The *FTP* initiative is coordinated by a full-time outreach coordinator. A group of 12 paid community professionals (eight educators, three librarians, and the outreach coordinator) receive forty-five hours of training, and conduct mock workshops before beginning to facilitate parent workshops in their schools and libraries. Facilitators receive continuing education on a monthly basis, and have committed to a tenure of at least 18 months. *StL* is currently looking for ways to fund and support the program beyond this 18 month timeframe.

Activity, Artifacts, Dissemination & Education

In addition to setting up a content framework, we need also to construct an epistemological and methodological framework for the analysis. We do so in a hierarchical fashion.

At the highest level, we have chosen to adopt an activity theory perspective. In activity theory, the unit of analysis is continually developing activities—events, transactions, practices—and the analysis is organized around objects that motivate, guide, and give meaning to activity. Objects have both physical and semiotic properties, and affect human interactions with their environment, as tools for physical and mental activity. Because of activity theory's emphasis on social factors and the interaction between agents and objects, it is useful for capturing the process of scientific dissemination, the practices of which depend heavily on tools and networks of social interaction.

In identifying objects that organize events and transactions of importance, we use Latour's concept of artifact (Latour, 1987). It is a fairly broad conceptualization of artifact, in which artifacts are physical entities that have been given meaning by human beings through utilization and construction.

Using this artifact-oriented approach to examine the dissemination of scientific information, specifically in the context of educational dissemination, and compare our findings to the existing research in other areas of scientific dissemination. Based on this analysis, we find that the scientific content is altered by organizational goals, available materials, etc; that it is important to distinguish explicit, tacit, and incidental features of artifacts; and that the distinction between the "scientific content" of the artifact and elements added during these alterations is often not identified by facilitators and parents.

Method

In this study, we take the perspective that the *FTP* can be conceived of as an activity system with the primary purpose of knowledge management and community dissemination. Drawing upon concepts from activity theory, social networks theory, and distributed cognition, we describe and analyze the development and consequences of stakeholders' understandings, goals, values, artifacts, actions, and organizational dynamics. We collected data over the full 18 month existence of the program, using observation, video recordings, field notes, focus groups and stimulated recall interviews, artifact collection, and surveys.

Extended observation and videography was conducted throughout the life of the program; all training sessions and most of the parent workshops were observed and/or recorded, and most of the ongoing monthly meetings have

been observed. In addition, several meetings of the grant oversight committee, the Mayor's Literacy Task Force, have been attended by at least one of the authors. Field notes provide in depth descriptions of activities, settings, and interpersonal dynamics, were the only means of establishing a record of events where we were not granted permission for videography, or when it was not appropriate to record a particular event.

Focus groups with the facilitators took the form of discussions that allowed us to collect information about their perspective, and the meaning they attached to particular artifacts and events. Video-elicited and artifact-elicited interviews are used to obtain an in-depth perspective of the local meanings teacher create in relation to key perceptions, goals, experiences, actions, and elements of this program.

Artifact collection and documentation refers to the process of gathering/recording objects and conceptual symbols. Artifacts are objects that have both material and conceptual characteristics and that have been transformed through the history of this program. This category includes curriculum binders, slides, handouts, props, toys, logos, memos, announcements, electronic newsletters, websites, acronyms, jargon, and definitions.

Content area questionnaires are used to assess teachers' knowledge of infant brain development before training began, and at intervals after training. These assessments include fact-based, open-ended, and problem-solving items. A separate motivation survey was designed to address affect and efficacy in relation to distinct aspects of participation; training, instruction, curriculum materials, trainers, and programmatic characteristics.

Results & Discussion

The *First Teacher Project* is best described as an activity system configured into a dynamic network of information management. This network relies upon the interconnection of different levels of cognitive mediation (e.g., object, social, organizational). Our analysis is primarily based on the study of how these mediations become embodied into the conceptual to material continuum of artifacts. We use Collins et al (2002) hierarchy of mediating artifacts to categorize *what, how, why,* and *where-to* artifacts. The *what category* refers to artifacts that serve as a means to achieving an object (e.g., using chart paper to write down parent questions). *How* artifacts contribute to understanding how to achieve purposes or goals (e.g., using a case study to demonstrate how routines help babies). *Why* artifacts motivates achievement of the goal (e.g., presenting statistics of neglect and abuse linked to academic achievement to encourage parent-child bonding). *Where-to* artifacts motivate the evolution of all activity elements (e.g., identifying a pocket population that was not targeted and re-defining main project goals).

Artifact analysis is primarily an in depth description of the history and meaning of tools and signs that evidence intentionality and activity of agents within this network of information management. Artifact analysis is a process of analytic induction that focuses on how artifacts evidence actions that occur in specific settings and in connection to specific meanings. We use Erickson's (1990) five methods of evidentiary inadequacy to determine the degree to which we have a) adequate amounts of evidence, b) adequate variety of evidence, c) trustworthy evidence, d) adequate disconfirming evidence, and e) adequate discrepant case analysis.

An example of an artifact is the brochure community professionals put together to attract participants to the parent workshop. At one point, this brochure may represent everything target parents know about the project. However, parents are unaware of the history of this artifact, how the printed language reflects interpretations of science, how explicit goals of the workshop relate to assumptions about needs in this community, or how this workshop expects to influence parenting. The brochure is a byproduct that reflects negotiated goals, program priorities, perceptions of the target population, and a way to sum up the essential components of a newly developed expertise. The final draft of the brochure is edited by the project coordinator after asking community professionals to develop drafts, after discussing these drafts during taskforce meetings, and after receiving approval from all stakeholders. In this way, the development of a simple communication product is informative of the way this project is represented to the larger target population, the role of distributed cognition and distributed practice, and the protocols and the organizational structure necessary to develop this double-sided page. And the workshop brochure is just the entry point to the vast world of artifacts that are part of this BBE curriculum. As the parent arrives to the actual workshop he/she will be exposed to graphs, binders, slides, toys, props, sounds, video-clips, case studies, analogies, metaphors, acronyms, jargon, and abstract ideas.

It is important, too, to recognize that artifacts are not necessarily bounded physically, but by the role they play in a network of activity. We address this in our analysis by examining agent-artifact units, i.e. units comprised of an artifact and the agent who is currently making use of the artifact. Thus, a brochure handed to a parent by their child's teacher is a different agent-artifact unit than a brochure taken from a stand at the door of a library.

Content transformations

The main goal of the *FTP* is to translate neuroscience into recommended practices that will improve parenting and normal child development outcomes. Research techniques and directions, however, often do not directly support this goal. Much of the neuroscientific research available, however, has been conducted using deficit models, and highly constrained tasks and environments. Therefore, application to normal developmental practices is rarely an explicit element of the scientific report. Thus, when a report in a journal is read by a curriculum developer, the developer-report unit is a different entity than the scientist-report unit, and the report is used for different purpose (developing parenting recommendations vs. informing peers of experimental results), establishes credibility in different ways (appearance in a prestigious journal vs. surviving the actual peer-review), and becomes a symbol for establishing

authority rather than a document containing information to be examined.

The effects of this transformation are several. One way in which this is done is through broad generalizations into maxims that would be difficult to find objectionable. Statements that encourage parents to provide a stimulating but not overwhelming environment, to not neglect their children emotionally or physically, to create a loving and protective environment. The training providers believe that by taking these unobjectionable messages and pairing them with laboratory research that is tenuously connected, they will make these messages more persuasive by making them more authoritative and making them appear to be based in "science."

Another approach is to take deficit model findings and transform them into "best practice" recommendations. The logic, roughly, is that if the absence of certain elements has a deleterious effect, then parents should be encouraged to make sure these elements are present. While this is not always faulty logic, it can at times produce the implication that since less is bad, more is better, and that greater amounts of play, visual stimulation, exposure to human faces, and so on, will have a beneficial effect beyond that which normal caregiving would provide. Research studies based on abnormal case studies produce dramatic research findings on how neurological disorders, neglect and abuse can adversely affect brain development. However, this program is not designed to target parents of children with major disabilities, but to target the general population. In this way, research findings from deficit models are discussed outside of their context, and derived applications may involve unwarranted alterations of the science content. For example, facilitators are taught that physiological and psychological traumatic events can chronically elevate an individual's cortisol levels, which in turn may result in the destruction of neurons or a reduction of synaptic connections. Children who have high levels of cortisol in response to trauma have been shown to experience more developmental delays (Gunnar, 1996). A key artifact here is a video-clip interview of neuroscientist who explains how cortisol levels show how the brain responds to stress levels. In the context of a parent workshop or facilitator training, this functions not so much as a way to deliver information but to prove the curriculum's scientific backing. That sustained high levels of cortisol can cause delays does not imply either that transient elevation from minor stresses will cause problems, nor does it imply that extremely low stress will facilitate development. With community facilitators there is a tendency to blur two distinctions: the difference between stress and trauma, and the distinction between temporary and permanent changes in cortisol levels.

The content may also be transformed because of the physical constraints imposed as artifacts are paired with new agents. An example is the inclusion of infant massage experiments in the curriculum. A meta-analysis conducted by the Cochrane Review found the evidence to be weak, though in the direction of supporting the use of massage with infants receiving neo-natal intensive care (Vickers, Ohlsson, Lacy, & Horsley, 2004). Findings regarding its use in other areas appear likewise ambiguous.

Those experiments supporting infant massage as beneficial are incorporated into popular books (e.g., Field, 2000) by clinicians and researchers that wish to make their case with the public. These are then taken by curriculum developers and integrated with specific *how-to* activities and instructions that guide parents into giving leg, foot, arm and hand, face and head massages to infants. *How-to* activities often have not been equally researched, though this distinction is not made in the materials given to facilitators during training. A focal artifact here is a written description created by the curriculum developers where they describe that, ideally, parents are to take into consideration the age of the child to determine the type, duration and frequency of massaging a baby: A massage for a newborn baby should be limited to 3-5 minutes, while a month old baby can receive a 10 minute massage. In addition, it is said that parents should be attentive to determine individual differences in responding and tolerating touch. When the community professionals attended their training, these written instructions are verbally described by the trainers who also modeled concepts by using realistic baby dolls. Participants practice the massage on these dolls, which then become part of their representation of infant massage.

However, the specifics of the infant massage curriculum are not covered in the same fashion by facilitators as they bring this information to parents. The infant massage demonstration and hands-on activity is time-consuming, so the facilitators do not have the same opportunity to emphasize this topic as do the developers. Moreover, they have only one doll, making even demonstrating to a group somewhat difficult. The facilitators rely on slides showing bullet points that summarize the main ideas on how touch enhances bonding. Moreover, we observed that discussions often wandered onto interesting but misleading tangents, such as formal training in infant massage therapy. The superficial overview in the context of such a discussion is misinterpreted by some parents as a need to seek a special training. There is not a deliberate plan to distort information, but the way information is presented has an unexpected effect.

