading of monosyllabic English words has been substantially developed (e.g. Harm & Seidenberg, 1999). However, there is still little application to languages other than English. The cognitive modelling of the processing of Chinese orthography suffers from an input representativeness problem (cf. Chater & Christiansen, 1999) due to its complexity; there is ongoing debate as to how to represent Chinese characters in a psychologically realistic way. Most of the proposed computational models of Chinese character reading either have not been computationally implemented (e.g. Perfetti & Tan, 1999), or have employed relatively small-scale training data (e.g. Chen & Peng 1994). Cognitive modelling research in Chinese reading thus has lagged behind research in the reading of English.

Chinese has a radically different orthography from any alphabetic language. The basic writing units of Chinese are characters, which usually contain meaningful morphemes, instead of the letter-based representations of speech segments found in alphabetic languages. In general, there are four different ways of composing Chinese characters: *pictographs*, *indicatives*, *ideographs*, and *semantic-phonetic compounds*. A semantic-phonetic compound (or simply a *phonetic compound*) contains both semantic and phonological information. Such compounds comprise about 81% of the 7,000 most frequent characters in the Chinese dictionary (Li & Kang, 1993). Hence, understanding how Chinese readers recognize these phonetic compounds is an important goal in psycholinguistic cognitive modelling.

A phonetic compound can be decomposed into two major components: a semantic component, which bears information about the meaning of the character, and a phonetic component, which may have partial information about the pronunciation of the character. Most phonetic compounds have their semantic radicals on the left and phonetic radicals on the right (SP characters). For example, the character "沐" means "taking a bath" in English and is pronounced as "mu4" in Pinyin[1]. It consists of a semantic radical on the left, which means "water", and a phonetic radical on the right, which is pronounced the same as the character. We call these characters *regular phonetic compounds*. Some characters may be pronounced slightly differently from their phonetic radicals, such as "柚". Its phonetic radical "由" is pronounced as "iou2" in Pinyin. However, "柚" has a different tone – it is pronounced as "iou4". These characters are referred to as *semi-regular phonetic compounds*. Finally, there are some characters pronounced very differently from their phonetic radicals, such as "洒" (sa3) and "西" (xi1). We call them *irregular phonetic compounds*. The opposite structure to an SP character exists, in which the phonetic radical is on the left and the semantic radical is on the right (PS characters). The ratio of SP characters to PS characters is about 9:1 (Hsiao & Shillcock, *in preparation*).

A *regularity effect* has been found in the processing of Chinese phonetic compounds: Chinese readers name regular characters faster than irregular characters. There is also a frequency by regularity interaction in Chinese, as in English (see, *.e.g.*, Hue, 1992; Liu, Wu & Chou, 1996; Seidenberg, 1985.)

Researchers have also studied Chinese character reading in brain-damaged patients (Yin & Butterworth, 1992) and found similar disorders as those found in

[1] The Chinese Pinyin system is a spelling system based on the Latin alphabet. The number at the end indicates the tone type.

English word reading. Chinese deep dyslexics were found to be able to pronounce irregular characters well but had difficulties pronouncing pseudo-characters with real semantic and phonetic radicals. On the other hand, Chinese surface dyslexics tended to regularize irregular characters and were able to pronounce about 50% of pseudo-characters according to their phonetic radicals (Zhou, 1999).

There is clear evidence that the human fovea is split precisely about the vertical midline: the left and right visual hemifields are projected contralaterally to the right and left hemispheres respectively (see, e.g. Fendrich & Gazzaniga, 1989). On the basis of anatomical and other evidence, a "split-fovea model" of English word reading has successfully captured several reading phenomena (see, *e.g.*, Shillcock Ellison & Monaghan, 2000; Shillcock & Monaghan, 2001). Chinese phonetic compounds provide opportunities not available in alphabetic languages for examining the plausibility of this split-fovea model, since phonological information only comes directly from half of a character. In other words, the split fovea architecture seems to correspond fortuitously to the major functional division in the structure of Chinese phonetic compounds; the model "carves the problem at its joints". Also, when an input character is irregular, the model faces an XOR-like problem, which makes interaction between the two halves necessary. Here we report our results of applying this split-fovea architecture to the modelling of Chinese character pronunciation.

Simulations

Phonological Representations

The sound system of Chinese differs from that of English. One of the most salient differences is the four distinct tones in standard Chinese (i.e. Mandarin)[2]. The pronunciation of each character has only one syllable, and every syllable has a nucleus and a tone associated. Characters with the same nucleus but different tones are usually not related in their meanings or orthography. In addition to a nucleus and a tone, there are three optional components associated with a syllable: a consonant at the beginning, a glide in the middle, and a glide or a consonant from a restricted class at the end (Wang, 1973). In total, syllables in Chinese have eight possible forms.

In Chinese syllables, all consonants can appear in the initial consonant position, and all vowels can appear in the nucleus position. On the other hand, there are only three possible vowels in the medial glide position, and five possible consonants and vowels in the ending position. According to the phonetic features of the Chinese Pinyin system ("Mandarin Consonants and Vowels"), there are 14 features for consonants: *bilabial, labiodental, dental, alveolar, palatal, velar, stop-aspirated, stop-unaspirated, nasal, fricative, affricative-aspirated, affricative-unaspirated, glide, and liquid*. Hence, we encoded every consonant in terms of these 14 features. Vowels were encoded with 8 features: *front, central, back, high, mid, low, unround, and round*.

In our phonological representation, the two major parts were the initial consonant, which consisted of 14 nodes for the 14 consonant features, and the nucleus vowel, which consisted of 8 nodes for the 8 vowel features. The glide was represented together with the vowel features in the nucleus vowel section. The same applied to the vowel features in the ending position. After 8 vowel feature nodes, we used 3 nodes to represent the features of the consonant in the ending position (*nasal, dental,* and *velar*). Notice that there are only two consonants (n and ng) possible in the final position. The last 2 nodes represented high and low tones respectively. 4 different tones in Chinese were represented with different combinations of the high and low tones (Yip, 2002). In total, the distributed phonological representation consisted of 27 nodes (see Figure 1).

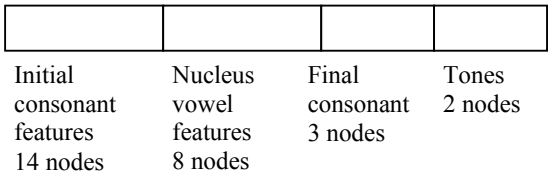

Figure 1: The phonological representation.

Orthographic Representations

Chinese characters consist of several individual strokes. There are some 20+ distinct strokes in Chinese orthography. Together, a few strokes may comprise a "stroke pattern", a recurrent orthographic unit of Chinese characters. Some stroke patterns can be characters by themselves. Units can be constructed recursively to form another composite unit. Those units that are integral stroke patterns and cannot be further decomposed into other units have been referred to as *single bodies* (Chen et al, 1996).

Researchers have long believed that Chinese character recognition starts from an analysis of features and the number of individual strokes (e.g., Seidenberg, 1985), in contrast with letters in alphabetic writing systems. In recent years, researchers have found evidence that this recognition by skilled readers is based upon well-defined orthographic constituents, instead of individual strokes (Chen, Allport, and

[2] Some dialects in China, such as Cantonese or Southern Min, may have more than four different tones.

Marshall, 1996; Zhou & Marslen-Wilson, 1999). Hence, in the orthographic representation, we used the basic stroke patterns defined in Cangjie, a Chinese transcription system developed by Ban-fu Chu in 1978. From a database analysis, there are 179 such stroke patterns comprising the radicals of all left-right structured Chinese phonetic compounds (Hsiao & Shillcock, *in preparation*). Hence, we used these 179 stroke patterns to encode the orthographic representation of the Chinese characters whose pronunciation we modelled.

Training and Test Corpora

The training corpus contained all left-right structured Chinese phonetic compounds and all their radicals which exist as characters on their own. During training, each character was presented according to its log token frequency, taken from a Chinese lexical database (Hsiao & Shillcock, *in preparation*). The database contains about 3,000 of the most frequent Chinese phonetic compound characters. Among them there are 2,159 left-right structured phonetic compounds and 880 radicals that are also existing characters. The test corpus contained the same phonetic compounds, but not the radicals on their own.

Network Architecture

Anatomical evidence has shown that the human fovea is precisely split about a vertical midline: when an alphabetic word or a Chinese character is fixated, the parts to the left and right of the fixation point are directly projected contralaterally. In modelling Chinese character recognition, we initially abstracted from real fixation behaviour and assumed that a character consisting of a semantic and a phonetic radical side by side could receive three possible fixations (see Figure 2). Characters were presented in the three fixation positions equally frequently during training. The task for the model, as for the reader, was to coordinate the information across the hemifields/hemispheres (Shillcock *et al.*, 2000).

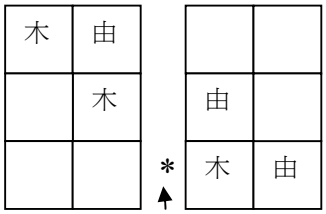

Figure 2: The complete pattern of inputs.

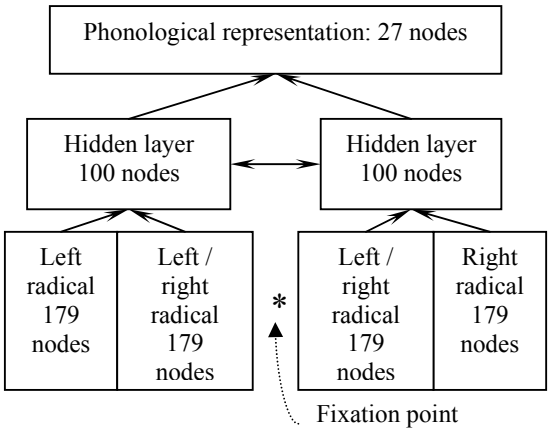
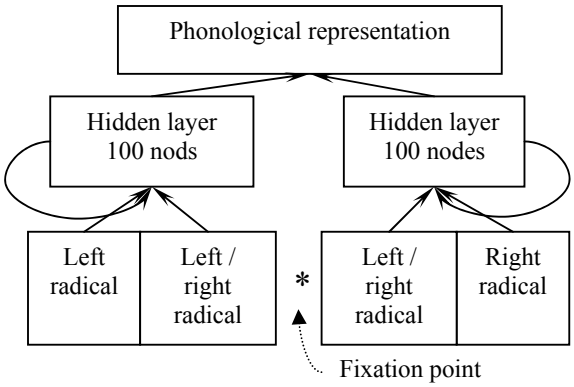
The network consisted of three layers. Adjacent layers were fully connected. Input units were localist representations of stroke patterns, capturing the claim that stroke patterns are functional units of character recognition. The characters were all represented in each of the three positions necessary to accommodate the input schema shown in Figure 2. Each position represented each of the 179 possible stroke patterns. The input was mapped, via a hidden layer, onto a feature-level phonological output. For characters with more than one pronunciation, only the most frequent pronunciation was employed.

The model is shown in Figure 3. To solve the task, "interhemispheric" communication is necessary, in the form of "callosal" connections between the two sets of hidden units.



Total number of links: 97,000

Figure 3: The split-fovea model for mapping Chinese orthography to phonology, with callosal connections.



Total number of links: 97,000

Figure 4: The model with no callosal connections.

Figure 4 shows a comparison model with no callosal connections in the hidden layers, which was trained on

the same task. In order to compare the performance of the two different architectures, we equalized their computational power by putting recurrent links on the hidden layers of the model with no callosal connections. Hence, both models had identical parameters and numbers of weighted connections. Thus, the principal difference between the models was the network architecture. We report elsewhere the more comprehensive comparison with a non-split model. The learning algorithm was discrete back propagation through time (Rumelhart, Hinton, and Williams, 1986).

Results

We ran each of the two different models three times and analyzed their average performance. Figure 5 shows the performance of the two models on regular and irregular characters, in terms of summed square error (SSE) at different stages during training. Neither of the two models had difficulty learning this task well. The split architecture encouraged the model to discover the formal similarities within the radicals in the two halves of the characters; that is, that most phonological information came from the right half of the characters. The divided visual system fortuitously mirrored this distinction in the orthography.

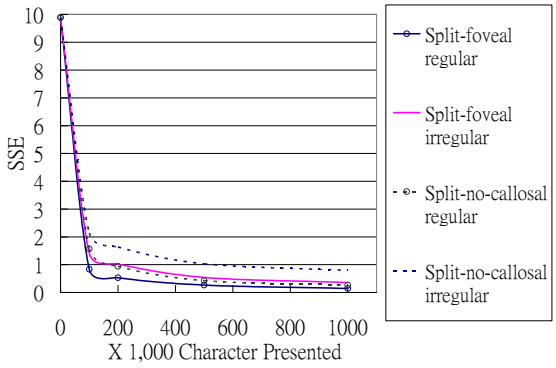


Figure 5: Performance of different models on regular and irregular characters.

The implemented split-fovea model provides an approach to understanding dyslexia in terms of hemispheric desynchronization (Shillcock & Monaghan, 2001). In the current simulations, the split-fovea model with callosal connections outperformed the model with no callosal connections (equivalent to extreme hemispheric desynchronization) on both regular and irregular characters; it especially exhibited more difficulty learning irregular characters, which constitute an XOR-like problem for the model with no callosal connections. Chinese surface dyslexics demonstrate reading impairments similar and analogous to those of dyslexics in alphabetic languages: poorer performance reading irregular characters (Yin & Butterworth, 1992). Hence, the implemented split-fovea model provides cross-language support for the hemispheric desynchronization account of dyslexia.

The model with no callosal connections made regularization errors on irregular characters, as we might predict from the nature of the problem it faced. Table 1 shows some examples of such regularization errors. As can be seen, most characters were mistakenly pronounced exactly like their phonetic radicals; some were given the same pronunciation but with a different tone. Interestingly, we found some which were pronounced as other irregular characters with the same phonetic radical (e.g., 俗 in Table 1). This shows that the pronunciation of an irregular character was not only affected by its phonetic radical, but also by orthographic "neighbours" which share the same phonetic radical.

Character	Correct pronunciation	Generated pronunciation	Phonetic radical pronunciation
猜	cai1	qing1	qing1 (青)
帖	tie3	zhan4	zhan4 (占)
横	heng2	huang2	huang2 (黄)
俗	Su2	yu4 (欲, 裕)	gu3 (谷)
沙	sha1	shao2	shao3 (少)
冶	ye3	tai2	tai2 (台)
杯	bei1	bu4	bu4 (不)

Table 1: Examples of regularization errors generated by the split model with no callosal connections.

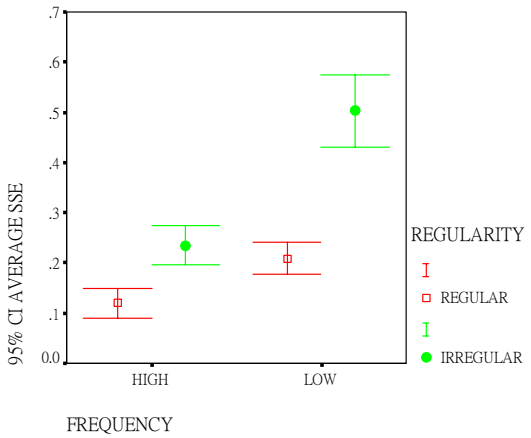

Figure 6: Interaction between frequency and regularity in the model with callosal connections after two million character presentations.

Figure 6 shows the interaction between frequency and regularity effects in the split-fovea model with callosal connections, after two million character presentations. This same interaction has been shown in experiments on Chinese character recognition (see, e.g., Shu et al, 2000; Hue, 1992; Liu, Wu & Chou, 1996; Seidenberg, 1985.). The model also produced this behaviour: the regularity effect was clearer among low frequency characters; there was a significant interaction between regularity and frequency (ANOVA analysis, $F(1,1075) = 16.296$, $p < 0.001$). The same significant interaction was also found in the version of the model with no callosal connections ($F(1,175) = 6.809$, $p < 0.01$).

We also examined the model's behaviour on SP and PS characters. It showed that there was no significant difference in the average SSE between the two groups in both split models with and without callosal connections ($F(1,2155) = 1.730$, $p > 0.05$; $F(1,2155)=2.117$, $p > 0.05$). A significant interaction between position of the phonetic radical (i.e. SP or PS characters) and regularity was also found in both models ($F(1,2155) = 4.719$, $p <0.05$; $F(1,2155) = 5.479$, $p <0.05$. See Figure 7 and 8). In the split model with callosal connections, there was a significant regularity effect among SP characters ($F(1,1940) = 127.486$, $p < 0.001$), but not among PS characters ($F(1,215) = 3.048$, $p > 0.05$). This may reflect the fact that only 24% characters are regular in the PS group, compared with 39% in the SP group (Hsiao & Shillcock, *in preparation*). On the other hand, the split model with no callosal connections did not exhibit the same behaviour: there were significant regularity effects among both SP characters ($F(1,1940) = 140.654$, $p < 0.001$) and PS characters ($F(1,215) = 6.493$, $p < 0.001$. See Figure 8). Here the modelling makes a testable prediction regarding human behaviour. Elsewhere we verify this prediction (Hsiao & Shillcock, *submitted*).

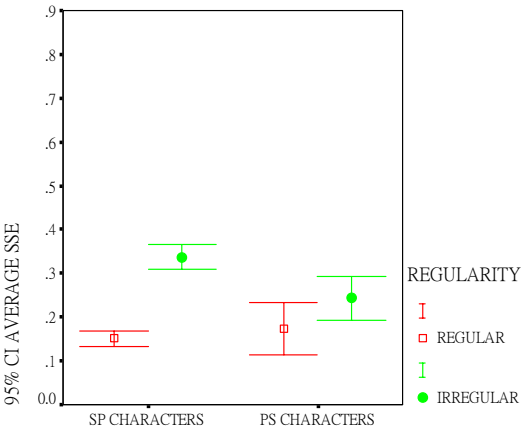

Figure 7: Interaction between position of phonetic radicals and regularity of characters in the split model with callosal connections.

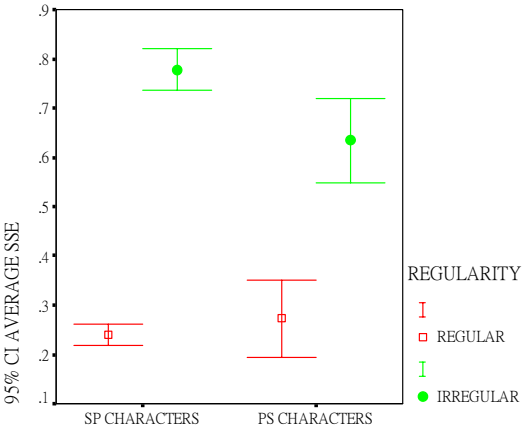

Figure 8: Interaction between position of phonetic radicals and regularity of characters in the split model with no callosal connections.

Conclusion and Discussion

We have presented a connectionist model of Chinese character recognition, an extension of the anatomically based split-fovea model, and we have compared the processing of Chinese phonetic compounds in architectures with and without callosal connections. We have incorporated several simplifications concerning the nature of the orthographic input and fixation behaviour, but several dimensions of our modelling have been of a psychologically realistic scale and the modelling has succeeded in capturing a number of behaviours and also in making experimentally testable predictions.

On the task of orthography to phonology mapping, the split-fovea architecture facilitates the network's discovery of the relationship between character substructure and pronunciation. The split architecture fortuitously corresponds to the major functional division in the stimuli we have used. This modelling further demonstrates the potential value of incorporating the anatomical constraints of the visual pathways into the computational modelling of reading: the requirement of a staggered input (Figure 2) effectively parses the stimuli (a process that is more apparent in modelling the reading of alphabetic inputs).

Also, we have examined the performance of the model with no callosal connections and found behaviour similar to that of Chinese surface dyslexics. The performance of the "callosally impaired" model is worse than the split-fovea model especially on irregular characters. A further examination showed that most

errors made were regularization errors, which matches the behaviour of surface dyslexics. The modelling hence provides cross-language support for the hemispheric desynchronization account of surface dyslexia.

The model also has made some testable predictions from its performance. It shows that the regularity effect is more salient among characters with their phonetic radicals on the right than on the left. This interaction reflects a statistical fact that there is greater regularity among characters with phonetic radicals on the right. Hence, these phonetic radicals become better cues for pronunciation.

How speech processing affects our attention to visually similar objects: Shape competitor effects and the visual world paradigm

Abstract

It was investigated how spoken language is mapped onto the mental representations of objects in the visual field. Specifically, the visual world paradigm was used to test the hypothesis that during 'passive' listening tasks attention is directed more towards objects in the visual field that match the physical shape of the concept of the word concurrently heard than towards objects that do not match on physical shape. Participants listened to sentences containing certain critical target words of concepts with a typical shape (e.g. '*snake'*) while concurrently viewing a visual display of four objects. We found that participants tended to fixate conceptually unrelated objects with a similar physical shape (e.g. cable) as soon as information from the target word (e.g. '*snake'*) started to acoustically unfold. The results indicate that (contrary to some priming studies, e.g. Moss et al., 1997) shape information is accessed long before the offset of the spoken word. We discuss the findings with respect to the applicability of the visual world paradigm for the investigation of the access of lexical representations and theories of active vision.

Humans 'translate' between spoken language and concurrent visual input in such a natural way that we are hardly ever consciously aware of the processes involved. Surprisingly, there has been little research that has attempted to explore explicitly the interaction of these processes. A notable exception has been the research within the 'visual world paradigm' (the measuring of eye movements around a visual scene or display of objects in response to concurrent speech: Cooper, 1974; Tanenhaus et al. 1995) using both linguistic and visual contexts. Cooper (1974) established that when participants were presented simultaneously with spoken language and a visual field containing referents of the spoken words, participants tended to spontaneously fixate the visual referents of the words currently being heard. For example, participants were more likely to fixate the picture of a snake when hearing part or the entire word '*snake'* than to fixate pictures of unrelated control words. Cooper (1974) also found that participants were more likely to fixate pictures showing a lion, a zebra, or a snake when hearing the semantically related word '*Africa'* than to fixate semantically unrelated control words. Cooper's (1974) early study thus established two main findings: first, during the acoustic duration of a spoken word participants show a strong tendency to fixate objects that the word refers to. Second, his study highlighted the influence of semantic relationships on language-mediated fixation behavior: participants are more likely to fixate a visual referent that has some semantic relationship with the word heard than a semantically unrelated visual referent (see Huettig & Altmann, 2004; Yee & Sedivy, 2001; for follow-up studies). The primary goal of research in the visual world paradigm following Cooper's (1974) pioneering study has been to use eye movements as a tool to shed light on linguistic processing. For example, Allopenna, et al. (1998) asked participants to '*Pick up the candy. Now put it …*' in the context of a visual display of objects including (among other things) a candy and a candle. They found evidence for a phonological competitor effect: eye movements to both the candy and the candle increased as the word '*candy'* acoustically unfolded but that soon after its acoustic offset, looks to the candle decreased while looks to the candy continued to rise. The Allopenna et al. (1998) study provided evidence for a standard competitor effect as predicted by theories of auditory word recognition such as TRACE (e.g. McCleland & Elman, 1986). Importantly the study demonstrated this effect in real-time as the speech stream was unfolding acoustically (see also Dahan et al., 2001; for more evidence that the visual world paradigm provides fine-grained measures of lexical processing).

However, far less attention has focused on examining the interaction of spoken language with directed attention and the *visual* properties of the presented objects. In this regard, Cooper (1974) also found that participants tended to fixate a picture of a snake when hearing the word '*wormed'* (in the context '*just as I had wormed my way on my stomach*'). This finding (although not discussed by Cooper) suggests that there may also be a strong link between lexical processing and the visual properties of an object such as an object's shape (although it cannot be ruled out that in Cooper's experiment participants mistook the snake for a worm and therefore directed their attention to the picture of the snake when hearing '*wormed'*).

The visual world paradigm and the access of lexical representations Importantly, Cooper's study (1974) is indicative that similar processes to semantic priming are taking place when people map spoken words onto related visual objects. The semantic priming paradigm (Meyer & Schvanefeldt, 1971) has proven to be particular useful for

the investigation of lexical representations. The currently dominant view is that a word's representation is composed of smaller units (or 'features') of different kinds that are accessed during spoken word recognition. Recent distributed models of spoken word recognition (e.g. Gaskell & Marslen-Wilson, 1997) assume that some aspects of a word's meaning may be activated more rapidly than others resulting in a dynamic pattern of changes in the semantic properties throughout the duration of the spoken word. Evidence supporting this notion comes, for example, from priming studies by Moss et al. (1997) that found a significant priming effect for functional properties of words early during the duration of the word but priming for perceptual targets (e.g. the shape overlap between *hook* and *curve*) only at the offset of the prime word. In order to investigate these time-course issues the visual world paradigm may be particularly useful because of the closely time-locked, fine-grained measures the method provides.

In the current study we explored how the physical shape of objects in a visual display interacts with language-directed attention. Participants' eye movements were measured, during the acoustic duration of certain target words (concepts with a typical shape, e.g. '*snake'*), to conceptually unrelated visual objects that have a similar shape (e.g. the image of a cable). If participants shift their attention to conceptually unrelated objects with a similar shape (e.g. cable) when the word '*snake*' unfolds during online speech, then the inspection of the time-course of fixation probabilities should shed light on the issue whether (lexical) shape information is accessed only at word offset or before. In other words, if (lexical) 'perceptual' information such as shape is not accessed before the offset of the spoken word then the prediction is that there should be no increased attention to shape competitors (e.g. cable) *before* the offset of the acoustic target words (e.g. '*snake'*).

The visual world paradigm and 'active vision' Our study explored the effect of 'shape overlap' between spoken words and visual objects on *overt* attention. Relevant in this regard is that most vision research has focused on what Findlay & Gilchrist (2003) term 'passive vision': the assumption that image interpretation is largely passive and that parallel processing occurs across the visual image with algorithms charting the "progress from a grey-scale retinal input to an internal representation in the head". Findlay & Gilchrist (2003) reject this view in favor of 'active vision': the notion that *overt* gaze orienting is an essential and crucial feature of vision. This approach emphasizes the importance of re-directing attention overtly (rather than covertly) by moving the gaze in order for the attended location to obtain the instant benefit of high-resolution foveal vision. These proposals are similar to the notion that the perceptual system offloads information by leaving it in the environment rather than just passively passing information on to the cognitive system for propositional representations to be created. According to this view, perceptual information in the environment is accessed when needed, with the visual world functioning as a kind of external memory (e.g. O'Regan, 1992). Objects in this situated memory are represented in a spatial data structure which contains 'pointers' to the real-world location of the object. Thus, the system need not store internally detailed information about the object, but can instead locate that information, when it has to, by directing attention back to that object in the environment. Essentially, the focus in active vision research is on understanding why and when gaze is re-directed. In other words active vision places vision in a context. And one important variable that impacts on (and guides) active vision is spoken language.

Importantly, there was one second preview of the visual display in our study and the target words unfolded approx. five seconds after the onset of the visual display. This means that all four objects were fixated (usually several times) before the onset of the target word. Therefore the prediction is that on 'passive vision' accounts, arguably, there is no need for an *immediate* shift in overt attention towards a conceptually *unrelated* object (e.g. cable) when the word '*snake'* unfolds. In other words on 'passive vision' accounts all relevant information has already been encoded and is available to the system for further cognitive processing. On active or situated vision accounts, however, the prediction is that on hearing the target word, overt attention will be re-directed to the shape competitor to retrieve more information about that object to establish its fit with the specification provided by the target word.

Methods

Participants 48 participants from the University of York student community took part in this study. All were native speakers of British English and had either uncorrected vision or wore soft contact lenses or glasses.

Materials The experiment made use of three conditions. 21 items were created consisting of two types of spoken sentences containing a target word (e.g. *'snake'*) for two sets of visual stimuli. In the 'target set' the visual stimulus was a picture depicting a fully matching referent (e.g. a snake) for the acoustic target word plus three distractors depicting objects from different conceptual categories. The stimuli in the 'shape competitor set' consisted of the same four pictures, in identical positions, except that the target picture (e.g. the snake) was replaced by a picture depicting an object with a similar shape as the target word (e.g. a cable, Figure 1).

The sentential stimuli were constructed for three conditions: neutral sentences with the pictures of the 'target set' (the neutral condition), sentences biasing the visual target referent (biasing snake) with the pictures of the 'target set' (the biasing condition), and the same sentences as in the biasing condition but where the picture of the target object (e.g. snake) was replaced by a picture of a shape competitor (the competitor condition, e.g. the picture of a cable). The rationale for presenting the shape competitor in a biasing context was simply to make it relatively unlikely that participants would anticipate, prior

to the target word, that the shape competitor would be the object of attention (even though it was not going to be referred to directly). The neutral sentences were included in order to establish a baseline against which the efficacy of the biasing context could be determined.

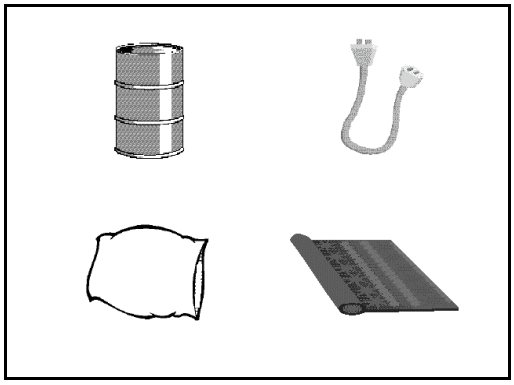

Figure 1. Visual stimulus in the competitor condition (depicting: physical shape competitor of the acoustic target word '*snake'*: cable, 3 distractors)

In sum, for the neutral condition, the sentence did not provide any contextual bias up until the target word that would favor any of the pictures depicted in the visual scene ('*In the beginning, the man watched closely, but then he looked at the snake and realized that it was harmless*'). In the biasing condition, the sentence was constructed to contextually bias towards the depicted target object (e.g. the snake): '*In the beginning, the zookeeper worried greatly, but then he looked at the snake and realized that it was harmless*'. In the competitor condition the sentence was identical to the biasing condition. However, the picture of the shape competitor (e.g. cable) was semantically unrelated to the target word (e.g. *'snake'*) and thus the sentential context did not provide any contextual bias towards the picture of the shape competitor. The target-competitor pairs were: anchor/arrow, apple/moon, banana/sword, bell/hat, button/coin, candle/tube, cigar/carrot, chimney/rocket, dice/ice cube, football/planet, globe/orange, horseshoe/magnet, lighthouse/flask, microphone/cone, mirror/frame, pencil/column, plate/wheel, racket/saucepan, scissors/chopsticks, snake/cable, wheelbarrow/sledge.

Norming study In order to determine the relative similarity in physical shape of the target concept activated by the acoustic target word with the depicted objects a norming study was conducted. Twelve participants provided normative data. Participants were presented with the written target word (e.g. *snake*) and the actual visual items. Participants were asked to judge how similar the typical physical shape of the target concept (*snake*) was with the physical shape of the depicted objects on a scale from 0 to 10 (zero representing: 'absolutely no similarity in physical shape', 10 representing: 'identical in physical shape'). The mean similarity for the shape competitors was 7.1 (SD = 1.8) and for the distractors 1.4 (SD = 0.7). These differences in the shape similarity judgments between the shape competitors and the visually dissimilar distractors were highly significant ($F1$ (1, 11) = 268.89, MSE = 0.07, $p < 0.01$; $F2$ (1, 20) = 200.35, MSE = 0.17, $p < 0.001$).

Procedure and Design There were 21 experimental items (counterbalanced across the three conditions). For 14 of the experimental items per participant the visual stimulus included a visual referent matching the full 'target specification' of the target word (e.g. the acoustic word '*snake*' and the picture of a snake in the 'neutral condition' and the 'biasing condition'). For 7 of the experimental items there was no picture matching the full 'target specification'. For these items there was only a 'physical shape match' between the acoustic target word and the shape competitor picture (e.g. the acoustic target *snake* and the picture of a cable in the 'shape competitor condition'). 15 additional filler items were added, which all included a fully matching visual referent of an acoustic target word. There were four practice trials. Thus 82% of the 40 trials included a *fully* matching target visual referent (e.g. hearing '*snake'* and seeing a snake). This design made it very unlikely that the participants were able to note the physical shape relationship and adopt a conscious strategy accordingly. In addition, participants consistently stated in self-report that they neither moved their eyes according to some kind of explicit strategy nor noticed the 'shape manipulation'.

Participants were seated at a comfortable distance in front of a 17' display and wore an SMI EyeLink head-mounted eye-tracker, sampling at 250Hz from the right eye (viewing was binocular). They were told that they should listen to the sentences carefully. They were also told that they could look at whatever they wanted but were asked not to take their eyes off the screen throughout the experiment. The onset of the visual stimulus was one second before the onset of the spoken stimulus. The onset of the acoustic target word was on average 4 seconds after the onset of the spoken sentence and thus the acoustic target word started to unfold on average 5 seconds after the onset of the visual stimulus. The entire experiment lasted approximately twenty minutes. Participants' eye movements were recorded as they listened to the sentences.

Results

Fixation probabilities: *p*(fix) The probability of fixating a type of picture at a defined moment in time, *p*(fix), will be reported. The visual display consisted of four quadrants, each with one object. Gaze positions were categorized by the quadrant in which an object was depicted. The *a priori* probability of fixating one of the four pictures in absence of any bias was thus 0.25.

Table 1: *P*(fix) at the acoustic onsets and offsets of the target words (e.g. '*snake'*) and difference scores per condition

condition	neutral		biasing		competitor	
type of picture	target (snake)	distractor	target (snake)	distractor	competitor (cable)	distractor
p(fix) at onset	.27	.24	.39	.19	.25	.24
difference score at onset	.04		0.21		.01	
p(fix) at offset	.50	.15	.52	.14	.33	.22
difference score at offset	.35		.38		.11	

Table 1 shows *p*(fix) for the type of picture at the time points of critical interest: the acoustic onset of the target word (e.g. the acoustic onset of '*snake'*), and the offset of the target word (e.g. the acoustic offset of '*snake'*). The probability to fixate the three distractors was averaged to obtain one distractor value. Note that we did not add any time to account for the time it takes to program a saccade. All measures and analyses were based on the *real* acoustic time points. Figure 2 shows the time-course of *p*(fix) in the three conditions from the acoustic onset of the target word for 1000 ms.

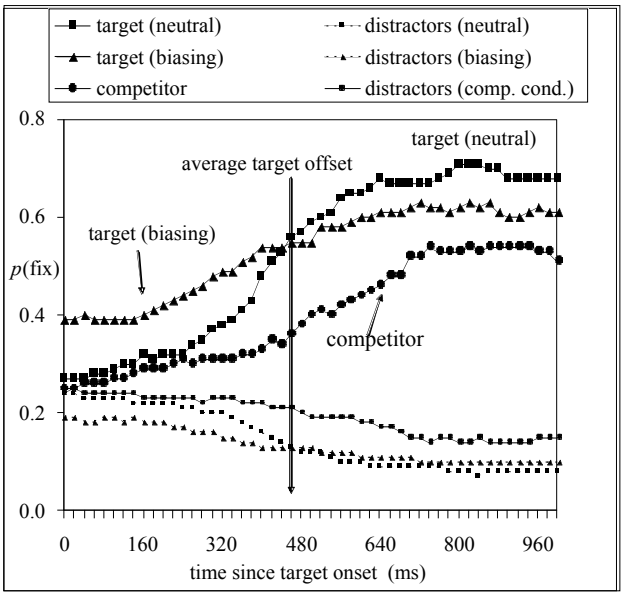

Figure 2. Time-course of *p*(fix) to the target in the neutral condition and the biasing condition, and to the shape competitor in the competitor condition (and averaged distractors of each condition).

Fixations of the different types of pictures at the acoustic onset of the target word is of interest in order to assess whether there were any biases in attention before information from the critical target word (e.g. '*snake'*) became available. It was predicted that at this point there would be no such bias in the neutral condition and the competitor condition if the context had been neutral with respect to directed attention to any of the pictures. However, it was predicted that at the acoustic onset of the target word there would be a bias towards the target picture (e.g. the snake) in the biasing condition because of the biasing sentential context. These predictions are apparently born out by the data. Table 1 shows that *p*(fix) at the onset of the target word was around 0.25 in the neutral and competitor conditions but that there was a strong bias towards the target object in the biasing condition. The acoustic offset of the target word reflects the point when the entire spoken target word has been heard by the participants. Fixations at this point are of interest in order to assess whether the acoustic unfolding of the target word resulted in changes in overt attention. Table 1 and Figure 2 show that the target and competitor fixations had increased in the neutral and the competitor conditions, whereas in the biasing condition the probability to fixate the target increased further. Nonetheless, Table 1 and Figure 2 suggest that *p*(fix) of the targets in the neutral and the biasing conditions was higher than *p*(fix) of the shape competitors in the competitor competition. In other words as acoustic information from the target words became available the probability to fixate the target picture *and* the shape competitor picture increased. However, *p*(fix) of the target pictures increased much more than *p*(fix) of the shape competitors.

Statistical analyses In order not to violate statistical assumptions (in particular that pertaining to the independence of observations), difference scores obtained in each condition are compared For instance to assess a bias to look at a critical picture (target or competitor vs. a distractor referent) the differences in fixation probabilities to these stimuli are considered. Such difference scores reveal both the magnitude and direction of the effects. In the current study *p*(fix distractor) was subtracted from *p*(fix target) and *p*(fix competitor). Any positive difference reveals a bias of looks towards the critical picture, a negative difference reveals a bias of looks towards the distractors, and difference scores close to zero reveals neither bias. The use of error bars in the form of 95% confidence intervals plotted around the sample means provides a quantitative visual representation of the faith that should be placed in the pattern of sample means as an estimate of corresponding patterns of population means. Figure 3 shows the mean of the difference scores for participants and items at the acoustic onset of the

target words (e.g. '*snake'*) in the three conditions. Error bars represent the 95% confidence intervals of the means computed individually for each difference score.

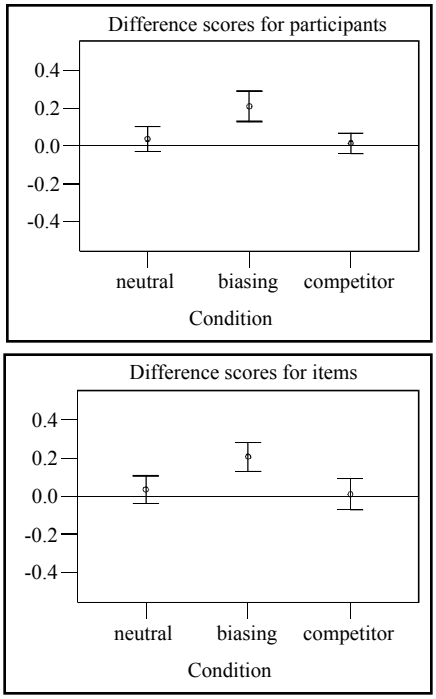

Figure 3. Means of the difference scores (participants and items) at the acoustic onset of the target words (Error bars represent the 95% confidence intervals)

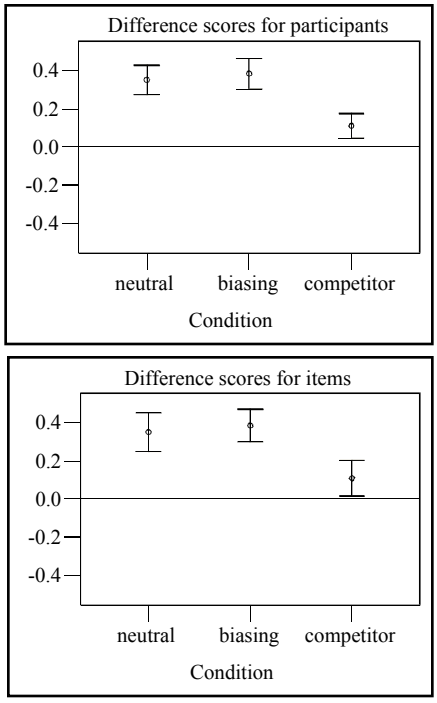

Figure 4. Means of the difference scores (participants and items) at the acoustic offset of the target words (Error bars represent the 95% confidence intervals)

Figure 3 shows that at target onset there were no reliable differences between looks to the critical pictures and the distractors in the neutral and the competitor conditions. In other words there were no differences in directed attention for type of picture at the acoustic onset of the target. However, there was a reliable bias in directed attention towards the target object in the biasing condition. Thus the contextual manipulation had been successful.

Figure 4 shows the mean of the difference scores for participants and items at the acoustic offset of the critical words. There was a reliable bias in directed attention to the critical pictures in all three conditions. Importantly, there was a statistically robust higher probability to fixate the shape competitor (e.g. the cable) than the distractors at the acoustic offset of the target word (e.g. '*snake'*).

General Discussion

Our findings directly link online conceptual processing during lexical access in speech to attentional behavior in the visual world. They extend Cooper's (1974) work by showing that during 'passive' listening tasks attention is also directed significantly more towards objects that match the shape of the word concurrently heard than towards objects that do not match on shape.

Importantly, the competitor effect was significant at the offset of the acoustic target words. This means that the shape competitor effect started to occur as soon as information from the target word acoustically unfolded given that the average duration of the target words was 447ms and that the *minimum* latency to program and initiate a saccade is 150 to 200 ms (e.g. Saslow, 1967). This result is contrary to priming studies (Moss et al., 1997) that found activation of perceptual (including shape) information only at the offset of the prime word. The current study suggests that the visual world paradigm is particularly sensitive for capturing the access of conceptual and perceptual information during lexical processing. Note that Moss et al. (1997) included five different types of 'perceptual' properties in their study. A reason for the discrepancy to our results thus may be that Moss et al. (1997) did not distinguish between different 'perceptual' properties such as color and shape. In other words they may have found delayed priming for perceptual targets because of the differential properties of the items they selected for their perceptual condition. An alternative explanation is that the information (from the spoken words) provided for the attentional system to visual objects involves such a tight 'loop' that other means of observing the access of (lexical) perceptual representations (e.g. the lexical decision task) can only do so at some delay. Similarly the activation in our study may have partly originated through spreading activation from shape information portrayed within the visual display. The shape information may have activated concepts sharing those features resulting in an earlier access of shape information during spoken word recognition. Our data do not show to what extent this activation may have originated from the visual display.

Notably, the present results are in line with the predictions derived from active or situated vision accounts that on hearing the target word, *overt* attention may be re-directed *immediately* towards only partly matching objects in order to retrieve more information and to establish their fit with the target specification as provided by the target word. Arguably, our findings coupled with the fact that there was one second preview of the visual display and that the target words unfolded approximatly five seconds after the onset of the visual display, cannot be as *easily* incorporated in 'passive vision' accounts.

Pickering, McElree, & Garrod (submitted) have recently proposed that participants may engage in a covert naming strategy in visual world experiments. Pickering et al. state that "many effects in this paradigm may be partly the result of participants' regularly naming the objects covertly… further research is needed to determine the extent to which visual world results depend upon linguistic recoding (covert naming) of the objects". The current data do not rule out that our participants on occasion named an object covertly. However, the immediate and robust shift in directed attention to a conceptually unrelated and clearly identifiable shape competitor with a different name (e.g. cable) on hearing the target word (e.g. '*snake'*) does *not* fit comfortably with their suggestion. The current study thus casts doubt on the claim that participants *regularly* name objects in visual world studies.

The shape competitor effects are unlikely to be limited to the passive listening task we employed. Dahan & Tanenhaus (2002) recently presented evidence that similar visual form competitor effects also occur when participants are required to engage in an explicit physical task (moving the objects mentioned in spoken sentences using a computer mouse). Our procedure of a 'passive' listening task is strong evidence that these perceptual competitor effects are not limited to certain specific 'goal-directed' task demands.

In sum, the findings are best compatible with the notion of a rich mapping process between spoken language and concurrent visual input. On a methodological note, the visual world paradigm promises to be a valuable research tool for investigations into the access of (lexical) perceptual and conceptual representations as well as into issues in visual perception.

Acknowledgments

FH would like to thank Gerry Altmann and Graham Hitch for discussion of this research.

Abstract

One of the important tasks of language acquisition is the ability to distinguish between an inflectional derivation from a target word, which is a variant of this word (e.g., *tool* → *tools*), and a completely new word (e.g., *tool* → *stool*). In an attempt to explain the ability to solve this problem, it has been proposed that the beginning of the word is its most psychologically salient portion. However, it is not clear whether this phenomenon is specific to language or whether it stems from a more general cognitive mechanism, with beginnings of sequences being more salient than endings. The three reported experiments were designed to answer this question. In these experiments, participants judged the similarity of test sequences to target sequences across three domains: linguistic, musical and visual. The test items were judged as more similar to an original target item if information was added to the end of that item rather than to the beginning of the item across all three domains. This suggests that there may be a more general cognitive mechanism underlying the well-documented suffixation preference, according to which changes in the end of the word are more readily interpreted as inflectional derivations from the target word.

Introduction

One of the important tasks of language acquisition is the ability to distinguish between an inflectional derivation from a target word, which is a variant of this word (e.g., *tool*→ *tools*), and a completely new word (e.g., *tool* → *stool*).

There are multiple types of inflections that exist across languages, including prefixation (e.g., adding a morpheme before the stem), suffixation (e.g., adding a morpheme after the stem), infixation (e.g., adding a morpheme inside the stem), and nonconcatenative devices (e.g., interleaving a string of vowels with a string of consonants).

Two types of inflections are frequently present in many European languages, prefixes and suffixes, and it has been established that suffixes are easier to acquire (e.g., interpret suffixation as an inflectional derivation) than prefixes. This finding is not specific to the English language. Cross-linguistically, the suffixing preference results in stems generally being ordered before the added morpheme because language users prefer to process stems before the added morpheme (Hawkins & Cutler, 1988). Overall, suffixing is more frequent than prefixing (Hawkins & Gilligan, 1988). A number of explanations have been proposed, although any single explanation alone may not fully account for this phenomenon.

First of all, there are positional differences with the addition of a morpheme at the beginning and the end of the word, which is important because words take place in time (Gasser, 1994). For example, words are often recognized before they are completed (Tyler, Marslen-Wilson, Rentoul, & Hanney, 1992). The information that reaches the ear first may be the key to the identification of that piece of information. If this is the case, then the temporal aspect of language may be the underlying reason for suffixation preferences in language.

Similarly, the psychologically most salient part of any word is its beginning portion (Clark 1991; Hawkins & Cutler, 1988). This is to say that the effect of distorting a word is more severe if the distortion is at the beginning of the word (e.g., prefix) rather than the end (e.g., suffix). This is true in both comprehension and production. In comprehension, adding a morpheme to the end of a word does not affect the recognition of the word, and in production, it is easier to produce a familiar sequence

followed by a modification in the form of a suffix than the reverse, a modification first and then the familiar word (Clark, 1991).

These contentions seem to be supported by the literature on language acquisition. In particular, Slobin (1985) claimed that children use procedures or strategies called Operating Principles (OP) in their linguistic development. He proposed many different principles that children use, but the one of importance for this area is OP (ATTENTION): BEGINNING OF UNIT. This principle states that children pay attention to the first syllable of an extracted speech unit. They store it separately and in relation to the unit with which it occurs. If a child were specifically attending to the beginning of a word, then adding a morpheme to the end of the word would be less detrimental to the recognition of that word than adding the morpheme to the beginning of the word.

Clark has done much research on the area of children and inflections that add support to suffixation preference from a developmental perspective. She has found that children acquire inflections from their earliest word use and continue to comprehend and produce them throughout their linguistic development (1995). In general, children begin to add noun and verb inflections between 18 and 24 months; however, they consistently learn suffixes before prefixes, even when these inflectional forms express equivalent information (1995; 1998). In addition, children aged 5 to 7 find nonsense suffixes are easier to imitate than nonsense prefixes (1998).

Overall, children seem to find it easier to process information added to the ends of words than to the beginnings, and it has been argued that the beginning of the word is its most psychologically salient portion. This would explain why children are better at learning suffixes rather than prefixes. These findings map quite well onto the adult research on inflectional morphology.

However, it is not clear whether this phenomenon is specific to language or whether it stems from a more general cognitive mechanism.

We suggest that this ability may reflect a more general property of processing of temporally organized information: changes in the beginning of a sequence are easier to detect than at the end of the sequence. If this is the case, then non-linguistic information that has temporal structure may also give rise to inflection-type effects, such that changes at the end of the sequence would more likely be considered variants of the original string than changes at the beginning of the sequence.

To test this hypothesis, we conducted three experiments, using language (Experiment 1), music (Experiment 2), and visual sequences (Experiment 3).

Experiment 1: Inflections in the Linguistic Domain

Method

Participants There were 17 participants in this experiment. The participants were undergraduate students from The Ohio State University who participated to fulfill a psychology course requirement. Five participants failed to correctly respond to at least 70 % of the catch items and were excluded from this experiment.

Design and Materials The stimuli consisted of 42 sets, with each set consisting of a 2-syllable artificial Target word followed by two Test words. One of the Test words was the Target with a morpheme added to the beginning (Test-Pre). The other Test word was the Target with a morpheme added to the end (Test-Post).

The Target words were constructed by randomly connecting discrete syllables (e.g., *Ta-Te*) with .06 sec between syllables (see Johnson & Jusczyk, 2001; Saffran, Aslin, & Newport, 1996, for details of stimuli creation). The Test words were created by either adding a syllable to the beginning of the Target word (Test-Pre: *BE-Ta-T*e), to the end of the Target word (Test-Post; *Ta-Te-BE*), adding nothing to the Target word (Test-Identical: *Ta-Te*), or changing the Target word completely (Test-Different: *Pu-La-Fi*).

On each trial, participants received a Target word, followed by two Test words (the order of each of the Test words was counterbalanced), and their task was to determine which of the Test words was more similar to the Target.

There were six types of sets determined by pairing of the types of Test words: Pre-Post, Pre-Identical, Post-Identical, Pre-Different, Post-Different, and Identical-Different. The first type was the focal interest (e.g., 25 Pre-Post sets), whereas the remaining 5 conditions were catch trials (3 sets for each condition, and 2 additional Identical-Different sets for the practice trials). The set types varied within participants.

Procedure Each participant received 2 randomly presented practice trials with a break to ask the experimenter any questions, and then the remaining 40 trials were presented randomly. *Presentation* software was used to deliver the instructions, present the stimuli and record the responses.

The participants were instructed that they would hear a 2-syllable Target word followed by two Test words, and they were to decide which of the Test words was more similar to the initial Target word. If the first Test word was most similar, they were to press "F" on the keyboard, and if the last Test word was most similar, they were to press "L". To start each new trial, they were instructed to press the space bar.

There was 1 sec in between each word, and the order of the Test words was counterbalanced across sets. The Target word was heard from both of the computer speakers

while the first Test word was heard only from the left speaker and the second Test word was heard only from the right speaker.

Results and Discussion

Overall, participants were accurate on catch trials, exhibiting over 90% accuracy (M = 94.90%), above chance, one-sample t (16) = 25.43, p < .001.

However, the analysis of participants' responses to Pre-Post items was of considerable interest. Data analyses focused on the percent of participants' responses in which the Test-Post item was considered more similar to the Target than the Test-Pre item. Overall, in more than 85% of responses (M = 88.00%) participants deemed the Test-Post item to be more similar to the Target than the Test-Pre item, above chance, one-sample t (16) = 9.64, p < .001. Thus, as expected there was a clear tendency to choose the Test-Post items as more similar to the original Target word than the Test-Pre words.

Having established that the procedure captures the effect in the domain of language, we conducted Experiments 2 and 3, using the same procedure with music tones and visual patterns.

Experiment 2: Inflection-type Effects in the Domain of Music

Method

Participants There were 18 participants in this experiment. The participants were undergraduate students from The Ohio State University who participated to fulfill a psychology course requirement.

Design and Materials The design was the same as in Experiment 1, except the sets were made up of a 2-note Target melody and two Test melodies. The Test items were created by adding notes to either the beginning (Pre) or the end (Post) of the Target melodies.

Procedure The overall procedure was identical to Experiment 1. The main exception was that instead of hearing words, the participants were instructed that they would hear a small Target musical melody followed by two Test melodies. From this, they were to decide which Test melody was the most similar to the original Target melody.

Results and Discussion

Overall, participants were accurate on catch trials for this experiment as well, exhibiting over 90% accuracy (M = 91.85%), above chance, one-sample t (17) = 20.35, p < .001.

Similar to Experiment 1, data analyses of central interest focused on the percent of participants' responses in which the Test-Post item was considered more similar to the Target than the Test-Pre item. Once again, the participants were more likely to choose the Test-Post items as more similar to the Target than the Test-Pre items (M = 71.56%), above chance, one-sample t (17) = 4.03, p = .001.

Experiment 3a: Inflection-type Effects in the Visual Domain

Method

Participants There were 17 participants in the visual domain. The participants were undergraduate students from The Ohio State University who participated to fulfill a psychology course requirement. Using the same exclusion criterion as in Experiment 1, 2 participants were eliminated from this experiment.

Design and Materials The design was the same as in Experiments 1 and 2. The stimuli in this experiment consisted of object sequences. There were a total of 25 objects that were randomly connected to form the Target sequences. The Target sequences were composed of either all red, blue, green or orange shapes. Each set consisted of a Target sequence made of two simple objects that flashed for 1 sec each while centered at the top of the computer screen (e.g., Cross, Heart).

Then, 1 sec later, the first of two Test sequences appeared at the bottom of the screen. There was 1 sec in between each Test sequence, and the order of the Test sequences was counterbalanced across sets. The first Test sequence appeared on the bottom left of the computer screen, and the second Test sequence appeared on the bottom right of the screen. The Test items were created by adding an object (e.g., Diamond) for 1 sec either at the beginning of the Target sequence (Test-Pre; Diamond, Cross, Heart), at the end of the Target sequence (Test-Post: Cross, Heart, Diamond), no change at all to the Target sequence (Identical: Cross, Heart) or changed the sequence completely (Different: Star, Light Bulb, Lock). The object that was added was of a different color than the Target sequence: a red Target sequence would have a blue object added (and vice-versa), and green and orange were similarly paired.

Procedure The overall set up of the experiment was similar to Experiments 1 and 2. In this experiment, the participants were instructed that they would see a Target sequence of objects on the top of the screen followed by two Test sequences on the bottom of the screen. They were to decide which Test sequence was more similar to the initial Target sequence.

Results and Discussion

Participants were accurate on catch trials with an overall accuracy over 95% (M = 98.04%), above chance, one-sample t (16) = 63.23, p < .001.

Similar to Experiments 1 and 2, participants were more likely to choose the Test-Post items as more similar to the Target than the Test-Pre items (M = 91.53%), above chance, one-sample t (16) = 13.72, p < .001.

Having established that this effect is present in the visual domain, it was important to investigate the effect of temporal information in this domain. Therefore,

Experiment 3b was conducted as a control experiment for the visual domain without the addition of temporal information.

Experiment 3b: The Visual Domain without Temporal Information

Method

Participants There were 18 participants in the visual control condition. The participants were undergraduate students from The Ohio State University who participated to fulfill a psychology course requirement.

Design and Materials The design was the same as in the previous experiments. The stimuli in this experiment consisted of the same object sequences that were used in Experiment 2 without the addition of temporal information. That is to say that the participants viewed a row of stationary shapes instead of a dynamic sequence of shapes.

The Target appeared at the top of the screen while the Test items simultaneously appeared at the bottom of the screen. Once again, the positioning of the Test sequences was counterbalanced across sets. One Test sequence appeared on the bottom left of the computer screen, and one Test sequence appeared on the bottom right of the screen. Similar to Experiment 3a, the Test items were created by adding an object (e.g., Diamond) either to the left of the Target sequence (Test-Pre; Diamond, Cross, Heart,), to the right of the Target sequence (Test-Post: Cross, Heart, Diamond), no change at all to the Target sequence Identical: Cross, Heart) or changed the sequence completely (Different: Star, Light Bulb, Lock).

Procedure The overall set up of the experiment was similar to the previous experiments. In this experiment, the participants were instructed that they would see a Target sequence of objects on the top of the screen and two Test sequences on the bottom of the screen. They were to decide which Test sequence was more similar to the initial Target sequence.

Results and Discussion

Participants were accurate on catch trials with an overall accuracy over 95% (M = 95.55%), above chance, one-sample t (17) = 42.26, $p < .001$.

Similar to Experiments 1, 2 and 3a, participants were more likely to choose the Test-Post items as more similar to the Target than the Test-Pre items (M = 80.89%), above chance, one-sample t (17) = 7.52, $p < .001$.

However, when this control condition is compared to the original visual domain experiment, it appears that the absence of temporal information attenuates this effect. There is a higher propensity to choose the Test-Post items as more similar to the Target than the Test-Pre items when there is the addition of temporal information, independent-samples t (33) = 2.07, $p < .05$.

General Discussion

The results of the three reported experiments clearly indicate that across the three domains, the beginning of the sequence was more salient than the end of the sequence, and as a result, the addition of a single element to the beginning of the sequence was perceived as a greater change than the addition of a single element to the end of the sequence. Presence of this tendency across the three domains indicates that this tendency is not limited to language. More specifically, the "suffixation preference" found in the linguistic domain appears to be analogues for sequences of musical tones and visual patterns, all having a temporal component.

Results of Experiment 3b indicate that the temporal component is fundamental: once the temporal component is removed and stimuli are presented simultaneously, the effect is diminished.

Therefore, the suffixation preference, which is often considered a useful linguistic bias for solving the inflectional problem, does not appear to be specific to language, but rather it stems from processing of temporally organized information.

To better understand this phenomenon, it is important to investigate this bias in native speakers of languages that do not have the same dominant suffixing preference (e.g., Thai). This may further reveal the direction and strength of this tendency.

In addition, there are several important questions that are to be answered in future research. First, it is unclear whether this tendency to consider the beginning of a sequence as more salient than the end of a sequence appears as a domain-general attentional bias or whether it first manifests itself in the domain of language, and then gets extended to other temporally organized domains. Although the former possibility seems more likely, a developmental study using the same set of stimuli is necessary to answer this question.

Given the fact that the effect exists in the visual domain even without temporal information, it is important to investigate possible explanations. Since the visual images without temporal information were presented in a manner that resembles the structure of written material, it is possible that this structure brought about the positional biases similar to those in the linguistic domain. For example, while reading English, one visually scans from left to right; therefore, this same mechanism could account for the effect in Experiment 3b even without temporal information. To better understand the phenomenon, it is necessary to structure the visual information so that a left to right scanning pattern does not temporally constrain the information (e.g., vertical presentation of the stimuli). In addition, this explanation may be further expanded if the effects would vary not only according to the presentation of the stimuli, but also developmentally. This explanation could be ruled out if children who do not yet read readily show this effect in the visual domain without temporal information.

Another important question is how flexible is this tendency in non-linguistic domains. The suffixation preference is very flexible in the domain of language

(otherwise people would not be able to acquire various kinds of inflectional morphology), and if it stems from a general mechanism, this tendency has to exhibit flexibility in other domains as well. These issues are currently under investigation.

In sum, the results suggest that when information is added to the end of a Target sequence, it is perceived as more similar to the original Target than if the same information was added to the beginning of this Target. This was true across all three domains investigated, suggesting that there might be a general cognitive mechanism of processing of temporal information that may underlie the suffixation preference, which is prominently present in the linguistic domain.

Acknowledgments

We would like to thank Zach Schendel for the creation of the musical stimuli. This research is supported by grants from the National Science Foundation (REC #0 208103 and BCS # 0078945) to Vladimir M. Sloutsky.

Abstract

30 undergraduates participated individually in a three-day-drawing experiment. It was explored whether an experience copying others' drawing facilitated subjects' artistic creativity. Results showed that drawings by subjects who previously had copied others' drawings were rated more creative than the drawings of subjects who had not copied. Two further analyses revealed how subjects could produce creative drawings. First, in the examination of constraint relaxation processes, subjects were initially constrained by a belief that they should draw things realistically. Then, they relaxed this constraint by means of copying abstract pictures. Second, according to protocols of the copying process, copying forced subjects to explore their original expression through a comparison with other artwork. It seemed that copying enabled them to generate new drawing ideas.

Introduction

It is often said that people cannot produce original works through the imitation of others. In the domain of art, many art educators believe that copying others' work inhibits people's, particularly children's, artistic creativity. They claim that artistic expression should be as free as possible from copying (Lowenfeld, 1957). It is well known, however, that artists of impressionism created their original paintings by means of imitating Japanese prints, *Ukiyoe*. In addition, some famous painters, e.g., van Gogh and Picasso, created their original paintings through copying the work of old masters (Galassi, 1996; Homburg, 1996). The question of whether copying inhibits or facilitates creative art has been controversial among artists, art researchers, and art educators (Duncum, 1988).

In some modern cultures, including Japanese culture, many art lay people (i.e., nonartists) seem to think that representational and realistic paintings have higher value than other forms of painting. That may be due to the content and methods of art education in school settings. Especially in Japanese elementary and middle schools, students spend the majority of their time in art class sketching. This may lead them to believe that drawing is primarily to represent objects in the real world on paper (Kozawa, 2001). In other cultures, it is also reported that people prefer realistic paintings to abstract or other types (Cupchik & Gebotys, 1988; O'Hare, 1976). Such beliefs might limit the range of students' means of expression. It is predicted that subjects would create new drawing styles if their constraints become relaxed. Therefore, we focused on copying others' work as a candidate for an intervention that could relax constraints and investigated its effect on creative drawing.

Method

Subjects. 30 undergraduates participated in this study. None of them had special training in drawing since at least middle school.

Experimental Design. A three-day-experiment (pre-treatment-post design) was conducted. All of the subjects were initially required to create two original drawings in the pretest phase. In the treatment and posttest phases, subjects were divided into three groups. In the Experimental Group (EG), subjects were asked to copy two pieces of an artist's drawings, then to create their own original drawing. In the Reproduction Group (RG), subjects were also asked to copy, then to draw a new picture using the artist's style. In the Control Group (CG), subjects were asked to draw their own original drawings in every session.

Materials. Subjects were required to draw pictures using as subject matter the materials displayed in Table 1. A4-sized Kent paper and a black ballpoint pen were offered to subjects for each drawing. The pictures copied by subjects in the two groups were abstract paintings by a Japanese modern artist (Figure 1).

Procedure. Each subject participated individually in a three-day-experiment; one session per day, each lasting approximately 90 minutes. Subjects were asked to draw two pictures in each of the pretest and treatment phases. The second picture in each phase was presented three minutes after the first one was completed. In the posttest, subjects drew a picture and then were asked to

Table 1: Materials presented to subjects.

	Experimental Phases		
	Pretest	Treatment	Posttest
1st drawing	a cocktail glass	a shell (Venus Comb Murex)*	an orange and a shell (Common Spider Conch)**
2nd drawing	a paprika and a pinecone**	a potted plant*	-

* For EG and RG, the pictures to copy were drawn with each of these materials by an artist and presented alongside the materials.
** These sets of materials were counterbalanced among subjects.

complete a questionnaire (described later in detail) and were interviewed about their drawings. Thus, each subject drew five pictures in total during three days.

Subjects in CG were instructed as follows in all phases: "Draw your own ORIGINAL picture using this (these) material(s) as subject matter." Subjects in EG were instructed in the same way in the pre and posttest phases. But, they were told in the treatment phase: "A painter drew this picture using this material as subject matter. Please copy the picture onto a blank piece of paper while imagining the painter's intention." Subjects in RG were instructed in the same way as EG in the pretest and treatment phases. However, they were told in the posttest phase: "Recall the previous day's experience of copying a painter's picture and then draw a picture with these materials in the painter's style. How would you represent the subject matter if you were the painter?"

We asked subjects to talk aloud while drawing, and recorded their verbal protocols and behavior with three videocassette recorders. Except for this procedure, we placed upon the subjects' activities as few restrictions as possible in order to promote maximum spontaneity (e.g., They were not told explicitly that there was a time limit on their drawing).

Results and Discussion

Preliminary Analysis

In the posttest phase, drawings in RG were quite different from those in EG and CG in terms of content and number of elements in each picture (Figure 2). The mean number of elements in a drawing was significantly greater in RG (23.8) than in EG and CG (10.2 and 5.4, respectively) [for group by phase interaction, $F(2,27)=5.05$, $p<.05$]. All drawings by subjects in RG consisted of much repetition of simple geometrical elements, but those by subjects in EG had no such characteristics. Thus, although subjects in EG

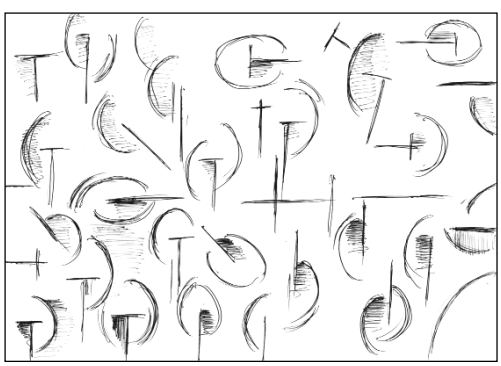

Figure 1: Example of the artist's drawings that subjects in the EG and RG saw.

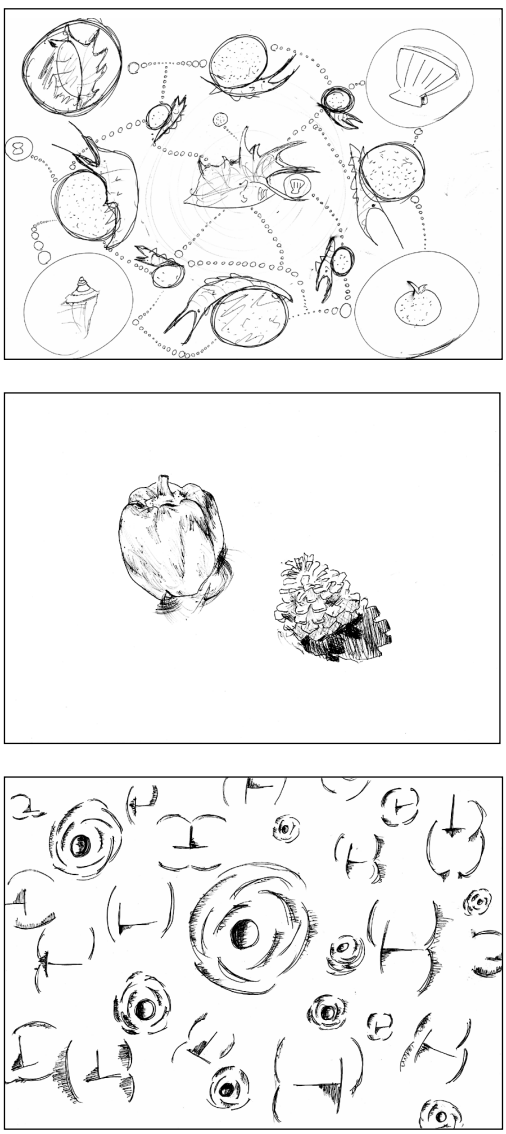

Figure 2: Examples of drawings in the posttest phase (EG; CG; RG, respectively from the top).

and RG copied pictures in the same manner, subjects in EG did not reproduce the artist's style of pictures, but created their own styles.

Analysis of Products: Rating Creativity of the Drawings

In order to compare the creativity of drawings in EG with that in CG, a new scale was constructed that included three aspects of artistic creativity: six items of aesthetic attractiveness (e.g., "vitality of expression"); nine items of originality (e.g., "originality of her or his view or sense of value"); and two items of technical skills (e.g., "technical skill in picture composition"). Thus, in total, 17 items were included in the scale with all items ranging from 1 to 5. Because our critical question was to reveal whether or not the artistic creativity of subjects who copied others' art works was superior to that of subjects who did not copy, the comparison of the two groups would be sufficient to answer the question. Thus, we excluded the drawings by subjects in RG from this analysis.

Two professional modern artists separately rated subjects' pre and posttest drawings using the scale. They were not informed of which drawings belonged to which condition. A result of factor analysis with Principal Component Analysis showed that the scale has one factor construction and was adequate for the evaluating creativity of drawings (eigenvalues for the first three factor were 10.58, 2.06, and 1.05, and the first factor accounted for 62.2% of the total variance). Since the coefficient alpha for internal coherence was .96 for all 17 items, we regarded the simple sum of the 17 items as the creativity score for each drawing.

A three-way ANOVA (two experimental groups X two raters X two expositional ordering of drawing materials) was performed for post-pre subtracted scores.

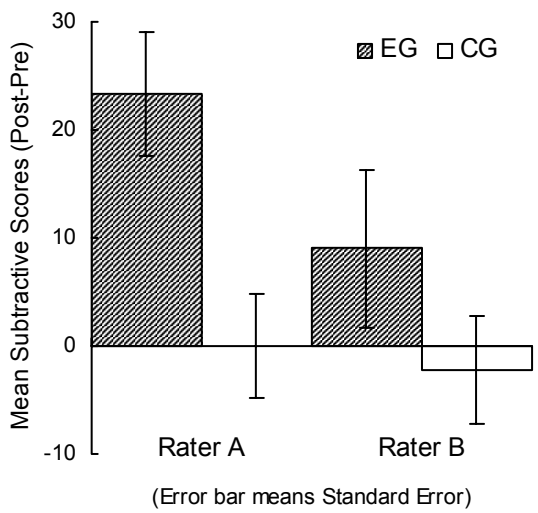

Figure 3: Comparison of creativity rating between subjects in EG and in CG

Drawings by subjects in EG were rated significantly higher than those in CG (Figure 3) [$F(1,16)=5.54$, $p<.05$]. The fact that scores were significantly different between the two raters suggested that norms of artistic creativity would vary among artists [$F(1,16)=4.65$, $p<.05$]. However, it was important to note that the two raters evaluated the posttest drawings by EG subjects in the same way. There was no interaction among the three factors. Findings suggest that copying other's drawings provided the subjects opportunities for creating new styles of drawing.

Analysis of Process 1: Relaxation of Students' Constraints

Why could subjects who had copied other's works produce more creative drawings? Note that the pictures the subjects had to copy (abstract style) were fairly different from typical pictures that subjects normally encounter (representational style). If subjects were constrained by their beliefs that drawing must follow a representational expression style, copying drawings in an abstract style might relax the constraint by making them aware of other stylistic possibilities.

In order to conduct further analyses of the process of creation, we focused on the following three aspects: (1) number of pictures that included realistic contents; (2) strength of the subjects' realistic intention; (3) number of subjects who reported a failure of creative drawing.

Number of Pictures that Included Realistic Contents. If subjects were constrained by their beliefs that drawing had to be realistic, such beliefs would affect the content of their drawings. In this study, we coded a drawing as constrained by such beliefs if it contained at least one of the following aspects: (1) drawings that designate a specific scene made up of either realistic elements or stylized ones (e.g., one similar to an illustration of a storybook); and (2) drawings in which subjects sketched only the materials presented (example of drawing from CG condition in Figure 2). We took these two types of drawings to indicate that subjects drew without their own figurative interpretations.

The numbers of drawing which contained the contents described above were approximately equal in the pretest phase in both conditions (70% in EG and 80% in CG) [$p=1.00$ with Fisher's exact test]. The frequency of that in EG, however, significantly decreased compared to that in CG in the posttest phase (20% and 90%, respectively) [$z=-2.21$, $p<.05$ with test by standardized scores].

Strength of Subjects' Realistic Intention. Did subjects actually intend to draw pictures so realistically? In order to capture their intention, we investigated how much they paid attention to technical viewpoints related to realistic sketch-like drawing. We assumed that the more subjects thought they had to draw realistic and photo-like pictures, the more strongly

they would attend to such technical viewpoints. If copying pictures in an abstract style relaxes such a constraint, then the degree of EG subjects' attention to such technical aspects would decrease in the posttest.

After posttest drawing, subjects were asked to answer a questionnaire intended to measure their realistic intention during both the post and pretest drawing. This questionnaire consisted of 11 items on five-point scale (ranged from 1 to 5, including two inverse items) that covered a variety of aspects of realistic intention (e.g., "I paid attention to capturing the materials' form exactly"; "I tried to express the quality of the materials' surface"). For the 11 items, the coefficient alpha was .86.

A two-way ANOVA (three experimental groups X two phases) for the sum of item scores revealed a significant interaction [$F(2,27)=9.82$, $p<.001$]. Further analysis revealed that, while there was no significant difference on groups in pretest phase [$F(1,54)=0.01$, *n.s.*], in posttest phase, scores in EG and RG significantly decreased compared to scores in CG (Figure 4) [$F(1,54)=7.93$, $p<.001$; $p<.05$ with Steel's multiple comparison for difference scores of post-pre test]. In addition, subjects' scores in the pretest phase were on average about 70 % or more of the maximum score and thus seemed to show their strict intention to use a realistic drawing style. Hence, we can conclude that the subjects did, in fact, have representational constraints in the beginning of the study and that the constraints were then relaxed by means of copying pictures with an abstract style.

Number of Subjects Who Reported a Failure of Creative Drawing. We asked subjects to report what they devised in the posttest drawings. Their answers were divided into categories and the contents and the number of responses were analyzed.

Characteristically, half of the subjects in CG reported

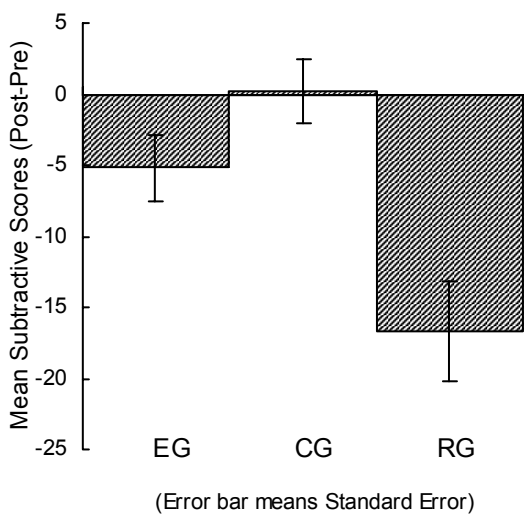

Figure 4: Subjects' intention to draw realistically.

that they could not come up with any new ideas and just sketched what they saw (e.g., "I thought that I could not draw well if I pay too much attention to originality. So, I decided to draw the materials as they are"). In EG, however, no subject reported such a comment [$p<.05$ with Fisher's exact test]. This result implies that subjects in CG were kept constrained by their beliefs and could not produce new ways of drawing.

Analysis of Process 2: Generation of New Ideas

The previous section revealed that copying relaxes subjects' constraint. However, even if their constraints are relaxed, it is insufficient for production of a new style of drawing. Because, in order to create a new style of drawing, subjects need to generate concrete ideas for drawing. In order to reveal how subjects in EG came up with new ideas when their constraints were relaxed, we focused on subjects' copying process in the treatment phase.

We presumed that thought processes during copying include two aspects: (1) understanding others (in this case, a creator who produced the artwork) and (2) understanding oneself. The former aspect is an effective one in order to reproduce others' artworks. The knowledge about the pictures would be deepened by means of inferring the creator's art making process. In this point of view, however, copying can be risky since people may lose their own originality. Thus, many people have claimed that copying might be harmful to creation. As we pointed out, this is a well known argument.

In contrast, the second aspect, understanding oneself, is not so well known. In this aspect of thought processes, the copiers' own expression may become clarified by means of comparisons with others' artworks. Thus, people's generation of new ideas might be facilitated through their searching for originality. This aspect may be particularly important for creativity, because it might promote the copier's ability to produce her/his own original artworks.

It is hypothesized that subjects in EG experienced these two aspects of thought processes when copying and were able to generate new ideas to draw. In the rest of this section, we will focus on the protocols by EG and RG subjects during copying an artist's artworks and describe whether or not the protocols include evidence of these two aspects. Of course, these aspects are double-faced, and one cannot work without the other. In this study, however, we will pragmatically separate them into two aspects and examine each.

Copying to Understand Others. In this aspect, getting to know the processes by copying could deepen knowledge of the products. For example, F. Natsume (cartoon artist; 1992) copied a famous Japanese cartoonist's work. He found that the lines of this cartoon give a very round and centripetal impression. This characteristic of the lines has an important role in

creating this cartoonist's characters' special features such as bravery and cuteness. The case shows that he deepened his knowledge about the cartoon through copying its lines.

In addition, understanding others' works requires changing one's standpoint. In order to really copy, it is necessary for us to understand the other's underlying intention of the procedure. When copying, we are forced to infer the underlying intention of the other's works. This process makes us switch our standpoint from an observer to a creator.

Thus, copying facilitates understanding a creator. Did actual copying processes include this aspect? We focused on subjects' protocols during the copying phase (treatment phase in EG and RG) and analyzed whether or not their protocols exemplify understanding others.

In copying, subjects noticed concrete features of elements/parts in the artist's drawings.

- *Why did he draw this horizontal line?* (subject =ID3)
- *He doesn't draw outlines, does he?* (ID3)
- *I copy it paying attention to the distance with other parts.* (ID14)
- *I must use stronger lines. My lines were not clear at all.* (ID19)

Subjects also tried to understand the artist's intention.

- *I think, the thick parts of the leaves indicate this plant's vitality.* (ID16)
- *Each element in the picture may not represent each leaf of the real plant.* (ID7)

In this way, copying process did have an aspect of understanding others. Subjects in RG could reproduce the new picture in the artist's style because they would engage such a process and deepen their knowledge about the artist.

Copying to Understand Oneself. It seems that understanding others also facilitates understanding oneself. Consider the following case. Even if you had no opinion about an issue at first, you may often form your own opinion while listening to others'. In the domain of art, there would exist such a case that the deeper you understand someone's artworks, the more you become aware of your originality.

There are many such examples in art history. For example, Picasso and van Gogh copied old masters' artworks, exploring their own original style rather than keeping the styles of the artworks exactly (Galassi, 1996; Homburg, 1996). Picasso talked about his copying (Sabartés, 1959):

> *Suppose one were to make a copy of The Maids of Honor (Las Meninas); if it were I, the moment would come when I would say to myself: suppose I moved this figure a little to the right or a little to the left? At that point I would try it without giving a thought to Velázquez. Almost certainly, I would be tempted to modify the light or to arrange it differently in view of the changed position of the figure. Gradually I would create a painting of The Maids of Honor sure to horrify the specialist in the copying old masters. It would not be The Maids of Honor he saw when he looked at Velázquez's picture; it would be my Maids of Honor.*

This case shows that Picasso actively explored his own expression through copying Velázquez's work. It is a different aspect from the one that focuses on learning particular techniques or expressions (i.e. understanding other's works).

Why does copying facilitate self understanding? We propose the following two reasons. At first, when copying other's works, you constantly compare other's expression with your own. This "comparison" process forces you to actively interpret the differences between the other's works and your own. This is the first step in searching for your own original expressions. Secondly, particularly in copying artworks, you can externally compare a model with your copy. This encourages you to notice differences between the two.

Our protocol data show subjects' self understanding. First, subjects' own visions emerged. They interpreted the figures in their own way as well as inferred the artist's intention.

- *It looks like fossil fishes are swimming.* (ID7)
- *It looks like insects are flying.* (ID12)
- *They look like ribs or fish bones.* (ID3)

Some subjects felt uncomfortable with the other's works. It seemed that such feelings prompted them to explore their comfortable expressions.

- *Why did he/she draw such cross marks? I cannot find them in this material* [= a shell]. *I don't understand it.* (ID19)
- *I don't like patterned figures like this. Because it's monotonous.* (ID1)

Some subjects became aware of their own expression by means of the comparisons with other's work.

- *His lines end smoothly, but mine stopped tightly.* (ID1)
- *In the previous copy, I failed to draw pictures well, because I drew the elements too big and lost balance.* (ID14)

- *This picture reminds me of previous day's paintings* [Subject's own drawings in the last session]. *I now understand that mine were not so original.* (ID1)

These findings enable subjects to understand what kinds of expressions they usually use and what kinds of expressions they want to create.

General Discussion

This study revealed that an experience copying others' drawings facilitated subjects' artistic creativity. It was also showed that at least two underlying processes affected this performance. First, constraint relaxation processes enabled subjects in the EG to explore drawing styles beyond the familiar realistic and representative style. Second, generating new ideas through comparison with other's works prompted subjects to notice their own original expression. Based upon these findings, we propose a model about copying to creation (Figure 5). It is suggested that constraint relaxation and generation of new ideas (including two aspects of copying) together can facilitate a new style of drawing.

Some recent studies investigated the effect of experimenter-presented examples on a creative generation task. For instance, Smith, Ward, & Schumacher (1993) found that people unconsciously tend to incorporate features of the examples in their creation (conformity effect). This effect varied with conditions; for example, the effect was enhanced with a delay between exemplar presentation and creation test (Marsh, Landau, & Hicks, 1996). In addition, it was related to inadvertent plagiarism because people fail to monitor their source of novel knowledge appropriately. These studies suggest that examples may negatively affect creation. However, it is well known that no idea is completely original; all forms of creation are strongly affected by already existing things. Thus, the question that we want to answer here is how people create new ideas even if they have a tendency to be heavily influenced by old ideas, as previous studies suggest. Although this research is still in an early stage, we propose that the process of understanding oneself in comparison with others works is a key mechanism of creation.

One reason why previous studies did not focus on this aspect is perhaps that the subjects in these investigations saw exemplars for only a few minutes and thus did not have enough time to involve themselves in the process of understanding. In contrast, in our experiment, the subjects spent about forty minutes copying pictures. This long, active exposure to examples may have forced them to engage in the process of understanding themselves.

Despite this, copying others' works may not be the only means of making people more creative. If they were just told verbally to consider other forms of drawing or presented others' works as exemplars without copying, then they might also be able to draw more creatively. We are currently conducting another experiment to test these possibilities.

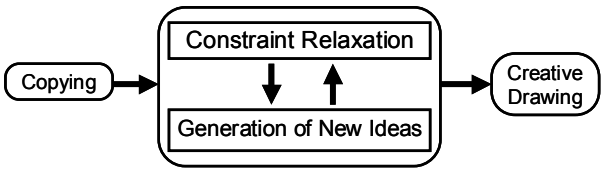

Figure 5: Interactive processes in copying.

Sensorimotor Contingencies, Event Codes, and Perceptual Symbols

Jason Jameson (j-jameson@northwestern.edu)

Evanston, IL 60208-2710 USA

Abstract

Cognitivism, the traditional approach to understanding cognition, has argued for the essential role of symbolic computations over internal mental representations. But this view has been criticized on a number of grounds, one in particular being the assumption of amodality: that the symbols involved in processing are arbitrarily related to their referents. An opposing view—the framework of Perceptual Symbol Systems—holds that the elements of thought should be treated not as amodal symbols, but rather as modality specific, analog representations that simulate particular aspects of perceptual experience. Though this approach has been gaining in popularity from intuitively appealing theoretical accounts, and suggestive empirical support, it has suffered from a lack of specificity for key constructs. To address this problem, this paper presents a more detailed study of the foundational concept of *perceptual symbol*. The proposal builds from recent work on the skill-based nature of visual perception (the Sensorimotor Contingency Theory), and research that provides tools for representing the inseparable link between perception and action (the Theory of Event Coding). From these two sources, the characterization of a perceptual symbol as a selective re-enactment of perceptual experience, treated as a unit, will be elaborated and defended.

Introduction

Cognitive science, for much of its short history, has been dominated by a view of cognition that emphasizes the necessary role of computation, and which holds that cognitive processing is rule-governed manipulation of internal mental representations (Fodor, 1975, 1983; Fodor & Pylyshyn, 1988; Johnson-Laird, 1989; Minsky, 1975; Newell & Simon, 1972; Pinker, 1998; Pylyshyn, 1984). The symbols that comprise these representations are what codify knowledge, and indeed *are* knowledge. Under this interpretation, symbols possess several key properties, the most important of which, for the purposes of this paper, is amodality: that a symbol is arbitrarily related to the thing it represents (Barsalou, 1999; Markman & Dietrich, 2000). In addition, specific psychological theories that adopt this framework "generally assume that knowledge resides in a modular semantic system separate from episodic memory and modality-specific systems for perception, action, and emotion" (Barsalou, et al., 2003). This view of cognition has undoubtedly met with much success (for accessible overviews, see Johnson-Laird (1989) and Pinker (1998)).

There are critics, however, who have challenged this framework (Barsalou, 1999; Carlson, 1997; Clancey, 1997; Clark, 1997; Damasio, 1994; Dourish, 2001; Dreyfus, 1972; Gibson, 1979; Glenberg, 1997; Harnad, 1990; Hutchins, 1995; Lave & Wenger, 1991; Rumelhart & McClelland, 1986; Searle, 1980; Smith & Thelen, 2003; Suchman, 1987; Thelen, 1994; Thelen, Schoner, Scheier, & Smith, 2001; Thomas, 1999; Van Gelder, 1998; Varela, Thompson, & Rosch, 1992). In particular, one approach questions the requirement that the symbols used in cognitive processing should be amodal. Instead, in a Perceptual Symbol System (PSS), the symbols are modality-specific representations that do bear a principled resemblance to the things represented (Barsalou, 1999; Barsalou, et al., 2003). Specifically, these symbols are perceptual in the sense that they re-enact selective aspects of experience. But this view, though promising, remains underspecified in important ways. This paper is an attempt to clarify a fundamental construct of the PSS approach, the *perceptual symbol.*

The specific goals of this paper are: (1) to present an account of conceptual representation that is at odds with the traditional view in one important respect—that the symbols used in thought are amodal; (2) to review theoretical arguments and empirical evidence that suggest that PSS should be taken seriously as a plausible alternative to Cognitivism; (3) to show that there are certain respects, however, in which the PSS framework is underspecified, specifically with respect to the foundational concept of a *perceptual symbol;* (4) based on the assumption that to clarify the concept of *perceptual symbol* requires some understanding of what perceptual experience is, to present one type of skill theory of perception that provides a comprehensive account of how perception *and* action interact to support perceptual experience; (5) to connect this account to perceptual symbols by adopting representational structures called *event codes* that possess key properties required by a PSS; (6) to review consistent empirical evidence that the properties of event codes that hold at the fine level of basic sensorimotor interaction might also hold during higher level cognitive processing; and (7) to suggest limitations and remaining questions for future study.

Why a Perceptual Symbol System?

The framework of Perceptual Symbol Systems (PSS) is a perceptually-based approach to conceptual representation that has gained in popularity for many theoretical and empirical reasons. On the theoretical side, the view is more sophisticated than its empiricist predecessors. First, it appears that the rejection of perceptually oriented approaches was too hasty (Barsalou, 1999). For example, the criticism that perceptual symbols are just holistic records of perceptual experience (like internal pictures that lack any interpretation) is based on the assumption that perceptual

symbols could not also be treated as discrete, componential units; and in this regard, be used productively in forming multimodal symbolic structures. But under this new construal, perceptually-based conceptual systems can acquire the power to represent a variety of concepts ranging in abstractness, and thereby possessing the desired flexibility shown by humans (Barsalou, et al., 2003).

Second, because of the analog relationship with their referents, perceptual symbols provide a great deal of implicit information about the things they represent (Zwaan, 1999). This information can then be made explicit through perceptual processes like scanning and selective attention (Goldstone & Barsalou, 1998). An amodal system requires that knowledge be expressed in terms of syntactically well-formed sentences, usually expressed in a first-order predicate calculus, or LISP-type language. This requirement places a heavy burden on a system if it must represent *all* knowledge explicitly (even the most mundane kind—for example, that cars have four wheels).

Third, the foundations of amodal symbol systems are not without problems, specifically in terms of how the symbols are acquired—the transduction problem (Barsalou, 1999)—and how the symbols relate back to the world—the symbol grounding problem (Harnad, 1990). If perception and cognition are realized by fundamentally different cognitive processes, then how does one representational language get *transduced*—that is, translated—into the other? Conversely, how does the output of cognitive processing connect with the world to enable purposeful interaction? In other words, how do the symbols become *grounded*?

Fourth, though presumed to be flexible by virtue of the (amodal) form of the symbols (such as using the symbol CAT to stand for all cats), amodal symbol systems lack the flexibility of human cognition. To get around this problem, amodal representations have been supplemented with specific episode information (Markman & Dietrich, 2000).

Fifth, amodal conceptual systems are well known to be able to account for numerous findings after the fact (Anderson, 1978; Solomon, 2001), but of far greater importance is the power of a theory to make *a priori* predictions. The amodal view cannot easily predict perceptually-motivated effects, whereas a perceptually-based view can do so with ease (Barsalou, et al., 2003).

In addition to the theoretical support, a growing body of empirical research suggests a strong influence of perceptually-based knowledge on conceptual processing. For example, in a property-listing task, people will generate response that depend on the nature of the perceptual variables involved in the simulation (e.g., listing "roots" for "rolled-up lawn", rather than for "lawn", because roots are less occluded in a rolled-up lawn)(Barsalou, Solomon, & Wu, 1999). From studies in text comprehension, in an effort to comprehend a text passage, people appear to construct online simulations of the situations described in the text. In other words, comprehension of language becomes "preparation for situated action" (Richardson & Spivey, 2000). The situation models (Zwaan, 1999) that underlie this comprehension process are fundamentally experiential, and not surprisingly, derive much motivation from the PSS framework. In research motivated by these ideas, people have been found to recognize a picture of an object (for example, a nail) more quickly if the object is in the same orientation, vertical or horizontal, implied by a text passage read earlier ("The nail was hammered into the floor/wall")(Stanfield & Zwaan, 2001). In related work, sentences such as "Open the drawer" are judged as sensible more quickly if at the same time people move in a manner consist with the implied motion (in this case, pulling rather than pushing)(Glenberg & Robertson, 2000). People also appear to re-enact the eye movements that accompanied earlier perceptual processing (Laeng & Teodorescu, 2002; Mast & Kosslyn, 2002; Richardson & Spivey, 2000). These results are just a few of the many that have provided support for the PSS framework (for a more detailed review, see Barsalou, et al., 2003)

The Structure of a Perceptual Symbol System

A PSS is a conceptual system composed of an integrated set of simulators (which in practice can be interpreted as the concepts). The simulators are composed of frames, which integrate perceptual symbols, and provide structure for event sequencing. Moreover, each simulator implies a simulation competence—the potential for producing an indefinite number, and limitless variety of perceptual simulations. Finally, processes of selective attention and memory integration provide the requisite representational power for the system to act as a fully functional conceptual system in the classical sense (Barsalou, et al., 2003; Fodor & Pylyshyn, 1988).

For a PSS to function as a conceptual system, it should possess certain properties. (1) The conceptual system should be able to *interpret* novel experience. This is what fundamentally distinguishes a conceptual system from a simple recording system (Barsalou, 1999). A conceptual system is selective and is able to bind tokens (perceived individuals) to knowledge of types stored in long-term memory. A record (e.g. a picture), on the other hand, is an undifferentiated—uninterpreted—mass. (2) A conceptual system should allow the thinker to go beyond the information given, to use stored knowledge to make inferences. (3) Conceptual systems should have the potential for generating an indefinite number of thoughts; that is, they should be productive.

For a conceptual system to do this, it must be composed of things that have special properties. What exactly these properties are is contested, but Markman and Dietrich (2000) have provided an illuminating analysis of the issue, and their general approach will be adopted here. Specifically, they have argued that *internal mediating states* can possess certain characteristics: (1) they may be enduring; (2) discrete; (3) abstract (amodal); (4) rule-governed; or (5) they may possess a compositional structure (for more detail on these properties, see Markman & Dietrich, 2000). Internal mediating states in the cognitivist

tradition hold all five. Those in the dynamical systems approach hold fewer. Relaxing one or more of these constraints can affect the representational capacity of a conceptual system.

There are two important ingredients that support the interpretive capabilities of a simulator, and as a result, the representational power of a PSS: the frames, which integrate and organize perceptual symbols; and the "potentially infinite set of simulations that can be constructed from the frame" (Barsalou, 1999). Thus, to understand what CAR means is to know, not only the perceptual symbols that comprise the representation for cars, but it is to know also how to interact with cars—to be able to organize the complex action sequences involved in effective interaction with cars. This means that the frames would be composed of perceptual symbols from several different modalities, and that a simulation could thus be considered a multimodal, selective re-enactment of perceptual experience

The importance of simulators and simulations for supporting the conceptual functions of the PSS cannot be overstated. However, given the role of perceptual symbols in supporting simulations, much work remains to be done in specifying their properties (such as how the symbols are encoded, stored, and used). There are difficulties, however, in getting a clear sense of what a perceptual symbol is, and how it fits in with the functional architecture of a PSS.

Most definitions of a perceptual symbol tend to emphasize the neural substrate, and specifically, that perceptual symbols are "records of the neural states that underlie perception" (Barsalou, 1999). But a limitation of this approach is that it captures just one aspect of the information contained within perceptual symbols. Though much current research tries to incorporate properties of classical cognitive architectures into neural networks, what is needed is a more explicit account of the functional structure to complement the neural description. What is needed, then, is a better sense of what information goes into a perceptual symbol and how that information is stored so that it can support the conceptual functions of a Perceptual Symbol System. In other words, we need a theory of perception, and a theory of how the products of perception are represented.

Perception as a skill

The perspective in this paper holds that perception is a skill: that it is the ability to engage in purposeful and effective interaction with the world (Ballard, 1983; Clark, 2002). The approach outlined is just one of many types of "skill" theories of perception, but it is one of the most elegant and best developed. Specifically, this Sensorimotor Contingency Theory holds that to perceive is to engage in skilled exploration of an environment, with the exploration mediated by the implicit knowledge of the lawful dependencies that hold between actions and sensory consequences (O'Regan & Noë, 2001). Thus, these lawful dependencies are assumed to play an essential role in providing content for perceptual symbols.

The SCT

The main goal of the Sensorimotor Contingency Theory (SCT) is to provide an answer to the so-called "hard problem" of visual consciousness: to explain how physical or informational processes could give rise to the qualitative character of experience (Chalmers, 1996). The solution to the problem is framed in terms of an interpretation of visual perception as a "mode of exploratory activity that is mediated by knowledge of sensorimotor contingencies" (O'Regan & Noë, 2001). This idea is in opposition to views, such as Muller's Doctrine of Specific Nerve Energies, in which what makes one sensory modality different from another is due to the nerve pathways that gather information. Rather, what makes modalities differ is that each is supported by different sets of sensorimotor laws: the dependencies between motor outputs, and the sensory consequences of those actions. In other words, the laws are the implicit, *procedural* knowledge of the expectancies derived from an agent's interaction with an environment. For more details, and supporting evidence, see O'Regan & Noë (2001),

According to this view, sensorimotor contingencies are a key ingredient in most, if not all aspects of cognition. As the authors describe it, "To see is to explore one's environment in a way that is mediated by one's mastery of sensorimotor contingencies *and* to be making use of this mastery in one's planning, reasoning, and speech behavior" (O'Regan & Noë, 2001). How to scale up to these behaviors remains to be seen, however. It is this role that the PSS should fill—to account for the emergence of abstract thought from this fundamental perception-action interface.

But there are a number of problems to be overcome in attempting to extend these principles to the PSS framework. The main limitation is that no indication is given for how sensorimotor contingencies should be represented, or even whether they should be represented at all. For reasons given in Markman and Dietrich (2000), it is too early to abandon representation as an explanatory construct in theories of cognition. So, to be able to characterize a perceptual symbol as a selective reenactment of perceptual experience, to be treated as a unit, not only must there be some sense of what perception consists in, there must also be a way to represent the information that supports both perception and cognition. In addition, the representation should possess the right properties to support the functional requirements of a conceptual system. The Theory of Event Coding (TEC), and specifically, the *event code,* is proposed to fill this role.

The TEC

The Theory of Event Coding (TEC) addresses the relationship between perception and action planning. In opposition to traditional approaches, the TEC does not assume independence between the two processes, but instead emphasizes that both functions are supported by a common representational medium. At the heart of the TEC is the notion of an *event code*, which "consists of the codes that represent the distal features of an event" (Hommel, et

al., 2001). These codes, then, are what underlie perception-action dependencies, but also, more generally, cognitive processes. In their words, "The theory holds that cognitive representations of events (i.e., of any to-be-perceived or to-be-generated incident in the distal environment) subserve not only representational functions (e.g., for perception, imagery, memory, reasoning) but action related functions as well (e.g., for action planning and initiation)" (Hommel, et al., 2001). The principle of common coding is a core assumption of the theory. The other—the principle of effect cause of actions—places special emphasis on the roles of specific types of feature codes within the event code; that is, the feature codes for actions are initiated by the resultant changes in sensory input caused by the actions.

As representational constructs, the event codes are discrete, compositional, and the individual elements retain an identity, even when they participate in more complex structures (Hommel, personal communication, Feb. 2004). In all, these considerations implicate an important functional role that event codes may play as representational constructs within the PSS.

Scaling up

Because the TEC has focused on fine sensorimotor interactions, such as "arrows or circles that come and go on a screen, or hand and fingers that go up and down on a key pad" (Hommel, et al., 2001), how are these event codes integrated to produce more complex event structures? Why start with the TEC rather than, say, with CHREST (Lane, Cheng, & Gobet, 2000) or PLAN (Chown, Kaplan, & Kortenkamp, 1995)? There are several reasons. First, the TEC is compatible with CHREST (as a model of active perception) and PLAN (a model of navigation that uses cognitive maps), and indeed they may all share a common logic (Hommel, et al., 2001). Second, the TEC was adopted primarily for practical reasons: It seemed to bear most closely on the issues addressed in the SCT, and would prove the shortest leap to make from non-representational to a representational description of sensorimotor dependencies. Third, it appeared that the best bet was to start small, at the principled "bottom", and then to work up. But associated with this is a riskier bet: that because of the recursive nature of the event codes, the integrative mechanisms operating at the lower-levels worked also at the higher levels. Fourth, the connection from the TEC to PSS had already been suggested by other researchers, specifically Richardson and Spivey (2001). Finally, some recent evidence in word learning suggests that the principles operating in the TEC might also hold at higher levels. Specifically, Terry Regier and his colleagues have suggested that more attention is paid to the *endpoint* than to the beginning of a spatial event (Regier & Zheng, 2003). Furthermore, as evidence of this, Regier and Zheng found that finer semantic distinctions are present in spatial terms at the endpoints of spatial events than at their beginnings. Specifically, in a task that required participants to judge whether two events, presented very briefly, were the same or different, fewer errors were committed in a "joining" task (e.g., where a lid would be put either on or in a container) that required attention be devoted to the endpoint, than in a "separation" task, in which a lid would be taken either off or out of a container, and attention would be required at the starting point. These results are consistent with the potentially important role of *goals,* and the principle of effect cause of actions, in encoding event sequences at a more general level.

Discussion

Much talk is made in this paper about perceptual symbols being "selective", suggesting that not all information from perception is used during cognitive processing. But what exactly does this mean? That the components of cognitive processing are less vivid, in the sense that *all* information carried over is less definite, less certain? Or does it mean that only specific kinds of information are carried over, such as spatial information, but that the information is no less definite, no less certain than when it was originally processed?

What are the laws of sensorimotor contingency that describe particular core aspects of experience, such as our experience of space, or time? Already much fascinating work has addressed the problem of doing this for space (Philipona, O'Regan, & Nadal, 2003), but then how might that knowledge map onto cognitive psychological research on space? And perhaps of even greater interest, how does our more abstract notion of time map onto that (Boroditsky & Ramscar, 2002; Gentner, Imai, & Boroditsky, 2002)?

What implications does this view have for the problem of reference—determining how cognitive structures connect with the external world (Evans, 1982)? On the one hand, it seems that there might be no such problem, since in both cases, the thing representing, and the thing represented are one and the same. Truly, the "external world" is itself an assortment of mental entities. In other words:

> Despite the importance of realism in many philosophical theories of concepts and meaning, this assumption seems superfluous and unempirical, and it introduces a number of additional problems to be dealt with that could be avoided without it. Rather than making a realist assumption, it would be easier to adopt a *coherence-based* framework. That is, the only information that any person has about the outside world comes from perceptual representations, which are themselves mental entities. Thus, rather than being concerned with whether a particular concept correctly refers to all and only proper extramental entities, it would be better to generate a theory in which the use of the concept attempts to remain consistent with other representations in the system. (Markman & Stillwell, in press)

But to someone still wary of the potential problems this (apparently) neo-idealistic position might suggest, the claim isn't so risky: we need not take on the assorted difficulties a Berkelyian idealism might, since we wouldn't be making claims about ontological status of the world (and whether it still would exist even if one were not immediately

perceiving it), but only claims about what is psychologically efficacious—that is, about the cognitive structures that matter to the thinker. But is this true? If it is the case that only a *subset* of information is carried over from perceptual processing to cognitive processing, though derived from the same source, might there still be a problem of reference?

Also related: what information is carried over from perceptual to conceptual processing? Isn't this "selection/extraction" problem eerily similar to the transduction problem faced by amodal theories of cognition? What are the principles that determine which sets of sensorimotor contingencies will be exercised during, say, activation of the perceptual symbol for DOG, and deducing from a perceptual simulation that a dog, if it wags its tail, is happy?

What implications does this view have for understanding "meaning"? Might it be the case that "meaning" is a quale, much like the "redness" of red, or the "hotness" of hot? That is, could the meaning of, say, "apple" be the qualitative feeling of what-it-is-like to interact effectively with apples, based on the implicit, procedural knowledge of the sensorimotor contingencies that define the actual and allowable interactions with apples? Given that O'Regan and Noë (2001) claim that the knowledge of sensorimotor laws, and the current exercise of that knowledge, determine the qualia of experience, is it too much of a leap to claim that the meaning of objects arises from the whole stretch of competent engagement with them? Admittedly, the problem of meaning and reference is a difficult one—beyond the scope of this paper—but the hope is that this discussion will serve as an "intuition pump" for more detailed analyses.

Conclusion

The main goal of this paper has been to elaborate a link between three deeply related, and mutually enriching areas of study. However, much of the difficulty still remains in determining how exactly the (putative) underlying processes (such as how event features are integrated into event codes) give rise to the functional properties of a PSS. But clearly, the possibility that sensorimotor contingencies, event codes, and perceptual symbols comprise the fundamental components of thought further suggests a deeper result: that now we might be more assured that suggestive correlations between perception and cognition (Goldstone & Barsalou, 1998) could now be given a principled causal basis for their interaction. We might now be in a better position to understand just in what respects perceptual processes might hold at the conceptual level; and accordingly, how we as researchers, and possessors of minds, might broaden and enrich our investigations.

Acknowledgments

Abstract

Studies of experts with different specialties in a domain suggest that goals may play an important role in category learning and inductive reasoning. Little experimental research, however, has addressed the potential influence of goal-directed activity on such processes. In the current study naïve participants acquire and utilize knowledge about a novel natural kind domain over a number of experimental sessions. Different groups of participants utilize different goals in their interactions with the experimental items. Participants utilizing a goal that requires the use of a certain subset of item features are found to develop categories around these features. Moreover, in a subsequent inductive reasoning task, these same participants perform in a manner that is highly consistent with the use of a goal-related category structure.

Introduction

Several researchers have encouraged a broadening of the methodology that has long predominated the psychological study of human categorization (e.g., Barsalou, 1991; Markman, & Ross, 2003; Medin, Ross, Atran, Burnett, & Blok, 2002; Murphy, 2002; Shafto, & Coley, 2003; Solomon, Medin, & Lynch, 1999). It is argued that categorization is implicated in a number of cognitive processes, such as, problem solving (Chi, Feltovich, & Glaser, 1981; Ross, 1996), inductive reasoning (Osherson, Smith, Wilkie, Lopez, & Shafir, 1990; Proffitt, Medin, & Coley, 2000), and communication (Solomon et al., 1999; Markman & Ross, 2003), hence the study of categorization ought to reflect its multifaceted character. One area of research that has exemplified this broadened approach is the study of experts. These are individuals with extensive knowledge and experience in a given domain, such as, chess, medicine, birds, or trees.

Traditionally, studies of expertise have attempted to design tasks that elicit superior performances from experts in laboratory conditions so it may be systematically analyzed (Ericsson, & Smith, 1991). In most cases the performance of experts is compared with the performance of non-experts, typically recruited from undergraduate populations. However, recent research suggests that comparisons *among* experts with different specialties in a single domain may also provide valuable insight into the nature of expertise. With regard to theories of categorization, such comparisons could help to identify factors that contribute to the organization of conceptual knowledge that may be masked when research is restricted to expert-novice comparisons.

Inter-expert research has found that experts with different specializations in a domain may categorize and reason about domain-related information in characteristically different ways. For example, Medin, Lynch, Coley, and Atran (1997) found that different types of tree experts (taxonomists, landscapers, and maintenance workers) organized the same set of familiar tree species in distinct ways. Of particular interest is their finding that both landscapers and maintenance workers formed categories of trees based on their goal-related properties, such as, "weediness," "landscape utility," and "aesthetics." Moreover, in a subsequent inductive reasoning task maintenance workers made a number of inductive inferences consistent with their goal-related categorizations of the tree species. Proffitt et al. (2000) found that tree experts would often rely on causal-ecological relations over taxonomic relations in making inferences in their domain of expertise. As noted by Medin et al. (1997), the categories utilized by some types of tree experts closely resemble the goal-derived categories described by Barsalou (e.g., 1991): They crosscut the scientific/taxonomic organization of the domain and appear to be assembled around ideal attribute values.

Exploring the Influence of Goal Use

The above studies suggest that the nature of a domain, like trees, is but one factor contributing to the category structures that individuals form for it. It follows that research focusing exclusively on the effects of category structure on category learning may be missing an important aspect of this learning process (see also Markman & Ross, 2003). It may be that the influence of goal-directed activity on category learning is quite extensive, perhaps veiled by the characteristic ways in which members of a culture interact with the world. Indeed, cross-cultural studies have identified variations in categorization that may be related to such differences (e.g., Medin et al., 2002).

It is clear that evidence of cross-cultural and inter-expert variation in categorization and reasoning pose substantial challenges to the prevailing paradigm in categorization research. However, it is notoriously difficult to identify the causes of such variability. Numerous differences clearly exist between cultural groups, and even studies of different expert specialists from the same culture cannot control for differing experiences with the members of a domain.

Moreover, the relations between domain structure and domain use are likely to be highly complex. For instance, morphological properties can be related to both the taxonomic status of an object as well as its utility. Because domain structure and use are parameters that may vary freely in the real world, it is challenging to interpret cross-cultural and inter-expert comparisons. For these reasons experimentation is needed to isolate the roles played by these different factors.

Ross' recent work (e.g., 1996, 2000) represents an attempt to utilize experimental tasks to investigate the influence of goals on categorization, focusing particularly on the relation between categories and problem solving (cf. Chi et al., 1981). This research has demonstrated that the use of a category can alter its representation by enhancing the perceived importance of use-related features. For instance, in the domain of medical diagnosis, participants that learned that certain disease symptoms were good predictors of a treatment also perceived these symptoms as more diagnostic of the disease, even though they were no more diagnostic than other features that accompanied them. This research has primarily investigated how use affects an already-learned category. Thus, it is an unsettled question as to how goal-directed interaction affects category formation, particularly in natural kind domains. Examining the effects of goal-directed activity on inductive reasoning would provide an interesting extension of this line of research.

Overview

To examine the effects of goal-directed activity on categorization and inductive reasoning, the present study exposes naïve participants to an artificial natural kind domain (the "Creatures"). Over a four-session learning phase, these participants acquire knowledge about the different types of features possessed by the Creatures and use this knowledge to assess the Creatures according to a particular goal. These goals are manipulated between groups: One group is given a goal that directs them to utilize a certain subset of the Creatures' features, while the other group is given a goal that does not direct them to utilize any subset of features over another. Changes in categorization are assessed by having participants sort the Creatures both before and after the learning phase. An induction task is used to assess how goal-directed activity influences reasoning about the domain.

It is hypothesized that the performance of goal-directed activities will influence participants' categorizations and reasoning, but only in the case where participants must utilize a certain subset of the Creatures' features to perform the goal-related tasks. If these participants learn to re-organize their domain knowledge around ideal (i.e., goal-relevant) features, then a category structure that is based on goal-related features should provide a good account of their categorizations and their inductive inferences.

Method

Participants

Eight undergraduates from the University of Illinois at Chicago participated in this study to fulfill a course requirement. Participants were run individually. Four participants were randomly assigned to each condition.

Materials/tasks

Experimental stimuli. A set of 16 artificial Creatures was designed such that it could be sorted into three structurally equivalent hierarchies on the basis of three different feature types: Features related to Avoiding Predators (AP), Features NOT related to Avoiding Predators[1] (NAP), and Pictorially-represented features (PR). The PR features were represented in an illustration of the Creature, while the AP and NAP features were written in point form below the illustration (see Figure 1).

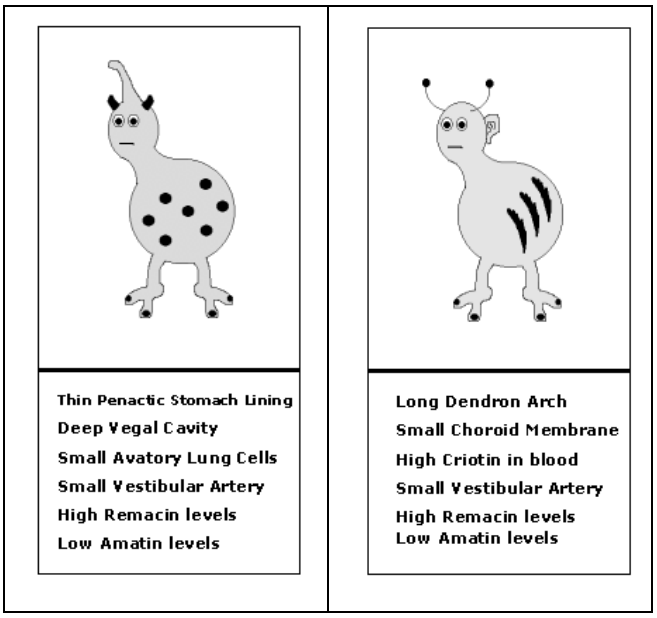

Figure 1: Examples of Creature cards. *Note.* Actual cards were in color.

Fourteen features of each type were distributed among the Creatures according to the structures in Figure 2. The dendrograms in Figure 2 show that for each feature type (AP, NAP, and PR), eight of the features are possessed by 2/16 Creatures, four of the features by 4/16, and two of the features by 8/16. These dendrograms can be understood as ideal category structures for each feature type – that is, they represent the three different category structures that would be formed by using each of the three different feature types. It is of interest to compare participants' categorizations with these ideal structures.

[1] These features were coherently related to another goal: assessing the Creatures according to how well they would serve as a source of nutrition. Participants in this experiment were not informed of this other goal.

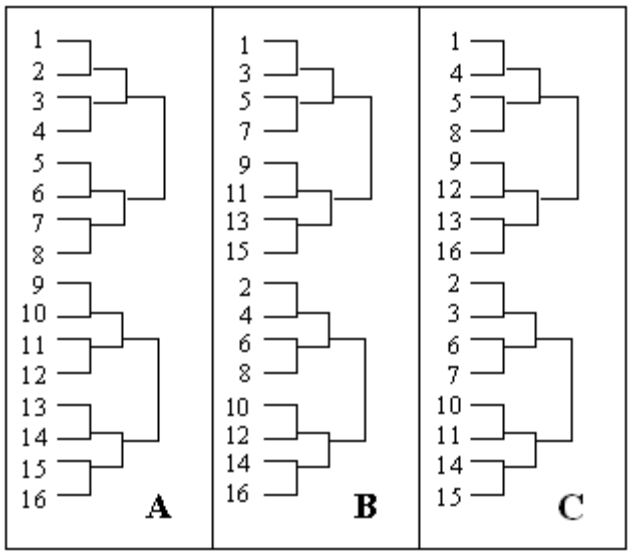

Figure 2: Dendrograms representing categories based on (A) Written features related to Avoiding Predators, (B) Written features NOT related to Avoiding Predators, and (C) Pictorially-represented features.

Goal Information. The independent variable in this study was whether or not participants were given a goal requiring them to utilize a certain subset of Creature features. All participants were informed that a large corporation had purchased an island habitat, and they want to introduce the Creatures to it. Participants in Group AP (Avoid Predators) were told that the corporation was interested in maximizing the survival of the Creatures on the island, and that they wanted to determine which Creatures would be best suited for avoiding predators. Participants in Group C (Control) were told that the corporation was interested in cataloguing the Creatures, and wanted to determine which Creatures would be easiest to monitor. Participants in both conditions were told that the corporation had hired them as a consultant, and that their job was to assess the Creatures according to either: (a) how well-suited they are for avoiding predators (Group AP) or (b) how easy they will be to recall (Group C). Participants were informed that the Creatures' features would be useful for making their assessments, and that they would learn more about the Creatures' features at the next session of the experiment.

Pre-training Tasks. Before engaging in goal-directed activities, participants had to be familiarized with the features that they would utilize. This pre-training is important in ensuring that differences between the two goal groups are not due to differences in familiarity with and knowledge of the features. The pre-training consisted of two parts, a learning phase and a test phase.

1. Feature Learning Task. In this task participants were required to study several computer screens of information about the Creatures' features and their relations to other properties. Half of these properties were coherently related to avoiding predators (AP) and half were not related to avoiding predators (NAP – see footnote 1). For example, participants had to learn that a "thin penactic stomach lining" means that the Creature cannot dig holes for hiding, and that a "small vestibular artery" means that the Creature has low vitamin C levels. Participants were permitted to study this information at their own pace.

2. Feature Memory Test. This test was designed to determine whether participants had learned the information about the features from the feature learning task. This computerized test consisted of 14 multiple choice questions about Creature features. Participants were required to re-take the test until they completed it without error. They were given up to 5 attempts per day. Four versions of this task were constructed. Each version contained the same questions, but with a different ordering of both questions and options.

Goal-directed Activity. The main task for the majority of the experiment was a **Creature Assessment task**. The task combined memory and decision making about the creatures. Students performed this task on days 2-5. At the beginning of each trial of this task, the subject was shown a Creature card on a computer screen for 10 s. Following this display the subject completed a 2-page assessment form. On page 1 the subject checked boxes next to the features possessed by the Creature that was just displayed. Participants in the AP condition were asked to check only the boxes next to the Creature's features that are relevant to avoiding predators. Participants in the C condition were asked to check the boxes next to all of the Creature's features. On page 2 of the assessment form the subject responded to 3 questions. Participants in the AP condition were asked: (1) Do you think the Creature that you were just shown will be good at avoiding predators in the habitat? (2) What about the Creature influenced your decision? (3) Rate the Creature on a scale of 1-10 according to how good it is likely to be at avoiding predators. Participants in the C condition were asked: (1) Do you think the Creature that you were just shown will be difficult to recall later on? (2) What about the Creature influenced your decision? (3) Rate your memory for the Creature on a scale of 1-10, according to how difficult it is likely to be to remember it. Following completion of the response form, the subject advanced the screen and the next item was displayed. Each of the 16 Creatures was shown in a different order once per day.

Dependent Measures. Two dependent measures were used to assess changes in categorization and reasoning about the Creatures. A sorting task (the Category Construction Task) was administered both before and after the training sessions. An Inference task was given on the final day of the experiment.

1. Category Construction Task. In this task, participants were asked to construct categories using the 16 Creature cards. Before sorting the cards, the subject was shown each card one-by-one for about two seconds. Following this initial exposure the Creature cards were randomly arrayed

on a table in front of the subject. The subject was instructed to find the "best way" to organize the cards. First, the subject was asked to form 8 pairs of Creatures and to provide justification for each group that they made. Second, the subject was asked to form 4 groups of 4 Creatures using the pairs that they constructed, and to provide further justifications. Finally, the subject was asked to combine the 4 groups of Creatures into 2 groups of 8 Creatures, and to provide justifications. This task was performed on both Day 1 and Day 6 of the experiment. On Day 6 the participants were instructed to use their knowledge of the Creatures when constructing categories, and they were not shown each card one-by-one as on Day 1. Otherwise, the procedure was the same on each day.

2. Inference Task. In this task participants were presented with a Creature on a computer screen and informed that the item has been found to possess a novel feature, "Sarca." The original item was removed after 10 s and 2 different Creatures were then shown. The subject was then asked to decide which of them is most likely to also possess the novel feature attributed to the first item. Following their response a blank screen was displayed for 2 s, followed by the next trial. Participants received two types of trials in which a more pictorially similar option (the PR option) was competed with either a more AP-related or NAP-related option. In AP vs. PR trials one option shared one more PR feature with the original item than did the other option. This other option, however, had one more AP-related feature in common with the original. Importantly, both options had exactly the same NAP-related features in common with the original. Thus, these trials tested whether participants would infer that the novel property would be more likely to generalize to a Creature that is more pictorially similar or one that is more similar with respect to AP properties. NAP vs. PR trials were analogously designed to compete an option sharing more PR features with one sharing more NAP-related features. The number of AP vs. PR and NAP vs. PR trials was matched. Trial order was randomized to create a single task list that was administered to all participants.

Procedure

The experiment took place on six consecutive weekdays (participants were not run on weekends). On day 1, participants performed the category construction task and received information about their goal. On day 2, participants learned about the properties related to the Creatures' features and subsequently completed the first version of the feature test. Participants then completed assessments of the Creatures, either with respect to how well suited they would be for avoiding predators (Group AP) or with respect to how easy it would be to recall them later on (Group C). Days 3-5 were the same in format. On these days, participants completed different versions of both the feature test and Creature assessments. Finally, on day 6 they completed the category construction task followed by the inference task.

Results

Feature Memory Test. Figure 3 displays the mean number of blocks (test attempts) to criterion across the four days that the test was administered. A 2 (Group) x 4 (Day) repeated measures ANOVA was conducted on the mean number of blocks to criterion. Participants that did not reach criterion on a given day were given a default score of 6 (five being the maximum number of attempts permitted). Across the first 3 days there were five instances in which a subject did not reach criterion, but by day 4 all participants reached criterion in 4 trials or less. The ANOVA revealed a significant effect of Day, $F(3, 18) = 11.61$, $MSE = 1.09$, $p < .01$, with no main effect of Group $F(1, 6) = 1.06$, $MSE = 6.62$, *ns*, and no interaction between Day and Group, $F(3, 18) = 1.95$, $MSE = 1.09$, *ns*. A follow-up comparison revealed a significant difference between the number of blocks to criterion required on Day 1 ($M = 4.6$) and Day 4 ($M = 1.9$), $F(1, 18) = 27.5$, $MSE = 1.10$, $p < .01$. These findings indicate that participants required fewer attempts to reach criterion by the final day.

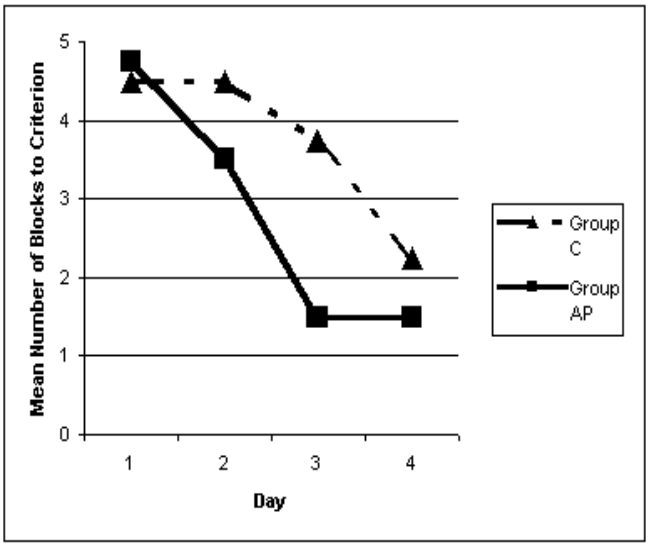

Figure 3: Mean number of blocks to criterion by day on the Feature Memory Task

The pattern of change in the number of blocks to criterion is consistent with the decline in error rates across days (see Figure 4). A 2 (Group) x 4 (Day) repeated measures ANOVA was conducted on mean error rates. This ANOVA revealed a significant effect of Day, $F(3, 18) = 9.16$, $MSE = 0.002$, $p < .01$, with no main effect of Group $F(1, 6) = 1.62$, $MSE = 0.005$, *ns*, and no Day x Group interaction, $F(3, 18) = 0.68$, $MSE = 0.002$, *ns*. A follow-up comparison revealed a significant difference between the error rates on Day 1 ($M = 0.13$) and Day 4 ($M = 0.04$), $F(1, 18) = 18.0$, $MSE = 0.002$, $p < .01$. These findings indicate that participants' accuracy on the Memory Test improved across the four days it was administered. Examination of the decrease in both blocks to criterion and error rate across days provides

evidence that participants in both groups learned and retained information related to all features.

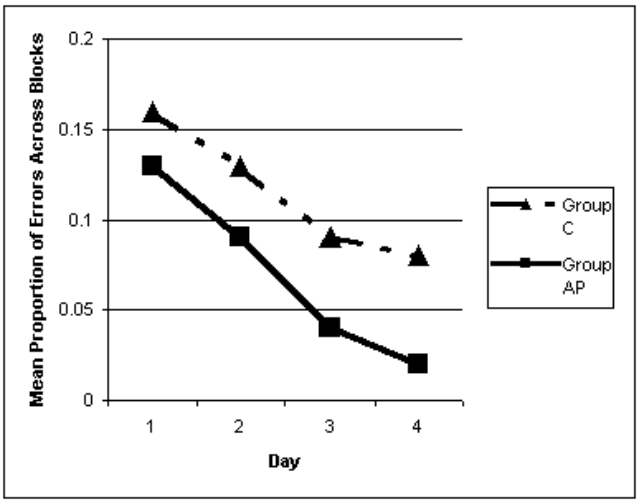

Figure 4: Mean error rate per block by day on the Feature Memory Task

Category Construction Task. Treatment of the category construction data closely follows Medin et al. (1997) and Shafto and Coley (2003). Participants' categorizations of the Creatures were converted to dendrograms (see Figure 2). Each subject's dendrogram was then used to derive a 16 x 16 pairwise distance matrix. A number was assigned to each cell of the matrix corresponding to the level in the dendrogram at which the pair of Creatures was combined. Creatures paired together at the lowest level (i.e., when the subject was instructed to make pairs of Creatures) were assigned a distance of 1; Creatures paired at the next level (groups of 4) were assigned a distance of 2; Creatures at the highest level (groups of 8) were assigned a 3; Creatures NOT paired at any level were assigned a default distance of 4. Only the 120 unique cells above the diagonal were used in subsequent analyses because of their redundancy with the cells below and because the cells on the diagonal (the distance between a Creature and itself) are irrelevant. Distances were averaged across participants in each group to create four different matrices representing initial and final category construction for Group C (C-1 and C-2) and AP (AP-1 and AP-2). Initial and final matrices for each group were correlated with one another and with the matrices derived from the ideal category structures (Figure 2).

Table 1 displays the correlations between the ideal category structures (APi, NAPi, and PRi) and the initial and final structures for each group (C-1, C-2, AP-1, and AP-2). The first thing to note in Table 1 is the relatively low intercorrelations among the ideal structures. This implies that a high correlation between a group structure and an ideal structure cannot be attributed to covariance among the ideal structures. Turning to the performance of the two groups, it is evident that on average participants in Group C initially sorted the Creatures in ways that were highly correlated with both the APi and PRi structures. In their final performance of the task, these participants produced category structures that are still significantly correlated with the APi structure, but are not significantly correlated with the PRi structure. Group AP's categories also have a high correlation with PRi at the initial stage, but unlike Group C they do not evidence a significant correlation with APi. However, at the final stage Group AP shows a high correlation with APi and a nonsignificant correlation with PRi. In summary, both groups appear to shift away from using PR features in their final category constructions, but only the participants in Group AP show an increased relation to APi.

Table 1: Correlations between ideal and subject category structures

Structure	NAPi	PRi	C-1	C-2	AP-1	AP-2
APi	0.15	0.15	0.50**	0.45**	0.13	0.91**
NAPi		-0.16	-0.08	0.03	-0.17	0.12
PRi			0.55**	-0.07	0.92**	0.12
C-1				0.41	0.49**	0.55**
C-2					-0.02	0.48**
AP-1						0.10

** $p < .01$ (two-tailed). *Note.* C-1 = Group C, initial sort; C-2 = Group C, final sort; AP-1 = Group AP, initial sort; AP-2 = Group AP, final sort

Inference Task. Participants' choices were scored according to whether they were consistent with the use of non-pictorial information. Thus, in the AP vs. PR trials the participant's choice was scored as a 1 if they chose the AP-related option and a 0 if they chose the PR option. In NAP vs. PR trials, NAP choices were scored as a 1, PR choices as 0. The mean proportion of non-PR choices was calculated for participants for each trial type. Figure 5 displays the mean proportion of non-PR choices for each trial type. A 2 (Group) x 2 (Trial Type) repeated measures ANOVA revealed no main effect of Trial Type, $F(1, 14) = 2.0$, $MSE = 0.05$, *ns*, and a main effect of Group, $F(1, 14) = 36.7$, $MSE = 0.031$, $p < .01$, however, there was also a significant Group x Trial Type interaction, $F(1, 14) = 6.58$, $MSE = 0.002$, $p < .05$.

Of primary interest is the comparison between the mean proportions of non-PR choices for each trial type with the proportion expected by chance (.50). For Group AP, the mean proportion of non-PR choices was significantly higher that chance on the AP vs. PR trials, $t(19) = 5.15$, $p < .01$, but did not differ from chance on the NAP vs. PR trials, $t(18) = 0.35$, *ns*. For Group C, the mean proportion of non-PR choices was marginally lower than chance on the AP vs. PR trials, $t(19) = 2.04$, $p < .10$, but did not differ from chance on the NAP vs. PR trials, $t(18) = 0.98$, *ns*. Thus, participants in Group AP most often generalized a novel property to a Creature more similar with respect to AP properties, but performed at chance level when AP-related similarity did not distinguish the two options. Participants in Group C did

not show this pattern, and evidenced a slight tendency toward the PR option in the AP vs. PR trials.

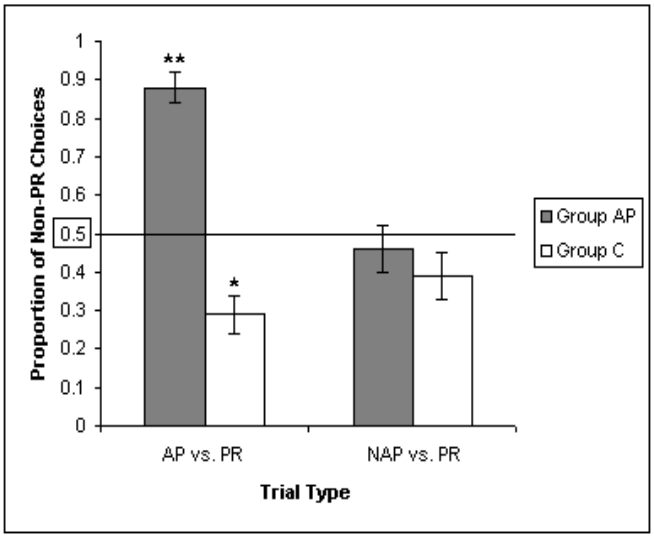

Figure 5: Mean proportion of Non-PR choices for each trial type in the Inference Task. *Note.* Asterisks indicate that the mean differs from chance (.50), ** $p < .01$ (two-tailed), * $.05 < p < .10$ (two-tailed).

Summary and Discussion

The main hypothesis of this experiment was that the utilization of a certain subset of Creature features in a goal-directed task would influence categorization and reasoning. It was further predicted that an ideal goal-related category structure would account well for the performances of these participants.

The results of the category construction task are consistent with these predictions. The APi structure correlated highly with Group AP's final categorizations. Even though Group C's categorizations also correlated highly with APi, this correlation showed no increase from this group's initial performance. The APi structure also accounts well for Group AP's performance on the inference task. When the APi structure distinguished between the two options, the participants often chose the AP-related Creature, when the APi structure did not distinguish the two options, participants performed at chance level. Altogether these findings suggest that participants in Group AP developed categories organized around a particular subset of goal-related Creature properties (AP-related properties). Participants in Group C did not evidence such change. By controlling the frequency of participants' exposure to the domain as well as its structure, the differences between groups can be attributed to differences in the goal-directed tasks that each group performed.

This research is still in its early stages and would surely benefit from increasing the sample size and adding further tests of participants' new domain knowledge. Nevertheless, the findings of this experiment serve to highlight the role that goal-directed activity could play in categorization. Given the extensive and varied nature of such activity within and across cultures, this role may deserve more attention than it has previously been paid.

Acknowledgements

This research was completed as part of a Master's degree requirement at the University of Illinois at Chicago, and was supported by a fellowship from the National Sciences and Engineering Research Council of Canada. Special thanks to Jeremy Eagles and Melinda Jensen for their assistance in running participants and entering data, and to Len Newman, Jim Pellegrino, and Rob Youmans for helpful discussions.

Abstract

Intellectual expertise means knowledge and ability that a person has that allows them to solve complex problems. It is important to understand how people become experts so that we can improve educational strategies, and help learners achieve their full academic potential. Unfortunately, the process of acquiring intellectual expertise is not well understood. Artificial neural networks (ANNs) have already been successful in modeling other types of human learning. This paper shows that they can also be trained as a model of expert human learning, and address many of the difficulties found in trying to study expertise in humans. The results confirm three hypotheses: (1) An artificial neural network can be used as a model to investigate how people learn under different training scenarios; (2) Different methods for delivering the training material result in different final performance; (3) The best performance is achieved by incrementally increasing the complexity of the material. These results provide educators with computational evidence that structured, integrated delivery methods are better for learners than oversimplification and isolation of learning tasks.

Introduction

An intellectual expert has achieved a level of cognitive development in which she or he can rapidly grasp subtleties of complex problems, and produce very high quality solutions. A goal of formal education is to help students achieve an expert level of understanding in their chosen field. It is important to understand the nature of expertise so that we can improve educational strategies. As a result of many research studies about expertise, we know a lot about the characteristics of experts. However, there is a lot we do not understand about how to become an expert. It is not easy to create experts, whether human or computational. The learning process is complex and human studies are difficult. Understanding how to acquire intellectual expertise has proven elusive for educators, psychologists and students alike.

A primary goal of the study reported here is to increase understanding of the process by which humans become intellectual experts. In particular, how can people develop the ability to look at a problem statement and immediately select the best solution strategy? The second main goal is to understand this process in the context of formal instruction; specifically, how does the strategy by which material is delivered to the learner affect learning and conceptual development?

This paper presents results from a series of computational experiments examining how different delivery methods influence learning and conceptual development. These experiments use a real-world adult educational problem: the ability to identify correct solution strategies for calculus integration problems. The goal is to show that an artificial neural network can be used as a model to investigate how people learn under different training scenarios, and that different delivery methods result in different overall performance. The main results include: (1) errors are higher on final exams when different problem types are learned in isolation; (2) cramming just prior to taking final exams does not significantly improve performance. Different delivery strategies affect learning in different ways: (1) traditional sequential delivery methods inhibit learning and retention; (2) integrated delivery methods increase learning and retention; (3) the best performance comes from delivery methods that incrementally increase the complexity of material. These results can be applied to developing better training methods for people.

Prior Research on Intellectual Expertise

Studies of human expertise and understanding have revealed key information about experts. We know that experts and novices categorize problems differently, and that this categorization takes place before the subject attempts to solve the problem (Chi, Feltovich, and Glaser 1981). We also know that experts can categorize problems without solving them (Robinson and Hayes 1978). Finally, there is strong evidence that routine problems are solved not by intense calculating but rather by recognizing a type of problem (categorizing) and then using the stored knowledge about how to solve problems of that type (Reiman & Chi '89 referenced in (Ross and Spalding 1991).

Most studies of expertise have focused on what an expert knows, rather than the process by which she or he attained expertise. As a result, we know a lot less about this learning process than we do about expertise itself. Expert behavior does not simply follow a script: the greatest expertise is the result of long-term practice (Hayes 1989) that is consciously goal directed, self-monitoring, and self-adjusting within the setting of each particular task (Garner 1990). In addition, many studies have shown that meta-cognition (self-appraisal and self-management of cognition) is critical for successful academic learning (literature surveyed by Paris and Winograd (1990)). Since we know that experts categorize extremely well, it is possible that categorization ability and goal-directed meta-cognition enhance one another. When these abilities merge, intuition may be the result: there is strong evidence that experts rely upon their accurate intuition and a holistic recognition of appropriate actions (Dreyfus and Dreyfus 1986).

Cognitive scientists have often studied mathematics learning, due to the abstract nature of its concepts. Bruner has even suggested that learning mathematics may be viewed as a microcosm of all intellectual development (Bruner and Kenney 1965). A particularly interesting early connectionist model of mathematics learning was presented by Viscuso, Anderson, and Spoehr (1989). Their artificial neural network (ANN) simulated qualitative reasoning while doing multiplication. In summarizing their model, Viscuso et al correctly pointed out that the most important contribution of their model was that it mimicked the manner in which experts rely not so much on formal logic and rules but on their "sense" of what is correct. Another interesting ANN system learned to perform arbitrarily long addition problems (Cottrell and Tsung 1993). Their model learned the implicit underlying rule of addition. This system showed that ANNs can account for conceptual development: the network learned an important concept on which it had not been explicitly trained. In the decade since these studies were published, there has been quite a bit of work in related areas, such as the development of basic numerical abilities in infants and children (literature surveyed in (Ahmad, Casey, and Bale 2002)), and in childhood strategy development (Bray, Reilly, Villa, and Grupe 1997). However, we still do not understand how adult human experts learn to "sense" important concepts. It is important to understand this ability, so that we can better educate students.

The Calculus Domain

Calculus, at its most fundamental level, is based upon abstract cognitive concepts. As a result, understanding how people best learn calculus requires understanding the mind. The current educational debates over mathematics and science education partly result because we do not understand enough about how the brain produces cognition and conceptual understanding. In order to become calculus experts, students need to understand complex concepts and intuitively select the most efficient methods to solve problems. Educators need to understand what methods of delivering material will most help students achieve these abilities.

In the last decade math and science have been at the center of an increasingly wide-spread national concern with properly educating citizens for the new technological age. In college, students who want to major in science or engineering usually have to first perform well in calculus, which turns out to be a major obstacle for many of them.

In order to clearly identify what kinds of problems calculus students were having at at the University of Texas at Austin (UT), we conducted structured interviews with mathematics faculty and teaching assistants (TAs). The results fit well with the psychological literature on expert/novice behavior. Faculty and TAs reported that novice learners (in this case UT students) are often unable to select the correct solution strategy. This problem arises before they even have a chance to exhibit computational difficulties and prevents many from reaching timely, correct solutions. Conversely, the experts claimed an ability to "just see" the correct strategy, yet were unable to articulate how they knew. Probing revealed that although there are "rules of thumb" to assist in this domain, they are not comprehensive and do not cover many common scenarios. Experts instead pointed to general patterns and categorization that they have learned to recognize via extensive practice.

Successful problem solvers categorize math problems based upon underlying structural similarities and fundamental principles (Schoenfeld and Herrmann 1982). These categories are often grouped based upon solution strategies, that the experts then use to calculate an answer (Owen and Sweller 1989). How such strategies are formed is poorly understood. What regularities are most likely to be noticed, and how does the form in which the initial procedure is learned affect what is noticed? From the point of view of education, are there ways of managing how learners practice, to enhance the likelihood that they will notice these regularities, and incorporate this information into their problem-solving strategies?

One of the first instructional decisions is what order to present the material in, and how to move from one concept to the next. There are many possible orderings of material, and a computational model can be used to explore them. The model presented in this paper, described in the next section, contributes to achieving this research goal.

The ANN Model

The particular calculus problem chosen for the study is to decide whether a given integration problem should be solved with Simple Integration (Simple), Integration by U-Substitution (Usub), or Integration by Parts (Parts). This section describes the architecture of the artificial neural network as well as the training and test data, its encoding, and the experimental methods used in all the experiments described in this paper.

Architecture and Data

The model is an artificial neural network utilizing the backpropagation algorithm (for details of the algorithm see Bishop 1995) created using the LENS network simulator (Rohde 1999). The network is fully connected, and has 55 input nodes and 20 hidden nodes. The 55 input nodes make up a vector large enough to represent the features of one calculus integration problem containing up to four terms. The 20 hidden units were determined to be appropriate by experimentation; the results were not effected by small changes in size.

The input data consists of 957 calculus integration problems based upon examples found in college level calculus textbooks. Feature coding is a logical choice for representing them, given that both novices and experts use the features of a problem to determine which approach to use (Chi et al. 1981). The 55 unit input vector contains a series of 0s and 1s that map operators/operands to their location in the calculus integration problem. Short problems are padded with blanks. The vector consists of

- Four 2-unit terms representing constants and variables.
- Four 8-unit Unary Operators, representing $\sin, \cos, \tan, \cot, \sec, \csc, \ln$, exponentiation $e(x)$.
- Three 5-unit Binary Operators, representing multiplication, division, exponentiation $\hat{}$, addition, subtraction.

For example, the problem

$$3 + cos(x) - sin(y) + ln(x)$$

is coded in postfix form as: 01 00000000 10 01000000 00 10000000 10 00000010 00010 00001 00010, where the components are

01 : No Variable; Constant (i.e. 3)
00000000 : NONE (i.e. no unary operator for the constant)
10 : Variable (i.e. x); No Constant
01000000 : cos (of the variable x)
10 : Variable (i.e. y); No Constant
10000000 : sin (of the variable y)
10 : Variable (i.e. x); No Constant
00000010 : ln (of the variable x)
00010 : +
00001 : -
00010 : +

The network has three output nodes, each of which represents one of the possible integration strategies, Simple, Usub, Parts. Because the network is trained with one active target at a time, it learns to represent how confident it is in each choice (Bourlard and Wellekens 1990). For example, if the network reports activation values at 12%, 85%, 3%, then it is quite confident in the second category, considers the first category possible but unlikely, and the third category extremely unlikely (but not absolutely impossible). This percentage represents the *confidence level* that the network has in each answer.

Experimental Design

The calculus integration problems were divided into 10-fold cross-validation training and test sets (splits, or learning experiments). In each experiment the training set was input to the network, one problem at a time, in random order, and the test set was used to measure performance. Validation sets were not used because each learning experiment represented training one subject and the training time had to be constant, to compare how well the subjects learned. Three different types of learning experiments were run. Each experiment was run ten times, randomly resetting the initial network weights each time. Thus the whole study consisted of 300 learning experiments. This way it was possible to model the behavior of many different subjects and watch for both emergent patterns and individual variation.

During the test phase, there was always only one correct answer to a problem. This answer, called the "Best", was the answer suggested in a textbook, or by a calculus expert (faculty, TA). For each test problem the network reported how confident it was that the solution strategy was either Simple, Usub or Parts. If the confidence level for all solutions was below 80%, the problem was considered having "stumped" the network.

Results

Two sets of experiments (Drill and Test, Fully Integrated Learning) validated the ANN as a model of human learning. These experiments showed that the model accurately matches results from past educational research. In addition, these experiments provide insight into how the learning process occurs. The third set of experiments provided a computational prediction that a different type of learning (Incremental) produces the best performance.

Validating the Model: Drill and Test Learning

The first set of experiments, called "Drill and Test", mimicked a classic form of delivery that results in poor long-term retention in humans (Resnick and Ford 1981). In this method, concepts are introduced to the learner one at a time, with no overlap between topics. At the end of each topic, the learner is given a midterm exam (of previously unseen examples) on that concept.

After it has been trained with all concepts, the learner is given an opportunity to "cram", i.e. train on all concepts for a short period of time. At the end of all material, there is a comprehensive exam consisting of the entire test set.

In order to monitor the progress of learning quantitatively, and to compare to other approaches, each network was also tested during each epoch in two ways: (1) with the current midterm exam, illustrating the performance that the teacher would see in the classroom (Figure 1a), and (2) with the comprehensive exam, monitoring progress in learning the entire task, but broken into separate numbers for the different concepts (Figure 1b).

The main result was that the model, like humans, only remembers the most recently introduced concept well. More specifically, in 100 experiments run using Drill and Test, most networks (83%) rapidly learned to identify each of the concepts in turn (Simple, Usub, Parts). On midterm exams, the network often recognized 100% of the problems belonging to the concept that had just been studied. However, in spite of the opportunity to cram first, when the comprehensive final exam was given, these learners performed poorly, averaging 41.65% (standard deviation 6.35). The highest score was 54.55%. The remaining 17% of network learners were unable to make the switch from Simple to Usub problems, and then to Parts problems: their Usub and Parts midterms usually scored 0%. When these learners crammed and then took their comprehensive exams, they scored on average 17.29% (standard deviation 4.95), with a high score of 26.92% All learners in these experiments were extremely confident in their answers, even when they were wrong.

Validating the Model: Fully Integrated Learning

A second set of experiments mimicked human learning using an approach called "Fully Integrated Learning". This approach is inspired by the immersion experiences popular in foreign language learning (Spolsky 1989): the learner is placed in an environment where she or he is completely surrounded by the stimuli to be learned. The cognitive mechanisms that enable a foreign language student to sort out important grammatical features might not be that different from those cognitive mechanisms that sort out features of mathematical structures. In the Fully Integrated Learning experiments, there was only one training period, during which the networks were trained on all of the problem types simultaneously. During each epoch, the Simple, Usub and Parts training problems were input to the network in random order. Exams using the entire test set were given after every training epoch.

Fully Integrated Learning produced significantly better results than the Drill and Test delivery experiments (Figure

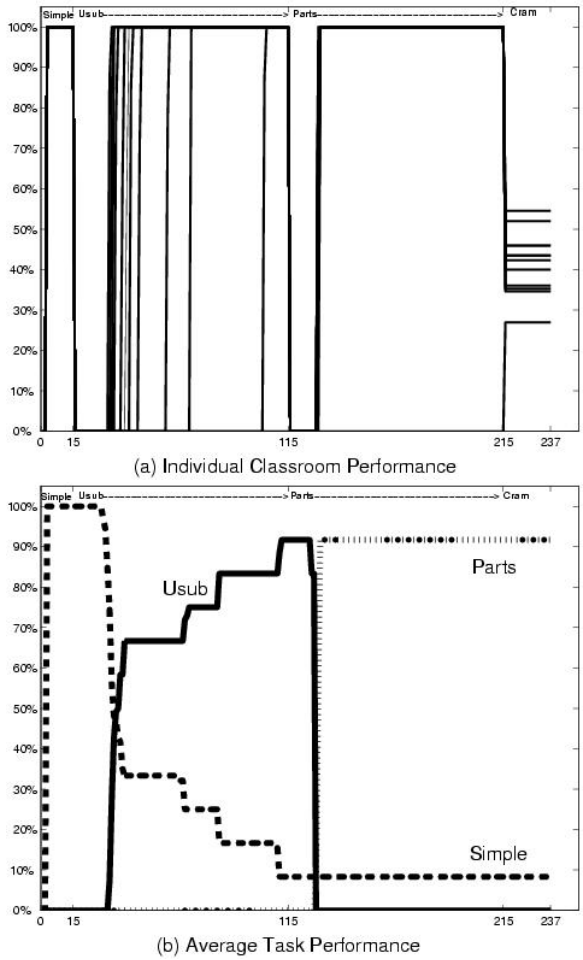

Figure 1: **Drill and Test Learning.** (a) The classroom performance of 12 representative learners, i.e. their accuracy on the current midterm (Simple, Usub, Parts, Cram periods) and comprehensive exam. Exam scores are on the y-axis, and the training epoch is shown along the x-axis. Scores on the comprehensive exam were poor - even with the aid of a cram session the highest score was 54.55%. (b) The average performance of all learners on the comprehensive exams, broken down by concept. Each problem type is forgotten when a new topic is learned.

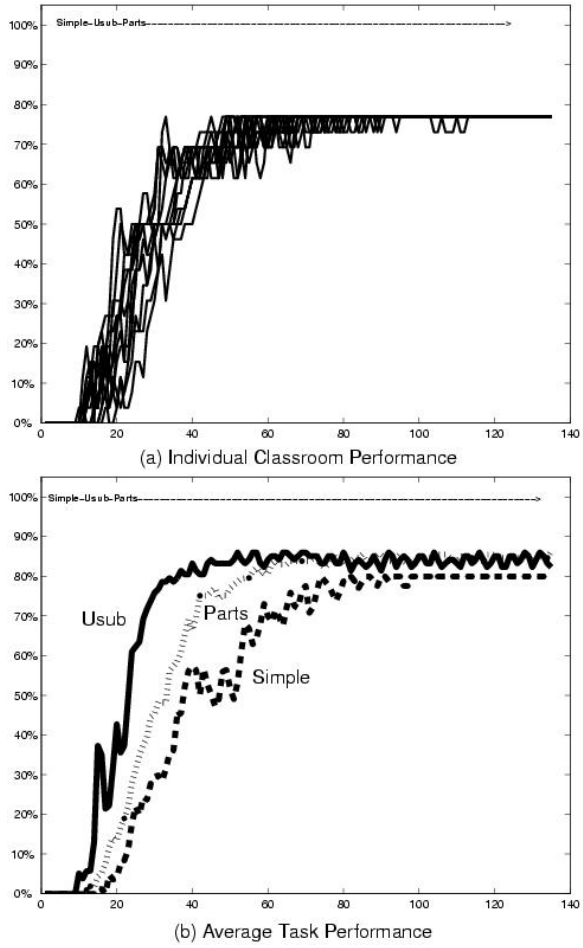

Figure 2: **Fully Integrated Learning.** (a) The classroom performance of 12 representative learners on the comprehensive test set over the course of learning. The learners initially failed the exams, but their scores rapidly increased, and finally plateaued. Improvement was not smooth, reflecting the trial and error process of learning. The best exam score was 80.76%. (b) Average performance of all learners broken down by concept. Usub problems were learned fastest, Simple problems slowest. Final results for Simple, Usub and Parts were similar.

2). The average score on the final comprehensive exam was 76.99% (standard deviation 7.94). The highest score was 80.76%. In contrast to Drill and Test, confidence in Fully Integrated learning closely reflected exam scores. The errors that were made on the exams followed a pattern of slow, gradual learning, spread across all problem types. The Fully Integrated Learning results as a whole replicated human data showing that immersion results in better longer-term retention than does Drill and Test.

Extending the Model: Incremental Learning

The third set of experiments was designed to test the hypothesis that the best learning of material is obtained by a delivery approach called "Incremental Learning". This approach is inspired by the result in the machine learning community that it is often most effective to tackle large computational tasks by starting with small problems and gradually increasing their complexity (Elman 1991; Gomez and Miikkulainen 1997). When there are a large number of co-dependent variables, it is hard to discover the role that each one plays in the problem and its solution. Therefore, an Incremental Learning delivery introduces new, increasingly complex concepts along with reinforcement of old concepts.

As with the Drill and Test experiments, there were three training periods. The network was first trained to identify Simple problems. During the second training period, Usub problems were added to the Simple problems, and for the third training period, Parts problems were added. The classroom performance was measured with Simple tests during the the first period, Simple and Usub test problems during the second, and the entire test set during the third (Figure 3a). The progress in learning the entire task was monitored with the entire test set, broken down by concept (Figure 3b). As in the Drill and Test experiments, Simple-only midterms very rapidly reached scores of 100%. When Usub prob-

lems were introduced, test scores began to fluctuate severely. Scores would drop to, or near, zero, rebound, and then drop again, as the network struggled to distinguish the new concept (Usub) from the old concept (Simple). Over time, although fluctuation continued, overall test scores increased. In a few cases, SU midterm scores reached 100%, however the majority of cases peaked at 70-75%. When Parts problems were introduced, the pattern of fluctuating scores was accentuated. Midterm scores immediately plummeted, although it is interesting to note that even the downward drop was often not smooth, but marked by brief plateaus and recoveries. Performance continued to deteriorate for longer than in the SU training segment, with scores fluctuating lower and lower. In contrast to the SU midterm scores, SUP midterm scores appeared to tighten in closer and closer to complete failure (for a while nearly all midterms fluctuated well under 20%). This behavior is predictable, because it is harder to distinguish three concepts from one another than two concepts. Eventually, performance began to improve, with prominent individual differences, as each network learner identified subtle patterns to accurately identify each concept. Eventually, virtually all midterm scores surpassed 70%. The average score on the final comprehensive exam was 81.9% (standard deviation 8.23). It is important to note that the final test results for Incremental Learning were better than either Drill and Test or Fully Integrated Learning, in spite of interim results that sometimes appeared poorer than either other type of experiment. The maximum exam SUP score was 95.6%, higher than any score reached in a Fully Integrated learning experiment. As evaluated with a t-test, the Incremental Learning final exam scores were higher than those of the Fully Integrated learning ($t = 1.9574, df = 11.869, p = 0.07423$).

The types of errors that the network made followed a pattern. As each new training period began, the network appeared to "flail", choosing first one answer then another on successive exam questions. However, this "flailing" gradually lessened and the network learned to correctly select each problem type simultaneously. As with the Fully Integrated Learning experiments, the learners' confidence levels closely reflected exam scores. The Incremental learning experiments showed that the best performance is achieved by introducing increasingly complex concepts gradually, allowing learners to build on their existing knowledge, and gradually pay more attention to finer distinctions.

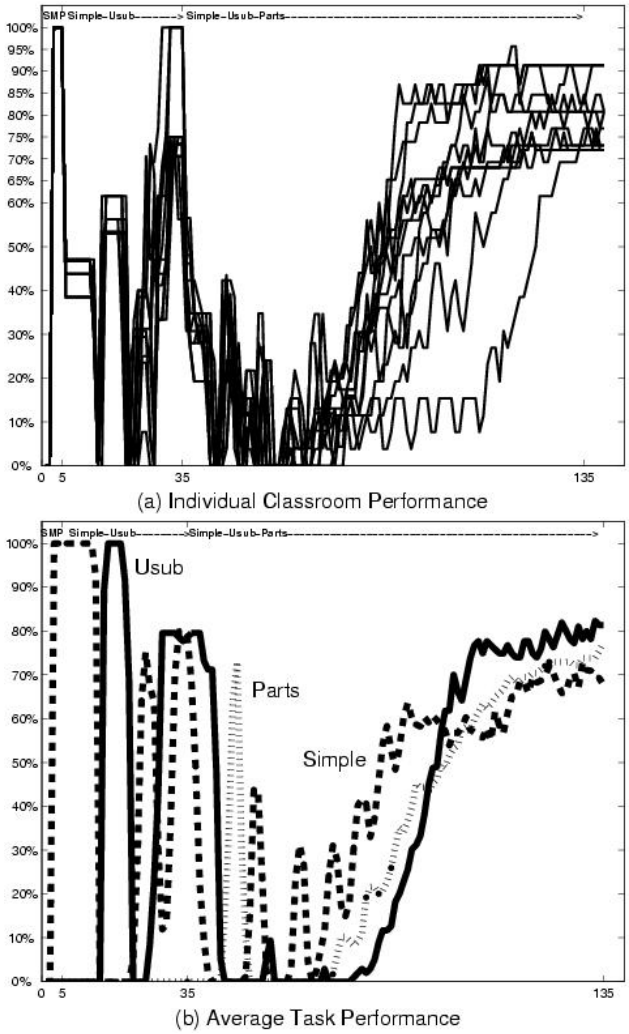

Figure 3: **Incremental Learning.** (a) The classroom performance of 12 representative learners on the current midterm (Simple, Simple-Usub, Simple-Usub-Parts). The maximum comprehensive exam score was 95.6%, higher than any score reached in a Fully Integrated learning experiment. (b) Average performance of all learners broken down by concept. Each problem type followed the same pattern of fluctuation between learning and apparent forgetting. Over time fluctuation lessened and performance improved for all problem types. Simple problems fluctuated the most and the longest.

Discussion and Future Work

Calculus integration problems that are often given to novice learners were used to study the process of learning to accurately categorize them by solution strategy. These strategies - Simple Integration, Integration by U-substitution, Integration by Parts - represent complex concepts that students need to intuitively master in order to become calculus experts. Drill and Test experiments and Fully Integrated experiments validated the model by showing that it can mimic known data about human learning. Drill and Test experiments supported the hypothesis that delivery methods that rigidly separate concepts during learning result in poor long-term retention of material. Also supported was the hypothesis that when concepts are reinforced inconsistently, only the most recently introduced concept is remembered, and that cramming does not improve learning. The nearly perfect midterm exam scores seen in Drill and Test experiments were misleading. They implied a level of interim learning and understanding which was not supported when the final exam require the learner to distinguish complex concepts.

Fully Integrated learning experiments supported the hypothesis that if problems that belong to one concept are introduced along with problems that belong to other concepts, error rates are smaller than when the same concepts are introduced separately. Over time, Fully Integrated learners performed quite well on their exams and although they are not perfect, can be claimed to have learned the task.

The results for Incremental Learning were very different from either Drill and Test or Fully Integrated learning. By introducing new problem types in a structured manner, the

network learner is allowed to focus on a smaller set of characteristics at the beginning of learning. Just as the first concept (Simple integration problems) is acquired, additional problems (Usub) are mixed in. The resulting confusion is apparent in the fluctuating midterm scores. Over time, as the learner grapples with the two contrasting problem types, confusion diminishes and midterm scores rise. When Parts problems are introduced, it becomes again more difficult to discriminate between the concepts. However, it is far more difficult to compare three related problem types than two. The confusion lasts longer and is more difficult to resolve, and individual learner differences become more apparent. Fortunately, the "priming" effect of the previous training segments allows most Incremental Learning learners to eventually do well, and in most cases better than the Fully Integrated learners.

An interesting direction of future research is to analyze the conceptual development that took place in the model during the different types of delivery methods. Using techniques such as Independent Component Analysis (ICA) of hidden layer representations it may be possible to discover how the network learners represent the problems as the learning progresses. In addition, the predictions on Incremental Learning can be tested in a study with human subjects. If confirmed, these results strongly suggest that a structured incremental approach should be used in teaching for expertise.

Conclusion

The experiments reported in this paper support the following three hypotheses: 1) An artificial neural network can be used as a model to investigate how people learn under different training scenarios 2) Different delivery methods result in different overall performance 3) Incremental Learning results in better performance than either Drill and Test or Fully Incremental learning. These results provide new insight into how humans learn complex cognitive tasks. As a result, educators have computational evidence that structured, integrated delivery methods lead to better performance for learners than oversimplification and isolation of learning tasks. They also have evidence that introducing many complex concepts at the same time does not produce the best learning either. The work encourages educators to focus on finding the optimal balance between introducing complexity and providing structured guidance. Finally, educators are reminded that interim results that reflect struggle with complex concepts will result in longer term performance gains than near perfect results in the short term.

Abstract

Transfer between isomorphic domains was investigated. Thirty college undergraduate students learned two isomorphic artificial systems. One system was concrete in the sense that it was perceptually rich and dynamic, while the other was abstract, involving written symbols. The results show significant positive transfer from the abstract domain to the concrete domain and no significant transfer from the concrete to the abstract.

Introduction

One of the goals of successful learning is transfer, or the ability to apply acquired knowledge outside the learned situation. Although a desired outcome of learning, spontaneous transfer is notoriously difficult to achieve. In the past few decades, numerous studies document poor or non-existent spontaneous transfer across isomorphic situations (Ben-Zeev & Star, 2001; Gholson et al., 1997; Holyoak, Junn, & Billman, 1984; Holyoak & Koh, 1987; Schoenfeld & Herrmann, 1982). Poor performance has been attributed to surface features distracting from underlying structure.

Which aspects of the learning situation facilitate transfer? A widely held belief in the education community has been that learning and transfer of mathematical and scientific knowledge is facilitated by the use of concrete representations of more abstract mathematical and scientific principles. In the past several decades, the use of concrete representations has been a growing part of the mathematics curriculum. Concrete representations include both physical manipulatives as well as specific instantiations of abstract concepts. They are often perceptually rich and meaningful. Mathematical concepts are traditionally represented in an abstract symbolic form, while applications of the mathematics to scientific and real-world scenarios can be thought of as concrete instances of the abstract concept.

The National Council of Teachers of Mathematics (NCTM) reform movement launched in 1989 promoted the role of such representations in the curriculum. For example, Dienes blocks (Dienes, 1960) are used in elementary mathematics education to teach arithmetic and place value. Dienes blocks are concrete proportional representations of the base-ten number system. The belief of educators who use the blocks is that through their use, young children will not only be able to represent and execute arithmetic problems, but will also be able to gain insight into the structure of the base-ten number system (Fuson & Briars, 1990).

Much support for the use of either concrete manipulatives or concretely situated applications in the learning of mathematics comes from constructivist educators. Cobb, Yackel, and Wood (1992) propose that students actively construct mathematical knowledge in social contexts. Furthermore, they suggest that topics which are applications of mathematics such as those from real-world or scientific situations provide good initial instructional activities. That is, instruction of mathematical concepts should be initiated through applications of the mathematics as opposed to initiated in symbolic form.

These approaches to learning and transfer seem to echo the Piagetian theory, according to which education should parallel the process of cognitive development, and the ability for abstraction is not achieved before the formal operational stage (Inhelder & Piaget, 1958). At the same time, children's reasoning during the preceding stage (i.e., the concrete operational stage) was said to be limited to objects and physically possible situations. If learning parallels the process of development, then transfer from more concrete to more abstract representations should be more efficient than the reverse.

However, there are strong reasons to doubt this view. First, it has been demonstrated that concrete, perceptually rich objects are more likely to be considered objects than symbols denoting other entities (DeLoache, 1987; 2000). In a series of studies by DeLoache and colleagues, very young children were shown the location of a toy in either a photograph or a physical model of a scale room. They were then asked to retrieve the toy from the actual room. Almost all (88%) of the children shown the photograph were able to make an errorless retrieval of the toy, while only 16% of the children shown the physical model were able to do so. When the model was placed behind a screen, children's retrieval rate improved. Furthermore, slightly older children are very successful in this task. However, when older children were encouraged to play with the model, performance dropped significantly. These studies demonstrate that children have difficulty treating perceptually rich objects as symbols. Decreasing the salience of the object increased the ease of its symbolic use.

Second, there is a large body of literature on analogy (analogy is variant of transfer of knowledge from one domain to another) indicating that properties that are not a part of to-be-learned knowledge (i.e., surface features) may hinder rather than facilitate learning (e.g., Ross, 1987; 1989).

Third, there is recent evidence that there might be a competition between abstract and concrete representations of the same situation, and salient concrete representations may distract learners from more abstract regularities (Goldstone & Sakamoto, 2003).

Finally, there is evidence that transfer from abstract instantiations of knowledge may be in fact easier than transfer from concrete to abstract instantiations (Bassok & Holyoak, 1989). Bassok and Holyoak examined transfer between more abstract algebraic knowledge and more concrete physics knowledge, namely between arithmetic-progression problems and isomorphic constant-acceleration problems. High school and college students (who were unfamiliar with both of these domains) learned one of these topics and then were posed word problems involving the other topic. The measure of transfer was whether the learned method had been applied to the structurally isomorphic problems in the unstudied domain. Students who had learned arithmetic-progression first easily and spontaneously applied the learned method to correctly solve constant-acceleration problems. However, the students who learned the physics topic showed essentially no transfer of method to the arithmetic-progression problems. The results of this study suggest that transfer is more likely to occur from a more abstract instantiation to a concrete isomorph.

While the Bassok and Holyoak study (1989) certainly implies that more transfer occurs from abstract to concrete domains, confounds in the study limit such a broad conclusion. The chosen topics in mathematics and physics, as any mathematical and physical topics, do not exist in isolation. Any individual has many associations with each, including related prior learning as well as attitudes and beliefs. Specifically, the amount of mathematics learned through elementary, middle, and high school is significantly more than the amount of physics learned. This disparity of learning most likely exists between mathematics and any of its isomorphic applications. Furthermore, through the course of education, students develop an expectation that mathematical concepts can effectively and appropriately be applied to other domains such as physics, chemistry, economics, to name just a few. It is doubtable that student have as strong expectations that scientific strategies can be used to solve purely mathematical problems.

The purpose of this study was to investigate transfer across two isomorphic domains: one that used a set of abstract symbols, and another that used concrete perceptually-rich objects. To eliminate potential confounds stemming from prior knowledge, both domains were artificially constructed to be algebraic Abelian groups of order three. In other words, each is isomorphic to the integers under addition modulo three. Therefore, both domains included three classes of entities and a set of specific transformation rules described in Figure 1. The first, more abstract, domain (hereafter "Mathematics") was presented to the participants as a symbolic language in which three types of symbols, denoted as ♦, ❄, and ★, combine to yield a resulting symbol. The combination of symbols is expressed as written statements such as ★, ❄ → ♦. The second, more concrete, domain (hereafter "Science") involved interactions between three-dimensional objects from three classes. The objects dynamically interact to form a resulting object. The appearance of the objects

and interactions was designed to be dissimilar to any particular science.

The goal of the reported experiment was to investigate transfer across the two isomorphic artificial domains. Transfer was measured by comparing average test scores on a given domain as a function of prior learning of another domain.

Method

Participants

Participants in the experiment were undergraduate students from Ohio State University who received partial credit for an introductory psychology course. Thirty students participated in the experiment. Fifteen participants were in the math-then-science condition and fifteen were in the science-then-math condition. Information was presented to individual participants via computer.

Materials and Design

Materials included two sets of entities (i.e., abstract meaningless symbols and concrete, perceptually-rich objects), and a set of transformations rules (see Table 1).

Table 1. Example of stimuli and transformation rules across the two domains.

	Mathematics	Science
Elements	♦ ❄ ★	
Associativity	For any elements *x*, *y*, *z*,: ((*x* , *y*) , *z*) is equivalent to (*x* , (*y* , *z*))	
Commutativity	For any elements *x*, *y*: *x* , *y* is equivalent to *y* , *x*	
Identity	There is an element, I, such that for any element, *x*: *x* , I is equivalent to *x*	
Inverses	For any element, *x*, there exists another element, *y*, such that: *x*, *y* is equivalent to I	
Specific Rules:	♦ is the identity	 is the identity
	❄ , ❄ → ★ ★ , ★ → ❄	Operands / Result    

Information about each domain was given as a computer presentation. The training in both domains was essentially isomorphic. The rules of the domain, namely commutativity, associativity, and the rules governing specific elements, were explicitly stated.

The experiment included four phases presented over one hour: (1) Training in domain X, (2) Test in domain X, (3) Training in domain Y, (4) Test in domain Y, with participants randomly assign to a particular order of learning (i.e., math-then-science or science-then-math).

Training included introduction of transformation rules, followed by questions with feedback. Several detailed examples were given. Testing consisted of twenty multiple choice questions designed to measure recall of the given rules and deeper conceptual understanding of the system. For both domains, the test questions were completely isomorphic and were presented in the same order.