Artifacts & Expectations

During the initial intensive period of training, *NDI* structured the content of its curriculum around two acronyms *STEPS* for security, touch, eyes, play, and sound and *ABC*'s of learning for attention, bonding, and communication. These acronyms were developed as a way to organize the curriculum, and resulted from feedback of prior *FTP* programs that had been implemented in different communities. Those prior programs received a similar training with very little organizing structure, and limited curriculum materials. *FTP* trainees received a binder with five major divisions that corresponded to the *STEPS* acronym, their training was structured around these topics, and each of the *STEPS* concepts was discussed as relating to the *ABC*'s. In addition, *NDI* developed a wide array of materials that included slides, power-point presentations, video-clips and activity sets called the brain boxes. In turn, the facilitators structured their first parent workshop series as five meetings, each of which reflected the *STEPS*

structure. The different sites reported that five workshops proved to have a high turnover, and *StL* decided along with *NDI* to structure the curriculum around 3 meetings. Then, the curriculum started to be reorganized around the *ABC*'s as the guiding acronym, with the *STEPS* concepts subsumed. These acronyms are artifacts that reflect which concepts are central to *NDI*, how those concepts help organize activity, and the affordances those acronyms have. These acronyms are just one way of organizing knowledge that links neuroscience with parenting and child development, and they in fact seem to be useful in organizing workshops and discussions. Our preliminary findings suggest that these acronyms act as a paradigm through which experts, trainees, and parents think about and recall infant brain development information. For example, during a focus group activity we asked facilitators to write down which are the most compelling ideas they take from this training, and most participants referred to the acronyms. Other ways in which this acronyms influence information management and distributed cognition is that they implicitly convey the idea that these categories are all encompassing, and that scientific information is stable. We discuss these ideas further in the next section.

Artifacts may set up expectations because of their appearance or immediately perceived function. If they are improperly designed, or if the design is misinterpreted, problems can occur. To illustrate this point we refer to the script NDI puts together for facilitators to guide their presentation as they conduct the parent workshops. The script is text that corresponds to a particular slide and elaborates the main ideas represented. The parent workshop is usually structured around a series of slides, and the series of slides are connected through an overarching curriculum concept (e.g., security, eyes, touch). Most facilitators plan their parent workshops by reviewing this script, and they often refer back to the script as they conduct their presentations. This way of implementing the workshop is efficient in conveying many concepts to the parents who are part of the audience, and it also creates consistency and a good point of reference across facilitators. On the other side, the script winds up dictating most of what is said during the parent workshop. The script sets the tone for the presentation of information slide after slide, with facilitators either rephrasing or reading off the script. As a result, it is not infrequent to observe that the workshop is run as a forty-slides presentation with very few questions asked. Therefore, the script drives the workshop, leaving a small amount of time for unscripted events, which is taken up making introductions, allowing for breaks, doing take-home activities, and checking out materials.

Furthermore, the script and slides seem to endorse the perception that these curriculum materials are a self-contained representations of brain-research; sufficient to achieve the main goals of the workshop. Facilitators do not feel the need to continue exploring the science beyond this point. During continuous support meetings, NDI has emphasized the importance of speaking more explicitly about the specific brain research facts and language. Facilitators try to adjust by using the language that is part of the script, but do not go beyond this information.

As facilitators become more experienced in conducting the parent workshop, however, they take greater ownership of the content. They rely less on the script and make use of personal examples that have been effective in the past. Still, when parents ask questions that relate to more specific details of the research, facilitators have difficulty addressing those questions. A parent asked how scientists know that children see blurry at first and they see faces very clearly around three months. Even though an explanation of techniques used to determine babies' responses is provided for facilitators, they only seem reliably aware of the information presented through the script. They have a very hard time addressing those issues if they feel the question must have a right answer that is lying somewhere in a library. Facilitators are often more successful if they can find examples that relate to their own personal experiences as caregivers or teachers. They are capable of finding connections that are relevant and that help illustrate the main points, but when questions are asked about the scientific content that cannot be grounded in case from their experience, facilitators quickly face difficulties.

Conclusions

The unique characteristics of community based programs for the dissemination of scientific information include a rapid training turnaround and the opportunities to document how science concepts are transformed through actions, objects, social interaction, and organizational elements.

Community-based programs for the dissemination of science are complex activity systems that manage information in ways that reflect elements such as organizational knowledge, learning, and culture. In this particular case, the *FTP* program based high-level goals by presenting them as truisms that are difficult to challenge (e.g., parents should create a loving environment), while tacit low-level goals go underdetermined (e.g., research based on deficit models is applied to the general population). As a result, neuroscience is translated in ways that bypass issues of ecological validity.

Artifacts with flawed designs, or artifacts that are misinterpreted are likely to create problems that can go unidentified. Scripts that are meant to guide facilitators end up dictating the pace of the parent workshops in ways that limit parents' active participation, and in ways that communicate to facilitators that these materials are a finished-all-inclusive product. Finally, the development of artifacts such as communications (e.g., newsletters, brochures) give insight into how goals are proposed, negotiated, and enacted. This analysis also illustrates how the entire system works as a network that manages information.

Abstract

Previous research has demonstrated that students can learn by tutoring other students. Tutors are thought to learn because they generate instructional explanations and monitor their own understanding while teaching. We analyzed verbal data from tutorial sessions to explore how the *tutees* influence this process. We found that tutors were primarily responsible for introducing topics, but the tutees stimulated more thorough discussions of topics. We also found that tutee questions influenced tutor explanations and metacognition. Tutor responses to "deep" questions were more likely to contain inferences and self-monitoring than responses to "shallow" questions. In sum, tutees had a significant and positive influence on the tutors' learning activities and opportunities.

Introduction

Peer tutoring and cross-age tutoring are popular and cost-efficient educational interventions in which students provide instruction for other students. One reason for the widespread use of these interventions is their effectiveness – with training, students seem quite capable of successfully teaching each other and younger pupils (e.g. Cohen, Kulik, & Kulik, 1982; Greenwood, Carta, & Hall, 1988). Another reason for the popularity of peer and cross-age tutoring programs is the robust finding that the tutors also benefit academically from the teaching experience (e.g. Allen & Feldman, 1973; Annis, 1983; Cloward, 1967; Cohen et al., 1982; Greenwood et al., 1998; Morgan & Toy, 1970; Rekrut, 1992). Based on such findings, some researchers have advocated reciprocal tutoring programs in which the participating students take turns being the tutor and tutee. In general, these programs are educationally effective (e.g. Fantuzzo, King, & Heller, 1992; Fantuzzo et al., 1989; Fuchs et al., 1997; King, Staffieri, & Adelgais, 1998; Palincsar & Brown, 1984).

Why do students learn by tutoring? Some evidence suggests that tutors learn by generating instructional explanations, which facilitates integration and organization of knowledge. For example, Coleman, Brown, & Rivkin (1997) found that when students were told to teach a peer by explaining, they learned better than students told to teach by summarizing and better than students who did not teach. Similarly, Fuchs et al. (1997) showed that training students to give each other conceptually-rich explanations during reciprocal tutoring was more effective than classroom instruction and reciprocal tutoring without such explanations. Additional evidence indicates that tutoring may also encourage students to engage in metacognitive self-monitoring, which helps learners to detect and repair missing knowledge and misconceptions. For example, King et al. (1998) trained reciprocal tutors to give quality explanations and to ask each other questions that stimulated critical thinking and self-monitoring. They found that these explaining and metacognitive activities resulted in better learning than explaining activities alone. Explaining and self-monitoring have also been shown to improve learning in solo studying (e.g. Chi, 2000; Chi, deLeeuw, Chiu, & LaVancher, 1994) and collaborative learning (e.g. Coleman, 1998; Webb, Troper, & Fall, 1995), which further highlights the efficacy of these activities.

In this paper, we explore the hypothesis that tutees influence the learning activities of the tutors in important ways. In other words, tutors might be able to learn by explaining and self-monitoring, but tutees may affect how and whether these activities occur. One way that tutees may guide the tutorial session is by choosing which topics are discussed and in how much detail, thus creating or limiting opportunities to think about the underlying ideas. Another powerful way in which tutees may influence the learning activities of the tutor is through the kinds of questions they ask. As described above, King (e.g. King, 1994; King et al., 1998) has shown that when students construct and ask each other questions based on high-level question stems (i.e. questions prompting for comparisons, justifications, causes-and-effects, evaluations, etc.), they produce better explanations and learn more effectively. Coleman (1998) has demonstrated very similar findings in collaborative learning settings with students using high-level explanation prompts. Research on naturalistic tutoring has shown that tutees do occasionally ask "deep" questions in tutoring sessions, although the majority of questions are "shallow" (Graesser & Person, 1994). These deep questions, although they may be rare, should stimulate deeper responses.

In order to address these hypotheses about the influence of the tutee on tutor learning, we analyzed tutor learning in a non-reciprocal and naturalistic (i.e. little or no training) tutoring context. This design allowed us to be more sensitive to the benefits and processes of tutoring. In reciprocal tutoring, by definition, students learn from both teaching and being taught, and thus it is almost impossible to assess the specific contribution of tutoring activities to learning in these settings. Similarly, it is possible that when tutoring programs are highly structured (i.e. training on when and how to explain, ask and answer questions, etc.), important aspects of spontaneous tutoring behaviors that positively or negatively impact learning may be obscured.

Method

Background

In a larger study, we compared learning by self-explaining to learning by explaining-to-others. Overall, we found that self-explaining was superior to explaining-to-others on measures of both deep and shallow learning. Self-explaining also seemed to more naturally foster productive learning activities. However, the focus of the current analyses is on the learning outcomes and activities associated with providing instruction for other students.

Conditions

The data we analyze here was obtained from two tutoring conditions. In one condition, a student who had read and studied a text about the human eye and retina (the tutor) taught this information to another undergraduate (the tutee) in a face-to-face setting. In a second condition, a student who had read and studied the human visual system test (the tutor) produced a videotaped explanatory lesson that could be later used by a different student to learn the material (an "anticipated" tutee). The face-to-face tutoring condition can be conceptualized as an "instructional dialogue" whereas the videotape condition can be thought of as an "instructional monologue." The participants received no formal training for the tutoring task. The tutors were simply instructed to explain the text information by "going beyond what the text says." Students in the instructional dialogue condition were encouraged to try to answer the tutees' questions.

Participants

Twenty-four college undergraduate students participated in the instructional dialogue (n = 7 tutor/tutee pairs) and instructional monologue conditions (n = 10 tutors) of the original study. In order to ensure that all participants had low prior knowledge about the learning domain (the human eye and retina), students who had taken certain biology, physiology, and neuroscience courses were not eligible to participate. Participants were paid for their time.

Materials

Human Visual System Text All tutors initially read and studied a short text describing the structure and functions of the human eye and retina. The text was divided into topic-based sections, with each topic presented on a separate page. These topics included both familiar, everyday concepts (e.g. the pupil) and unfamiliar, technical ideas (e.g. refractive properties of the vitreous humor), thereby providing ample opportunities to make connections with prior knowledge and explore new ideas. However, the text itself provided few examples or analogies. The text was accompanied by a labeled cross-section diagram of the whole eye and a schematic diagram of the retina. Prior research has shown that the availability of diagrams can support and stimulate effective explaining (Ainsworth & Loizou, 2003).