The presentation of the two domains differed by storyline. The artificial mathematics was presented as a symbolic language discovered on an archaeological search. Symbols of different categories combine to yield a resulting symbol. The artificial science was explained to be a phenomenon observed on a planet outside of our solar system. Objects from different classes of shapes interact to form a resulting shape. The presentation of the artificial science included movie clips demonstrating the interactions. Two or more objects move toward each other. When they come in contact, an interaction occurs and results in a predictable object.

Each subject was randomly assigned to one of two orders: math-then-science (M→Sc) or science-then-math (Sc→M). Participants in the first group received training and testing in the artificial mathematics immediately followed by training and testing in the artificial science. Subjects in the second group received training and testing first in the science and then in the mathematics. Following training and testing in both domains, a brief interview was conducted.

Students' scores on the mathematics and science tests were recorded. They were also asked to rate the similarity of the two domains on a scale from one to five. A rating of one indicated that the domains are completely different and a rating of five indicated that the domains are structurally identical with different representations of the objects.

Test scores for mathematics and science were compared across the two conditions, math-then-science and science-then-math. Transfer due to mathematics first was taken to be the difference in the average science score for M→Sc and the average science score for Sc→M. In other words, transfer is the improvement in science score due to having

previously learned the mathematics. Similarly, transfer due to science was taken to be the difference in average mathematics score for Sc→M and the average mathematics score for M→Sc.

Procedure

All training and testing was presented on a computer screen. Participants were tested in a quiet room in a lab by a female experimenter. They proceeded through training and testing at their own pace, and their responses were recorded by the researcher. After training and testing in both domains, a brief interview was conducted.

Results and Discussion

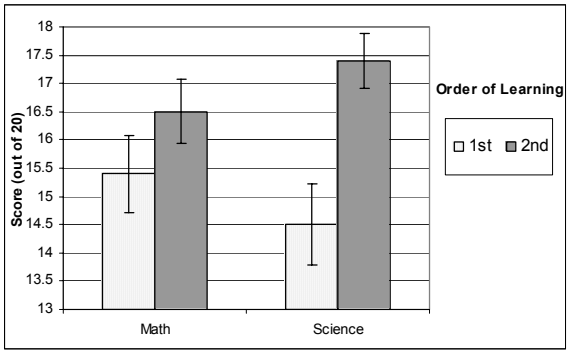
Students were able to learn the artificial mathematics and the artificial science. With the exception of one student, all test scores were significantly above chance (i.e., 7/20) in both math-then-science and science-then-math conditions. The one student who had a science score of 9/20 was removed from the data analysis. This score is not significantly different than chance and is also greater than two standard deviations from the mean (mean = 16.8, standard deviation = 2.8).

All students indicated that they noticed similarities between the two topics. Under both conditions the students rated the domains as highly similar. On a similarity scale from one to five, the mean rating given by math-then-science participants was 4.4 (*SD* = .65). The mean rating given by science-then-math students was 4.6 (*SD* = .63).

The data on transfer across the domains are presented in Figure 1. These data were subjected to a 2 (Domain: Math vs. Science) by 2 (Order: Learned First vs. Learned Second) mixed ANOVA with Domain as a repeated measure. The analysis revealed a significant Domain by Order interaction, $F(1, 27) = 24.15$, $p < .0001$. At the same time, none of the main effects was significant, both ps > .28.

Planned comparisons indicated that there was a significant difference in performance as a function of learning order. Students in the math-then-science condition performed significantly better on the science test than students in the science-then-math condition, independent-samples $t(24) = 3.26$, $p<.01$. However, there was no significant difference in mathematics scores across conditions, $p > .229$.

Figure 1. Mean test scores for mathematics and science shown as first and second domain studied.



The higher average science score for the M→ Sc group suggests that their prior knowledge of the mathematics improved their learning of the science. Therefore, significant transfer was found from the abstract symbolic domain to the concrete, but the reverse was not found.

In order to understand why the symbolic representation promoted transfer, while the concrete representation did not, it is necessary to take a closer look at the process of transfer. Not only does transfer require recognition and mapping of analogous relational structure from a source domain to a target domain, the elements of the source domain need to act as symbols. In other words, the objects or aspects of the source domain need to act as placeholders that can refer to something else, namely the objects of the target domain. Concrete representations are perceptually rich and consequently engage the perceptual system. Perceptually rich representations can easily convey associated properties and overall similarity (Goldstone & Barsalou, 1998). However, the specific characteristics of objects or elements are often irrelevant to concepts. Maintaining dissociation between the relational structure and the characteristics of the given elements is often crucial to accurate analogical reasoning. The salience of surface attributes often misleads students in the course of problem solving by distracting them from the underlying structure (Ben-Zeev & Star, 2001; Gholson, Smither, Buhrman, Duncan, & Pierce, 1997; Holyoak, Junn, & Billman, 1984; Holyoak & Koh, 1987; Schoenfeld & Herrmann, 1982). Perceptual objects convey affordances that may be helpful, but may also be irrelevant to the underlying concepts.

However, concrete representations may be beneficial under some conditions. For example Goldstone and colleagues (Goldstone, Son, & Patton, under review) have argued that maximum transfer occurs through "concreteness fading" where concrete representations progressively become idealized.

The conclusions of their study were that transfer is promoted through multiple representations. Furthermore, the authors conclude that while idealized displays promote internal representation not deeply embedded in a single domain, concrete displays have the advantage of a strong intuitive link between the real world and the modeled world. In other words, concepts can get a partial free ride from familiar concrete instances. However, in the course of learning mathematics and science, there are many concepts for which obvious concrete models may not exist. In the absence of a familiar concrete model on which concepts can freeload, does an artificially constructed concrete representation have benefits over a symbolic representation?

This notion of concepts getting a free ride from concrete representations as suggested by Goldstone and his colleagues is certainly appealing and is intuitively very reasonable. From a pedagogical perspective, there seems to be definite merit in concreteness fading provided that instructors do not allow learning to become deeply embedded in the concrete example. For students, the concept may become the concrete model and not the abstraction necessary for true understanding and transfer. Furthermore, many concepts may not have obvious and familiar representation in the real world. Mathematical concepts, by their very nature, are not bound to concrete contexts. Their transfer depends on attending to their relational structure and not salient surface features of a particular instance.

The goal of this experiment was to take a closer look at the merits of abstraction and concreteness for transfer. The familiarity or intuitive link between the concrete model and the concept were intentionally removed. No significant transfer from the concrete to the abstract was found, while significant transfer from the abstract to the concrete was exhibited.

Concrete representations may be difficult to treat as symbols in novel, complex concepts. Perceptually rich representations convey more information than leaner representations. As the degree of richness increases, it likely becomes more difficult to recognize the representation as an object itself as well as a reference to its intended referent. Successful transfer requires the elements of the source domain to be treated as symbols. Concrete representations engage the perceptual system. Rich percepts convey much information, a large portion of which is unrelated to a task in question. When that information correlates with the conceptual structure, learning may be facilitated. However, when the attributes are irrelevant to the concept, learners may not see the relevant analogy. Even when the analogy is perceived, it is difficult for rich percepts to be used as symbols, as demonstrated in this experiment. Participants in both the math-then-science and the science-then-math conditions recognized similarities between the domains. However, only the students who learned the symbolic mathematics prior to the concrete science were able to transfer information

Abstract

Research on multiple cue judgment with continuous cues and a continuous criterion has been dominated by statistical modeling of the cue utilization with linear multiple regression. In this study we apply two cognitive process models to investigate the relative contributions of explicit abstraction of the cue-criterion relations and memory for concrete exemplars in a multiple-cue judgment task. The task was an extension of a previous task with binary cues (P. Juslin, H. Olsson., A-C. Olsson, 2003) and involved multiple continuous cues that either combined by addition or multiplication. As predicted by the process model $\sum$ (P. Juslin, L. Karlsson, & H. Olsson, manuscript) explicit abstraction of cue-criterion relations were induced in the additive task, while exemplar memory was induced in the multiplicative task.

Introduction

Multiple-cue judgment research has traditionally been concerned with statistical modeling of judgment data. Rather exquisite regression models have been developed that describe multiple-cue judgment as *a*) well fitted by a linear additive model; *b*) only taking a few cues into account; *c*) hard to report on subjectively; *d*) characterized by cue weightings that differ greatly between individuals; and *e*) plagued by considerable inconsistency in the weighting of the cues (see Brehmer, 1994; Cooksey, 1996; Hammond & Stewart, 2001).

In the light of the cognitive revolution it might seem puzzling that this field of research has not benefited from the growth of cognitive modeling as a means to track the underlying cognitive representation and process of judgment, a growth seen in related fields like categorization learning (but see for example Bott & Heit, 2004; Busemeyer, Byun, DeLosh, & McDaniel, 1997; or DeLosh, Busemeyer & McDaniel, 1997, single-cue learning). Categorization – which is in many ways similar to multiple-cue judgment (see Juslin, Olsson, & Olsson, 2003) – has invited extensive investigation of the cognitive representations and processes that underlie behavior. A plethora of models, ranging from an emphasis on how abstract rules or prototypes guide category decisions to a domination of memory for category exemplars are thus available in cognitive science today. In this study we apply the methods of cognitive modeling to a typical multiple-cue judgment task. By connecting research on cognitive science to judgment and decision making research, we can gain an understanding of what cognitive representations and processes guide the judgments, and how this is manifested in the results of the traditional statistical modeling (e.g., Cooksey, 1996).

Arguably, it is not mere coincidence that linear, additive models fit multiple cue judgment data well and that categorization is often well captured by exemplar models that entail a linear additive combination of retrieved exemplars (Juslin, Karlsson, & Olsson, manuscript). Imagine how you sequentially consider and weigh the pros and cons of different aspects of a car before you purchase it (its looks, reliability, etc). You may weigh them differently but positive qualities *add* to and negative qualities *subtract* from your overall opinion. Likewise, you may sequentially consider exemplars of similar cars that you are aware of: similar cars (e.g., same model) that have worked properly *add* to the appeal of the car and cars that that have been frustrating *subtract* from it.

We have proposed a general process model, $\sum$, that captures the essentials of multiple-cue judgment, both when it is driven by consideration of cue-criterion relations and exemplar retrieval (Juslin et al., manuscript). The assumptions in $\sum$ are that our controlled and explicit thought processes have an architectural constraint enhancing sequential, real-time consideration of multiple pieces of evidence (cues or exemplars). The process involves successive adjustment of an estimate, a process structurally compatible with linear, additive cue integration (Einhorn, Kleinmuntz, & Kleinmuntz, 1979) and exemplar models (Nosofsky & Johansen, 2000).

The key assumption is that, in effect, all integration of information involves addition (or subtraction). This hypothesis suggests that explicit and controlled thought processes are apt at performing cue-integration only in

tasks where the cue-criterion relations in the task indeed combine by addition. By contrast, a task that involves non-linear or multiplicative cue combination requires capitalization on exemplar memory (Medin & Schaffer, 1978; Nosofsky & Johansen, 2000). Exemplar memory involves no strong computational commitments to particular task structures. With a division of labor between distinct representations we are better equipped to adapt to different task structures. We propose that the judgment process adapts to specific task environments and predict that in a multiple-cue judgment task with continuous cues we can induce a shift between qualitatively distinct processes by manipulating the structural properties of the environment: additive cue combination should promote cue abstraction and multiplicative cue combination should promote exemplar memory.

Judgment Task and Cognitive Models

The judgment task involves judgment of a continuous criterion based on continuous cues. The task concerns judgments of the effectiveness of different species of herbs as medical treatments to a lethal virus. The effectiveness is measured as the *maximal amount of a chemical substance* (mg) that can be extracted from the species. The species have four continuous dimensions (C_1, C_2, C_3, C_4), and each cue dimension can take a value between 0 and 10. The judgment of effectiveness requires inference from these dimensions, which are presented as verbal statements (e.g., weeks of bloom per year, geographic place of growth).

The tasks involve two manipulations. First, there is one condition in which all cues are related to the criteria positively and linearly, and one condition in which two cues are positively and two cues are negatively linearly related to the criterion. This manipulation makes the task a matter of function learning. Second, there is a manipulation of whether the effects of the four cues on the criterion combine by *addition* or *multiplication*.

In the additive condition the criterion is a linear, additive function of the continuous cues:

$$c = 500 + 4 \cdot C_1 + 3 \cdot C_2 + 2 \cdot C_3 + 1 \cdot C_4 + \varepsilon . \qquad (1)$$

C_1 is the most important cue with *coefficient* 4 (i.e., a relative weight .4), C_2 is the second to most important with coefficient 3, and so forth. The cues are uncorrelated. ε is a normally and independently distributed random error with a standard deviation that produces a multiple correlation R between cues and criterion of .9 (i.e., defining the ecological validity of the cues).

In the multiplicative condition the criterion c is a multiplicative function of the four cues:

$$c = 509.05 + 0.54545 \cdot e^{(C_1 \cdot 4 + C_2 \cdot 3 + C_3 \cdot 2 + C_4 \cdot 1)/18} + \varepsilon , \qquad (2)$$

with the same coefficients as in the additive task (Eq. 1). The effectiveness varies between 500 and 600 mg of chemical substance in the additive task and 509 to 650 mg in the multiplicative task. However, the training ranges are hold equal for the two conditions. The range of cue values observed in the two tasks is therefore the same. Moreover, the criterion in the multiplicative condition is an exponential function of the criterion presented in the additive condition.

We use two structural models to derive predictions, a cue-abstraction (CAM) and an exemplar model (EBM). $\sum$ implies that in the additive task CAM should be the correct structural description of the process, whereas in the multiplicative condition EBM should be the appropriate description[1]. The CAM assumes that participants abstract explicit cue-criterion relations in training that are mentally integrated at the time of judgment. When presented with a probe the participants retrieve rules connecting cues to criterion (e.g., "More weeks in bloom gives more effectiveness"). The rules specify the sign and importance of each cue with a cue weight. For example, after training the rule for C_1 may specify that high C_1 goes with an increase in the criterion.

The CAM implies that participants compute an estimate of the criterion c based on sequential consideration of cues. For each cue, the estimate of c is adjusted according to the cue weight ω_{iA} (i=1…4). The final estimate $\hat{c}_{CA}$ is a linear additive function of the cues C_i,

$$\hat{c}_{CA} = k + \sum_{i=1}^{4} \omega_{iA} \cdot C_i , \qquad (3)$$

where $k = 500 + .5 \cdot (100 - 10 \cdot \sum \omega_{iA})$. If ω_{1A}=4, ω_{2A}=3, ω_{3A}=2, and ω_{4A}=1, Eq's 1 and 3 are identical and the model produce perfect judgments. The intercept k constrains the function relating judgments to criteria to be regressive around the midpoint (550) of the interval [500, 600] (Juslin et al., manuscript).

Although ruled out by the predictions of $\sum$, we also consider the possibility that participants have correctly abstracted the multiplicative cue-criterion relations by fitting a multiplicative cue-abstraction model to the data:

$$c = 509.05 + 0.54545 \cdot e^{(\sum_{i=1}^{4} \omega_{iM} \cdot C_i)/18} \qquad (4)$$

where ω_{1M} are the best fitting subjective cue weights in the multiplicative cue abstraction model.

EBM is commonly applied to classification, but here we apply it to a continuous criterion. EBM implies that participants make judgments by retrieving similar exemplars (herb species) from memory. When the exemplar model is applied to judgments of a continuous criterion variable, the estimate $\hat{c}_E$ of the criterion c is a weighted average of the criteria c_j stored for the J exemplars, where the similarities $S(p,x_j)$ are the weights:

$$\hat{c}_E = \frac{\sum_{j=1}^{J} S(p, x_j) \cdot c_j}{\sum_{j=1}^{J} S(p, x_j)} . \qquad (5)$$

[1] $\sum$ is a model of the real-time process of judgment that becomes structurally identical with a CAM when the representations fed to the process are abstracted cues and structurally identical to an EBM when the process is fed by exemplars. The structural description refers to the relationships between stimulus features and the response (Juslin et al., manuscript).

p is the probe to be judged, x_j is exemplar j (j= 1…J), and $S(p,x_j)$ is the similiarity between probe p and exemplar x_j. Eq. 5 is the *generalized context model* (GCM: Nosofsky, 1984; 1986), which generalizes the original version of the context model (Medin & Schaffer, 1978). The similarity $S(p,x_j)$ between exemplars is found by transforming the distance between them. The distance between a probe p and an exemplar j is,

$$d_{pj} = h\left[\sum_{M=1}^{M} w_m \left| x_{pm} - x_{jm} \right|\right], \qquad (6)$$

where x_{pm} and x_{jm}, respectively, are the values of the probe and an exemplar on cue dimension m, the parameters w_m are the attention weights associated with cue dimension m, and h is a sensitivity parameter that reflects overall discriminability in the psychological space (the sensitivity parameter is usually denoted c, but we changed that to avoid confusion with the criterion c). Attentional weights vary between 0 and 1 and are constrained to sum to 1. The similarity $S(p,x_j)$ between a probe p and an exemplar j is assumed to be a nonlinearly decreasing function of their distance (d_{pj}),

$$S\left(p, x_j\right) = e^{-d_{pj}}. \qquad (7)$$

In the experiment, herb species with a criterion above 590 and below 510 are not included in the training phase. This makes it possible to distinguish between the models as they provide different predictions (Figure 1). In the training phase, all exemplars have effectiveness between 510 and 590. If participants have estimated the correct cue weight for each cue they should compute the most extreme judgments for the extreme exemplars that are left out in the training phase. More specifically, whenever participants have correctly identified the sign of each cue (i.e., whether it increases or decreases the criterion) they should make more extreme judgments for the exemplars with all cues at their maximum and the exemplars with all cues at their minimum, as illustrated on the left-side of Figure 1. By contrast, the exemplar model computes a weighted average of the criteria between 510 and 590 stored with the exemplars and this can never produce a value outside of this observed range (Erickson & Kruschke, 1998; but see DeLosh et al., 1997). Moreover, because of the nonlinear similarity function of the GCM the most extreme judgments tend to be made for the second to most extreme exemplars. For these exemplars the judgment is dominated by retrieval of the identical stored exemplars and these identical exemplars are the most extreme that were encountered in the training phase. These predictions are illustrated on the right side of Figure 1.

For new exemplars in the mid range of the criterion cue abstraction suggests no systematic difference between new exemplars and old exemplars matched on the criterion: the cognitive process is the same regardless of whether a specific exemplar has been encountered before or not. The exemplar model predicts more precise judgments for the old exemplars because for these exemplars the participants can benefit from previous identical exemplars with the correct criterion c.

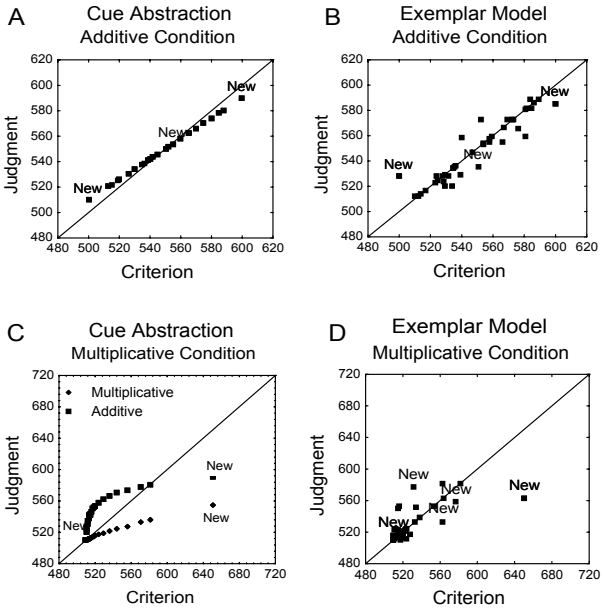

Figure 1: Predictions by cue-abstraction model (CAM) and exemplar model (EBM) in additive and multiplicative task environments. Panel A: CAM in additive task environment (with slightly regressive weights, 3.2, 2.4, 1.6, & .8). Panel B: EBM in additive task environment (s = .25 and h = 10). Panel C: Additive [CAM(A)] and multiplicative [CAM(M)] cue-abstraction models in multiplicative task environment (with weights, 3.2, 2.4, 1.6, & .8). Panel D: EBM in multiplicative task environment (s = .25 and h = 10). The choice of values for the parameters is arbitrary and only used for illustrative purposes.

The Experiment

In the experiment we manipulated whether participants were confronted with a task that involved additive or multiplicative cue combination. For the reasons outlined in the introduction, we predicted that the additive task (Eq.1) should promote explicit cue abstraction with additive cue integration (Eq. 3). A multiplicative task (Eq. 2) should cause a shift to a qualitatively different process, that is, to exemplar memory (Eq. 5).

The sign of the linear relations between cues and criterion was also manipulated. For half of the participants all four cues were positively related to the criterion and for half of the participants two cues were positively and two cues were negatively related to the criterion. In line with the assumptions of ∑, we predict that in an additive task, whether cue directions are negative or positive should not affect the ability to perform cue abstraction. In a multiplicative task, both with homogeneous

and heterogeneous cue directions, exemplar memory is predicted to prevail over cue abstraction.

Method

Participants

Thirty two undergraduate students volunteered, receiving a payment of 60-99 SKr, depending on their performance. Twenty participants were male and 12 were female, all in the age between 20 and 32.

Materials and Procedure

The experiment consisted of a training phase and a test phase. In the training phase, the participant learned to judge the effectiveness of each species of the herb by means of outcome feedback. The effectiveness was measured as the amount (mg) of the fictitious chemical substance *Ranulin*. In the training phase, the effectiveness varied between 510 and 590 mg. The species were shown as four written propositions on a computer screen. At each trial in the training phase, the participant was to answer the question "How many milligrams of Ranulin does this specie contain?". After giving a response they received the correct answer: "This specie contain 540 milligrams of Ranulin". The four dimensions were: number of weeks in bloom, the optimal amount of iron in the ground, the degrees of latitude where it does well, and the amount of water it emits per leaf area. Each dimension varied "pseudo-continuously" in 11 equidistant steps that ranged between 0 and 10, yielding a total of 11^4 different exemplars. In the training phase, a random sample of 300 exemplars was drawn from this distribution and shown to the participant. A pause of two minutes was given to the participant after the first 150 trials.

In the test phase, participants were to judge the effectiveness of the species of the herbs but now *without* outcome feed-back. In the test phase, new exemplars were included. The test phase consisted of 44 judgments of *a*) 20 randomly chosen old exemplars shown in training, *b*) 20 randomly chosen new exemplars, drawn from the training distribution and *c)* 4 extreme exemplars, with criterion values outside the training range (eg. the exemplars with cue values [0,0,0,0] and [10,10,10,10])

In the condition with heterogeneous cue directions, for half of the participants, negative sign was assigned to the cues with objective weight 4 and 2, and for half of the participants to the cues with weights 3 and 1.

Dependent Measures

The measure of performance is *Root Mean Square Error* (*RMSE*) of judgment (i.e., between judgment and criterion). Measures of model fit are *the coefficient of determination* (r^2) and *Root Mean Square Deviation* (*RMSD*) between predictions and data from the test phase.

Results

A two-way ANOVA with environment (additive vs. multiplicative) and cue directions (homogeneous vs. heterogeneous) as between-subject factors shows two main effects on RMSE (Table 1), but no interaction. In the additive condition performance is significantly better ($F(1.30) = 20.36$; $MSE = 32.36$; $p = 0.000$). Also, when the cue directions are homogeneous RMSE is lower compared to when the cue directions are heterogeneous ($F(1.30) = 20.36$; $MSE = 6.37$; $p = 0.018$)

Table 1: Judgment performance in the experiment as measured by the Root Mean Square Error (RMSE) between judgment and criterion.

		Condition		
Cue directions	Index	Add.	Mult.	Mean
Homogeneous	RMSE	11.69	21.23	*16.46*
Heterogeneous	RMSE	17.21	25.90	*21.56*
Mean	RMSE	*14.45*	*23.56*	

Mean judgments are shown in Figure 2. In the additive homogeneous condition the judgments are a linear function of the criterion and no extra- or interpolation effects are visible. The best fitting regression lines for old and new judgments coincides.

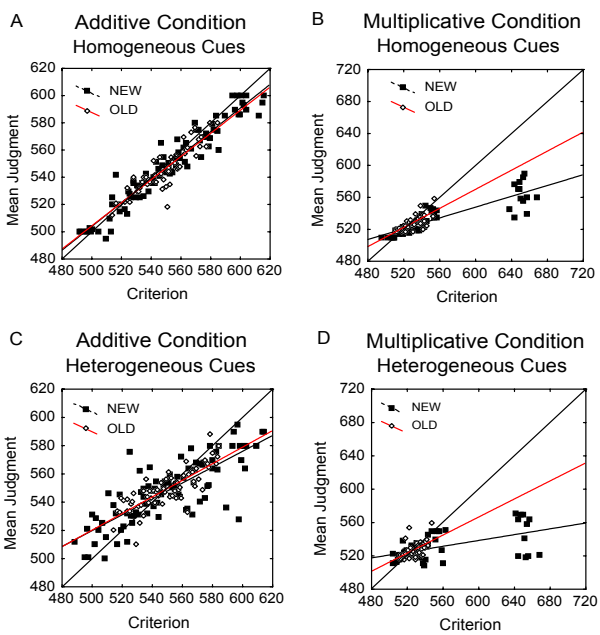

Figure 2: Mean judgments for the different conditions. Panel A: additive, homogeneous. Panel B: multiplicative, homogeneous. Panel C: additive, heterogeneous. Panel D: multiplicative, heterogeneous. Best-fitting regression lines are based on a) the old exemplars seen in training or b) the new exemplars introduced at test.

In the multiplicative homogeneous condition the judgments clearly deviate both from the identity line and the best fitting regression line based on old exemplars. Although the judgments are a positive function of the criteria in the training range there is evidence for an inability to extrapolate. The judgments are not extrapolated beyond the range of training.

In the additive heterogeneous condition (Figure 2C) the judgments are still close to the optimal judgment line, although there are signs of extra- and interpolation effects. In the multiplicative heterogeneous condition (Panel D) the mean judgments are a positive function of the criterion, but the inability to extrapolate is obvious.

Quantitative model predictions were obtained by fitting the models in the introduction (Eq. 3, 4 & 5) to the latter half of the *training phase* with Mean Square Error between predictions and data as the error function (Juslin et al., 2003; manuscript).

Table 2: Model fit: Root Mean Square Deviations (RMSD) and r^2 for the additive cue-abstraction model (CAM(A)) the exemplar model (EBM) and the multiplicative cue-abstraction model (CAM(M)) in the four conditions.

	CAM(A)		EBM		CAM(M)	
Cond.	r^2	RMSD	r^2	RMSD	r^2	RMSD
Add:						
Homogen.	.77	10.83	.75	13.73	-	-
Heterogen.	.53	12.67	.51	13.40	-	-
Mult:						
Homogen.	.21	28.26	.74	8.50	.70	12.20
Heterogen.	.18	48.62	.34	19.65	.32	18.97

The models were thus fitted to data from the training phase and applied with these parameters to the wider range of herb species in the *test phase*. This implies cross-validation for exemplars presented in training and genuine predictions for new exemplars. To capture individual differences, the models were applied to individual data. Table 2 shows the mean fit for the three models. In the additive condition cue abstraction is the overall dominant model, regardless of the cue directions. In the multiplicative condition exemplar memory describes the data best with regard to r^2 and the multiplicative cue-abstraction model yields a smaller mean *RMSD*. The rather low fit of all three models in the heterogeneous conditions may be explained by larger noise in these data since this task is presumably more difficult than the homogeneous task. Figure 3 shows the proportion of participants best accounted for by each model in terms of *RMSD*. In the additive homogeneous condition most of the participants are accounted for by the cue-abstraction model. In the multiplicative homogeneous condition the reverse is true, namely that the exemplar model produces the best explanation. In the additive heterogeneous condition the proportion of participants explained by the cue abstraction model decreases. In the multiplicative heterogeneous condition, as hypothesized the exemplar-based model continues to provide the best explanation of data for most of the participants. The multiplicative cue-abstraction model describes some of the participants in both the homogeneous and the heterogeneous multiplicative tasks.

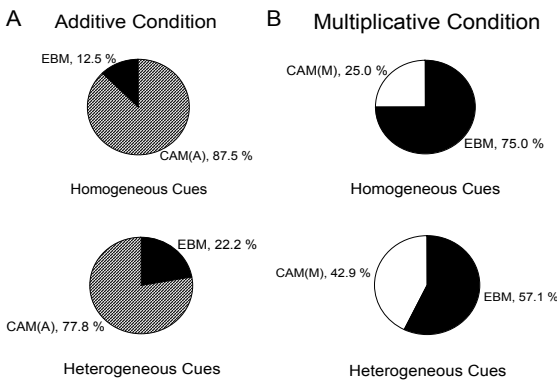

Figure 3: The proportion of participants accounted for by any of the three models in the additive and the multiplicative conditions in terms of *RMSD*. Panel A: additive condition. Panel B: multiplicative condition.

Discussion

The results reported in this paper support the assumptions made by ∑ that multiple-cue judgment processes conceal an effective division of labor between qualitatively distinct cognitive processes (Juslin et al., manuscript). Cognitive modeling supports the hypothesis that in a multiple-cue judgment task where the cues combine by addition, ∑ is fed with representations in form of abstracted knowledge of the relations between cues and criterion. On the other hand, in an environment where the cues relate to the criteria by a multiplicative function we seem to be equipped with no means to explicitly abstract the underlying structure. In such tasks, people seem to resort to the back-up process of exemplar-memory.

The fact that exemplar-memory plays part also in additive tasks is not a coincidence, since both processes allows accurate performance in training. That the multiplicative cue-abstraction model provide an explanation for some of the participants in the multiplicative task is more surprising. This is probably an effect both of large noise in data and of its high correlations to the exem-

plar model. Figure 2 B & C yields no evidence for successful extrapolation beyond the range of training.

The bad performance in the multiplicative heterogeneous condition, together with the low fit of the models makes it unfair to draw conclusions regarding what cognitive process that has dominated the judgments in this condition. What makes this task difficult to learn? A tentative hypothesis would be that in training there is a bias towards the abstraction of specific rules (eg. *rule bias;* see for example Ashby et al., 1998; Juslin et al., 2003; manuscript). Presumably, a period of extensive hypothesis testing is therefore taking place at beginning of training. However, the multiplicative heterogeneous task may be inductive of more extensive hypothesis-testing procedures. The back-up of exemplar memory is thus postponed, and thereby learning may be impaired.

An interesting approach to the interpretation of the data would be to consider how an exemplar-model augmented with linear extrapolation would account for the results (see *EXAM*; DeLosh et al., 1997; Busemeyer et al., 1997, for results on single-cue learning). *EXAM* suggests that, although learning has been in the form of exemplar-memory, abstraction of cue-criterion relations is possible at test. When encountered with a new exemplar at test, familiar exemplars and their stored criterion are retrieved from memory. An extrapolated judgment for the new exemplar is then made possible through linear regression based on the old exemplars. How this model explains the data reported in this paper remains to be tested, although a first qualitative evaluation of the data in Figure 2 can be made. Given the data in the additive condition, *EXAM* is likely to produce the same fit as the cue-abstraction model. In the multiplicative condition *EXAM* would predict no difference between the regression made on old exemplars and the regression made on new exemplars. This difference is however apparent in the data in Figure 2 (Panel B & C) and thus suggests the refutation of *EXAM* in favor of EBM.

The main interpretation to be drawn from the results reported in this paper is that the human judge, under the constraints imposed by $\sum$, adapt to different task structures by means of representational shifts. This highlights how the task is a powerful predictor of cognitive process in human multiple-cue judgment.

Abstract

Russian-English bilingual and English monolingual participants were tested on the Picture-Word Interference task modified for use with an eye-tracker. Distractor words were 1) non-words in English, but viable phonological words in Russian, 2) control bigram matched non-word stimuli, and 3) English translations of the Russian words. Russian-English bilinguals looked at the phonological Russian words more than monolingual participants, and took longer to name pictures accompanied by these stimuli than did monolingual participants. Proportion of eye-movements and reaction times to the other two types of distractor stimuli did not differ for the two groups. These results suggest that phonology of the non-target language is activated automatically during visual word recognition in the target language, even for written stimuli that do not carry orthographic information for the non-target language.

Introduction

The task of reading is hard enough when the reader reads in one language alone. In the case of a bilingual reader, the picture is even more complex: Not only does a bilingual reader need to process the written information in one language, but he or she may have to contend with information from his or her other language that also becomes activated. The activation of the non-target language during reading in the target language is implemented in the Bilingual Interactive Activation (BIA+) model of visual word recognition (Dijkstra & Van Heuven, 1998; 2002). The BIA+ model is a localist connectionist model with elements from both the dual-route models of reading (e.g., Coltheart et al., 1993; Coltheart et al., 2001; Ziegler et al., 2000) and the connectionist models of reading. (e.g., Plaut et al., 1996; Seidenberg and McClelland, 1989; Van Orden and Goldinger, 1994). The BIA+ model proposes that lexical access of a visually presented word in a bilingual is non-selective, i.e., when a word is presented, information for that word, both orthographic and phonological, is activated for both of the bilingual's languages.

Support for such non-selective processing of written information in bilinguals (i.e., activation of the non-target language orthography and/or phonology when involved in a reading task requiring use of only the target language) has accumulated over the past three decades (e.g., De Groot, Delmaar, & Lupker, 2000; Nas, 1983; Van Heuven, 2000; Van Heuven, Dijkstra, & Grainger, 1998). Activation of non-target language phonological information has been reported for bilingual readers of languages with shared alphabets, such as English and French (Jared & Szucs, 2002), Dutch and English (Dijkstra, Grainger, & van Heuven, 1999), Spanish and Catalan (Costa, Miozzo, & Caramazza, 1999), and Dutch and French (Brysbaert, Van Dyck, & Van de Poel, 1999). Activation of phonological information for the non-target language has also been reported in the case of bilinguals who speak languages with entirely different alphabets, like Hebrew and English (Tzelgov et al., 1996). However, it is still largely unknown whether phonological information for the non-target language is activated when the letter string in the target language carries little resemblance to the non-target language orthography (but see Feldman & Turvey, 1983; Lukatela et al, 1978).

In this experiment, we used a modified Picture-Word Interference (PWI) task to test whether phonological information for Russian is automatically activated during processing of non-words in English. The stimuli were constructed to contain English-specific letters, but constitute viable phonological Russian words. Using head-mounted eye-tracking methodology, we examined Russian-English bilinguals' ability to control their eye-movements to distractor words in the PWI task when these words contained phonological, but not orthographic information for Russian. The proportion of eye-movements to the distractor word signified the degree to which Russian phonological information drew the participants' eye-movements, while the reaction times to naming the target picture stimulus signified the degree to which the Russian phonological word interfered with picture naming in English.

Eye-tracking technology has been used to explore parallel activation of the two languages known to a bilingual during auditory perception tasks (e.g., Marian & Spivey, 2003 a, b). Eye-tracking has also been widely used in research of reading (e.g., Reichle, Rayner, & Pollatsek, 1999; Starr & Rayner, 2001). Unlike automatic eye-movements observed

in response to spoken instructions, eye-movements in reading are thought to be under partial cognitive control. The E-Z Reader model of eye-movement control in reading (Reichle, 1998; Reichle et al., 1999) posits that prior to programming an eye-movement to a particular word, a familiarity check takes place, which indicates whether a word is likely to be recognized by a reader. During this familiarity check, a reader gains information on low-level properties of the word (Engbert, Longtin, & Kliegl, 2002), which causes partial activation of the lexicon (e.g., Deutsch et al., 2002; Starr & Rayner, 2001). Experimental evidence shows that readers obtain both orthographic information (Liu et al., 2002), and phonological information (Wong & Chen, 1999) from the word before it is fixated. Models of eye movement control during reading account only for monolingual reading and it is still largely unknown whether control of eye-movements during bilingual reading is accomplished in the same way.

Recent research with bilinguals suggests that phonological information for the non-target language is automatically activated when reading in the target language. However, phonological activation for the non-target language when reading in the target language has not yet been explored for bilingual speakers whose two languages have partially overlapping alphabets. For these speakers, letter strings with alphabet-specific symbols often contain phonologically meaningful information for the non-target language. Russian-English bilinguals are faced with exactly this type of alphabetic overlap (Figure 1). Given the properties of the Russian Cyrillic alphabet and the English Roman alphabet, it is possible to test whether phonology of the non-target language is activated when its orthography is only partially present in the target language letter string. Consider the word COBA, which is the Russian word for "owl." COBA can be transcribed using the Roman alphabet, SAVA, which includes letters specific to the English alphabet. Letter strings like SAVA constitute phonological, but not orthographic, representations of Russian words. When they are presented to the Russian-English bilinguals, only phonology, but not orthography, associated with corresponding Russian words, should be activated.

The activation of the non-target Russian language during picture naming in English was measured using a modified PWI task. The objective of the PWI task is to name pictures, while ignoring the words also present on the screen. The interference from the distractor word is thought to arise due to the automatic reading of the word, which then interferes with selection of the appropriate name for the picture at the level of the lexico-semantic system. Thus, reading during this task is largely automatic; in fact, it is counter-productive to the successful and fast completion of the task. Unlike a classic PWI task, where a written stimulus is presented inside a picture, we separated the written stimulus and picture presentation, such that a picture was in one quadrant of the computer screen, while a written stimulus was in another quadrant of the computer screen. The instructions to the participants were the same as in the regular PWI task: To ignore the word, and name the picture. In the regular PWI task, these instructions do not prevent reading of the words because the words are presented inside

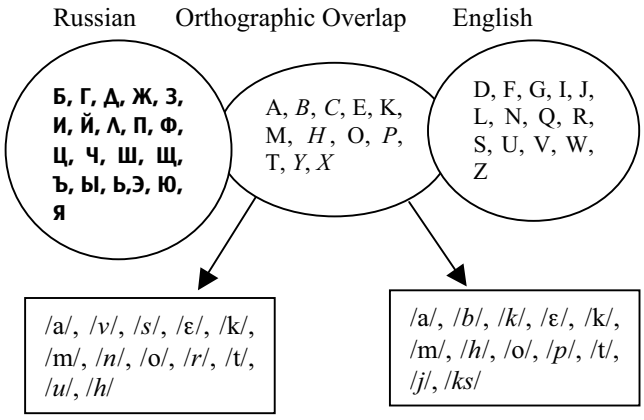

Figure 1: Overlapping symbols in orthographies of Russian and English, and the associated phonemes in each language.

the picture, and therefore, the participants necessarily look at them. In the modified PWI task, the word and the picture are in different locations on the screen so that the participant sees that there is a word, but does not need to look at it in order to recognize the picture. We tracked the participants' eye-movements while they were completing the task in order to determine whether particular words drew more eye-movements than others.

Based on the models of cognitive control of eye movements in reading (Reichle, 1998; Reichle et al., 1999), the proportion of eye-movements to distractor stimuli during the modified PWI task should be indicative of the degree to which participants were able to control their eye-movements to the written stimuli. The stimuli presented as distractors on the PWI task words were 1) phonological Russian words, 2) English translations of the Russian stimuli, and 3) control stimuli (non-words in both Russian and English that were controlled for English bigram frequencies to equal phonological Russian stimuli). We hypothesized that if phonology of Russian is automatically accessed even when the orthographic shape of the word is not Russian (i.e., contains English-specific letter symbols), Russian-English bilingual readers will make more eye-movements to the phonological Russian words than the monolingual English speakers. Consequently, we hypothesized that if the phonological information for Russian activates the lexico-semantic information for Russian, Russian-English bilinguals will have longer reaction times to the pictures accompanied by the phonological Russian words than monolingual English speakers.

Methods

Participants

Fifteen Russian-English bilingual speakers (Mean Age=24.27 years, SD=4.80) and 15 English monolingual speakers (Mean Age=21.00 years, SD=4.68) participated in the experiment. All Russian-English bilingual participants were born in the former Soviet Union, and immigrated to the United States at a mean age 14.56 years (SD=5.35). All bilingual participants filled out a Language Experience and

Bilingual Status Questionnaire (LEABS-Q) at the end of the experiment. LEABS-Q is a comprehensive questionnaire containing questions about language proficiency, modes and ages of language acquisition, current language usage, etc. (Marian, Blumenfeld, and Kaushanskaya, 2003). Self-reported proficiency measures were later determined based on the participants' answers.

Reading fluency and reading comprehension were assessed by administering a passage reading task in English to the monolingual participants, and in English and Russian to the bilingual participants. When tested in English, bilingual participants were found to read orally with similar speed, $t(28)=0.94$, $p=0.36$, have as many errors while reading, $t(28)=0.75$, $p=0.46$, and comprehend as much of the content, $t(28)=0.96$, $p=0.35$, as the monolingual participants. For bilingual speakers, fluency of reading, $t(14)=1.89$, $p=0.08$, and comprehension of content, $t(14)=0.38$, $p=0.71$ were comparable for Russian and English. However, bilingual participants were significantly faster when reading in English ($M=2.71$ words/sec, $SE=0.12$) than in Russian ($M=2.12$ words/sec, $SE=0.11$), $t(14)=4.44$, $p<0.01$.

Design

Two dependent variables were considered: reaction time, and proportion of eye-movements to the word. The experiment followed a 4x2 Mixed Design with two independent variables – condition (no word, phonological Russian word, non-word control stimulus, and English word) as a within-subjects variable, and group (bilingual vs. monolingual) as a between subjects variable. For the proportion of eye-movements data, condition variable included only three levels (phonological Russian word, non-word control stimulus, and English word).

Materials

Twenty-three target pictures of common concrete objects were selected from the IMSI MasterClips picture database; all pictures were transformed into black-and-white drawings of equal size using PhotoShop.

Twenty-three words that were semantically related to picture names, i.e. belonged to the same superordinate category, were selected. The 23 words were then translated into Russian to create stimuli that were phonological representations of Russian words, spelled using the English alphabet. For instance, for the picture of a duck, the distractor word selected was *chicken*, which translates to YTKA in Russian, and yields UTKA when spelled using the English alphabet.

Control stimuli for the phonological Russian stimuli were constructed by creating non-words comparable to Russian phonological words in length and bigram frequencies. Paired-samples t-tests confirmed that Russian phonological stimuli ($M=4355.02$, $SE=2244.50$) and phonological controls ($M=4263.35$, $SE=2362.53$) were similar in their bigram frequencies ($t(22)=0.36$, $p>0.05$).

For each picture, there were 4 conditions: (1) picture – no word, (2) picture – English semantic distractor, (3) picture – phonological Russian semantic distractor, and (4) picture – non-word control stimulus. The picture-no word condition was used as a baseline, to establish that eye-movements to words, if occurred, were due to the presence of the word in a particular location, and not to the location itself. For each condition, a panel divided into four quadrants was constructed – a picture was placed into the middle of one quadrant, and the word was placed into the middle of another quadrant. For each condition, a picture and all the words in the three conditions were placed in the same quadrants; the positions of pictures and words were counterbalanced across the four possible quadrants. To increase the time between target picture presentations, 16 filler picture stimuli were added to the experiment.

Apparatus

All stimuli were presented on a G5 Macintosh Monitor using SuperLab experimental software. Naming times were measured from the presentation of the picture to the onset of triggering the microphone response by the participant's voice. A headband-mounted ISCAN eyetracker was used to record participants' eye-movements during the PWI task. A scene camera, joined to the view of the tracked eye, provided an image of the participant's field of view. A second camera, which provided an image of the participant's left eye, allowed the ISCAN software to track the center of the pupil and the corneal reflection; gaze position was indicated by white crosshairs superimposed over the image generated by the scene camera. The output was recorded onto a digital mini-tape via a Cannon Digital Camera; it was later loaded into the FinalCut Editing software for frame-by-frame playback analysis.

Procedure

All participants were tested individually. Training for the Picture-Word Interference task was presented first. Each picture used in the PWI task was presented in the middle of the screen; the participant was instructed to name it into the microphone.

The Picture-Word Interference task was presented next. Prior to initializing the task, the calibration of the eye-tracking equipment was completed. To increase the sensitivity of equipment, calibration was done on 9 fixation points. The fixation values were then mapped onto the corresponding monitor locations; the fixation location was indicated by a white cross-hair that moved synchronically with the eyes. After successful calibration, the PWI task was initiated. Each participant was instructed to fixate on the cross that appeared prior to each picture stimulus; he/she was also instructed to name pictures into the microphone as fast and as accurately as possible, and ignore the text on the screen.

At the end of the experimental session, two proficiency measures were administered to each participant. The first was the reading ability measure: Each participant read a short passage in English into the microphone, and answered 8 multiple-choice questions about it afterwards. Each bilingual subject also read a short passage in Russian, and answered 8 multiple-choice questions about it. Lastly, the LEABS-Q was administered to each participant.

Coding

Reaction times were recorded using SuperLab software by measuring the time between the presentation of the picture and the initiation of the vocal response into the microphone. Accuracy was assessed by reviewing the participant's recorded performance. The eye-tracking data, consisting of super-imposed cross-hairs onto the field of view, were coded for proportion of eye-movements to the distractor words. Eye-movements to the distractor word were considered to have occurred when the crosshairs have crossed into the quadrant containing the word. Ten percent of the data were coded by a second, independent coder, who did not speak Russian. Point-to-point reliability for coding of proportions of eye-movements was 96%.

Results

Trials on which participants made errors accounted for 4.40% of the data. Picture naming errors were analyzed separately, while errors like false starts were omitted from the analyses.

Reaction times

A 4x2 Anova with condition (no word, Russian words, Phonological controls, and English translations) as a within-subjects variable, and group (monolingual and bilingual) as a between-subjects variable yielded a main effect of condition, $F(1, 28)=8.39$, $p<0.01$, and a significant two-way interaction between condition and group, $F(1, 28)=5.35$, $p<0.05$ (Figure 2).

Post-hoc pair-wise comparisons for condition adjusted for multiple comparisons using the Bonferroni method revealed that both groups had shorter reaction times to pictures without distractor words (M=809.70, SE=14.93) than to pictures accompanied by Phonological Russian words (M=861.77, SE=16.73), $p<0.05$, Phonological controls (M=852.80, SE=16.75), $p<0.05$, or English translations (M=855.36, SE=16.47).

Post-hoc pair-wise comparisons between groups for each condition revealed that bilingual participants had longer reaction times to Phonological Russian words (M=912.80, SE=23.66) than monolingual participants (M=810.74, SE=23.66), $F(1, 28)=9.30$, $p<0.01$. There was no significant difference between bilinguals' and monolinguals' reaction times to Phonological controls $F(1, 28)=3.28$, $p>0.05$, to pictures alone, $F(1, 28)=1.48$, $p>0.05$, or to English translations, $F(1, 28)=0.17$, $p>0.05$.

Proportion of Eye Movements to the Word

A 3x2 Mixed Ancova, with condition (Phonological Russian words, Phonological controls, and English translations) as a within-subjects variable, and group (monolingual and bilingual) as a between-subjects variable, with speed of reading as a covariate, was used to analyze the proportion of eye movements to the three types of distractor words.

Results revealed a main effect of group, $F(1, 27)=4.44$, $p<0.05$, with bilinguals looking more at the written stimuli (M=0.46, SE=0.04) than monolinguals (M=0.34, SE=0.04) and a marginally significant interaction between condition and group, $F(1, 27)=3.74$, $p<0.06$ (Figure 3).

Post-hoc Univariate Analyses of Covariance revealed that bilinguals looked more at the Phonological Russian words (M=0.50, SE=0.05) than monolinguals (M=0.31, SE=0.05), $F(1,27)=7.66$, $p<0.05$, but the two groups did not differ in their proportion of looks to the Phonological controls, $F(1, 27)=2.11$, $p>0.05$, or the English translations, $F(1,27)=2.09$, $p>0.05$.

Error Analysis

On the PWI task, monolingual participants committed 11 mis-naming errors, where a picture was named using the distractor word (for example, naming a picture of the chicken "duck"). Bilingual participants committed 8 mis-naming errors. Of these, 5 were committed with the English distractors being the word stimuli. The Mann Whitney test for independent samples revealed that monolingual speakers of English misnamed more pictures using the English

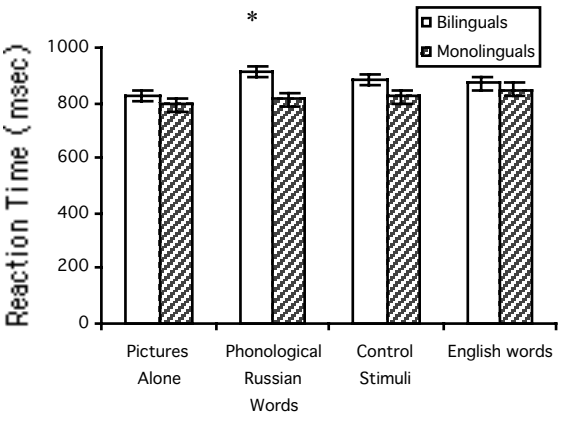

Figure 2: Reaction times of bilingual and monolingual participants when naming pictures alone, pictures, accompanied by phonological Russian words, by bigram-matched non-word control stimuli, and by English words.

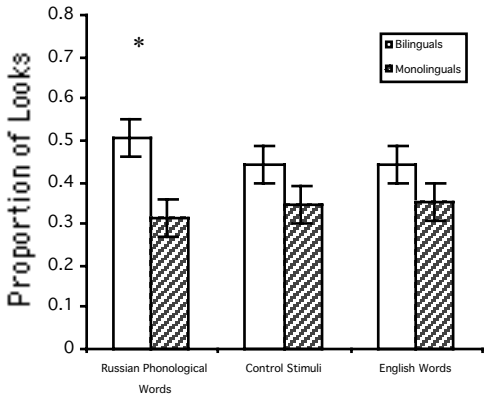

Figure 3: Mean proportion of looks to distractor stimuli made by bilingual and monolingual participants when distractors were phonological Russian words, bigram-matched non-word control stimuli, and English words.

distractor words than bilingual participants, Mann Whitney $U(15)=73.50$, $p<0.06$.

Three mis-naming errors were committed by bilingual participants with distractors being phonological Russian stimuli, such as naming a picture of a *collar* "sleeve," when the distractor word on the screen was RUKAV, a phonological word for "sleeve" in Russian. This number was not significantly different from the number of errors committed by monolingual participants, Mann Whitney $U(15)=90.00$, $p>0.05$.

It is interesting to note that while interference of Russian written stimuli did occur during naming of pictures in English, none of the bilingual participants had switched into Russian when naming pictures. Instead, a spontaneous translation of the Russian distractor into English had occurred, and this, in turn, interfered with naming of the picture. This pattern of errors is consistent with the observation made by Costa, Miosso, and Carammazza (1999), who suggested that items from two languages, while activated in parallel, do not compete for selection during production.

Discussion

Russian-English bilinguals looked at English non-words that composed meaningful phonological Russian words more than monolingual English speakers, while the proportions of eye-movements made to control non-word stimuli and to English translation equivalents were comparable for the two groups. This finding suggests that phonological information in the non-target language drew bilinguals' eye-movements. Therefore, phonological information for the non-target language was automatically activated for these stimuli. According to models of eye movement control in reading, the stimuli that carried phonological information for Russian drew the bilinguals' eye movements because these stimuli carried meaningful information for them, but not for monolingual speakers of English.

Literature on eye movements during reading suggests that before fixating a word, a reader obtains useful information from its parafoveal preview; this information is used by the reader to decide whether to fixate on the word or not (Reichle et al., 1999; Starr & Rayner, 2001). While the E-Z Reader model of eye-movement control in reading posits cognitive control of eye-movements during reading of sentences (Reichle, 1998), it also seems to explain the behavior of the participants in this experiment, where they recognized single words. The decision to look at the word during the modified Picture Word Interference task appears to be dictated by the amount and quality of information a reader gleans from its parafoveal preview. Russian-English bilinguals were better able to control eye-movements to English non-word stimuli that did not carry any phonological information for Russian, than to English non-word stimuli that did carry phonological information for the non-target language.

Testing bilinguals who speak languages with partially overlapping alphabets allows for separating the contributions of orthographic codes and phonological information they carry to the parallel activation of the two languages when processing print. Our findings are in line with connectionist models of visual word recognition (e.g., Plaut et al., 1996; Seidenberg & McClelland, 1989; Van Orden & Goldinger, 1994), which propose that phonological information for a word is automatically activated. The only way to obtain interference effects from phonological Russian words is by activation of the Russian language via its phonology because the orthographic information for Russian is not present in these stimuli. The dual-route models of visual word recognition, while allowing for an indirect phonological route to the lexicon, postulate that this route is specialized for reading non-words (e.g., Coltheart et al, 2001; Ziegler et al., 2000).

Russian-English bilinguals had longer reaction times when naming pictures accompanied by phonological Russian stimuli that constituted words semantically related to the picture names than monolingual speakers; reaction times to non-word control stimuli and English translations were comparable for the two groups. Because slower naming times on the PWI task result from the interference of the written stimulus with the picture name at the lexical-semantic level, this finding suggests that not only was phonology for the Russian language activated, as indicated by greater proportion of eye movements made to these by the bilingual than the monolingual speakers, but that this information was meaningful enough to get processed to the lexico-semantic level. This observation is further supported by the analysis of the error data: Although bilingual participants committed only 3 misnaming errors when the distractor word was a phonological Russian word, the mere fact that these errors exist support the idea that the phonological information for Russian was meaningful enough to activate the relevant lexico-semantic information.

In conclusion, we have successfully shown that phonology of the non-target language is activated for the target-language stimuli that bear little resemblance to the non-target language orthography. Furthermore, we have shown that activation of non-target language phonology is enough to produce interference effects during picture-naming in the target language. These findings extend the idea of parallel activation of languages in bilinguals to those languages in which shared orthographic symbols map onto distinct phonological representations, and inform models of bilingual reading on the role of phonology in the lexical access of written words. Finally, the idea that eye-movements during reading are under at least partial cognitive control offers an intriguing possibility that the bilinguals in this experiment exhibited a measure of cognitive control over interference from the non-target language during the modified PWI task. Future experiments might be able to explore the idea of cognitive control over language interference in bilinguals further by manipulating the amount of meaningful information present for the non-target language, and by testing different groups of bilingual speakers.

Should Politicians Stop Using Analogies? Whether Analogical Arguments Are Better Than Their Factual Equivalents

Abstract

In political argumentation, analogies are often used to convince an audience of one's views. For example, in political debates leading up to the Iraq War, one such analogical argument was that Saddam Hussein was like Hitler and therefore Saddam should be forcibly ousted. But are all analogical arguments really convincing? In this paper we investigate whether analogical arguments are actually more convincing than factual arguments. In Experiment 1 we asked people to rate analogical and factual arguments for various propositions and found that people considered factual arguments more convincing. In Experiment 2, we asked people to think more explicitly about the analogical mappings but still found that people considered the analogical arguments less convincing than the factual ones. These findings suggest that people are *not* more easily convinced by an analogical argument then a straight factual one, suggesting that perhaps politicians should re-consider their rhetorical tactics after all.

Introduction

Is the aftermath of the Iraq War like Germany post-WWII or Northern Ireland or, indeed, is it another Vietnam? In the furious political debate following the Iraq War, politicians on both sides have used different analogies to bolster their arguments. In science, analogies are often used to discover something new about natural phenomena, but in politics they are used to convince an audience of one's views. In this paper, we consider whether such analogical arguments are more convincing than their equivalent, factual arguments.

Though classical rhetoric has long advocated the use of analogy in argumentation (Plato, *Phaedo*, trans. 1871, 71c-d being a prime exponent of the craft) and political science regularly analyses the analogies used in political debate (Blanchette & Dunbar, 2001), we know of no studies that have systematically determined whether people actually find analogical arguments more cognitively convincing than their factual equivalents. This gap in the literature is all the more surprising when one considers the amount of research on the separate topics of argumentation and analogy. The nature of argumentation has been elaborated in a rich literature in philosophy, logic and psychology (e.g., Rips 2002; Voss & Van Dyke, 2001). Similarly, the nature of analogy has been empirically explored in many studies, supported by clearly articulated theory that has been modeled computationally (see Gentner, 1983; Holyoak & Thagard, 1995; Keane, 1997; Keane, Ledgeway & Duff, 1994; Hummel & Holyoak, 1997). Yet, the two areas have not been combined in a systematic study of their cognitive underpinnings. In the present paper, we attempt such a combination.

The Present Experiments

We propose a novel paradigm for assessing people's evaluation of arguments that pits analogical arguments and their factual equivalents against one another. In our experimental setup, people are presented with a proposition and a two-fact argument supporting this proposition (see Figure 1). They are then asked to rate how good they found this argument as a warrant or support for the proposition. For a given proposition, the argument was either two facts or two equivalent analogical facts.

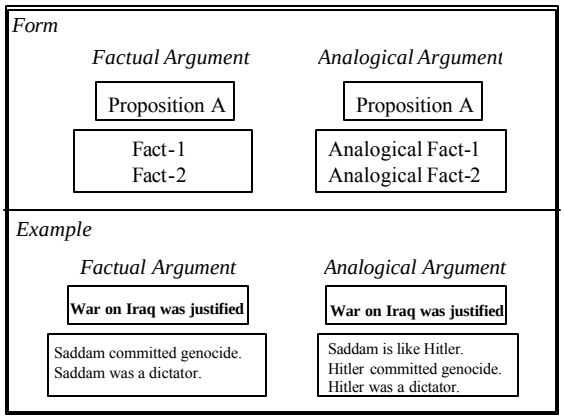

Figure 1: Abstract form and a gloss of a sample argument used in the experiments.

For example, the Iraq War argument suggests that going to war with Iraq was justified because Saddam was a dictator and had committed genocide in his country (see gloss in Figure 1). The analogical equivalent suggests that war on Iraq was justified because Saddam is like Hitler, and Hitler was a dictator and had committed genocide in his country. In this way, the analogical argument presents the same facts about Saddam but through the lens of a WWII analogy. This is the typical way in which politicians use analogies, suggesting a parallel in an analogous domain that supports their argument in a current domain.

From a cognitive perspective, there are several reasons why analogical arguments might be more convincing than factual ones. Essentially, an argument is defined as "a course of reasoning aimed at demonstrating the truth or falsehood of something" (Kuhn, 1991, pg.12). That is, in any argument the aim is to convince an audience of the truth or falsehood of certain facts, that these facts in some way support or warrant your proposition and that, therefore, your proposition is justified as right or correct (Toulmin, 1958; Kuhn, 1991). Therefore if there is agreement that Saddam's dictatorial powers and genocidal activities are bad and that these facts warrant the action of war as a response; then making war is, in some way, a necessary response to the facts given. One of the key steps in this process is getting the audience to accept the warrant as a necessary link between the facts and the proposition. Cognitive models of analogical thinking, show us that people use analogies to make high-level causal inferences about analogous domains (c.f., Keane, 1988). In this case, the comparison to Hitler provides a match to WWII where these dictator and genocide facts were viewed as essential reasons for military intervention. Thus, the analogy provides a previous case where the facts caused or strongly warranted military intervention, inviting the inference that war is therefore appropriate in Iraq too.

We report two experiments on the role on analogy in argumentation. These experiments used a wide variety of topical arguments from different domains covering alcohol abuse, military service, university entrance exams and traffic congestion policy. The analogies used also varied in the distance of the domains from one another; some involved close domains (e.g., Iraq War and WWII), others involved distant domains (e.g., Art and Foreign Languages). In the experiments, no single individual saw both the factual and analogical versions of a given argument. We also gathered people's ratings of their *a priori* belief in the proposition (i.e., their agreement/disagreement with it) to check for any belief bias in their assessment of the argument. In Experiment 1, we made a direct comparison of people's goodness ratings for the factual and analogical arguments to various propositions. In Experiment 2, we replicated this test with an intervention that encouraged people to reflect more on the analogy. To presage our findings, the evidence suggests that people are *not* more easily convinced by an analogical argument over a straight factual one, suggesting that politicians might indeed want to re-consider their rhetorical tactics.

Experiment 1

This experiment examined whether analogical arguments were deemed to be better (i.e., more convincing) than their factual equivalents for a variety of topical propositions. People were shown 10 different propositions (5 with factual arguments, 5 with analogical arguments) and asked to carry out two tasks on each: a belief task and an evaluation task. In the belief task, they were shown the proposition on its own and asked to rate their agreement/disagreement with it on a 7-point scale. In the evaluation task, they were shown the proposition and the argument (factual or analogical) and asked to rate its goodness as an argument for the proposition on a 7-point scale. The order of these tasks was counterbalanced in two different conditions. If our politicians are right then the analogical arguments should be considered to be better than their factual equivalents.

Method

Materials. Ten propositions were created based on either currently debated topics (e.g., the Iraq War, the school examination system, societal effects of drugs, utility of GM foods) or long-standing debated topics (e.g., the introduction of the death penalty, military service, public funding of the arts). For each of these propositions, a two-fact argument was created based on the typical reasons used to support these propositions. Analogies were then developed that had clear one-to-one correspondences to the conceptual objects and relations used in the original facts. Eight different materials sets were made up from random selections of particular materials and arguments, such that each set contained 10 unique propositions, 5 of which had corresponding analogical arguments with the other 5 having corresponding factual arguments. This material-group variable is not reported in the results as an analysis of people's ratings shows that it had no reliable effect on results found.

For every material set, two booklets were collated for the two tasks. The belief-rating booklet had a cover sheet explaining that people should rate how strongly they agreed/disagreed with the proposition on a 7-point scale, followed by 10 pages with a single proposition and rating scale shown on each page. The evaluation booklet had a cover sheet explaining that people should rate how good/bad they thought the argument was for the proposition on a 7-point scale regardless of their beliefs, followed by 10 pages with a proposition plus its corresponding (factual /analogical) argument and a scale shown on each page. The items in every booklet were randomly ordered for each participant.

Participants & Design. Thirty-two native English-speaking undergraduates at University College Dublin took part in the experiment. The order of the tasks was counterbalanced so that half the participants received the belief task before the evaluation task (belief-then-evaluation conditions) while the other half received the tasks in the opposite order (evaluation-then-belief conditions). So, the design was a 2 argument-type (factual or analogical) x 2 task-order (belief-then-evaluation or evaluation-then-belief) one with argument-type being within-participants and task-order being between-participants.

Procedure. In the evaluation task, participants read instructions that explained the 1-7 argument goodness scale (1 being "very bad", 7 being "very good" and 4 being "neither good nor bad"), and a sample proposition was

shown with a factual argument and another shown with an analogical argument. The participants were asked to take their time over each decision and to make "an *objective* assessment of the arguments. That is, to make a judgement regardless of your agreement or disagreement with the proposition". Each proposition-argument pair was presented on a separate page with a marked space for participants to note their 1-7 goodness rating. In the belief task, the instructions and materials were presented in the same way, except that the proposition alone was presented and the instructions explained that people were to rate how strongly they disagreed/agreed with the proposition on the 1-7 agreement scale (1 being "strongly disagree", 7 being "strongly agree" and 4 being "no opinion").

Table 1: Percentage of good arguments and mean goodness ratings for both experiments

	Analogical		*Factual*	
Measure / *Experiment*	%Good	Mean Rating	%Good	Mean Rating
Expt. 1				
belief-then-evaluation	21.3%	2.59	58.8%	4.3
evaluation-then-belief	30%	3.11	42.5%	3.76
Mean	25.6%	2.85	50.6%	4.03
Expt. 2				
belief-then-evaluation	33.8%	3.43	68.4%	4.59
evaluation-then-belief	43.8%	3.80	46.2%	3.90
Mean	38.8%	3.6	57.2%	4.25

Results

Table 1 summarises the main results of the Experiment showing that the factual arguments were considered to be better than the analogical ones on several different measures.

Percentages of Good and Bad Arguments. A rough feel for people's responses to the arguments can be gleaned by re-classifying their ratings into ordinal groups of good (> 4), bad (< 4) or indifferent (=4) according to how they rated the argument on the goodness scale. Overall, 320 arguments were evaluated in the experiment, 160 factual and 160 analogical. Of the factual arguments, 38.1% (61) were rated as bad and 50.6% (81) as good (the remainder being indifferent). Of the analogical arguments, 67.5% (108) were rated as bad and 25.6% (41) as good (the remainder being indifferent). Collapsing across the order conditions, this result was found to be reliably different using a Chi-squared analysis, $\chi^2(1) = 26.032$, $p < 0.0001$, N=291. However, an inspection of the percentages clearly shows that task-order has an impact too, in that more arguments were considered to be good in the belief-then-evaluation conditions (40%) than in the evaluation-then-belief conditions (36%). Indeed, on the face of it, there appears to be an interaction between task-order and argument-type that is more easily revealed using the ratings measure.

Ratings of Arguments. A 2x2 ANOVA was carried out on the ratings data for the between-participant variable of task-order and within-participant variable of argument-type. All analyses of variance by participants and by items were performed by respectively treating participants (F_1) and sentences (F_2) as a random factor. These analyses revealed a main effect of argument-type with the factual arguments (M=4.03) being rated as being better than the analogical arguments (M=2.85), $F_1 (1, 286) = 40.02$, $p < 0.0005$, MSe = 111.628; $F_2 (1, 307) = 40.30$, $p < 0.0005$, MSe = 111.628. There was also a reliable interaction between task-order and argument-type $F_1 (1, 286) = 8.10$, $p < 0.005$, MSe = 22.578; $F_2 (1, 307) = 7.20$, $p < 0.008$, MSe = 19.938. Planned pair-wise comparisons revealed that the factual/belief-then-evaluation condition was reliably different to all the other conditions using Bonferroni adjustments (ps<0.0005). None of the other comparisons were reliably different to one another.

The Impact of Belief on Evaluation. One of the key questions was whether people's prior beliefs in the proposition would have any impact on their rating of the goodness of the argument, even though we asked people to be as objective as possible. If people were rating the arguments in line with their beliefs then we should, for example, find that people gave high goodness ratings to arguments in which they strongly agreed with the proposition and low goodness ratings to arguments with which they strongly disagreed. However, there is little evidence of such a relationship. The correlation between participants' belief ratings and their goodness ratings for the items is low and not reliable, using Pearsons product-moment correlation $r(319) = 0.36$, $p<0.0005$.

Discussion

This experiment reveals three main findings: (i) analogical arguments are *not* considered to be better than their factual equivalents, (ii) people's *a priori* agreement/disagreement with the proposition does not affect their subsequent evaluation of the goodness of an argument for that proposition, (iii) people find factual arguments much better if they are first asked to rate their belief in the proposition.

The first of these findings should be a surprise for most politicians, as it shows that they might as well be using straight-forward factual arguments to present their views. In the next experiment, we explore whether this result may have occurred because people did not process the analogy sufficiently to draw out all its implications.

The second finding suggests that people can separate their belief in the proposition from their assessment of its goodness, when they are instructed to do so. In other words

that people can maintain a level of objectivity in evaluating arguments.

The third finding of a task-order effect was as unexpected as it is interesting. It shows that if someone rates their belief in a proposition and subsequently sees a factual argument for that proposition they consider it to be better than the same argument presented before they give their belief rating (this effect does not occur for analogical arguments). Why should this occur? One possibility is that when people are first asked to rate their agreement with the proposition, they must think of their own arguments for the proposition. Then, when they are subsequently shown some arguments for the proposition many participants may find them more convincing because they are similar to their own arguments. In contrast, when participants are first asked to evaluate the argument and proposition (before being asked for their belief) there is less opportunity to think of their own arguments, less opportunity to recognize similarities and, hence, less of a boost to the goodness rating of the argument. No parallel benefits are found for the analogical arguments because people do not readily think of their own analogical arguments when rating their belief in the proposition (see Gick & Holyoak, 1980; Keane, 1985, 1988, on people's tendency *not* to explore analogical possibilities without instructions to do so). In the next experiment, we attempt to replicate this task-order effect to determine whether it is robust.

Experiment 2

In Experiment 1, we found that people failed to be convinced by analogical arguments relative to their factual equivalents. This result could be due to the amount of cognitive processing people have to carry out on analogical arguments as opposed to factual arguments. In the analogical case, they must understand the analogical arguments, map the corresponding objects and relations between the two domains, then apply the mappings to the proposition's domain and, finally, evaluate it. In the factual case, they merely have to understand the argument, relate it to the proposition and evaluate it. Maybe participants in Experiment 1 did not bother to draw the analogy and, hence, marked these arguments down. We should note that this explanation is somewhat implausible as we know from the literature that people readily appreciate and understand analogies (see Keane, 1988; Holyoak & Thagard, 1995). So, in this experiment, we explicitly asked people to report their mapping of key objects between the two domains to ensure that the analogy was being properly processed. We also ran the task-order manipulation again to see if it could be replicated.

Method

Participants, Materials & Design.. Thirty-two native English-speaking student volunteers at University College Dublin took part in the experiment. The materials were the same as those used in Experiment 1, as were the grouping of material sets and organization of task booklets. As before, the design was a 2 argument-type (factual or analogical) x 2 task-order (belief-then-evaluation or evaluation-then-belief) one, with argument-type being within-participants and task-order being between-participants.

Procedure. The procedure was as in Experiment 1, except for one change to the analogical argument materials. In each case where an analogical argument was presented, people were shown two boxes listing three key objects from each domain of the analogical argument (as shown in Figure 2). The participants were asked to draw lines between the corresponding objects in the analogy. For example, in the Saddam Hitler analogy, Hitler corresponds to Saddam, Germany corresponds to Iraq etc. They were asked to perform this mapping before they rated the analogical argument in the evaluation task.

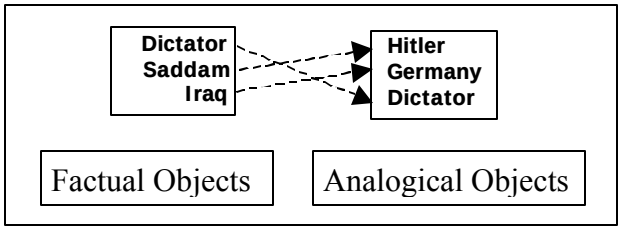

Figure 2: Example of the object-mapping task used in Experiment 2

Results and Discussion

Table 1 summarises the main results of the experiment showing that the factual arguments were considered to be better than the analogical ones on several different measures. The pattern of findings replicates those found in Experiment 1, with a strengthening of the effects being found.

Percentages of Good and Bad Arguments. Re-classifying people's responses into the ordinal groups of good (> 4), bad (< 4) or indifferent (=4) we found that (i) of the 159 factual arguments evaluated 35.2% (56) were rated as bad and 57.2% (91) as good (the remainder being indifferent), (ii) of the 160 analogical argument evaluated 52.5% (84) were rated as bad and 38.8% (62) as good (the remainder being indifferent). Collapsing across the task-order conditions, this result was found to be reliably different using a Chi-squared analysis, $\chi^2(1) = 11.093$, $p < 0.0009$, N=293.

Ratings of Arguments. A 2x2 ANOVA was carried out on the ratings data for the between-participant variable of task-order and within-participant variable of argument-type. All analyses of variance by participants and by items were performed by respectively treating participants (F_1) and sentences (F_2) as a random factor. These analyses revealed a main effect of argument-type with the factual arguments (M=4.25) being rated as being better than the analogical arguments (M=3.6), F_1 (1, 255) = 14.17, $p < 0.001$, *MSe* =

37.154; F_2 (1, 279) = 7.06, $p < 0.016$, MSe = 38.465. There was also a reliable interaction between task-order and argument-type F_1 (1, 255) = 8.63, $p < 0.006$, MSe = 22.623; F_2 (1, 279) = 10.02, $p < 0.005$, MSe = 23.646. Planned pair-wise comparisons revealed that the factual/belief-then-evaluation condition was reliably different to all the other conditions using Bonferroni adjustments (*p*s<0.005). None of the other comparisons were reliably different to one another. So, again, we replicate the task-order x argument type interaction found in the previous experiment. The main effect of task order was not reliable.

The Impact of Belief on Evaluation. Again, we found as in Experiment 1, that there is little evidence to suggest that people's prior beliefs in the proposition affected their assessment of the argument. The correlation between participants' belief ratings and their goodness ratings for the items is low and not reliable, using Pearsons product-moment correlation r(318) = 0.243, p<0.0005.

Conclusions from Experiments 1 and 2. So, again we find that the analogical arguments were considered to be less convincing than the factual ones, even when we ensure that people have mapped the analogy appropriately. However, it is noteworthy that, relative to Experiment 1, their analogical arguments seem to be rated as slightly better (e.g., 38.75% are considered good arguments in Experiment 2, relative to 25.63% in Experiment 1).

General Discussion

The results of these experiments suggest that politicians should stop using analogies, as they do not seem to provide much more than a sugar coating on the convincingness of a straight, factual argument. Overall, we have shown several novel findings about the use of analogy in argumentation. First, we have seen that analogical arguments are generally not considered to be as good as factual arguments. Second, we have seen that it is very hard for analogical arguments to challenge the goodness of factual arguments (in other experiments we have found that even when the full factual argument is given along with the analogical argument, the evaluations do not go higher than the plain factual arguments). Third, we have found that factual arguments' ratings can be boosted if people are asked to reflect on the proposition in advance of rating them. Finally, we have seen that people can separate their beliefs in a proposition from their evaluation of an argument to that proposition, showing a noteworthy objectivity in their evaluations. To traditional rhetoricians this evidence may seem unwelcome and unconvincing. In the remainder of this section, we consider three main objections that might be raised to our findings.

The Arguments Were Not Very Good. One argument against the evidence would be to maintain that the arguments used were not very good; that if you had better arguments then different results would be found. Unfortunately, we do not have data on how many people in a population find a given argument to be good or bad relative to some proposition, so it is hard to judge whether our arguments are in some way unrepresentatively poor. What we do know is that people only found 35-38% of our factual arguments to be bad (50%-60% of these arguments being considered good). On the face of it, using the "you can fool some of the people all of the time…" adage these figures appear to be reasonable levels of goodness. As such, we would argue that there is no obvious deficiency in the arguments used. Furthermore, we should also note that many of the arguments used were ones that people have used to support these propositions in everyday life.

Maybe Our Analogies Are Not Very Good. If one admits that the arguments are adequate, then a further objection could be that the analogies were, in some way, inadequate. Again this is a hard objection to assess given that we have little idea of the space of possible analogies used in argumentation. What we can say is that all of the analogies used conform to what is deemed to constitute an analogy in the literature; they involve one-to-one mappings, they involve matching relational structure and they suggest inferences by analogy connecting the arguments and the proposition (c.f., Gentner, 1983; Hummel & Holyoak, 1997; Keane et al., 1994). But, what if some are, in some way, better than others.

To explore this possibility, we presented a separate group of 16 participants with a mixture of 10 analogies and non-analogies asking them to rate the goodness of the analogies on a 7-point scale. Of the 10 materials used in the experiment only one received a bad goodness rating (i.e., < 4), all of the reminder being rated as being good (with mean ratings from 4.25 to 5.25). Overall, people reliably distinguished the analogies (M= 4.6) from the non-analogies (M = 2.5), using a dependent t-test, t(157) = 8.10, $p < 0.0005$. So, the failure of the analogical arguments cannot be attributed to the poorness of the analogies.

Are There Other Ways in to Improve Analogies? A final objection is that we have not appropriately intervened to boost the analogy. We saw that asking people to plot the object mapping improves their goodness ratings for the analogy arguments. Perhaps there is some other intervention that might boost them further. It is unclear to us what this intervention might be. However, this objection in a sense misses the point. If we did find some intervention that promotes analogical arguments is it quite likely to be quite artificial. In the cut and thrust of political debate the facts of the matter are generally known (though may not be stated explicitly) and the analogy is provided to be understood on the spot (without, for example, asking people to specify the object mappings).

Abstract

So far, information visualizations, i.e., graphical representations of huge amounts of abstract data which do not have a natural visual representation, have mainly been used to support *information-retrieval tasks*. In this paper we investigate whether information visualizations are also suitable to foster tasks that focus on *knowledge acquisition or learning*. In addition, we address the issue of how information visualizations have to be designed to be efficient learning tools. We conducted an experimental study which provided evidence that information visualizations can foster knowledge acquisition and that 2D-information visualizations are better suited for knowledge acquisition than 3D-ones. In addition, we found slight performance improvements due to using color to code information.

Technological innovation allows storing fast growing quantities of information. Accordingly, it has become increasingly important to develop efficient methods to structure large and complex information sets. Recently, there have been several attempts to tackle this challenge by using information visualizations, i.e., graphical representations of large amounts of abstract data which do not have a natural visual representation (Wiss, Carr, & Jonsson, 1998). For instance, information visualizations have been used to display abstract data like document collections or text-based information contents in the WWW. So far, information visualizations have mainly been investigated with regard to technical issues and in the context of information-retrieval tasks – where they proved to be very useful to improve users' ability to use information. However, it is not clear whether information visualizations can also foster knowledge acquisition or learning. Additionally, little is known about the cognitive processes involved in, and maybe supported by the use of information visualizations as learning tools. Therefore, the aim of our empirical study was to investigate to what extent multidimensional information visualizations are superior compared to a non-spatial representation when the task is to memorize a data set and to acquire an understanding of the relationships embedded within this set. Moreover, we were interested in the design of information visualizations for learning. Particularly, we investigated experimentally whether information visualizations should be two-dimensional or whether a third spatial dimension may be helpful for knowledge acquisition. Finally, the question is addressed whether knowledge acquisition with spatial information visualizations can be further enhanced by using color coding to represent attributes of data.

Figure 1 shows a simplified sketch of the type of spatial information visualization used in the empirical study presented in this paper. In this sketch, three attributes of four information units A, B, C, and D are represented by means of three spatial dimensions.

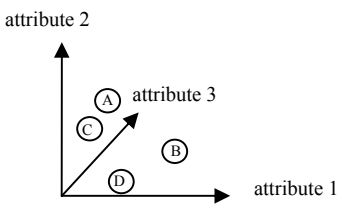

Figure 1: Simplified sketch of a 3D-information visualization.

Information units pool those parts of data sets that belong together. The units can be described by their values on numerous different attributes. Typically, only a subset of these attributes can be represented spatially. Thus, other attributes of the information units may be represented textually or by other codes (e.g., color coding).

What is the Pedagogical Potential of Information Visualizations?

There are different cognitive theories arguing that information visualizations may be efficient tools to enhance the acquisition of knowledge on large and abstract data sets,

whereby knowledge acquisition refers to understanding and memorizing abstract data and their interrelations.

- Firstly, *theories of computational effectiveness* pay specific attention to the inferences learners have to make in order to understand a task or a domain. The argument here is that some representational codes facilitate some inferential (learning) processes better than others. In their seminal work, Larkin and Simon (1987) found for example that search processes in physics are performed much easier with diagrammatic representations than with textual ones. This idea that different representations with the same "content" can still offer different processing opportunities is called "computational effectiveness" (Larkin & Simon, 1987). Following this idea, spatial information visualizations may allow learners to draw inferences very easily on how different information units are related to each other with regard to those attributes that are represented spatially. In this respect, information visualizations are rather similar to concept maps because both of them allow arranging information units spatially in a specific way. Concept maps are 2D-diagrams that illustrate relationships between concepts in a domain by representing these concepts as nodes. These nodes are connected by labeled lines in order to represent their interrelations. It could already be shown that concept maps foster processes of knowledge acquisition (Tergan, 2003), as these representations provide learners with a better understanding of the structures underlying a domain without imposing high cognitive demands on them to extract this information. Due to the aforementioned similarities between information visualizations and concept maps, these processing advantages should also hold for information visualizations.

- Secondly, the *cognitive theory of multimedia learning* (Mayer, 2001) is based on a dual-channel assumption which proposes that textual information is processed and encoded in a verbal system, whereas pictures or graphics are predominantly processed in a pictorial system. The theory assumes that a well-designed combination of text and graphics leads to better memory retention than the use of only one representation. The reason for this is that using the capacity of both memory systems should lead to more information being processed than using only one of the systems. In addition, dual coding might contribute to the construction of a stronger mental model, if the information of both processing systems has to be integrated actively. In addition, research on spatial cognition differentiates between a what-system and a where-system for visual cognition (Landau & Jackendoff, 1993). The where-system is used to process the location of objects, whereas the what-system is dedicated to identify features of an object itself. Memory studies revealed that the where-system operates more effectively with respect to speed and accuracy than the what-system (e.g., Amorim, Trumbore, & Chogyen, 2000). Representing attributes of information units by means of two or three spatial dimensions (instead of a purely textual representation or color coding) might accordingly improve the processing of these attributes by deploying a more efficient processing system.

- Thirdly, following the *cognitive load theory* (Sweller, van Merriënboer, & Paas, 1998), instructional procedures should be designed to prevent cognitive overload. More specifically, the amount of cognitive processing not directly relevant to learning - and thus causing extraneous cognitive load - should be reduced. The necessity of avoiding high levels of extraneous load is especially relevant when the contents to be learned are complex in relation to learners' level of prior knowledge. In this case, the representation of the learning contents imposes a considerable amount of intrinsic cognitive load so that substantial extraneous load can lead to overload in that no more capacity for processes of understanding is left. Cognitive processes directly relevant to understanding and learning are causing germane cognitive load. There are thus two reasons why information visualizations might be particularly appropriate to facilitate learners' acquisition of complex data structures that consist of highly interrelated information units. Firstly, distributing different attributes of information units across different memory and processing systems might provide additional processing resources that can be used to increase germane cognitive load. Secondly, providing learners with a spatial representation of some attributes of information units might reduce extraneous cognitive load by reducing search processes as well as making it easier to draw inferences on how different information units are related to each other with regard to these attributes.

According to these theoretical considerations it can be hypothesized that information visualizations might have a substantial pedagogical potential because they allow to deploy cognitive resources available for learning in a way that is more appropriate than it is with conventional representations of large sets of information units (e.g., spreadsheets).

How to Design Information Visualizations for Knowledge Acquisition?

Beyond the general claim that information visualizations are tools that might foster the acquisition of knowledge on large and abstract data sets, we are also interested in the issue of designing profitable visualizations. Particularly, the study reported in this paper addresses how dimensionality of information visualizations and color coding of attributes might affect learning.

2D- versus 3D-information visualizations?

Although, there are a few empirical studies investigating the dimensionality of information representation in general, nearly none of these studies is related to information visualization or even learning with information visualization. Furthermore, these findings seem to be rather inconsistent and depending heavily on the concrete tasks accomplished with the information representation. For instance, Park and Woldstad (2000) found that 2D-displays are superior to 3D-displays for performing telerobotic tasks. Contrarily, the study of Risden, Czerwinski, Munzer, and Cook (2000) compared 2D- and 3D-browsers with regard to the ease of information retrieval and concluded that 3D-visualizations are preferable. However, only a small number of studies demonstrated the superiority of 3D-representations. In sum, the existing evidence is by no means

sufficient to decide whether information visualizations should be 2D or 3D in the context of learning tasks.

From a more theoretical point of view, one might assume that representing three attributes of information units spatially should be superior to representing only two attributes in a spatial format because of the abovementioned advantages of spatial representations in general (i.e., distribution of information across processing systems, superiority of the where-system, computational effectiveness). However, 3D-information representations might at the same time impose additional extraneous cognitive load onto learners due to the fact that they are usually associated with an increased interactivity and with additional orienttation demands. For instance, 3D-visualizations usually have to be equipped with the option to look at information units from different viewpoints (e.g., by rotating the visualization) to counteract the problem that information units might be concealed by other units. As a result, this interactivity may impose additional cognitive processing demands because learners must control the interaction with the environment and maintain orientation.

We studied the role of the dimensionality of information visualizations empirically to decide whether the advantages or the disadvantages of introducing a third spatial dimension prevail in knowledge acquisition.

Should information visualizations for knowledge acquisition be color-coded or not?

The issue whether it might be helpful to enhance information visualizations by color coding of particular attributes of information units seems to be less ambiguous than the role of dimensionality. As color is a basic element of visual perception (Treisman, 1987), color coding can be expected to make information more salient. Therefore, color coding should provide learners with a better understanding of the structures underlying a domain. It has been shown that coloring objects increases learners' ability to retrieve object information from memory. As the color of objects is stored in long term memory together with other object information (e.g., Hanna & Remington, 1996), color information provides an additional cue for memory retrieval. It can thus be hypothesized that color-coded information visualizations should be superior to those without color coding. However, it remains an open question whether color coding and dimensionality will interact when they are combined with each other. On the one hand, combining spatial representation and color coding results in multiple memory traces which should enhance learning; on the other hand, encoding the same attribute of an information unit by means of two different representational codes might make it necessary to map two representational systems onto each other. This might involve the processing of redundant information which in turn can result in additional extraneous cognitive load and learning impairments. Therefore, it is unclear and subject to experimental investigation whether introducing a double coding of particular attributes of information units will support or hinder knowledge acquisition.

Experiment

In this experiment we first investigated whether information visualizations are more suited to foster knowledge acquisition than text-based information representations. Secondly, we analyzed whether dimensionality and color coding of information visualizations influence learning.

Method

Participants Subjects were 100 students (56 female, 44 male) of the University of Tuebingen, Germany. Average age was 24 years.

Materials and procedure This work is associated with the European project "Mummy" of the Computer Graphics Center in Darmstadt (Germany), which focuses on mobile knowledge management using multimedia-rich portals for context-aware information processing, e.g., at construction sites. Therefore, our experimental environment was designed to provide architects with an overview on the details of their construction projects. Each project is described by values on six different project attributes, namely "rate of return", "construction costs per sqm", "number of problems", "construction progress", "size of construction site", and "construction volume".

With regard to the procedure, first the participants received a booklet for measuring different control variables like retentiveness in a paper-pencil test. Afterwards, they received an introduction to the experimental environment and its usage. To ensure that all participants saw the same information, the exploration of the environment during the subsequent practice phase was standardized. In the learning phase subjects were given 50 minutes to accomplish five tasks. In the context of these tasks they had to find 14 of the 42 information units and had to learn the data contained in these information units. Consecutively, subjects received another booklet containing 35 test tasks. In this test phase the learning materials were no longer available. There were no time limits during testing. Finally, participants had to fill out a questionnaire asking for difficulties regarding the use of the learning materials, the strategies used as well as assessing the cognitive load experienced during learning.

Design and dependent measures As an experimental baseline, the information on the construction projects was represented by means of a spreadsheet which listed 42 construction projects (i.e., information units) alphabetically (Figure 2). The first column in Figure 2 represented the name of the construction projects, whereas the other columns contained the values of these projects with regard to the six aforementioned attributes. The last column listed further project information beyond these attributes.

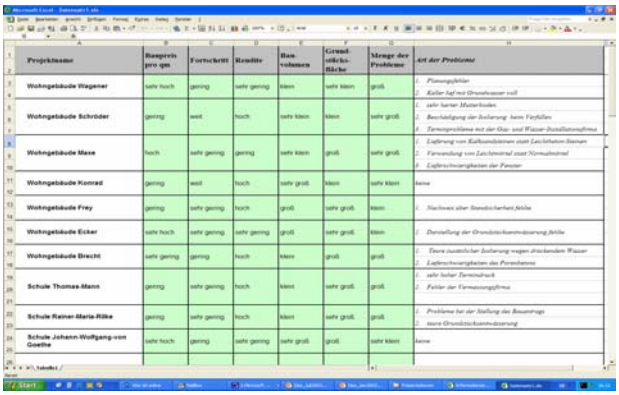

Figure 2: Excel spreadsheet representation (baseline).

To reduce complexity, the range of possible attribute values was restricted to four (i.e., very small, small, big, and very big). Due to the spreadsheet size it was impossible to see the data of all projects without scrolling. A pilot study showed that using this spreadsheet to memorize the abstract data set and to recognize relations between information units was a very difficult task for the subjects.

In order to implement our experimental manipulation, we represented the same data set by means of information visualizations that were either 2D or 3D and that were either monochrome or used color to represent one of the attributes. All of the manipulations (i.e., dimensionality and color coding) referred to the same specific attribute ("construction progress") and the way it was represented. In the 2D-information visualizations both "size of construction site" and "construction volume" were visualized spatially, i.e., they were represented by the axis of the 2D-information space (Figure 3). Information units were arranged in this information space according to their values on these two attributes. In Figure 3 the information units are represented by squares (labeled by their project name). The value of the attribute "construction progress" was represented by a digit attached to the project label. This digit was visible in all four information visualizations.

Figure 3: Two-dimensional color-coded information visualization with opened pop-up window.

The remaining project attributes ("rate of return", "construction costs per sqm", and "number of problems") as well as the further project information could be accessed through pop-up windows by clicking on the information units. In Figure 3, one pop-up window is opened. The pop-up windows could be moved with the mouse by learners in case the window concealed information of interest. To facilitate orientation, the project label of the viewed information unit changed its color from white to red and position lines from the information unit to the axes appeared while contacting the unit with the mouse pointer (position lines, see Figure 4).

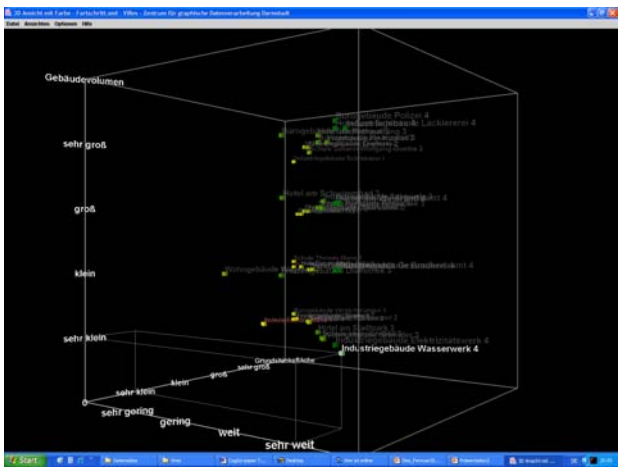

Figure 4: Three-dimensional color-coded information visualization with position lines.

In the 3D-information visualizations a third axis was included to visualize the attribute "construction progress" spatially (Figure 4). To ensure that all information units would be visible in the 3D-information visualizations, the users were allowed to rotate the vertical axis by moving the visualization with the mouse button pressed. To avoid "lost in navigation phenomena", users could push a home-button to attain the start perspective again at anytime.

The colored conditions differ from the monochrome information visualizations depending whether "construction progress" was additionally represented by means of color coding. In the monochrome conditions the information units were always presented in blue against a black background. However, in the colored conditions the information units were displayed in colors ranging from light yellow to dark green – indicating the values of "construction progress".

To sum up, the information visualization conditions differed in the representation format for the attribute "construction progress". In all information visualization conditions the values on this attribute were represented symbolically as a digit. In addition, in 3D-information visualizations the values on "construction progress" were visualized on the third axis. In 2D-conditions there was no spatial representation of this attribute. Furthermore, in polychrome information visualizations the values on the attribute "construction progress" were represented by means of the color of the information units. In monochrome conditions no color was used to visualize this attribute.

Dimensionality and color coding were both varied between subjects resulting in a 2x2-design (plus the baseline spreadsheet condition). Subjects were randomly assigned to the spreadsheet or to one of the four information visualization conditions.

With regard to the dependent measures, as a first dependent variable we measured *performance* with regard to the different knowledge tasks. Overall performance was calculated as the sum of both correct answers and partial correct answers. For 10 of the 35 tasks, partial credits were assigned to score subjects' answers. In the remaining tasks one point was assigned for each correct answer. For each task a maximum of one point was possible resulting in a maximum overall score of 35 points. *Relational performance* referred to tasks that asked for comparative judgments with regard to attribute values, whereas *item-specific performance* focused on specific attribute values. Both measures consisted of 15 tasks each. Five further tasks assessed *structural performance* which was concerned with the recognition of correlational structures within the data set. Furthermore, in each case four tasks were used to assess where-performance, what-performance, and varied-performance. *Where-performance* assessed knowledge on the attributes that were visualized spatially in all information visualizations, whereas tasks on *what-performance* registered knowledge on information always presented as text. Finally, *varied-performance* was concerned with knowledge on "construction progress", i.e., on the attribute whose representation was varied across conditions.

As a second dependent variable we measured learners' confidence with regard to the correctness of their answers. Learners rated each answer to a task with regard to whether they felt low, middle, or high confidence that their answer had been correct. In the *overall confidence* measure these ratings were summed across all tasks, whereby higher rating indicated higher confidence. This overall measure was subdivided into *confidence for correct answers* displaying a participant's belief in that a correct answer was correct. *Confidence for wrong answers* indicated a participant's conviction that a false answer was correct. Because there were 35 items for which every subject had to rate his or her confidence and because ratings ranged from one to three a maximum of 105 points was possible for each of the confidence scores.

As a third dependent variable, we assessed learners' subjective cognitive load by asking them how much *effort* they had to invest into learning and how *difficult* it had been to remember the contents. The effort and the difficulty ratings were given on a five-point scale, ranging from very low to very high.

Results and Discussion

The analysis of the data is divided into two parts: First, we compared the baseline spreadsheet condition to the overall means of all information visualization conditions in order to answer the question whether information visualizations in general are helpful for acquiring knowledge on large data sets compared to a purely text-based representation. In the second analysis, we assessed the effects of dimensionality and color coding by comparing the four information visualization conditions in an ANCOVA (dimensionality x color coding with retentiveness as a covariate, see below).

Do information visualizations foster learning? In a first step, we tested whether subjects achieved higher performance with information visualizations than with a spreadsheet, i.e., here we did not further differentiate between the different kinds of information visualizations. A two-tailed t-test for independent samples showed in fact a higher overall performance for information visualizations (M=20.80) compared to the spreadsheet (M=17.88; $t(98)=2.18$; $p<.05$). However, which kinds of information visualizations produced this effect? To answer this question, each of the four different kinds of information visualizations was compared to the spreadsheet separately (Table 1). Whereas the 2D-conditions were both superior to the baseline (without color coding: $t(38)=2.20$; $p<.05$; with color coding: $t(38)=3.53$; $p<.001$), there were no differences between the 3D-conditions and the spreadsheet condition (without color coding: $t(38)=0.34$; $p=.74$; with color coding: $t(38)=1.28$; $p=.21$).

Table 1: Means for performance, confidence, and cognitive load ratings for the information visualization conditions.

		Information visualizations			
		two-dimensional		three-dimensional-	
		monochrome	with color	monochrome	with color
Performance	**overall performance (35 tasks)**	**21.80**	**23.38**	**18.43**	**19.60**
	relational performance (15 tasks)	9.55	10.15	8.10	8.75
	item-specific performance (15 tasks)	10.35	10.98	8.88	9.10
	structural performance (5 tasks)	2.40	2.85	1.95	2.05
	where- performance (4 tasks)	3.05	3.10	2.70	2.40
	what- performance (4 tasks)	1.60	2.25	1.85	1.80
	varied-performance (4 tasks)	2.40	2.50	1.60	1.75
Confidence	**overall confidence (max. 105 points)**	**72.46**	**75.63**	**67.25**	**64.60**
	confidence correct answers (max. 105 points)	47.48	51.66	35.80	35.65
	confidence wrong answers (max. 105 points)	23.08	21.97	29.45	27.05
Cognitive load	**effort** (max. 5 points)	**3.65**	**3.60**	**4.15**	**3.95**
	difficulty (max. 5 points)	**3.40**	**3.35**	**3.75**	**3.75**

Which representation format of information visualizations is the most suitable for knowledge acquisition? In all analyses of variances reported here, we used retentiveness as a covariate because it was strongly associated with the dependent variables. In a first step we analyzed subjects' overall performance by an univariate ANCOVA (dimensionality x color coding).

Subjects who were presented with a 2D-information visualization outperformed subjects in the 3D-conditions ($F(1,75) = 15.16$; $p<.001$). Additionally, we obtained a marginally significant main effect for color coding in favor of "with color coding" ($F(1,75) = 2.87$; $p<.10$). There was no significant interaction between the two factors. The superiority of the 2D-information visualizations was not only confirmed for overall performance but also for the detailed performance measures - with one exception. There was no significant difference for the what-performance, but this was not astonishing because the information necessary to answer the respective tasks was represented the same way across all conditions. There were no main effects for color coding in the detailed performance measures.

Concerning the overall confidence learners felt regarding the correctness of their answers, we found that subjects learning with 2D-information visualizations were more certain that their answers were correct than subjects in the 3D-conditions ($F(1,75)=8.71$; $p<.01$). Further analysis revealed that learners in the 2D-conditions were not only more convinced that the correct answers they had given were correct ($F(1,75)=18.16$; $p<.001$). Moreover, they also felt more uncertain that their false answer might be correct ($F(1,76)=5.33$; $p<.05$). This pattern of results suggests that subjects in the 2D-conditions had a more accurate assessment of what they really knew. There were no main effects for color coding nor was there an interaction with respect to the overall confidence variable.

With regard to the cognitive load ratings registered after the test phase we found that subjects using 3D-information visualizations indicated that they had to invest more effort into learning than did those in the 2D-conditions ($F(1,76)=4.51$; $p<.05$). In addition, they also evaluated learning as being more difficult than subjects in the 2D-conditions ($F(1,76)=3.30$; $p<.10$). There were no main effects for color coding nor were there interaction effects.

Summary and Conclusions

In our experiment we provided evidence for the suitability of information visualizations for knowledge acquisition. Moreover, we demonstrated that in general 2D-information visualizations are more suitable to foster knowledge acquisition than 3D-ones. This could be due to the fact that learners had to invest more effort and experienced more difficulties during learning in the latter conditions. The question of whether these demands resulted from the necessity to rotate the 3D- information visualization will be addressed in further studies. With regard to the influence of color coding, there were only slight performance increases when information was displayed in color.

Abstract

How do people acquire and use knowledge about domain structures, such as the tree-structured taxonomy of folk biology? These structures are typically seen either as consequences of innate domain-speci c knowledge or as epiphenomena of domain-general associative learning. We present an alternative: a framework for statistical inference that discovers the structural principles that best account for di erent domains of objects and their properties. Our approach infers that a tree structure is best for a biological dataset, and a linear structure ("left"–"right") is best for a dataset of people and their political views. We compare our proposal with unstructured associative learning and argue that our structured approach gives the better account of inductive generalization in the domain of folk biology.

Psychologists have argued that cognition in different domains draws on qualitatively different mental representations. Tree structures appear well-suited to representing relationships between animal species [1, 2, 10], while a one-dimensional structure (the liberal-conservative spectrum) seems better for representing people's political views. The possibility of different structures raises a fundamental question: how do people learn what kind of structure is appropriate in each domain?

The standard approach to this question is to reject one of its assumptions. Nativists deny that core structures are learned, at least for evolutionarily important domains like folkbiology. Instead, infants come equipped with innate knowledge about which structures are appropriate for which domains. Atran [1], for example, argues that folkbiology is a core domain of human knowledge, and that the tendency to group living kinds into hierarchies re ects an "innately determined cognitive structure." More generally, Keil [8] has argued that ontological knowledge obeys an innate "M-constraint", requiring the extensions of predicates to conform to rigidly tree-structured hierarchies of objects.

Alternatively, empiricists generally deny that structured representations are present at all. Domain-specific representations are merely emergent properties of unstructured, domain-general associative learning architectures. McClelland and Rogers [12], for example, have recently suggested that the acquisition of semantic knowledge in domains such as intuitive biology can be explained as learning in a generic connectionist network. Their architecture never explicitly represents any tree structure, although with repeated training, its hidden unit representations may implicitly come to approximate the taxonomic relations between biological species.

This paper proposes an alternative approach – structure learning – that combines important insights from both of these traditions. Our key contribution is to show how structured domain representations can be acquired within a domain-general framework for Bayesian inference. Like nativists, we suggest that different domains are represented with qualitatively different structures, and we show how these structured representations serve as critical constraints on inductive generalization. Like empiricists, though, we emphasize the importance of learning, and attempt to show how domain structures can be acquired through domain-general statistical inference. This is not only more parsimonious than the nativist position, but allows us to explain the origin of structured representations in novel domains, where the prior existence of domain-specific innate structure is highly implausible.

After describing our structure learning framework, we present two empirical tests of its performance. First, we show that it chooses the appropriate domain structure for both synthetic and real-world data sets. It correctly chooses a tree structure for a biological domain (animal feature judgments), and a linear structure for a political domain (US Supreme Court decisions). Second, we model two classic data sets of inductive judgments in biology [13] and show that our framework performs better than an unstructured connectionist approach.

Bayesian structure learning

Our proposal takes the form of a rational analysis. We aim to demonstrate the computational plausibility and explanatory value of Bayesian structure learning, but leave for future work the question of how these computations might be implemented or approximated by cognitive processes. Assume the learner's data consist of a binary-valued object-feature matrix D specifying the features of each object in a given domain. In biology, for instance, the rows of D might correspond to species, and the columns to anatomical and behavioral attributes. The entry in row i and column j would then specify the value of feature j for species i. Structure-learning includes computational problems at two levels. First, which *structure class* is most appropriate for the domain? Second, given a structure class, which structure

in that class provides the best account of the data?

For instance, suppose that a learner exposed to biological data ends up organizing animal species into a taxonomic tree. The first problem asks how she knew to use a tree rather than some other kind of structure. The second problem asks why she settled on one specific tree instead of the many other trees she might have chosen. Our focus here is on the first problem – the problem of inferring the right structure class for a domain. A solution to the second problem, however, falls out of our probabilistic approach.

We assume that learners come to a domain equipped with a hypothesis space of structure classes, either constructed from innate primitives or based on analogies with previously learned domains. For simplicity, this paper considers a hypothesis space of just three canonical classes: taxonomic trees, one-dimensional (linear) spaces, and independent feature models. People surely have access to other classes, including higher-dimensional spaces, at (non-hierarchical) clusterings, and causal networks. We leave it to future work to characterize the full range of structure classes accessible to human cognition. In particular, it is an open question whether this space is small enough to be explicitly enumerated as we do here, or is so large (perhaps infinite or uncountable) that it can be specified only implicitly through some generating mechanism. Future work should also consider the possibility that multiple structures may apply within a single domain.

Given a set of probabilistic models, Bayesian techniques can be used to evaluate which of the models is most likely to have generated some data [7]. Before these techniques can be applied to inferring domain structures, we need to associate each structure class in our hypothesis space with a probabilistic generative model for the features of objects. The next section defines these models, but here we show how Bayesian inference can be used to choose between them.

Let D be an object-feature matrix generated from one of several structure classes. The posterior probability of each class C_i is proportional to the product of the likelihood $p(D|C_i)$ and the prior probability $p(C_i)$. If we assign equal prior probabilities to each class (as we do throughout this paper), the best class is the class that makes the data most likely.

Computing the likelihood $p(D|C_i)$ requires integrating over all structures $\mathcal{S}$ belonging to structure class C_i:

$$p(D|C_i) = \int p(D|\mathcal{S}, C_i)p(\mathcal{S}|C_i)d\mathcal{S}, \qquad (1)$$

Intuitively, this means that a structure class C_i provides a good account of object-feature data D if the data are highly probable under a range of structures $\mathcal{S}$ in class C_i, and if these structures themselves have high prior probability within C_i. The following section explains how the fit of each structure to the data, $p(D|\mathcal{S}, C_i)$, is computed for several structure classes.

We estimate the integral in Equation 1 using stochastic approximations. First we run a Markov chain Monte Carlo simulation to draw a sample of m structures, $\{\mathcal{S}_j\}$, from the distribution $p(\mathcal{S}|D, C_i)$. We then approximate $p(D|C_i)$ by the harmonic mean estimator [7]:

$$p(D|C_i) = \left(\frac{1}{m} \sum_{j=1}^{m} \frac{1}{p(D|\mathcal{S}_j, C_i)} \right)^{-1}. \qquad (2)$$

This estimator does not satisfy a central limit theorem, and can be thrown off by a sample with very low likelihood. Despite its limitations, it is often sufficient to identify a model that is very much better than its competitors. In future work we plan to estimate these integrals more accurately using path sampling [4].

From structures to probabilistic models

We will work with three probabilistic models, each appropriate for a different structure class, and show how to compute the likelihoods $p(D|\mathcal{S}, C_i)$ for structures in each class. For simplicity we assume here that all features are binary, but our framework extends naturally to multi-valued or continuous features.

C_T: Taxonomic trees

Class C_T is the set of taxonomic trees — rooted trees with the objects in D as their leaves. This is a natural representation when the objects are the outcome of an evolutionary process. We restrict ourselves to ultrametric trees — trees where each leaf node is at the same distance from the root.

Assume that each feature is generated by a mutation process over the tree. We formalize the mutation process using a simple biological model [11]. Suppose that a feature F is defined at every point along every branch, not just at the leaf nodes where the data points lie. Imagine F spreading out over the tree from root to leaves — it starts out at the root with some value and could switch values at any point along any branch. Whenever a branch splits, both lower branches inherit the value of F at the point immediately before the split. Figure 1(a) shows one mutation history for a binary feature on a tree with four objects.

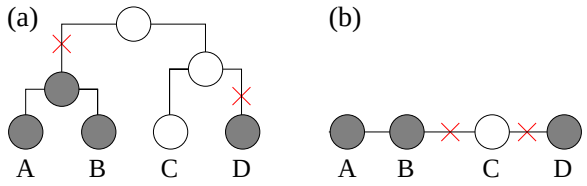

Figure 1: (a) A tree with four objects (A, B, C and D) and three internal nodes. A mutation history for a single feature is shown. The feature is off at the root, but switches on at two places in the tree. Shaded nodes have value 1, clear nodes have value 0, and crosses indicate mutations. (b) A line with four objects.

We formalize this model of mutation using a Poisson arrival process. Under this process, the probability that

F switches values between the beginning and end of any branch b is

$$p(\text{switch along branch } b) = \frac{1 \quad e^{-2\lambda|b|}}{2}, \qquad (3)$$

where $|b|$ denotes the length of b, and λ is the mutation rate. Note that the mutation process is symmetric: mutations from 0 to 1 are just as likely as mutations in the other direction. Asymmetric mutation processes may be more appropriate in some contexts.

Assume that the features are conditionally independent given the tree (i.e., their mutation histories are independent). We can then compute $p(D|\mathcal{T}, C_T)$, the probability of the data given tree $\mathcal{T}$ by multiplying probabilities for each feature vector taken individually. The necessary calculations can be organized efficiently using a Bayes net with the same topology as $\mathcal{T}$ [9].

Computing the total likelihood $p(D|C_T)$ requires integrating over the space of all trees (including variations in branch length and topology), as in Equation 1. We used the MrBayes [6] program for Bayesian phylogenetic inference to draw a sample of trees $\{T_i\}$ from the distribution $p(\mathcal{T}|D, C_T)$. We then estimated the likelihood $p(D|C_T)$ using the harmonic mean estimator (Equation 2).

C_L: One-dimensional (linear) spaces

Although trees seem appropriate for representing biological species and their properties, other domains will have other kinds of structures. Euclidean spaces figure prominently in mathematical models of similarity comparison, judgment, and choice, and probably should appear in any canonical list of structure classes. Let class C_L indicate the set of one-dimensional linear structures. Extensions to higher dimensions are easy in principle, if computationally more demanding.

A line $\mathcal{L} \in C_L$ is a one-dimensional structure where every node corresponds to an object in the domain. A line is a degenerate tree, but unlike the trees of the previous section, lines have no latent nodes. A four-object line is shown in Figure 1(b).

Features are generated over a line according to the mutation model of the previous section. Imagine that Feature F starts at the leftmost node with some value and spreads to the right with the possibility of switching value at any point. Again, the probability that adjacent nodes separated by a branch of length $|b|$ have different values of F is $\frac{1-e^{-2\lambda|b|}}{2}$.

As with C_T, we estimate the likelihood $p(D|C_L)$ with an approximate (MCMC) sum over all linear structures.

C_0: Independent Features

Class C_0 is similar to a null hypothesis. Unlike the previous models, it assumes no underlying relationships between objects in the domain. Each feature is distributed over objects independently of all other features. The pattern of overlap in feature extensions is thus completely unconstrained. More formally, C_0 assumes that feature vectors (columns of D) are generated by ipping weighted coins. Unlike the previous two cases, the likelihood $p(D|C_0)$ can be computed analytically. Suppose that θ_i is the weight of the coin for feature i, and our prior on θ_i is $\theta_i \sim$ Beta(,) (for each of our experiments we use = = 1). If column i of matrix D contains m_i ones and n_i zeros, it can be shown that $p(D|C_0) = \prod_i B(m_i + \ , n_i + \ )/B(\ , \ )$, where $B(\cdot,\cdot)$ is the beta function.

Model complexity and Occam's razor

The three models C_T, C_L, and C_0 vary significantly in their complexity. Both the tree model C_T and the linear model C_L include the independent feature model C_0 as a special case: when each object in C_T or C_L is a long way from its neighbors, feature values at adjacent object nodes are generated in effect by tosses of a fair coin. C_T is also more complex than C_L: in a domain with n objects, there are roughly 2^n more distinct tree structures than distinct linear structures, and the mutation process operating over each tree involves roughly twice as many potential mutation events.

A key feature of Bayesian model selection is that it automatically penalizes unnecessarily complex structures. Some form of Occam's razor is essential when comparing candidate domain structures of different complexities, where the more complex structure (e.g., trees) can more easily mimic the simpler structure (e.g., linear orders) than vice versa. A more naive approach to structure learning, such as choosing the structure that accounts for the most variance in the object-feature matrix D, would be biased against choosing the simpler model class, even when it really generated the observed data.

Empirical tests of structure learning

Synthetic Data

We created three synthetic datasets (unconstrained, tree-structured and linear) with 16 objects and 120 features each. The unconstrained set was constructed using model C_0. The tree-structured set was built by running the mutation process of C_T over a balanced tree with 16 leaf nodes. The linear set was built similarly by running the mutation process over a line with 16 nodes.

Table 1 shows log likelihoods computed for each dataset and structure class. The first row shows that the linear model C_L is better than the tree model C_T on the unconstrained data, but that both are worse than the independent features model C_0. Similarly, the linear model is preferred for the synthetic linear data. The results for the synthetic tree data are more interesting. Even though the data were generated over a tree, the structure class of choice is C_L.

To see why a linear order is a good hypothesis when a tree-structured domain is first encountered, imagine a picture of the true tree, then remove all the branches and internal nodes, leaving behind only the leaves in some linear order. Now join each leaf node to its immediate neighbors. This linear order is a better hypothesis than the true tree at first. The linear model C_L is simpler than the tree model C_T, and if the mutation rate is small, most concepts generated over the tree will be connected subsets of the linear order. Only as more features

Data	C_0	C_L	C_T
Synthetic Unconstrained	<u>59</u>	31	0
Synthetic Linear	0	<u>544</u>	300
Synthetic Tree	0	<u>210</u>	168
Biology	0	230	<u>339</u>
Political	0	<u>1312</u>	883

Table 1: Scaled log-likelihoods for three synthetic and two real-world datasets. Each row has been scaled additively so that its smallest entry is zero.

accumulate should a rational learner conclude that the extra complexity of a tree-structured model is necessary.

To confirm that the true domain structure will eventually win out, we generated a tree-structured set with 32 objects and 240 features and computed log likelihoods as more and more features were observed. Figure 2 shows that the linear structure is preferred while the number of observed features is small, but that the correct tree structure dominates in the end. This transition suggests that our Bayesian model may offer some insight into the dynamics of development. Piaget and others have argued that children move from simple to relatively complex conceptual structures as they mature. Our model shows an analogous shift in tree-structured domains.

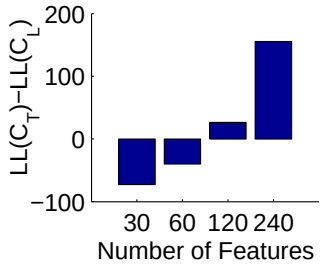

Figure 2: Differences between the log likelihoods of trees (C_T) and linear structures (C_L) on synthetic tree-structured data. Linear structures are preferred at first but the true structure becomes clear as more features are seen.

Biological and Political Data

We used our framework to infer the structure of a biological data set (expected to be tree-structured), and a political data set (expected to be linear). The biological set was constructed from human feature judgments collected by Osherson et al. (1991). Subjects were given 48 animals and 85 features (eg 'lives in water', 'has a tail') and asked to rate the "relative strength of association" between each animal and feature. Subjects gave ratings on a scale that started at zero and had no upper bound. Ratings were linearly transformed to values between 0 and 100, then averaged. We created a binary dataset by thresholding all values at the global mean.

The political dataset was taken from the Supreme Court database collected by Harold Spaeth (1998). We looked at the Burger court which served from 1981 to 1985. Spaeth records 8 possible types of voting behavior: we considered only the cases where every judge either joined the majority, dissented, or cast a regular concurrence (which we treated the same as a majority vote). This left a binary dataset containing votes for 9 judges on 637 cases.

Of the three classes in our hypothesis space, Table 1 confirms that trees provide the best account of the biological data and linear structures are best for the voting data. Note that a more naive approach to structure learning fails here. An additive tree model accounts for more of the variance of the Supreme Court data than a one-dimensional metric scaling solution. Choosing the model that accounts for the greatest proportion of the variance incorrectly favors trees, since it ignores the greater complexity of the tree model.

Once the structure class is known, we can identify the member of that class that makes the data most likely. For the animal data, we took our MCMC sample from the posterior over tree structures, and identified the most representative tree using the `consense` program in the PHYLIP package [3]. The resulting tree is shown in Figure 3(a). Similarly, the best linear structure for the Supreme Court data is shown in Figure 3(b).

The ultimate reason why trees are appropriate for biological data is that evolution is a branching process. It is harder to say a priori why the voting data should be one-dimensional, but the political spectrum ("left"–"right") is an extremely common notion, and others have analyzed Supreme Court data and found that the first dimension of a multidimensional linear model explains almost all of the variance [15]. Our results may explain in part why people represent these domains as they do, but the analysis is mute with respect to the precise mechanisms that give rise to these cognitive structures. Multiple learning mechanisms probably operate in both these domains. Likely mechanisms include inferences drawn from feature observations, as modeled explicitly by our Bayesian learning algorithm, as well as cultural transmission of knowledge, which surely occurs for structures like the "left"–"right" metaphor.

Structure learning versus empiricism

The conventional empiricist critique of structured domain representations has three lines of attack, well articulated recently by McClelland and Rogers [12]: (1) structured representations such as taxonomic trees are too rigid to deal naturally with exceptions or gradients of typicality; (2) it is not clear how structured representations can be induced from raw data; (3) unstructured associative learning architectures can match all of the supposed advantages that structured representations claim. Our work challenges all of these critiques. Previously [10], we showed that robustness to exceptions and sensitivity to typicality fall out naturally from defining a probabilistic generative model of object features in terms of a mutation process over a taxonomic tree (or other domain structure). Point (2) was addressed in the previous section, and now we turn to point (3). We show that learning explicitly structured domain representations provides a powerful source of inductive bias for reasoning about novel properties, and that this power is not easily matched by a generic connectionist architecture.

We compared our tree-structured model for the

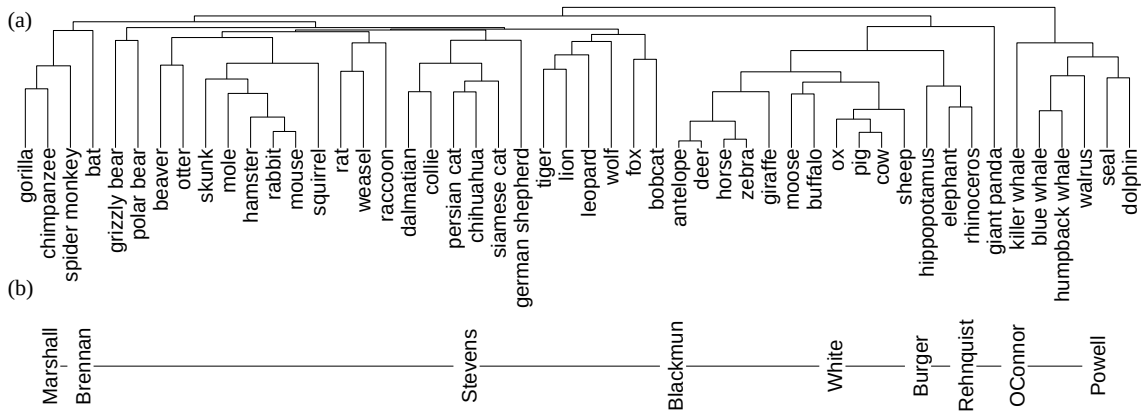

Figure 3: Structures (found via Bayesian structure learning) that best characterize two domains: (a) Mammal species and their properties, and (b) Supreme Court Judges and their decisions.

animal-feature data described above[1] with a connectionist model inspired by the work of McClelland and Rogers [12]. The network includes one input unit for each animal species and one output unit for each feature. We explored a wide range of network parameters in an attempt to achieve the best possible performance (see below). Following McClelland and Rogers, we trained each network on the full matrix D of object-feature associations, then tested how well the hidden-unit representations supported inductive projections for novel features.

In the inductive projection task, a new feature is introduced, and one or more examples of species with that feature are provided to the learner. The learner's task is to infer which other species have this novel property. Like Rogers and McClelland, we modeled this task by introducing a new output unit for the novel feature, freezing all weights except those connected to the new unit, and training the new unit's weights until it reliably produced the correct feature values for the given examples. We then tested the new unit's output when other species were presented as inputs.

We modeled this same induction task using our tree-based Bayesian framework, as described in [10]. Given a tree $\mathcal{T}$ inferred for the domain, the mutation process in model C_T induces a prior distribution over all possible labellings of the species (i.e., the leaves of $\mathcal{T}$). Given one or more examples of a novel property, this prior together with the machinery of Bayesian concept learning allows us to infer the most likely value of that property for all other species in the tree [10]. We used the tree shown in Figure 3(a), and set the mutation rate for the novel property to the value that best fit the 85 features in the biological data set. The resulting tree-based model has no free parameters.

The inductive projections of each model were compared with human argument ratings collected by Osherson et al. [13]. Osherson used a ten-animal domain: horse, cow, chimp, gorilla, mouse, squirrel, dolphin, seal and rhino. The specific set contains 36 two-example arguments, and the conclusion species is always "horse". The general set contains 45 three-example arguments, and the conclusion category is "all mammals." Unfamiliar (blank) predicates – e.g., "have biotinic acid in their blood" – were used for all these arguments. The tree-based Bayesian model rates the strength of general arguments by computing the probability that all ten animals in the domain have the property. The connectionist model rates general arguments by computing projections to each animal separately and adding these ten scores.

Table 2 shows correlations between model predictions and human judgments of argument strength. The first column summarizes the performance of two separate neural networks, re ecting the best performance we ever observed on each data set over a thorough two-stage exploration of the space of possible networks[2]. In the first stage, we tested many different network topologies and varied the learning rate, the number of training and testing epochs, and the presence or absence of momentum and bias. We then took the best-performing networks from the first stage and ran every possible combination of the two best architectures, three best learning rates, two best numbers of testing epochs, and three best numbers of training epochs. The best networks were trained for 20,000 epochs, tested after 250 epochs of training on each testing example, and had no momentum and a bias of -2. They had two hidden layers, typically with 10-30 units each, and a learning rate between 0.005 and 0.01. Even allowing different neural networks for the two datasets, we were unable to match the performance of the tree-based Bayesian model.

Our model differs from these connectionist models along at least two important dimensions, either or both of which could account for its superior performance. First, it uses explicit taxonomic structure and second, it uses Bayesian statistical inference. To isolate the ef-

[1] In order to model the behavioral judgments described below, we supplemented these data with feature ratings for two additional species, cow and dolphin, to give a total of 50 species.

[2] The majority of these tests were conducted with the original 48-animal feature ratings (substituting ox for cow and blue whale for dolphin), before we collected feature ratings for cow and dolphin. Qualitatively similar results were observed with the 50-animal dataset. The results reported in Table 2 re ect the best performance observed across either dataset.

	NN	NN (T)	Bayes (U)	Tree-Bayes	Sim Cov.
Specific	0.62	0.86	0.16	0.95	0.75
General	0.41	0.68	0.38	0.91	0.77

Table 2: Correlations between human judgments and five models for the specific (row 1) and general (row 2) inductive projection tasks described in the text.

fect of structure we implemented models that incorporate only one of these factors. NN(T) is a neural network that uses an explicitly taxonomic representation but not Bayesian inference. The network has 19 input units and a single output unit for the novel property. Input features are derived from the ten-animal tree — the subtree of Figure 3 that includes the ten animals used in this task. Each input node corresponds to a node in the tree, and a species is represented by switching on an input unit for each of its parent nodes in the tree (including a distinctive feature for itself). Species that appear nearby in the tree will share a relatively large number of ancestors and will therefore have similar representations. Bayes(U) is a model that uses Bayesian inference but without any explicit structural representation constraining hypotheses. The model is inspired by Heit's (1998) suggestion that priors for Bayesian induction could be derived from familiar features stored in memory [5]. Each of the 85 observed feature vectors is identified with a candidate hypothesis for generalization, e.g., the feature "nocturnal" gives rise to the hypothesis that the new property is true of all and only the nocturnal species. We assigned a prior probability of $\frac{1}{86}$ to each of these hypotheses and reserved a further $\frac{1}{86}$ for the hypothesis including all mammals.

Table 2 shows that NN(T) performed better than all of the networks explored previously. The tree-based Bayesian model performed better than Bayes(U) or a feature-based version of Osherson et al.'s (1990) similarity-coverage model (which also assumes no domain structure). These results suggest that generic approaches to biological induction may be improved by adding explicit representations of taxonomic structure. The tree-based Bayesian approach also performed better than the tree-based neural network, suggesting that both rational statistical inference and structured domain representations play important roles in guiding people's generalizations.

Conclusion

Our results are preliminary, with a focus on the domain of biology and just the taxonomic aspect of knowledge in that domain. No strong general claims can be made until we push this inquiry more deeply in the domain of biology, and more broadly into other domains. Even so, our work suggests a viable alternative to traditional nativist and empiricist accounts of domain knowledge. Contrary to a strong nativist view, the organizing structural principles of a domain may be learned. Contrary to a strong empiricist view, explicit representations of domain structure may be valuable for guiding inductive projections from sparse data. Structured domain representations and domain-general statistical learning thus need not exclude each other, and indeed are complementary. Statistical learning suggests how novel domain structures can be acquired, and these structures provide a powerful inductive bias for future statistical learning.

Acknowledgments We thank S. Sloman for providing the biological dataset (originally collected by Osherson and Wilkie), Doug Rohde for his neural net package, and Tom Griffiths and Sean Stromsten for helpful suggestions. Key Actions in Insight Problems: Further Evidence for the Importance of Non-Dot Turns in the Nine-Dot Problem

Trina C. Kershaw (tkersh1@uic.edu)
Department of Psychology
University of Illinois at Chicago
1007 W. Harrison St., Chicago, IL, 60607

Abstract

Key actions are single actions or behaviors that can be singled out as leading to the solution of a problem. In the nine-dot problem (Maier, 1930), Kershaw and Ohlsson (2004) proposed that non-dot turns are the key action necessary for solution. In two experiments, non-dot turns are further analyzed as the key action necessary for solving the nine-dot problem and its variants. Non-dot turns are found to be predictive of solution, while the classic conception of drawing lines outside the dots does not distinguish between solvers and non-solvers.

Key Actions in Problem Solving

Problem solving in everyday life, as well as the laboratory, can be quite difficult. Often a problem or activity can seem unduly difficult when one does not know the *key action* necessary for completing the problem. A key action can be defined as a single action or behavior that can be singled out as the key to the solution. Examples of key actions abound in everyday life. A proper roux cannot be made without engaging in continual stirring. Algebra problems become routine once one understands how to balance the equation and isolate the variables. Finally, as I have learned one too many times, data will invariably disappear if I have not completed the key action of backing it up!

In laboratory problem solving, many insight problems can be solved through the production of a key action. For example, using the pliers as the pendulum weight is the key action necessary for solving Maier's (1931) two-string problem, and moving objects in three-dimensional space is necessary for the six matches problem (Scheerer, 1963) and the eight-coin problem (Ormerod, MacGregor, & Chronicle, 2002). As a third example, the key action necessary for solving the prisoner and rope problem (Metcalfe & Wiebe, 1987) is to unravel the rope into two strands, then tie the ends of the two strands together to escape the tower.

Sometimes the key action can be realized without much struggle, depending on an individual's prior knowledge. A friend (and fellow insight researcher) worked on a farm growing up, where the splitting of rope to make it longer was a common occurrence. He instantly knew how to solve the prisoner and rope problem; the key action was easy to discover. In other insight problems, however, the key action is not easy to discover. The common use of pliers hinders their use as a pendulum weight in Maier's (1931) two-string problem (cf. Birch & Rabinowitz, 1951). Additionally, other insight problems may have multiple factors of difficulty preventing the discovery of the key action, such as in the nine-dot problem (Maier, 1930).

Finding the Key Action in the Nine-Dot Problem

The nine-dot problem (Maier, 1930; see Figure 1) is quite possibly the most difficult insight problem that has been studied, with a typical solution rate for unaided participants of 0% (MacGregor, Ormerod, & Chronicle, 2001). Problem solvers are required to connect all the dots in a 3 x 3 matrix by using four straight lines, without lifting their pens from the page or retracing any lines.

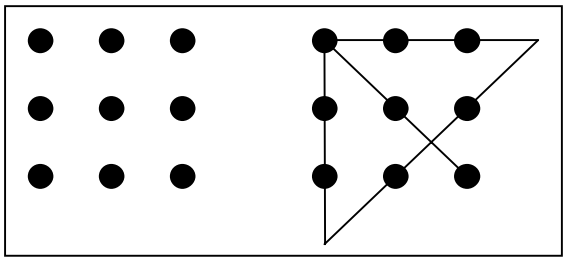

Figure 1: The Nine-Dot Problem and its Solution

The classic conception of the key action necessary for solving the nine-dot problem is that participants should draw lines that extend beyond the dots (Maier, 1930; Maier & Casselman, 1970; Scheerer, 1963). In a related conception, Lung and Dominowski (1985) claimed that the key action was drawing lines that did not begin or end on dots.

Kershaw and Ohlsson (2001) hypothesized that the key action necessary for solving the nine-dot problem was making non-dot turns, or turns that occur in the empty space between dots. The conception of non-dot turns as the key action came about through an inspection of two of MacGregor et al.'s (2001) nine-dot problem variants. The variant with no non-dot turn had a solution rate of 88% after four attempts, while the variant that required one non-dot turn only had a solution rate of 27% after four attempts. Kershaw and Ohlsson (2004) continued in this line of reasoning by explaining that the likelihood of producing a key action is dependent on the cognitive factors that underlie that action. In the nine-dot problem, multiple factors of difficulty are operating that each lower the probability of making a non-dot turn. Kershaw and Ohlsson (2004) distinguished three classes of difficulty: perceptual, knowledge, and process.

Perceptual factors include Gestalt properties of the nine-dot problem such as goodness of figure and figure-ground relationships. Making a non-dot turn requires that one both breaks the good figure of the square and views the white space beyond the dots as part of the problem. Knowledge factors refer to an individual's prior knowledge. Making a non-dot turn is hindered by people's prior experience with dot puzzles, such as connect-the-dot games played by children (cf. Weisberg & Alba, 1981). Process factors include the size of the search space, the specificity of the goal state, and the amount of mental lookahead necessary to find the solution. Making a non-dot turn is difficult because it is not obvious where to draw the first line or what the end state of the problem will be. In addition, people vary in the amount of mental lookahead they possess (cf. MacGregor et al., 2001), which affects the process of making non-dot turns. Kershaw and Ohlsson (2004) showed that perceptual, knowledge, and process factors interact to suppress the probability of producing the key action of non-dot turns in the nine-dot problem.

In the following experiments, non-dot turns are again examined as the key action necessary to solve the nine-dot problem. Experiment I follows up on Kershaw and Ohlsson (2004) but adds an additional possible facilitating factor: giving participants the first line of the solution, which should narrow the search space. Experiment II uses a think aloud methodology to explore what behaviors precede the production of non-dot turns.

Experiment I

Prior research by Kershaw and Ohlsson (2004; Kershaw, Ohlsson, & Coyne, 2003) has shown that increasing the number of non-dot turns leads to greater problem difficulty, such that the more non-dot turns a given problem requires, the harder that problem will be to solve.

Kershaw and Ohlsson (2004; Kershaw et al., 2003) increased solution rates through a training procedure that targeted the multiple factors of difficulty -- perceptual, knowledge, and process -- that hinder the production of non-dot turns. This training procedure was used in Experiment I.

A new facet of the procedure was to give participants the first line of the solution to each target problem. Weisberg and Alba (1981) raised the solution rate of the nine-dot problem to 62% by giving participants the first line in addition to instructing them to go outside of the box set up by the dots. The placement of this first line was chosen based on an analysis by MacGregor et al. (2001). For two of the target problems, the first line extended into the non-dot space.

The addition of the first line influenced the predictions for this experiment. One prediction was that first line would not affect the order nor the magnitude of the solution rates for the five target problems that were reported by Kershaw and Ohlsson (2004), with the 11-dot problem being the easiest and the three-turn problem being the most difficult. A second prediction was that the order of solution rate would remain the same, but that the magnitude would increase for all five problems. A third prediction was that the first line would differentially affect the solution rates for the problems, such that the displaced nine-dot and three-turn problems would show the greatest increase in solution rate due to their first lines cutting into the non-dot space.

Method

Participants and Design One hundred fifty undergraduates from UIC's participant pool participated in the experiment for course credit. No demographic data were collected about the participants.

Participants all received the same training, and one of five target problems.

Materials The first part of the training, the shape training, had a perceptual component in which participants learned to distinguish the shape of the nine-dot problem solution from other shapes (see Kershaw & Ohlsson, 2004; Kershaw et al., 2003). The second part of the training, the dot connecting training, featured problems made of black, filled dots presented on a grid of other unfilled dots as well as problems made of black dots that were alone on the page (see Kershaw & Ohlsson, 2001, 2004; Kershaw et al., 2003). In addition, the training contained a dialogue component in that participants were informed of the purposes of each training task.

The five target problems were taken from Kershaw and Ohlsson (2004; see Figure 2, the nine-dot problem was also used). The problems were modified by adding a diagonal line from the bottom right to the top left of the problem. The placement of the first line was chosen based on an analysis by MacGregor et al. (2001, Experiment 4). Participants were told to treat this line as the first line of the solution that they had to produce.

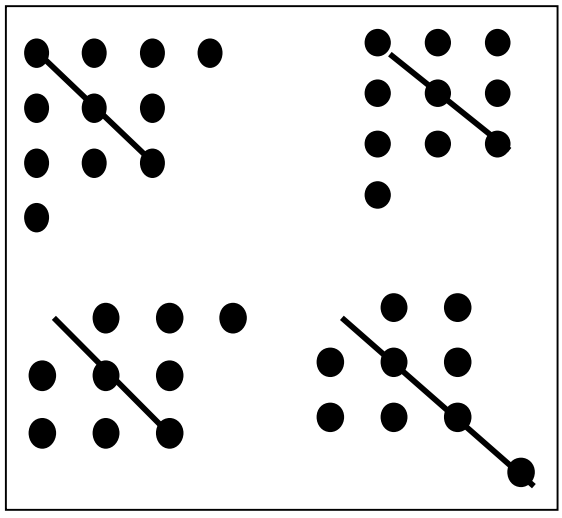

Figure 2: 11-Dot, 10-Dot, Displaced Nine-Dot, and Three-Turn Problems with First Line

Procedure Participants were seen in groups. Participants completed the shape training, and then the dot connecting

training. During the shape training, participants were told that the shape they learned was the shape that would be required to solve the target problem. During the dot connecting training, participants were told that it was necessary to draw lines outside the dots and turn in the empty space between dots. Participants were also shown the correct answer for judging a shape or connecting dots for each judgment or problem that was completed. In addition, they were continually reminded that what they were learning in the training would be applicable to the target problem.

After completing the training, participants attempted one of five target problems (the 11-dot, 10-dot, nine-dot, displaced nine-dot, or three-turn). Participants were given four minutes to connect all the dots using four straight lines. They were instructed to view the line in the problem as the first line, and to draw the remaining lines such that all lines could be drawn without lifting their pens from the page or retracing the lines.

Results

Kershaw and Ohlsson (2004) found the following solution rates for the five target problems (in the training condition): 11-dot, 97%; 10-dot, 80%; displaced nine-dot, 50%; traditional nine-dot, 40%; three-turn, 30%. In contrast, the respective solution rates for this experiment were 83%, 60%, 38%, 40%, and 50% (see Figure 3). However, individual chi-square tests between each problem's solution rate for this experiment and Kershaw and Ohlsson's (2004) data were all non-significant (*p*s > .05).

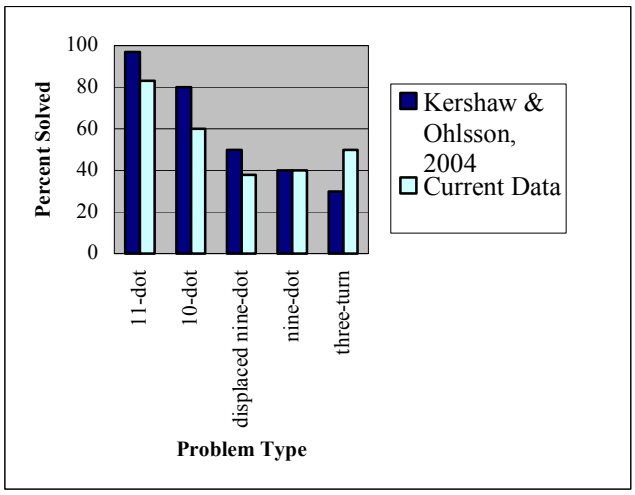

Figure 3: Comparison of Solution Order and Magnitude for the Five Problem Types

Effect of the number of non-dot turns Despite differences in exact solution rates, the new data are similar to those reported by Kershaw and Ohlsson (2004). First, there are overall differences in solution rate between the problems, χ^2 (4, N=150) = 17.02, $p < .05$, $\lambda = .15$. The standardized residuals were examined. The participants who solved the 11-dot problem (25/30 or 83%) caused the greatest standardized residual, 2.2; therefore, this cell made the greatest contribution to the chi-square. When the 11-dot problem was removed from the analysis, the differences between the other problems were not significant, χ^2 (3, N=120) = 4.02, $p > .05$, $\lambda = .09$. Therefore, once a non-dot turn was introduced, all problems became equally difficult.

An alternative way to examine the influence of the number of non-dot turns is to determine the probability of making a non-dot turn (cf. Kershaw & Ohlsson, 2004). The percentage of participants who made any non-dot turns versus correct non-dot turns was calculated for the nine-dot and three-turn problems, both of which require two unassisted (not affected by the first line) non-dot turns. Sixty-five percent (39/60) of the participants made one non-dot turn. Of these participants, 100% (39/39) made two non-dot turns. In contrast, 52% of the participants (31/60) made one correct non-dot turn. Of these participants, 94% (29/31) made two correct non-dot turns.

Effect of drawing lines beyond the dots The nine-dot problem forms a good Gestalt, but the dot groups that make up the other problems do not. The tendency to draw lines that extend beyond the boundary of the dots, the classic explanation of difficulty for the nine-dot problem, was measured across the problem types. The 11-dot problem was excluded from this analysis because drawing lines outside the dots is unnecessary for solution.

Eighty-three percent (99/120) of the participants drew lines outside of the dots. In the 10-dot (24/30), displaced nine-dot (28/30), and three-turn (29/30), participants were equally likely to draw lines outside of the dots, χ^2 (2, N=90) = 5.19, $p > .05$, $\lambda = .07$, despite differences in solution rate. In contrast, participants who attempted the nine-dot problem were less likely to draw lines outside of the dots (18/30). This effect is striking when the nine-dot problem is compared to the three-turn problem, both of which required two unassisted non-dot turns, χ^2 (1, N=60) = 11.88, $p < .05$, $\lambda = .26$. Although the solution rate for these two problems did not differ, the three-turn problem led to a greater rate of drawing lines outside the dots than the nine-dot problem.

Discussion

The results of Experiment I are comparable to Kershaw and Ohlsson (2004) in solution magnitude, the probability of making a non-dot turn, and the prevalence of drawing lines outside the dots. The order of solution rates did differ in that the three-turn problem had the third-highest solution rate in the current data, compared to the lowest solution rate in Kershaw and Ohlsson's (2004) data. However, as in Kershaw and Ohlsson's results, the problems that required non-dot turns did not differ significantly from each other. In addition, individual comparisons between each problem across the two data sets were not significant.

The current data do not support any of the predictions fully. Providing the first line of the solution did not affect the magnitude of solution rate, as predicted, but did affect the order of the solution rate. The solution percentages appear to support the third prediction, that solution magnitude would be affected differentially, but the rate increased for the three-turn problem yet decreased for the displaced nine-dot problem. However, as mentioned above, individual comparisons between the problem types across data sets did not reveal any significant differences.

The current data give further support to the non-dot turn as the key action necessary for solving the nine-dot problem and its variants. As soon as a non-dot turn was introduced, the solution rate dropped by at least 20%. In addition, drawing lines that went outside the dots was not enough to solve the problem. Eighty-three percent of the participants who attempted the 10-dot, displaced nine-dot, nine-dot, or three-turn problems drew lines outside of the dots, but only 47% of the participants correctly solved one of these four problems.

As noted previously, giving participants the first line did not increase the solution rate, as compared to Kershaw and Ohlsson (2004). This finding is interesting compared to similar manipulations used by Weisberg and Alba (1981) and MacGregor et al. (2001). Weisberg and Alba (1981) achieved a solution rate of 62% by giving participants the first line and telling them to go outside the dots. MacGregor et al. (2001, Experiment 4), in contrast, achieved a 6% solution rate after the first 10 attempts, and 47% after 10 additional attempts by giving participants the first line of the nine-dot problem. One explanation, in light of the current data, is that the extensive training used in Experiment I overshadowed any benefit of the first line for the problem variants. Although the solution rate was raised for the three-turn problem, its solution rate was not significantly different than the rate found for the three-turn problem by Kershaw and Ohlsson (2004), nor were there any differences in solution rate across the two experiments for any of the nine-dot problem variants. Untrained participants, in contrast, would most likely benefit from being given the first line, and would thus show differences in comparison to the control group in Kershaw and Ohlsson (2004, Experiment 3).

Experiment II

Experiment I further established non-dot turns as the key action required for solving the nine-dot problem. Experiment I also showed that the classic conception of difficulty for the nine-dot problem, the inability to draw lines beyond the boundary of the dots, did not hold up as a difficulty for the other problem types. However, participants were less likely to draw lines outside the dots for the nine-dot problem, thus supporting the Gestalt factor.

The aim of Experiment II was to examine how participants explore the search space of the nine-dot and 10-dot problems. Both Kershaw and Ohlsson (2004) and Experiment I showed that making non-dot turns is important, but did not show the process that participants go through when making a non-dot turn. Experiment II used a think-aloud methodology to examine the individual thoughts and actions that lead to the making of non-dot turns. Verbal protocols and other trace methods, such as eye movements, have been used effectively to understand the processes involved in achieving insight in problems such as the mutilated checkerboard (Kaplan & Simon, 1990) and in matchstick arithmetic (Knoblich, Ohlsson, & Raney, 2001).

Half of the participants received the training used in Experiment I, and the other half were not trained. The participants received either the nine-dot or 10-dot problem as their target problem. One prediction for Experiment II is that participants who received training will be more likely to solve their target problems, and will show a greater incidence of behaviors that lead to non-dot turns. Based on solution rates found in Experiment I and Kershaw and Ohlsson (2004), no difference in solution rate is expected between the 10-dot and nine-dot problems.

Method

Participants and Design Twenty undergraduates from UIC's participant pool participated in the experiment for course credit. No demographic data were collected about the participants.

The design of Experiment II was a 2 x 2 factorial. The two independent variables were type of training (control and training) and target problem (nine-dot and 10-dot).

Materials The training materials used in Experiment II were the same materials used in Experiment I. The control group did not receive any training. In addition, all participants were given a long division problem as a practice for thinking aloud while solving the target problem. A video camera was used to record each participant's verbalizations and actions.

Procedure Participants were seen individually. As in Experiment I, the participants who received training learned to distinguish the shape of the nine-dot problem solution from other shapes, and learned how to connect dots. They were shown the correct answer for each training exercise and were reminded that the material learned in training would be useful for solving the target problem. Participants in the control group did not receive any training.

Before beginning the target problem, participants practiced thinking out loud by solving a long division problem. Participants were then given four minutes to attempt the target problem. They were told to connect all the dots by using four straight lines, without lifting their pens from the page or retracing any lines. They were instructed to talk out loud while working on the problem. If the participant stopped verbalizing while working on the problem, the experimenter reminded the participant to

continue talking. Each participant's verbalizations, as well as his or her actions, were recorded using a video camera.

Protocol transcription Each participant's verbalizations and actions were transcribed into a verbal protocol by either the author or a research assistant. Protocols were constructed so that the participant's words and actions were grouped together. Actions were described in terms of drawing or simulating lines, and were transcribed by using a map that numbered the dots in each problem.

Results

Effects of training and problem type Solution rates for the problems across training types are as follows: 10-dot training, 60% (3/5); 10-dot control, 20% (1/5); nine-dot training, 40% (2/5); nine-dot control, 0% (0/5). A chi-square analysis was conducted to determine the effect of problem type. There was no significant difference between the number of solvers for the 10-dot and nine-dot problems, χ^2 (1, N=20) = .952, $p > .05$, $\lambda = .13$, as predicted.

A second chi-square analysis was conducted to determine the effect of the training. Participants were more likely to solve their target problem when they had received training than when they had not, χ^2 (1, N=20) = 3.81, $p = .05$, $\lambda = .25$, as predicted.

Analysis of behaviors that lead to non-dot turns Participants' verbal protocols were examined to determine the behaviors that led to making non-dot turns, the key action necessary for solving the 10-dot and nine-dot problems. Based on our previous work (Kershaw & Ohlsson, 2001, 2004; Kershaw et al., 2003), we hypothesized that several actions would show that participants were affected by the training and understood the requirements of the problem: 1) making diagonal lines, 2) making triangle shapes, 3) making the arrow-like shape of the nine-dot problem solution, and 4) making lines that extended beyond the boundary of the dots. For the purposes of this paper, the two actions that will be analyzed are making arrow shapes and making lines that extend beyond the boundary of the dots. In addition, participants' verbalizations may reveal attention to particular areas of the problem, or a rehearsal of strategies.

The participants' verbalizations were surprisingly unhelpful in determining what thoughts preceded making non-dot turns. The majority of participants limited their verbalizations to keeping track of the number of lines they had drawn so far. Only four of the 20 participants verbalized anything about going outside of the dots. Examples of these verbalizations include: "outside the line here" (said while moving a pen from the bottom right dot to the top left dot) and "let's see, I should probably think more about going outside," which was not accompanied by an action.

The use of arrow shapes and lines that extended beyond the dots illustrated the effect of the training in the solution attempts of the participants. Eight participants in the training group made at least one arrow shape, while only three participants in the control group made an arrow shape; this difference was significant, χ^2 (1) = 5.05, $p < .05$, $\lambda = .47$. Likewise, all 10 participants in the training group made lines that extended beyond the dots, while only two participants in the control group attempted such dots. This difference was also significant, χ^2 (1) = 13.33, $p < .05$, $\lambda = .78$.

In addition, these actions were better indicators of events that precede non-dot turns than participants' verbalizations. Participants who solved their target problems drew arrow shapes and extended lines beyond the dots in the correct places before making non-dot turns. In contrast, some participants who did not solve their target problems also drew arrow shapes, but drew them exclusively inside the dots. Other non-solving participants drew arrow shapes and extended lines, but did not make non-dot turns. As in Experiment I, drawing lines that extended beyond the dots was not enough to solve the target problems. Participants needed to extend their lines in the correct places, and make non-dot turns.

Discussion

The results of Experiment II followed up those of Experiment I and Kershaw and Ohlsson (2004) by showing the importance of non-dot turns in solving the nine-dot (and 10-dot) problem(s). In addition, Experiment II showed, like Kershaw and Ohlsson (2004), the effectiveness of training for raising the solution rate for the nine-dot and 10-dot problems.

Experiment II contributes to this line of research by providing a means to analyze the process of attempting the nine-dot problem (or one of its variants). This initial analysis of the verbal protocols revealed that participants who receive training are more likely to produce actions that are necessary for solving the problem, such as drawing an arrow shape, extending a line beyond the dots, and making a non-dot turn. However, as shown in Experiment I and in Kershaw and Ohlsson (2004), making non-dot turns is a difficult key action to execute. Participants must extend lines beyond the dots in the correct place and form the arrow shape of the solution correctly. Merely extending any line beyond the boundary of the dots will not lead to solution.

General Discussion

Key actions can be identified in many different types of problems and in everyday life, from using pliers as a pendulum weight in Maier's (1930) two-string problem to learning to continually stir a roux. In the nine-dot problem, the key action is making a non-dot turn (Kershaw & Ohlsson, 2001, 2004; Kershaw et al., 2003). While some key actions are easily discovered and produced, making a non-dot turn is hindered by interacting factors of difficulty: perceptual, knowledge, and process.

In Experiments I and II, making non-dot turns was compared to the classic conception of the key action necessary for solving the nine-dot problem, drawing lines that extend beyond the dots (Maier, 1930; Maier & Casselman, 1970; Scheerer, 1963). In both experiments, drawing lines outside the dots was not sufficient to solve a target problem. As a striking example, nearly all the participants in Experiment II readily drew lines outside of the dots in the 10-dot, displaced nine-dot, and three-turn problems. However, less than half of the participants actually solved one of these problems.

Experiments I and II provided further support for Kershaw and Ohlsson's (2004) analysis of the importance of making non-dot turns. Other insight and everyday problems are best solved through different key actions. Further study will allow for the identification of these key actions, and the determination of what cognitive factors underlie the production of such actions.

Acknowledgments

Thanks to Stellan Ohlsson for his assistance in planning the experiments and his ever-helpful comments. I also thank Colleen Coyne for her help in collecting some of the data for Experiment I and transcribing some of the protocols in Experiment II.

Abstract

Previous research suggests that members of East Asian cultures show a greater sensitivity to context (vs. target) information than do members of Western Cultures. We suggest this difference is rooted in a greater chronic fear of isolation (FOI) in East Asians than in Westerners. To support this hypothesis, we first compare chronic levels of FOI between East Asian and Western participants. Then we manipulate FOI in a group of Western college students and assess their recognition memory for object as a function whether the background is the same or different from when the picture was first seen. Consistent with our proposal, the manipulation affected people's sensitivity to background context in picture recognition in a manner consistent with previous studies of cultural differences.

Introduction

Previous research has uncovered cultural differences in reasoning and decision making performance between East Asian and Western populations (Nisbett, Peng, Choi, & Norenzayan, 2001). Clearly the study of cultural differences has practical implications for international commerce and theoretical implications for claims about the universality of cognitive processing.

This work is based on the observation that cognitive and perceptual orientations can differ in the degree to which they are analytic versus holistic. For instance, Masuda and Nisbett (2001) showed Japanese and American subjects pictures of animals and fish with a surrounding background. Later, subjects were shown pictures of animals or fish they had seen as well as new animals and fish appearing either with the same background or in a new background. Japanese (but not American) subjects were more likely to correctly recognize an old animal when it appeared with the original background than when it appeared in a new context.

Findings like this suggest there are significant differences in reasoning between cultures, but only a few studies in cross-cultural research have manipulated potential causal variables in studies. For example, Briley and Wyer (2002) manipulated the degree of group membership and cultural identity in Asian and Western college students. They found that experimentally induced feelings of being part of a group produced a greater preference for equality and compromise in individual choice tasks in both populations. Similarly, Gardner, Gabriel, and Lee (1999) examined the causal role of self-construal by investigating whether priming independent or interdependent self-construals within a culture could result in differences in psychological worldview that mirror those traditionally found between cultures. For instance, in one experiment of the study, they found that European-American participants primed with interdependence displayed shifts toward more collectivist social values and judgments that were mediated by corresponding shifts in self-construal. These studies provide insight into our understanding causes of observed cultural differences (Chiu, Morris, Hong, & Menon, 2000; Hong et al., 2003).

In previous work, we proposed that these cultural differences may be caused by a higher chronic fear of isolation (FOI) in East Asian populations than in Western populations (Kim & Markman, 2003). FOI is the degree to which people are anxious or afraid about being cut off from peers and relatives (Gilbert, Fiske, & Lindzey, 1998; Noelle-Neumann, 1984). Communication theories define FOI as a force that leads people to conceal their views when they believe they are in a minority (Noelle-Neumann, 1984). This pressure is assumed to be related to their fears of being negatively evaluated by others. The theory maintains that mass media works simultaneously with majority public opinion to silence minority beliefs on cultural issues. On this view, FOI prompts those with minority views to examine the beliefs of others and to conform to what they perceive to be a majority view. In this paper we discuss a difference in chronic FOI between cultures and then present a study that addresses the relationship between FOI and attention/memory respectively.

Different sensitivities to FOI between East Asian and Western culture

Before discussing how a difference in degree of FOI can influence judgment and decision making, we must first show that members of different cultures are likely to differ in their chronic level of FOI.

As a measure of FOI, we used the Fear of Negative Evaluation scale (Watson & Friend, 1969).[1] This 30-item instrument measures social anxiety about receiving negative evaluations from others. Scores on this scale reflect a fear of the loss of social approval. Items on the measure include signs of anxiety and ineffective social behaviors that would lead to disapproval by others. We gave this scale to 41 Asian students enrolled in University of Texas Austin and their spouses participated for the measurement of FOI in East Asian population. The participants were all born in East Asia (31 Korean 6 Japanese, 4 Chinese) and had a native language other than English. The length of stay in the US was less than 5 years before their participation ($\underline{M}$ = 3.1 years). Western participants were 49 undergraduate students at the University of Texas (all born in the US). Both groups filled out Fear of Negative Evaluation scale along with questions for demographic information. The East Asian Group showed significantly higher scores on the FNE ($\underline{M}$ = 17.54) than did the Western group ($\underline{M}$ = 11.54), $\underline{t}$ (88) = 11.56, $p < .01$. This finding supports the proposal that members of East Asian culture have a higher chronic FOI than do members of Western culture.

The social anxiety literature provides some insight about why different cultures have different levels of FOI. Cross-cultural differences in social anxiety have been studied in various ways, and the consensus among researchers is that members of relatively society-oriented cultures have more social anxiety than do those in individual-oriented cultures. For example, Okazaki and colleagues (Okazaki, 1997; Okazaki, Liu, Longworth, & Minn, 2002) found that Asian-American report higher distress on various measures of social anxiety. A practical merit of such studies is that they enable a comparison of two cultures controlling out other confounding variables such as language or culture-specific patterns in reporting /interviewing. For this reason these results provide insight into chronic differences in social anxiety between cultures. Other cross-cultural comparisons assessed the difference in social anxiety between Asian and Western populations. For example, Sato and McCann (1998) studied Japanese and American students and found a positive relation between social anxiety and interdependent self-construals (which are typical of collectivistic cultures). Similarly, Dinnel, Kleinknecht, and Tanaka-Matsumi (2002) shows that TKS (Taijin Kyofusho, a Japanese variant of social anxiety) - like symptoms (e.g., fear of offending others) were more likely to be reported Japanese university students than by their American counterparts. It is unlikely that social anxiety discussed in the current study is more related to other subcomponents then FOI.

Given that members of East Asian and Western culture differ in chronic FOI, it is important to discuss why this difference might lead to differences in reasoning. Social anxiety, especially FOI, motivates people to focus on social activity, to interact with other members in the social network and to consider others' responses seriously (Gilbert, 2001; Scheufele, Shanahan, & Lee, 2001). Thus, members of collectivistic cultures are expected to be generally more interested in relations among items in the environment than do members of individualistic cultures (Morris & Peng, 1994; Nisbett et al., 2001). It is also possible to observe such differences within a single culture by manipulating a potential cause. For example, as discussed earlier in the previous section, Gardner (1999) showed that manipulation of self-construals by priming interdependence induced a more collectivistic thinking in Western participants. Note that such patterns of behavior and thinking caused by primed interdependence are consistent with observed patterns rooted in a greater level of FOI (Gilbert et al., 1998; Noelle-Neumann, 1984).

In sum, social anxiety is higher in Eastern than Western populations. Increased social anxiety leads to increased attention to relations among items and to context. We connected these two and suggested that levels of FOI are positively related to the degree of dialectical thinking which has been treated as characteristic reasoning mode of collectivism culture (Kim & Markman, 2003).

We developed this idea further in the current study by examining the influence of a manipulation of FOI on recognition memory. As discussed above Masuda and Nisbett (2001) found that members of collectivist culture were more holistic in their analysis of scenes than were members of an individual culture. If a high level of FOI indeed makes people to attend to interpersonal relationships (and more broadly to relations between objects and their environments), then inducing a high level of FOI should make Americans less likely to attend to target information, which in turn should increase their memory for context vs. target information.

Manipulation and measurement of FOI

In our studies, FOI was manipulated as an independent variable following the method used by Kim and Markman (2003). Participants in the High

[1] There are other scales that have been used to measure FOI, but these scales also ask questions about physical rather than social isolation.

FOI group described experiences in which they were socially isolated from others (e.g., "you might have been anxious once when your friends were not talking to you at all, or when you went to a new place where you didn't know anyone and had difficulty meeting new people"). The Low FOI group described experiences in which they caused someone else to be socially isolated from other (e.g., "you might have been at a party and you didn't talk to one of your friends who did not know many people at the party and you felt bad about it later"). Many clinical techniques such as prolonged exposure treatment that is used to treat post-traumatic stress disorder are based on the premise that asking a patient to recall and describe a previous experience and associated emotion will activate and retrieve relevant feelings and memories, and put the person into that state again (Foa, Cashman, Jaycox, & Perry, 1997). Then we measured a person's FOI with the Fear of Negative Evaluation (FNE) scale as a manipulation check.

Experiment

Method

Participants

Eighty nine American undergraduate students (all born in the US) of the University of Texas participated in the study. Half of participants were randomly assigned to the High FOI condition and the other half were to the Low FOI condition.

Materials

In the first phase of the study, 24 animal pictures were presented. Each picture has an animal and a particular background (see Figure 1).

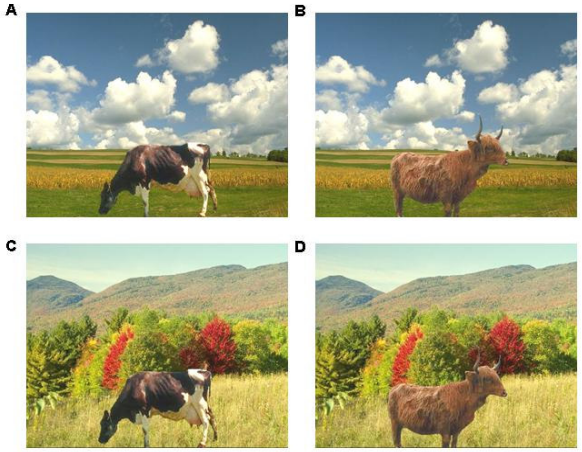

Figure 1. Sample pictures used in this study. (A) A study picture. (B) A new animal in the old background. (C) An old animal in a new background. (D) A new animal with a new background.

In the second phase, participants saw 96 pictures. 24 of them were same with the pictures seen in the first phase (old animal and old background). To create the rest of the 72 pictures, an additional 24 animals (new animal) and 24 backgrounds (new background) were used and the combination between the animal and the background information was manipulated. Because each animal could have one of two different backgrounds – the original background or a novel background, there were four different conditions: (a) old background and old animal, (b) old background and new animal, (c) new background and old animal, and (d) new background and new animal (see Figure 1). All of these pictures were used in Masuda and Nisbett's (2001) study.

Procedure

Participants were asked to describe their previous experiences relating to an anxiety producing situation. In the High FOI condition, participants wrote about being socially isolated from others. In the Low FOI condition, participants wrote about socially isolating someone else from them or other people. After completing this self-descriptive priming task, participants in both conditions responded to the Fear of Negative Evaluation scale as a manipulation check.

Then participants viewed 24 photos of animals in naturalistic environments. After a 2-minute delay, participants viewed 96 photos in a recognition memory test that varied whether the animals were old or new and whether the background was old or new. Subjects responded whether they had seen the animal in the photo regardless of the background of the test photo.

Results

First, we checked the effectiveness of our FOI manipulation. Average values on the Fear of Negative Evaluation scale were significantly higher in the High FOI condition ($\underline{M}$ = 15.61) than in the Low FOI condition ($\underline{M}$ = 10.60), $\underline{t}$ (87) = 3.92, $p < .01$. Note that the mean score of High FOI group approaches that seen in the East Asian group ($\underline{M}$ = 17.54) we measured.

For "old" and "new" responses, we subtracted people's accuracy for the pictures with the new background from their accuracy with the original background. Positive scores indicate sensitivity to the context.

The pattern of data in this study shows the same pattern observed by Masuda and Nisbett (2001) (see Figure 2). There was a significantly higher index ($\underline{M}$ = 2.39) for the High FOI condition than for the Low FOI condition ($\underline{M}$ = 1.22), $\underline{F}$ (1, 87) = 6.01, $\underline{p}<.05$. This effect is mediated by level of FOI. In an ANCOVA including FNE score, there is a significant correlation between FNE and the response index ($\underline{r}$ = .33, $\underline{p}$ <.01) and the main effect of FOI is reduced in significance, $\underline{F}$ (1, 87) = 1.91, $\underline{p}$ = .171.

For "new" responses there is also a marginally significant difference between the High (M = -1.43) and Low FOI conditions (M = -2.01), F (1, 87) = 1.18, p<.28. (Masuda and Nisbett (2001) found no significant difference between their Japanese and American subjects for "new" responses.) This finding is consistent with the hypothesis that participants in the High FOI condition attend more on background information than do those in the Low FOI group even when misleading cues of original background interfered with recognition.

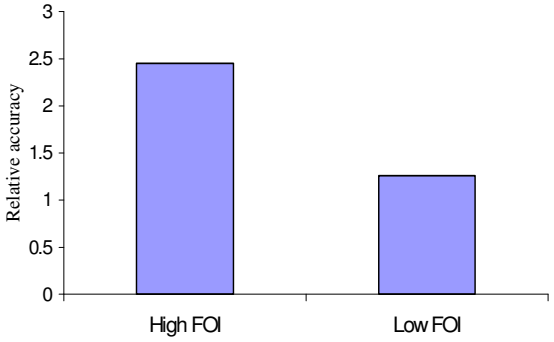

Figure 2. Participants' relative accuracy for "old" response.

Interestingly, this combination of results does not indicate greater overall accuracy between groups. A calculation of d' shows no difference for the High FOI condition (M = 1.74) and the low FOI condition (M = 1.76), F (1, 87) = .01, p = .916.

General discussion

This experiment demonstrated the influence of fear of isolation on attention and memory. Inducing a higher level of FOI in American college students made their attention more similar to that of East Asian students observed in previous studies. Participants in the High FOI condition showed greater accuracy for the memory of background information than did those in the Low FOI condition. When Fear of Negative Evaluation scale values were incorporated into the analyses as a covariate, they were significantly related to the degree of sensitivity to context, and the strength of the effect of FOI manipulation was decreased.

However, an alternative interpretation of the current results is that the induction of low FOI primarily induced the feeling of guilt, and hence a more *negative mood* than in the condition designed to induce high FOI. Some previous studies showed that negative mood leads to more analytic thinking (Bolte, Goschke, & Kuhl, 2003). For example, according to the personality systems interaction theory (Bolte et al., 2003; Kuhl & Kazen, 1999), an increase in negative affect supports a analytic processing mode whereas positive affect induce a relatively more holistic thinking. We tested this possibility in another study, in which participants' relative preference for dialectical proverbs were measured, and found that there was no meaningful difference on emotion scales (e.g., hedonic tone and general arousal) between the two FOI groups and that only FNE scale values explained the variation in the relative preference for dialectical proverbs within/between group (Kim & Markman, in preparation). Thus it is unlikely that emotion systematically influenced the current results.

It is also important that, as discussed earlier, East Asian participants exhibited a significantly greater FOI than did Western participants. Note that East Asian without FOI manipulation showed a greater average values on the Fear of Negative Evaluation scale than did those in the High FOI group in the current experiment.

These findings are consistent with the hypothesis that chronic differences in FOI in members of East Asian and Western cultures lead to the differences in attention observed in the previous studies (Masuda & Nisbett, 2001). We are not claiming that FOI is the only cause of cultural differences in reasoning. Indeed, differences in culturally accessible concepts such as collectivism and individualism may influence cognition either by affecting level of FOI through some other route (Aaker & Lee, 2001; Hsee & Weber, 1999). This issue has been much discussed in communication theories, which have yielded no clear consensus on whether FOI is an antecedent or an intervening variable. For example, Shoemaker, Breen, and Stamper (2000) tested whether FOI is antecedent to opinion formation or an intervening variable between opinion formation and willingness to voice the opinion. Their path analysis suggested that FOI is an antecedent variable, but they could not exclude possibility that it is an intervening variable. However, it seems that FOI is a robust causal factor explaining previously observed difference between cultures. Kim and Markman (2003) found that a manipulation of FOI induced a difference in degree of dialectical reasoning.

Thus, chronic levels of Fear of Isolation may be a causal factor underlying observed cultural differences in reasoning. The mechanisms that relate FOI to these reasoning differences will be the subject of future research, but we speculate that high levels of FOI lead people to think more about their relationship to others, and hence are more open to compromise in reasoning and more attentive to contextual and situational factors that guide behavior.

The current study also has implications for Cognitive Science in general. Most behavioral research assumes that the average performance of participants

reflects the basic functioning of the cognitive architecture. However, work on cultural differences points out dimensions along which performance on cognitive tasks may reflect learned strategies rather than constraints of the cognitive architecture itself. In line with this viewpoint, the study we present in this paper indicates that “some” of the observed cultural differences may reflect straightforward differences in chronic social anxiety rather than fundamental differences in knowledge gathered over years of experience within a culture.

Finally, it is important to bear in mind that we induced significant differences in memory for objects based on a simple manipulation of a participant's level of fear of isolation. As these findings demonstrate, a straightforward change in motivational state can lead to a large difference in basic cognitive functioning. This work highlights the need to include more research on the influence of motivation on cognitive processing within the canon of research in Cognitive Science.

Abstract

Two experiments using social stimuli tested a recurrent neural network model's predictions for cue competition for causes and effects. The delta-rule based model predicts the presence of cue competition for effects as well as for causes as a result of an asymmetry in the bidirectional associative strengths between the relevant cue-outcome pairs. This model can capture cue competition for effects when cues are encountered in the cause-effect direction, unlike associative and feed-forward models. Results support the model's prediction of cue competition for both effects and causes. The implications of these results for causal model theory and for various associative accounts of cue competition are discussed.