Learning Assessments Learning outcomes were assessed using two written measures. For the Definition Test, students provided definitions of key terms. For the Question Test, students responded to short-answer questions testing recall, integration, and application of information. The Definition Test can be viewed as a measure of the students' shallow learning, and the Question Test can be considered a measure of deeper learning. Both measures were scored by tabulating the number of correct and relevant ideas produced.

Procedure

The study was divided into two sessions in order to facilitate recruitment and scheduling of participants. In the first session, the tutors read and studied the text for 30 minutes and then completed both learning assessments (tutor pre-test). It should be noted that the tutors studied the text without foreknowledge of their future teaching task. The purpose of this design was to bypass complications due to preparation-to-teach effects (Bargh & Schul, 1980; Renkl, 1995). The tutees also completed both learning assessments in this phase, but did not have the opportunity to read about the visual system (tutee pre-test). In the second session, the tutors either taught an actual tutee or produced a videotaped lesson (30 minutes duration). Afterwards, the tutors and tutees completed the learning assessments again (post-test).

Coding of Tutor Activities

The tutorial sessions of the dialogue and monologue conditions were transcribed and segmented according to changes in the topic of discussion. These segments formed the boundaries of episodes, which were categorized by the type of learning activity that occurred. Several different activities were observed and are briefly described below.

Summary In "basic" summaries, the tutor paraphrased the current contents of the text without elaborating on the text ideas. In "elaborated" summaries, the tutor paraphrased the text, but also provided additional information or inferences not contained in the text. Neither type of summary was significantly correlated with learning outcomes.

Review In "basic" reviews, the tutor reviewed previously discussed information without elaboration. In "elaborated" reviews, the tutor reviewed previously covered material, but also provided new information and inferences. Elaborated reviews were highly metacognitive (i.e. students monitored themselves for understanding and accuracy) and positively correlated with learning outcomes.

Sense-Making In sense-making episodes, the tutor generated inferences and integrated text concepts in order to address a perceived misconception or one's own curiosity. Sense-making episodes were highly metacognitive (i.e. students monitored themselves for understanding and accuracy) and positively correlated with learning outcomes.

Analyses and Results

Tutor and Tutee Learning

Our results indicated that the two tutoring conditions were not equally effective for learning (Table 1). Tutors in the instructional dialogue condition performed better than tutors in the instructional monologue condition on post-test measures of shallow learning (Definition Test) and deeper learning (Question Test), although only the Definition Test difference was statistically significant after controlling for pre-test differences, $F(1,14) = 9.22$, $p = .009$.

In order to establish that the dialogue tutors were effective instructors, we compared the tutors' final scores to their tutee's final scores. For both tests, the tutees performed almost as well as their tutors, suggesting that the tutors were mostly successful in teaching their pupils (Table 1). Neither difference was significant. Although the tutees learned somewhat less than the tutors, it is still quite impressive given that the tutees were exposed to the material only once (the tutoring session) and never read the text.

Table 1: Mean Definition Test and Question Test scores.

Measure	Monologue Tutors	Dialogue Tutors	Dialogue Tutees
Definition Test	21.3	33.0	27.5
Question Test	20.2	28.0	25.4

Spontaneous and Elicited Tutor Activities

These learning outcome differences were paralleled by the extent to which the tutors engaged in episodes of integrative and metacognitive activity (Table 2). Overall, the dialogue tutors produced more elaborated review and sense-making episodes than monologue tutors, $F(1,14) = 5.47$, $p = .035$ and $F(1,15) = 16.22$, $p = .001$, respectively. No other differences were significant.

Table 2: Overall mean frequency of episodes.

Episode Category	Monologue Tutors	Dialogue Tutors
Summary		
Basic	10.5	13.0
Elaborated	4.4	5.4
Review		
Basic	3.1	6.3
Elaborated	0.2	1.7
Sense-making	0.4	3.7

In order to examine this finding more closely, we further distinguished between activities that the tutors self-initiated and activities that were elicited by the tutee. An episode was coded as "tutee-initiated" if the tutee selected the topic or asked a question leading the tutor to engage in some activity. All other episodes were categorized as "tutor-initiated". All of the monologue tutors' activities were counted as tutor-initiated because no tutee was present.

The pattern of episode frequencies (Table 3) suggests that tutors in both conditions preferred to summarize the text, while tutees in the dialogue condition elicited most of the reviewing activities. Direct comparisons of the mean frequencies of tutor and tutee-initiated activities confirmed this impression. Dialogue tutors initiated significantly more basic and elaborated summaries than dialogue tutees; $F(1,12) = 8.2$, $p < .05$ and $F(1,12) = 8.3$, $p < .05$, respectively. However, the tutees initiated significantly more basic and elaborated reviews; $F(1,12) = 7.5$, $p < .05$ and $F(1,12) = 5.3$, $p < .05$, respectively.

Table 3: Mean frequency of tutor-initiated and tutee-initiated episodes.

Episode Category	Monologue Tutor-Initiated	Dialogue Tutor-Initiated	Dialogue Tutee-Initiated
Summary			
Basic	10.5	9.7	3.3
Elaborated	4.4	4.7	0.7
Review			
Basic	3.1	1.3	5.3
Elaborated	0.2	0.2	1.5
Sense-Making	0.4	2.3	1.4

The critical difference between the monologue tutors' activities and the tutor-initiated activities of the dialogue tutors was in the occurrence of sense-making episodes; $F(1,15) = 4.5$, $p < .05$. No other difference was significant. Tutors engaged in sense-making when they realized that they had a flawed or incomplete understanding of some concept and needed to revise their own knowledge. Thus, in addition to eliciting productive reviewing of the material, the tutees seem to also directly and indirectly facilitate the tutors' recognition and repair of their own misconceptions. Perhaps the tutee's misunderstandings and questions served as a signal to the tutor that the tutor's explanations were incorrect or unclear, and this realization spurred the tutor to engage in sense-making in order to understand the material better and to be a more effective teacher.

In sum, these results provide evidence that tutors in non-reciprocal tutoring settings, and with minimal training, can learn from generating instructional explanations and self-monitoring. However, when tutors provided instruction to an actual tutee, they learned and explained more effectively. Thus, it appeared the tutees did in fact contribute to the tutors' learning activities in meaningful ways. In the next sections, we explore two hypothesized mechanisms for this influence, topic selection and tutee questions.

Topic Coverage

One way that tutees may guide the tutorial session is by choosing which topics are covered and how much time is spent on those topics. Topics that receive more thorough consideration should be better learned. To examine the coverage of topics in the tutoring sessions, each episode was coded by whether it contained a novel topic (i.e. topic was

introduced in that episode) or whether it contained a continuation of a previous topic. A continuation episode could contain a review or elaboration of the topic, and thus represents a deeper or more thorough discussion (Table 4).

Overall, we observed a clear pattern in which the tutors were primarily responsible for introducing new topics in the tutoring session (76% of novel episodes were tutor-initiated), whereas tutees stimulated much of the subsequent discussion of topics (61% of continuation episodes were tutee-initiated). This pattern was statistically significant; $\chi^2(1,N=349 \text{ episodes}) = 50.0$, $p < .001$, and indicates that tutees directly influenced opportunities for tutors to delve more deeply into the text information by selecting topics for review or elaboration.

Table 4: Introduction and continuation of topics of discussion by tutors and tutees.

Topic Selector	Novel Topic	Continued Topic
Tutor	134 (76%)	67 (39%)
Tutee	42 (24%)	106 (61%)
Totals	176	173

Tutee Questions and Tutor Responses

Another important mechanism by which tutees might influence the learning activities of the tutor is through asking questions. By asking deeper questions, tutees may stimulate a more enriched discussion and higher quality tutor explanations, which should facilitate learning.

Because the episodes used in previous analyses could contain multiple tutee questions, we re-segmented the dialogue tutoring protocol data using "question-response exchanges" as the unit of analysis. A "question" was defined as an interrogative statement in which the tutee requested information (or verification of information). For the purposes of this paper, we excluded questions that were not directly relevant to the content (i.e. questions about task procedures or off-topic issues were not counted). A "response" was defined as any information or feedback (or lack thereof) provided by the tutor in answer to the question.

Tutee questions were then labeled as either "shallow" or "deep." A deep question was one that either required the tutor to generate an inference or contained a tutee-generated inference that the tutor had to evaluate. A shallow question was one that did not contain or require any information beyond the text contents. Tutor responses to these questions were similarly coded as "shallow" or "deep," depending on whether they contained inferences or novel elaborations of the text. Tutor responses were further classified as being "metacognitive" or "non-metacognitive," based on whether they contained self-monitoring statements (a statement such as "I don't know that" or "This is easy to remember").

Out of a total of 240 content-relevant questions asked across the seven dialogue tutoring pairs, 37% (88 questions) were classified as deep and 63% (152 questions) were shallow. Our results indicated that shallow questions were much more likely to receive a shallow response, but deep questions were equally likely to elicit a deep or shallow response (Table 5). In other words, deep questions were more likely to receive a deep response (41%) than were shallow questions (14%). It was fairly rare for a question to be ignored (receive no response). The overall pattern was significant; $\chi^2(2,N=240 \text{ questions}) = 26.1$, $p<.001$.

Table 5: Tutee questions and subsequent shallow or deep tutor responses.

Question Depth	No Response	Shallow Response	Deep Response	Totals
Shallow	15 (10%)	116 (76%)	21 (14%)	152
Deep	12 (14%)	40 (46%)	36 (41%)	88

Analyses of self-monitoring in tutor responses to tutee questions showed a similar pattern (Table 6). Shallow tutee questions tended to elicit non-metacognitive responses. However, the tutees' deep questions elicited metacognitive responses from the tutors about half the time. This pattern was significant; $\chi^2(1,N=240 \text{ questions}) = 20.8$, $p<.001$.

Table 6: Tutee questions and subsequent metacognitive or non-metacognitive tutor responses.

Question Depth	Metacognitive Response	Non-Metacognitive Response	Totals
Shallow	32 (21%)	120 (79%)	152
Deep	42 (48%)	45 (52%)	88

In order to confirm that tutor responses to deep questions were both deep and metacognitive (rather than one or the other), we cross-tabulated tutors' shallow versus deep and metacognitive versus non-metacognitive responses (Table 7). This analysis generally confirmed that deep, inferential responses were more likely to contain self-monitoring statements. Shallow responses were more likely to be non-metacognitive. This pattern was significant; $\chi^2(1,N=212 \text{ responses}) = 43.3$, $p<.001$.

Table 7: Tutors' deep and metacognitive responses

Response Type	Metacognitive Response	Non-Metacognitive Response	Totals
Shallow	29 (19%)	127 (81%)	156
Deep	37 (66%)	19 (34%)	56

In summary, the nature of the tutees' questions had an substantial impact on the subsequent integrative and metacognitive activities of the tutors. When tutees asked shallow questions, the tutors responses were frequently shallow and non-metacognitive. However, when tutees asked deep questions that contained or required an inference, the tutors were more likely to respond with a deep and metacognitive response.

Examples of Question-Response Exchanges

The following excerpts demonstrate how these processes occurred in a tutorial session. In the first example, a tutor and tutee are discussing the blind spot in the retina. The tutor summarizes background information and the tutee follows up with a deep question that leads the tutor to generate a novel analogy. The text provided only a structural description of the blind spot with no analogies.

Tutor: This is the blind spot [points to diagram]. You can't see anything there because that's where the optic nerve leaves the eye. So there aren't receptors right there. (paraphrase)
Tutee: Okay, wait. The blind spot is where all the nerves are located? (shallow question)
Tutor: Yeah. Like, that's where all of the optic nerves come together. They go all around and that's where they all pull together and go back to the eye. Or back to the brain. So right there, there aren't any receptors. (shallow, text-based response)
Tutee: So how does that affect your vision? (deep question)
Tutor: If something comes in and your lens refracts it to that point then you don't see it. (new inference)
Tutee: Oh, okay.
Tutor: So, it's just like when you're driving and there's that little spot in the mirror where you just won't see the person behind you. It's like that, except for the eyes. (deep response; novel analogy)

In the second example, a tutor and tutee are talking about the relationship between the iris and the pupil. The tutee's deep question causes the tutor to engage in sense-making activity, drawing on her prior knowledge in order to visualize and better understand these eye components. The text only discussed how the iris/pupil regulates the amount of light that can enter the eye, but did not describe how the iris reacts to light.

Tutor: The iris is the colored part of your eye. And it can expand or contract radially or circularly (paraphrase).
Tutee: What's radially? Like outward? (shallow question)
Tutor: Um. It explains that on the next page [skims text]. Yeah. That's outward. And when the radial muscles contract, the pupil gets larger. (shallow, text-based response)
Tutee: Okay. So, pretty much… contract is to make it smaller. So wouldn't the iris get smaller? (deep question)
Tutor: *Oh*. That makes so much sense now. Yeah. Like when your iris gets smaller, your pupil gets bigger. Like when someone's coming out of dark room or they get surprised. Your pupil gets really big and your iris gets really small. (new inference; draws on prior knowledge to visualize)
Tutee: Mm hmm.

Missed Opportunities for the Tutors

It is important to note that the mapping between tutee question quality and tutor response quality was far from perfect. About half of the tutees' deep questions failed to elicit a deep, metacognitive response from the tutor.

There are several potential explanations for this problem. One explanation is that the tutee's deep question contained an obvious inference and the tutor did not feel it was necessary to elaborate. Another explanation is that the tutor evaded the question because he or she did not have the requisite knowledge to answer it. A third reason might be that the tutor did not recognize the depth of the tutee's question. Chi, Siler, & Jeong (in press), have shown that even adult, non-peer, tutors often fail to diagnose a tutee's understanding. In all cases, the tutors miss out on an chance to build on their existing knowledge, fill knowledge gaps, or remediate errors – to learn, in other words.

The following excerpt provides an example of one of these missed opportunities. In this example, a tutor and tutee are discussing light refraction and the role of the cornea and lens in that process. The tutee asks two deep questions about the function of the cornea. Unfortunately, the tutor cuts this potentially productive exchange short rather than attempting to repair his knowledge gap.

Tutor: I'm going to talk about refraction, which is bending of the light. Most of it is done with the cornea [points to diagram]. But there's additional light bending done through the pupil. Or through the lens, I mean. And this is changed by altering the thickness of the lens. (paraphrase)
Tutee: The cornea doesn't change at all? (deep question)
Tutor: The cornea just stays the same. (new inference)
Tutee: Okay. Then how is it responsible for 70% of the focusing power? (deep question)
Tutor: I don't know. It doesn't say. (expresses ignorance and misses opportunity to repair this knowledge gap)

Conclusion

Previous research has established that students benefit academically from teaching other students. These learning outcomes have most often been attributed to the tutors' generation of instructional explanations and metacognitive self-monitoring while teaching. However, these mechanisms have been relatively understudied outside of reciprocal tutoring settings, which confound the benefits and processes of tutoring and being tutored. The analyses presented in this paper provide some converging evidence from a non-reciprocal tutoring setting that students learn by teaching due to explaining and self-monitoring activities. In addition, these behaviors were unstructured, indicating that tutors can learn even without a great deal of support and training (although well-structured interventions probably support more efficient and consistent learning behaviors).

Our findings show that the tutees played a very important role in shaping the learning activities and learning opportunities of the tutors. Although tutors paraphrased the text and introduced many of the topics discussed in the tutoring sessions, tutees stimulated much of the reviewing activity in which topics were covered more thoroughly. Tutees also directly and indirectly facilitated sense-making activities in which the tutors became aware of their own misconceptions and then attempted to repair them. These

elaborated reviewing and sense-making activities were likely guided by the kinds of questions that the tutees asked. Shallow questions tended to receive shallow and non-metacognitive responses from the tutors. However, deep questions asked by the tutees provided an important (if not always consistent) impetus for integrating ideas, generating inferences, and self-monitoring. More research is needed to understand how and why "missed opportunities" occur.

Acknowledgments

Funding for this research was provided by a grant awarded to Rod Roscoe by the University of Pittsburgh, FAS Office of Graduate Studies, and in part by the National Science Foundation, Grant Number NSF (LIS): 9720359, to the Center for Interdisciplinary Research on Constructive Learning Environments (CIRCLE, www.pitt.edu/~circle).

College Park, MD 20742 USA

Abstract

Recent trends in the philosophy of mind and cognitive science can be fruitfully characterized as part of the ongoing attempt to come to grips with the very idea of *homo sapiens*—an intelligent, evolved, biological agent—and its signature contribution is the emergence of a philosophical anthropology which, *contra* Descartes and his thinking thing, instead puts doing at the center of human being. Applying this agency-oriented line of thinking to the problem of representation, this paper introduces the guidance theory, according to which the content and intentionality of representations can be accounted for in terms of the way they provide guidance for action. We offer a brief account of the motivation for the theory, and a formal characterization.

Introduction and Background

Recent trends in the philosophy of mind and cognitive science can be fruitfully characterized as part of the ongoing attempt to come to grips with the very idea of *homo sapiens*—an intelligent, evolved, biological agent—and its signature contribution is the emergence of a philosophical anthropology which, *contra* Descartes and his thinking thing, instead puts doing at the center of human being. Work that falls under this broad umbrella includes accounts of human cognition which stress embodiment and environmental situatedness (Anderson, 2003; *forthcoming*-a; Ballard et al., 1997; Clancey, 1997; Clark, 1995; Varela, Thompson, & Rosch, 1991), pragmatic and evolutionary accounts of human knowledge and culture (Barkow, Cosmides, & Tooby, 1992; Guignon, 1983; Hacking, 1983; Munz, 1993; O'Donovan-Anderson, 1997; Rescher, 1990) and action-oriented accounts of perception (Aloimonos, 1992; Ballard, 1991; Gibson, 1966; Milner & Goodale, 1995; O'Regan & Noë, 2001), to name only a few categories, and a few of the many works in each. The current essay introduces the results of our effort to build a theory of representation on the basis of the same kind of agency-oriented approach. It is *only* an introduction, and many difficult issues will have to be treated briefly, or not at all. The interested reader is encouraged to consult the fuller treatment given in (Rosenberg & Anderson, *forthcoming*).

A representation is something that stands in for, is in some sense *about*, something else. How is one thing ever *about* another? To answer this question is usually to analyze this relation of aboutness—the intentionality of a representation—in terms of some other, presumably more basic relation. For instance, a typical causal theory of representation might hold that a given representation **R** is about **E** just in case it has a certain specified set of causal relations to **E**, for instance, that perceiving an instance of **E** will cause one to represent with **R** (Fodor, 1981; 1987). Likewise an information-content approach might hold that a given representation is about that object from which the information it contains in fact derived (Dretske, 1981; 1986; 1988). Conceptual role theories, on the other hand, try to analyze meaning in terms of the role played by the concept in inferential and other conceptual/cognitive processes: roughly speaking, the representation **R** is about **E** just in case it is used to make warranted inferences about **E** (Harman, 1982; 1987). Naturally, there are also theories that try to combine these two approaches, producing the so-called "two-factor" accounts (Block, 1986; Loar, 1981; Lycan, 1984). There is no need, nor is this the place, to rehearse the standard critiques of these various theories (but see Anderson, *forthcoming*-b). However, by way of situating and introducing our own account of representational content, let us say that we find the various causal approaches too *input focused*, meaning they give too much importance to the ways in which the environment affects the organism to endow its states with representational meaning, and while the conceptual role theories seem to us a step in the right direction in that they draw attention to the importance of cognitive actions taken by the subject with its representations, *none* of the theories outlined above give sufficient weight to the full range of what a subject *does* with its representations.

In contrast, we ask first not what a representation *is*, but what it *does* for the representing agent, and what the agent does with it; what is a representation *for*? Our contention is essentially that representations are what representations do, and that what a representation *does* is provide guidance for action. Whatever the details of its instantiation or structure, whatever its physical, informational, or inferential features (and these are quite various across different representing systems), what makes a given item *representational* is its role in providing guidance to the cognitive agent for taking actions with respect to the represented object. In our view, each of those other special features a given representing token might possess—e.g. co-variance with,

openness to the causal influence of, or resemblance to its object—correspond to one of the range of strategies that our various representation-forming and representation-consuming systems have evolved to solve the biologically fundamental problem of providing autonomous organisms with guidance for action.

On the guidance theory action is fundamentally intentional: it is first and last a directed engagement with the world. Our basic claim is that representations come into existence and derive their content from their role supporting the basic intentionality of action. The fact that subjects take action with respect to things is what confers content on representations; it is how representations reach outside the organism and touch things in the world. The guidance theory presumes, then, that the intentionality of representation can be grounded in the intentionality of action.

A Formal Account of the Guidance Theory

Let us say that a token *provides guidance* to a subject by making its features available to the subject's motor systems and rational control processes for use in making discriminating choices between possible actions or possible ways of executing actions. Below we introduce the foundations of the guidance theory in terms of a set of propositions, which together characterize the most central features of the theory.

(1) An ***entity*** is anything that can be represented: a property, a concrete particular, an aspect of a thing, a state of affairs, a number, etc.

(2) A ***subject*** is any representation-consuming cognitive engine. To be a representation consumer, it must be capable of interacting in the world in a rational, goal directed way due at least partly to guidance it receives from tokens within its cognitive systems.

(3) A ***circumstance*** is a circumstance of the subject. A circumstance consists in the subject's internal states, including the subject's bodily changes, registrations, representations, expectations, priorities, values, options for action, homeostatic self-evaluations, procedural knowledge, motor schemas and also the subject's immediate environment.