Introduction

Since the advent of research on causal induction many researchers have focused on causal models that explain the competitive nature of learning cues that predict or indicate the occurrence of an event (e.g., Rescorla & Wagner, 1972; Gluck & Bower, 1988; Shanks, 1991; Waldmann & Holyoak, 1992). The first account of competitive learning of cues was the Rescorla-Wagner (1972) model. When multiple cues are present preceding an event, these cues compete with each other for predictive strength, resulting in the competitive learning of cues. A classic example of this is blocking, whereupon learning that stimulus A predicts outcome X during initial training, there is a deficit in learning that B also perfectly predicts X when AB are presented together preceding X in the second training phase.

Although cue competition of causes is well established in both the animal and human causal learning literature, the question of whether competition occurs among multiple effects of a common cause has produced somewhat inconsistent findings and has resulted in a heated debate (e.g., Shanks, 1991; Waldmann & Holyoak, 1992; Van Hamme & Wasserman, 1993; Price & Yates, 1995; Matute, Arcediano & Miller, 1996; Shanks, & Lopez, 1996). Cue competition for effects describes a two-stage conditioning phenomenon whereupon first learning that cause A perfectly predicts the occurrence of effect X during Phase 1 of training, there is a deficit in subsequently learning that cause A also perfectly predicts the occurrence of effect Y when the XY compound is presented together after the presentation of cause A during the Phase 2 training.

A number of researchers have provided evidence for cue competition for effects. Some researchers (e.g., Shanks, 1991; Shanks & Lopez, 1996; Price & Yates, 1995; Cobos, Lopez, Cano, Almaraz & Shanks, 2002) interpret the findings as consistent with associative learning theories. Others (e.g., Matute et al., 1996; Miller & Matute, 1998) assert that the findings are more consistent with contiguity theory, which assumes that associations are learned noncompetitively and bi-directionally through simple contiguity, and that cue competition takes place at judgment.

In contrast, proponents of causal model theory (e.g., Waldmann & Holyoak 1992; Melz, Cheng, Holyoak & Waldmann, 1993; Waldmann, 2000) deny the evidence for cue competition for effects, suggesting that whereas causes compete, effects do not. They argue that multiple effects should not compete with each other because they provide new information about the effects of a common cause.

The goal of this paper is to contrast the predictions of a recurrent neural network, with associative learning theory, causal model theory and contiguity theory's predictions for cue competition for causes as well as for effects. Two experiments designed to test the different predictions for the occurrence of cue competition between effects will be presented. These experiments use various social behaviors as target stimuli for cues and outcomes in an attempt to extend the research in multiple cue contingency learning beyond the traditional settings of biological, physical or abstract events and their consequences.

In addition, these studies assess both directions of reasoning between causes and effects. Typical research in this domain only investigates one direction of reasoning and thus cannot say anything about the relative strength of the forward link from causes to effects and the backward link from effects to causes.

Cue Competition in Associative Models

The Rescorla-Wagner (R-W) model (Rescorla & Wagner, 1972) formally describes the change in associative strength during learning by: $\Delta V_{cs(n)} = \alpha_{cs}\beta_{us(n)}(\lambda_{us(n)} - V_{total(n)})$, where $\Delta V_{cs(n)}$ is the change in the associative strength (V) of CS as a result of a pairing with US on trial n; α_{cs} is the learning rate parameter of the CS; $\beta_{us(n)}$ is the learning rate parameter of the US on trial n; $\lambda_{us(n)}$ is the asymptote of learning or the maximum associative strength that the US can support on trial n; and $V_{total(n)}$ is the sum of associative strengths of all CSs present on trial n, or the extent to which the US is predicted on trial n. The basic principle behind the R-W model is that associative learning is determined by the extent to which an US is surprising, represented by the difference

between the US that is actually presented on trial n and the US that is expected on the basis of the summed predictive value of all the cues that are present on trial n.

With respect to blocking and cue competition, the R-W model predicts the consequences of presenting multiple causes. Cue competition for causes is observed in blocking experiments because by the end of Phase 1 training, the animal has learned that CS_1 perfectly predicts the US. During Phase 2 training, when CS_1 and CS_2 are presented together with the US, no learning occurs for CS_1CS_2 because changing the associative strength of the CS_2 cannot improve the already perfect predictability of the US.

However, the R-W model is unable to naturally handle cue competition between multiple effects of a common cause, because it is a predictive model that assumes a cause-to-effect directionality in learning associations. In other words, the difference term (– V_{total}) only applies to the ability of cue (CS) to predict outcome (US), but not outcome to cue. However, several researchers have obtained cue competition for effects and have provided associative accounts for them (e.g., Shanks, 1991; Shanks & Lopez, 1996; Price & Yates, 1995; Cobos et al, 2002). In order to do so, these researchers have had to resort to the somewhat convoluted procedure of presenting participants with the effects *preceding* the cause (for instance, where symptoms predict the disease that caused them). In other words, the R-W model can accommodate cue competition for effects by using a diagnostic learning procedure, where the multiple effects can be presented as antecedent events, which are understood to occur after their cause, even though the effects are presented prior to the cause. Thus the effects (antecedents) compete with each other in predicting the cause. However, the R-W rule cannot handle the more typical situation in which causes occur before effects.

Gluck and Bower (1988) and Shanks (1991) demonstrated that a simple two layer feedforward network using the delta rule, which is closely related to the R-W rule, correctly predicted competition of cues (symptoms) for a common outcome (a rare disease). The delta rule is an error-correcting learning rule that says that the changes in weights, Δw_{ij}, from input node i to output node j is given by the following equation: $\Delta w_{ij} = \partial (t_j - o_j) a_i$, where a is the activation on input node i; t is the target activation on output node j; o is the observed or actual activation on output j; and ∂ is the learning rate (constant). As in the R-W rule, the change in weight between the input and output nodes, Δw, depends on the extent to which the target activation of the output differs from the observed activation of the output.

However, this network can only learn forward links from cues to outcomes. Thus, as with the R-W rule they could capture cue competition for effects only by assuming diagnostic learning where the effects precede the cause.

We will show that a recurrent network model with delta-rule learning does not have this limitation, but can handle cue competition for effects when causes precede effects.

Cue Competition in Causal Model Theory

Causal model theory argues that people use meaningful world knowledge about the basic characteristics of causal relations in conjunction with contingency information to build causal models of the relations between causes and effect (Waldmann & Holyoak, 1992). The causal model theory uses a contingency rule to deal with a multiple cue situation, where the contingency is the difference between the proportion of cases in which the effect and cause co-occur and the proportion of cases in which the effect occurs in the absence of the cause. When the causal model is predictive, cue competition between causes is expected in the classic blocking paradigm because during Phase 2 training, the new cue, Cue_2, always co-occurs with first cue, Cue_1. Waldmann and Holyoak (1992) argue that because "it is impossible to determine whether the observed unconditional contingency between Cue_2 and the effect is genuine or spurious," this should lead to uncertainty, which should further lead to a lowered predictiveness of Cue_2, or partial blocking (p. 226). On the other hand, they assert that effects do not compete with each other, because each effect provides further information about the cause and there is no uncertainty (Waldmann & Holyoak, 1992; Waldmann, 2000).

Waldmann has done a number of studies that fail to find cue competition for effects (with the exception of Study 2 in Waldmann and Holyoak (1992)). However, he typically uses complicated learning tasks where effects temporally precede causes (diagnostic learning). This has apparently been motivated by the necessity of using diagnostic learning to compare the predictions of the R-W rule.

Cue Competition in Contiguity Models

Some researchers propose that a noncompetitive, contiguity theory of learning may better accommodate cue competition for effects by asserting that cue competition does not arise during learning, but during later judgment (e.g., Matute et al., 1996). Further, Matute et al. (1996) found that the wording of test questions moderates the observance of cue competition for effects. They obtained cue competition for causes when they used test questions that implicitly probed the conditional probability of an effect given a cause compared to its probability given an alternative cause (p[E|C] with p[E|C']), and they found cue competition for effects when they probed the conditional probability of a cause given an effect compared to its probability given an alternative effect (p[C|E] with p[C|E']). Their work seems to suggest that the direction of the relationship queried may be related to whether evidence is found for cue competition.

Cue competition in Recurrent Neural Networks

Recently, Read (2003) demonstrated that a recurrent network, based on McClelland and Rumelhart's (1988) auto-associator, with bidirectional links between the input and output nodes and using a modified version of the delta rule, can predict cue competition for both causes and effects. Unlike a feed-forward model, the recurrent model acquires bidirectional links or associations between the input and output nodes, and thus is able to accommodate cue competition for effects with predictive learning, where the cause *precedes* the effects.

One of the reasons this literature has become so confusing is that in order to use the R-W rule or a feed-forward network as a model of cue competition for effects, one must test cue competition for effects with diagnostic learning,

where effects are encountered before causes. However, with the recurrent network with delta-rule learning, this is not necessary. The current model allows one to test an associative model, closely related to R-W, with the more natural situation in which causes temporally *precede* effects.

In a recurrent neural network, the associative strengths of the bidirectional links between any two events may differ, and this possible asymmetry can be illustrated in the classic blocking paradigm. In the recurrent model, the observation of blocking depends on the direction of the association between the redundant cause B and the common effect X. If the association between cause A and X is trained in phase 1, then when A and B are subsequently paired preceding X, the link from B→X should exhibit competitive learning because, when B is activated, X is already activated due to the simultaneous presence of the previously trained cause A, which is a perfect predictor of X. Thus, there is little change in the link from B→X during Phase 2 training because B does not provide any new information about X. However, the link from X→B should not exhibit cue competition during Phase 2 training, as activating X does not predict B because B is not initially predicted by anything. Therefore, there is a great discrepancy between the target activation of B and the actual activation of B, which results in a greater weight change in the link from X→B. The result is that the link from X→B will be stronger than the link from B→X, suggesting that cue competition should only be observed in the link from B→X. As seen in Figure 1, Read demonstrated this asymmetry in weights using the recurrent model, with delta rule learning, with a learning rate of .15, with 10 passes through 10 learning instances with the same contingencies as in the current experimental stimuli.

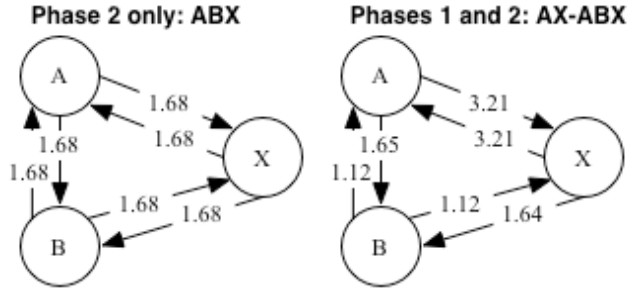

Figure 1: Weights demonstrating cue competition for causes after Phase 1 and 2 training (but not after Phase 2 only training). A and B are causes, X is the common effect.

Similarly, the recurrent model predicts cue competition for effects using the same rule. Again, the model predicts an asymmetry between the associative strengths of the links from A→Y and Y→A. The associative link from Y→A should exhibit competitive learning because when Y is activated during Phase 2 training, A is already highly activated from the simultaneous presence of X, which is a perfect predictor of A. Thus, there is very little weight change in the link from Y→A. However, the link from A→Y should not exhibit cue competition in learning because when A is activated during Phase 2 learning, Y is not initially predicted by anything. Therefore, the discrepancy between the target and the actual activations of Y are large, resulting in a bigger weight change in the link from A→Y. Thus, the associative strength from A→Y should be stronger than the associative strength of Y→A. Read's simulation results in Figure 2, with the same parameters, reflect this as well.

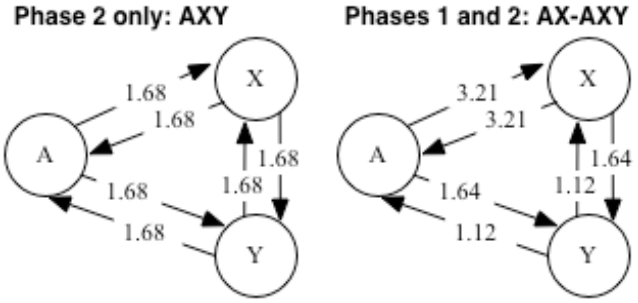

Figure 2: Weights demonstrating cue competition for effects after Phase 1 and 2 training (but not after Phase 2 only training). A is the cause and X and Y are the effects.

Purpose. Our purpose is threefold. First, we will provide further evidence that cue competition for effects occurs. Second, we will demonstrate that this effect can be obtained using social stimuli. Finally, we will test the predictions of the recurrent network model for cue competition and the asymmetry in the associative strengths of the bidirectional links between the cue and the target outcome. We will ask subjects to make judgments about the associative strengths of each of the two possible links between a cue and an outcome. Doing this in the same study has not previously been done. It is expected that cue competition for effects will be observed as well as the asymmetry in the associative strengths of the two possible links: the target outcome, Y, will exhibit cue competition with outcome, X, for the weight from Y→A, but not for the weight from A→Y.

We will get directional measures of strength by asking subjects to make conditional probability judgments between all pairs of nodes. Interpreting these judgments depends on the relationship between weights and conditional probabilities. As O'Reilly and Munakata (2000) show, in neural networks, the weight from an input i to an output o is a function of the conditional probability of the input given the output (p [i|o]). The output node can be thought of as corresponding to a hypothesis and the input node to data concerning the hypothesis. Thus, the weight from input to output captures the conditional probability of the data given the hypothesis. The critical implication is that judgments of the conditional probability p[Y|A] will be sensitive to the strength of the weight from Y to A whereas judgments of p[A|Y] should be sensitive to the weight from A to Y.

Study 1

Stimuli were four unrelated behaviors that had no known preexisting relationship with each other: breaking a glass (cause A); shaving one's head (effect X); lighting a tree on fire (effect Y); and meditating (filler effect Z). Information was presented simultaneously in list format (as Van Hamme et al. (1993) and Matute et al. (1996) did) with a dashed line break in between the antecedent and subsequent events to separate the common cause from the multiple effects.

Participants were instructed to learn the causal relationships between the antecedent and subsequent events. Finally, questions designed to assess the conditional probabilities and probe the associative strengths between all four behaviors were used (A→X; X→A; A→Y; Y→A; X→Y; Y→X; A→Z; Z→A).

Method

Participants. 93 undergraduates from the University of Southern California volunteered for extra credit. The study was a between subjects design with repeated measures on judgments, where the experimental group received both Phase 1 and Phase 2 of training, and the control group only received the Phase 2 training.

Materials and Procedure. Subjects were randomly assigned to the experimental or control group and seated in front of a computer, on which the entire experiment was done. The cover story asked subjects to imagine that they were anthropologists in the distant future traveling to a long lost human colony on a faraway planet to study their culture and social customs. They were instructed that their goal was to learn the various behavioral patterns of the colonists by observing individual instances of sets of behaviors. They were instructed to learn the causal relationships among the behaviors. Before seeing the behaviors, all subjects made initial judgments about the extent to which the four stimulus behaviors were related to each other to establish that they had no known relationship. They were asked to rate the extent to which the occurrence of one behavior affected the likelihood of another behavior on a scale from -10 to 10, where -10 indicates "strongly inhibits," 10 indicates "strongly promotes", and 0 indicates "no relationship." These questions and rating scale were also used for the testing after the training phase(s).

After the initial ratings, subjects in the experimental condition received Phase 1 training, where they saw 10 behavior sets exhibited by 10 individuals. Each set was presented individually on separate screens along with the name of the individual exhibiting the behaviors. Each set was displayed until the subject pressed the space bar. Eight of the 10 sets involved "breaking a glass" (cause A) followed by "shaving one's head" (effect X); 2 of the 10 sets involved "breaking a glass" (cause A) followed by "meditating" (filler effect Z). The order of the 10 sets was randomized for each participant. After Phase 1, subjects started Phase 2 training, where they saw 10 more behavior sets exhibited by 10 new individuals. Eight of the 10 sets involved "breaking a glass" (cause A) followed by "shaving one's head" (effect X) and "lighting a tree on fire" (effect Y). As in Phase 1, two of the 10 sets involved "breaking a glass (cause A) followed by "meditating" (filler effect Z).

Subjects in the control condition only received Phase 2 training. Immediately after training, they made judgments about the extent to which one behavior affects the likelihood of another behavior, for all four behaviors in both directions. Thus, subjects made judgments about the extent to which "breaking a glass" affects the likelihood of "shaving one's head" (A→X); "shaving one's head" affects the likelihood of "breaking a glass" (X→A); "breaking a glass" affects the likelihood of "lighting a tree on fire" (A→Y); "lighting a tree on fire" affects the likelihood of "breaking a glass" (Y→A); "shaving one's head" affects the likelihood of "lighting a tree on fire" (X→Y); "lighting a tree on fire" affects the likelihood of "shaving one's head" (Y→X); "breaking a glass" affects the likelihood of "meditating" (A→Z); and "meditating" affects the likelihood of "breaking a glass" (Z→A).

Results and Discussion

The mean of the eight initial ratings was -.62 for the experimental condition, and -.49 for the control, indicating that the four behaviors had no preexisting causal relationships. The mean of the eight final ratings was 5.77 for the experimental condition, and 6.19 for the control, indicating that subjects learned the causal contingencies.

A between-groups comparison for each of the eight final ratings found all of them to be non-significant with one exception. As predicted, the difference between experimental and control group judgments of the Y→A rating (p[Y/A]) was found to be highly significant, $t(91)=3.02$, $p=.003$ (experimental M= 5.29 vs. control M=7.21) (See Figure 3). This provides evidence for cue competition between effects in the direction predicted by the recurrent network.

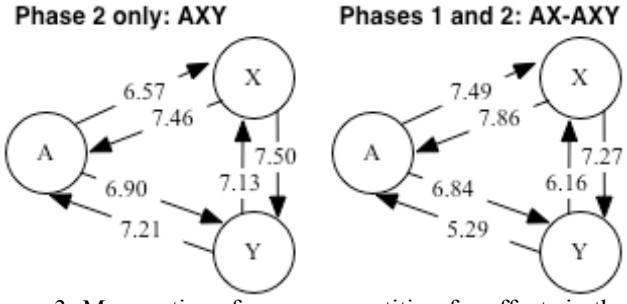

Figure 3: Mean ratings for cue competition for effects in the AXY (control) and AX-AXY (experimental) conditions. A is the cause, X and Y are the two competing effects.

Although the results of Study 1 were consistent with our predictions, we wondered whether the test questions did a good job of measuring conditional probabilities. After learning the behavioral contingencies, subjects were asked to make some "final estimates about the extent to which the occurrence of the first behavior affects the likelihood of the occurrence of the second behavior." However, for the backward reasoning test questions (e.g., X→A, Y→A, and Z→A) the actual test questions asked subjects to indicate the likelihood that an individual doing X (or Y or Z) had previously done A. In other words, the task instructions implicitly asked subjects to make forward casual judgments from the first listed behavior to the second, while the actual test questions asked subjects to make backward causal judgments from the first listed behavior to the second (at least for the backward reasoning questions). Thus, it is unclear whether we were successful in measuring the bidirectional associative strengths among the four behaviors.

Study 2

Study 2 involved several changes. First, the wording of the test questions was changed to more clearly measure

conditional probabilities. Test questions probing the associative strength of the link from A→X were more clearly phrased as the probability of A given X (p[A|X]), X→A was more clearly phrased as the probability of X given A (p[X|A]), and so forth (The phrasing of the new questions is presented later). Next, because the recurrent network model also predicts cue competition for causes as a result of asymmetrical associative strengths in the links between the redundant cue and outcome, the design from Study 1 was used to investigate cue competition for causes as well as for effects. For the Effects condition, the design and stimulus behaviors (Cause A, Effects X, Y and Z) were identical to those of Study 1. For the Causes condition, Cause A and Effect X remained the same with the addition of a new redundant Cause B, ("ringing a bell") in the Phase 2 training portion, and changing the previous filler effect Z to filler cause Z. Finally, Study 2 was conducted on the web.

Method

Participants. 168 adults ranging from ages 18 to 67 participated in this study on the Internet. Mean age was 39.28 (SD = 12.792). Participants were from previous on-line studies, unrelated to causal reasoning, who indicated that they were interested in future on-line studies. They were recruited by email and were residents of the US, with three exceptions. They were entered into a lottery for a $50 cash prize, with the odds of winning at 1/50. The study was a between subjects design with repeated measures on judgments. As before, the experimental groups for causes and effects received both Phase 1 and Phase 2 training, and the control groups only received Phase 2 training.

Materials and Procedure. Subjects clicked a link in their email directing them to the study. Upon clicking the button that initiated the experiment, subjects were randomly assigned to one of four conditions: experimental and control conditions for Causes and experimental and control conditions for Effects. Subjects were presented with the same cover story as in Study 1. Because Study 1 showed that there were no preexisting relationships between the behaviors, the initial judgments were dropped for Study 2.

The procedures for the Effects conditions were identical to Study 1. Procedures for the Causes conditions were identical to those for Effects, with the exception of changes in the behaviors. In Phase 1 for the experimental group, 8 of the 10 sets involved "breaking a glass" (cause A) followed by "shaving one's head" (effect X); 2 of the 10 sets involved "meditating" (filler cause Z) followed by "shaving one's head" (effect X). In Phase 2, 8 of the 10 sets involved "breaking a glass" (cause A) and "ringing a bell" (redundant cause B) followed by "shaving one's head" (effect X). As in Phase 1, 2 of the 10 sets involved "meditating" (filler cause z) followed by "shaving one's head" (effect X). Control subjects only received Phase 2 training.

The order of the eight test questions was randomized for each subject. Immediately following training, subjects were asked to make final judgments about the extent to which the occurrence of one behavior affects the likelihood of the occurrence of another behavior in terms of conditional probabilities for all four stimulus behaviors both directions. They made their judgments by clicking on a radio button on a rating scale from 0 to 10, where 0 indicates "No chance", 5 indicates "50-50", and 10 indicates "Certain". The test questions were phrased: for p[A|X], "Assuming that someone shaves their head, how likely is it that they had broken a glass," and for p[X|A], "Assuming that someone has broken a glass, how likely is it that they will shave their head?," and so forth.

Results and Discussion

As presented in Figure 4, the results for the Effects condition in study 2 replicate those of Study 1.

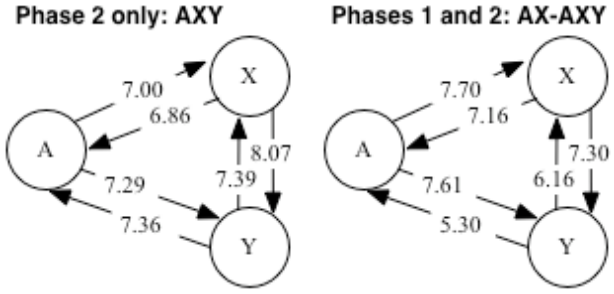

Figure 4: Mean ratings for cue competition for effects in the AXY and AX-AXY conditions in Study 2.

Between groups comparison of the final ratings for the experimental and control conditions showed a difference in the critical variable of Y→A rating, (p [Y|A]) $t(70)=3.75$, $p=.00$ (M=5.30 for experimental vs. M=7.36 for control). No other comparisons were significant. Cue competition for effects was asymmetric in the predicted direction.

For the Causes condition, there was a significant difference between the experimental and control groups for the critical variable of B→X rating (p[B|X]), $t(76) = 2.57$, $p = .01$. However, the difference for the non-critical variable of X→B (p[X|B]) was also significant, $t(76) = 2.88$, $p = .00$, as presented in Figure 5. Cue competition for causes is obtained, but contrary to the network model's predictions, there is no asymmetry in the associative strengths.

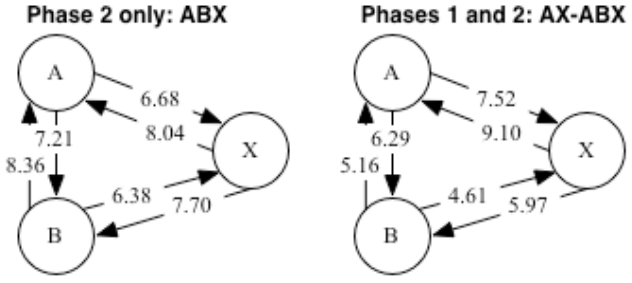

Figure 5: Mean final ratings for cue competition for causes in the ABX and AX-ABX conditions in Study 2. A and B are the competing causes, and X is the common effect.

General Discussion

These results replicate the well-established phenomenon of competition between causes (e.g., Van Hamme et al., 1993; Waldman & Holyoak, 1992) as well as the more controversial competition between effects (Shanks, 1991; Price &

Yates, 1993; Matute et al., 1996). Further, these studies show that this effect can be obtained with social behaviors and is not limited to biological or physical events.

The present study is the first to study cue competition for causes and effects by systematically exploring all possible directional links between causes and effects. Studies 1 and 2 demonstrated that cue competition between effects occurs on the weight from the redundant effect Y to the cause A, rather than on the weight from the cause A to the redundant effect Y. However, Study 2 seemed to indicate that cue competition between causes occurs on both the weight from the redundant cause B to effect X as well as on the weight from effect X to the redundant cause B.

The results clearly contradict causal model theory, which states that effects do not compete. As for the associative learning and the neural network models, the results support their prediction of competitive learning and the presence of cue competition between effects.

One advantage of the recurrent model is that it provides an account of cue competition for effects without the necessity of requiring diagnostic learning (effects precede causes). Further, the recurrent model predicts and the current results confirm that the extent of cue competition depends on the direction of the weight or relationship between cue and effect. Previous models would have been unable to make such a prediction.

The results for cue competition between effects are consistent with the idea that the weights are sensitive to the conditional probabilities between causes and effects. These studies show that cue competition between effects occurs on the weights from Y to A and not from A to Y after AX-AXY training. This makes sense in terms of conditional probability, in that, taking both Phase 1 and 2 into account, every time Y was presented, it was always preceded by A, and thus p(A|Y) is 100%. (note the weight from A to Y should encode this conditional probability). However, whenever A was presented, Y followed A only half the time (during Phase 2), and thus p(Y|A) is 50% (the weight from Y to A should encode this conditional probability). Thus, the asymmetry in cue competition between effects is consistent with the conditional probabilities.

However, with regard to cue competition for causes the same does not seem to apply. A conditional probability analysis should predict a similar asymmetry. Instead, the results indicate no asymmetry in the bi-directional associative links between the redundant cause and the common effect; cue competition occurs when reasoning both from B→X and from X→B. It is unclear why we do not get weight asymmetry for cue competition for causes. However, in further research, using different social stimuli, we did find the predicted asymmetry, suggesting that the current results may be specific to the current stimuli.

We note one other caveat. Research in this area has not separated the effects of learning from the judgment process. Future studies in cue competition should be designed to examine the various types of processes that participants may use to arrive at their judgments of contingency.

Feature- vs. Relation-Defined Categories: Probab(alistic)ly Not the Same

Abstract

Relational categories underlie many uniquely human cognitive processes including analogy, problem solving, and scientific discovery. Despite their ubiquity and importance, the field of category learning has focused almost exclusively on categories based on features. Classification of feature-based categories is typically modeled by calculating similarity to stored representations, an approach that successfully models the learning of both probabilistic and deterministic category structures. In contrast, we hypothesize that relational category learning is analogous to schema induction, and relies on finding common relational structures. This hypothesis predicts that relational category acquisition should function well for deterministic categories but suffer catastrophically when faced with probabilistic categories, which contain no constant relations. We report support for this prediction, along with evidence that the schemas induced in the deterministic condition drive categorization of novel and even category-ambiguous exemplars.

Relational and Feature-Based Categorization

Most mathematical models of human category learning start with the assumption that people represent categories as lists of features, and assign instances to categories by comparing the features of an instance to the features stored with the mental representation of the category (either a prototype or stored exemplars; e.g., Bruner, Goodnow, & Austin, 1956; Kruschke, 1992; Kruschke & Johansen, 1999; Nosofsky, 1992; Rosch & Mervis, 1975; Shiffrin & Styvers, 1997). Accordingly, most studies of human category learning in the laboratory investigate how people learn categories with exemplars consisting of well-defined (to the experimenter, at least) features.

In the real world, as some researchers have forcefully pointed out (e.g., Barsalou, 1993; Keil, 1989; Murphy & Medin, 1985; Rips, 1989; Ross & Spalding, 1994) categories are less often defined in terms of lists of features than in terms of *relations* between things: either relations between the features or parts of an exemplar (e.g., the legs need to be in a particular kind of relation to the seat in order for an object to serve as a chair), or relations between the exemplar and the user's goals (e.g., any object that affords sitting can, in some circumstances, be considered a chair), or relations between the exemplar and other objects in the world (e.g., what makes an object a "conduit" is a relation between that object and whatever thing flows through it, whether it be water, light, electricity, information, or karma). In spite of their importance in human cognition, comparatively little is known about how people learn relational categories.

Relational category learning is important because relational concepts (i.e., mental representations of relational categories) play an essential role in virtually all aspects of human thinking, including our ability to make and use analogies, problem solving, scientific discovery, and even aspects of perception (see, e.g., Gentner, 1983; Gentner et al., 1997; Green, 2004; Hesse, 1966; Holyoak & Thagard, 1995; Hummel, 2000). The utility of relational representations is that they permit generalization from a small (often as few as one or two) number of examples to a large (potentially infinite) number of new cases (as in the case of inferences generated through the use of analogies, schemas and rules; Gick & Holyoak, 1983; Pirolli & Anderson, 1985; Ross, 1987).

Relational concepts cannot be adequately represented as lists of features (as assumed by most current models of category learning), but instead must be mentally represented as relational structures such as schemas or theories (Gentner, 1983; Holland, Holyoak, Nisbett, & Thagard, 1986; Hummel & Holyoak, 2003; Keil, 1989; Murphy & Medin, 1985). This observation suggests that the operations governing relational schema induction may also underlie the acquisition of relational categories (see, e.g., Kuehne et al., 2000).

At least one theory of schema induction, Hummel and Holyoak's, 2003, LISA model, predicts that a schema induced from two or more examples retains (roughly) the structured intersection of what the examples have in common. For example, consider two analogous stories about love triangles. In the first, Abe loves Betty, but Betty loves Chad, so Abe is jealous of Chad; in the second Alice loves Bill, but Bill loves Cathy, so Alice is jealous of Cathy. Drawing an analogy between these stories maps Abe to Alice, Betty to Bill, and Chad to Cathy (along with the roles of the *loves* and *jealous-of* relations). The schema LISA induces from this analogy retains what the examples have in common, and de-emphasizes the ways in which they differ. For example, since the analogy maps males to females and vice versa, the resulting schema effectively discards the actors' genders, stating (roughly) "person1 loves person2 but person2 loves person3, so person1 is jealous of person3," where persons1…3 are generic people, rather than being specifically males or females (see Hummel & Holyoak, 2003).

Importantly, this intersection discovery process also takes place at the level of whole propositions. For example, if the second story contained a proposition stating that, as a

result of her jealousy, Alice was mean to Cathy, but the first story had no corresponding proposition, then LISA would simply drop this proposition in its entirety from the resulting schema.

If we assume that relational category learning is a process of relational schema induction, then this property of dropping unmapped propositions (i.e., unmapped relations) from the induced schema (i.e., category representation) leads to a counterintuitive prediction: If a relational category has a probabilistic structure, such that every member of the category shares some relations with every other member of the category, but there is no relation that *all* members share, then category learning should fail catastrophically. The reason is that the process of schema induction will drop any relation that is absent from any exemplar from the emerging schema. If every relation is absent from some exemplar (i.e., no relation is present in every exemplar), then schema induction will eventually drop every relation from the schema. By the end, the induced schema will be the empty set.

To clarify, consider a simple relational category with four exemplars, each with three relations chosen from the set r1, r2, r3 and r4 (for our current purposes it does not matter what r1…r4 are, only that they are relations of some sort). Let exemplar 1 (e1) contain the relations r1, r2 and r3. That is, e1 = [r1, r2, r3]. Similarly, let e2 = [r2, r3, r4]; e3 = [r1, r3, r4]; and e4 = [r1, r2, r4]. Note that mapping, for example, e1 to e2 results in a schema (s1,2) that contains relations r2 and r3 (which e1 and e2 share), but lacks r1 (which e1 possesses but e2 does not) and r4 (which e2 possesses but e1 does not): s1,2 = [r2, r3]. Mapping s1,2 onto, say, e3, produces a schema containing only r3, and mapping that schema onto e4 produces a schema containing no relations. The resulting schema is clearly not a useful basis for classifying exemplars as members of the category.

The point is that relational category learning is predicted to be extremely difficult when the categories have a strictly probabilistic structure (i.e., with no relation shared by all exemplars). By contrast, if there is even a single relation that is shared by all exemplars, then category learning should improve dramatically relative to the purely probabilistic case. Categorization performance should also improve dramatically, even with purely probabilistic categories, if the relational structure is replaced with a feature-based structure. Learning of feature-based categories is well known to be robust to probabilistic category structures, a fact that underlies prototype effects (e.g., Posner & Keele, 1968).

In summary, we predict a sharp dissociation between relational and feature-based category learning with respect to their robustness to probabilistic category structures: Both relational and feature-based categories should be learnable when they have a deterministic structure, even if only a single relation or feature reliably predicts category membership; similarly, feature-based categories should be learnable whether they have a deterministic structure or a probabilistic one. By contrast, relational categories should be extremely hard to learn from examples when those examples are presented in a probabilistic structure.

We tested this hypothesized dissociation between relational and feature-based category learning using a 2x2 design, in which relational vs. feature-based categories were crossed with probabilistic vs. deterministic category structures. In order to control all extraneous sources of potential effects, the same basic stimulus set was used in all four conditions; only the assignment of stimuli to categories varied.

Method

Subjects. 33 UCLA undergraduate students participated for course credit.

Instructions. Participants were read a cover story describing a computer manufacturer trying to determine the function of accidentally unlabelled computer chips. Subjects then engaged in a training phase followed by a transfer phase. During both phases, subjects were instructed to indicate the category to which the onscreen stimulus belonged by pressing one of two keys. The categories were labeled "math" chips and "graphics" chips.

Materials. On each trial, the subject saw an exemplar consisting of an octagon and a square, arranged on a fixed background designed to resemble a computer chip (see Figure 1). Each exemplar had both relational properties (e.g., octagon *bigger than* square) and featural properties (e.g., octagon of size 3).

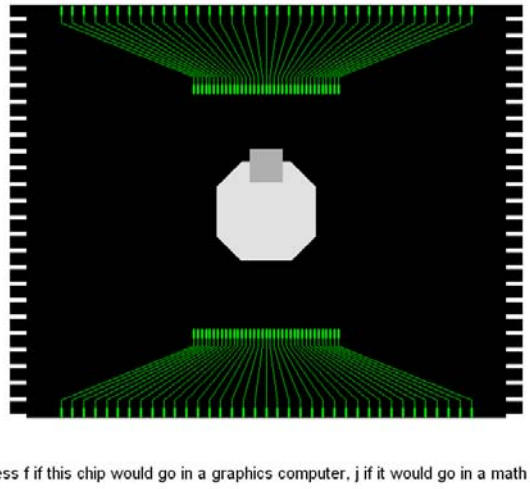

Figure 1: Example stimulus.

The properties of each exemplar were determined by an identical family resemblance category structure (see Table 1). The prototypes of the two categories were defined as (1,1,1,1) and (0,0,0,0), and distortions were made by chang-

ing the value of one or more dimensions to its opposite[1]. Each column in Table 1 represents an exemplar, and the particular value on each dimension (1 or 0) defines the value of a relation (in the relational condition) or a feature (in the featural condition) for each exemplar. The values for both the relational and featural properties are listed in Table 2. For example, the relational prototype with structure (1,1,1,1) would have an octagon *bigger, darker, above,* and *in front of* a square, while the prototype with structure (0,0,0,0) would be the exact opposite. The properties were set up so that using features could not result in learning to criterion in the relational condition, and using relations in the feature condition would also lead to sub-criterion responding.[2] Stimulus generation and display as well as response collection were done with a program written in Matlab.

Design. The experiment used a 2 (category structure: probabilistic vs. deterministic) X 2 (relevant property: features vs. relations) between-subjects design. The only difference between the conditions in terms of the stimuli used was that, in the deterministic condition, a single distorted exemplar from each category was not presented during training, so that one dimension was constant for all exemplars of a category. The choice of which dimension was held constant was counterbalanced across subjects.

Table 1: Family resemblance category structure. Each column represents an exemplar, and each row a dimension.

Category A					Ambiguous						Category B				
1	1	1	1	0	1	1	1	0	0	0	0	0	0	1	0
1	1	1	0	1	1	0	0	1	0	1	0	0	1	0	0
1	1	0	1	1	0	1	0	1	1	0	0	1	0	0	0
1	0	1	1	1	0	0	1	0	1	1	1	0	0	0	0

Procedure. During the training phase subjects classified only distorted exemplars of each category (depicted in the light gray columns of Table 2). All distortions for each category were shown in random order exactly once per block. Responses were followed by accuracy feedback, during which the exemplar remained on the screen. Subjects pressed the space bar to proceed to the next trial. The training phase continued until the subject responded correctly on at least seven out of eight trials for two consecutive blocks[3], or until they had finished 75 blocks (600 trials) without reaching this criterion.

Following the training phase, subjects were informed that they would be tested on chips for which feedback could not be given. During this transfer phase subjects classified all 16 possible exemplars, including the prototypes and ambiguous exemplars. Subjects completed five blocks, with each block showing all 16 exemplars in random order exactly once.

After the transfer phase, each subjects completed a questionnaire in which they were asked to write down the criteria they used to categorize the exemplars.

Table 2: Category definitions.

Relational categories

Exemplar	Relation	Exemplar	Relation
1	Bigger	0	Smaller
1	Darker	0	Lighter
1	Above	0	Below
1	In Front	0	Behind

Feature-based categories

Exemplar	Feature	Exemplar	Feature
1	O *size* 3	0	O *size* 2
1	O *shade* 4	0	O *shade* 3
1	S *size* 1	0	S *size* 2
1	S *shade* 1	0	S *shade* 2

Note: Prototype exemplars are shown with their defining properties on each dimension. In the relational condition, each dimension defines how the octagon (O) in the stimulus relates to the square (S). For the featural condition each dimension defines specific feature values.

Results

Training. Only 5 of the 7 subjects (71%) in the relational probabilistic (RP) condition learned to criterion within 600 trials. 25/25 subjects (100%) in the other conditions learned to criterion within the 600 trial limit. In the analyses that follow, the 2 subjects in the RP condition who never learned to criterion are treated as though they reached criterion on trial 601. Given that our hypothesis predicts that learning in the RP condition will be harder (and therefore take longer) than learning in the other conditions, this assumption is extremely conservative.

The mean number of trials to criterion is shown in Figure 2 for each condition. Subjects in the RP condition took more trials to reach criterion than those in the FD (featural deterministic), FP (featural probabilistic), and RD (rela-

[1] Note that the exemplars marked "Ambiguous" are equal distance between the two prototypes, having exactly two values different from each.

[2] In the relational condition, stimuli from different categories could have the same features (and stimuli from the same category could have different features) as long as the specified relations held; features were thus non-diagnostic. For the featural condition, the relations *in front* and *above* had no relevance to the category structure, and were pseudo-randomized. The relations *bigger* and *darker* were made irrelevant by choosing values such that the octagon was never smaller or lighter than the square (though it could be the same size, since only three sizes were used). See the Discussion section for further analysis of feature and relation values.

[3] This criterion level (87.5%) was selected because strategies involving tracking only one or two relations in the probabilistic condition would not meet the criterion level (both would result in 75% correct responding).

tional deterministic) conditions. A planned contrast comparing the RP condition to the other three revealed that this difference was statistically reliable ($p < 0.01$). There was also a significant main effect of category type (relational vs. featural, $F(1,33)=4.64$, $p < 0.05$). The main effect of category structure (deterministic vs. probabilistic) and the interaction were both marginally reliable ($0.05 < p < 0.15$).

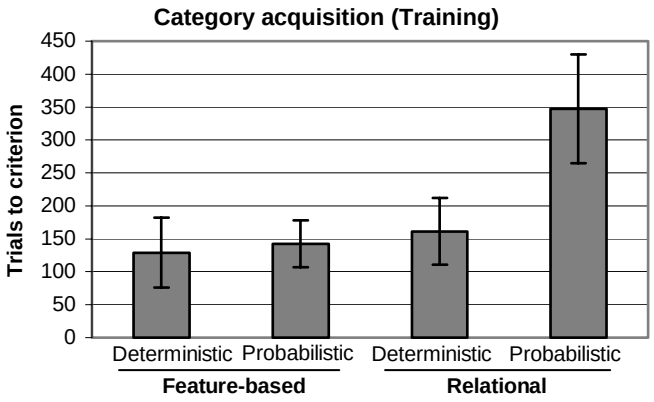

Figure 2: Average number of trials required by subjects in each condition to reach criterion during training.

Transfer. The key prediction for the transfer phase was that subjects in the deterministic condition would categorize exemplars based on whatever dimension was held constant during training. This prediction applied especially to the relational condition, which could not rely on holistic processing. To test this hypothesis we analyzed classification of the ambiguous exemplars, which were equidistant between the two prototypes. Subjects who used all category dimensions equally should be unsystematic in their classification of these ambiguous exemplars. By contrast, subjects who attend to a single dimension should classify ambiguous exemplars according to that dimension only (as detailed in Table 3). If a classification response for a dimension that was held constant during training matched the response pattern in Table 3, then +1 was scored for that response; classifications that did not match Table 3 response patterns were scored as -1. Under this scoring system, consistently responding to ambiguous exemplars in the direction predicted by the constant training dimension results in a positive score; consistently responding in the direction opposite the constant dimension results in a negative score; and unsystematic responding results in a score near zero.

Classification of ambiguous exemplars in accordance with the dimension that was constant during training was significantly above chance ($p < 0.01$). Breakdown into featural and relational conditions showed a non-significant trend for the relational condition to evoke classifications based on the constant training dimension more often than the featural condition (Figure 3).

Discussion

The results showed that acquisition of relational probabilistic categories takes significantly longer than acquisition of deterministic relational categories, or featural categories of any kind (probabilistic or deterministic). Importantly, the ease of acquisition in the deterministic relational condition shows that this effect is not due strictly to the relational nature of the task. Instead, the catastrophic failure represents an interaction between the relational nature of the stimuli and the probabilistic structure of the categories. This interaction is consistent with the hypothesis that relational category learning is a process akin to relational schema induction by intersection discovery: When the intersection is the empty set (as it is in the probabilistic condition but not the deterministic condition), relational category learning suffers markedly. By contrast, feature-based category learning is much more robust to the probabilistic category structure, presumably because feature-based category learning is not a process of relational schema induction; instead, as predicted by models of feature-based category learning, it may be that learning feature-based categories can be accomplished simply by cataloging and matching features.

Table 3: Classification of exemplars based on single dimensions

Exemplar	Dim 1	Dim 2	Dim 3	Dim 4
1 1 0 0	A	A	B	B
1 0 1 0	A	B	A	B
1 0 0 1	A	B	B	A
0 0 1 1	B	B	A	A
0 1 1 0	B	A	A	B
0 1 0 1	B	A	B	A

Note: Table entries indicate how each exemplar would be categorized by a subject who attended only to a single dimension (columns in the table). For example, a subject who attended only to the first dimension (Dim 1) would classify the first, second and third exemplars as As since their values on that dimension are all one, and B for the fourth, fifth and sixth exemplars (the values of which are zero on that dimension).

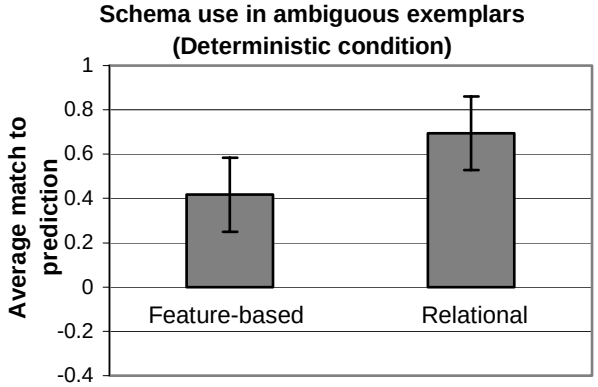

Figure 3: Average match to predicted classification pattern. Positive values indicate schema-based classification; zero corresponds to unsystematic responding.

The significant match of subjects' responses with single-dimension classification predictions in the deterministic condition also shows that subjects do preferentially use dimensions that are constant during training to classify novel and even category-ambiguous exemplars.

Is it possible to explain these results in other ways? One possibility is that rather than attending to the relations, subjects in the relational conditions may instead be tracking the feature values of certain dimensions. On this hypothesis, there is no schema induction going on in any condition; instead, responding is based on the values of particular features. This account obviates the need for a separate process to explain relational categorization.

However, analysis reveals that subjects tracking a feature of a single dimension would only classify 5/6 correct in the deterministic condition, and 2/3 correct in the probabilistic condition. Both of these values are below the 7/8 criterion, suggesting that subjects who reach criterion were not doing so by tracking a feature of a single dimension.

The possibility remains that subjects were tracking the values of multiple features or dimensions, although these seem unlikely strategies for a number of reasons. First, even when tracking the values of a single feature the subject must hold in mind three or four values and their associations with each category (for example, each size of the octagon and its corresponding category). Each additional feature or dimension would double the number of values necessary to track. This strategy does not seem plausible given the well-known limits on the capacity of working memory. Also, subjects' responses to the debriefing questionnaires in the relational conditions did not suggest such strategies were being used; instead, they generally reported the use of one or two relations as diagnostic, often along with some exception exemplars. Thus it seems more likely that subjects were indeed attending to the relations between the components of each stimulus rather than tracking feature values of those components.

Another hypothesis to explain the difference between the featural and relational conditions is that subjects were memorizing all the possible exemplars, and a difference in the number of distinct exemplars made the relational condition harder. This view must also hold that the deterministic conditions do not rely on such memorization, in order to explain the results. This view has some merit, though two factors reduce its likelihood.

First, the total number of distinct exemplars in the featural condition is not very different than the relational condition: 128 vs. 144. While this is a difference between the categories, it is difficult to ascribe the extra difficulty of the relational probabilistic condition to its having an extra 16 exemplars.

Second, although debriefing questionnaires did indicate subjects were memorizing some of the exemplars in the relational probabilistic condition, these were of very limited number (usually ~2 exemplars) and were memorized as exceptions to a more general classification rule. Thus while it remains a theoretically possible explanation, the "number of exemplars" view is not very compelling.

Preliminary analysis of the debriefing forms for subjects who learned to criterion in the relational probabilistic task suggest that what is learned is often a classification rule (such as might result from a schema induction process) along with a few memorized exceptions. Subjects often mentioned one or two relations in their classification rules; only one subject reported attending to all four dimensions; unsurprisingly, this subject was the only one who deduced the formal category structure (that is, that three out of four of the dimensions are necessary for category membership).

Subjects in the featural probabilistic condition also failed to show feature-tracking strategies in their debriefing questionnaires. Instead, their responses often showed a reliance on emergent properties of the stimuli such as high vs. low contrast. Questionnaires from the deterministic conditions tended to show a focus on the dimension that was constant during training, and mentioned particular features in the featural condition and relations in the relational condition. Thus subjects' explicit responses often fit well with the predictions about processing.

Why should relational categories rely on schema induction processes? One possibility is that feature-based categories tend to give rise to emergent properties, since their features are fixed at some value or limited range of values. However, it is much more difficult for emergent properties to arise in relational categories, because they can take on many different and overlapping values. The lack of emergent properties may explain the dependence of relational categorization on deterministic dimensions. This view is consistent with subjects' self-reported strategies.

Another interpretation of the present results is that people are either unwilling or unable to perceive, predicate and categorize patterns across four relations. This deficit may be due to working memory constraints, strategy choice, or low prior experience with similar situations. Studies of working memory suggest that we can hold about four chunks or role bindings in working memory (e.g., Halford, Wilson, & Phillips, 1998); holding four two-place relations exceeds this limit. It may be that people can learn some probabilistic relational categories with experience by recoding relations as features; others may be learned by dividing the probabilistic category into deterministic subcategories, or by perceiving a unifying causal relation for the entire category.

In conclusion, the results of the present experiment suggest that relational category learning relies heavily on finding common relations across exemplars. In contrast, feature-based category learning appears to function robustly whether common elements are present or not. These findings are consistent with the view that relational category learning is a kind of relational schema induction that depends on intersection discovery. Performance on the transfer trials also support this conclusion in that dimensions that were constant during training dominated classification of novel exemplars, even those that were category-ambiguous. Such findings suggest that relational category

learning may be fundamentally different from feature-based category learning, though more work is needed to distinguish these modes of category learning.

Abstract

Known theories of categorization operate under the assumption that most concepts are fundamentally similar. The current research argues that this assumption is unwarranted: Different types of concepts may differ in how they are represented and learned. We specifically focus on natural-kind and nominal-kind concepts, concepts that differ in their statistical structure. Natural kinds consist of highly redundant and intercorrelated features, whereas nominal kinds consist of isolated rules that do not correlate with other features. If these types of concepts are fundamentally different, they should exhibit important dissociations in how they are learned. Two learning regimes were contrasted: one in which participants were shown instances of the concept without being given a definition of the concept (implicit learning regime), and one in which participant were given a definition of the concept without being shown individual instances (explicit learning regime). Preschoolers and adults participated. The results show a strong dissociation between the two kinds of concepts in terms of acquisition, indicating that existing theories of categorization are incomplete.

Introduction

The ability to form categories by overlooking differences for the sake of generality is a critically important component of cognition. While the importance of concepts and categories is widely accepted, a number of puzzling questions remain unanswered. How do categories arise? Which processes underlie categorization? And how are categories represented in the cognitive system?

Several influential approaches have emerged in an attempt to answer these questions. According to the "classical view," categories are represented by sets of features that are individually necessary and jointly sufficient to determine category membership (Bruner, Goodnow, & Austin, 1956; Vygotsky, 1986/1934; for a review see Smith & Medin, 1981). For example, the concept *prime number* includes two features: an integer, and no remainder when divided by one or by itself. Each feature is necessary and they are jointly sufficient to determine whether or not a number is a prime.

By the 1980s, the classical view came under severe attack for its inability to predict and account for several key phenomena in the study of concepts, such as, for example, the gradedness of category membership. (Mervis & Rosch, 1981; see also Murphy, 2002, Smith & Medin, 1981, for extensive reviews).

With the demise of the classical view, two theoretical approaches to conceptual development have emerged: the naïve-theory approach and the similarity-based approach. The naïve-theory approach argues that even if there are no truly defining features, features differ in their conceptual centrality, this centrality being often determined by a feature's causal status (Medin, 1989; Gelman & Coley, 1991; Keil, Smith, Simons, & Levin, 1998). For example, apples and basketballs are round, but the feature "roundness" is more central for basketballs than it is for apples.

On the contrary, the similarity-based approach suggests that categorization decisions are made on the basis of similarity between a to-be-categorized entity and existing categories (see Murphy, 2002; Sloutsky, 2003, for reviews). Categories could be represented as best examples or prototypes (Posner & Keele, 1968, Rosch & Mervis, 1975) or as sets of encountered exemplars (e.g., Nosofsky, 1986, 1992). In the former case, an entity is categorized as A if it is similar to A's prototype, whereas in the latter case an entity is categorized as A if it is similar to individual exemplars of A encountered previously.

Despite the differences among these theoretical approaches, there is an important commonality – they implicitly assume that all (or at least most the concepts) concepts are fundamentally the same, and therefore, that concepts have to be learned and represented in the same or a similar way.

However, it is possible that there are different classes of concepts that give rise to different types of representation. The particular distinction considered here can be mapped onto the normative distinction between *natural kinds* and *nominal kinds* (Kripke, 1972; see also Keil, 1989, for a review). Natural kinds refer to classes of entities that exist in nature (e.g., *bird*), and nominal kinds refer to more arbitrary groupings based on a small set of necessary and sufficient properties (e.g., *triangle, acceleration*).

Natural kinds may differ in several ways from nominal kinds. However, the difference highlighted in the current experiments pertains to the difference in their statistical

structure. Natural kinds have a rich correlational structure, meaning that the relevant features correlate among each other. For example, creatures that lay eggs also have feathers and fly. Nominal kinds, on the other hand, lack such correlations among relevant features. They are based instead on an isolated rule. For example, accelerated motion does not have any common features with other motions except the change in velocity or the change in vector of the moving body.

It seems that the classical view of categorization considered nominal kinds as most representative concepts, whereas the similarity-based positions considered natural kinds as the most representative ones. The current study asks whether the normative distinction between natural and nominal kinds is accompanied by a psychological distinction between these two types of concepts. If true, such psychological distinction should manifest itself in how natural kinds and nominal kinds are represented and learned. The goal of this research is to examine dissociations in learning of natural and nominal kinds.

Statistical Structure of Concepts

To reiterate, natural-kind concepts often have multiple correlations among features of category members. Nominal kinds, on the other hand, are typically based on a small set of features uncorrelated with other features. It could be said then that natural kinds are statistically dense, embedded in multiple redundancies, whereas nominal kinds are statistically sparse, that is based on a single rule embedded in irrelevant variance.

Because natural kinds are statistically dense, it is possible that natural kinds are acquired spontaneously and do not require explicit training. Even infants are sensitive to multiple correlations and can spontaneously acquire categories based on multiple correlations. (e.g., Younger, 1993). Therefore, is likely that the mere exposure to instances of a natural kind could suffice for the acquisition of the concept. For example, infants may learn to group dogs together after seeing a variety of dogs (Quinn, Eimas, & Rosenkrantz, 1993). The basis for this learning is extraction of statistical information from a set of exemplars (Mareschal & Quinn, 2001). In fact, explicit training of a natural-kind category may hurt the acquisition of the natural kind. Billman and Knuston (1996) showed that in an unsupervised-learning setting, adults could learn the concept that was based on redundant relations, while failing to learn the concept when it was based on an isolated or orthogonal relation.

Nominal kinds are statistically sparse, meaning that they lack redundancy, and that only a limited set of features or feature relations is relevant. Because only a small portion of total information is relevant for the membership in a concept, it might be difficulty for the learner to spontaneously determine what is relevant, without having explicit instruction. This might be especially true for relational concepts, those that are based on a relation among features, not the features themselves (e.g., the concept of *ratio*). There are few reasons to believe that mere exposure to a limited set of instances would result in an acquisition of a relational concept. On the contrary, even feedback-based learning of relational concepts proved to be a challenge (e.g., Bruner, et al., 1956).

Based on these considerations, we hypothesize that there might be an acquisitional dissociation between natural and nominal kinds, with the former requiring unsupervised exposure (i.e., implicit learning regime), and the latter requiring an explicit instruction about the relevant rule (i.e., an explicit learning regime).

Overview of Experiments

In the three reported experiments, we systematically manipulated two factors: the type of the concept to be learned ("natural kind" vs. "nominal kind") and the learning regime (implicit learning regime vs. explicit learning regime). Preschool children (Experiment 1) and adults (Experiment 2 and 3) participated in the four resulting conditions: implicit or explicit learning of a concept that mimics natural kinds, and implicit or explicit learning of a concept that mimics a nominal kind.

For both kinds of concepts, the same animal-like artificial stimuli were created, such that none of the single features were predictive of the category membership. Only the relations between features mattered. Similar to natural kinds in the real world, the natural kind of the current experiment was based on multiple correlations among features (e.g., creatures that had a dark body also had a long tail and lots of wings). Conversely, in the nominal kind of the current experiment only one, arbitrary selected, relation was predictive of category membership.

In the implicit learning regime, the learners were presented with instances of the target category without being told the defining rule of the category. Conversely, in the explicit learning regime, the learners were given the defining rule of the category without being shown specific instances.

We predicted an interaction between learning regime and kind of concept. The concept that is based on redundant relations (i.e., "natural kind") should be best learned in the implicit learning regime, and the concept that is based on an isolated relation (i.e., "nominal kind") should be best learned in the explicit learning regime.

Experiment 1

The goal of the first experiment was to examine the acquisition of natural-type and nominal-type concepts under different learning regimes by young children.

Method

Participants Participants were 61 5-year-olds (32 girls and 29 boys), recruited from suburban middleclass preschools. The mean age in each condition (natural/implicit, natural/ explicit, nominal/implicit, nominal/ implicit) in months was 58.1 (*SD* = 4.6), 61.9 (*SD* = 2.7), 60.4 (*SD* = 5.2), and 60.3 (*SD* = 4.7), respectively. Additional 28 children were tested

(n = 8, 5, 7, and 8 in the respective conditions) and omitted from the sample because their performance in the catch trials did not meet the criterion (see Procedure).

Stimuli The stimuli were colorful drawings of unfamiliar animals presented on a computer screen. Each instance had the following six parts: a body, antennas, horizontal and vertical wings, a tail, and buttons on the body (Figure 1). These six parts could vary in at least one characteristic. They could vary in size (e.g., long or small tail), in shade (e.g., dark or light body), or in number (e.g., few or lots of buttons).

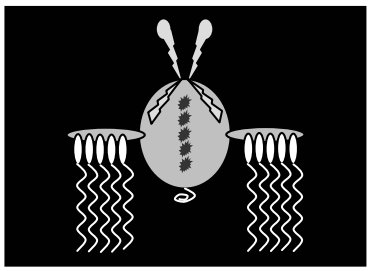

Figure 1: Example of the stimuli.

Two types of categories were created, one that included multiple correlations of features (i.e., they approximated a natural kind), and the other that were based on a single arbitrary selected relation (i.e., they approximated a nominal kind). Each type of category consisted of a target category and a contrasting category. Table 1 shows examples of items to illustrate how stimuli differed between natural and nominal kinds, and between target category and contrasting category.

For the natural kind, the sizes, shades, and number of parts correlated systematically. In the target category, a light body had light antennas, short horizontal wings, a short tail, few vertical wings, and few buttons. And a dark body had dark antennas, long horizontal wings, a long tail, many vertical wings, and many buttons. In the contrasting category the correlations were reversed. For example, a light body went with dark antennas, short horizontal wings, a long tail, few vertical wings, and many buttons. No single feature was predictive of the category.

For the nominal kind, only the number of parts mattered, while the correlations among sizes and shades were varied randomly. In the target category, there were *more* buttons than tails and vertical wings together, and in the contrasting category, there were *fewer* buttons than tails and vertical wings together. The numbers of buttons, tails, and vertical wings were chosen in such a way that neither the number of a single part nor the correlation between two of the parts were predictive. This ensured that no other information (e.g., difference in quantity) was redundant with the rule.

An additional set of stimuli was created that functioned as catch items. These items were from the contrasting category but with very salient changes. They had a diamond shaped body, no buttons, and no horizontal wings.

Table 1: Structure of Exemplar Items Used in Experiments 1 and 2

	Target Cat.		Contrasting Cat.	
	Item 1	Item 2	Item 1	Item 2
Natural Kind				
Parts				
Body	light	dark	light	dark
Antennas	light	dark	dark	light
Horiz. wings	short	long	short	long
Tails	short	long	long	short
Vert. wings	few	many	few	many
Buttons	few	many	many	few
Nominal Kind				
Parts				
Tails	1	3	3	5
Vert. wings	4	2	4	6
Buttons	7	9	5	9

Note. For the nominal kind, the numbers refer to the actual number of a particular part for the nominal kind (e.g., 1 = one tail).

Procedure The cover story presented to children involved the creature Fritz who lives on planet Elbee and who would like to get a pet. Pets on planet Elbee are called Ziblets and come from a magical store that carries both pets and dangerous wild animals. Children's task was to determine whether or not an animal from this magical store is a Ziblet.

The procedure had two phases: a training phase and a testing phase. In the training phase, children were given information about Ziblets (target category in Table 1). In the implicit learning regime, they were shown 24 pictures of Ziblets, presented one by one. They were told: "I will show you the Ziblets that other families on planet Elbee have as pets. Can you look at them and try to remember them?" In the explicit learning regime, children were presented with the defining rule. They were either told (for the natural kind) "A Ziblet with a dark body has dark antennas, long horizontal wings, a long tail, one or two short vertical wings and two or three light buttons; and a Ziblet with a light body has light antennas, short horizontal wings, a short tail, four or five long vertical wings and five or six dark buttons", or they were told (for the nominal kind) "For a Ziblet, the number of buttons is smaller than the number of tails and vertical wings together". Each separate part mentioned in the rule (e.g., a long tail) was depicted on the computer screen.

The testing phase was identical in both learning regimes. Sixteen testing trials were presented in random order, half of them being instances of the target category (Ziblets) and half of them being instances of the contrasting category (Non-Ziblets). Children's task was to determine whether an

instance is a Ziblet or not. Six catch trials followed intermixed with instances of the target category. To be included in the study, children had to reject four of the catcher trials.

Results and Discussion

Accuracy scores were calculated for each participant by subtracting the number of correctly accepted Ziblets from the number of incorrectly accepted Non-Ziblets and transforming the difference into a proportion. An accuracy score of zero (i.e., no difference between proportion of hits and proportion of false alarms) would be expected by chance.

Figure 2 shows the mean accuracy scores for each condition. A 2 (concept: natural, nominal) by 2 (learning regime: implicit, explicit) between-subjects ANOVA revealed a significant interaction ($F(1,53) = 14.46$, $p < .001$), with the mean accuracy scores being above chance in the conditions natural/implicit ($t(15) = 4.07$, $p < .01$) and nominal/explicit ($t(15) = 3.2$, $p < .01$) but not in the conditions natural/ explicit and nominal/implicit.

An analysis of individual pattern of responses corroborated this trend. Eleven children in the natural/implicit condition (69%) and 12 children in the nominal/explicit condition (75%) had an accuracy score above 0.20. Conversely, only 5 children in the natural/explicit condition (31%) and only 3 children in the nominal/implicit condition (23%) had an accuracy score above 0.20.

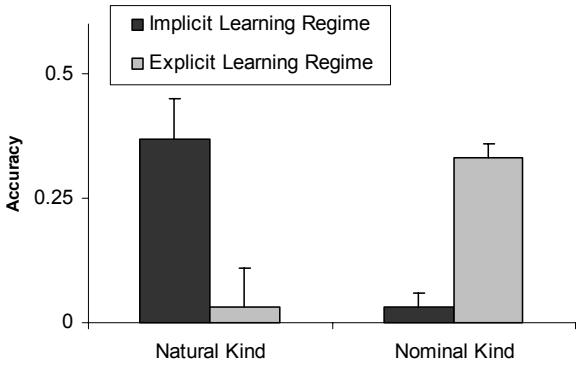

Figure 2: Accuracy Scores for Children.
Error bars represent standard errors.

In short, as predicted, children could learn the natural-type concept in the implicit learning regime, but not in the explicit learning regime; and they could learn the nominal-type concept in the explicit learning regime but not in the implicit learning regime. These findings cannot be due to differences in stimuli, as the same cartoon animals were used for both natural and nominal kinds. Furthermore, the findings cannot be due to differences in procedure, given that the learning regime for the natural kind (either implicit or explicit) was closely matched with the learning regime for the nominal kind.

These results reveal an important dissociation: while the implicit learning regime favored acquisition of concepts resembling natural kinds, the explicit learning regime favored acquisition of concepts resembling nominal kinds, thus supporting the contention that there is a psychological distinction between natural kinds and nominal kinds.

Experiment 2

The goal of this experiment was to extend the findings of Experiment 1 to adult participants. Adults participated in the same four conditions that were used for children in Experiment 1: natural/implicit, natural/explicit, nominal/ implicit, and nominal/explicit.

Method

Participants Participants were 54 introductory psychology students at a large mid-western university who participated for class credit. Additional nine adults (two or three in each condition) were tested and omitted from the sample because their performance in the catch trials did not meet the criterion (see Procedure).

Stimuli The stimuli were identical to the ones used in Experiment 1.

Procedure Adults were asked to learn about creatures called Ziblets in order to distinguish them from creatures that are not Ziblets. In the implicit learning regime, they were presented with 24 instances and asked to remember them. In the explicit learning regime, they were given the same defining rule that was presented to children. Again, no instances were presented; only pictures of the parts accompanied the rule.

Thirty-two testing trials followed in which instances were presented on the screen, and adults had to determine whether they see a Ziblet or not. Half of the instances were from the target category (Ziblets) and half of them were from the contrasting category (Non-Ziblets).

Eight catch trials followed intermixed with three trials from the target category. To be included in the study, adults had to respond correctly in at least 6 catch trials. At the end of the procedure, adults were asked to give a verbal description of the difference between Ziblets and other animals presented on the screen.

Results and Discussion

Mean accuracy scores are presented in Figure 3 (with standard error as error bars). A 2 (concept: natural, nominal) by 2 (learning regime: implicit, explicit) between-subjects ANOVA revealed a significant effect of learning regime ($F(1,50) = 13.15$, $p < .01$) with accuracy scores being higher in the explicit learning regime ($M = 0.57$, $SD = .45$) than in the implicit learning regime ($M = 0.23$, $SD = .34$), and a significant interaction ($F(1,50) = 11.9$, $p < .01$). When presented with the natural kind, participants performed above chance in both learning regimes ($t_{implicit}(13) = 5.3$, $p < .001$; $t_{explicit}(13) = 3.68$, $p < .01$), but when presented with

the nominal kind, they performed above chance only in the explicit learning regime ($t(10) = 6.12$, $p < .001$).

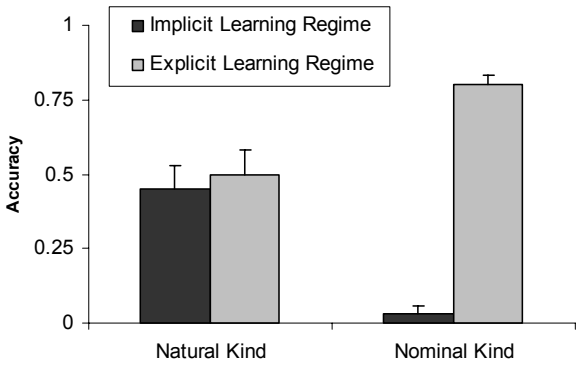

Figure 3: Accuracy Scores for Adults.
Error bars represent standard errors.

Adults' verbal responses were analyzed in terms of whether or not they contained the defining rule. For the natural kind, a response was coded as correct when the statement included at least one of the correlations. For the nominal kind, a response was coded as correct when the statement included the numerical relation. Table 2 shows the pattern of results. As expected, adults could verbalize the defining rule of the nominal kind in the explicit but not in the implicit learning regime. For the natural kind, even though adults' categorization accuracy did not differ as a function of learning regime, their verbal responses did. Only three the adults could verbalize the rule of natural kinds in the implicit learning regime whereas seven adults could verbalize the rule in the explicit learning regime[1].

Table 2: Number of Correct Verbal Statements
(Percentage correct in parentheses).

	Concept	
Learning Regime	Natural	Nominal
Implicit	3 (21%)	0
Explicit	7 (50%)	8 (73%)

Overall, learning of nominal kinds in adults exhibited tendencies similar to those in young children: participants ably learned the concept when presented with the defining rule of the concept, and they performed poorly when they were presented with instances of the category.

At the same time, unlike young children for the natural-kind concept, adults performed equally well under different learning regimes. This was surprising, given that the rule of the natural concept was rather lengthy, involving statements about the characteristics of six parts. We content that real natural kinds involve more than six simple correlations, thus making explicit learning of real natural kinds more difficult than explicit learning of current categories. This contention, however, remains speculative, and it will be examined in future research.

[1] The finding that some adults failed to verbalize the correct rule even in the explicit learning regime may be an artifact of the procedure. Instead of describing the difference between Ziblets and Non-Ziblets, a large majority of the adults described the difference between test items and catch items.

Experiment 3

The goal of this experiment was to document that the dissociation found in Experiments 1 and 2 is not limited to the particular nominal kind used in those experiments. Recall that the nominal kind used in Experiments 1 and 2 was based on a mathematical relation – a relation that may differ considerably from the correlations relevant for the natural kind. This difference was minimized in Experiment 3 by using the same target category that was used for the "natural kind" in the previous experiments. The contrasting category was new. It was constructed in such a way that only one correlation – rather than multiple correlations – was violated. To distinguish between target category and contrasting category, adults had to keep in mind all correlations. Therefore, the category to be learned was statistically sparse (all correlation mattered, no redundancy was present) without differing in content form the correlations of the "natural kind".

Method

Participants A new group of 28 students participated in this experiment (14 in the implicit learning regime, and 14 in the explicit learning regime). Additional 3 adults were tested and omitted from the sample because their performance in the catch trials did not meet the criterion.

Stimuli The stimuli of the target category were identical to the ones used in Experiments 1 and 2. Table 3 shows in abstract notation the characteristics of the contrasting category (Non-Ziblets) used in this experiment. These items differ from the Ziblets in only one of the correlations, rather than in all three correlations.

Table 3: Exemplar Items of the Contrasting Category used in Experiment 3

	Contrasting Category					
	Item	Item	Item	Item	Item	Item
Parts	1	2	3	4	5	6
Body	0	1	1	1	1	1
Antennas	1	0	1	1	1	1
Horiz. wings	1	1	0	1	1	1
Tails	1	1	1	0	1	1
Vert. wings	1	1	1	1	0	1
Buttons	1	1	1	1	1	0

Note. The numbers refer to the values of the respective characteristics (1 = light, small, or few; 0 = dark, large, or many). The target category is the same as in Experiment 2 (shown in Table 1)

Procedure The procedure was identical to the procedure used for the natural-kind concept in Experiment 2. Participants were presented either with the implicit or the explicit learning regime.

Results and Discussion

Mean accuracy scores were calculated for each learning condition. A significant difference was found ($t(31) = 3.76$, $p < .001$), with adults in the implicit-learning condition performing worse than adults in the explicit-learning condition (implicit: $M = 0.17$, $SE = .05$; explicit: $M = 0.44$, $SE = .06$). These results further indicate that the dissociation between natural kinds and nominal kinds reflects the structure of the to-be-learned categories rather than the property of the particular relation used in Experiments 1 and 2.

General Discussion

The results reported here support a psychological distinction between concepts that differ in their statistical structure. Concepts that are based on highly redundant features were best learned through an implicit learning regime (especially for children); and concepts that are based on non-redundant features were best learned through an explicit learning regime. The latter findings applied whether the concept was based on a mathematical relation (Experiment 2) or on a set of correlations between two features (Experiment 3). This suggests that the dissociation in acquisition reflects the statistical structure of the category rather than the particular relation.

Though not directly investigated in these sets of experiments, we argue that statistically dense concepts resemble natural kinds, while statistically sparse concepts resemble nominal kinds. It is likely then that natural kinds (e.g., the concept of *bird*) require a different learning environment than nominal kinds (e.g., the concept of *acceleration*). Furthermore, it is possible that this learning dissociation reflects itself in the way the concepts are represented. For example, it is possible that effects of gradedness are more likely to be found with natural kinds than with nominal kinds.

Finding dissociation in learning between different types of concepts indicates that a theory of categorization is incomplete if it pertains only to one kind of concept. A more complete account would address the processes of categorization for both natural and nominal kinds.

Visual Imagery in Deductive Reasoning: Results from experiments with sighted, blindfolded, and congenitally totally blind persons

Abstract

We report three experiments on visual mental imagery in deductive reasoning. Reasoning performance of sighted participants was impeded if the materials were easy to envisage as visual mental images. Congenitally totally blind participants did not show this visual-impedance effect. Blindfolded participants with normal vision showed the same pattern of performance as the sighted. We conclude that irrelevant visual detail can be a nuisance in reasoning and impedes the process.

Introduction

Various sorts of evidence are compatible with the conjecture that visual mental imagery is a vital part of human cognition, including the famous studies of the mental rotation and the mental scanning of images (Shepard & Cooper, 1982; Kosslyn, 1980). The aim of the present paper, however, is to show that visual mental imagery is *not* necessary in reasoning. It can even be a nuisance in reasoning and impedes the process. The article is motivated by the distinction between visual and spatial representations and processes that has been introduced by Ungerleider and Mishkin (1982). In addition, the article is motivated by studies showing that congenitally totally blind persons are as good as sighted in the construction and application of spatial representations (e.g. Kerr, 1983), but differ from sighted people in their use visual images.

The paper begins with a brief summary of previous findings on imagery and reasoning. We focus on deductive reasoning, in which the truth of the premises ensures the truth of the conclusion. We then outline our hypothesis regarding the connection between visual images, spatial representations, and congenital blindness. We report three experiments that test this hypothesis. Finally, we draw some general conclusions about visual imagery, spatial representations, and reasoning.

An influential study of imagery and deductive reasoning was carried out by DeSoto, London, and Handel (1965), who investigated so-called three-term series problems, such as "Ann is taller than Beth.", "Cath is shorter than Beth", "Who is tallest?" and argued that reasoners represent the three individuals in a visual image, and then "read off" the answer by inspecting the image. There are several other authors who argued in the same vein (e.g. Huttenlocher, 1968; Shaver, Pierson, & Lang, 1976; Clement & Falmagne, 1986). Other authors did not find evidence that imagery plays a role in reasoning (e.g. Sternberg, 1980, Richardson, 1987; Johnson-Laird, Byrne, & Tabossi; 1989; Newstead, Pollard, & Griggs, 1986). In Knauff and Johnson-Laird (2000; 2002) we argued that a possible resolution of the inconsistency in the previous results is that these studies have overlooked the distinction between visual images and spatial representations (e.g. Ungerleider & Mishkin, 1982; Logie, 1995; Smith et al., 1995). We conducted a series of experiments to test this hypothesis. We initially accomplished rating studies to identify a set of verbal relations that varied in the ease of constructing visual images and spatial representations from it. Their results yielded three sorts of verbal relations:

1. *visuospatial relations* that are easy to envisage visually and spatially; e.g. above – below;
2. *visual relations* that are easy to envisage visually but hard to envisage spatially, e.g. cleaner – dirtier;
3. *control relations* that are hard to envisage both visually and spatially, e.g. smarter – dumber

From the three sorts of verbal relations we constructed a set of three-term- and four-term-series problems. In three experiments, visual relations such as *cleaner* and *dirtier* significantly impeded the process of reasoning in comparison with control relations such as *smarter* and *dumber*. In contrast, visuospatial relations, such as *front* and *back*, which are easy to envisage visually and spatially, speeded up the process of reasoning in comparison with control relations (Knauff & Johnson-Laird, 2002). In a subsequent neuroimaging study (fMRI) we showed that in the absence of any correlated visual input, all types of reasoning problems evoke activity in spatial areas of the brain (right superior parietal cortex, and bilaterally in the precuneus), but that only the problems based on visual relations also activated early visual areas corresponding to V2 (Knauff, Fangmeier, Ruff, & Johnson-Laird, 2003). We explained the findings by an interplay of visual images and spatial representations. For example, given the premises:

The cat is above the ape.
The dog is below the ape.

the participants construct a spatial array representing the relative positions of the three individuals:

cat
ape
dog

They evaluate a possible conclusion by checking whether it holds in the representation. Perhaps the ability to envisage spatial representations is a precursor to many forms of abstract reasoning (Johnson-Laird, 1996). Likewise, relational terms that lead naturally to spatial representations should speed up the process of reasoning. In contrast, a visual relation, such as *dirtier*, may elicit irrelevant visual detail. One imagines, say, a cat caked with mud, but such a representation is irrelevant to the transitive inference. It takes additional time to replace this vivid image with one in which dirtiness is represented in degrees. In other words, the visual relations, which are hard to envisage spatially, lead to a mental picture, but the vivid details in this picture impede the process of thinking.

If visual relations impede reasoning in sighted people, what happens if congenitally totally blind people reason with the same materials? In the last two decades, comparisons between blind and sighted people have been made on a large variety of visuospatial tasks, involving mental scanning, mental rotation, memory for paths and words, etc. (e.g. Kerr, 1983; Marmor & Zaback, 1976; Zimler & Keenan, 1983). They always reported the same results: people who are blind from birth are able to envisage abstract spatial arrangements, but unable to envisage visual mental images. Most of the explanations rely on the distinction of two different neural pathways associated with the processing of "what" and "where" information (Ungerleider & Mishkin, 1982). The distinction is well-established in numerous fields of cognitive science (e.g. Kosslyn, 1994; Landau & Jackendoff, 1993), and is supported by investigations with brain damaged patients (e.g., Newcombe, Ratcliff, & Damasio, 1987), neuroimaging studies (e.g., Smith et al., 1995), and experiments on visual and spatial working memory (c.f. Logie, 1995).

The "what" and "where" distinction in mental imagery has also been studied with congenitally blind participants. Vecchi (1998) conducted experiments in the dual-task paradigm with participants who were blind from birth and report that mental imagery can rely on purely spatial representations without a visual component. In a PET study, Büchel, Price, Frackoviak, and Friston (1998) demonstrated that congenitally blind people show task-specific activation in parietal association areas, whereas blind participants who lost their sight after puberty show additional activation in the primary visual cortex in the same task (Braille reading). Luzzatti et al. (1998) in a case study showed that visual and spatial imagery can be differentially impaired after brain injuries. All these studies clearly show that visual and spatial imagery are functionally independent processes which must rely on different neural systems.

What does that mean for the hypothesis that the ability to envisage spatial representations is a precursor to reasoning, but visual imagery can impede the process? The results concerning visual and spatial imagery in the congenitally blind motivate the following hypothesis:

Relations that elicit visual images containing details that are irrelevant to an inference should impede the process of reasoning in sighted people. They, however, should not hinder the reasoning of congenitally totally blind people, because they are able to construct spatial representations without being sidetracked by irrelevant visual images.

The aim of the following experiments is to test this hypothesis. In Experiment 1 sighted students solved three-term-series problems with the three sorts of verbal relations, in Experiment 2 people who were blind from birth, and in Experiment 3 sighted people who were blindfolded to remove any visual input.

Experiment 1: Sighted Participants

In our previous experiments (Knauff & Johnson-Laird, 2000; 2002) the reasoning problems were presented visually as sentences on the screen. The aim of the first experiment was to replicate the visual-impedance effect with sighted people but with an auditory presentation of the materials.

Participants. We tested 24 sighted undergraduate students from the University of Oldenburg (mean age 22.7; 18 female, 5 male), who received a course credit for their participation.

Materials. The experiment used the set of verbal relations that has been identified in Knauff and Johnson-Laird (2000; 2002). The three sorts of relations were:

1. *visuospatial relations:* above – below, front – back
2. *visual relations:* cleaner – dirtier, fatter — thinner
3. *control relations:* better — worse, smarter – dumber

From these verbal relations we constructed a set of three-term series problems which all concerned the same terms (*dog*, *cat*, *ape*). Here is an example of a problem with a valid conclusion:

The dog is cleaner than the cat.
The ape is dirtier than the cat.
Does it follow:
The dog is cleaner than the ape?

All sentences of the reasoning problems were recorded as audio files, edited for similar length and normalized for loudness and peak gain. Half of the problems had valid conclusions and half had invalid conclusions. The participants were told to evaluate whether the conclusion followed from the premises. In the example, cleaner and dirtier are used once in each premise, and cleaner occurs in the conclusion. But, in the experiment as a whole, each relation and its converse occurred equally often in each premise and in the conclusion.

Design. The participants acted as their own controls and evaluated 8 inferences of all three sorts (visuospatial, visual, and controls), making a total of 24 three-term series problems. The relations in these problems were those given above. The problems were presented in a randomized order over the set of participants.

Procedure. The participants were tested individually in a quiet room, and they sat at a PC that administered the experiment. The reasoning problems were presented in auditory format via headphones. The participants were told to evaluate whether or not the conclusion followed necessarily from the premises. They were instructed to respond as accu-

rately and quickly as possible. They made their response by pressing the appropriate key on the keyboard, and the computer recorded their response and latency. Prior to the experiment, there were four practice trials.

Results and Discussion. Table 1 presents for all three of our experiments the percentages of correct conclusions and their mean latencies for the different sorts of relational inferences. The present inferences were relatively easy (92.5% correct overall) and there was no significant difference between accepting valid conclusions (94.5% correct) and rejecting invalid conclusions (95.2% correct). Thus, we pooled the results from these conditions.

The MANOVA for dependent measures on the accuracy data revealed a reliable difference across the three sorts of problems, $F(2, 46) = 5.30$, $p < .01$. There was also a difference in the mean number of correct responses between the visual problems and the control problems, $F(1, 23) = 6.57$, $p > .02$, and the (not orthogonal) contrast between visuospatial and visual problems was significant, $F(1, 23) = 6.57$, $p < .02$. The response latencies also showed the predicted trend (visual relations resulted in longer response latencies than control problems and reasoning with these problems in turn took longer than with visuospatial problems), but the main effect across the three sorts of problems was statistically not significant, $F(2, 46) = .53$, $p > .6$.

The main goal of the experiment was to test a new experimental setup that can be used with the blind people later on. The experiment was successful in showing that the visual-impedance-effect also appears with the auditory presentation of the materials. Thus, we can use the same experimental setting in the later studies. A second corollary from the findings is that the visual-impedance effect does not depend on the visual presentation of the materials. It rules out that the impedance is simply due to interference between the visual process of reading the premises and conclusions and the mental activity of envisaging a visual mental image to solve the problem. Instead, the findings again emphasize the importance of distinguishing between visual and spatial representations. Visual relations such as *fatter* and *thinner* impeded the process of reasoning in comparison with control relations such as *smarter* and *dumber*. In other words, the visual relations, which are hard to envisage spatially, lead to a mental picture, but the vivid details in this picture impede the process of thinking.