(4) A subject ***standardly uses*** tokens (of a type) to provide guidance with respect to an entity **E** in a given (type of) circumstance **C** if, and only if, the subject has an enduring conscious preference or conditioned reflex to use the tokens (i.e., members of the type) to provide guidance with respect to **E** when in circumstance **C**.

(5) An *action* can be a motor process or a cognitive process. This yields two clauses in the definition of action:

> **(5.1)** In the case of a motor process, a motor process is an *action* if, and only if, it is activated under control of perceptual/cognitive feedback processes capable of effectively modulating or bringing about changes in the organism or in the world
>
> **(5.2)** In the case of cognitive processes, a cognitive process is an *action* if, and only if, it is a mental process under intentional control whose results contribute to circumstances (as defined above) used to direct motor processes. A cognitive process is under intentional control if the working of that cognitive process is subject to modification by processes of attention, short-term memory, valuation, assent and dissent, practiced learning, and consciously administered self-criticism and praise.

As mentioned already, the fact that subjects take action with respect to things is what confers content on representations; it is how representations reach outside the organism and touch things in the world. The central importance of the intentionality of action means that it is vital to correctly understand—without regress—what it is for an action to be taken with respect to something.

(6) An action is taken ***with respect to an entity*** **E** if, and only if,

> **(6.1)** The action is a motor program, **E** is the focus of the intended change or efforts at control in the world; or
>
> **(6.2)** The action is a motor program and an assumption of information about **E** is a motivating reason that the given action, rather than some alternative non-**E** involving action, was undertaken; or
>
> **(6.3)** The action is a cognitive process undertaken to discover or confirm facts, to modify values, or to decide between alternative actions, and an assumption of information about **E** is necessary if the process as a whole is to provide guidance for the subject's motor actions.

This definition uses three further terms—*motivating reason*, *focus*, and *assumption of information*—that present the potential for regress and require further discussion.

Motivating Reason

For an account of motivating reason, we hold only that any analysis must be such that it would be applicable to goal-directed behavior of entities that do not have representations at all. For example, it must be of a piece with how we would identify the motivating reasons for why a plant turns toward the sunlight. The plant's behavior is goal-directed behavior even if it is not action in the sense defined above, and the motivating reason for the behavior is to maximize the amount of sunlight available for photosynthesis. Because the plant does not have representations, a correct account of motivating reason cannot appeal to representational content.

We also distinguish motivating reasons from applications of causal force. A child may go to bed early on Christmas Eve to encourage Santa Claus to bring presents, and this may be the child's motivating reason, even though Santa Claus is not capable of applying causal force on the child's mind. A hungry wolf may look for prey and its motivating reason may be a future state of satiety, even if the cause of its behavior is a present internal state. Any account of motivating reasons must allow for motivating reasons that are non-representational facts and entities, even for agents that possess representations.

At its heart, the concept of a motivating reason is deeply tied to concepts of rational interpretation like the one found in Daniel Dennett's description of the intentional stance (Dennett, 1987). We take no position here on the basis of, or constraints on, any specific standards of rational interpretation.

Focus

As it is used above, the idea of an action's focus is intended to express a functionalist concept. When a subject is performing an action it places itself into a potential feedback loop with its environment. Its purpose is to monitor the result of the action and to plan adjustments to its course of action.

(7) The ***focus*** of an action is the ultimate entity being monitored through the feedback channels taken to provide indications of its status.

A subject may monitor the focus directly, or indirectly by monitoring the status of some entity being used as an indicator of facts about the focus. Because indicators are made part of an extended guidance control system, indications about the focus will cause in the subject beliefs, decisions or equivalent states about further appropriate actions or perhaps that action may cease. When the focus is monitored through an indicator the subject may have an indirect causal connection to the focus or even no causal connection at all. An example of an indirect causal connection to a focus would be an engineer monitoring a gauge that is itself monitoring engine pressure. Examples of focii to which there is no causal connection are things like the time of day or a mathematical operation on numbers. To monitor the first we might monitor an indicator like a clock face and to monitor the second we might monitor a progression of numerals manipulated according to established rules. In both of these cases the focus of the action is something that is not present and to which the subject is not even indirectly causally connected, but which can be monitored nevertheless, despite the lack of causal causation, by establishing a connection to something else that can be manipulated to vary systematically with facts about the focus.

Identifying the focus of an action in a given case requires establishing the facts about what the subject is monitoring in its circumstances, and understanding these facts in terms of the subject's motivating reasons.

Assumption of Information

An assumption of information is to be cashed out in terms of facts about the actual operation of the representing system (or subject). Beginning with an example will make the concept easier to grasp. Imagine a computer processing a user's command to print a document. To do this, the computer must determine to which printer it should send its own commands. To guide this action, the computer reads several character strings contained on its hard disk, one identifying the printer and others with other information about the printer. These strings guide it regarding where it should send its print commands and what protocol it should use to communicate with the printer. From the perspective of the guidance theory, here is the key fact: these character strings represent what they do both because of the circumstances in which the computer is reading them and also because of the *assumptions* built into those circumstances. The computer processes the strings *as if* they conveyed information about the printer to which it sends its commands and which communication protocol it should use. There is no regress involved in claiming it makes this assumption, because the assumption itself is not a matter of having representational content. There is no representation inside the computer with the content: *I assume that this string has information about the printer*. Even more strongly, its ability to make an *assumption* of information does not require that the computer actually *possesses* information, nor that it ever did.[1] In the case described, the character string the computer accesses could have been placed on the disk via the output of a random number generator and by coincidence be effective in directing it to the printer. Even were that to be true, the string still would be providing guidance and the computer would still be making an assumption that the string contained information about the correct printer. Therefore, the ability to make an assumption of information does not require an ability to have or obtain information.

Rather, the assumption of information about the printer is a matter of *know-how* that is built into the architecture of the computer: how it accesses representations, in what circumstances it accesses them, how it reads and interprets their structure, what actions it initiates and monitors upon accessing them, how those actions cause it to interact with the world, and so forth. We can provide a candidate analysis of this *know-how*. To do this, we first need to define, for any given token, the class of actions it supports. The class of actions a token **T** supports is relative to the kinds of circumstances **C** where the system is prepared to use the token for guidance. It consists of all the actions the system can initiate or modulate in **C** due to its processing of **T**. Let us label this class of supported actions $\mathbf{A}_{\mathbf{supp}}$.

(8) An action **A** is a member of the class of actions, $\mathbf{A}_{\mathbf{supp}}$, supported by a token **T** used by a subject **S** in circumstances **C** if, and only if, **S** in **C** would use **T** for guidance regarding the initiation or manner of execution of **A**.

We should think of the actions in $\mathbf{A}_{\mathbf{supp}}$ as focus-neutral descriptions of an action in need of association with a focus in particular initiations. So, for example, if in some circumstances a system is prepared to use a token for guidance in running, the action *running* is the focus neutral description. If the specific initiation of this action occurs when the focus of the action is a bear, the focus-neutral action "running" is initiated as the focus-specific action "running away from a bear." Actions obtain a focus in the way discussed above.

Furthermore, since subjects do not initiate actions at random, for each action in $\mathbf{A}_{\mathbf{supp}}$, there will be a (possibly

[1] This, assuming that possessing information depends on causal history and connection, which may not be the case.

very large but) finite set of circumstances capable of triggering the initiation of the action. We can call this set of triggering circumstances $\mathbf{A_{circ}}$. The number of triples $\mathbf{<A \in A_{supp}, C \in A_{circ}, Focus>}$ representing supported actions **A** initiated in circumstances **C** with focus **Focus** provides a class of counterfactual *action scenarios*, $\mathbf{A_{scene}}$, in which the token **T** provides guidance for a subject. These are the action scenarios in which **T** *participates*.

Most actions are complex, both in the sense that they have many different specific features that must be managed (e.g., the trajectory and velocity of a running motion), and in the sense that they almost always require initiating smaller or tangential actions involving entities besides its focus if they are to succeed in affecting their intended change or control (e.g., jumping over the branch on the ground while running from the bear). Because of the complexity of action, subjects needing to execute an action will almost always use representations other than the tokens representing the focus of the action. In fact, activation of these further tokens is necessary to fill out the circumstances in which all the tokens are used.

These other active representations will fall into several categories: conscious representations with foci of their own serving the larger action program; unconscious but potentially conscious representations supporting the interpretation of the circumstances and manner in which the action is executed; and sub-conscious representations that can never be conscious but that provide support for basic perception, adjusting bodily movements, and triggering emotion. We should construe the entities towards which the supporting tokens provide guidance as sub-foci in sub-actions lying under the umbrella of the main action. Therefore, these further tokens, the ones that support the guidance for the main action within a given $\mathbf{A_{scene}}$, have functional roles determined by their potential relationships to their own foci within the circumstances **C** of $\mathbf{A_{scene}}$.

Relative to these action scenarios, the guidance theory supposes that in each $\mathbf{A_{scene}}$ where an active token succeeds in having reference[2] the token can be mapped to an entity through its functional role under the rational constraints associated with assigning motivating reasons to their sub-actions. This supposition is justified because, in providing guidance, a token will make features of itself available to the subject, which the subject can use to differentially control its actions with respect to an entity which is a focus or sub-focus of a given action.

The know-how involved in an assumption of information, then, is a question of the way that the subject's decoders and action mechanisms process and/or respond to representations (i.e., how it accesses representations, in what circumstances it accesses them, how it reads and interprets their structure, what actions it initiates and monitors upon accessing them, how those actions cause it to interact with the world, and so forth) given the subject's capabilities, needs, environment, and cognitive architecture. The general idea is that assumptions of information consist in non-representational facts about how the subject *works*, not in further representational facts about, or representations used by, the subject. Although this account is clearly preliminary, it does at least show how the idea of an assumption of information can be interpreted, and used as part of the machinery involved in determining the content of a representation, without initiating a vicious regress or involving circular appeals to representational content.

This brings us, finally, to the cumulative definition of representation. On the guidance theory, *representation* is simply tracking in the sense defined below:

(9) A token **T** *tracks* an entity **E** for a subject **S** in token circumstances **C** if, and only if, **T** is standardly used to provide guidance to **S** for taking action with respect to **E** in **C**.

(10) A token **T** *represents* an entity **E** for a subject **S** in token circumstances **C** if, and only if, **T** tracks **E** for **S** in **C**.

By linking representation to guidance in this way, the guidance theory distributes responsibility for the existence of representational content across a representational token (the representation) and an interpretative decoding mechanism (the decoder) integrated with a subject's action-determining processes. The effect of distributing responsibility is to introduce new degrees of freedom regarding the exact physical or informational requirements for something to be a representation, as the requirements on the representation will depend on the capabilities of the decoder and the circumstances in which it is used. In general, the demands on each part of the coupled system vary inversely with the demands on the other. A representation that is highly structured and closely coupled with what it represents needs a less sophisticated decoding mechanism, while a very sophisticated (or very rigid and simple) decoding mechanism may embody (or presume) so much implicit domain knowledge that it can get by with very sparse representations.

Representation and Misrepresentation

One of the most important problems that any theory of representation must solve is the problem of normativity: representations are assessable for accuracy, and therefore they can be in error. To be complete, the guidance theory must account for this feature of representations. Because the guidance theory is an action-based theory of representation, the natural thing to do is to base error on the failure of action and the way that a representation's guidance contributes to that failure. The intuitive idea, then, is that a representation is in error if it provided guidance to an action that failed in its intent, and it failed partly or wholly because of the guidance provided by that representation. This intuitive idea can be formalized as follows:

(11) An action *fails in its intent* if, and only if,

(11.1) It is a motor action and the intended change is not achieved or the intended process is not brought under control; or

[2] The concept of error will be defined formally in the next section.

(11.2) It is a cognitive process and it (a) confirms a representation that is in error[3]; or (b) disconfirms a representation that is not in error; or (c) modifies a value in a way that the subject later regrets; or (d) recommends a course of action that fails.

(12) An action **A** fails in its intent *because of **R*** if, and only if, (a) **A** failed; and (b) **A** was taken with respect to an entity **E**; and (c) **R** provided guidance for **A** w.r.t. **E**; and (d) **R** has feature **F**; and (e) **R** with **F** represents that **E** has property **P**; and (f) **A** failed because **E** was not **P**. Note that the term "represents" in clause (e) is to be read in light of the current theory of representation.

(13) A token representation **R** *is in error* for subject **S** and action **A** in token circumstances **C** if, and only if, **A** would fail because of **R** if taken by **S** in **C**.

The representation may be said to be in error for **S** *simpliciter* if and only if the class of actions for which **R** provides guidance in **S**'s circumstances **C** is dominated by actions that would fail because of **R**.

Comparison to Related Work

The guidance theory, broadly speaking, takes both a naturalistic and a functional perspective on representation. It is motivated by the same fundamental insight regarding the epistemic importance of action and interaction as gave rise to the theory of interactive representation (Bickhard, 1993; 1999). However, we offer a significantly different development and formalization of this shared insight. For instance, Bickhard's analysis relies heavily on control theory, cashes out representational content in terms of 'environmental interactive properties', and assumes some version of process ontology. The guidance theory, while compatible with these possibilities, does not require them. Still, the relative advantages of these two analyses remain largely to be determined. While there are many other naturalistic theories of representation on offer, very few adopt the functional perspective in as thoroughgoing a way as we do. For instance, Dretske (1986; 1988) adopts the functional perspective largely as a post-hoc fix to what remains an information-content approach to representation, so as to be better able to account for *mis*information. In contrast, Ruth Millikan does take the functional perspective as the starting point for her theory of representation, and the guidance theory thus bears the most resemblance to hers (Millikan, 1984; 1993). Thus, although the current article is meant only as a concise introduction to the guidance theory, and is not the place for any detailed comparisons with rival theories, it is nevertheless worthwhile to say a few words about Millikan's theory in particular.

The resemblance between the guidance theory and Millikan's own biologically inspired theory is strongest when she writes things like: "Cognitive systems are designed by evolution to make abstract pictures of the organism's environment and to be guided by these pictures in the production of appropriate actions." (Millikan, 1993:11) However, the impression of similarity fades quickly as the details are examined. For while we agree on this very general characterization of cognitive systems, we differ as to the core point: that mental representations must be pictures and, even when they are pictures, we differ as to what makes such "abstract pictures" *representations*.

There are three main components to this very basic disagreement. First, on our view, a given mental token is a representation just in case it is standardly used by a given organism to guide its behavior with respect to the intended object; Millikan, in contrast, suggests that it is only a representation if it is the result of (or consumed by) a properly functioning system, performing the function it was selected to perform: "It is not the facts about how the system *does* operate that make it a representing system and determine what it represents. Rather, it is the facts about what it would be doing if it were operating according to biological norms." (Millikan, 1993:10-11)

Second, and deeply related to the first, Millikan relies heavily on the notion of such a "proper function" to explain the possibility of representational error (a representation is in error when the relevant representation-producing or representation-consuming system is not functioning according to biological norms). In contrast, our theory allows for the possibility that a system serving some function other than that for which it was selected, or mal-functioning in some very lucky way, could, in its use of mental tokens, be *representing* just in case (roughly speaking) the mental tokens in question were being used to (successfully) guide the agent's actions with respect to the indicated objects. Rather than analyze representational error in terms of mal- or non-standardly-functioning systems, we cash it out in terms of failure of action. Although we think representational systems *did* evolve, and attention to their evolutionary history can help us understand how and why they function as they do, we believe a system can sometimes competently perform a function, including representing, for which it was not selected, and in these cases its unusual provenance should be no barrier to recognizing this fact.

Third (and finally), whereas Millikan's view of behavior and action revolves around the function or purpose of the organism or its parts (a movement by the organism is only a behavior of that organism if it can (or perhaps must) be understood in terms of the organism's proper function or biological purposes), our own definition of action includes motor and cognitive processes effected for a broader range of motivating reasons. Although some element of teleology is apparently necessary to ground the idea of a motivating reason for acting, it is not clear to us that this must necessarily be accounted for in terms of natural selection. It could be the teleology of the subject itself, understood as having a subjective purpose like maintaining its homeostatic condition, pursuing hedonic value, or maintaining adherence to a moral, political, or aesthetic principle. A more detailed discussion relating the guidance theory to some alternative theories, including Millikan's, can be found in (Anderson, *forthcoming*-b).

[3] This clause in the definition is an embedded recursion, not a circularity.

Conclusion

The guidance theory is an action-focused theory of representation according to which content is derived from the role a representational vehicle plays in guiding a subject's actions with respect to other things. What qualifies an element of experience as a representation is, strictly speaking, only that the element of experience be capable of providing a subject with guidance for its actions with respect to entities. To be capable of providing guidance an element of experience only needs to have features useful for exploitation by the subject's action-producing mechanisms.

In the full formalization, we show that the guidance theory can account for various problem cases of representational content such as abstract, fictional and non-existent objects (Rosenberg & Anderson, *forthcoming*). Twin-Earth and swampman are discussed in (Anderson, *forthcoming*-b). Future work will consider the evolutionary development of representation in more detail, and the implications of the guidance theory for the correspondence theory of truth, for scientific realism, and for consciousness and phenomenal content (Rosenberg, 2004).

Abstract

In this study, we design a learning environment that supports reflective activities for information seeking on the Web and evaluate its educational effects. The features of this design are: (1) to visualize the learners' search processes as described, based on a cognitive schema, (2) to support two types of reflective activities, such as "reflection-in-action" and "reflection-on-action," and (3) to facilitate reflective activities by comparing their own search processes to other learners' search processes. We have conducted an experiment to investigate the effects of our design. The experimental results confirm that (1) the participants' search performance in the instructional group supported by our instructional design improved effectively than in the control group, (2) they changed their ideas about important activities when seeking information on the Web, and (3) they activated their search cycles more than the control group did.

Introduction

In the field of learning science, many researchers have investigated metacognitive activities that facilitate learners' problem solving and deep understanding (Lin & Lehman, 2001). Metacognition is generally referred to as knowledge and activities to monitor, control, and manipulate individual cognitive processes (Brown et al., 1983). Several studies have shown that experts or good learners practice metacognitive strategies more actively than novices or poor learners (Chi et al., 1989; Ertmer, Newby, and MacDougal, 1996; Leinhardt & Young, 1996). Additionally, based on the findings from these studies, various systems or instructional designs that support learners' metacognitive activities have been developed, and their educational effects have been examined (Aleven & Koedinger, 2002; Hershkowitz & Schwarz, 1999).

Metacognitive activities to monitor and control individual cognitive processes are fostered by various activities connected with cognitive efforts, such as self-explanation, self-regulation, and reflection. We focus on reflective activities within these metacognitive activities. Reflection is defined as a cognitive activity for monitoring, evaluating, and modifying one's thinking and process (Lin, Kinzer, & Secules 1999). In this study, based on the standpoint that metacognitive activities help students learn with greater understanding, we examine effective methods for supporting reflective activities.

Lin et al. (1999) proposed that there are at least two levels of reflection in learning: reflection on a product and its value and reflection on a process by which the product was created. They suggested that supports reflection on a process is more important because the process is less explicit than the product for learners. Moreover, they identified a process display as one of the scaffolds that supports reflection on the processes. A process display shows learners explicitly what they are doing to solve a task or learn a concept. This method allows learners to observe and analyze their own problem-solving processes and evaluate the effectiveness of their learning. For example, Geometry Tutor, which was designed by Anderson, Boyle, & Reiser (1985) to help students learn geometry, displays learners' geometric reasoning processes as a proof graph that consists of tree diagrams of their own solution paths between the "given" and "goal" states of problem-solving. Schauble, Raghavan, & Glaser (1993) also developed the Discovery and Reflection Notation (DARN) system, which shows students a graphical trace notation to support students' reflection on their scientific reasoning with computer-based laboratories. Although many studies have developed systems that provide students with learning processes, the educational effects of reflection on the problem-solving processes are not clear. It is also necessary to examine how we should show learners their problem-solving processes and how learners should reflect on their problem-solving processes. In this study, we design a learning environment that supports learners' reflection on problem-solving processes when seeking information on the Web and evaluate its educational effects.

First, in order to show learners their problem-solving processes, we have developed a feedback system for search processes that provides learners with their own information-seeking processes, which are described based on a cognitive schema. In problem-solving studies, a cognitive schema has been widely used to describe human problem-solving processes. We use such a cognitive schema to visualize learner's problem-solving processes and provide them with learners. We then investigate whether a cognitive schema can be applied as a cognitive tool in learning science. We will explain our system and the cognitive schema in the next chapter. Second, in order to help learners reflect on their problem-solving processes more effectively, we focus on two types of reflective activities that are referred to as "reflection-in-

action" and "reflection-on-action," proposed by Schön (1987). Schön categorized reflection as "reflection-in-action" and "reflection-on-action" from the viewpoint of a context and time. The former refers to monitoring ongoing learning activities, while the latter means revisiting and monitoring critical events in one's own learning experiences after learning activities. Schön suggested that these two types of reflection are imperative factors for learning in any field with the purpose of effective learning transfer. In this study, we investigate an educational design to support these two types of reflective activities.

A Search Process Feedback System

We constructed a feedback system for search processes that supports learners' reflections on their problem-solving processes when seeking information on the Web. This system supports learners' reflection on their own search processes by (1) providing visual support for their search processes, and (2) prompting searchers to reflect on their search processes.

A Search-Process Describing Schema

The system describes learners' information-seeking processes on the Web based on a schema for describing search processes, and allows these processes to be shown in real time. The search-process description schema was proposed to analyze searchers' processes for seeking information on the Web (Saito & Miwa, 2002). This schema was constructed based on the Problem Behavior Graph (PBG), proposed by Newell & Simon (1972), which is well known as one of the most fundamental schema for describing the subjects' problem-solving processes.