Experiment 2: Congenitally Totally Blind Participants

This experiment directly tests the hypothesis that the visual relations do not impede the reasoning of congenitally totally blind people, because they are able to construct spatial representations without being sidetracked by irrelevant visual images.

Participants. We tested 10 congenitally totally blind participants (mean age 24.8; 7 female, 3 male). According to the German Law, a person is congenially totally blind, if she or he has less than 5% of normal vision and got blind before the age of 2. Most of the participants were blind from birth due to retinopathy of prematurity. The participants we recruited from two self-helping groups for the blind. All participants gave their informed consent prior to the participation in the study.

Materials, Design, and Procedure. The materials and the design were identical to Experiment 1. The instructions were read to the participants by one of the experimenters. The participants were tested individually in a quiet room at the institutions, and they sat in front of a Laptop that administered the experiment. Except of the two keys associated with "yes" and "no" and the spacebar, all other keys were removed from an external keyboard.

Results and Discussion. The second row of Table 2 presents the mean latencies and correct responses to the three sorts of relational inferences. Overall, the blind responded correctly to 76.2 % of the inferences and again there was no significant difference between accepting valid conclusions (76.7% correct) and rejecting invalid conclusions (75.8% correct). Hence, we pooled the results from these conditions.

The ANOVA showed no significant difference in reasoning accuracy between the three sorts of problems, $F(2, 18) = .36$, $p > .70$, and none of the single contrast revealed a significant difference (visual vs. control: $F(1, 9) = 2.38$, $p > .63$; visuospatial vs. control: $F(1, 9) = .70$, $p > .79$; visuospatial vs. visual: $F(1, 9) = .74$, $p > .41$). In the response latencies there was also no difference between the three sorts of problems, $F(2, 18) = .928$, $p > .41$, and not one of the single contrast showed a significant difference (visual vs. control: $F(1, 9) = 1.51$, $p > .24$; visuospatial vs. control: $F(1, 9) = 1.32$, $p > .28$; visuospatial vs. visual: $F(1, 9) = .35$, $p > .56$).

The results shed new light on the role of visual images and spatial representation in reasoning. Mental representations must be derived from perception and thus the representations of persons who are blind from birth must be different to that of sighted persons. In particular, haptics or auditory perceptions lead to spatial representations without a visual component. This account is supported by several studies that report the same *pattern of performance* in highly spatial tasks in sighted and congenitally blind persons. In a classical study by Kerr (1983) congenitally totally blind and sighted showed almost the same pattern of response times depending on imagined distance, image size, etc. Kerr concluded that "picturability" does not affect the recall of "mental images" in the blind. The only difference was that sighted participants reported forming the images while the blind did not (or at least significantly slower). Marmor and Zaback (1976) explored Shepard and Metzler's mental rotation tasks and found that blind people also show longer reaction times for larger rotation angles. Zimler and Keenan (1983) found similar results in congenitally blind children and adults. In addition, they reported that the haptic images of the blind maintain the same *spatial* information just as the visual images of the sighted do. Obviously, people who are blind from birth do not tend to construct visual mental images. But they are able to construct and to employ spatial representations. In fact, most of our blind partici-

pants reported not using visual images. Instead, they reported that they located the objects of the inference on a spatial scale or in degrees, representing, say "dirtiness". Although such introspections certainly can be wrong, they agree with the experimental findings: The blind are able to construct spatial representations without being irritated by irrelevant visual images.

Experiment 3: Blindfolded Participants

Is there an alternative explanation for the different patterns of results in sighted and blind participants? One possible account is that the visual-impedance effect in the sighted is simply due to interference between the visual input from the surrounding and the mental activity of envisaging a visual mental image. To rule out this explanation in the third experiment the participants had normal vision, but were blindfolded to eliminate any visual input. If the visual-impedance-effect is due to interference between visual imagery and visual perception, they should be also resistant to the impedance effect of visual relations—much as the congenitally blind people are. If, in contrast, the tendency of sighted people to construct visual images is responsible for the visual-impedance effect, then the pattern of results should be similar to that in Experiment 1.

Participants. We tested 30 sighted undergraduate students of University of Oldenburg (mean age 23.3; 18 female, 10 male). They were completely blindfolded to remove any visual input. They received a course credit for their participation.

Materials, Design, and Procedure. The design, the materials and the procedure were identical to Experiment 1 and 2. As in Experiment 2, the instructions were read to the participants by one of the experimenters and except for the two keys associated with "yes" and "no" and the spacebar, all other keys were removed from an external keyboard.

Results and Discussion. Overall, there were 90.8% correct responses and there was no significant difference between accepting valid conclusions (90.2% correct) and rejecting invalid conclusions (91.6% correct). They were pooled again. The MANOVA showed a reliable difference in accuracy across the three sorts of problems, $F(2, 58) = 3.71$, $p < .03$. There was also a significant difference in the mean number of correct responses between the visual problems and the control problems, $F(1, 29) = 5.80$, $p < .03$ and the visual problems and the visuospatial problems, $F(1, 29) = 4.29$ $p < .05$

The response latencies showed that visual problems were slower than control problems, which in turn were slower than the visuospatial problems. The main effect across the three types of problems is statistically significant, $F(2, 58) = 4.22$, $p < .02$. The difference between visual and control relations did not reach statistical significance, $F(1, 29) = 2.25$ $p > .14$, but the difference between visual and visuospatial problems was reliable, $F(1, 29) = 7.01$, $p < .02$.

The pattern of performance in the blindfolded participants is almost identical to that of the sighted participants in Experiment 1. There was again the trend visual > control > visuospatial (although the single contrast between visual and control problems did not reach statistical significance in the lantencies). These data clearly show that the characteristics of the reasoning problems lead to the visual-impedance effect. It is not simply due to interference between the visual input from the surrounding and the mental activity of envisaging a visual mental image.

Table 1: Percentages of correct responses and their mean response latencies (in s) in the three experiments as a function of the different sorts of relations: visual relations, control relations, visuospatial relations.

	Visual inferences	Control inferences	Visuospatial inferences
sighted (Exp 1)	86.9%	94.8%	94.8%
	1.26	1.01	.97
blind (Exp 2)	75.0%	73.6%	79.9%
	5.24	5.29	6.06
blindfolded (Exp 3)	86.7%	92.9%	92.9%
	1.42	1.08	.86

General Discussion

The starting point of our studies was the distinction between visual and spatial modes of representation in reasoning. Previous studies enabled us to identify visuospatial relations, such as *above-below*, which are easy to envisage both visually and spatially, visual relations, such as *cleaner-dirtier*, which are easy to envisage visually but hard to envisage spatially, and control relations, such as *better-worse*, which are hard to envisage both visually and spatially. Our former studies showed that visual relations significantly impede the process of reasoning by slowing it down. We refer to that as *visual-impedance-effect* (Knauff & Johnson-Laird, 2002).

In the present studies we tested a group of sighted participants, one group of congenitally totally blind participants, and one group of blindfolded participants with normal vision. In the sighted participants the visual relations significantly impeded the process of reasoning by slowing it down. The blindfolded did show the same impedance effect. But, the participants who were blind from birth were not affected by the ease of envisaging the verbal relations visually. They showed the same reasoning performance across all sorts of problems.

What might cause visual imagery to impede reasoning in the sighed participants? A theory that relies on visual imagery as the medium for reasoning is implausible, because individuals can reason about relations that they cannot visualize. Similarly, such a theory cannot readily explain why relations that are easy to envisage visually impeded reasoning. One could object that the ability to visualize the visual relations was impeded by the concurrent visual perception. In fact, several studies have shown that visual imagery and visual perception interfere and that visual imagery performance is impaired under this condition (c.f Logie, 1995). Our

third experiment with the blindfolded participants, however, clearly falsifies this hypothesis. An explanation based on formal inference rules (Rips, 1994; Braine & O'Brien, 1998), is also questionable, because it does not account for the effects of content, and does not immediately suggest an explanation of the visual impedance effect.

The present findings support a spatial account of reasoning. The initial idea has been introduced by Huttenlocher (1968) and was further elaborated in the mental models theory of reasoning (Johnson-Laird, 1983; Johnson-Laird & Byrne, 1991). The model theory does not rely on linguistic processes like rule-based-approaches of reasoning (Braine & O'Brein, 1998; Rips, 1994). Such processes are relevant only to transfer the information from the premises into a spatial array and back again, but the reasoning process itself totally relies on non-linguistic processes for the construction and inspection of spatial mental models. The mental models mirror the spatial relations between the represented objects. In contrast to visual images, mental models can represent any possible situation and can abstract away from such visual details as colors, textures, and shapes (Johnson-Laird, 1983; Johnson-Laird & Byrne, 1991). Mental models can also represent class-inclusion, temporal order, and abstract relations such as ownership (c.f. Johnson-Laird & Byrne, 1991). Several studies have shown that the content can facilitate inferences in certain cases and impede them in other cases (e.g. Johnson-Laird & Byrne, 2001). Likewise, a visual relation, such as *dirtier than*, can elicit a vivid visual detail, such as an animal caked with mud that is irrelevant to an inference. It will then take additional time to retrieve the information needed to construct the appropriate spatial mental model for making the inference.

The blind participants, however, did not show this visual impedance effect. This provides additional support for the spatial account of reasoning. Clearly, people who are blind from birth do not tend to use visual mental images, unless they are forced to do so, as in the studies from the literature. But they are able to construct and to employ spatial representations. Such models represent the objects of the inference in degree or on a spatial scale. For this reason, they are not sidetracked by irrelevant visual images and thus perform *relatively* better than sighted persons in the visual problems.

There are, however, some ambiguities in the data from the blind. First, the data are in line with other studies that compared blind and sighted people on a large variety of visuospatial tasks. They consistently reported that blind persons in *absolute* terms perform less accurately or more slowly than the sighted on such tasks (e.g. Kerr, 1983). Such an overall deficit of the blind participants is also visible in the present studies. The sighted participants solved on average 92.2% of the inferences correctly, but the blind participants only 76.2%. The sighted needed 1.08 seconds on average to respond to a problem; the participants who were blind from birth needed 5.3 seconds. Even the blindfolded participants from Experiment 3 performed much better than the blind persons. The dominant approach to explain such findings runs somewhat counter to our own account. It is usually seen as a *visual imagery deficit* of the congenitally blind. In particular, haptics or auditory perceptions also lead to spatial representations, but it is argued that these representations might be sub-optimal compared to vision-based representations (a recent discussion can be found in Fleming, Ball, Collins, & Ormerod, in press). From this view, our blind participants show less good performance, because they are less good in visual mental imagery. However, this account cannot readily explain why the impedance effect of visual relations disappears in the blind. If a visual imagery deficit is responsible for the overall performance deficit of the blind, the impedance effect should be even more pronounced in the blind compared to the sighted.

A second critical aspect in the data is that 9 out of 10 blind participants showed a minor increase of response latencies in the visual problems. The differences were particularly small and apparent only in the visual inspection of the data. However, one could argue that under these conditions the non-effect in the MANOVA (and in the post-hoc computed nonparametric tests) is just due to the small number of participants. If the effect would turn out to be reliable it could have two causes: It could either indicate that even the blind try to envisage the visual relations in a visual mental image (what is implausible due to the above reasons) or that the relations differ in the degree to which they imply transitivity. Spatial relations are unequivocal, but visual relations might be more dubious. Given, say, the following premises:

The cat is fatter than the ape.
The ape is fatter than the dog.

Reasoners might have wondered whether the fatness of cats, apes, and dogs, is commensurable. They claim that, say, an elephant is thin is relative to elephants, and so it is sensible to assert that a thin elephant is fatter than a fat dog. The criterion for fatness shifts from one animal to another. This factor might have confused reasoners in our experiment, and impeded their inferences with the visual relations. A related factor is the degree to which the premises accord with the participants' existing beliefs. For example, the preceding premise (The cat is fatter than the ape) might strike some individuals as implausible. However, these explanations are unlikely, because in the experiments as a whole, each such plausible premise is matched with one using the converse relation (The cat is thinner the ape), and so this factor seems not likely to account for our results.

A last point is that we did not use purely spatial relations, i.e., those that are hard to envisage visually but easy to envisage spatially. If, as our findings suggest, the visual character of the materials leads to an impairment of reasoning performance, whereas the possibility of spatially envisaging the materials speeds up reasoning, then tasks based on purely spatial relations should be processed most quickly. Indeed, we found a (not significant) trend in this direction in Knauff & Johnson-Laird (2002). However, we encountered some technical problems with these relations and some colleagues overall doubt the existence of such relations.

In conclusion, our results suggest that the content of verbal relations can affect the process of inference. If the con-

tent yields information relevant to an inference, as it does with visuospatial relations, then reasoning proceed smoothly, and may even be slightly faster than with other sorts of content. But, if the content yields visual images that are irrelevant to an inference, as it does with visual relations, then reasoning of sighted persons is impeded and takes reliably longer. People who are blind from birth are *immune* to such impedance effects, since they do not tend to use disrupting visual images. A word of caution, on the other hand, is that the visual and spatial nature of representations in reasoning also depends on the nature of the problem. Transitive inferences might elicit spatial representations, but that does not rule out that other problems rely on visual images in addition.

Abstract

In a seminal article, Tanenhaus, Spivey-Knowlton, Eberhard & Sedivy (1995) showed that eye-movements to real-world objects reflect a rapid interplay of utterance and visual environments in sentence comprehension. Further, Kamide, Scheepers & Altmann (2003) found that when *linguistic and world knowledge* constrain the domain of reference in a visual scene, people even anticipate as yet unmentioned arguments/referents. Studies by Knoeferle, Crocker, Scheepers & Pickering (2003) have since revealed that when linguistic and world knowledge did not disambiguate an initial syntactic and role ambiguity, *depicted agent-action-patient events* permitted anticipation of thematic role-fillers online. This paper opposes linguistic and world knowledge on the one hand, and visual scenes on the other hand in order to determine their relative importance in auditory comprehension. We observed a preferred reliance of auditory sentence comprehension processes on information that had to be extracted from depicted event scenes. Determining the nature and time-course of the interaction between linguistic/world knowledge and visual scenes is a first step towards developing a theory of real-time auditory sentence comprehension in visual environments. Our finding has implications for theories of the language faculty (e.g., Jackendoff, 2002).

Introduction

How do we understand utterances online in visual environments? As a first hypothesis, we might assume that the presence of visual environments does not affect language comprehension processes. Crucially, however, language refers to things in the world. It has further been demonstrated that in on-line comprehension reference to entities is established rapidly, and that referentially relevant non-linguistic information influences how the linguistic input is structured (Tanenhaus, Spivey-Knowlton, Eberhard & Sedivy, 1995). In auditory comprehension in visual environments, the unfolding utterance provides linguistic, semantic, and world knowledge. The scene in turn *affords* information about entities and events in the immediate environment (e.g., an outstretched hand affords the prospect of shaking hands) (Gibson, 1966; see Steedman, 2002, for a formal description of object and event affordances). Mental representations that issue in parallel from distinct cognitive components such as the auditory and visual system have to be integrated in "real-time". Comprehension in visual scenes hence moves from single-mode understanding to bi- or even multi-modal understanding.

The architecture of the language faculty

Since visual scene and linguistic information interact in online comprehension (e.g., Kamide et al., 2003; Knoeferle et al., 2003; Tanenhaus et al., 1995), adequate description of auditory comprehension in visual environments requires that we embrace a theoretical account which situates language comprehension with respect to other cognitive systems such as the visual, auditory, or motor system. Jackendoff (2002) proposes one such framework. The individual levels in Jackendoff's architecture are modular in the sense of being domain-specific (i.e., their representational vocabulary is specialized), but unlike Fodorian modularity (Fodor, 1983), linguistic structures interact with one another, and with other cognitive sub-systems. This variety of modularity permits communication between phonological, syntactic, and conceptual structure. Moreover, it also allows communication between conceptual structure and perception or action via interface processors (Jackendoff, 2002, pp. 220f.).

While Jackendoff's theory provides for the interaction of linguistic/world knowledge and visual information, it is underspecified with respect to the precise nature and time-course of this interaction. In order to develop a theory of real-time comprehension on the basis of his architecture, further experimental work is required. As a first step in this direction, we need to clarify how linguistic and world knowledge is integrated with object and event affordances that have to be extracted from the visual environment.

Previous work emphasizes both the importance of visual scenes in determining online comprehension when the utterance was structurally ambiguous (Tanenhaus et al., 1995; Knoeferle et al., 2003), and the importance of stored linguistic/world knowledge in anticipating which object in a scene will be referred to next (Kamide et al., 2003)[1].

[1] We use the term 'stored knowledge' to refer to linguistic/world knowledge which is stored in memory. The terms 'world knowledge' and 'stereotypical knowledge' are used synonymously to mean stereotypical relationships between scene entities (e.g., a cat is a stereotypical agent for chasing mice).

Stored knowledge versus depicted event scenes

Kamide et al. (2003) have shown that unambiguous case-marking, lexical expectations and world-knowledge influence anticipation of post-verbal arguments depicted in the scene. In German, a case-marked article can determine the grammatical function and thematic role of the noun phrase it modifies. Both SVO (subject-verb-object) and OVS (object-verb-subject) orders are grammatical. Participants inspected images showing a hare, a cabbage, a fox and a distractor object while hearing sentences such as *Der Hase frisst gleich den Kohl* ('The hare (subj) eats soon the cabbage (obj)') and *Den Hasen frisst gleich der Fuchs* ('The hare (obj) eats soon the fox (subj)'). The subject and object case-marking on the article of the first noun phrase together with world knowledge extracted at the verb allowed anticipation of the correct post-verbal referent. This was evidenced by anticipatory eye-movements to the cabbage after participants had heard 'The hare (subj) eats …' and to the fox after having encountered 'The hare (obj) eats …'. Hence, when the utterance is unambiguous, and linguistic/world knowledge restricts the domain of potential referents in a scene, the comprehension system may anticipate mention of scene objects.

Knoeferle et al. (2003, accepted), in contrast, considered ambiguous utterances, where neither case-marking nor stereotypical knowledge could assist in disambiguation. Specifically, they examined the time course with which listeners were able to resolve an initial structural and thematic role ambiguity in German sentences. As the linguistic input did not determine the correct syntactic analysis and thematic role-assignment of the sentence, listeners had to rely on depicted events in the scene for interpretation of the utterance. The events showed, e.g., a princess washing a pirate, while a fencer painted her. The princess was thus determined as either patient or agent of an event depending on the depicted action (washing/painting respectively). Listeners heard *Die Prinzessin wäscht/malt den Pirat/der Fechter*. ('The princess (amb.) washes/paints the pirate (obj./patient)/the fencer (subj./agent)'). Once the verb had identified the relevant depicted action, anticipatory eye-movements to the appropriate other event participant (the pirate or the fencer) were observed. The anticipation of a patient and agent role-filler for initially ambiguous German subject-verb-object and object-verb-subject sentences respectively suggests rapid use of depicted events in resolving structural and thematic role ambiguity online. This finding was also shown for the English main clause (MC)/reduced relative (RR) ambiguity, and hence generalized to another language and construction.

Teasing apart the relative effects of visually perceived events and stored linguistic/world knowledge in online sentence comprehension is of relevance for theories of the architecture of the language system such as the one proposed by Jackendoff (2002). Such endeavor may ultimately allow us to propose a more concrete theory of processing mechanisms within such a framework and to hence develop it into a situated theory of real-time sentence comprehension. What the above studies have shown, is that stored knowledge and visual-scene information are both rapidly applied, and that each may guide comprehension processes online. It is further clear, that utterance, world knowledge and the immediate visual scene interact during online comprehension. What remains unclear is the nature and time-course of that interaction. Among other questions, we might ask: What is the relative importance, or priority of different information sources, such as linguistic, scene, and world knowledge? Does scene information guide comprehension, or is the use of scene information determined by stored knowledge?

To further investigate this empirical question, consider an example from German. As noted above, German has a rich case marking system where grammatical function is usually indicated by unambiguous case morphemes. Word order constraints are less rigid in German than in English, and both subject-verb-object (SVO) and object-verb-subject (OVS) order are grammatical with SVO being the preferred reading (e.g., Hemforth, 1993). On hearing an OVS sentence fragment such as *The pilot* (object/patient[2]) *jinxes*… while inspecting the example scene in Figure 1, a number of processes occur. When we hear *The pilot*, object case-marking permits assignment of a patient role to the noun phrase while establishing reference to the pilot in the scene. As there are no constraints on inspecting the scene, perceivers might notice a wizard holding a telescope, and a character resembling a detective who is serving some food. Having encountered an agent and the verb, we might expect post-verbal mention of an agent. At this point, our knowledge that a wizard is a likely jinxing-agent can combine with the fact that the wizard is the only entity whose affordances match the expectations raised by the verb. The combination of entity affordance and stereotypical knowledge allows us to anticipate the wizard as a likely-to-be-mentioned agent. The decisive contribution is, however, made by the utterance, as the verb provides knowledge of stereotypical thematic role-fillers of a jinxing-action (a wizard). The scene affords no information about a jinxing-*relation* between two event participants, as there is no depicted jinxing-action. In contrast, when we hear *The pilot* (object/patient) *serves food to*…, verb-based knowledge of stereotypical agents of a serving-food action (e.g., a cook), cannot provide any guidance, as the scene affords no such entity. However, the scene does afford a depicted food-serving event performed by the detective. While stereotypical knowledge does not allow determination of thematic role-relations in this case, the affordances of the depicted scene events do. Based on findings by Kamide et al. (2003) and Knoeferle et al. (2003, accepted), we would expect unmistakable resolution of the temporal uncertainty regarding the yet-to-be-mentioned agent in both of the above examples once people have heard the verb.

Imagine we heard instead *The pilot* (object/patient) *spies-on*… In this case, the scene affords both a stereotypical

[2] In our materials, a grammatical subject and object correspond to an agent and patient respectively in the scenes.

agent (the detective), and an immediately depicted agent of a spying event (the wizard) as potential agents (see Fig. 1). When we hear *spies-on*, lexical access makes available the meaning of the lexical item and stereotypical knowledge related to it (see Ferretti, McRae & Hatherell, 2001). After encountering the verb, word meaning, stereotypical knowledge of *spy-on*, and scene affordances are available to anticipate either a depicted spying-event and its agent (the wizard), or a stereotypical agent (the detective).

Do listeners rely more on extracting thematic role relations from stereotypical knowledge provided by the utterance (*spy-on* + WORLD KNOWLEDGE –> *detective*), or do they rely on thematic relations afforded by the scene (*spy-on* + WIZARD-SPYING-EVENT -> *wizard*) in incremental interpretation? For the ambiguous *spy-on* example thematic role-relations that are provided by the visual scene, conflict with stereotypical knowledge of who-does-what-to-whom. The comprehension system has to choose between two available, yet conflicting types of information in determining online thematic role-assignment.

While Jackendoff's framework does not make explicit predictions, there are reasons to expect a priority of stereotypical/world knowledge in online thematic role-assignment in such architecture. Jackendoff (2002, pp. 282) argues against a strict separation of linguistic meaning and world knowledge (see also Levinson, 2000). Experimental evidence confirms such an assumption. Ferretti et al. (2001) found that verbs immediately activated stereotypical knowledge of agents (*arresting-cop*) or patients (*arresting-criminal*), but not locations (*swam-ocean*). They conclude that this type of world knowledge is part of thematic-role knowledge, and immediately activated upon encountering the verb (see also McRae, Ferretti & Amyote, 1997). Stored knowledge about stereotypical agents is hence readily available for online thematic role-assignment processes. Non-stereotypical thematic role-relations afforded by scene events, however, must be newly acquired by a perceiver, and via a different perceptual system (the visual system). On the basis of experimental evidence for the tight coupling between word meaning and world knowledge (e.g., Ferretti et al., 1997), we expect comprehension processes to rely in preference on stored knowledge over scene information. Indeed, such a prediction would also appear to follow from traditional assumptions concerning the modularity of the language faculty with respect to other perceptual faculties such as the visual system (e.g., Fodor, 1983).

In summary, we expect the following: when the verb determines either a depicted or a stereotypical target agent only (Table 1, a1 and a2), both verb-derived knowledge of stereotypical role-fillers and affordances of the scene events should allow anticipation of the appropriate target agent. This would replicate - within a single study - findings by Kamide et al. (2003) and Knoeferle et al. (2003). When the verb is *serves-food-to* (a1), we expect a higher percentage of anticipatory looks to the only depicted food-serving agent (the detective) than to the respective other agent in the scene (the wizard). Conversely, when the verb is *jinxes* (a2), more looks should occur to the stereotypical agent (the wizard) than to the other agent in the scene (the detective). In the interesting case of competition, when the verb (*spy-on*) allows more than one potential scene entity as target agent, no interaction is expected. Rather, we should observe a main effect, with the point of interest being the direction of the main effect. The fact that stored stereotypical knowledge is readily available from memory, argues for guidance of online thematic role-assignment processes by stereotypical knowledge rather than by event affordances acquired from the scene in a Jackendoffian framework. This should be revealed in a higher percentage of inspections to the stereotypical spying-agent (the detective) than to the depicted spying-agent (the wizard) for sentences b1 and b2 (see Fig. 1 and Table 1). Crucially, these looks should occur before people hear the disambiguating second noun, and hence reveal online expectations of thematic role interpretation.

Experiment

Method

Participants Twenty-four German native speakers with normal or corrected-to-normal vision were paid 5 euro for taking part in the experiment.

Materials We created 48 images using commercially available clipart and graphic programs. For each of these images, a female native German speaker recorded 4 sentences, which described either a depicted event (e.g., wizard-spying) or a stereotypical event (e.g., detective-spying, see Fig. 1; Table 1).

Design A set of 24 items was created. Each item consisted of 8 spoken sentences and 2 images (Table 1 and Fig. 1 show examples for the 4 sentences for one image of an item set). The two versions of an image only differed in the actions performed by the respective characters. This ensured that each of the target agents (wizard, detective) was a stereotypical and a depicted agent in turn, and that each verb referred once to a depicted event, and once to a stereotypical event. Actions were typically depicted as a character holding an instrument. The way in which actions or characters were depicted did not differ between the two image versions. The middle character on each image (e.g., the pilot) was always a patient ('being acted upon'). The entities to the left and the right of the patient character were performing an action upon the patient entity, and hence always had an agent-role. The two agents were balanced for position (left vs. right). An example image (see Fig. 1) showed two such agent-action-patient events, e.g., wizard-spying-on-pilot and detective-serving-food-to-pilot.

Table 1: Sentences for the example image in Figure 1

Image	Condition	Sentence	PATIENT	VERB	ADV	AGENT
Fig. 1	No-Competitor & depicted target	a1	Den Piloten	*verköstigt*	gleich	der Detektiv.
			The pilot (PAT.)	serves-food-to	soon	the detective (depicted AGENT)
			'The detective will soon serve food to the pilot.'			
Fig. 1	No-Competitor & stereotypical target	a2	Den Piloten	*verzaubert*	gleich	der Zauberer.
			The pilot (PAT.)	jinxes	soon	the wizard (stereotypical AGENT)
			'The wizard will soon jinx the pilot.'			
Fig. 1	Competitor & depicted target	b1	Den Piloten	*bespitzelt*	gleich	der Zauberer.
			The pilot (PAT.)	spies-on	soon	the wizard (depicted AGENT)
			'The wizard will soon spy on the pilot.'			
Fig. 1	Competitor & stereotypical target	b2	Den Piloten	*bespitzelt*	gleich	der Detektiv.
			The pilot (PAT.)	spies-on	soon	the detective (stereotypical AGENT)
			'The detective will soon spy on the pilot.'			

Figure 1: Example of an image for Experiment 1

In addition to the affordances of the depicted events (a telescope affording a spying action), each of the characters also had entity affordances (a detective affording a spying action). The event and entity affordances were always incongruous for any one item entity in this experiment (e.g., a detective was never depicted as performing a spying action). Rather, one agent on each image was a stereotypical competitor for the depicted event performed by the other agent (e.g., the detective was a stereotypical competitor for the depicted wizard-spying event), while carrying out a different action (serving-food) himself. Note, however, that 25 % of the fillers showed plausible events, e.g., a criminal being arrested by a cop). By manipulating the verb people heard, we created four conditions, crossing the factors *competitor* (competitor, no-competitor) with *information type* (depicted target, stereotypical target). For the no-competitor conditions (see Table 1, sentences a1 and a2), the verb permitted either a depicted or a stereotypical target only: "verköstigen" ('serve-food-to') determined the detective (Table 1, a1) as depicted agent; "verzaubern" ('jinxes') identified the wizard as stereotypical agent (Table 1, a2). For the competitor condition (see Table 1, sentences b1 and b2) the verb "bespitzeln" ('spy-on') allowed two scene entities as likely targets (Fig. 1): the wizard, being depicted as performing a spying-action, and the detective, a stereotypical agent for a spying-action. Sentences were unambiguous OVS sentences (see Table 1). They always started with an object case-marked noun phrase referring to a patient role-filler (Fig. 1, the pilot). The middle character was not engaged in an action, and its gaze and position did not bias towards either the left- or the rightward entity. Conditions were matched for length and frequency as much as possible (CELEX). For the image in Figure 1, the sentences in Table 1 were recorded.

Procedure An SMI Eye-Link head-mounted eye-tracker monitored participants' eye-movements. Images were presented on a 21″ multi-scan color monitor at a resolution of 1024 x 768 pixels together with the spoken sentences. The image appeared 1500 ms prior to utterance onset. Each participant saw only one condition of each item, and the order of appearance of items was randomized individually for every participant. It was further ensured that no participant heard any utterance or part of it more than once. There were eight experiment lists. Each consisted of 24 experiment and 48 filler items. Consecutive experiment trials were separated by at least one filler trial. Before the experiment, participants were instructed to listen to the sentences and to inspect the images. There was no other task. The entire experiment lasted approximately 30 min.

Analysis The critical time region we chose for the analysis extended from the late verb (200 ms prior to adverb onset) to the start of the second noun phrase (labeled 'ADV', see Table 1). For this region, participants had heard most of the verb, but had not heard the disambiguating second noun. The *X-Y* coordinates of participants' fixations were assigned to regions for the entities and scene background. Consecutive fixations within one object region (i.e., before a saccade to another region occurred) were added together, being counted as one *inspection*. For the inferential analysis hierarchical log-linear models were used, which combine characteristics of a standard cross-tabulation chi-square test with those of ANOVA. Log-linear models are adequate for count variables because they neither rely upon parametric

assumptions concerning the dependent variable (e.g., homogeneity of variance), nor require linear independence of factor levels (Howell, 2001). Entities were coded depending on their event role. For Figure 1, for instance, the wizard was coded as 'stereotypical agent', and the detective as 'depicted agent' for the no-competitor conditions (a1 and a2 respectively), and vice versa for the competitor conditions (b1 and b2, see Table 1). The inspections to a character within the ADV time region were a dependent variable in the statistical analysis. Inspection counts for the ADV analysis region were adjusted to factor combinations of *character* (stereotypical agent, depicted agent), *competitor condition* (competitor, no competitor), *information type* (depicted target, stereotypical target) and either participants (N = 24) or items (N = 24).

Results

Figures 2 and 3 show the proportion of inspections to the characters (depicted agent, stereotypical agent) during the ADV time interval. Figure 2 shows inspection percentages to the entities in the two information type conditions (depicted target, stereotypical target) for the No-Competitor condition, Figure 3 for the Competitor condition.

For the No-Competitor condition (a1, a2, see Table 1), when the verb singled out either a depicted (a1) or a stereotypical agent (a2), a significant interaction of information type (depicted target, stereotypical target) and character (depicted agent, stereotypical agent) revealed clear disambiguation using either depicted or stereotypical information (all ps < 0.0001). This was due to a significantly higher percentage of inspections to the depicted agent in the depicted (a1) than in the stereotypical target condition (a2), and a significantly higher percentage of inspections to the stereotypical agent in the stereotypical target condition (a2) than in the depicted (a1) (see Fig. 2).

In contrast, for the Competitor condition (b1, b2, see Table 1), when stored stereotypical knowledge and scene affordances competed and provided conflicting information, we expected no interaction since the stimuli between b1 and b2 were identical (see Table 1). Rather, we found a main effect. We observed more anticipatory looks to the agent of the depicted spying-event (the wizard), than to the stereotypical agent (the detective) for sentences b1 and b2 (see Fig. 3). These looks occurred after people had heard *The pilot* (object/patient) *spies-on*…. and before they heard the respective second noun phrase, which then disambiguated towards the depicted or stereotypical target type. Log-linear analyses showed that the main effect of depicted agent was significant ($p < 0.0001$ by part. and items) in the absence of a significant interaction (ps > 0.6).

Importantly the observed main effect for the Competitor condition (b1 and b2) is only meaningful in comparison to the significant interaction found in the No-Competitor condition (a1 and a2). The difference between the main effect for the Competitor condition (b1 and b2), and the significant interaction for the No-Competitor condition (a1 and a2, see Table 1) was significant. Analyses revealed a three-way interaction between character (depicted agent, stereotypical agent), competitor condition (competitor, no-competitor) and information type (depicted target, stereotypical target) ($p < 0.001$ by part. and items).

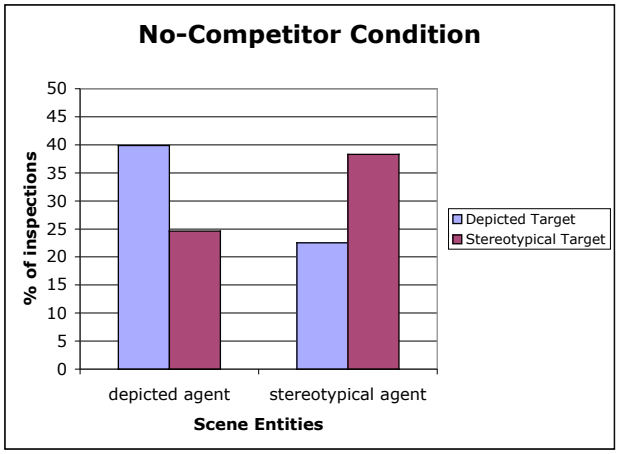

Figure 2: Percentage of inspections to characters during the analysis region ('ADV') in the No-Competitor Condition

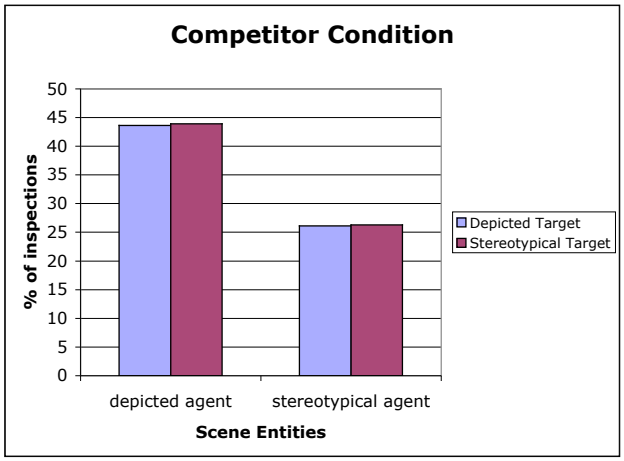

Figure 3: Percentage of inspections to characters during the analysis region ('ADV') in the Competitor condition

Discussion

Within a single study the observed pattern of eye-gazes has shown that both stereotypical knowledge and information that has to be newly acquired from depicted event scenes, allow rapid thematic role interpretation of an unfolding utterance. Our results thus confirm previous findings that thematic-role knowledge (e.g., Ferretti et al., 2001; Kamide et al., 2003) and depicted scene events (e.g., Knoeferle et al., accepted) each are readily available for online comprehension. In the face of competition, however, people have a clear preference for relying on thematic relations acquired from depicted events. We argue that our findings are an important step towards developing a fully specified theory of comprehension that is able to make explicit predictions of auditory sentence comprehension in visual environments. For architectures of the type proposed by Jackendoff (2002), they point to the necessity of incorporating a processing (rather than an architectural)

account for the preferred reliance of the comprehension system on thematic role-relations afforded by depicted event scenes.

Clearly, the observed preferred reliance of listeners on information that they had to newly acquire from depicted scenes, and via a different perceptual system (the visual system), counters our initial expectations of a priority of stored stereotypical knowledge. When stored knowledge and scene compete and provide conflicting information, it is not stereotypical knowledge, which influences our interpretation of the scene. Rather, when verb meaning identified relevant depicted events, the scene guided interpretation of the utterance. Our findings hence indicate an active contribution of thematic role-relations afforded by scene events in online thematic role-assignment. It should nonetheless be highlighted that scene events only influenced thematic role-assignment once they had been identified by the verb.

Such utterance-mediated influence of depicted events suggests a highly efficient interaction between the visual and comprehension systems, where lexical items single out scene entities and events, which then may influence online interpretation. Under this view, we would expect that reference from verbs to the depicted actions in the scene is a pre-requisite for the influence of scene events on online comprehension processes.

Studies by Knoeferle, Crocker, Scheepers & Pickering (accepted) found, however, that depicted scene events allowed online thematic role-assignment and structural disambiguation even before people had encountered a sentence-final verb. The insight that emerges from their finding, and the ones presented in this paper, is that visual scene information has great importance in online comprehension. Indeed, reference from verbs to depicted actions is not an indispensable pre-requisite for the guiding influence of depicted events in auditory comprehension. In sum, this speaks to a *strong* – albeit not necessarily unconstrained - guidance account of the influence of visual scenes on online comprehension processes. Further research is required to establish whether there are constraints on the influence of depicted event scenes on online thematic role-assignment, and under which conditions they apply.

An Adaptive Perspective

In many cases, people find themselves in relevant situations where both spoken language and immediate scene context are available. When watching movies, for instance, people seem to rapidly integrate their knowledge of the world with the movie events unfolding over time in front of their eyes. Clearly, cognitive processes such as understanding an unfolding utterance and an immediate event may occur simultaneously. Yet, when both types of information are available in our environment, the pattern of eye-gazes we observed provides strong evidence for a preference of the immediate environment over expectations of stereotypical events. Further, the rapid impact of the immediate situation identifies the comprehension system to be highly adapted towards acquiring new information from its environment rather than relying on linguistic and world knowledge, a conclusion which bears important implications for both developmental and evolutionary accounts of the language comprehension system.

Abstract

This paper presents an unusual prediction made by the DUAL-based model of judgment JUDGEMAP and its verification. The model is shortly presented as well as the simulation data obtained with it. These data predict that people will use the information on an irrelevant dimension when judging another dimension. This prediction is then tested in a psychological experiment and confirmed.

Introduction

Suppose that you are judging how tall a person is. Do you expect that the color of his or her eyes will play a role in that process? Or suppose you are judging the quantity of oil in the bottle you are buying, do you expect that the font used on its label will have an effect? Finally, suppose you are judging the length of a given line segment. Do you expect that the color of the line will make a difference?

Both our intuition and the theories of judgment would answer these questions negatively. Basically they would assume that when judging length we ignore all irrelevant features (including color) and only physical length plays a role. Of course, many other factors, like order of presentation and context, may play a role, but only the length of the lines will take part in the judgment.

This paper is challenging this assumption of standard theories of judgment and is trying to answer the above seemingly stupid and self-evident questions and surprisingly to show that all features (including the irrelevant ones) do matter or more precisely they may matter under certain circumstances.

Approaches to Judgment

There are a number of theories of judgment and a few running models. Most of the theories originate from psychophysics and are mathematical in their nature; they do not describe the process of judgment, but only characterize the end result. Since we are interested in describing the process of judgment we will briefly outline only the main approaches proposed so far in that direction.

Judgment as measuring similarity/dissimilarity with a standard. The classical ideal point approach proposed by Coombs (1964, Wedell & Pettibone, 1999) falls into this category. He believes individuals have their "ideal points" and therefore judging a stimulus can be described as comparing it to this standard and measuring the distance toward it. The Adaptation Level Theory (Helson, 1964) falls into the same category, however, here the standard (adaptation level) is changed depending on context. Finally, the Norm Theory (Kahneman & Miller, 1986) follows a similar approach, however, the standard here is called "norm" and what is more important is that this norm is constructed on the spot rather than retrieved from long-term memory. A comparison set is constructed in working memory consisting of known exemplars and its norm is computed. Thus all three theories can be described as relying on comparison of the target stimulus with a standard (Figure 1), but they differ in the degree to which they subscribe to the constructivist approach toward this standard.

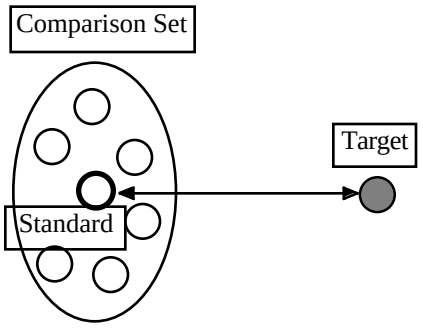

Figure 1. Judgment as comparison with a standard.

Judgment as classification task. Within this approach the comparison set is subdivided into subcategories each of them corresponding to a judgment label (or scale element) and the target stimulus is classified within one of these subcategories. The Range-Frequency Theory (Parduci, 1965, 1974) postulates the constraints which should be met by such category subdivision: the range of value variation within all subcategories should be about the same, and the number of examples in all subcategories should be about the same. The Theory of Criterion Setting (Treisman & Williams, 1984, Treisman, 1985) is a process model that explains how dynamically we change the boundaries of the subcategories. Finally, the ANCHOR model (Petrov &

Anderson, 2000, in press) describes the process of learning of these subcategories and solves the classification task by comparing the target stimulus to the prototypes of each subcategory, these prototypes are supposed to be hold in long-term memory and are called anchors (Figure 2). The comparison set represented by the set of anchors is dynamically formed.

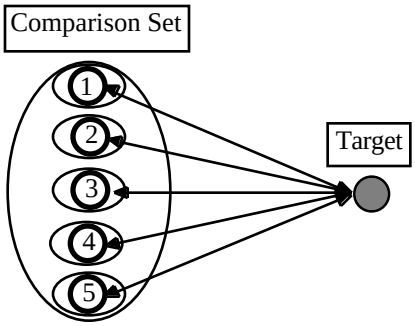

Figure 2. Judgment as classification task. Comparing the target to the standard of each of the subcategories.

Judgment as a mapping task. The DUAL-based model of judgment discussed in this paper follows a third approach: The target stimulus is not compared to the comparison set, but is rather included in it and then a mapping is established between the elements of the comparison set and the set of rating labels (or scale elements). This mapping should be as close as possible to a homomorphism, i.e. the relations among the elements of the comparison sets should be kept among their corresponding rating labels. Thus the process of judgment involves construction of the comparison set, joining the target to it, and mapping between the comparison set and the rating labels (Figure 3).

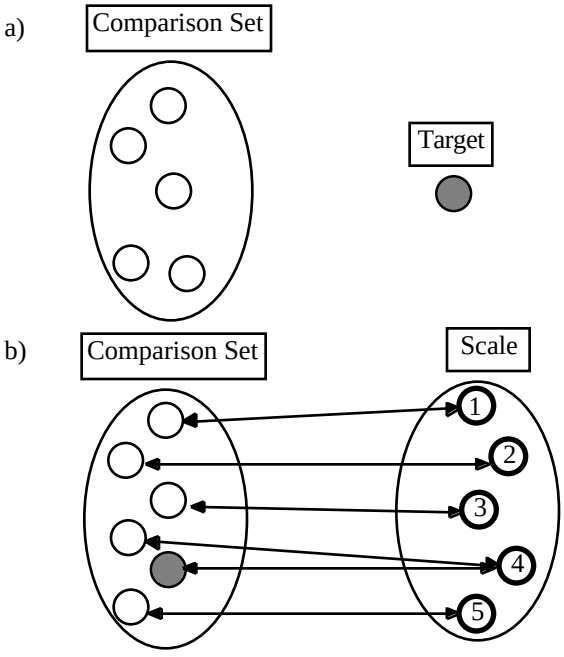

Figure 3. Judgment as mapping in the DUAL-based model.

DUAL-Based Model of Judgment

The current model – JUDGEMAP (Judgment as Mapping) – is based on a general cognitive architecture – DUAL (Kokinov, 1994b, 1994c). This architecture is a hybrid (symbolic/connectionist) one and is explicitly designed to model context-sensitivity of human cognition. It is based on decentralized representations of concepts, objects, and episodes and parallel emergent computations.

The AMBR1 (Kokinov, 1988, 1994a) and AMBR2 (Kokinov, 1998, Kokinov & Petrov, 2001) models are built on DUAL and integrate memory and analogy-making. Since the process of judgment, as described above, involves memory (construction of the comparison set in working memory) and mapping (which is a central mechanism in analogy-making) the JUDGEMAP model is most naturally integrated in DUAL and borrows many of the mechanisms developed for analogy-making in AMBR. Because of the lack of space the model is described only in broad strokes. Interested readers are invited to consult the literature on DUAL and AMBR for more details.

Construction of the comparison set. The comparison set is formed from perception (the target as well as potential context stimuli) and from long-term memory (familiar or recently presented exemplars as well as generalized prototypes, if such exist in LTM). The mechanism responsible for that construction is spreading activation. The sources of activation are the INPUT and GOAL nodes, i.e. the perceived target (and possibly context) stimuli and the goal to judge the stimuli on a scale predefined in the instruction (e.g. a scale from 1 to 7). Thus the representations of the target and the scale elements become sources of activation which is then spread through the network of micro-agents. Naturally, concepts related to the representation of the target become active, e.g. various features of the target – these include both relevant and irrelevant features (of course, relevant features receive more activation than irrelevant ones). The activation spreads further from the general concepts (like RED, GREEN, etc.) towards specific examples of the concepts (other red or green objects). However, there are only a few links from the general concepts to their exemplars – only to the most familiar (typical) exemplars or to recently experienced ones. Thus gradually a number of exemplars (and possibly prototypes) are activated and become part of working memory – all these form the comparison set (Figure 4).

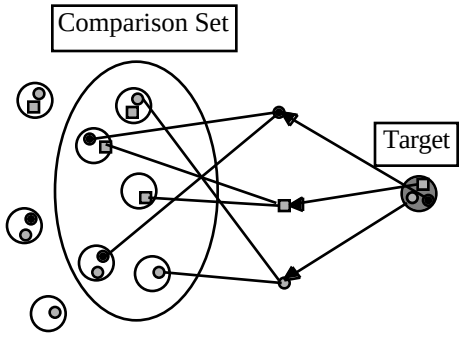

Figure 4. Formation of the comparison set in WM by the spreading activation mechanism of DUAL.

Mapping of the comparison set onto the scale elements. We can now consider the comparison set as a retrieved base and map it onto the scale elements which are the target. The mapping process should preserve the relations among the elements of the comparison set among their images on the scale. The mapping should also follow the range-frequency principle described in the previous section. How is the mapping achieved in JUDGEMAP? Similarly to AMBR, a constraint-satisfaction network is constructed by the marker-passing and structure-correspondence mechanisms. This network consists of temporal agent-hypotheses representing possible correspondences between members of the comparison set and elements of the scale. These initial hypotheses are formed according to the range principle. Excitatory and inhibitory links are constructed among the hypotheses and the spreading activation mechanism selects the winning hypotheses which form the mapping (Figure 5). The competition among the hypotheses implements the frequency principle. As result of this process not only the target stimulus but also each element of the comparison set receives a judgment. This does not mean that people would be aware of all these judgments – most or even all of them might remain unconscious.

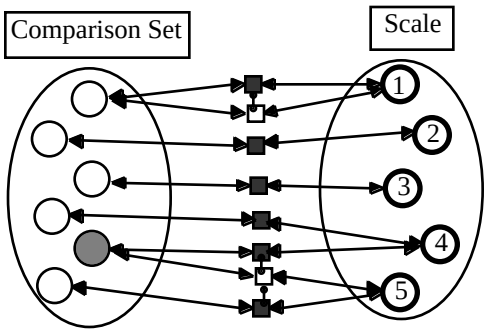

Figure 5. The process of mapping accomplished by the constraint satisfaction mechanism. The winning hypotheses are in black.

Speculative prediction. Since the activation spreads from the target stimulus (represented in a decentralized way by many agents), exemplars, similar in some respect to it (sharing some feature with the target), can be potentially activated and thus become members of the comparison set in working memory. This means that in addition to currently perceived stimuli, to recently activated exemplars, and to highly familiar (typical) exemplars, exemplars which are simply similar to the target will also participate in the comparison set. Moreover, these exemplars might be similar along the relevant (judged) dimension or along an irrelevant dimension.

Let us consider the following example. Suppose we are judging the length of line segments but the lines are colored. Let the target stimulus be a red line of certain length. In this case we may expect that there will be more red lines in the comparison set (Figure 6) – they will be activated through the RED concept which is shared with the target. On the other hand, if the target stimulus is a green line of the same length, more green lines will become part of the comparison set (Figure 7). Now, if it happens that the known red lines are longer than the known green lines, then the two target stimuli (differing only in color) will be included in different comparison sets and thus judged differently and there will be a shift in favor of the green target. Therefore the speculative prediction of JUDGEMAP will be that even such irrelevant feature of the line like its color will play a role in the judgment process. This prediction is in sharp contrast to all theories and models described in the first section, which assume that only the relevant features play a role.

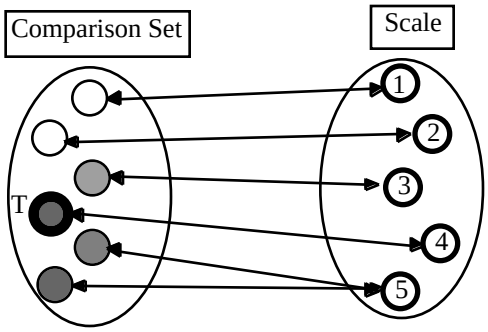

Figure 6. The target stimulus is red and therefore we expect more red exemplars in the comparison set. They happened to be larger in size and thus they compete for the upper part of the scale. In this case the target stimulus (of the same size as in Figure 7) will compete with them and will be mapped onto 4.

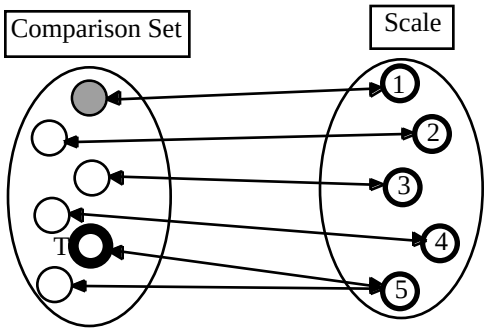

Figure 7. The target stimulus is green and therefore we expect more green exemplars in the comparison set. They happened to be smaller in size and thus they compete for the lower part of the scale. In this case the target stimulus (of the same size as in Figure 6) will compete with them and eventually will be mapped onto 5. In this way we receive an upward shift in the judgment.

Thus we will first describe a simulation experiment with JUDGEMAP that tests in practice this speculation and will also give us a rough estimation of the order of this color effect (if any). If we are successful, we will run a psychological experiment to text the model's prediction and thus verify the model.

Simulation Experiment

In this simulation experiment we use a stimulus set of 56 lines. They are all in the long-term memory of the model. The lines differ in length and color. There are 7 different sizes (from 10 units of length to 34 unit with increment of 4 units) and two different colors (red and green). Thus in each size group there are 8 lines. The frequency of the red (respectively green) lines varies across the size groups. In size group one (the shortest lines - length 10 units) there are 7 green and 1 red line, in the second shortest group (length 14 units) there are 6 green and 2 red lines, etc. In the largest group size (length of 34 units) there are 7 red lines and one green line. Thus we have positively skewed distribution of the green lines and negatively skewed distribution for the red lines.

Each line is represented by a coalition of 5 agents standing for the line itself, for its color, for its length, and for the two relations (color_of and length_of). In addition there are agents standing for the numbers from 0 to 8, but only the agents standing for 1 to 7 are instances of "scale element".

On each run of the program we connect one of these lines to the input list thus simulating the perception of the target stimulus, and connecting the agent standing for "scale_from_1_to_7" to the goal node thus simulating the instruction for rating on a 7 point scale.

We have produced 42 variations of the knowledge base of the system thus simulating 42 different participants in the experiment. The knowledge bases differ mainly in the associative and instance links among the agents, thus although all our "artificial participants" will know the same lines and the same concepts, they will activate different instances in the comparison set.

For each of these knowledge bases we have run two judgment trials: one for a red line of size 22 and one for a green line of the same size.

Simulation Results

The results from the simulations are presented in Figure 8. As we can see the mean rating of the green lines are in most cases slightly higher than the mean rating of the red lines with the same length.

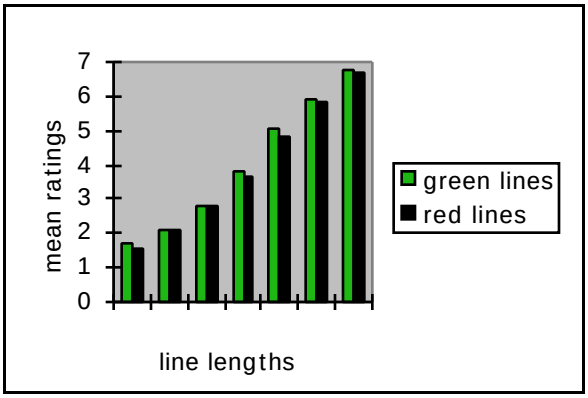

Figure 8. Simulation data. The mean rating of each line with a certain length (1-7) and color (green and red) obtained from all subjects.

Thus the mean of the mean ratings of all red categories is 4.012, while the mean of the mean ratings of all green categories is 4.065, which makes a difference of 0.053 which turns out to be almost significant tested with repeated measurements analysis ($F(1,41)=3.917$, $p=0.055$). The data show that the possible size of the color main effect is very small, but may still be significant. This prediction makes sense: on one hand it is small enough, so that we can ignore it in everyday life and this explains why our intuition says that irrelevant information does not play a role in judgment. On the other hand, the simulation predicts that the irrelevant information does play a role and shifts a bit the evaluation. This means that under specific circumstances this shift might be larger and become significant.

The experiment described below is designed to test this prediction of the model. Basically it replicates the simulation experiment with a larger number of lines.

Psychological Experiment

In this experiment human participants rate the length of red and green lines of various sizes. The interesting question is whether we will obtain a main effect of color, i.e. whether there will be a difference between the ratings of the red and green lines of the same size.

Method

Design

The experiment has a 14x2 within-subject factorial design. The independent variables are length (varying at 14 levels) and color (varying at 2 levels: green and red) of the lines. The dependent variable is the rating of the length of the lines on a 7-point-scale. The experimental question is whether there will be a main effect of color, which is supposedly an irrelevant factor in judging length.

Material

A set of 14 color lines has been presented horizontally against a gray background on a 17-inch monitor. The shortest line is 12 pixels, the longest one is 727 pixels and the increment is 55 pixels. Each particular line length has been shown eight times in red or green color. The short lines were predominantly green while the long ones were predominantly red. The color distribution within the set of all 112 lines (14 lengths x 8 times) is presented in Table 1. The frequency of the stimuli was calculated in order to receive a positively skewed distribution for the green color and a negatively skewed one for the red lines.

Table 1. Frequency of the presented stimulus lines (where 1 represents stimulus length 12 pixels, 2-67 pixels and so on).

lengths	*number of the green lines*	*number of the red lines*
1 & 2	7	1
3 & 4	6	2
5 & 6	5	3
7 & 8	4	4
9 & 10	3	5
11 & 12	2	6
13 & 14	1	7

Procedure

The participants were tested individually in front of a computer screen where all 112 stimuli were shown sequentially and in random order. They were instructed to judge the length of each line presented on the screen on a seven point scale: 1-"it is not long at all", …, 7-"it is very long". No feedback was provided to the participants and no time restrictions have been imposed on them. The whole experiment typically lasted about 15 minutes.

Participants

The participants were 18 undergraduate students (9 men and 9 women none of whom was color-blind) from the introductory classes in psychology at New Bulgarian University who participated in order to satisfy a course requirement.

Results and Discussion

We had 14x2=28 data points for each participant. The results averaged over subjects are shown in Figure 9. Each bar stands for the mean rating that a line of the corresponding size and color has received during the experiment. The repeated measurements analysis showed that the difference (0.046) between the mean judgment of the green lines (4.239) and the mean judgment of the red lines (4.193) is significant ($F(1, 17)=5.966$, $p=0.026$).

Surprisingly enough we obtained a difference (0.046) that is almost the same as the difference we obtained in the simulation (0.053). No tuning of the model was possible since we did not have the experimental data in advance.

Thus the prediction of the JUDGEMAP model has been experimentally confirmed.

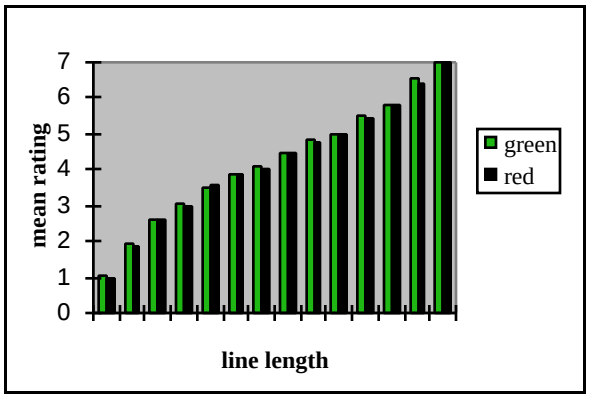

Figure 9. The mean rating of each line with a certain length (1-14) and color (green and red) obtained from all subjects.

Conclusions

The JUDGEMAP model of human judgment has been presented. This model is based on a general cognitive architecture (DUAL) and is thus integrated with the memory and analogy-making model AMBR. Moreover, this model inherits the underlying assumptions of DUAL and AMBR: human cognition is context-sensitive (Kokinov, 1994c), judgment included; human memory is constructive (Kokinov & Hirst, 2003), analogy-making is at the core of human cognition (Gentner, Holyoak & Kokinov, 2001) and its mapping mechanisms may be used in judgment.

The JUDGEMAP model is similar to the Norm theory and the ANCHOR model with respect to the constructive approach to the formation of the comparison set. However, unlike all the models described in the first section judgment in JUDGEMAP is not based on comparison of the target with some aspect of the comparison set, but rather the target stimulus is included in the comparison set and it receives a rating along with all other members of this set. This rating process is based on establishing a mapping between the comparison set and the set of scale elements which mapping preserves the order relations.

Unlike all other models JUDGEMAP does not ignore the irrelevant features of the to be judged targets, moreover these irrelevant features play a role in the construction of the comparison set (retrieving similar objects according to these irrelevant dimensions). The model makes a strange prediction that the color of the target line may play a role in the rating of its length and thus predicts a shift of the mean rating (although a small one) with the change of color. This prediction has been tested in a psychological experiment and has been confirmed.

The size of this color effect is very small, but the stimuli have been very simple and the features unremarkable. It is difficult to imagine that the green color reminds us of a particular green line. That is why we plan to repeat the experiment with more complex stimuli (human figures and clothes) and more memorable features (human faces). It is possible the size of the effect in this case to become larger.

Acknowledgments

We would like to thank the AMBR research team for their continuous support and stimulating environment as well as Stefan Mateeff and Maurice Grinberg for the valuable discussions.

Abstract

With this paper, we introduce the agreement production error (APE) model. APE is a model of comprehension and production performance that applies a theory of memory and cognition (ACT-R 5.0) to the task of linguistic processing embedded in a variety of psycholinguistic experimental paradigms.
With its roots in the ACT-R theory, agreement errors are modeled as a combination of symbolic processing and chunk activation dynamics. Whether a plural or a singular verb is produced depends on the accessibility of the Subject's plural marking. The activation of plural-marking chunks decays, so that it might not be found when its retrieval is attempted at the verb, resulting in a general singular error (Hemforth and Konieczny, 2003). This effect is then modulated by task and construction specific variations.

Introduction

When people speak or write they occasionally produce verbs not agreeing in number with the subject. This happens particularly often when the singular subject is followed by a plural modifier in constructions like (1; quoted form Bock & Miller, 1991).

(1) The readiness of our conventional forces are at an all-time low.

The mechanism underlying this error is attributed to the marked plural feature percolating up the tree too far (Vigliocco & Nicol, 1998). This account is substantiated by the fact that no comparable singular/plural mismatch effect for constructions with marked plural heads has been established so far.
Very recently, Haskell and MacDonald (2002) proposed the principle of proximity as an alternative explanation. They showed that in disjunctions like (2), subjects have a strong preference to match the number marking on the verb with the more local noun. In addition to distributional evidence, this was taken to indicate that the classical attraction error at least partially and at least in English is caused by number marking on a close interfering noun.

(2) a. The hat or the gloves is/are red.
b. Is/are the hat or the gloves red?

In a series of five written production experiments, Hemforth and Konieczny (2003) tested the proposed mechanisms in German.
In this paper, we follow up on this work and present a new model, APE, that accounts for the written production data in the experiments reported. The paper is organized as follows. We will start by summarizing the two most important experiments from Hemforth and Konieczny (2003). After that, the model will be outlined. Since APE is based on ACT-R 5.0, a short introduction to this theory is provided beforehand. The paper ends with a general discussion and conclusion.

Error patterns in written production

The first experiments replicated the classical results on subject-modifier-verb constructions. Two factors were varied in the first experiment: The factor "Match": matching (1,4) or mismatching (2,3) number marking on head noun and local noun, and the factors "Number of the head noun": singular (1,2) or plural (3,4) head noun.
(1)Die Farbe auf der Leinwand _____ trocken.
The color on the canvas _____ dry.
(2) Die Farbe auf den Leinwänden _____ trocken.
The color on the canvasses _____ dry.
(3) Die Farben auf der Leinwand _____ trocken.
The colors on the canvas _____ dry.
(4)Die Farben auf den Leinwänden _____ trocken.
The colors on the canvasses _____ dry..

Hemforth and Konieczny (2003) found a clear effect of the number of the head noun on the percentage of agreement errors. Neither the factor "Match" nor the

number x match interaction reached significance. However, whereas no difference in matching versus mismatching local nouns could be established for sentences with plural marked head nouns, planned comparisons showed an effect with singular marked head nouns. This result replicates the well-known modifier attraction effect (e.g. Vigliocco & Nicol, 1998, Bock & Miller, 1991).

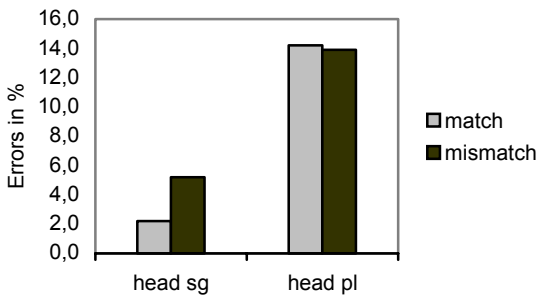

Figure 1: Agreement errors for NP-PP-V constructions

In line with earlier experiments on written production (e.g., Branigan et al., 1995; Hölscher & Hemforth, 2000), we found a considerably high number of agreement errors for plural marked head nouns, reflecting a general tendency to produce singular verbs. Nevertheless, the result for singular heads is compatible with both the feature percolation hypothesis and proximity. Hemforth and Konieczny (2003) therefore ran a series of experiments on Subject-Object-Verb (SOV) constructions. An object attraction effect for singular subjects would rule out feature percolation, because the object is not embedded within the subject.

Object attraction?

The experimental factors varied in three further experiments were "Match": matching (9,12) or mismatching (10,11) number marking on Subject NP and local object NP, and "Number of Subject": singular (9,10) or plural (11,12) Subject NP.

(9) Ich habe gehört, dass der Mann die Frau besucht _____.
I have heard that the man(masc,nom) the woman visited _____.

(10) Ich habe gehört, dass der Mann die Frauen besucht _____.
I have heard that the man(masc,nom) the women visited _____.

(11) Ich habe gehört, dass die Frauen den Mann besucht _____.
I have heard that the women the man (masc, acc) visited _____.

(12) Ich habe gehört, dass die Frauen die Männer besucht _____.
I have heard that the men the women visited _____.

In all three experiments, the number marking on the Subject had a strong effect on the number of agreement errors: more errors were produced following a plural Subject. However, less errors were produced when the local Object-NP was also plural marked.
The lack of an object attraction effect for singular subjects is consistent with the feature percolation hypothesis and contradicts proximity.

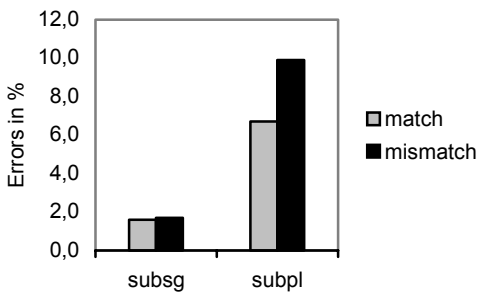

Figure 2: Agreement errors in SOV-constructions

The mismatch effect for plural subjects, however, is not predicted by feature percolation. Hemforth and Konieczny (2003) proposed *feature reactivation* as an explanation. According to that hypothesis, the plural feature of the subject (head) is subject to activation decay so that activation can be below the retrieval threshold when the verb must be produced. This mechanism would account for the general tendency to produce singular verbs. In SOV constructions, however, the subject plural feature can be reactivated by an object plural feature, because both subject and object are arguments of the verb.

APE: A hybrid model of agreement errors

The data so far suggest that both syntactic constraints and proximity affect agreement errors. For one, there are certain effects restricted to certain syntactic constructions ("feature percolation"), and second, there are effects of locality and interference best dubbed in terms of decay and reactivation. The Agreement Production Error (APE) model is built atop the ACT-R architecture, which provides us with mechanisms for *i.* declarative chunk activation and decay, embedded in a *ii.* symbolic processing architecture with *iii.* cost-dependent rule selection, and *iv.* task-specific modelling.

An informal introduction to ACT-R 5

ACT-R (Anderson and Lebiere, 1998; Anderson et al., submitted) is both a theory of cognition and a modelling framework, where scientists can build their specific models using well defined and empirically justified concepts that serve as the model's building blocks.

ACT-R distinguishes declarative from procedural knowledge. Both employ advanced sub-symbolic mechanisms.

Chunks are the elements of *declarative memory*. They bundle information in a collection of attribute value pairs, by which chunks get linked to other chunks to form networks of declarative knowledge. When chunks are created, they start out with a certain base level activation that decays over time, following the power law of forgetting. If their activation falls below a certain threshold, their chance for being retrieved by a production approaches zero.

When a chunk is retrieved from declarative memory, its base level activation is permanently pushed a bit upwards. The more often it is used, the higher it will be activated (power law of learning). In addition to base level activation, a chunk can temporarily receive additional activation spreading from associated chunks stored in the goal of the current production rule. The rationale is that chunks relevant for the problem stated in the current goal should benefit from being within the current focus of attention.

Production rules interact with declarative memory via retrieval of chunks. A retrieval request may succeed or fail, depending on whether or not a matching chunk exists, and on that chunk's activation. Among several matching chunks, the one that is activated highest has the highest probability of being retrieved. A retrieved chunk is stored in the retrieval buffer, where the next production can use it. Given a certain constellation of chunks in the available modality specific buffers (goal, retrieval, visual, audio, etc.), multiple production rules might apply to this state, but only one will be picked for firing. In ACT-R, conflict resolution in the case of multiple potential production instantiations is determined by the *utility* value of each rule in the conflict set. The *utility* is in turn a function of the past history of success and the cost associated with solving the problem by picking this rule.

If there are two productions in the conflict set, one of which has a high probability of being successful but which takes a while for getting there, and the other is quick but has only a mediocre success history, the choice will depend on the amount of time the user devotes to the problem. If the focus is on accuracy, plenty of time can be spent solving the problem so that the more successful rule will be picked. If the focus is on speed, the faster rule will be picked even though it's not unlikely that it will fail.

Basic modelling decisions

While ACT-R provides only limited means of representing and processing declarative and procedural knowledge, there are still many alternative ways in which knowledge can be modelled. We settled on the following modelling decisions before we actually started:

- Restricted use of direct storage. We do not store linguistic elements in slots of goals unless it is required for declarative reasons. Newly created chunks are released into declarative memory and retrieved when needed. Binding a chunk to a slot in the goal for procedural reasons is too strong a computational assumption, since stored chunks are excluded from activation decay.
- As a consequence of this, syntactic nodes have to be retrieved from memory in order to become integrated with other nodes. For instance, when the verb is processed, all its complements and adjuncts must be retrieved from memory to form an integrated interpretation.
- The cost of integrating a word is hence a function of the accessibility of its dependents in memory. Integration will be the easier, the more locally its dependents have been processed beforehand (cf. Gibson, 1998)
- The restricted use of direct storage has also consequences for the agreement mechanism, because NPs have to be retrieved all the time to get attached to modifiers or for incremental interpretation. The continuous retrieval of NPs influences their activation, so that some will be more accessible than others when the plural feature is to be assigned.

The sentence processing mechanism

The current model version performs the completion task as used in Hemforth and Konieczny (2003). First, a series of noun phrases are processed before the model produces a verb.

Processing starts with a goal that represents the current processing state during the assembly of the sentence elements. Each word read from the screen triggers the retrieval of a lexical element and is integrated into the currently processed phrase marker. The first NP is marked as the subject of the clause. When a modifier is processed, its host will be retrieved for attachment.

At each top level element of the sentence, a propositional interpretation is sought that matches the concepts associated with the processed phrases to a long term proposition (cf. Budiu & Anderson, 2000). If such an interpretation can be found, the concepts are hooked to that proposition.

In verb-final constructions, multiple arguments might precede the verb. In the absence of thematic

information of the verb, APE anticipates the verb by retrieving a proposition in the background knowledge that integrates the arguments processed so far. The more arguments have been read, the more likely will the interpretation match the right one when the verb is read, so that actually integrating the verb will become easier (Konieczny and Döring, 2003). In this view, anticipation is at the conceptual rather than the syntactic level.

Modelling agreement

Representation of number. Singular is the default number of nouns, whereas plural has to be assigned explicitly. A noun phrase is hence considered singular unless it is marked plural.

The plural feature is modelled as a chunk that links the plural attribute to a noun phrase, rather than as a slot in an NP chunk. As a chunk, a plural feature is subject to ACT-R's activation dynamics.

Producing number. Verb production is modelled by distinct production rules for singular and plural forms. The plural rule attempts to retrieve the plural feature of a noun phrase marked as subject of the sentence. If it succeeds, the plural form is generated from the base form. If it fails, the singular rule produces the singular base form.

The plural rule has higher utility, due to its better accuracy in actually producing the right verb when the subject is plural. The singular rule is less specific and therefore error prone, but less cost intensive.

Where syntax matters. The German production data suggest that plural attraction is construction specific: While there is a robust modifier attraction effect for singular subjects in SMV constructions, there is none in SOV. This result has been predicted by the *feature percolation hypothesis*.

Feature percolation is an encoding error by nature, in which the plural feature is erroneously assigned to the head noun instead of the embedded noun.

ACT-R, however, lacks a direct mechanism for encoding errors (i.e. the creation and release of false chunks). The only place where errors can occur in ACT-R is during retrieval of chunks.

Modelling "Feature percolation". In APE, the construction specific encoding error is modelled as a retrieval error during the search for an NP that the plural feature is to be assigned to. That is, during plural assignment, the newly created plural feature requires a root NP that has to be retrieved from memory. At the modifier in a complex-NP construction, the head NP at that point is highly activated due to the fact that is had been retrieved for modifier attachment shortly before plural assignment. Since both the head NP and the modifier NP are about equally strongly activated, there is a certain chance that the head NP, not the modifier NP is retrieved for plural marking. If that happens, the subject has inherited the plural marking from the embedded NP.

In SOV constructions, no attachment takes place between the Subject and the Object-NP. Therefore the Subject NP is not going to be retrieved before the plural assignment of the Object. Retrieving the root NP for the object plural feature is hence less error prone.

On the other hand, the subject NP will be retrieved *after* the object has been assigned to the new plural feature, because subject and object are both needed for incremental interpretation, i.e. the anticipation of a matching relationship between both. The interpretation depends upon the number of the entities to be integrated, as the examples () and () illustrate.

(8) Gestern haben die Professoren den Studenten … Yesterday have the professors$_{nom}$ the student$_{acc}$ "*Yesterday, the professors have … the student*."

(9) Gestern hat der Professor die Studenten … Yesterday has the professor$_{nom}$ the students$_{acc}$ … "*Yesterday, the professor has … the students."*

Things that multiple professors are likely to do to a single student (examined, rejected, etc.) can be different from things that a single professor is likely to do to multiple students (taught, etc.). Number is hence an important feature at the conceptual level and useful for interpretation anticipation.

Differential plural re-activation in SOV constructions. During the process of incremental interpretation of each new verb-complement, each previous concept participating in the proposition, and, importantly, its plural feature - if it exists - will be retrieved and hence its activation will be pushed a bit. That is, when the object in SOV constructions is processed, the plural marking of the subject will be re-activated. This will only happen, however, if it can be successfully retrieved when the object is interpreted. There is a slight chance that the plural feature cannot be found here because its activation has already decayed too strongly. This chance, however, will be lower, if the plural feature receives additional activation from the goal, which is the case if the object is marked for plural. The additional amount of source level activation results in a higher retrieval probability for the subject plural marking if the object is plural. Therefore, the subject plural will be reactivated more often, so that it can be retrieved better and more often when the verb is produced.

Implications

Whether a plural or a singular verb is produced depends on the accessibility of the Subject's plural marking. The activation of plural-marking chunks decays, so that it might not be found when its retrieval is attempted at the verb, resulting in a general singular error (Hemforth and Konieczny, 2003). This effect is then modulated by task and construction specific variations. The model will

come in variants for different experimental paradigms, which are nevertheless based on the same core for verb-production. The first model variant presented here performs the completion task for written production and is hence a combined sentence processing and production model. It first reads two NPs, embedded in a variety of constructions, and then produces a verb. Modifier attraction errors (cf. Bock & Miller, 1991; Vigliocco & Nicol, 1998) are due to encoding errors during plural marking (feature percolation). The plural feature of the modifier-NP sometimes gets wrongly assigned to the Subject-NP. This effect is due to the necessity of reactivating the Subject-NP in processing the modifier-NP and is therefore restricted to modifier-NPs (Hemforth & Konieczny, 2003). In SOV constructions on the other hand, at each new NP, all verb arguments get reactivated to allow incremental interpretation and verb-anticipation (Konieczny and Döring, 2003). During this process the plural feature of an Object-NP can reactivate a plural feature of the Subject, reducing the singular error in S-O-V constructions (Hemforth & Konieczny, 2003).

The model is currently extended to other types of tasks to be able to account for task-specific-differences.

Aural repetition and completion. In this task, the participants are first presented with a preamble and then have to repeat and complete it with a verb in order to form a full sentence. This type of task has been used in the majority of experiments on agreement errors (e.g. Bock and Miller, 1991, Franck, Lassi, Frauenfelder and Rizzi, 2003, Bock and Cutting, 1992, Hartsuiker, Antón-Méndez and van Zee, 2001, Vigliocco and Nicol, 1998) and is generally claimed to test "pure" production, because subjects actually utter the whole sentence and not just the verb as in a completion task. Nevertheless, there is an inevitable comprehension component in this task as well, as the preamble has to be presented to the participants in some form. Instead of accounting for only the production part, we model the entire task, including reading and memorizing the preamble, repeating and completing it. Processing the preamble entails forming declarative representations for phonological and syntactic/conceptual information as in the completion task. To repeat the preamble, the model will have to retrieve either its phonological or syntactic representation. After repetition of the preamble, the verb should than be produced in the same way as in the present model. The difference between this task and the written completion task is in the higher activation of all elements of the preamble, as it is not only read once, but than (partly) retrieved and repeated. This should have no influence on the encoding error, but should make the general singular error much less frequent, which is in fact what has been observed in the experiments above. Moreover, the model predicts a floor effect for length variations of the intervening material in this paradigm, which is in fact was has been found (e.g. Bock and Miller, 1991, Bock and Cutting, 1992).

Time pressure. In the experiments reported by Hartsuiker, Antón-Méndez and van Zee, 2001, participants had to perform the production task under time pressure. The model predicts the observed effects: Under time pressure, productions that consume too much time are more likely to be ignored in favor of faster but less accurate productions. In particular, the plural-feature will sometimes be left underspecified for its root. Under-specified plural-features will then erroneously be retrieved at the moment of the production of the verb. This would happen even with plural-features of intervening object noun phrases, hence accounting for the object-attraction-effect obtained by Hartsuiker et al. Moreover, time pressure should increase the general singular error due to a change in the utilities of the productions which determine the number of the verb: the more accurate, but also more time consuming plural rule will have a lower utility than in other paradigms. This will lead to the singular rule firing more often, which produces the singular base form without checking for the plural feature.

Dual task paradigms. Finally, the model can also be extended to dual-task-paradigms, as applied by Fayol, Largy and Lemaire, 1994, and Hemforth, Konieczny and Schimke 2003, in which participants have to perform a second working-memory consuming task in addition to the sentence completion or production task. The cognitive load created by this second task will lead to less attention, i.e. source activation, being devoted to relevant chunks during the processing of the preamble. This will make both the encoding error and the singular error more likely, because they are both due to retrieval errors that become more likely if decay is stronger or starts from a lower level. As predicted, a higher overall number of errors was found in the experiments cited above.

The influence of a specific experimental paradigm may further interact with properties of the language which is investigated. Such an interaction may eventually explain a cross-linguistic difference which has been observed in SOV-constructions: In contrast to the German results reported above, several studies conducted on French SOV-construction found a mismatch effect in the SP-condition ("object attraction", see for example Fayol , Largy, Lemaire, 1994; Franck, Lassi, Frauenfelder, und Rizzi, 2003). In French, if there is an object in preverbal position, it always has to be a clitic pronoun. As these pronouns are very short, they have to be processed in less time than a full NP. Under such conditions, the model would predict the same effect as under time pressure: the plural-feature may be left underspecified for its root and

might then be retrieved when the verb has to be produced, leading to a plural-error.

Conclusion

We have introduced APE, an activation-based model of agreement errors in production. The model emphasizes the activation dynamics of the plural feature as the major source of variability in the data. Syntax effects are accounted for via operations that some constructions require that others do not. For instance, while modifiers have to be attached to their hosts, objects are not attached to subjects. On the other hand, objects, like other arguments, participate in anticipating the verb, while modifiers to NPs do not (to same extent, at least). These construction-specific operations interact with the activation dynamics of the plural feature in systematic ways that have been demonstrated to cover a wide variety of agreement phenomena discussed in the literature. The model predicts that time and feature re-use are crucial variables in production. Unlike purely linguistic production models of agreement errors, it can account for differences in task demands and non-linguistic factors of agreement performance.

Acknowledgments

We would like to thank Rob Hartsuiker, Michel Fayol, Julie Franck, Gerhard Strube and two anonymous reviewers for their helpful comments on earlier versions of this work.

Creativity Over the Lifespan in Classical Composers: Reexamining the Equal-Odds Rule

Aaron Kozbelt (AaronK@brooklyn.cuny.edu)
Department of Psychology, Brooklyn College, CUNY
2900 Bedford Ave.
Brooklyn, NY 11210-2889 USA

Abstract

This investigation extends Simonton's (1977) seminal study of lifespan creativity to eighteen eminent classical composers' total output. Major and minor work production was positively correlated over the lifespan, consistent with Simonton's chance-configuration theory of creativity. However, contrary to Simonton's (1977) null finding, here strong, positive, linear and weaker, negative, quadratic age trends were consistently found in predicting hit ratio (proportion of masterpiece-level music to total music composed per age period). This uniformly replicated in several analyses examining alternative explanations for this pattern. Most individual composers' hit ratios increased with age; none declined. The results indicate that composers' perspicacity in evaluating ideas mostly increases with age, suggesting greater importance for evaluation and elaborative problem solving processes in creative productivity than implied by a chance-configuration account.

Introduction

How does creativity change over the lifespan? Do eminent creators learn to be more creative and to reliably intuit which ideas are worth elaborating? Or is creative productivity primarily driven by chance and by individual differences that are largely impervious to learning or to external influences? Dean Keith Simonton's (1977) seminal study of ten eminent classical composers was one of the first to address these questions in a comprehensive, methodologically sophisticated way. His results strongly argue for the second alternative: illustrious composers apparently do not learn to write a larger proportion of great music as their careers progress, and productivity is remarkably immune to external perturbations like wars or civil unrest. Simonton's (1977) analysis has become a cornerstone of his "chance-configuration" theory of lifespan creative productivity (Simonton, 1984a, 1988, 1997, 1999), the most comprehensive, elaborated, and parsimonious psychological theory of this complex phenomenon.

However, is it really the case that creativity, or at least perspicacity, does not improve, even in distinguished composers? Classical music aficionados may think of Beethoven, Haydn, or Verdi, and be hard pressed to think of any late, major works by these composers that are not critically acclaimed, even when compared to their earlier efforts. In contrast, thinking of comparably lauded early works by these composers is probably much harder (Hayes, 1989; Weisberg, 1999). Nevertheless, Simonton's (1977) quantitative analysis implies that these instances are illusory.

Understanding lifespan learning and creativity clearly has important theoretical and practical implications, and multiple approaches may prove fruitful. For instance, alternative definitions of "great" music might be used to examine how well Simonton's (1977) results generalize. Also, his nomothetic analysis did not investigate individual differences in career trajectory. Varied trends can cancel each other, accounting for the null finding. Of particular interest are two types of trajectories: 1) a completely flat agewise function, consistent with the "equal-odds rule" and a chance-configuration account, and 2) an agewise increase in hit ratio, consistent with an expertise acquisition or problem solving framework. (Of course, trajectories can also decline or exhibit curvilinear functions.)