Usually, we begin the search with a search engine when we want to find something on the Web. Following that, we consider keywords and search queries to input to a search engine, and browse the results of a search or each Web page. In this schema, a phase in which keywords and search queries are considered is defined as a search in the Keyword space, while a phase in which information on the Web, such as the results of a search and Web pages, is searched is defined as a search in the Web space. Furthermore, the Web space is subdivided into the Result-of-Search space and the Web-Page space. Figure 1 shows a sample description of the search-process description schema.

The searchers' processes are described as transitions of nodes and operators through these three search spaces. A node represents a searcher's behavioral state, and each node's components differ from space to space. In the Keyword space, a node consists of a serial number and search queries, a node in the Result-of-Search space consists of a serial number, search queries, and the number of search results page, and a node in the Web-Page space includes a serial number and the depth of links. An operator shows an operation to the node. The following six operators are defined in this schema:

Search: searching with a search engine

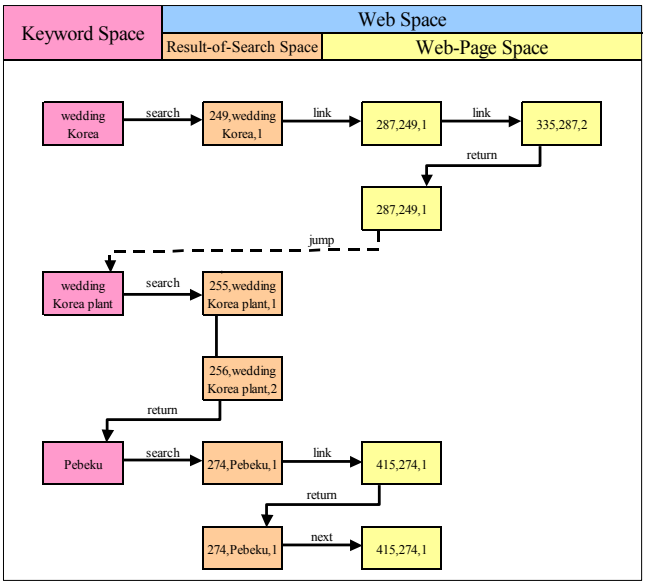

Figure 1: Sample description of the search-process description schema.

Link: going to a page connected with a link

Next: going forward to the next page after having gone backward

Return: going backward to the last page just visited

Jump: revisiting a page

Browse: browsing search results just obtained

Prompting

The system prompts questions to help learners reflect on their own search processes presented by the system. When the system prompts a question, learners are required to answer the question while referring to the learners' own search processes. Table 1 shows each type of question presented by the system. The following three types of questions were used: (a) questions on the Keyword space, (b) on the Result-of-Search space, and (c) on the Web-Page space.

Experiment

We have devised an instructional design that includes the search process feedback system as a core part of the design and two types of reflection. In this section, we conducted an experiment to evaluate how support for reflection affects learners' problem-solving processes and their search performance.

Participants

Thirty-eight university freshmen participated in our experiment as a part of a class. The participants were divided randomly into two groups. One group (the instructional group) was supported based on our instructional design, whereas the other (the control group) was

Table 1: Each type of prompt presented by the system.

Types of Prompts	Questions
Keyword Space	What kinds of keywords did you use, or how did you combine these keywords ?
Result-of-Search Space	How many results of search pages did you browse per search ?
Web-Page Space	How many links did you click on per page ?

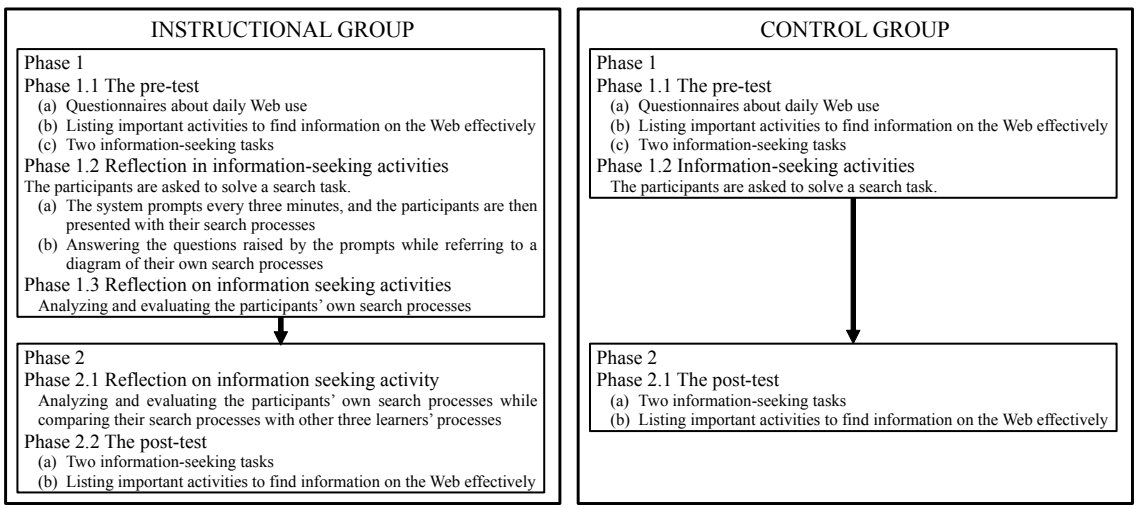

Figure 2: Summary of the experimental procedure.

not supported. The instructional group comprised 19 participants, as did the control group. We examined the participants' experiences of using the Web. The average time consumed per day was 26.5 minutes for the instructional group and 33.3 minutes for the control group. There was no significant difference between the two groups ($t(37) = .879, n.s.$).

The experiment consisted of two phases, which were separated by an interval of at least one day. Figure 2 shows a summary of the experimental procedure. In the following, we explain the experimental procedures.

Pre- and Post-tests

We conducted the pre- and post-tests to confirm whether the participants' search performance and their ideas about information seeking on the Web improve through their reflective activities. Each test consisted of (1) listing at least five important activities to find information on the Web effectively, and (2) solving two information-seeking tasks to measure the participants' search performance. In the information-seeking tasks, the participants were asked to find target information within ten minutes for each task, using a normal Web browser, where none of the participants were provided with their search processes. The tasks were counterbalanced between the participants.

The instructional group

Phase 1.2 Reflection in information-seeking activities In Phase 1.2, the participants in the instructional group experienced "reflection-in-action," wherein the participants reflect on their own search processes while seeking information on the Web. Following the pre-test, we explained to them the experimental task and how to use the system. Next, they were asked to solve a search task using the system. The search task lasted for about 20 minutes, and the participants in the instructional group were shown a prompt every three minutes then presented with their search processes described by the system. They considered the questions raised by the prompts while referring to a diagram of their own search processes, and entered their answers to the answer sheet.

Phase 1.3 Reflection on information-seeking activities In Phase 1.3, the participants in the instructional group experienced "reflection-on-action." After the search task, the participants reflected on their own search activities, analyzing and evaluating their own search processes for twenty minutes as instructed by an experimenter. First, they analyzed their search processes based on the perspective of a search among the three spaces (the Keyword space, the Result-of-Search space, and the Web-Page space) while referring to their own search processes. Second, they considered the advantages and disadvantages of their search processes and how to improve those disadvantages. Following that, they filled in their answer sheets with their ideas.

Phase 2.1 Reflection on information-seeking activities In Phase 2.1, the participants in the instructional group also experienced "reflection-on-action." In contrast to Phase 1.3, the participants reflected on their search activities through comparing their own search

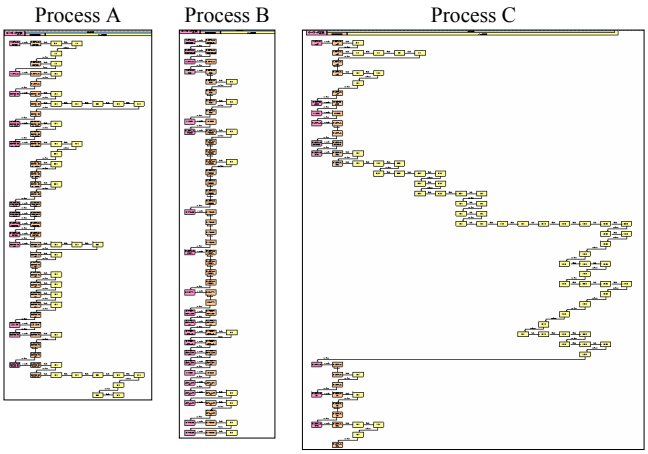

Figure 3: The three processes presented to the participants in the instructional group.

processes with the other three learners' processes that had been selected from the control group by one of the authors.

The presented three processes are shown in Figure 3. Process A is a process by a participant who found a correct answer. One feature of this process is that the balance of searching each space is relatively well coordinated (balanced search). Process B and Process C are processes of participants who could not find a correct answer. In contrast to Process A, these processes tend to cling to a search of one or two of the three spaces. The participant followings Process B hardly searched the Web-Page space at all. He or she repeatedly shuttled between searching in the Keyword space and the Result-of-Search space (breadth-first search).

The participant followings Process C searched the Web-Page space in great detail (depth-first search). The instructional group was provided with these three processes plus information on whether each participant found the correct answer. Then, they analyzed and evaluated their own search activities while comparing their own search processes to the three typical processes, just as in Phase 1.3.

The control group

The participants in the control group engaged in the pre- and post-tests and the search task in Phase 1.2. In Phase 1.2, the participants in the control group solved the search task without receiving the prompts and the presentation of their own search processes.

Effectiveness of the instructional design

In this section, we evaluate the effects of our instructional design based on the experimental results. We compare changes from the pre- to post-tests in the instructional group with those in the control group based on the following three points: (1) the participants' search performance, (2) their ideas about important activities in information-seeking on the Web, and (3) their search processes.

Three out of thirty-eight participants were eliminated because one did not understand the experimental instruction and the others did not participate in Phase 2. Therefore, we analyzed the results of the 35 participants: 17 participants from the instructional group and 18 participants from the control group.

Search Performance

The scores of the search tasks in the pre- and post-tests were estimated to determine whether the participants could locate Web pages containing the target information. The participants' performances in the pre- and post-tests are shown in Table 2. Each score (0, 1, and 2) shows the number of tasks in which the participants could find a correct answer, and each frequency in each cell of this table show the number of the participants getting each score. We compared the number of participants who increased their scores from the pre-test to post-test with the number of participants who did not.

From the result of the chi-square test, Groups (the instructional/control groups) × Performances (improving/not improving), we found that the number of participants who improved their search performance from the pre- to post-tests significantly differed for the two groups ($\chi^2(1) = 4.13, p < .05$). This result indicates that the participants, who engaged in reflective activities supported by our instructional design, improved their search performance more effectively.

Table 2: Participants' performances in pre- and post-tests.