Simonton's own Darwinian chance-configuration model is the most thoroughly researched theory of lifespan creativity (see Simonton, 1988, 1997). Its basis is the blind generation and selective retention of ideas (Campbell, 1960). Creative ideation follows a constant probability of success, or the "equal-odds" rule. Simonton (1999, pp. 188-197) has further argued that this ratio cannot be increased by any means; a creator's hit ratio stays constant with age.

This theory has profound psychological implications. First, it suggests there is little learning or improvement in perspicacity. Creators lack the ability to judge their ideas or works reliably, either as final products or works-in-progress. At a social level, it suggests that creators have little control over the ultimate fate of their products. Thus, mass-production is the best strategy for those who seek eminence. The chance-configuration theory counterintuitively predicts that the high point of a creator's career will simultaneously result in the most masterpieces and the most ephemera: writing one masterwork does not guarantee further success.

Numerous studies support this theory. High correlations (typically r = .50 to .75) are often found between the production of major and minor works over the lifespan (see Simonton, 1997). Comprehensive studies of the output of ten great composers (Simonton, 1977) and ten eminent psychologists (Simonton, 1985) also found no agewise hit ratio changes. However, Kozbelt (in press) found a very strong agewise increase (r (age, annual hit ratio) = .91, $p <$ .0001) in Mozart, a composer in Simonton's (1977) sample.

Thus, at least some composers' hit ratios may improve with age. This is consistent with an expertise acquisition or problem solving perspective (Newell, Shaw, & Simon, 1962; Weisberg, 1999). From this view, creating a musical composition is an open-ended problem, on which composers bring their musical skill to bear. Expertise acquisition studies (Ericsson, Krampe, & Tesch-Römer, 1993) suggest

individual differences in musical ability are largely attributable to deliberate practice rather than innate talent. Likewise, Hayes (1989) examined 76 composers and found that in almost all cases, at least ten years of intensive study were required before a composer wrote his first masterwork, defined by recording counts. This result seems inconsistent with Simonton's (1977) finding of no change in hit ratio over composers' entire careers, since clearly great composers are writing *some* great works in their maturity. Thus, despite potentially important structural differences between expert performance and creative performance (Simonton, 2000), agewise improvement may be a possibility, particularly if skilled performance is a central component of creativity.

As noted earlier, individual variation may overwhelm a seemingly flat aggregate agewise trajectory. Galenson (2001) has found a systematic dichotomy among painters, linking career trajectories (based on the average value of work produced at various times) with creative processes. "Finders" peak early and largely plan their work in advance, proceeding with little revision. "Seekers" peak at reliably later ages and engage in much revision as they work. A comparable dichotomy among composers was suggested by Simonton (1986). He found that the most aesthetically successful works appeared early or, better, very late in composers' careers.

The present study tests the robustness of the equal-odds rule and also examines individual composers. It adopts Simonton's (1977) basic methodology of cross-sectional time-series. However, the present investigation also seeks to vary or improve the measurement of some constructs (e.g., how "masterpieces" are defined or how works can be more sensitively weighted in the analysis). Further, it seems important to confirm that the null finding on hit ratio replicates on a larger sample of composers, since, as noted above, few studies directly and comprehensively examine this important question. Moreover, a career-long flat hit ratio seems inconsistent with the finding that composers generally write no great works in the first decade or so of their careers (Hayes, 1989; Weisberg, 1999). Unfortunately, Simonton's (1977) original data are no longer extant, due to computer technology changes (Simonton, personal communication). While catalogs of composers' works are fairly standardized, many works of questionable authenticity or dating hover at the periphery of such catalogs, so revisiting and extending this type of analysis seems worthwhile.

The four models described above permit a characterization of aggregate and individual career hit ratio trajectories. The chance-configuration theory predicts no change in hit ratio with age, a positive correlation between major-minor work production over the lifespan, and is fairly agnostic on work quality. The problem solving perspective predicts a likely increase in hit ratio and masterpiece quality over time and is fairly agnostic on major-minor work production correlations.

Method

Composers Composers were selected from three sources: one list based on eminence (Farnsworth, 1969,p. 228), one based on performance frequency (Moles, 1958/66, p. 28), and one list of aesthetic significance ratings of composers' masterpieces (Halsey, 1976). The top ten composers in the first two lists were automatically sampled. Other composers who had numerous masterworks listed by Halsey (1976) were also included. The 18 composers examined were J.S. Bach, Bartók, Beethoven, Brahms, Chopin, Debussy, Dvořák, Handel, Haydn, Mendelssohn, Mozart, Schubert, Schumann, Richard Strauss, Stravinsky, Tchaikovsky, Verdi, and Wagner. Collectively, their lives span three centuries and their works account for 54% of all classical music performed (Moles, 1958/1966, p. 28).

Works Chwiałkowski's (1996) comprehensive catalog provided lists and dates of all known works of the 18 composers (6,560 compositions total). Arrangements, revisions, and lost works were excluded from most analyses.

Age at Composition Age at composition for each work was also determined (using Chwiałkowski, 1996). When composition spanned multiple years, the median (rounded up if necessary) was used. For aggregate analyses, works were grouped into consecutive five-year age periods for each composer (cf. Simonton, 1977): 5 – 9, 10 – 14, etc. Thus, each composer contributed data only during his active composing career. Ages were put into mean-deviation form based on the entire sample of composers, yielding an *age linear* variable. Age linear scores were also squared, yielding an *age quadratic* variable to test for curvilinear effects.

Works were also pooled into one-year age windows for finer-grained analyses. A total of 714 age periods were tallied across the 18 composers. *Age linear* and *age quadratic* measures were calculated in the same way for one-year windows as for five-year windows.

Weighting Performance times were used to weight each work. Times were taken from recordings (74% of works), estimates based on scores or listings in composers' work catalogs (14%), averages based on comparable works by the same composer (8%), and estimates using Simonton's (1977) genre-based system when no other information was available (4%).

Masterpiece definitions Four criteria were used to define masterpieces. Two used Halsey's (1976) list of musical masterpieces: 1) all works listed by Halsey, 2) only works given one of the two highest ratings (scores of 1 or 2) by Halsey ('stringent Halsey'). Two used recording counts from 1) the *RED Classical Catalog* (Ford, 2003), or 2) *The Penguin guide to compact discs* (March, Greenfield, & Layton, 2001). Each composer's works were rank-ordered from most to least recorded, and cumulative performance durations were computed from the top down until the total approached 50%. Top works were designated masterpieces for each measure.

Concurrent productivity Two variables were related to overall output. One, *years in interval*, logged how many years per period involved actual composition. This ranged from 1 to 5 (periods when no music was written were not analyzed). The other, *output*, tallied the total amount of music (in minutes) each composer wrote in each five- or one-year period. To minimize overall productivity differences, individual *z*-scores for output were computed for each composer separately.

Results

Because each composer's works were exhaustively tabulated, not sampled from a larger population, inferential statistical tests are arguably inappropriate (cf. Simonton, 2000). Therefore, effect sizes and parameter estimates accompany inferential results, whose hypothetical *p*-values can be used as a heuristic for discussion.

Lifespan productivity

Lifespan productivity generally increases quickly early in a creator's career, peaks, and then declines more gradually (Simonton, 1977, 1997). When age is expressed in mean-deviation form, output usually correlates positively with *age linear* and negatively with *age quadratic*. When these effects are combined, they form the backwards, inverted J-curve characteristic of creative output over the lifespan.

To confirm this trend for the present set of composers, as in Simonton (1977), data from all composers were put into the same time-series for a multiple regression analysis. To minimize inter-composer productivity variance, *z*-scores for output across 5-year age periods were computed for each composer separately. These defined the dependent variable. *Age linear* and *age quadratic*, as well as *years in interval*, were then used to predict productivity. A total of 179 age periods were included in the analysis.

The regression was significant, F (3, 175) = 38.74, $p < .0001$, adjusted $R^2 = .39$. *Age quadratic* and *years in interval* were highly significant, respectively, ß = -.35 and .45, both $p < .0001$. The amount of variance uniquely accounted for by each variable is given by the squared semi-partial correlations, here $sr_i^2 = .09$ and .18, respectively. The regression coefficient for *age linear* was marginally significant, ß = .11, $p = .08$ ($sr_i^2 = .01$). Thus, the overall lifespan trajectory of total productivity echoes the frequently observed single-peaked function, although its present shape is closer to an inverted U than to a backwards, inverted J.

The peak age for productivity can be computed by finding the residual *output* after regressing *years in interval*, setting up a polynomial regression using *age linear* and *age quadratic* to predict residual *output*, and taking the derivative of the regression equation. When this was done, peak productivity was found to occur at 39.7 years. When untransformed productivity was analyzed, the results essentially replicated (peak = 37.1 years).

When age was statistically controlled, the results indicating an inverted U-curve replicated. In fact, peak age for productivity lies almost exactly in the middle of standardized career lengths ($z = +0.04$).

Major-minor work correlations

Recall that the chance-configuration theory predicts a positive correlation between major and minor work production over the lifespan. Here, major works were defined by inclusion in Halsey (1976). Major and minor works were positively correlated, r (177) = .36, $p < .0001$ ($r^2 = .13$), supporting the chance-configuration theory. However, only two individuals showed statistically reliable correlations: Strauss, $r = -.50$, $p = .05$, and Bach, $r = .93$, $p < .0001$. Among individual composers, the median $r^2 = .16$.

Hit ratio over the lifespan

This is the main analysis of interest. Recall that Simonton (1977) found that hit ratio was essentially flat over the entire durations of ten great composers' careers, showing no systematic change with age. However, this finding seems inconsistent with Hayes's (1989) finding that composers write no masterworks in the first decade or so of their careers. To investigate this issue with the present sample of 18 composers, a hit ratio was computed for each composer in each age period using each of the four measures (basic Halsey, stringent Halsey, *RED*, and *Penguin*).

Composers vary considerably in their overall lifetime hit ratios. When defined by all works included in Halsey (1976), these range from .18 (Handel) to .70 (Wagner). The M (SD) hit ratio among the composers was .44 (.17). Thus, to minimize variance due to inter-composer hit ratio differences, *z*-scores for hit ratios were computed separately for each composer on each measure.

Intercorrelations between hit ratios determined by the four masterpiece criteria were all highly correlated, with correlation coefficients ranging from .45 to .74. To simplify matters, an unrotated, principal components analysis was conducted and revealed two factors. Factor 1 accounted for 71.6% of the variance, with an eigenvalue of 2.87 and loadings ranging from .75 to .91. Factor 2 accounted for 16.1% of the variance, with an eigenvalue of .65 and loadings ranging from .63 to -.36. The stringent Halsey criterion, defining composers' very greatest masterworks, had the lowest loading on Factor 1 and the highest loading on Factor 2, and this pattern was exaggerated in varimax rotated and oblique analyses. This measure was thus analyzed separately. (In practice, the results reported below do not substantively differ depending on whether three or four measures are combined, or if each of the four measures is examined individually.)

Hit ratio multiple regression To test hit ratio trends over the lifespan, all composers were initially put onto the same time-series. Each composer contributed data only during his active composing career. In each age period, individual *z*-scores of hit ratios from the basic Halsey, *RED*, and *Penguin* measures were averaged, yielding the dependent measure (basic hit ratio). Individual *z*-scores for *output* in each age period, used as the dependent measure for productivity, were used here as a statistical control. *Age linear*, *age quadratic*, and *output* predicted hit ratio.

Contrary to Simonton's (1977) findings and the

predictions of the chance-configuration theory, the regression was highly significant, F (3, 175) = 40.0, p < .0001, adjusted R^2 = .40. Both *age linear* and *age quadratic* (but not *output*) significantly predicted hit ratio, *age linear* ß = .65, and *age quadratic* ß = -.43, both p < .0001 (sr_i^2 = .36 and .13, respectively). Since output was not significant, taking the derivative of the second-order polynomial regression equation yields the peak age for hit ratio: 52.6 years, almost 15 years after the peak for overall output. The basic hit ratio trajectory is shown in Figure 1.

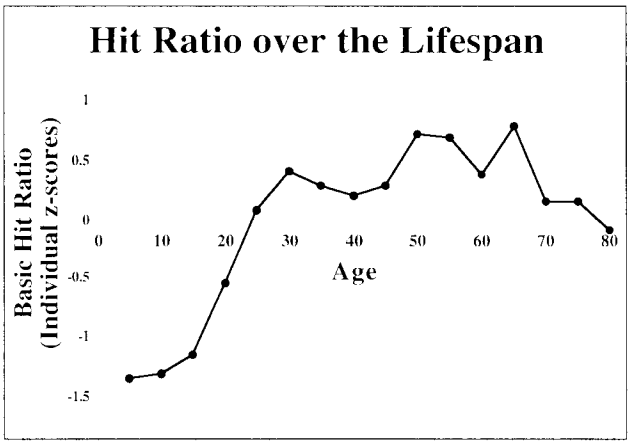

Figure 1: Average basic hit ratio over the lifespan (*z*-scores computed for each composer individually).

Subsample and individual analyses Why do these results differ so strikingly from Simonton's (1977)? Perhaps the additional eight composers affected the results. However, this is not the case: when his ten composers and the additional eight are analyzed separately (recalculating age *z*-scores for each subsample), the results essentially replicate: for Simonton's (1977) ten composers, the regression equation accounts for 37% of the variance in hit ratio, *age linear* ß = .64, p < .0001, (sr_i^2 = .38) and *age quadratic* ß = -.26, p < .05, (sr_i^2 = .04); for the remaining eight, the regression equation accounts for 41% of the variance in hit ratio, *age linear* ß = .63, age quadratic ß = -.52, both p < .0001 (sr_i^2 = .33 and .19, respectively) .

Each composer was also individually analyzed. In these analyses, one-year age windows were used and age *z*-scores were recomputed. The hit ratio of almost every individual composer was impacted by age (median adjusted-R^2 = .34). In particular, thirteen composers showed reliable (p < .05) positive *age linear* effects (median individual sr_i^2 = .22). Five showed reliable negative *age quadratic* effects (median individual sr_i^2 = .02). Only Bach and Strauss showed no age-related trends. The linear increase seems quite robust; the mid-career quadratic boost is consistently weaker.

Stricter hit ratio criterion The stricter Halsey criterion (reversed ratings of 4 or 5) was also tested. Hit ratios and individual hit ratio *z*-scores were recalculated, and the same three-predictor regression was performed. This demanding criterion reduces power, as happens whenever hit ratios approach 0 or 1. Despite this, the regression remained highly significant, F (3, 175) = 15.05, p < .0001, adjusted R^2 = .19, *age linear* ß = .49, p < .0001, (sr_i^2 = .20) and *age quadratic* ß = -.19, p < .05, (sr_i^2 = .02). *Total output* was not significant. Individual analyses, using one-year age windows, revealed ten composers with reliable (p < .05) positive *age linear* trends (median individual sr_i^2 = .12). *Age quadratic* was a weaker predictor (median individual sr_i^2 = .03). Three composers showed reliable quadratic trends, one (Wagner), negative, and two (Bartók and Schubert), positive, indicating a late surge in great masterwork production. Taking the derivative of the polynomial regression equation (after accounting for *output*) yields a peak age was 65.1 years for stringent hit ratio, notably later than that for productivity (late thirties) or the basic hit ratio measure (early to mid-fifties).

Mature works Perhaps these results, particularly the repeatedly observed *age linear* effect, are an artifact of composers' unacclaimed early works (recall Hayes's (1989) ten-year rule), which dampen hit ratio at career outset. To test this, the first two age periods of each composer (plus the third periods of Bartók and Dvořák, when both hit ratios were 0) were dropped from the analysis. Age *z*-scores were recalculated. The average of the basic Halsey, *RED*, and *Penguin* hit ratios defined hit ratio. The three-predictor regression remained significant, F (3, 140) = 7.79, p < .0001, adjusted R^2 = .13. *Age linear* positively predicted hit ratio, ß = .29, p = .001 (sr_i^2 = .07). *Age quadratic* and *output* each negatively predicted hit ratio, respectively, ß = -.30, p = .001 (sr_i^2 = .08), and ß = -.15, p = .09 (sr_i^2 = .02). The agewise effects are attenuated during compositional maturity, but the effects remain reliable.

Arrangements and revisions Not incorporated into any previous analyses were arrangements and revisions that were included (albeit minimally weighted) in Simonton's (1977) analysis. As a final test of the work measure, arrangements, revisions, and datable lost works were included in the analysis. Simonton's (1977) weighting system was employed. Hit ratios were recalculated using inclusion in Halsey (1976) as masterpiece criterion. A total of 8,057 data points were included. The number of age periods also increased, to 186. Untransformed hit ratios in each age period were used as the dependent measure, and *years in interval* was used as a control, echoing Simonton (1977). The results replicated and are comparable in strength to most previous analyses. The three-predictor regression remained significant, F (3, 182) = 31.85, p < .0001, adjusted R^2 = .33. *Age linear* positively predicted hit ratio, β = .57, p < .0001 (sr_i^2 = .27). *Age quadratic* negatively predicted hit ratio, β = -.30, p < .0001 (sr_i^2 = .06). *Output* was a marginally significant predictor, β = .13, p = .05 (sr_i^2 = .01). Eight composers showed significant positive *age linear* trends, and three showed significant *age quadratic* trends (two negative, one positive).

Thematic measure A final analysis used a measure based on musical themes or melodies rather than entire works (cf.

Simonton, 1977). Hit ratio in each age period was defined by the number of melodies included by Barlow and Morgenstern (1948, 1950) in all works listed by Halsey (1976) divided by the total number of anthologized melodies from that age period. Fewer age periods (141) were represented by this measure than the work measure, since not all periods contained anthologized themes. Age *z*-scores for the sample were recalculated. Here, *total themes* per period was used as a control. The three-predictor regression predicting hit ratio remained significant, contrary to Simonton's (1977) report: F (3, 137) = 9.64, $p < .0001$, adjusted $R^2 = .16$. *Age linear* positively predicted hit ratio, ß = .37, p < .0001, ($sr_i^2 = .12$) and *age quadratic* negatively predicted hit ratio, ß = -.26, $p = .002$, ($sr_i^2 = .06$). *Total themes* was marginally significant, ß = .15, $p = .06$, ($sr_i^2 = .02$).

Alternative analyses In addition to the analyses reported here, additional analyses ruled out further candidate alternative explanations for the inconsistency of the present results with those of Simonton (1977). Among the analyses performed were those using the raw average hit ratio for the basic *Halsey*, *RED*, and *Penguin* criteria, rather than individually z-transformed hit ratios; using an aggregate one-year age window rather than a five-year age window; computing age based on years of musical study (career age) rather than chronological age; analyzing only mature works using a one-year window dating from the onset of musical study or of musical composition; and performing all of these analyses on each two subsamples of composers: Simonton's (1977) ten and the additional eight. The same pattern of a significant, positive *age linear* trend coupled with a significant (but weaker), negative *age quadratic* trend was found in each analysis.

Discussion

Without exception, the present results contradict Simonton's (1977) null finding on agewise changes in classical composers' hit ratios. *Age linear* increases were uniformly found in analyses using two sets of masterpiece criteria, two measures of overall output (works and themes), two weighting systems, statistically controlling for individual differences in lifetime hit ratio, analyzing only composers' mature works, including arrangements and revisions and lost works, and separately examining two subsamples of the composers. Individual analyses generally showed reliable ($p \leq .05$) *age linear* increases in at least half of the sample, and no change in hit ratio in the rest. A weaker, negative *age quadratic* trend was also frequently evident, suggesting a mid-career boost in hit ratio. These findings support the problem solving and peak age perspectives and seem largely inconsistent with the chance-configuration theory. An increase in the quality of masterpieces, also significant in about half of individual composers, further supports the problem solving and peak age perspectives. The chance-configuration theory was supported, however, by a somewhat lower (though still reliable) positive correlation between the production of major and minor works.

It remains unclear why these results differ so dramatically from those reported by Simonton (1977). Numerous alternative explanations (e.g., including arrangements and revisions, using various masterpiece criteria) were tested and ruled out. More detailed comparisons are difficult to make, since Simonton (1977) reported few descriptive statistics about the analyzed compositions, and sometimes the reported statistics contradict the present data (e.g., in the number of age periods analyzed). Unfortunately, because of computer technology advances, his original data are no longer retrievable (Simonton, personal communication).

Aspects of the observed agewise changes are compatible with both the problem solving and chance-configuration perspectives. For instance, much of the improvement in hit ratio occurs in the early part of composers' careers, consistent with expectations about skill and expertise acquisition as a precondition for outstanding creative achievement (Hayes, 1989; Weisberg, 1999). However, age trends during compositional maturity accounted for only one-third to one-half as much variance as those spanning composers' entire careers, which is at least *somewhat* more consistent with the chance-configuration theory.

The slight hit ratio decline late in life is inconsistent with both theories. The problem solving perspective does not posit a mechanism to explain a drop in perspicacity late in life. The hit ratio decline among elderly composers also violates the equal-odds rule applying until the end of creators' lives. However, this decrement should be interpreted cautiously, due to a low N and high variability in hit ratios of composers in their seventies and beyond.

The pattern of peak ages is more difficult to reconcile with the chance-configuration theory. Overall productivity peaks first, in composers' late thirties, consistent with previous work (see Simonton, 1997). Hit ratio defined by the three less stringent masterpiece criteria peaks around age 53. The more stringently defined hit ratio peaks even later, at 65 years. Note also that these data are not minor statistical aberrations, as they represent parameters for the career landmarks of these 18 composers.

These results dissociate two predictions of the chance-configuration theory. Many studies, including this one, show positive major-minor work correlations. However, such correlations do not preclude an agewise improvement in hit ratio and cannot by themselves rule out alternative theoretical models. Comprehensive analyses of agewise hit ratio trends, as performed here, are also necessary.

The consistent *age linear* increase and late peaks for hit ratio and masterpiece quality suggest that at least some creators boost creativity as their careers progress. While certainly quantity of ideation provides the raw material for creative productivity, the present results suggest that some creators are perspicacious and able to consolidate gains as they elaborate ideas. Thus, goal-directed problem solving and evaluation processes, as well as accumulated expertise (Hayes, 1989; Simonton, 2000; Weisberg, 1999), play substantial roles in creative productivity. Naturally, creators' instincts are not perfect, but many composers'

intuitions about the value of their ideas appear to have been sound, and they seem to have improved these intuitions substantially with age.

The evaluative and elaborative processes that might permit an increase in hit ratio and masterpiece quality remain ill defined, but these results suggest that both cognitive and motivational variables play key roles. Average hit ratio does not increase linearly but is a more curvilinear, single-peaked function. Later in their lives, composers write less music than in midcareer, but a progressively higher proportion is masterpiece-level, and the masterpieces themselves are of higher quality. What older composers lack in energy, they appear to make up for in wisdom.

The underlying psychological processes may also be informed by further ideographic analyses. Here, over half of the 18 composers showed systematic agewise increases in hit ratios and masterpiece quality, and the rest showed few agewise changes. Further research linking career trajectory with characteristic creative processes of composers (cf. Galenson, 2001) may inform the conditions under which improvement in hit ratio or masterpiece quality may be realized.

The present data must be interpreted with caution. They represent a single (but robust) violation of the equal-odds rule. However, they clearly show that the equal-odds rule does not universally characterize creative productivity. In addition to ideographic analyses, comprehensive studies like this one are necessary to determine the extent of equal-odds rule application (or violations) in other domains. At a minimum, the results suggest that there can be important roles for elaborative and evaluative problem solving processes, as well as for learning, in creative productivity.

Acknowledgments

I thank two anonymous referees, Arthur Reber, Laraine McDonough, David Owen, and Neil Macmillan, who offered constructive conceptual and methodological advice at various stages of the project's development. Dean Keith Simonton provided valuable information on the methodology and weighting system of his 1977 study. I also thank the Brooklyn College Library, the New York University Elmer Bobst Library, the New York Public Library for the Performing Arts, as well as the Tower Records, HMV, and Virgin Megastores of New York City for access to musical scores, reference books, and recordings. Cynde McKenzie, Jodie Cohen, and Bracha Schoffman assisted with some data coding.

Constructing and Revising Mental Models of a Mechanical System: The role of domain knowledge in understanding external visualizations

Sarah Kriz (kriz@psych.ucsb.edu)
Department of Psychology, University of California

Abstract

External visualizations such as diagrams and animations are frequently used to teach people about the workings of mechanical systems. The present study considers the types of mental models that can be constructed from visual-spatial (non-verbal) materials alone, and the extent to which people revise their incorrect mental models. Comparing 10 high physics knowledge participants to nine low physics knowledge participants, we assessed how these two groups constructed and revised mental models of a flushing cistern. High domain knowledge participants extracted more meaningful information from the materials, although their initial models of the system were not as accurate as expected. However, after answering comprehension questions and viewing the learning materials again, high domain knowledge participants were more likely to revise their mental models into correct representations of the system, whereas the participants with low domain knowledge continued to rely on incorrect models. The discussion of these findings focuses on how prior knowledge may contribute to understanding visual instructional materials.

External visualizations (e.g., diagrams and computer animations) are often used to inform people about how a complex system behaves. Physical systems such as machines are causally and temporally complex, and understanding these systems depends on an appreciation of the spatial relations between their components and how these change over time. The spatial and temporal aspects of mechanical movements can be illustrated directly via visual-spatial representations, while the same information presented in a verbal format might be more difficult to understand.

It seems plausible that the design of external visualizations could greatly affect one's success at extracting relevant information from the display. For example, adding accompanying text that describes aspects of phenomena presented in the visualizations may help in providing additional information that a diagram alone could not provide. Previous studies researching the integration of text and diagrams have shown that people with low domain knowledge or low spatial ability rely heavily on accompanying textual descriptions (Hegarty & Just, 1993; Kalyuga, Chandler, & Sweller, 1998). These studies also suggest that as a person becomes more familiar with a domain, the reliance on textual explanations decreases. However they have not specifically addressed which types of information are best understood from diagrams and animations by people with different amounts of background knowledge.

The purpose of the present study is to examine how understanding a mechanical system is achieved when visual materials such as diagrams and animations are presented without accompanying textual or verbal explanations. As part of a larger research objective, we analyze how purely visual materials are understood by both high and low physics knowledge participants. By examining how people with varying degrees of domain knowledge interpret visual materials, we can design future materials containing verbal descriptions that supplement informational gaps in the visual displays. We assume that these informational gaps will differ for low and high domain knowledge individuals, therefore, this study focuses on how domain knowledge contributes to the comprehension of visual materials conveying a complex mechanical system.

Constructing Mental Models

Creating a mental model of a complex system requires that a person identify the parts involved, understand their causal relationships, and relate the causal steps to the larger functions of the system. Our cognitive model of how people come to construct mental models from multimedia materials follows that outlined by Narayanan & Hegarty (2002). To summarize, there are five steps that a person must take to understand a machine from multimedia presentations. First, the system must be decomposed into individual components. Second, the learner must make representational connections to prior knowledge. Third, if verbal information is present, a person is required to make further referential connections between the visual media and the verbal explanations. Then, she must determine the causal chain of events. Finally, a dynamic mental model is constructed. In the present experiment, we are particularly interested in the second step-- how prior domain-related knowledge affects the construction and revision of mental models.

We predict that, in accordance with previous studies (Spilich et al., 1979; Chiesi, Spilich, & Voss, 1979; Lowe, 1994; 1999), high domain knowledge individuals will be more likely to construct initial mental models that incorporate high-level functional understanding, whereas people lacking domain-related knowledge will focus on the movements of the parts on a local level. Additionally, we expect the level of domain knowledge to influence the extent to which models are revised. Assuming that learning is an iterative process of understanding (Miyake, 1986), how people move from a state of understanding to a state of non-understanding may depend on their level of domain-related knowledge. As previous studies have shown (Chi, 2000; Chi et al., 1994), it is when conflicts between internal models and external information occur that people are more likely to revise their internal mental models. We propose that conflicts are more likely to be perceived by people with high domain knowledge because they are at an informational advantage for meaningfully evaluating their models.

Three Types of Mental Models

The stimulus used in this experiment was a British model of a toilet tank. While the purpose of the system is the same as an American model (i.e., to flush water into the toilet bowl), the mechanism used to accomplish this function differs vastly from its American counterpart. Thus, we assume that the participants in our experiment (American college students) did not have prior knowledge of the mechanism that they studied in this experiment.

Specifically, the main difference is the manner in which water exits the tank into the bowl. In the British model, water exits the tank through a siphon process. The siphon process begins when two disks (located at the bottom of the bell in the middle of the diagram) are pushed together (by pulling the handle) and push water up through the main siphon pipe. As water flows up the siphon pipe and down into the toilet bowl, the siphon process begins. This enables water to flow through the siphon pipe without the aid of the disks. The process ends when the water level in the tank falls below the siphon bell, and air enters the siphon pipe. This is reflected in Figure 1.

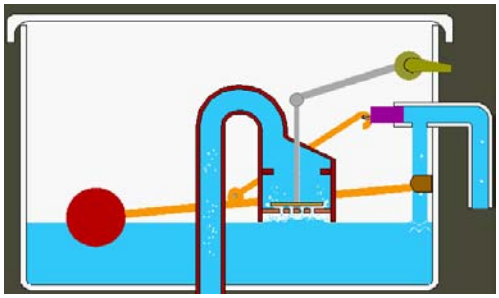

Figure 1: Air enters and stops the siphon process.

Data from this and previous experiments (e.g., Hegarty, Kriz, & Cate, 2003), indicate that people construct one of two types of mental models of the flushing cistern. The first (physically correct) model works according to the physical process of siphoning. As explained above, a siphon occurs when liquid in an enclosed system moves, via a pressure differential, from a point of high pressure to a point of lower pressure. In the case of the British toilet tank shown in Figure 1, a siphon enables water to continuously flow up and back down the large pipe in the middle in order to exit the tank. The siphon is broken when air, which is lighter than water, enters the enclosed system. This breaks the pressure differential, and the water flow out of the pipe stops.

The incorrect model of this system involves the disks as the main stopping agents. Participants with incorrect models may or may not understand the initialization of the siphon process. Their model is characterized, however, by the function of the disks. The incorrect model assumes that the water stops flowing out of the tank because the upper disk falls on the lower disk and creates a water-tight barrier, or seal. As Figure 1 illustrates, the two disks do not touch when the lower disk falls. If they did, air would not be able to enter. Therefore, the visual materials that participants view are in direct conflict with this model.

Many participants do not offer an explanation for how water starts and stops flowing from the tank to the bowl. A possible reason for this omission is that they have an informational "gap" (Chi, 2000) in their mental model. In other words, they are missing the knowledge necessary to explain the causal relationship between activity in the tank and the stopping of exiting water. However, it is quite possible that this process is, in fact, represented in their mental models but was simply not explained during the protocol. Because there was no method for empirically differentiating between these two possibilities, these cases were not considered in analyses.

Method

Participants

Nineteen adults (10 high domain knowledge, 9 low domain knowledge) volunteered for the study as paid participants. The high domain knowledge (HDK) participants were UCSB graduate students from Mechanical Engineering or Material Science, with the exception of one participant, who was the staff lab manager of the undergraduate Mechanical Engineering lab. All experts held Bachelors degrees in engineering or physics and had been studying physics and engineering for a mean of 6.4 years (range 5-8 years). It was assumed that the HDK group had knowledge of pressure differentials and siphoning, as these topics are covered in undergraduate physics and engineering courses.

The low domain knowledge (LDK) participants were UCSB graduate students from Social Sciences, Art, Humanities, or Biology, and all considered themselves physics novices. Four had taken introductory physics in high school and one had taken freshman physics in college. None had taken engineering courses.

Materials and Apparatus

Participants viewed a variety of visual displays depicting a toilet tank either in a resting state or in motion. The *labeled static diagram* showed a color picture of the toilet tank in its resting state and included labels naming the mechanical parts. The *unlabeled static diagram* was identical to the labeled version, but without the labels. The *four phases static diagram* was a series of four diagrams displayed together. Each diagram showed a different phase of the flushing process. The labeled, unlabeled, and four phases diagrams were all viewed as PowerPoint slides.

Three animations were also available to the participants. All of the animations consisted of a series of 134 bitmap images. The *computer-controlled animation* was displayed in Macromedia Flash MX and played at a rate of 6 frames per second. The participant pressed a button with the mouse in order to begin playing, but otherwise had no control over the speed or the direction of the animation. The *participant-controlled animation with arrows* was run in a Quicktime player, which allows one to control the speed and direction in which a video file plays. In both animations, arrows appeared at various points to indicate a part's direction of movement or to signal an important event. The *participant-controlled animation without arrows* was identical to the other participant-controlled animation except it did not contain arrows.

All materials were displayed on a 17" desktop monitor at 1024x768 resolution.

Procedure

Participants sat in front of the computer and were told, "You are going to view diagrams and animations that illustrate a toilet tank, but note that this is not an American model. Please view the materials and learn how the system works. You have as much time as you need to study the materials." They were then shown the six visual learning aids. The researcher briefly explained each learning aid, without mentioning the presence or absence of arrows in the animations, and demonstrated how to manipulate the controls of the Quicktime Player.

After viewing the material, the monitor was turned off and participants were given a booklet of comprehension questions. The first question asked to explain step-by-step what happens in the toilet tank after the handle is pushed. The next four questions were troubleshooting questions, in which novel breakdown scenarios were described. The participants were required to generate as many responses as possible that would account for the breakdown of the system. The final four questions were function questions that asked about the function of specific parts of the mechanical system. Participants were asked to provide written answers at their own pace.

Upon finishing the written portion of the experiment, the participants were then asked to view the visual materials again. The participant-controlled animation without arrows was displayed and participants were asked to orally report to the researcher where events began and ended. An "event" was not predefined by the researcher, and participants were allowed as much time as they needed to formulate their answers before reporting. When they were ready, participants reported what they saw as "events." This portion of the session was video taped for later analysis.

Results

Constructing Initial Mental Models

In order to assess participants' initial mental models of the system, we evaluated the first written question, in which participants described the step-by-step process of a flush. The two groups' responses showed both quantitative and qualitative differences. As Figure 2 shows, the HDK participants reported on average four more steps than the LDK participants, and this difference reached significance: $M = 16.8$ v. $M = 12.8$; $t(17) = 3.176$, $p < .05$. This difference indicates that the HDK individuals were able to extract more information from the visual materials.

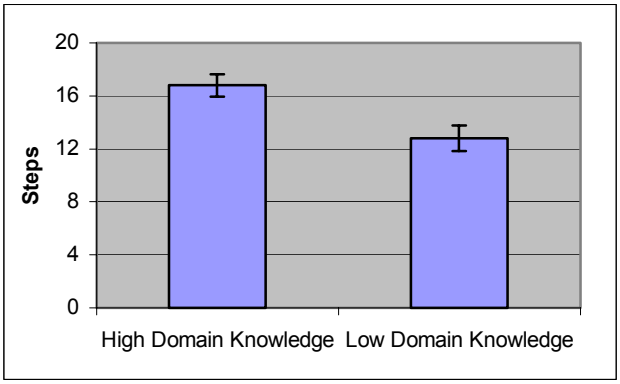

Figure 2: Mean number of steps in written responses.

Furthermore, the types of events that were mentioned by each group differed. The majority of participants (i.e., seven participants or more) in both groups reported eight common steps. However, the HDK participants tended to mention steps that the LDK students did not mention. (See Table 1.) Of note, the HDK participants tended to focus on the rising and falling of the water level, and that focus was not evident in the majority of the LDK participants' written reports.

To evaluate the accuracy of participants' initial mental models, the step-by-step written reports were evaluated for steps that reflected correct, incorrect, or unstated models of the siphon process. If participants mentioned the siphon process beginning when the disks pushed the water up the siphon pipe and ending when air entered the system, their models were considered correct. Incorrect models were those in which the disks were reported as stopping the water from leaving the tank. Finally, a mental model was coded as "not stated" if participants made no mention of the how the water stopped flowing out of the tank. As Table 2 shows, the distribution of initial model types did not differ at all between the two groups.

Table 1: Steps mentioned by at least 7 participants in their step-by-step written responses.

Steps	HDK	LDK
Push down on the handle	x	x
The upper disk moves up	x	x
The lower disk moves up	x	
Water enters siphon pipe	x	x
The upper disk moves down	x	x
The lower disk moves down	x	
Water level falls below siphon bell	x	
Water level lowers in tank	x	
Float lowers	x	x
Inlet valve opens	x	x
Water flows from inlet pipe to tank		x
Water level rises	x	
Float rises	x	x
Inlet valve closes	x	x

Data from the troubleshooting and function question responses reveal, however, that high and low knowledge participants did differ on how strongly they relied on incorrect models in later comprehension questions. Figure 3 reflects the mean number of troubleshooting and function question answers that contained the incorrect model. The data indicate that the LDK participants used incorrect mental models significantly more often than the HDK participants to account for system breakdowns and overall functions of the tank: M= 3.4 v. M=1.6; $t(17)$=2.535, p<.05.

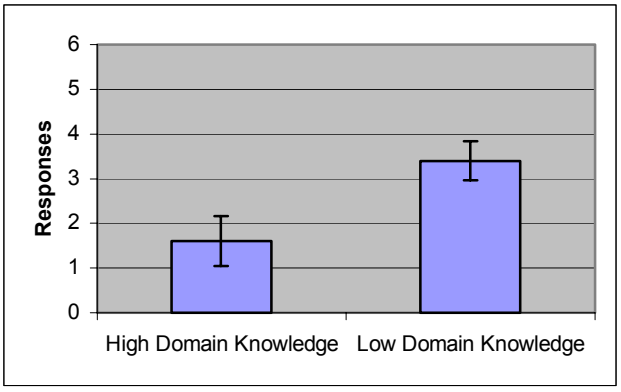

Figure 3: Mean number of troubleshooting and function responses conveying incorrect model.

Revising Mental Models

Although the written step-by-step responses and the orally presented event structure responses resulted from slightly different tasks, a paired samples t-test yielded no significant differences for either group in the number of steps mentioned between the two tasks. Thus, we were able to compare the written and oral reports in order to assess model revisions.

In their oral reports, the majority of participants in each group (at least 7) mentioned three steps that were not in their written reports. For the LDK participants, these included: (1) the lower disk moves up, (2) the lower disk falls down, and (3) water stops flowing into the siphon pipe. The three events that the majority of HDK participants mentioned in their oral reports but not in their written response were: (1) water flows into the toilet bowl, (2) the siphoning process begins, and (3) the siphoning process is broken. The striking difference between the two groups is in the perceptibility of the added steps. The three steps commonly added by the LDK participants are directly perceptible from the animation, which they were allowed to view while giving their reports. On the other hand, the HDK group added steps that were not directly perceptible from the animation, but instead involved higher-level processes and functions.

The number of participants in each group who changed from one model to another is shown in Table 2. As is evidenced in this table, the majority of the HDK participants moved from an incorrect or unstated model to a correct model. Whereas two HDK participants began the study with a physically correct model, eight of the ten finished the study with this model. That is, they orally reported that the siphon phenomenon, not the disks, ends the outflow process. Contrary to this, the LDK participants show no clear pattern of model revision. Many of their final models remain incorrect. In sum, the steps reported in the written response compared to the oral response clearly showed signs of model revision in the HDK sample, whereas no pattern was evident in the LDK data.

Discussion

Initial Models

The results of this study indicate that HDK participants were able to extract more information about the flushing cistern system from the visual materials provided. They not only reported more initial steps than the LDK individuals, but were also better at integrating higher-level causal changes, such the rising and falling of the water level, into their initial reports. As predicted, and following previous findings on reasoning with external visualizations (Lowe, 1994; 1999), the LDK participants' step-by-step reports revolved around small mechanistic movements and did not indicate a functional understanding of the system.

A comparison of HDK and LDK participants' written protocols revealed that the types of models constructed initially were similarly distributed across the two groups. This result was rather surprising, given that we expected the engineers to fully comprehend the siphon process upon viewing the materials. Additionally, we expected reading the label "siphon pipe" to prime this siphon schema. Our findings conflict with previous accounts of experts solving physics problems (Chi, Feltovich, & Glaser, 1981), as well as lay beliefs that people trained in a certain domain are able

Table 2: Summary of Initial and Final Models.

HDK	Initial Model	Final Model	LDK	Initial Model	Final Model
E01	Correct	Correct	N02	Incorrect	Not Stated
E02	Incorrect	Incorrect	N03	Incorrect	Incorrect
E03	Not Stated	Correct	N04	Not Stated	Incorrect

to understand domain-related phenomena quickly and easily. As evidenced by their later oral reports, the engineers were able to spontaneously report the siphon process, indicating that they had the relevant domain-knowledge, yet they did not grasp the process in their initial viewing of the materials.

Here we offer a possible explanation for why many of the HDK participants did not incorporate the siphon process into their initial mental models. In the initial viewing phase of the experiment, participants were trying to integrate their prior domain-related knowledge with the external visualizations in order to create a cohesive causal model of the system. Because the HDK individuals have a larger body of prior knowledge than the LDK participants, they have more explanations in competition. Two sources of knowledge that may contribute to the understanding or misunderstanding of how water stops exiting the tank are: (1) domain-specific knowledge about a siphon process and pressure differential, as described previously, and (2) domain-general knowledge of "damming." From experience with the real world, we know that flowing liquid can be stopped by solid objects. Integrating the damming principle with the external visualizations leads to the incorrect model of the disks blocking the outgoing water. This integration of domain-general information seems to be how LDK individuals reason about the flushing cistern. Although both explanations were available to the HDK participants, the domain-specific explanation may not have been adequately cued by the visual materials. Thus, the HDK relied on their domain-general knowledge until they had reason to switch to using domain-specific understanding. This explanation is purely speculative, and further studies exploring these issues need to be conducted.

Model Revision

While the distribution of both groups' initial model types were found to be relatively similar, analyses of their final oral reports revealed that the model revision process differed across the groups. Although both groups did, on average, add three steps that were not present in the majority of the initial models, the steps differed qualitatively across the groups. The LDK participants seemed to perform "model addition" after answering the comprehension questions and reviewing the visual materials. They *added* visually salient information that was left out of their initial models. However, the LDK participants did not *change* their model to the correct model. Moreover, the sealing of the disks continued to be the dominant view of how the water stopped exiting the tank, even though this explanation was in direct conflict with what was shown in the visual materials. These findings are consistent with previous findings that LDK individuals do not integrate functional information into their mental models (Spilich et al., 1979; Chiesi, Spilich, & Voss, 1979; Lowe, 1994; 1999) and that they tend to stay at a kinematic/behavioral level of explanation, even after spending additional time with the learning materials (Hale & Barsalou, 1995).

The HDK participants in this study can be described as truly revising their mental models. Rather than simply adding perceptually salient steps to their final models, the majority of HDK participants changed their models to include the beginning siphon process and the correct explanation for the ending of the siphon process. The HDK participants did not tend to rely as heavily on their initial incorrect model while answering the troubleshooting and function questions. This indicates that the HDK group was more flexible in generating other responses to the questions, possibly because they had more prior knowledge available to them.

There are many possible explanations of how the revision process occurred. Because a variety of activities took place between the initial written step-by-step explanations and the final oral reports, we can only speculate on the possible causes of revision. One possibility is that the troubleshooting and function questions lead the HDK group to internal conflicts within their models. Troubleshooting

[1] The participant incorporated both the correct and incorrect models into his final model.

questions can be used to induce causal knowledge of a system (Hale & Barsalou, 1995), and can also be used to judge deep comprehension (Graesser & Olde, 2003). While providing responses to these questions, HDK participants might have become aware of conflicts between their initial mental model and the possible explanations for the breakdown scenarios presented in the troubleshooting questions. Alternatively, viewing the visual materials a second time may have contributed to model revision. As the HDK participants were able to compare their mental models to the information presented in the visual tools, they may have realized inconsistencies in their models.

The LDK group, on the other hand, did not seem to experience conflicts between their models and their troubleshooting and function responses, nor between their models and the external representations. Although their models conflicted with what was shown in the learning materials, none of the participants explicitly identified a conflict. These participants may have refrained from revising their mental models even after re-viewing the materials because they began to rely on their mental models as perceptual evidence (Rozenblit & Keil, 2002). The HDK group, on the other hand, seemed to be more sensitive to conflicts between their mental models and information that did not match.

Conclusion

This study demonstrates the limitations of visual materials such as diagrams and animations for communicating about how machines work. Although the animations showed how the parts of the mechanism move when it is in operation, LDK individuals were unable to construct an accurate mental model from the visual materials, and tended to construct erroneous mental models that were in fact inconsistent with what they viewed. Most HDK individuals were able to construct the correct mental model eventually, but this took some time and occurred only after engaging in other activities such as answering troubleshooting and function questions.

The results of this study suggest that materials designed for low domain knowledge participants must explicitly describe the siphon process (e.g., through language), while materials targeting learners with adequate domain knowledge may need to merely induce these learners to access the relevant domain information they already possess. Thus, examining the mental models constructed from visual materials alone can provide insights into the design of instructional materials for individuals with different amounts of background knowledge, and suggest when and how visual-spatial instruction materials should be supplemented by verbal instruction.

Causal Structure in Conditional Reasoning

Tevye R. Krynski (tevye@mit.edu)

Abstract

Causal reasoning has been shown to underlie many aspects of everyday judgment and decision-making. We explore the role of causal structure in conditional reasoning, hypothesizing that people often interpret conditional statements as assertions about causal structure. We argue that responses on the Wason selection task reflect the selection of evidence expected to maximally reduce uncertainty over candidate causal structures. We present a model in which people's selections depend on their interpretation of which causal relationship is asserted by a given conditional statement.

Introduction

Consider the following statement: "If a pot falls in the kitchen, then you will hear a clang". Is this statement true? Not if something breaks its fall, like a pillow. Now consider the statement: "If a clang is heard then a pot has fallen in the kitchen." Is this statement true? Not if something else can cause a clang, such as falling silverware. The first statement is not always true because there are conditions that can disable the mechanism by which falling pots cause clangs to be heard. The second statement is not always true because there are alternate causes of clangs other than falling pots. As this example illustrates, causal knowledge often underlies how people reason about conditional statements.

Recent research has shown that causal reasoning permeates many aspects of cognition, including associative learning (Waldmann, 2000; Glymour & Cheng, 1998), category learning (Rehder, 2003; Ahn, 1999), and judgment under uncertainty (Krynski & Tenenbaum, 2003). In this paper we analyze the role of causal structure in conditional reasoning (Over & Jessop, 1998), and argue that people's responses on the Wason selection task reflect sophisticated abilities to induce causal structure.

An important open question in causal reasoning is how people's background knowledge interacts with observations when inferring causal structure. Causal domain knowledge places important constraints on which cause-effect relationships exist and how the effects depend functionally on the causes (Pearl, 2000; Krynski & Tenenbaum, 2003; Ahn, Kalish, Medin, & Gelman, 1995). This effectively specifies a hypothesis space of candidate causal structures, which we model using causal Bayes nets (Pearl, 2000). Observational evidence can then be used to determine which causal structure is most likely. We propose that this interplay of causal domain knowledge and observational evidence underlies people's judgments on the Wason selection task.

The Wason selection task presents subjects with a conditional statement of the form "if p then q", and asks subjects to choose evidence to determine whether the statement is true. Prior accounts of people's responses on the selection task have emphasized logical reasoning (Wason, 1966; Ahn & Graham, 1999), probabilistic reasoning (Oaksford & Chater, 1994), or social reasoning (Cosmides, 1989), as well as others. In contrast, we argue that the selection task often engages causal reasoning: for conditional statements in which p and q are causally related, people choose cards that will be most useful to determine which of several candidate causal structures is correct for a given situation.

We have developed a model that extends Oaksford & Chater's (1994) probabilistic information gain framework to handle causal hypotheses. The information gain framework of O&C proposes that in the Wason selection task, people seek to reduce their uncertainty among hypotheses about the relationship between the antecedent (p) and the consequent (q) in a conditional statement of the form "if p then q". The model of O&C (1994) proposes that these hypotheses are assertions about conditional dependencies (e.g., q depends on p, q is independent of p, etc.), whereas we propose that these hypotheses are assertions about causal structure (e.g., p causes q, p does not cause q, etc.).

Our causal framework enables us to explain some previously puzzling results from the literature, as well as compelling intuitions that are not predicted by other approaches. We also address an important open question with both logical and probabilistic accounts: they leave unspecified how people interpret conditionals to determine which hypothesis is being asserted. We propose that the interpretation of conditionals often depends on causal domain knowledge, which imposes constraints on candidate causal structures, as well as pragmatic considerations.

Why interpret conditionals causally?

In contrast to O&C's proposal that conditional statements assert a conditional dependency, we propose that people interpret conditional statements in which p and q are causally related as assertions about causal structure. The underlying reason for this is that conditional dependencies are often a symptom of some underlying causal relationship. "If p then q" states that there is some dependency between p and q, which in turn implies there is some mechanism by which p and q are related; i.e., p causally influences q, q causally influences p, or they have some common cause. The term "causally influences" does not necessarily mean

"directly causes"; causal influence can be generative, inhibitive, enabling, permissive, or otherwise.

Examples of the prevalence of causal interpretations come from statements in which the logical interpretation and the causal interpretation are at odds; in these cases, the causal interpretation tends to take precedence. Some conditionals are logically false but seem true because they are causally true. For example, "If you spin around then you will get dizzy" seems true enough, although it's possible to spin around without getting dizzy, therefore it's logically false. Other conditionals are logically true but seem false because they are causally false. For example, "If you drink coffee during the day then you will fall asleep at night" sounds false because it seems to be saying that coffee causes you to fall asleep, but it is logically true (assuming you eventually fall asleep every night). These examples suggest that it is often, but not always, more natural to interpret conditionals as causal assertions, rather than logical implications.

Causal Structure Induction

We adopt the following Bayesian framework: given conditional statement "if p then q", reasoners consider a total hypothesis space T of candidate causal structures relating p and q. The conditional statement is interpreted to be asserting that a specific causal relationship holds between p and q. T then partitions into a subspace of structures S consistent with the statement, and its complement, T-S, inconsistent with the statement. Testing the conditional amounts to testing whether the true structure, s^*, is in S or T-S. The probability that the conditional is true is the probability that s^* is in S: $P(s^* \in S) = P(S) = \sum_{s \in S} P(s)$.

Initial degrees of belief in these hypotheses are represented as prior probabilities, and those structures that do not satisfy the constraints of causal domain knowledge are not considered. For example, people know that falling pots can cause noise, but noise cannot cause pots to fall, hence no structures with noise causing falling pots will be included in T. In this case of the conditional "if a pot falls, then it makes a noise", T could be the set of all causal structures consistent with domain knowledge in which falling pots exist, and S could be the subset of structures in T in which falling pots are a cause of noise.

Data can help determine how likely the conditional statement is to be true. Using Bayesian belief updating,

$$P(S \mid d) = \sum_{s \in S} P(s \mid d) = \sum_{s \in S} \frac{P(s)P(d \mid s)}{P(d)}$$

According to the information gain (IG) approach (O&C, 1994), when determining whether a particular conditional statement is true, the most informative data are those that are expected to maximize information gain, I_g:

$$I_g(S \mid D) = \sum_H P(H) \log \frac{1}{P(H)} - \sum_H P(H \mid d) \log \frac{1}{P(H \mid d)}$$

However, O&C (1996) propose that when $P(S)$ is not 0.5, a better measure is the distance between the probability distributions of the new and old beliefs, as measured by Kullback-Leibler distance, (we will use this, and call it I_{KL}):

$$I_{KL}(S \mid d) = P(S \mid d) \log\left(\frac{P(S \mid d)}{P(S)}\right) + P(T-S \mid d) \log\left(\frac{P(T-S \mid d)}{P(T-S)}\right)$$

In the case of the Wason selection task, $I_{KL}(S|d)$ is the amount of information gained from turning over cards. The selection task can be used to test two claims: (1) people often interpret conditional statements in which p and q are causally related as assertions that a particular causal relationship holds, and (2) people select information with the goal of maximally reducing uncertainty in that assertion.

Applying the IG approach to the selection task

The Wason selection task and its variants present people with a conditional statement of the form "if p then q", where p and q can be any propositions. Cards are then presented which represent trials; one side specifies whether p was true on the trial, while the other side specifies whether q was true. Subjects are presented with four cards, having each of the four possible sides (p, q, $\neg p$, $\neg q$) facing up. The specific task instructions vary depending on the experimenter's intent, but they generally instruct participants to select only those cards necessary to turn over in order to determine whether or not the given conditional statement is true.

Consider the information gained from turning over a single card with v on the visible side and finding u on unseen side: (v,u take on values in $\{p, q, \neg p, \neg q\}$, subject to the constraints of the selection task):

$$I_{KL}(S \mid d) = I_{KL}(S \mid v,u) = P(S \mid v,u) \log\left(\frac{P(S \mid v,u)}{P(S)}\right) + P(T-S \mid v,u) \log\left(\frac{P(T-S \mid v,u)}{P(T-S)}\right)$$

$$P(S \mid v,u) = \sum_{s \in S} P(s \mid v,u) = \sum_{s \in S} \frac{P(s \mid v)P(u \mid v,s)}{P(u \mid v)}$$

Since it is generally obvious that the cards in the Wason selection task were not randomly sampled, but rather one card of each possible side (p, q, $\neg p$, or $\neg q$) was presented, no information can be gained from learning that the visible side of the card is v, thus $P(s \mid v) = P(s)$.

One more step is necessary for predicting card selection: summing over all possible values of the unseen side of the card to obtain the expected information gain from turning the card with v on the visible side, $EI_g(S,v)$:

$$EI_g(S,v) = \sum_u I_{KL}(S \mid v,u) P(u \mid v)$$

The IG approach proposes that subjects select cards in the Wason selection task as a function of expected information gain, with selection favoring cards with higher expected information gain.

Applying the IG approach to causal hypotheses

The Bayesian framework presented thus far is similar to O&C (1996), except that it treats conditional statements as asserting the validity of a set of hypotheses rather than a single hypothesis. We now turn to the major differences between our account and that of O&C:

(1) The hypotheses in our framework are assertions about causal structure rather than conditional dependency; hence, a causal framework predicts different values for information gain than do O&C.
(2) We propose that mapping conditional statements onto hypotheses about causal structure is inherently ambiguous and depends on pragmatic considerations.

Here we will discuss the implications of (1), leaving the implications of (2) for the next section.

The information gained from turning over card *v* and finding *u* on the other side depends on the hypotheses under consideration; in particular, $D_{KL}(S \mid v,u)$ depends on $P(v \mid u,h)$ for every $h \in T$, which in turn depends on the content of each hypothesis *h*. In the O&C (1994) approach, *H* is the hypothesis that *q* depends deterministically on *p*, while $\neg H$ is the hypothesis that *p* and *q* are independent, and these are the only two hypotheses considered. Thus,

$$P(q \mid p,H)=1; P(q \mid \neg p,H)=b; P(p \mid q,H)=a/b; P(p \mid \neg q,H)=0$$
$$P(q \mid p,\neg H)=P(q \mid \neg p,\neg H)=b; P(p \mid q,\neg H)=P(p \mid \neg q,\neg H)=a$$

where the parameters $a=P(p)$ and $b=P(q \mid \neg p)$ are the same for *H* and $\neg H$. Other possible hypotheses are proposed by O&C but not developed, specifically those in which *q* depends probabilistically on *p*, such that $P(q \mid p,H)<1$.

In our approach, the hypothesis space *T* consists of causal structures. The conditional statement asserts that a particular causal relationship holds between *p* and *q*, thus the true causal structure is in the set *S* of structures for which this relationship holds ($S \subset T$). For a given causal structure, *h*, $P(u \mid v,h)$ can be derived using the formalism of causal Bayes nets (Pearl, 2000). For the subsequent presentation we will work with a simple causal structure that provides a reasonable approximation to many of the causal structures asserted by common conditional statements. In this structure, a cause (*C*) generates an effect (*E*), but there are conditions (*D*) that can disable the mechanism, and there are alternative causes (*A*) of the effect (see Figure 1). *D* represents all disabling conditions aggregated together, and *A* represents all alternative causes aggregated together. The arrow coming from *D* in Figure 1 indicates that the presence of *D* blocks the causal path from *C* to *E*. This structure is the causal model behind Cheng's power-pc theory (Cheng, 1997) (where $P(\neg D)$ is equal to the causal power of *C* to generate *E*); the model can also be expressed as a noisy-or Bayes net (Glymour & Cheng, 1998). For this simplified structure, the total hypothesis space *T* contains all structures with one or more of the links shown in Figure 1 (subject to the constraint that the link from *D* cannot exist without the link from *C* to *E*).

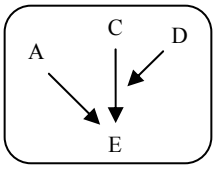

Figure 1: Noisy-or causal model

As an example of the model of Figure 1, consider a dropped pot (*C*) causing a clang (*E*). This can be disabled by various things (*D*), such as someone catching the pot or a pillow breaking the pot's fall. There are also alternate causes (*A*) of clangs, such as falling silverware.

Next we will use the semantics of the noisy-or Bayes net to derive $P(u \mid v,h)$, for the case where *h* is the hypothesis that the model of Figure 1 holds. This derivation works for all cases in which the cards in the selection task contain *C* on one side and *E* on the other, as is the case in our example "if a pot is dropped then a sound is heard" (here *p* is *C* ("a pot is dropped") and *q* is *E* ("a sound is heard"), hence *v, u* take on values in {*C, E,* $\neg C$, $\neg E$}):

$$P(E \mid C,h)=P(\neg D \vee A \mid h)=P(\neg D)+P(D)P(A)$$
$$P(E \mid \neg C,h)=P(A)$$
$$P(C \mid E,h)=\frac{P(C)P(E \mid C,h)}{P(E \mid h)}=\frac{P(C)\big(P(\neg D)+P(D)P(A)\big)}{P(A)+P(C)P(\neg D)P(\neg A)}$$
$$P(C \mid \neg E,h)=\frac{P(C)P(\neg E \mid C,h)}{P(\neg E \mid h)}=\frac{P(C)P(D)P(\neg A)}{P(\neg A)\big(P(\neg C)+P(C)P(D)\big)}$$

where the prior probabilities of *C* and *A*, *P*(*C*) and *P*(*A*), correspond to *a* and *b* in the O&C model, and the prior probability of *D*, *P*(*D*), is 1-*P*(*E*|*C*). (*P*(*D*) is taken to be zero in O&C's model for the case where *p* is *C* and *q* is *E*.) We do not require that the parameter values be the same across hypotheses, eliminating some objections to O&C's model. One could, for example, interpret a statement to be asserting that alternate causes are rare, hence *S* is all structures with P(*A*)<0.1. For simplicity, however, we will discuss only those interpretations in which a structural claim is being made (such as, a link exists from *A* to *E*); for these cases, the parameters will be the same across hypotheses.

Interpreting conditionals as causal assertions

Conditional statements are inherently ambiguous. Those for which *p* could be a cause of *q* we will call "forward" conditionals. They generally assert that *p causes q*, but the exact causal structure being asserted depends on pragmatics. For example, the statement "if a pot is dropped then it makes a clang" could have several different meanings, as demonstrated by the following hypothetical exchanges:

(1) A: "What sound will be made if I drop this pot?"
B: "If a pot is dropped then it makes a clang."
Meaning: dropped pots cause clangs
Causal Assertion: ***dropped pots*** *can cause* ***clangs***
Hypothesis Space: all structures in which ***dropped pot*** *is the cause and a* ***sound*** *is the effect*

(2) A: "I think a pot just fell."
B: "That's impossible; I didn't hear a clang. If a pot falls then it makes a clang."
Meaning: dropped pots always cause clangs
Causal Assertion: no D exists to block the path from ***dropped pots*** *to* ***clangs***
Hypothesis Space: all structures in which ***dropped pot*** *is a cause of* ***clangs***

In contrast, conditionals for which *q* could causally influence *p* we call "reverse" conditionals. They generally assert that *q is the only cause of p*, but again the exact causal structure being asserted depends on pragmatics. For example, the statement "if you hear a clang then a pot was dropped" could have several different meanings, as

demonstrated by the following hypothetical exchanges:

(1) A: "What are those sounds coming from the kitchen?"
B: "Those are items being dropped. For instance, if you hear a clang then a pot was dropped."
Meaning: falling pots are the primary cause of clangs, but not necessarily the only possible cause.
Causal Assertion: ***dropped pots*** *can cause* ***clangs***
Hypothesis Space: all structures in which ***dropped pot*** *is the cause and a* ***sound*** *is the effect.*

(2) A: "I heard a clang. What do you think happened?"
B: "It must have been a dropped pot. If you hear a clang then a pot was dropped."
Meaning: the only cause of a clang is a dropped pot.
Causal Assertion: no alternative cause A exists that can cause ***clangs****.*
Hypothesis Space: all structures in which ***dropped pot*** *is the cause and* ***clang*** *is the effect.*

Predicting card selection

The key point of distinction between our model and that of O&C is in predicting information gain, because EI_g is a simple function of information gain. $I_{KL}(S|v,u)$ depends on the particular set of causal structures in the hypothesis space T, as well as the set of asserted hypotheses S, and the parameters $P(C)$, $P(A)$, and $P(D)$. S in turn depends on pragmatic considerations. In Figures 2 and 3 we give qualitative predictions for S, T, and I_{KL} for common types of conditionals, which will motivate future experiments.

Some generalizations are worth noting: (1) $EI_g(p)$ is often high. (2) for rare p and q, when structures with no C to E link have sufficient priors (e.g., a uniform prior), $EI_g(S,q)$ is often high; (3) if the conditional assumes the C to E link exists, then structures with no C to E link will have low priors and $EI_g(S,q)$ will be low. In general, with pragmatic considerations, the model predicts selection of p and q cards if the conditional *asserts* that C causes E, and selection of p, $\neg q$ if the conditional *assumes* that C causes E.

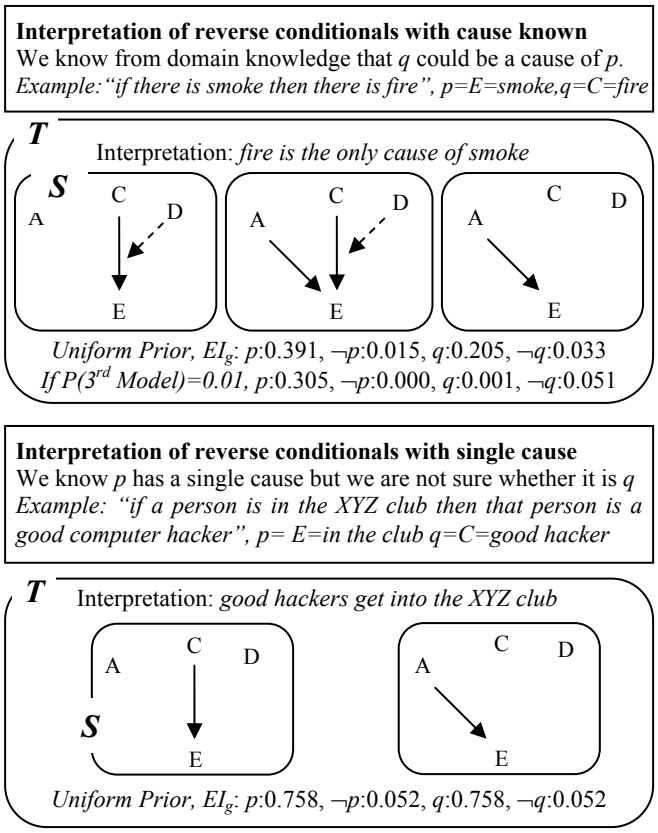

Figure 2: Predictions for reverse conditionals
Dotted arrows indicate a mixture of two hypotheses, one in which the arrow is present, and one in which the arrow is absent
All EI_g values assume $P(C)=P(A)=P(D)=0.1$

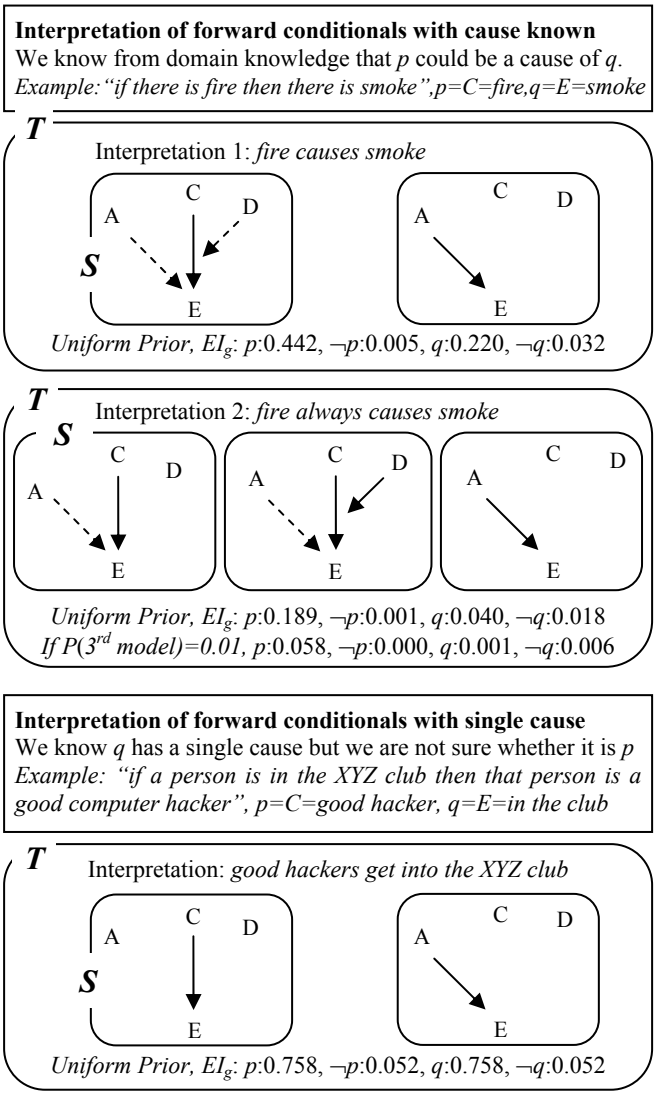

Figure 3: Predictions for forward conditionals.
Dotted arrows indicate a mixture of two hypotheses, one in which the arrow is present, and one in which the arrow is absent.
All EI_g values assume $P(C)=P(A)=P(D)=0.1$

Relation to previous analyses and phenomena

In this section we discuss how our approach accounts for previous phenomena on the selection task. We group these phenomena within a discussion of previous approaches, while highlighting the distinctive aspects of our approach.

Information-gain (Oaksford & Chater, 1994)

In many of their publications, O&C analyze a simple comparison in which H asserts complete dependency and $\neg H$ asserts a complete independency between p and q. In our model, this is identical to the assertion that T corresponds to all structures in which $p=C$, $q=E$, and D does not exist, while S corresponds to the subset of those structures in which a link exists from C to E.

With the richer hypothesis space of causal models, the information gain framework predicts some previous results on the selection task that are not predicted by O&C (see next section). O&C predict that the p and q cards should be chosen when both p and q are rare and that the p and $\neg q$ cards should be chosen when p or q is common. This is predicated on the assumptions that $I_g(p,\neg q)$ is 1, $I_g(p,q)$ is high for rare p and q, and $I_g(\neg p,q)$ and $I_g(\neg p, \neg q)$ are zero. Our analysis suggests that these assumptions are only valid if structures in T with links from C to E have sufficient priors. If these structures have very low priors, the $\neg q$ card should be more informative than the q card because $I_{KL}(S|p,q)$ and $I_{KL}(S|\neg p,q)$ will be low, hence $EI_g(S,q)$ will be low. For example, suppose one asserts that "if a clang is heard then a pot was dropped". It is reasonable to assume that dropped pots cause clangs, hence a low prior should be placed on any structure with no link from dropped pots to clangs. Thus, finding a dropped pot that clanged (p,q) will not be very informative, despite p and q being rare, but finding a dropped fork that produced a clang ($p,\neg q$) will be very informative, hence p and $\neg q$ should be chosen.

Almor & Sloman (1996) provide evidence that appears to contradict O&C (1994), in which p and q are rare, yet people choose the p and $\neg q$ cards. Some examples of their conditionals are "*if a product gets a prestigious prize then it must have a distinctive quality*", and "*if a product breaks then it must have been used under abnormal conditions*". O&C (1996) claim these results can be accounted for using their utility-theoretic analysis of deontic tasks. However, these statements would only be deontic if they were rules that people have to follow, but it is not apparent that this is the case. According to our analysis, the conditional is reversed (q causes p), leading subjects to interpret the statement as asserting the absence of alternate causes (A) while taking for granted the link from C to E, thus assigning low probability to structures without this link. For example, since there are other possible causes of a product breaking, subjects choose the $\neg q$ card (no abnormal usage) to see if p occurred (the product broke for some other reason), but there is no need to see if abnormal usage causes breakage.

A further point of differentiation is that our causal framework predicts the $\neg p$ card should be chosen in certain cases (when $I_{KL}(\neg p,q)$ and $P(q|\neg p)$ are both high).

Social Contracts and Precautions (Cosmides, 1989)

People have been found to provide high levels of logically correct responses to Wason selection tasks about social contracts (Cosmides, 1989; Fiddick, Cosmides, & Tooby, 2000). A debate has emerged over whether this is evidence for a specialized social reasoning engine. Social contracts do indeed seem to be special, but do people reason about them differently than other tasks? In our framework, what makes them special is that they all have a consistent causal structure, in which people follow rules to ensure that C produces E reliably. For example, in the social contract "if you pay $10 then you get a watch", the rules compel the seller to give the buyer a watch (E) once $10 is paid ($C$). When the link from C to E is assumed to exist, as is the case in most social contract tasks, one should assign a prior of zero to any hypothesis in T with this link missing. Since all the hypotheses with non-zero prior then contain links from C to E, our causal analysis predicts that only $I_{KL}(p,\neg q)$ is high, and hence only the p and $\neg q$ cards should be selected.

Precaution tasks (Fiddick et. al, 2000) have essentially the same structure as social contracts: they assume that the precaution is in force (i.e., the link from C to E exists), and ask subjects to determine whether the rule is being followed by everyone. Our analysis suggests that if instead the rule itself is questioned (i.e., is the rule in force?), people will interpret S as asserting that there is a link from C to E; since this link questioned, one should assign a non-zero prior to the structures in T in which this link is missing, making the q card useful (if p and q are rare) because $I_{KL}(p,q)$ is high.

The results of Fiddick et. al (2000) show that this is exactly what people do. Fiddick et. al (2000) published precaution experiments that show people choose q more than $\neg q$ in "standard" versions of precaution studies such as "*if you go hunting then you wear [orange] jackets to avoid being shot*". In the "standard" version, subjects are instructed to see if it is true that the jackets are for hunting, whereas in the "precaution" version they are instructed to see if any people are endangering themselves. This result confirms that when testing whether a social contract or precaution is in force, people will test the assertion that a link exists from C to E, and hence will choose the p and q cards (provided p and q are rare).

O&C (1994) propose a utility-theoretic account for how people make choices in social reasoning tasks. This is appropriate for tasks in which the participant is told that catching rule violators is important (i.e., has high utility). If, however, the participant is being asked simply to determine whether or not the rule is being violated, the assignment of utility to this information is not warranted. We avoid the difficulty of assigning utilities to information by using expected information gain as the sole basis on which to select cards. A causal analysis predicts the selection of p and $\neg q$ responses for any task in which structures without C to E links are given low priors, which should be the case in all social reasoning tasks that assume the rule is in force and ask subjects to detect violators.

Perspective Shifting

Perspective shifts (interpreting "if p then q" as "if q then p") have been explained as the result of adopting different perspectives on a rule – the enforcer vs. actor. We propose that perspective shifts occur when three conditions are met: (1) C is a known cause of E, (2) it is not obvious whether D exists, and (3) it is not obvious whether A exists. This sets

up the hypotheses in Figure 4. For example, "if you pay $10 then you get a watch" can be shifted to "if you got a watch then you paid $10" because our domain knowledge tells us that no disabling conditions exist (the buyer must get the watch once $10 are paid), and no alternate causes exist (the buyer cannot get the watch without paying).

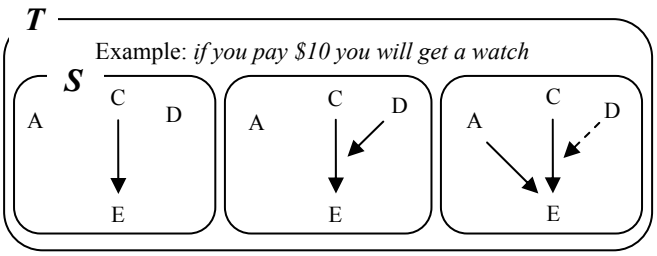

Figure 4: Perspective shifting hypotheses

On this view, perspective shifting occurs not just on deontic tasks, but in any situation in which the above three conditions are met. For example, "if water boils then it is over 100°C" could easily be interpreted to imply that "if water is over 100°C then it will boil". Perspective shifting can therefore occur, even in non-deontic situations, when the asserted structure does not contain *D* or *A* links.

Necessity and Sufficiency (Ahn & Graham, 1999)

Ahn & Graham (1999) show that most people choose the normative response if it is clear that the statement asserts either that *p* is a sufficient condition for *q* or that *q* is a necessary condition for *p*, or both. Asserting that *p* is a sufficient condition for *q* corresponds to asserting that *D* does not exist. For example, asserting that *flipping the switch* is sufficient for the *lights turning on* corresponds to asserting that nothing (*D*) can disable the switch. In contrast, asserting that *q* is a necessary condition for *p* corresponds to asserting that *A* does not exist in the causal model. For example, asserting that *flipping the switch* is necessary for *lights turning on* corresponds to asserting that nothing else (*A*) could turn on the lights. Both of these cases assume that the link from *C* to *E* exists, hence as before, *p* and $\neg q$ are the most informative cards (or *q* and $\neg p$ when a conditional with "must" is reversed to say "may"), which follows Ahn & Graham's predictions. Ahn & Graham (1999) also discuss cases in which *p* is asserted to be both necessary and sufficient for *q*, in which cases subjects choose all 4 cards. This corresponds to asserting that neither *A* nor *D* exist, and $I_{KL}(S|\neg p,q)$, $I_{KL}(S|p,\neg q)$ are both high.

An open question in Ahn & Graham's (1999) theory is how people know whether *p* is necessary or sufficient for *q* in cases when it is not explicitly stated. A cause can be necessary or sufficient for an effect, but it does not make sense to say that an effect is necessary or sufficient for a cause (e.g., a clang could not be necessary or sufficient for a pot to drop, because dropped pots precede clangs). Because of this causal asymmetry, some amount of causal reasoning must precede determination of necessity and sufficiency relationships. Furthermore, determining necessity or sufficiency can be done using just causal knowledge, as *p* is necessary for *q* if *A* does not exist, and *p* is sufficient for *q* if *D* does not exist.

Conclusion

Causal reasoning underlies many of our intuitive judgments in everyday life, and the results we present here demonstrate that causal structure plays an important role in a domain of reasoning previously thought to be governed by logic and probability. Our approach predicts a number of effects on the selection task that do not follow naturally from previous approaches. If used appropriately, the selection task is an excellent tool for testing people's abilities to gather evidence and become more informed about their world. Since knowing the causal structure of the world is of great value for making predictions in every life, it is perhaps not surprising that the cards people naturally select tend to be those that maximize the amount of knowledge that can be obtained about causal structure from a single observation.

On the Representation of Physical Quantities in Natural Language Text

Sven E. Kuehne (skuehne@northwestern.edu)
Qualitative Reasoning Group, Northwestern University
1890 Maple Avenue, Ste. 300
Evanston, IL 60201, USA

Abstract

In this paper we investigate the forms in which quantity information can appear in written natural language. Our focus is on physical quantities found in descriptions of physical processes, such as expansion, movement, or transfer. Using Qualitative Process Theory as our underlying formalism, we show how information extracted from natural language text corresponds to the five constituents of physical quantities. The results of this analysis can be used for the creation of interpretation rules and extraction patterns in NL systems.

Introduction

Ordinary people know a lot about the physical world around them. They know that water will eventually boil if you heat it on a stove, that a ball placed at the top of a steep ramp will roll down, and that a cup will overflow if you continue to pour coffee in it. When people talk and write about such phenomena in everyday language, references to continuous properties are usually part of these descriptions. From simple utterances like *"The coffee is hot"* to a more complicated comparison like *"The velocity of gas molecules is higher than the velocity of molecules in a liquid."* being able to identify and extract the information about physical quantities is essential to understand these sentences. Using Qualitative Process Theory (Forbus, 1984) as the underlying formalism, we investigate the forms in which continuous properties can appear in written natural language. Our focus is on *physical* quantities found in descriptions of *physical* processes, such as expansion, movement, or transfer.[1]

The way in which continuous parameters and processes are described in natural language is not accidental. Since Qualitative Process Theory is a formalism of how people reason about the physical world, the basic ideas of the theory should be reflected in the language that people use to communicate their understanding of physical phenomena. This paper shows that the natural language descriptions of physical processes contain abundant information about the constituents of physical quantities. Moreover, the results of this study can be used in a variety of applications, such as grammatical rules of a parser or in the design of information extraction algorithms.[2]

Physical quantities

In Qualitative Process Theory, all physical changes in *continuous properties* are caused by physical processes. The identification of continuous parameters is therefore an essential step in the extraction of information about physical processes from natural language text. In an earlier analysis (Kuehne & Forbus, 2002) we presented a scheme for the extraction process that uses FrameNet-compatible representations (Baker, Fillmore, & Lowe, 1998; Fillmore, Wooters, & Baker, 2001) to capture information about physical processes. The examples presented draw from the same corpus material (Buckley, 1979; Maton et al., 1994; Moran & Morgan, 1994) used in our previous analysis. Our goal here is to show how information about continuous parameters can appear in natural language, and the ways in which this information corresponds to the following five constituents of physical quantities:

- The *Entity* is a uniquely named object or an instance of a process associated with the quantity. For example, the word 'brick' in the noun phrase 'the temperature of the brick' denotes an entity.[3]
- The *Quantity Type* specifies the kind of parameter. The word 'temperature' in the noun phrase 'the temperature of the brick' is a reference to a quantity type.
- The *Value* specifies the numerical or symbolic value of the property. The number '3' in '3 liters of water' or

[1] The findings of this analysis are applicable to other types of quantities as well. The framework of QP theory determines just determines kind of information we are interested in, i.e. constituents of a physical quantity. Abstract and conceptual quantities are often referred to metaphorically by words with a physical basis and require a different semantic interpretation. 'The price is hot.' is does not have anything to do with temperature, unlike 'The water is hot.' However, the techniques for the extraction of information about such quantities are essentially the same.

[2] Although we use the results of the analysis for exactly these purposes, the findings are presented in a general way and not limited to any particular type of grammar or pattern language.

[3] The noun 'brick' actually refers a particular individual, maybe 'brick32', not the collection of all bricks.

the adjective 'hot' in 'the hot ground' are values associated with a quantity.
- The *Unit* specifies the physical units of the property. Example: The word 'kilograms' in '3 kilograms of lead.' Units usually appear in combination with a numerical value or with a quantifier.
- The *Sign of the Derivative* specifies how the parameter is changing. In the sentence "The temperature is increasing." the sign of the derivative is expressed by the word 'increasing', which indicates that the parameter is changing in a positive direction.

Only the first two of these five constituents are required to identify a physical quantity. The quantity type together with the entity are sufficient to talk about quantities like 'the temperature of a brick' or the 'the flow rate of heat'. Values, units, and information about changes are optional and often not explicitly stated.

Entities and quantities types

We begin with a look at the forms commonly used in natural language descriptions to express information about the two required constituents of physical quantities, the entity and the associated quantity type. The remaining three constituents, i.e. values, units, and changes, will be discussed in the subsequent sections.

Explicitly referenced quantities

Natural language text can refer to physical quantities either directly or indirectly, depending on whether the type of the quantity is explicitly mentioned in the sentence. *Explicit references* can be found in nouns, verbs, and adjectives that are morphologically related to quantity types.

Nouns

The quantity type can be explicitly mentioned as a noun, together with one or more entities that it is associated with.

(1) VOLUME flows from the *can* to the *ground*.
(2) The TEMPERATURE of the *brick* is rising.

Sentence 1 contains information about two physical quantities, the volume of some substance in the can and on the ground. The quantity type 'volume' is associated with both locations, i.e. the 'can' and the 'ground'. In (2) the quantity type 'temperature' is associated with a single entity.

The quantity type can also appear as the head of a compound noun. The remaining constituents of the compound noun can be treated as information about a specialization of the quantity type. For example, in (3) the quantity type 'radiation heat' is a specialization of 'heat'; in (4) 'heat energy' is a type of 'energy'.

(3) RADIATION HEAT flows from the *heater*.
(4) The HEAT ENERGY of the *water* increases.

Verbs

Verbs can refer to physical events as well as to quantity types associated with these events.[4] The verb in sentence 5 appears as a direct reference to the quantity type 'length'. Sentence 6 is slightly more complicated, because it allows two different interpretations. The obvious interpretation is to treat the verb as an explicit reference to a quantity, as it is in (5). In this case, the quantity type 'heat' is tied to both entities, the stove as the source of the heat flow and the kettle as the destination of the heat flow.

(5) The press LENGTHENS the *iron beam*.
(6) The stove HEATS the *kettle*.

Alternatively, (6) can be interpreted as an increase in temperature of the kettle caused by the stove. Even though the quantity type 'temperature' is not mentioned in the sentence, we might infer that heating the kettle also increases the temperature of the kettle. This is an inference that most readers of such a descriptions will readily draw, and it coincides with the kind of conclusions that are supported by QP Theory.

Adjectives

Certain adjectives can refer to quantity types directly, if the adjective is morphologically related to a quantity type. For example, in (7) the adjective 'denser' refers to the quantity type 'density'. The quantity type in this sentence is associated with both entities, i.e. 'iron' and 'wood'.

(7) *Iron* is DENSER than *wood*.

Implicitly referenced quantities

While the quantity types in explicitly referenced quantities are usually easy to identify and extract, *implicit references* to quantities are more difficult to figure out. Implicitly referenced quantities do not mention a quantity type. Instead, the reader has to use the contextual information provided by the sentence as well as available background knowledge. The following examples show how nouns, verbs, adjectives, and adverbs can determine a quantity that is not explicitly mentioned in a sentence.

Verbs

A quantity type can be implicitly referenced by a verb that describes a physical process, e.g. movement, expansion, or transfer. The sentence in which the verb occurs usually

[4] Events such as the increase or decrease of a parameter, e.g. the temperature of a brick, can be involved in an instance of a physical process. For one linguistic perspective on actions, processes, and events, see (Parsons, 1990).

provides additional contextual information for the interpretation of the implicitly referenced quantity.

(8) As the temperature rises, the *liquid* EXPANDS.

The verb 'expand' in (8) indicates that something is changing in different physical dimensions, i.e. in length, area, or volume. For the three-dimensional entity 'liquid' the appropriate quantity type is therefore 'volume'. The verb also includes implicit information about a positive change in the quantity, i.e. an increase in volume of the liquid, which we will address later.

Adjectives

The quantity type can be implicitly referenced by certain adjectives. For example, the quantity type described by the adjective 'hot' in (9) is 'temperature'. The comparative also encodes the ordinal relationship between the quantities associated with the two entities, i.e. the fact that the temperature of the stone is greater than the temperature of the water. Similarly, the quantity type expressed by 'lighter' in (10) is 'weight'.

(9) The *stone* is HOTTER than the *water*.
(10) The *upper air masses* are LIGHTER than the *lower air masses*.

For a correct interpretation the relationship between the adjective and the associated quantity type has to be known. The fact that the adjective 'hot' is associated with 'temperature' is a fact learned by a human reader and is typically provided as background knowledge in NL systems.

Verb/Adverb combination

Quantity types can also be determined by combining verbs and adverbs. The quantity type referenced in (11) is the rate of movement, or 'velocity'. The adverb alone is not sufficient to determine the quantity type. Although 'faster' is generally associated with velocity, it just qualifies the rate of change, i.e. that something is happening in less time. There are cases in which the quantity type referenced by 'faster' is not velocity. For example, 'expanding faster' in (12) refers to the rate of expansion.

(11) The *gas molecules* are MOVING FASTER than *molecules in a solid*.
(12) *Liquid A* is EXPANDING FASTER than *liquid B*.

All these cases have one thing in common: the referenced quantity is a rate, most likely associated with a process referenced by the verb ('movement', 'expansion', 'decay').

Noun/Verb combination

This type of implicitly referenced quantity uses a noun/verb combination to refer to the rate of change of a quantity.

(13) The less heat is supplied, the slower the *temperature* RISES.

The quantity type in (13) is not 'temperature' but the rate of change in temperature, resulting from a change in the amount of heat. The combination of 'rises' and 'temperature' determines the quantity type, while the combination of the verb 'rises' and the adverb 'slower' gives the direction of change.

Noun/Adjective combination

The quantity type is only implicitly referenced by a combination of a noun and an adjective.

(14) The BIGGER the *surface* [is], the more heat is absorbed.

The quantity type in (14) is the size of the surface (not the surface itself) associated with an unnamed participant or the size of a participant 'surface'. The adjective 'bigger' refers to the quantity type 'size' (or 'area'). Since 'big' can also refer to the quantity type 'volume', the dimensionality of the entity determines the appropriate quantity type in this case.

Representation of values in physical quantities

Knowing the type of a quantity and the entity it is associated with enables us to talk and reason about it. A simple noun phrase such as 'the depth of the water' contains enough information recognize it as a physical quantity, even without having any information about a particular value the quantity might have, the unit of that value, or the direction in which the quantity is changing. The following two sections examine how values and units of quantities appear in natural language text, and how changes in quantities can be identified.

There are three common types of references to values and units that can be found in natural language text: in the context of comparisons, as symbolic labels, and as quantitative information. We will discuss values and units together because units usually appear in combination with values.[5]

[5] Units can appear separately from values in definitional statements, like "Length is measured in Meters." or, even more explicit, "The unit of power is the Watt."

Comparison

Values in the context of a *comparison* appear in sentences like "The brick is warmer than the plate." The comparison orders the quantities, i.e. the temperature of the brick is greater than the temperature of the plate. However, it does not contain exact information about the possible values of the quantities. Even though the comparative 'warmer' might refer to a specific range of temperature, the exact values cannot be known or even guessed from the information provided by the sentence. The brick might be red hot, while the plate is frosted with ice.

It is impossible to determine how far the values associated with the two compared quantities are apart from each other. The only information that can be extracted from this sentence is the fact that the value of one quantity is greater than the other. With several of these comparisons along the same dimension, it is possible to identify the potential ranges of the values for particular quantities. For example, the temperature of a coffee is greater than the temperature of an ice cube, and it is lower than the temperature at the tip of a lit cigarette.

Symbolic labels

Values can also take the form of a *symbolic label* associated with an entity, e.g. "The brick is hot." Even though the exact temperature of the brick is unknown, the adjective 'hot' suggests a certain temperature range. The range might be different depending on the context of the sentence. In refrigeration 'hot' might be in a very different range of temperatures than in the context of metallurgy.

Nouns that are associated with the adjective can impose restrictions on the range of the value in certain cases. For example, (Bierwisch, 1967) compares two simple sentences, "*The room is tall*." and "*The space is tall"*. In the first sentence the noun 'room' might restrict the average range of values for the height to those for a typical room, e.g. between 8 and 10 feet. Without further information, this kind of assumption is more difficult to make for the second sentence. Is the space a small compartment or a crawl space? Or is it the inside of a cathedral? The range of typical values would be quite different for these two cases.

Adjectives that represent a value are generally quantity-specific, i.e. they refer to a particular type of quantity as in the sentence "The brick is hot." Alternatively, a quantity-neutral form could be used to express the same fact, e.g. "The temperature of the brick is high."[6]

While adjectives and adverbs such as 'hot' or 'slow' generally refer to a range of values along a dimension, natural language also uses symbolic labels to refer to concrete values, i.e. particular points along a dimension. The noun phrase 'boiling point of water' usually refers to the point where liquid water turns into steam and the value of approximately 212 degrees Fahrenheit. The noun phrase provides a label for this particular point.[7]

The structure for labels that describe limit points is not arbitrary. Usually the head of the noun phrase refers to a point on a scale (e.g. 'point', 'barrier'), while the noun modifier is associated with a process, a dimension, or a quantity type (i.e. 'boiling', 'sound'). These two parts are mandatory components of the label. Determining the quantity type and the dimension is difficult in many cases, e.g. we have to know that 'boiling point' is associated with 'temperature' and that 'sound barrier' actually refers to the speed of sound or velocity. Additionally, the label can take an optional complement phrase that restricts the compound noun. For example, the complement phrase 'of water' restricts the interpretation of boiling point to a particular substance. The key idea here is that the underlying mechanisms for handling limit points are essentially the same as those for symbolic references to intervals on a particular dimension.

Concrete numeric values and units

The most explicit form in which values can appear is *quantitative information*, i.e. by using concrete numeric information and units. For example, in (15) the quantity type ('temperature') is explicitly stated, together with detailed information about the numeric value ('120') and the unit ('degrees Fahrenheit').

(15) The temperature of the brick is *120 degrees Fahrenheit*.

Sentences that contain concrete numeric values and units typically do not use quantity-specific adjectives or adverbs instead of explicit references to the quantity type.

(16) *The water is 80 degrees Celsius *hot*.
(17) The water has 80 degrees Celsius.

Sentence 16 should be considered anomalous, because the adjective 'hot' provides at best redundant information in the form of a symbolic value. Units can refer indirectly to the quantity that they are associated with, as shown in (17). The association between units and quantity types (degrees Celsius as a unit for temperature) is a learned fact and has to be encoded as background knowledge.

Representations of changes in physical quantities

The values of physical quantities cannot always be treated as static information, because they can change while

6 The Cyc knowledge base (Lenat & Guha, 1989) handles values in a similar way. For example, the value `#$Hot` is the result of `#$HighAmountFn` of `#$Temperature`.

7 Note that the compound noun 'boiling point' would be an underspecified symbolic label because different substances have different boiling points. Other labels such as 'sound barrier' may not need the additional complement.

physical processes are active. The sign of the derivative indicates whether a quantity is changing and in which direction.[8]

The most obvious choice to express changes in the physical world is the use of verbs. For example, if water is flowing from one container into another, there are several ways of expressing the change of the amount of water in each container.

(18) The amount of water in container A is decreasing, while the amount of water in container B is increasing.
(19) Water flows from container A to container B.

Although (18) and (19) might be describe the same scenario, they are not equivalent. For example, (19) only implies a decrease of the amount of water in location A. It does not state this information explicitly. On the other hand, (18) implies a flow, without actually mentioning it. These distinctions are important for a semantic interpretation process, because the information that is directly available from the sentences is different.

Verbs with direct references to a quantity change

Verbs can directly refer to a change in a quantity and its direction, i.e. whether the quantity is increasing or decreasing, when the verb alone contains all the information about the change and the direction and we can therefore distinguish between verbs for positive and negative changes in quantities. For example, *gain, increase,* and *add* are verbs for positive changes, while *lose, decrease,* and *leak* are associated with negative changes.[9] Some verbs belonging to this class also allow prepositional phrase as a complement, which is restricted to the particular direction of change indicated by the verb itself (e.g. 'add to' vs. *'add from').

(20) The *brick* LOSES *heat* to the *room*.
(21) The *temperature of the water* is INCREASING.
(22) The *brick* GIVES OFF *heat*.

Some otherwise 'neutral' verbs can also fall into this class if they use specific particles to indicate a change in a quantity, as in (22).[10]

Verbs with directional prepositional phrases

Verbs associated with Transfer and Motion event do not contain a direct reference to changes in quantity. For example, verbs like *flow* or *move* indicate a transfer of something between two physical or conceptual locations, but they do not contain information about the actual direction of the change. Instead, this information is provided by directional prepositional phrases attached to the verb. The description of the transfer can be complete when both the source and the destination are identified by prepositional phrases, as in (23), or partial when only one of the directional prepositional phrases is attached, as in (24) and (25).

(23) Heat is *transferred* FROM inside the house TO the outdoors.
(24) Energy is *moved* TO a new location.
(25) The *fan* moves heat away FROM the processor.

Verbs in combination with quantity-specific adverbs

Quantity-specific adverbs can determine the change in a quantity in conjunction with a verb. Analogous to verbs with direct reference to a quantity change, the combination of verbs and quantity-specific adverbs can be associated with a decrease in a quantity, as in (26) or with an increase, as in (27).

Similar to the interpretation of the quantity type from verb/adverb combinations, there are cases in which the same adverb can refer to an increase (or a decrease) of a particular quantity type, depending on the verb with which it is used. For example, in the context of (27), the adverb 'faster' would indicate a positive change in the velocity of the molecules, while in (28) it will indicate an increase in the rate at which a substance dissolves.

(26) The *glass* is COOLING FASTER.
(27) The *molecules* are MOVING FASTER.
(28) The *substance* DISSOLVES FASTER.

Nouns with direct references to change

Nouns provide another way of describing changes in physical quantities. They can be divided into similar classes as verbs, i.e. nouns with direct references to a change in a quantity, and nouns that use directional prepositional phrases.

Nouns can directly refer to a change in a quantity, and analogous to verbs they can be divided into nouns that refer to positive, as in (29), and negative changes, as in (30).

(29) The INCREASE in *temperature* is significant.
(30) The DECREASE in *pressure* caused a failure.

Nouns with directional prepositional phrases

Similar to verbs of the Transfer and Motion domain, the corresponding nouns will also need directional prepositional phrases to describe changes in a quantity.

[8] Information about changes in quantities can support other aspects of QP theory, e.g. in determining relationships between continuous parameters such as direct and indirect influences.
[9] Another distinction could be made between verbs that can only used with extensive quantities. For example, heat can be *added*, while temperature cannot.
[10] The particle has to agree with the complement structure of verb. For example, the verb phrase *'gives in' cannot take 'heat' as its argument.

Again, the information about the transfer can be complete, as in (31) or partial as in (32).

(31) The *flow* of oxygen FROM the tank TO the capsule is blocked.
(32) The *transfer* of heat TO the kettle has been completed.

Discussion

Parts of our current research are concerned with the design of a controlled language for describing physical phenomena. One important aspect in the development of such a language is the goal to reduce possible syntactic and semantic ambiguity. The identification of patterns used for references to continuous parameters in natural language is an essential part of the semantic interpretation process, which must include the detection of directly referenced quantities as well as indirect references.

Research on the lexical semantics of adjectives has tried to establish taxonomies for the different semantic categories of adjectives (see Raskin & Nirenburg (1995) for an overview). Several of these taxonomies focus on the class of adjectives that we are most interested in for extracting information about physical quantities, i.e. qualitative (scalar, gradable) adjectives (Dixon, 1991; Frawley, 1992). From our perspective, using the semantics of Qualitative Process Theory, the taxonomies suggested by Dixon and Frawley are inconsistent. The breakup of types and subtypes appears to be arbitrary, because several of the types of quantities can be collapsed into a single type. In Dixon's taxonomy the adjectives of the 'speed' and 'physical property' types are separated from those classified as 'dimension'. Similarly, 'age' and 'value' are listed as separate types.

Many quantity-specific adjectives and adverbs form opposing pairs for the same quantity type along a single dimension. For example, 'tall' is the opposite of 'short' for the quantity type 'height', and 'wide' the opposite of 'narrow' for the quantity type 'width' (see Bierwisch (1967, 1989) and Kennedy (2001) for a detailed analysis of polar adjectives). For certain quantity types we can identify not just a single opposing pair but a set of quantity-specific adjectives. For the quantity type 'temperature' we can find adjectives such as 'warm', 'cool', 'tepid', and variations such as 'lukewarm' as references besides just 'hot' and 'cold'. It is an interesting question to speculate why this variety of quantity-specific adjectives exists for some quantity types but not for others. Frequent use or familiarity with the concept 'temperature' cannot explain this fact alone.

Understanding the connections between Qualitative Process Theory and natural language is important for understanding the general cognitive plausibility of qualitative models. It will also give us greater insight into how results from qualitative reasoning can be communicated back to human users in an intuitive way – by using natural language.

Learning Relational Categories by Comparison of Paired Examples

Abstract

Our central question is whether comparison of co-presented instances promotes category learning. We report results of four experiments testing acquisition of relational categories under conditions of Comparison learning versus traditional Single item learning. In order to control for frequency of exposure, the Single group received twice as many learning trials. Experiment 1 showed more accurate single-item classification at test for both old and new items by the Comparison group relative to the Single group. Experiment 2 used only within-category pairs in the Comparison condition (rather than both types of pairs), but no accuracy advantage was found. Experiment 3 repeated this design using a reduced training set and showed a learning effect of comparison and a marginal advantage in transfer to new items. In Experiment 4, a novel paradigm revealed further evidence of a facilitative effect for within-category comparison. The power of comparison to promote learning and transfer is discussed in terms of mechanisms of encoding and knowledge change.

Introduction

The present research addresses the effect of comparing co-presented instances during classification learning. Nearly all theorists propose that categorizing an instance involves some type of comparison between an instance and stored category representations. A further role for comparison in category learning is between presented instances and remembered instances. Sequential effects may occur if items presented in immediate or near succession are brought into temporal juxtaposition (e.g., Elio & Anderson, 1981). Learners may also experience remindings of previously encountered instances which can guide further processing (Spalding & Ross, 1994; Ross, Perkins & Tenpenny, 1990). Of considerable interest to our project, Ross and Spalding (2000) report that reminding-driven comparisons during category learning mediate attribution of abstract features to individual instances. We investigate the effect of comparison of instances presented together within a classification learning trial with the core prediction of better learning and transfer of relational categories.

This prediction is motivated by several sources including the rich literature supporting the structural alignment account of analogy and similarity (Gentner & Markman, 1997). Perhaps the most directly related evidence is the finding that 4-year-old children extend a label according to category match more frequently than by perceptual match when the label had been applied to two examples (Gentner & Namy, 1999). After only a single labeled example, children did not favor the category-based extension. Gentner and Namy conclude that a structural alignment process (invited by the common linguistic label) yielded a deeper, more conceptual encoding.

In light of recent findings that classification learning influences similarity, Boroditsky (in press) collected similarity ratings of pairs of object drawings from participants who had first listed either similarities or differences between the items. For both familiar and novel stimuli, items were rated more similar by participants who made comparisons than by those who did not. The effect depended critically on the items being similar – suggesting that comparison drew out a richer realization of the commonalities between alignable objects.

How might comparison work to mediate learning and representation? In the structural alignment framework, comparison influence encoding by: 1) highlighting common relations or alignable differences between examples; 2) projecting candidate inferences from one example to another; 3) promoting abstraction of shared structure as the basis for a generic knowledge structure; and 4) fostering re-representation that alters or re-organizes representational elements in one or both cases (Gentner & Wolff, 2000).

To illustrate, imagine a pair of cases for which a particular relation is encoded in the learner's mental representation of each instance. The process of comparing the representations would render this relation salient and promote abstraction and transfer (e.g., Loewenstein, Thompson & Gentner, 1999). Now, consider a common relation that is differently encoded in each case. Re-representation is posited as a means of aligning non-identical relational structures when there is semantic overlap (Gentner & Kurtz, in preparation) or a computational opportunity (Yan, Forbus, & Gentner, 2003). Next, consider a relation that has only been encoded in the representation of one of two instances. If there is sufficient surrounding structure in common, then a candidate inference would be projected from the more fully elaborated case to the sparser one (Gentner, 1983; Markman, 1997).

Finally, consider a common relation that is not encoded in the mental representations of either case. The mechanisms

listed above depend on the presence of relational information encoded in item representations. In the current project, we study learning in a novel domain and the underlying relation defining each category is far from self-evident to the uninitiated. In fact, short of resorting to exemplar memorization, the learning task is best characterized as trying to discover each relation. We posit a role for comparison in the discovery of relational content.

The notion of *manifest* versus *latent* representational content is of use here (Clement, Mawby, & Giles, 1994). While an individual may have somewhere in their idea of 'dog' the knowledge that dogs often feast on foodstuffs fallen to the floor during a family meal, this relational content is probably not routinely activated in a context-independent manner (Barsalou, 1982). Therefore, an analogy between a dog and vacuum cleaner might initially fall flat for someone who does not have the 'cleaning-up-of-table-scraps' aspect of their 'dog' concept activated. However, a thorough comparison of dog and vacuum cleaner could well activate latent matching content. Such *resurfacing* occupies a place between novel inference and highlighting, but, like the others, it relies on available relational content.

What is needed is a mechanism for articulating relational content over presumably unstructured initial inputs. Such processing is likely be of critical importance in any type of routine formation of structured mental representations since constraints are needed on which of the vast range of possible relations among objects, scenes, and situations in everyday experience should be explicitly encoded. As a number of theorists have put forth, language may be of particular use with regard to this problem.

We propose that comparison provides potential for a kind of *side-to-side* (as contrasted with top-down or bottom-up) interpretation process that promotes relational construal. The best evidence we can draw upon is the phenomenon of analogical bootstrapping in which intensive comparison of two partially understood depictions of a simple physics principle (heat flow) led participants to a deeper, more relationally-rich construal (Kurtz, Miao, & Gentner, 2001).

It is not clear how such analogical insight occurs, but here are two speculations. The first is consistent with the notion of progressive alignment (Kotovsky & Gentner, 1996) and states that observed commonalities at the level of lower-order representational elements (i.e., attributes, objects, first-order relations) may serve as entry points from which a familiar higher-order relation can be invoked. An example of instantiating a richer representation would be going from: *is-high(square)* and *is-low(circle)* to: *is-above (square, circle)*. The second speculation is that relations do not need to be built up so much as they need to be picked out of a crowd. The idea here is that many relations hold for any given case; too many to routinely articulate and encode. When given an opportunity to compare cases, the potential arises to find a manageable intersection of the relations.

In order to explore the power of comparison in knowledge change, our experimental question is as follows: can comparison promote the acquisition of novel categories defined by non-obvious relations? Relational categories have been treated theoretically (Gentner & Kurtz, in press; Markman & Stilwell, 2001) and have begun to receive empirical attention (Kurtz & Gentner, 2001; Rehder & Ross, 2001).

In a study using an early version of the present paradigm, Kurtz & Gentner (1998) found that participants reached a learning criteria for classification accuracy more quickly with trials consisting of within-category pairs than with single-instance trials. However, this can be attributed either to comparison or to more frequent exposure to training items, i.e., two instances per trial versus one. This creates a difficult circumstance for the researcher since fully convincing evidence for a comparison effect in learning (with frequency of exposure controlled) requires obtaining reliably higher classification accuracy on the basis of half the number of trials. This is the challenge we pursue.

An additional purpose of this project is the advancement of greater naturalism in the study of categorization. The dominant paradigm is a two-way classification task with instances that are clearly dimensionalized sets of perceptual or verbal features. Our stimuli are line drawings depicting a set of realistically varying "rock arrangements" having no clear reduction into a compositional set of underlying dimension values. Learners are asked to acquire three different categories to avoid two limitations inherent in binary classification: 1) a perfect success rate can be achieved based on an ability to identify examples of only one category and; 2) task demands encourage hypothesis-testing for a boundary over positively-defined concepts.

Experiment 1

One major concern in designing the first study was ensuring that the Comparison condition actually elicited comparison. An act of comparison can be shallow or intensive, and this difference can be a causal factor (Kurtz, et al., 2001). A failure to observe a comparison effect might be due to a failure by participants to compare. Classifying a within-category pair can easily be done with consideration of only one of the instances. Therefore, instead of all same-category pairs, we designed the Comparison condition to use an equal mix of within- and between-category pairs. In this mixed-pairs version, the status of any given pair is not known to the learner. Since the two instances may or may not belong to the same category, we collect two separate classification judgments on each learning trial. Accordingly, the participant must give direct consideration to each member of the pair. It is implicit in the task that the participant must consider whether or not to guess the same category for the two instances in each trial. However, classifying each instance could still be done largely independently despite taking place in a common task space.

For this reason, we used an orienting task at the beginning of each learning trial to encourage comparison. Participants were asked to consider the role played by one of the rocks relative to the rest of the arrangement and then to look for a

corresponding rock in the other instance. The orienting task for Single learners was to consider the role of one of the rocks in the arrangement. In both conditions this unenforced orienting task (no response was collected) was followed by a question that did require a response: whether or not the participant found the orienting task helpful. This was to discourage participants from ignoring the orienting task.

Method

Participants A total of 100 undergraduate students at Binghamton University received a course credit.

Materials A set of 36 images of rock arrangements was created on the computer. Rocks in each arrangement varied in color, shape, and size. A subset of 24 images were designated as the training instances and the remaining 12 images constituted the transfer set. The rock arrangements were evenly distributed across three categories given the names: "Tolar," "Besod," and "Makif." The category Tolar was defined by the presence of two stacked rocks similar in color and shape. Besod was defined by the presence of one rock supported by two others. Makif was defined by monotonically decreasing height from left to right. Care was taken that each instance conformed to exactly one of the relational categories. For the Comparison condition, a fixed set of pairings was established with an equal number of within-category and between-category pairs.

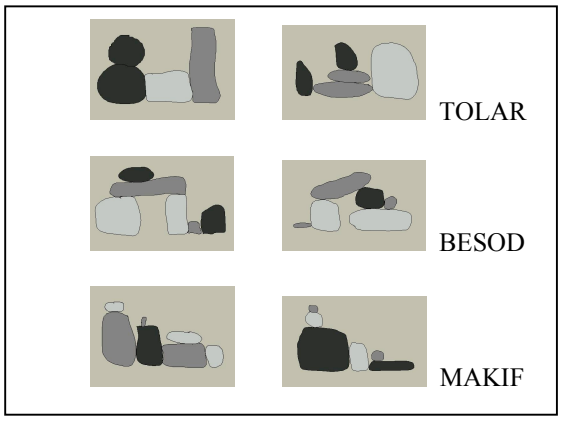

Figure 1: Sample Rock Arrangement Stimuli used in Experiments 1-3 Shown in Same-Category Pairs

Procedure Each participant was randomly assigned to one of the two conditions. Before the learning phase, participants read a set of instructions including a cover story about different rock arrangements created by the "Ladua" culture. Ss were instructed to try to learn to tell which rock arrangements belonged to which of the three types.

In the Single condition (n=50) an attempt was made to minimize the potential for temporal comparison by using a pseudo-random order in which each trial showed an instance from a different category than that of the previous trial. On each of the 48 learning trials participants were shown a single instance from the training set on the computer screen along with the orienting task: "Study the example, then focus on a single rock and consider the role it plays in the arrangement." Participants gave a forced-choice response regarding the helpfulness of the orienting task and were then asked to classify the rock arrangement into one of the three categories. After their choice was entered, corrective feedback was provided for a fixed interval of 3s. The stimulus image remained on screen for the entire trial.

In the learning phase of the Comparison condition (n=50), instances were presented two-at-a-time for 24 trials. On each trial, the presentation of the two instances on either the left or right side of the screen was randomized. The orienting task instructions for each trial were: "Study the examples, then focus on a single rock in one of the examples and consider the role it plays in that arrangement. Try to decide which rock plays a corresponding role in the other example." Participants made helpfulness judgments as in the Single condition. Ss were then asked to classify one of the instances followed by the other. Whether the left or right instance was queried first was alternated by trial. After the second response, corrective feedback for each of the responses was presented simultaneously for a total of 6s.

The learning phase in both conditions was followed by a common testing phase. Participants were presented with 24 old and 12 new items in random order and asked to classify each in a single-instance trial without feedback. Additional dependent measures were subsequently collected, but space limitations prevent their inclusion in this report.

Results and Discussion

The learning data reveal that it was not easy for most participants to acquire the relational categories in the allotted number of trials. We note that a set of pilot data showed that performance did not increase notably with twice the training. It is, however, important to remember that chance is 33.3% percent on a three-way classification, so the accuracy data reflects considerably more learning than it would appear at first glance. First we describe the learning data though we did not conduct statistical tests since the critical comparison between conditions is performance in the test phase when all participants respond to the same type of trial (single instance). Early (first quarter) classification accuracy shows that Comparison learners (M = .44, SD = .18) got off to a slow start compared to the Single group (M = .52, SD = .19), but they caught up by the final quarter: Single (M = .70, SD = .22) and Comparison (M = .69, SD = .25).

In the test phase, Comparison (M = .75, SD = .22) was significantly better than Single (M = .65, SD = .23) on old instances, $F(1, 98)= 4.73$, MSe = .234, $p < .05$. In addition, a transfer effect was found with Comparison (M = .72, SD = .22) significantly more accurate than Single (M = .59, SD = .27) in classification of novel instances, $F(1,98)= 7.29$, MSe = .444, $p < .05$. In sum, while Comparison learning presented a similar level of challenge during acquisition, a

reliable comparison advantage was found at test compared to Single learners receiving equal exposure.

Experiment 2

The goal of the second study was to determine whether a comparison effect would be found using only within-category pairs and a single categorization response per trial. The structural alignment view predicts a greater likelihood of comparison-driven effects on learning and encoding given the opportunity to compare alignable examples. However, as discussed, it is difficult to pin down the extent to which participants invoke a comparison process when making a joint classification response.

Method

Participants A total of 95 undergraduate students at Binghamton University received a course credit.

Materials The materials were the same as in Experiment 1. The assignment of pairs for the Comparison condition was accomplished by random generation of within-category pairings for each participant.

Procedure Each participant was randomly assigned to one of the two conditions. The Single condition (n=46) was conducted as in Experiment 1. The Comparison condition (n=49) followed the procedure of Experiment 1 except that participants were trained only on within-category pairs. Unlike Experiment 1, participants made a joint classification choice in response to both of the instances on each trial. Corrective feedback for the one response was shown for 3s.

Results and Discussion

A much different result was obtained relative to the findings of Experiment 1. Comparison learners with only within-category pairs showed good performance in the learning phase (M = .63, SD = .16) as compared to Single learners after an equal number of trials (M = .53, SD = .14), but not after an equal number of exposures (M = .60, SD = .14). No significant differences were found in test performance on old items (Comparison: M = .66, SD = .23 and Single: M = .67, SD = .21; $p > .8$) or transfer to new items (Comparison: M = .61, SD = .23 and Single: M = .63, SD = .24; $p > .6$). The evidence suggests that mixed pairs offer a more productive learning context than exclusively within-category pairs. This could be a benefit derived from evaluating whether or not co-presented pairs are from the same category. It could be due to useful contrastive evaluation of different-category items. However, it is worth noting on this point that no reliable difference was observed between learning accuracy on within-category and different-category trials in the Comparison condition of Exp. 1 ($p > .3$). Therefore, we are inclined to consider additional explanations. One possibility is that the joint classification task failed to fully encourage comparative evaluation of both instances in the trials. A final and somewhat compelling possible culprit is the 3s window for evaluating feedback as opposed to the 6s window for the dual-feedback in the Comparison condition of Exp. 1. In the current study, Comparison learners actually had half the overall amount of time to study images with their correct labels then was provided to Single learners.

Experiment 3

Given the lack of comparison advantage in Experiment 2, we considered the question of which is better: many different within-category comparisons over a large training set or repeated within-category comparisons over a small training set? It has been shown that larger category size promotes better transfer to novel examples when the instances in the training set are sufficiently variable (Homa & Vosburgh, 1976). Our hypothesis was that in the case of relational categories, repeated comparisons of within-category pairs in a smaller set would actually be more likely to promote an advantage of comparison in transfer accuracy. If Comparison learners in Exp. 2 underachieved due to a failure to fully compare and/or insufficient feedback time, repeated training on fewer examples might prove more conducive to comparison-driven learning.

Method

Participants A total of 87 undergraduate students at Binghamton University received a course credit.

Materials The materials were the same as in Experiment 1 except that the total number of examples in the training set was reduced to 12. Each category was represented by four, rather than eight, instances. All possible within-category pairings appeared once (determining 18 of the 24 trials in the Comparison condition). The remaining 6 trials were randomly determined for each participant including exactly one exposure of each training item.

Procedure The procedure was the same as in Experiment 2, though the same number of learning trials with fewer items in the training set yielded more exposures to each instance in the Single (n=42) and Comparison (n=45) conditions.

Results and Discussion

Comparison learners (M = .79, SD = .16) showed excellent overall accuracy on learning trials with the small category size relative to Single learners (M = .68, SD = .16). Although we have emphasized test performance rather than learning accuracy, Comparison learners were reliably more accurate across learning trials, $F(1, 85)= 10.39$, MSe = .25, $p < .005$) with equal frequency of exposures. The Comparison group (M = .68, SD = .16) also performed better on transfer items, $F(1, 85)= 3.91$, MSe = .18, p = .051, though the significance here was marginal. In performance on old items at test, a trend was found ($F(1, 85)= 2.54$, MSe = .09, p = .11) favoring the Comparison condition (M = .83, SD = .16) over Single (M = .76, SD = .21). These results provide yet another turnaround—the previous failure to find an advantage of comparison using within-category pairs is

overturned in the case of repeated comparisons with a small set of training items. The advantage is not limited to overlearning of the items in the small set since the results at test including transfer to new items favor Comparison. Our interpretation is that repeated comparison opportunities among increasingly familiar instances better allows the fruits of comparison to be borne out.

Experiment 4

We developed an additional paradigm to evaluate comparison of instances in category learning. The key difference is that in all conditions the orienting task is dropped and each learning trial begins with a single-instance classification judgment. In the Single condition, feedback is provided and the trial is done. In the Comparison condition, a within-category context item appears next to the target item, and the participant is asked for a second time to classify the initially presented target. Once the learner has made their second response, feedback is then provided based on the final response. Therefore, the only difference between conditions is that learners in the Comparison group are asked to repeat their classification choice in light of the availability of a context item from the same category for their consideration. We believe this is a naturally motivating and "unforced" version of comparison. A further advantage of this design is that since only the single target item is classified in each condition, we are better able to evaluate the impact of comparison during the learning phase.

Method

Participants A total of 50 undergraduate students at Binghamton University received a course credit.

Materials A full-sized stimulus set was used as in Experiments 1-2, but some alterations were made to the set. It was decided that the Tolar category was of a somewhat different character than the other categories since only two rocks in the entire arrangement participated in the relation of "same shape and color of two stacked rocks." In the other categories, the relation was more globally realized in the overall arrangement. A new relational definition and item set for the Tolar category was developed in terms of a symmetrical outline for each arrangement across the vertical axis. In addition, instances of the Makif and Besod categories were fine-tuned to ensure that the relation was globally realized in each rock arrangement. For example, the relation "one rock supported by two" would not be localized in a set of small rocks off to the side. These modifications were expected to make the learning task somewhat easier and the results more interpretable. Pairings for the Comparison condition were assigned such that all 28 possible same-category pairs in each category occurred once during learning and the remaining 12 learning trials were repetitions equated for instance exposure.

Procedure Each participant was randomly assigned to one of three conditions. Prior to the start of the learning phase participants read the instruction set. However, in order to help limit cases in which a learner embarked on a counterproductive approach, the instruction set was given the following addition: "Each of the three types is based on a distinct way of arranging rocks. Please note: It is not a small detail or a feature of one single rock. It is something about the way in which the group of rocks are arranged."

In the Single condition (n=20), participants completed 96 classification learning trials of single instances of the new set of rock arrangements in pseudo-random order. Feedback was given after each trial with study time self-paced rather than a fixed window. In the Comparison condition (n=17), each trial began exactly like a Single condition trial. However, participants did not receive feedback on their response. Instead they were shown another within-category instance from the training set as a context item. Participants were asked for a second time to classify the initial target item (this was reinforced by presenting the question under the target, not the context item). An accompanying instruction encouraged Ss to compare the target to the additional example from the same category. Participants were instructed to feel free to change their initial answers or not. Ss received feedback on their second response with self-paced study time.

A third condition called Identical (n=13) was conducted just as the Comparison condition except that the additional context item was a repeat of the target item—resulting in two identical images shown side-by-side. This task (responding twice to the same stimulus) was justified in the instructions as something Ss might find helpful.

In all conditions, participants went on to a test phase like that used in Experiments 1-3.

Results and Discussion

Means and standard deviations for the learning phase accuracy are shown in Table 1. One-way ANOVA showed a main effect of learning condition on classification accuracy in the first quarter, ($F(2, 47)= 5.22$, $MSe = .16$, $p < .05$), in the last quarter, ($F(2, 47)=3.19$, $MSe = .12$, $p < .05$), and in the overall performance, ($F(2, 47)= 3.77$, $MSe = .11$, $p < .05$). The first quarter difference was driven by the Identical group and most likely reflects participants adjusting to the somewhat odd repeated query. Planned comparisons showed that last-quarter accuracy (the final 24 trials) was significantly higher in Comparison versus Single, $t(35)= 2.22$, $p < .05$), as well as Comparison versus Identical, $t(28)= 2.27$, $p < .05$.

In the test phase there was a marginal main effect of learning condition on accuracy, $F(2, 47)= 3.167$, $MSe = .142$, $p = .051$. Planned comparisons showed that Comparison learners performed significantly better on old items ($M= .93$, $SD= .15$) than Single learners ($M = .82$, $SD = .18$), $t(35)= 2.06$, $p < .05$. Performance on new items was also better for the Comparison condition ($M = .87$, $SD = .18$) than the Single condition ($M = .70$, $SD = .20$), $t(35)= 2.71$, $p < .05$. Trends (presumably due to small sample size) were found in favor of Comparison over Identical for old items ($p = .08$) and new items ($p = .12$). No difference was found in

accuracy between the Single condition and Identical condition. We see in these results good evidence for better learning with the opportunity to compare to a within-category context item versus conditions with no additional comparison or a kind of item self-comparison that serves as a full control for exposure (equal number of classification responses; equal number and duration of item exposures).

Table 1. Classification Accuracy in Learning.

	Mean	SD
First quarter		
Single	.69	.18
Comparison	.71	.17
Identical	.52	.16
Last quarter		
Single	.81	.18
Comparison	.94	.15
Identical	.77	.24
Overall		
Single	.77	.16
Comparison	.84	.16
Identical	.67	.18

General Discussion

We conclude that comparison of instances during category learning is not necessarily of great impact, but when task constraints emerge that engage the learner to apply the machinery of comparison, superior performance in learning relational categories is achieved. These findings are most naturally understood in terms of learning to construct richer, more sophisticated encodings of category instances. While this is a difficult process, it is made easier by comparison.

Abstract

A novel approach to generating retrieval and transfer of structured knowledge is presented. We investigate the effect of comparing two analogous unsolved problems at test as opposed to comparing two solved analogous stories during initial study. We found that both procedures facilitate transfer relative to a standard baseline group studying one solved story and then attempting to solve a new analogous problem. In two studies we demonstrate that: 1) comparing two unsolved problems at test promotes analogical problem solving at least as effectively as comparing two fully solved problems during study; and 2) comparing two unsolved problems is helpful even when no source story is made available for retrieval.

Introduction

There is a wealth of cognitive science research about how people learn from examples and use them to solve new problems (Reeves & Weisberg, 1994). We also know that people are unlikely to spontaneously compare examples that seem different on the surface even though such comparison can provide learning and transfer advantages (Gick & Holyoak, 1983; Kurtz, Miao & Gentner, 2001). Retrieving analogous matches is therefore both important and demonstrably difficult. Research on retrieval shows that people have an easier time accessing examples on the basis of surface features than structural match (Catrambone, 2002; Gentner, Rattermann & Forbus, 1993; Ross, 1987). It is not that structural matches, particularly partial matches, are impossible or even rare, just that surface matches tend to predominate among novices, whereas experts seem able to exhibit structure matches more reliably (Dunbar, 2003; Novick, 1988).

We know that comparing examples can lead people to focus on common systems of relations which can in turn facilitate knowledge transfer (e.g., Loewenstein, Thompson & Gentner, 1999). The conventional wisdom in the field is that upon encountering a test problem, people are able to retrieve the earlier analogous cases, or a schema abstracted from those cases, to generate potential solutions to the problem (Gick & Holyoak, 1983). The implication is that the similarity function used in memory retrieval can link a current case to a prior case if the prior case is represented well in long term memory. The specific nature of such a superior representation is a challenging question for the field, but we take as a starting point the idea that a good representation is one that accurately encodes pertinent systems of relational structure and does so with sufficient generality to support transfer. This generality can be considered in terms of domain generality of encoded relational content (Clement, Mawby & Giles, 1994), uniformity of representational elements (Forbus, Gentner, & Law, 1995), or filtering out of mismatching irrelevant case details (Hummel & Holyoak, 1997).

We are currently intrigued by a new role for analogy in memory retrieval (see also, Loewenstein, Gentner, & Thompson, 2004). Our question is whether the benefits of this kind of representational "improvement" to the analogical source might also be observed with respect to the target (probe). Is a structural reminding more likely with a target that is better encoded? Theories of memory retrieval rely on a similarity function between the probe and stored items. Such similarity functions are symmetric. Since the empirical data suggest that only one side (i.e., the source) needs to be well-encoded to encourage a match, then it is plausible that a relevant, but regularly encoded source might become more retrievable on the basis of applying a probe with a superior encoding. In addition to being a theoretical possibility, there is a phenomenon, admittedly rare, of recalling an example with the sense of having a new understanding about it as a result of something we have just learned. The current line of thinking could explain such occurrences. Furthermore, it suggests a mechanism by which reflection upon a newly learned principle or abstraction could be a prod to retrieve prior examples, reinterpret them, and integrate the new knowledge with the old. Drawing analogies might then not only be a source of changes in knowledge from this point forward, but could also be a means for reorganizing the knowledge we already have and retrieving further analogous matches.

To reiterate, one of the seminal findings in the analogy literature is that problem solvers are more successful in retrieving an available solution strategy when they have previously made use of comparison to improve the encoding of the source analogs (Gick & Holyoak, 1983). We adapt this highly influential paradigm to ask the following question: Can comparison of target problems be used to facilitate analogical retrieval? There is considerable reason for skepticism. First, the advantage of source comparison is thought to rely on storing a generalized version of the solution principle, but in the case of target comparison the solution is not part of the compared cases—only the two problem statements are available. Secondly, the traditional

account suggests that structural reminding depends on having a well-represented source in memory—it may well follow that structural reminding is largely a dead end without a well-encoded source. Third, it is easy to imagine that having two problems to solve rather than just one could divide attention and processing resources in a detrimental manner. Finally, there is an extensive tradition of failed attempts to improve analogical problem-solving performance. Even so, if comparison at test can improve the encoding of targets such that retrieving structural matches is facilitated, this would have significant theoretical and applied ramifications. In the following two studies, we explore comparison-improved representation at the point of actual problem solving in hopes of gaining new insights into learning, retrieval, and transfer.

Experiment 1

In the current studies we use classic materials to study a novel set of questions about analogical problem solving: Duncker's (1945) tumor problem and its associated materials generated by Holyoak and colleagues (Gick & Holyoak, 1980, *inter alia*). In Experiment 1, we use these materials to examine whether retrieval is a two-way street. That is, if comparing two examples at study facilitates transfer at test (as shown by Gick & Holyoak, 1983), then can comparing two examples at test facilitate retrieval from study? In addition to the comparison being on-line rather than during initial study, the other key difference is that compared target problems do not include the solution.

We include two conditions to replicate prior data: a baseline group receiving one solved story at study and one problem at test (which will presumably yield little transfer) and a group comparing two solved stories at study and then receiving one problem at test (which will presumably show transfer). The key question is what will result in a new condition with one solved story at study and a comparison of two unsolved problems at test. Will participants who compare two test problems show greater success than participants in the baseline condition? Furthermore, to address the question of whether success hinges on transfer via retrieval of the source story, we include a group asked to compare and solve two problems without having first seen a solved story at study. Participants in this group are the only ones to receive no exposure at all to the relevant solution strategy.

Method

Participants A total of 293 undergraduate students at Binghamton University participated in partial fulfillment of a course requirement. Participants were randomly assigned to one of four conditions: Baseline, Source Comparison, Target Comparison, or Just Targets.

Materials The target case in all conditions was the well-known Radiation problem developed by Duncker (1945) and further studied by Gick & Holyoak (1980, 1983). The source and comparison cases were analogs based on the convergence principle used by Gick & Holyoak (1983). The source case was "The General" set in a military context and the comparison case was "Red Adair" set in a firefighting context. The comparison case was given with solution included during the study phase in the Source Comparison condition. We used the same Red Adair problem for comparison at test without the last lines that give the convergence solution in the Target Comparison and Just Targets conditions.

Procedure All phases of the experiment were conducted using paper packets for the presentation of instructions and materials as well as for the collection of responses. Separate packets were created for study and test phases. Participants did not receive the test packet until they completed and handed in their study packet (if a study packet was required by their condition).

In the Baseline condition (1:1, meaning participants were given 1 source story and 1 target problem), participants were instructed at the beginning of Part I to read the story (General) carefully and to gain sufficient familiarity that they could retell the story in their own words. Toward the bottom of the page, participants were asked: "What critical insight allowed the problem in the story to be solved?" In Part II, participants were asked to read the problem (Radiation) and to "use the space at the bottom of the page to explain how the problem can be solved."

In the Source Comparison condition (2:1), participants were instructed in Part I to carefully read two stories (General and Red Adair). The two stories were shown on the same page with General appearing first. At the top of the second page were two tasks to encourage better encoding. As in the control condition, participants were asked to gain sufficient familiarity that they could retell the stories in their own words. In addition, participants were asked to "Consider the parallels between the two stories" and complete a task in which five elements of Column A (General) had to be matched with elements of Column B (Red Adair). Each element had exactly one appropriate match. The columns were prepared in a jumbled order so that no correctly corresponding elements were directly across from one another. In Part II, participants were asked to solve the Radiation problem. The exact same procedure was used as in the Baseline condition.

In the Target Comparison condition (1:2), participants were presented with the General story using the exact same procedure as in the Baseline condition. In Part II, these participants were given two problems to solve (Radiation and Red Adair) The first page of the packet gave the following instructions: "What approach would you take to solve both of the following problems? After reading the problems carefully, please complete the matching task and then explain your proposed solutions in the space provided. Here's an important hint: The same strategy can be used to solve both problems."

Below the instructions were the two problems: Radiation followed by Red Adair. On the second page was a matching task between the Radiation and Red Adair problems

constructed in the same manner as above. On the last page, participants were again given the hint that "The same type of solution can be used" and asked to: "Please write down how these two problems can be solved."

In the Just Targets condition (0:2), participants were given Part II of the Target Comparison condition only. That is, they were asked to solve the Radiation and Red Adair problems without any prior exposure to the General story and its convergence solution. There was one additional procedural difference. The same-solution hint was provided, but in this case it was given only at the point when participants were actually asked to produce their solutions (rather than mentioning the hint twice).

An important point to clarify here is that this hint is distinct in type from the well-known use of a hint in the Gick & Holyoak studies. In that prior work the hint was to use the initial story as a basis for solving the target problem. That hint removed the fundamental obstacle in analogical problem solving: achieving a spontaneous structural reminding. The manipulation was of critical theoretical importance since it revealed that the Radiation problem was widely solved once participants accessed the source analog. In our current work, the hint has nothing to do with retrieval; instead it enforces mutual consideration of the two target problems.

Scoring A rater blind to condition scored each response for success in solving the Radiation problem in terms of the convergence solution. Responses were scored as correct if they captured the key principle of a multiplicity of low-intensity rays acting in concert on the tumor. The rater marked any responses they considered questionable for discussion with another rater. The agreed-upon scoring was then recorded. In occasional cases in which more than one solution was proposed, participants were given credit for the correct answer if it was produced.

Results

As expected, we replicated prior data showing that people who compared two source stories showed a transfer advantage relative to a baseline group who only read one source story (as shown in Table 1, 38% vs. 13% generated convergence solutions), $\chi^2(1, N=146) = 12.12$, $p < .01$. The important new result is that the group comparing at test, rather than study, performed as well or better than all other groups. The Target Comparison group performed better than the Baseline group (51% vs. 13%), $\chi^2(1, N=142) = 24.06$, $p < .001$. There was also a trend toward better performance by the Target Comparison group than the Source Comparison group (51% vs. 38%), $\chi^2(1, N=142) = 2.62$, $p = .11$. Critically, the Target Comparison group also performed better than the Just Targets (25%) group, $\chi^2(1, N=147) = 10.58$, $p < .005$. This suggests that participants who compared target problems were drawing upon the story from study since this was the major difference between the Target Comparison and Just Targets conditions. Finally, the Just Targets participants were marginally more likely to derive the convergence solution than were Baseline participants, $\chi^2(1, N=145) = 3.62$, $p = .06$. This suggests that comparing two unsolved target problems facilitated reaching the correct solution as compared to the Baseline condition of single cases at study and test.

Table 1: Proportion of convergence solutions by condition

Condition	N	Proportion generating convergence solution
Baseline (1:1)	70	.13
Source Comparison (2:1)	76	.38
Target Comparison (1:2)	72	.51
Just Targets (0:2)	75	.25

Discussion

We were able to replicate the well-known finding that comparing two examples at study yielded transfer benefits at test relative to a control group reading just one story at study. The intriguing result is that comparing two problems at test resulted in higher performance than the control group. Perhaps even more surprising, the Target Comparison group performed slightly, but not significantly, better than the comparison at study group. Confronted by one hard problem, these results suggest that a reasonable course of action would be to seek another problem with the same underlying structure!

Prior research suggests that abstracting the convergence schema was critical for success on the Radiation problem. Yet it is highly unlikely that the Target Comparison group abstracted the convergence schema from one example (otherwise the control group should have done well too). Our interpretation is that comparing analogous problems can lead to better representations of one or both problems. Such an encoding is likely to serve as a more effective retrieval cue for analogical problem solving. Due to having better representations of the problems via comparison, participants recalled the initial source story and borrowed its convergence solution. That is, retrieving prior examples on the basis of structure might be feasible if the probe is sufficiently well encoded, just as the comparison at study condition suggests that retrieval is feasible if the stored item is sufficiently well encoded.

The lower level of performance by the group who compared test problems, but did not receive a story at study, provides support for the claim that retrieval was a factor. Further tests are needed however to determine whether the single versus repeated hint played any role in this finding. The marginal advantage obtained in the Just Targets (0:2) condition over the Baseline condition indicates potential, not only for problem comparison as a means to achieve analogical retrieval, but also as a means to generate problem insight right then and there via analogical encoding.

In sum, we found that performance on a difficult problem can be greatly facilitated by an on-line technique. It is not necessary to construct improved representations at the time of encoding because one can do the necessary work through

comparison at test. Furthermore, such comparison is between problems, not between solved stories. The power of this comparison is not based on highlighting the convergence principle, but arises from comparison of two problem scenarios both amenable to a convergence solution.

Experiment 2

A second study was designed to replicate our basic finding and to further test whether drawing comparisons was an important component of the Target Comparison group's strong performance in Experiment 1. In this study we contrast the Target Comparison condition with a condition also receiving one study story and two test problems, but not guided with a hint to seek one solution for both problems. This Separate Targets condition still includes a matching task and the task to write down how "these problems can be solved," but the specific suggestion to work toward a single solution strategy is removed. If the Target Comparison group outperforms the Separate Targets group, this would serve as an indication that the depth of comparison of the problems is critical, just as comparing study problems is critical (Catrambone & Holyoak, 1989; Loewenstein, et al., 1999; Kurtz, et al., 2001). Additionally, in Experiment 1, the Source Comparison group tended to perform less well than the Target Comparison group, so a Source Comparison condition was included to test for a reliable difference.

Method

Participants A total of 224 undergraduate students at Binghamton University participated in partial fulfillment of a course requirement. Participants were randomly assigned to one of three conditions: Source Comparison, Target Comparison, or Separate Targets.

Materials, Procedure and Scoring The same source and target cases, the same use of paper packets, and the same scoring procedures were used as in Experiment 1. The Source Comparison (2:1) and Target Comparison (1:2) conditions were conducted using the same experimental and scoring procedure as in Experiment 1. The Separate Targets (1:2 without hint) condition followed the Target Comparison condition exactly with the exception that the initial hint and hint repetition were excluded from the text of the instructions.

Results

The main focus of this study was the contrast between the Target Comparison and Separate Targets conditions. People who received two problems, but no hint to compare them generated the convergence solution infrequently (16%, see Table 2). As in Experiment 1, the Target Comparison group frequently generated convergence solutions (40%), and did so reliably more often than did participants in the Separate Targets condition, $\chi^2(1, N=147) = 10.77$, $p < .005$. Thus an explicit instruction to compare and generate a common solution was critical to the effectiveness of the Target Comparison manipulation.

There was little difference between the Source Comparison (35%) and Target Comparison (40%) groups in this study, $\chi^2 < 1$. The previous study suggested there might be a difference between the two conditions, and the ordering of the means was consistent, but the difference in this study was minimal.

Table 2: Proportion of convergence solutions by condition

Condition	N	Proportion generating convergence solution
Source Comparison (2:1)	77	.35
Target Comparison (1:2)	72	.40
Separate Targets (1:2) without hint	75	.16

Discussion

This study replicated the effectiveness of comparing two target problems. It also confirmed an important boundary condition, namely that comparing the target problems toward drawing out a common solution was important. Merely receiving two target problems with minimal encouragement to assess their parallels was not effective. Indeed, solving two target problems separately led to comparable performance as solving one target problem (i.e., the baseline condition) in Experiment 1.

General Discussion

With these two studies, we provide grounds for a new emphasis, if not a new interpretation, of analogical retrieval and transfer. The usual assumption is that comparing examples facilitates generation of a representation of the common schema that clarifies the key structure and is less cluttered by unrelated contextual details than the original examples. It is clear that without drawing a comparison, people are unlikely to represent the structure in such a way that it can be retrieved and used to solve a new problem—an effect we replicated in Experiment 1. The current results open up the possibility that the benefit of comparison at study may be due to: 1) improving the encoding of the examples rather than creating a new general knowledge structure; or 2) allowing people to form better encodings of subsequent cases using a more sophisticated or general representational vocabulary.

The current studies were aimed at addressing this issue by turning it around: what if people study just one example (so they are unlikely to form any particularly clear or uncluttered representation), but they compare examples at test and then profit from having read the earlier single case. The results of our two experiments are consistent with people being able to retrieve single stored cases in just this fashion. We showed a distinct transfer advantage for a group that was: (1) specifically encouraged to compare two unsolved test problems and (2) had previously studied a single case. One may not need to store cases in a

particularly good fashion if one can later construct a superior retrieval probe.

There are multiple implications if a comparison today can facilitate retrieving a case learned yesterday. First, with respect to models of the retrieval process, it suggests a constraint on the similarity process that matches stored items to probes: it may well have to be symmetric. Second, it suggests a mechanism by which people can reorganize their knowledge. One may not have to "learn it right the first time" if, after appreciating a new abstraction, one is able to retrieve and perhaps re-represent a prior matching example. This supplies a concrete mechanism for gradual conceptual change in both development and the acquisition of expertise. Third, this implies that educators, particularly those who teach adults, can look to integrate people's prior experiences in their formal acquisition of domain expertise.

A second point arising from these studies is that drawing comparisons can facilitate learning in a new way. Typically, people draw comparisons to understand a principle or solution in a more general way. In our studies, people used comparison to generate better formulations of the problem at hand, not a better understanding of provided solutions. There are at least three reasons as to why this should facilitate problem solving. First, comparing two problems with the knowledge that that they have a common solution type means that idiosyncratic information can be ignored. Second, potentially misleading example-specific solution types can be ruled out. Third, it may allow people to formulate a more abstract or general version of the problem at hand. As Polya (1945) suggested, despite it seeming counterintuitive, sometimes a more general problem is easier to solve than a more specific problem. There may be interesting and important applications of this use of comparison both in education and in discovery.

We find these studies an intriguing first step. We are pursuing several related issues that might influence our interpretation of these studies. The Just Targets condition was given a weaker hint to compare than the Target Comparison condition, and as the Separate Targets condition showed: hints are important. We are running a new study that examines equal encouragement to draw comparisons. We are also interested in whether the Target Comparison condition benefits from one problem being easier to solve than the other (in which case its solution would be tested on the second problem) or whether it is the development of a more general version of the problem that is driving participants' success.

In conclusion, drawing comparisons may facilitate learning and transfer in multiple ways. It may enhance recalling prior experiences as much as generating knowledge that is likely to be later transferred. It may enhance clarifying a problem formulation as much as deriving generalizations from solved problems.

Pronouns Predict Verb Meanings in Child-Directed Speech

Abstract

Do statistical regularities between pronouns and verbs help children learn verb meanings? This question is addressed by an analysis of child directed speech. The results show that there are statistical regularities in the co-occurrences of pronouns and verbs that could be used to cue verbs that describe physical motion, psychological states, and features such as transitivity. The learnability of these regularities is demonstrated in a simulation study.

Introduction

It is well known that learning the meanings of verbs is a difficult task for young children. It is also well known that pronouns make up a substantial proportion of the nouns that children hear. The distributional relations between pronouns and verbs thus could play a role in early verb learning.

There are several reasons why verb meanings are difficult for children to learn. Whereas parents label objects (relatively) often, they rarely label events or relations. There are no observable referents for many verbs, such as psychological state verbs like *look*, *think*, *want*, *believe*, and *know*. Even verbs that refer to observable actions present ambiguities—for example, when does the opening of a door begin? Further, the aspect of an action that is relevant is ambiguous, and could be, for example, the manner or the path. Finally, verb meaning often depends on taking a particular perspective on a scene; consider the difference between "giving" and "receiving." In brief, meaning maps between verbs and the world are not transparent. Accordingly, many have suggested that word-word relations are particularly important to learning verbs (see, for example Gleitman, 1990; Gleitman & Gillette, 1995). Here we examine how statistical relations between pronouns and verbs in parental speech might help children learn the meanings of the verbs.

Pronouns are, by far, the most common syntactic subjects and objects in adult speech to children. Most syntactic subjects in spontaneous spoken adult discourse in general are pronouns (Chafe, 1994), and English-speaking mothers often begin with a high-frequency pronoun when speaking to their children, with *you* and *I* occurring most frequently (Valian, 1991). The sheer frequency of pronouns suggests that pronouns—and their statistical co-occurrences with verbs—may be developmentally very powerful.

Consistent with this idea, Childers & Tomasello (2001) suggested that children acquire lexically specific frames such as "I do it" as a way into learning syntactic frames. Cameron-Faulkner, Lieven, & Tomasello (2003) also observed that parents use the inanimate pronoun *it* far more frequently as the subject of an intransitive sentence than of a transitive one. As Cameron-Faulkner et al. note, this suggests that intransitive sentences are used more often than transitives for talking about inanimate objects. It also suggests that the use of the inanimate pronoun might serve as a cue to some semantic aspects of the verb.

Pronouns may also help learners partition verbs that express psychological attitudes toward events and states of affairs into two rough categories. Verbs that express deontic status, such as goals, purposes or intentions (*try to*), volitions or desires (*want to*), and compulsions (*have to*) tend to take infinitival complements, whereas verbs that express epistemic status, such as perceptions (*see that*), beliefs (*think that*), and knowledge (*know that*) tend to take sentential (propositional) complements (Tomasello, 2003). In the ecology of early childhood, parents tend to be the ones who *know* whereas children tend to be the ones who *need*. All this suggests the potential value of examining the distributional relations among pronouns and verbs in language to young children.

Experiment 1

The first experiment consisted of a corpus analysis to demonstrate patterns of co-occurrence between pronouns and verbs in the child's input.

Method

Parental utterances from the CHILDES database (MacWhinney, 2000) were coded for syntactic categories, then subjected to clustering and statistical analysis. The target children represented in the transcripts were aged approximately 1;4 – 6;1.

Materials The following corpora were used: Bates, Bliss, Bloom 1970, Brown, Clark, Cornell, Demetras, Gleason, Hall, Higginson, Kuczaj, MacWhinney, Morisset, New England, Post, Sachs, Suppes, Tardiff, Valian, Van Houten, Van Kleeck and Warren-Leubecker.[1]

Coding was performed using a custom web application that randomly selected transcripts, assigned them to coders, collected coding input, and stored it in a MySQL database. The application occasionally assigned the same transcript to all coders, in order to measure reliability. Five undergraduate coders were trained on the coding task and

[1] The full references for each corpus may be found in (MacWhinney, 2000).

the use of the system. Cluster analysis and other statistical analyses were performed using MATLAB and R.

Procedure Each coder was presented, in sequence, with each main tier line of each transcript she was assigned, together with several lines of context; the entire transcript was also available for viewing by clicking a link on the coding page. For each line, she indicated (a) whether the speaker was a parent, target child, or other; (b) whether the addressee was a parent, target child, or other; (c) the syntactic frames of up to 3 clauses in the utterance; (d) for each syntactic frame, up to 3 subjects, auxiliaries, verbs, direct objects, indirect objects and obliques. Nouns appearing in prepositional phrases were coded as obliques (with the exception of recipients indicated with "to", which were coded as indirect objects). Object complements were indicated by coding the direct object of the matrix verb as "<clause>" and coding the constituents of the complement clause as the next clause associated with the utterance. This was intended both to simplify the coding scheme and to avoid attributing too much grammatical knowledge to the child—we do not assume that the child can convert an utterance into an accurate parse tree, only that she can identify verbs and the nouns that surround them.

The syntactic frames were: no verb, question, passive, copula, intransitive, transitive and ditransitive. The *no verb* frame included clauses—such as "Yes" or "OK"—with no main verb. The *question* frame included any clause using a question word—such as "Where did you go?"—or having inverted word order—such as "Did you go to the bank?"—but not merely a question mark—such as "You went to the bank?" The *passive* frame included clauses in the passive voice, such as "John was hit by the ball." The *copula* frame included clauses with a copula (including *be*, *seem* and *become*) as the main verb, such as "John is angry." The *intransitive* frame included clauses with no direct object, such as "John ran." The *transitive* frame included clauses with a direct object (or an object complement) but no indirect object, such as "John hit the ball." The *ditransitive* frame included clauses with an indirect object, such as "John gave Mary a kiss."

In total, 59,977 utterances were coded from 123 transcripts. *All* of the coders coded 7 of those transcripts for the purpose of measuring reliability. Average inter-coder reliability (measured for each coder as the percentage of items coded exactly the same way they were coded by another coder) was 86.1%.[2]

We only considered parental child-directed speech (PCDS), defined as utterances where the speaker was a parent and the addressee was a target child. A total of 24,286 PCDS utterances were coded, for a total of 28,733 clauses. More than a quarter (28.36%) of the PCDS clauses contained no verb at all; these were excluded from further analysis. Clauses that were questions (16.86%), passives (0.02%), and copulas (11.86%) were also excluded from further analysis. The analysis was conducted using only clauses that were intransitives (17.24% of total PCDS clauses), transitives (24.36%) or ditransitives (1.48%), a total of 12,377 clauses.

We formed 2 matrices from these clauses: a verbs-by-subjects matrix and a verbs-by-objects matrix. The verbs-by-subjects matrix contained only verbs used with an overt subject; its size was 621 verbs by 317 nouns (subjects). The verbs-by-objects matrix contained only verbs used with a direct object; its size was 524 verbs by 907 nouns (objects). Each cell of each matrix contained the proportion of times that verb was used with that noun (as subject or object) in a coded clause.

For the purposes of exploratory data analysis, we then performed 4 cluster analyses. First, we took the 50 nouns most commonly used as objects and clustered them according to their proximity in verb space, i.e., the space formed by considering each verb as a dimension. Each noun was placed along each dimension according to the proportion of times it was used with the corresponding verb. Hence, a noun never used as the object of a particular verb would be at 0, and a noun always used as the object of a particular verb would be at 1. Second, we clustered the 50 most common subject-nouns in verb space. Third, we took the 50 verbs most commonly used with objects and clustered them according to their proximity in noun space (defined analogously to verb space). Finally, we clustered the 50 most common verbs-with-subjects in noun space.

Results

We cannot show the cluster diagrams here due to space limits. We summarize the main regularities observed.

The observed distribution of nouns in the corpus is consistent with Zipf's law — the numerical frequency of words decays roughly as an inverse power of their rank frequency. Moreover, the most frequent subjects and objects in the corpus are pronouns, as shown in Figures 1 and 2.

Our quantitative analysis of co-occurrence relationships is based on the log likelihood ratio as described by Dunning (1993) and recommended by Manning & Schutze (1999). Suppose we have observed N clauses with m subject-(or object-) types and n verb-types. Let

$$S = s_1, s_2, \cdots, s_m \text{ and } V = v_1, v_2, \cdots v_n$$

represent the subjects and the verbs respectively. Furthermore, let

$$K_S = k_{s_1}, k_{s_2}, \cdots, k_{s_m} \text{ and } K_V = k_{v_1}, k_{v_2}, \cdots, k_{v_n}$$

represent the observed frequencies of the subjects and verbs respectively and

$$K_{SV} = k_{s_1 v_1}, k_{s_1 v_2}, \cdots, k_{s_1 v_n}, k_{s_2 v_1}, \cdots, k_{s_m v_n}$$

[2] Cohen's kappa coefficient (Cohen, 1960), which adjusts for chance agreement, is only applicable for two raters. We know of no chance-corrected multiple rater agreement measures that are widely used in the language acquisition literature. However, given the number of variables, the number of levels of each variable (3 speakers, 3 addressees, 7 frames, and 6 syntactic relations), and the number of coders (5) in the present study, the probability of chance agreement is low.

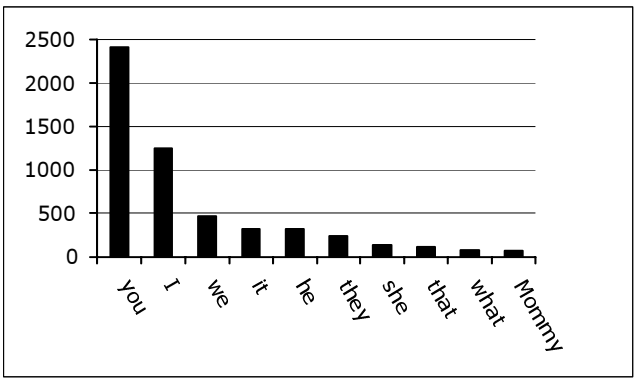

Figure 1: The 10 most frequent subjects in PCDS by their number of occurrences.

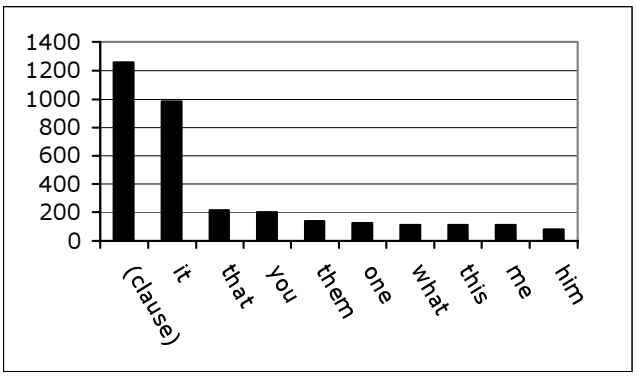

Figure 2: The 10 most frequent objects in PCDS by their number of occurrences.

represent the observed frequencies of subject-verb co-occurrences. Then the test statistic is the quantity:

$$-2\log\lambda = 2[\log L(p_1, k_{s_i v_j}, k_{v_j}) + \log L(p_2, k_{s_i} - k_{s_i v_j}, N - k_{v_j}) - \log L(p_0, k_{s_i v_j}, k_{v_j}) - \log L(p_0, k_{s_i} - k_{s_i v_j}, N - k_{v_j})]$$

Where the components are defined as follows:

$$L(p,k,n) = p^k(1-p)^{n-k} = k\log p + (n-k)\log(1-p)$$

$$p_0 = p(s_i) = \frac{k_{s_i}}{N}$$

$$p_1 = p(s_i \mid v_j) = \frac{k_{s_i v_j}}{k_{v_j}}$$

$$p_2 = p(s_i \mid \neg v_j) = \frac{k_{s_i} - k_{s_i v_j}}{N - k_{v_j}}$$

The test statistic -2logλ is χ^2 distributed with 1 degree of freedom. Intuitively, it represents how much more likely it is that s_i and v_j go together than should be expected purely by chance. It has also been demonstrated that this statistic identifies natural collocations in text corpora.

As expected, the inanimate pronoun "it" was more likely as the object of verbs of physical motion than as the object of psychological attitude verbs, whereas complement clauses were more likely to occur with psychological attitude verbs than with verbs of physical motion. As shown in Table 1, "it" tended to occur with physical motion verbs far more often than would be predicted by chance, and clauses occurred with most physical motion verbs, if at all, only about as much as would be predicted by chance. The verb "put" is an exception to this general rule, occurring with a clause more often than would be predicted by chance. As shown in Table 2, complement clauses tended to occur with psychological attitude verbs more often than would be predicted by chance, whereas "it" only occurred more often than would be predicted by chance with two of five psychological attitude verbs. The exceptions were *want* (uses such as "Oh, I want it now") and *know* ("No, that's wrong and you know it"). In any case, as shown in Figure 3, it is somewhat more likely that a physical motion verb will occur with "it" than with a complement clause, and substantially more likely that a psychological attitude verb will occur with a complement clause than with "it".

Table 1: The log likelihood ratio for uses of object "it" or a clause with physical motion verbs. * indicates p<0.01; — indicates no co-occurrences.

	"it"	(clause)
put	102.79*	70.70*
turn	72.58*	—
throw	39.55*	6.14
hold	32.17*	—
push	24.87*	3.02

Table 2: The log likelihood ratio for uses of object "it" or a clause with psychological attitude verbs. * indicates p<0.01; — indicates no co-occurrences.

	"it"	(clause)
think	—	399.13*
want	12.00*	283.28*
know	69.53*	134.44*
remember	—	37.22*
mean	0.91	15.81*

Table 3: The log likelihood ratio for uses of subject "I" or "you" with epistemic verbs. * indicates p<0.01; — indicates no co-occurrences.

	"I"	"You"
think	605.01*	24.7*
know	200.05*	108.17*
guess	60.00*	—

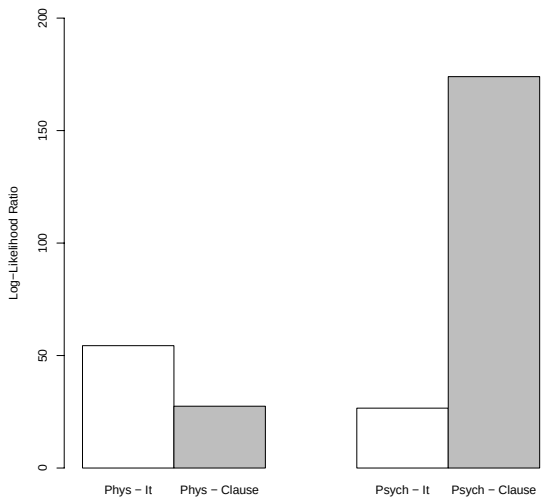

Figure 3: Mean log-likelihood ratio of the object pronoun "it" (white bars) versus a clause (gray bars) given a physical motion verb (left) or a psychological attitude verb (right).

We also found that "I" is more likely to be the subject of epistemic verbs, whereas "you" is more likely to be the subject of deontic verbs. As shown in Table 3, "I" occurred with epistemic verbs far more often than would be predicted by chance. The subject "you" also occurred more often with "think" and "know" than would be predicted by chance, but with a much lower likelihood.

As shown in Table 4, "you" tended to occur with deontic verbs far more often than chance would predict. The subject "I" was no more likely than chance would predict to appear with the verbs "like" and "need" and was only slightly more likely than chance to occur with the verb "want". In any case, as demonstrated in Figure 4, it is substantially more likely that the subject "I" will appear with an epistemic verb than it is that the subject "you" will appear with an epistemic verb. It is also somewhat more likely that "you" will appear with a deontic verb than "I" will appear with a deontic verb.

Table 4: The log likelihood ratio for uses of subject "I" or "you" with deontic verbs. * indicates p<0.01.

	"I"	"You"
want	6.72*	116.97*
like	0.03	74.24*
need	2.69	15.26*

We conclude by noting that there are many other significant co-occurrences in the corpus, some of which involve triadic correlations between specific verbs, specific nouns, and pronouns. For example the objects "book" and "story" are more likely to appear with the verb "read" than would be predicted by chance (LLR=131.51, 128.39). Both the object "book" and the object "this" are likely to appear with the phrasal verb "look at" (LLR=67.28, 88.01). Similarly, not only is "it" likely to appear as the object of "turn" (as discussed above), but so is "page" (LLR=81.89). Likewise for "play," which makes not only the objects "ball", "blocks", "game", and "house" more likely, but also the objects "this" and "it". These are potentially important on several fronts. The child may learn an association between pronouns such as "this" and "it" and inanimate objects, like books and pages. The pronouns "this" and "it" may then be used to help the child understand the meanings of other verbs that take inanimate objects as their objects. Conversely, the verb "tell" selects strongly for the pronouns "us" and "me" as well as for "Mommy" and "Daddy". Hence, the child may learn that verbs taking "us" and "we" as objects have to do with communicating with or directing attention toward other people.

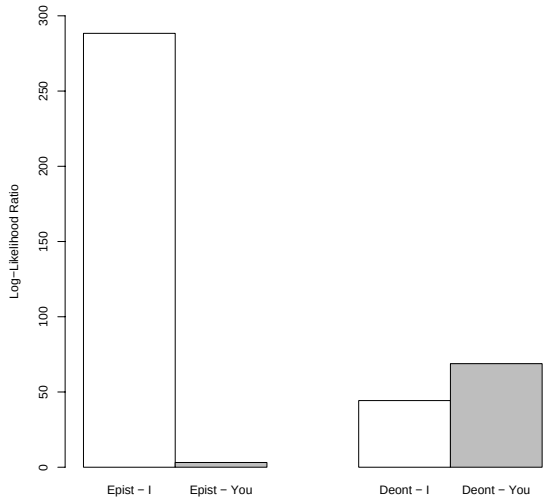

Figure 4: Mean log-likelihood ratio of the subject pronoun "I" (white bars) versus "you" (gray bars) given an epistemic verb (left) or a deontic verb (right).

Discussion

Although pronouns are "light" in their meaning, their referents determinable only from context, they may nonetheless be potent forces on early lexical learning by identifying some kinds of verb meanings as more likely than others. The results of Experiment 1 show that there are statistical regularities in the co-occurrences of pronouns and verbs that the child could use to discriminate verb meanings. Verbs that describe physical motion or transfer are likely to be followed by "it," whereas verbs attributing psychological state are likely to be followed by a relatively complex complement clause. Verbs having to do with thinking or knowing are likely to occur with subject "I," whereas verbs having to do with wanting or needing are likely to occur with subject "you." This regularity most likely reflects the ecology of parents and children—parents "know" and children "want"—but it could nonetheless be useful in distinguishing these two classes of meanings. The results thus far show that there are potentially usable regularities in the statistical relations between pronouns and verbs.

Experiment 2

To demonstrate that the regularities in pronoun-verb co-occurrences in parental speech to children can actually be exploited by a statistical learner, we trained a connectionist network to auto-associate subject-verb-object "sentences" from the input, then tested it on individual verbs and pronouns. We predict that the network should be able to learn the statistical regularities demonstrated in Experiment 1, specifically: (1) physical transfer verbs are likely to have "it" as an object, whereas psychological verbs are likely to take a complement clause, and (2) epistemic verbs are likely to have "I" as a subject, whereas deontic verbs are likely to have "you" as a subject.

Method

Data The network training data consisted of the subject, verb, and object of all coded utterances that contained the 50 most common subjects, verbs and objects. There were 5,835 such utterances. The inputs used a localist coding wherein there was exactly one input unit out of 50 activated for each subject, and likewise for each verb and each object. Absent and omitted arguments were counted among the 50, so, for example, the utterance "John runs" would have 3 units activated even though it only has 2 words—the third unit being the "no object" unit. With 50 units each for subject, verb and object, there were a total of 150 input units to the network. Active input units had a value of 1, and inactive input units had a value of 0.

Network Architecture The network consisted of a two-layer 150-8-150 unit autoassociator with a logistic activation function at the hidden layer and three separate softmax activation functions (one each for the subject, verb and object) at the output layer—see Figure 5. Using the softmax activation function, which ensures that all the outputs in the bank sum to 1, together with the cross-entropy error measure allows us to interpret the network outputs as probabilities (Bishop, 1995). The network was trained by the resilient backpropagation algorithm (Riedmiller & Braun, 1993) to map its inputs back onto its outputs. It is well known that this sort of network performs nonlinear dimensionality reduction at its hidden layers, extracting statistical regularities from the input data.

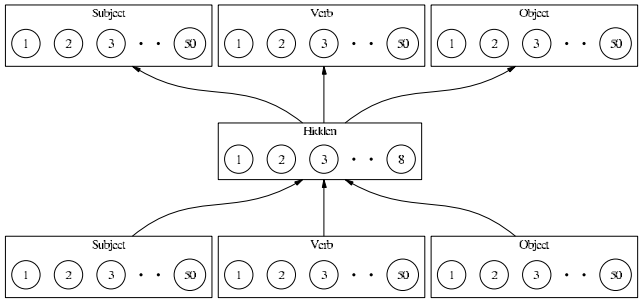

Figure 5: Network architecture

Training The data was randomly assigned to two groups: 90% was used for training the network, while 10% was reserved for validation. Starting from different random initial weights, 10 networks were trained until the cross-entropy on the validation set reached a minimum for each of them. Training stopped after approximately 150 epochs of training, on average. At that point, the networks were achieving about 81% accuracy on correctly identifying subjects, verbs and objects from the training set.

Testing After training, the networks were tested with incomplete inputs corresponding to isolated verbs and pronouns. For example, to see what a network had learned about *it* as a subject, it was tested with a single input unit activated—the one corresponding to *it* as subject. The other inputs were set to 0. Output unit activations were recorded and averaged over all 10 networks.

Results

To test the hypothesis that the network learns that psychological attitude verbs are more likely than physical motion verbs to take a clause as an object, we tested the networks with the frames "I ___ (clause)" and "You ___ (clause)" using psychological and physical verbs. The psychological verbs were "think," "want," "know," and "remember." The verb "mean" was not among the top 50 verbs used in the corpus and therefore was not used in the network training experiments. The physical verbs were "put," "turn," "throw" and "hold." The verb "push" was not among the top 50 verbs used in the corpus and therefore was not used in the network training experiments. As shown in Figure 6, the networks activated the psychological verbs more strongly at the output ($\underline{M}$ = 0.047, $\underline{SD}$ = 0.152) than the physical verbs ($\underline{M}$ = 0.002, $\underline{SD}$ = 0.014). This difference was significant, $\underline{t}(80) = -2.62$, $\underline{p} = 0.01$. Results are similar for the converse (physical verbs are significantly more activated when the object is "it") and for the epistemic / deontic distinction (epistemic verbs are significantly more activated when the subject is "I," whereas deontic verbs are significantly more activated when the subject is "you").

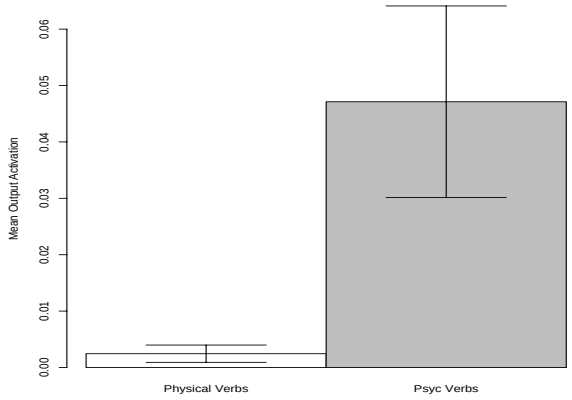

Figure 6: Network output activations for physical verbs versus psychological attitude verbs for the frames "I___(clause)" and "You____(clause)".

Conclusions

We have shown that there are statistical regularities in co-occurrences between pronouns and verbs in the speech that children hear from their parents, including regularities that distinguish between psychological and non-psychological verbs, as well as between deontic and epistemic psychological verbs. We have also shown that a simple statistical learner can exploit these regularities, not to learn the meanings of verbs per se (the network obviously does not know the meanings of the verbs), but to learn the formal associations between tokens of verbs and pronouns. How might this help the child learn the meanings of verbs? In the first place, hearing the verb framed by pronouns may help the child isolate the relevant event or action from the blooming, buzzing confusion around it; the pronouns can indicate animacy, gender, number and direction of causality. This would allow the child to focus on the relevant things. Second, if we suppose that the child has already learned one verb and its pattern of correlations with pronouns, and then hears another verb being used with the same or a similar pattern of correlations, the child may hypothesize that the meaning of the unknown verb is similar to the meaning of the known verb. For example, a child who understood "want" but not "need" might observe that "you" is usually the subject of both and conclude that "want," like "need," has to do with his desires and not, for example, a physical motion or someone else's state of mind.

Now that we have shown that the regularities exist and are learnable in principle, the next step is to show that children actually pick up on these regularities. We are planning a series of experiments with children from 24-36 months that will involve priming the children with movies showing actions corresponding to nonsense verbs in the context of various pronoun frames ("He zorps it," "It zorps," "They zorp this to her" and so on) and testing whether this influences their interpretations of these verbs, for example by having them select which of a pair of novel movies shows "zorping." This will provide a strong test of the hypothesis that children actually use pronoun distributional statistics to pick up on the meanings of novel verbs.

Future modeling experiments will attempt to capture not only the statistical relationships among verb-pronoun token co-occurrences but also their relationships with shared meanings, by associating words with featural representations of their meanings. We are also working on a mechanism for manipulating the statistical properties of the relevant conditional distributions to be used for generating network inputs in future simulations—the distribution of syntactic frames, the distribution of verbs given a syntactic frame, and the distribution of nouns (including pronouns) in each argument position given a verb. We expect that such a model could be used to test the utility of statistical associations between pronouns with verbs for a theoretical learner—simulations run with varying degrees of correlations could demonstrate not only whether but also just how much correlation is useful in principle.

Finally, work is underway to collect crosslinguistic data from Japanese and Tamil, verb-heavy languages with frequent argument dropping and case-marked pronouns referring to various levels of social status. We are especially keen to find out what sorts of cues children might be using in languages where pronouns are both rarer and "heavier" than they are in English.

Acknowledgments

This research was supported by NIMH grant number ROI MH 60200. Thanks to our coders for their hard work, to members of the Cognitive Development Laboratory at IU for useful discussions, and to three anonymous reviewers for thoughtful comments on an earlier draft.