(a) Instructional group

		Post Test			
		0	1	2	Sum
Pre Test	0	9	7	0	16
	1	1	0	0	1
	2	0	0	0	0
	Sum	10	7	0	17

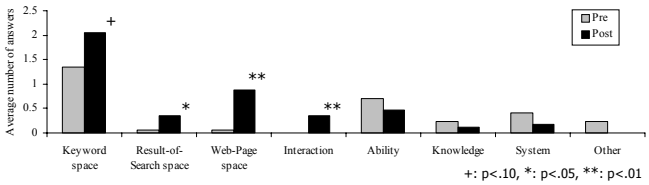
(b) Control group

		Post Test			
		0	1	2	Sum
Pre Test	0	11	1	0	12
	1	2	2	0	4
	2	0	0	0	0
	Sum	13	3	0	16

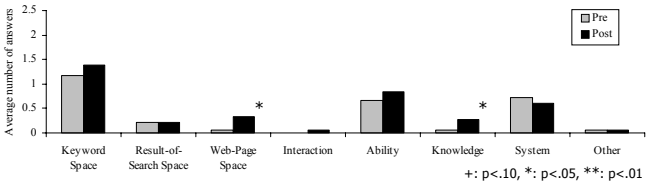
Important activities in information seeking on the Web

In the pre- and post-tests, the participants were asked to propose five activities that they considered important in information-seeking on the Web. The participants' answers in each test were categorized into the following eight types.

Keyword space: activities with search in the Keyword space



(a) Instructional group



(b) Control group

Figure 4: Average number of answers in each category in the pre- and post-tests.

Results-of-Search space: activities with search in the Results-of-Search space

Web-Page space: activities with search in the Web-Page space

Interaction: activities with transitions among multiple spaces

Ability: necessities of abilities and attitudes

Knowledge: knowledge required in information seeking on the Web

System: functions of a search system, such as a search engine

Figure 4 shows the average number of items in each category in the pre- and post-tests. In the instructional group, paired t-tests indicated significant differences in the increase of the number of items in "Results-of-Search space" ($t(16) = 2.582, p < .05$), "Web-Page space" ($t(16) = 3.846, p < .01$), "Interaction" among spaces ($t(16) = 2.954, p < .01$) and a slight difference in the increase of the number of items in "Keyword space"($t(16) = 2.073, p < .10$).

The items above were related to the search processes on which the participants reflected. On the other hand, in the control group, paired t-tests indicated significant differences in the increase of the number of items in "Web-Page space" ($t(17) = 2.557, p < .05$) and "Knowledge" ($t(17) = 2.204, p < .05$). These results indicate that the participants who reflected on their search processes in the instructional group acquired different notions as important concepts for the Web search than those in the control group; in particular, they realized their own search activities more profoundly.

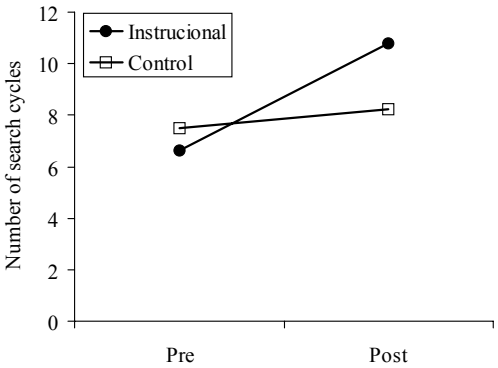


Figure 5: Average number of search cycles in the pre- and post-tests.

Search processes

Finally, we discuss whether the participants' processes improved with our instructional design by comparing the pre- and post-tests in each group. In this study, we consider learners' information seeking processes as a cycle of search in the Keyword space and the Web space. This approach, where problem solving is considered to be a search for multiple spaces, has been widely approved in the studies on scientific discovery and creative processes. These studies have suggested that target activities are developed while repeating the cycle of searching multiple spaces. Therefore, we focused on the cycle of searching multiple spaces. We defined one search cycle as "a set of transitions from the Keyword space to the Web-Page space." We counted the number of search cycles in each task, and Figure 5 shows the average number of search cycles in each group.

The number of search cycles was analyzed in a two-way mixed ANOVA with the group (the instructional/control) as a between-subjects factor and the test (pre-test/post-tests) as a within-subjects variable. There was a significant main effect of the test ($F(1, 33) = 6.37, p < .01$), indicating that the number of cycles increased from the pre-test to the post-test. The Group $\times$ Test interaction was also found to show a trend toward significance ($F(1, 33) = 3.07, p < .10$), which indicates that the participants in the instructional group more effectively increased the number of cycles than did in the control group. These results prove that the participants in the instructional group searched two spaces more actively in the post-test than in the pre-test.

Discussions and Conclusions

In this study, we proposed an instructional design that supports reflective activities by presenting learners' problem solving processes in information seeking on the Web and evaluated its educational effects. We conducted an experiment to evaluate the effects of our design. Experimental results revealed that the participants' search performance in the instructional group improved more effectively than in the control group. Additionally, their ideas about important activities in information-seeking

Table 3: Multiple scaffolds in our instructional design.

	Reflection in Action	Reflection on Action
Process Display	◯	◯
Process Prompt	◯	×
Process Models	×	◯
Reflective social discourse	×	×

on the Web and that their search processes also changed from the pre-test to the post-test in comparison with the control group. These results indicate that our design helps learners improve their search performances and acquire search skills.

Finally, we discuss scaffolds in our instructional design. In this study, we focused on the process display, pointed out by Lin et al. (1999) to support learners' reflection on their problem-solving processes. Furthermore, they also proposed the following three scaffolds for reflective thinking:

Process prompts: prompting students' attention to specific aspects of processes while learning is in action

Process models: modeling of experts' thinking processes that are usually tacit so that students can compare and contrast with their own process in action

Reflective social discourse: creating community-based discourse to provide multiple perspectives and feedback that can be used for reflection

Lin et al. (1999) suggested that it is important to incorporate all four scaffolds when developing designs because each method supports a different aspect of reflective thinking. We designed a learning environment in which learners could experience two types of reflection, such as "reflection-in-action" and "reflection-on-action", providing multiple methods for scaffolds referred by Lin et al. (1999) to support learners' reflective activities. Table 3 summarized types and methods of scaffolds in our design. In this paper, we empirically verified the effectiveness of combining these multiple methods for supporting reflective thinking.

Additionally, experimental results also imply that a cognitive schema is useful for not only analyzing human cognitive processes, but also supporting learning activities. However, we need to conduct further investigations on how each component in our educational design, such as a cognitive schema, "reflection-in-action," and "reflection-on-action," and above scaffolds, affects the learners' improvements.

Abstract

While computational cognitive modeling has made great strides in addressing complex dynamic tasks, the modeling of individual differences in complex tasks remains a largely unexplored area of research. In this paper we present a straightforward approach to modeling individual differences, specifically age-related cognitive differences, in complex tasks, and illustrate the application of this approach in the domain of driving. We borrow ideas from rigorous work in the EPIC cognitive architecture (Meyer et al., 2001) and extend them to the ACT-R architecture (Anderson et al., in press) and a recently-developed ACT-R driver model (Salvucci, Boer, & Liu, 2001) to model the effects of age on driver behavior. We describe two validation studies that demonstrate how this approach accounts for two important age-related effects on driver performance, namely effects on lateral stability and brake response during both normal driving and driving while performing a secondary task.

Introduction

Computational architectures and cognitive modeling have in recent years begun to account for increasingly complex and dynamic tasks, in domains such as piloting combat aircrafts (Jones et al., 1999) and controlling air traffic (Lee & Anderson, 2001). While such models have captured many aspects of human cognition and performance in these tasks, one aspect of complex tasks, namely individual differences, remains a largely unexplored area of research. The modeling community has seen several rigorous studies of individual differences in the context of cognitive architectures, perhaps most notably the work of Meyer et al. (2001) in the EPIC cognitive architecture (Meyer & Kieras, 1997) and that of Lovett, Daily, and Reder (2000) in the ACT-R architecture (Anderson et al., in press). However, due to their emphasis on specific sources of individual differences, these studies focused on relatively short laboratory tasks in controlled environments rather than more complex continuous tasks in dynamic environments.

Our goal in this paper is to generalize ideas from existing work on individual differences in simpler tasks to account for individual differences in complex dynamic tasks. We illustrate our approach in the domain of driving, a complex task that people perform on daily basis. There now exist several so-called "integrated driver models" (e.g., Aasman, 1995; Levison & Cramer, 1995) that attempt to combine the lower-level aspects of driving (e.g., steering control) with the higher-level aspects of the task (e.g., decision making, navigational planning). In particular, Salvucci, Boer, and Liu (2001) have developed and refined an ACT-R driver model that predicts many aspects of driver control, situational awareness, and decision making during common highway driving. However, to date, no integrated models of driving, including the ACT-R driver model, have accounted rigorously for any individual differences in driver behavior and performance.

This paper builds on previous work by presenting an account of individual differences, specifically age-related differences, in the complex task of driving. Not surprisingly, age plays a significant role in driver differences, often couched in broad terms as differences between younger drivers (roughly 20-30 years of age) and older drivers (roughly 60-70 years of age). Our approach borrows recent results of Meyer et al. (2001), who explored models of age-related individual differences in the context of the EPIC cognitive architecture. Age effects on driving offer a particularly interesting challenge to computational cognitive modeling: on the one hand, some studies have found that older drivers exhibit performance equal to that of younger drivers for certain combinations of driving and/or secondary tasks; on the other hand, other studies have found that older drivers sometimes experience extremely reduced performance, particularly in the presence of secondary tasks (e.g., using a cell phone). Thus, the effects of age are far from trivial and must be taken in the fuller context of both the complex behavior necessary for driving and also the complex interaction between the driver and the "artifact" (i.e., vehicle, road, etc.) through which the driver's behavior is externalized.

In the next section of the paper, we describe our basic approach and its instantiation in the ACT-R cognitive architecture. We then present two modeling studies that validate our approach for complementary tasks and aspects of behavior, namely drivers' ability to maintain lateral stability on the road and drivers' ability to respond (i.e., brake) to sudden external stimuli. While our work in this paper emphasizes driver behavior and the ACT-R cognitive architecture, the fundamental ideas generalize well to other complex task domains and other modeling frameworks. Thus, our ultimate goal is to explore the interaction between basic individual differences and their downstream effects on performance in complex dynamic task environments.

Modeling Age Effects in Driving

The various types of age-related differences that might arise in driving can be categorized broadly in terms of "hardware" and "software" differences (Meyer et al., 2001). Hardware differences arise from fundamental changes to the human system — for instance, a slowdown in cognitive processing, visual processing, or motor movement. Software differences arise in modifications or differences in the strategies used to accomplish tasks — for instance, intentionally slowing down and backing away from a lead vehicle when talking on the phone. In this paper, we focus on hardware differences, specifically differences in cognitive processing. While there is no doubt that both hardware and software differences play a role in effects on driver performance, we wish to explore to what extent modeling of basic hardware differences can account for critical effects on performance found in recent driver studies.

The ACT-R Cognitive Architecture

The ACT-R cognitive architecture (specifically version 5.0: Anderson et al., in press; see also Anderson & Lebiere, 1998) is a production-system cognitive architecture based on two types of knowledge stores, declarative and procedural. Declarative knowledge embodies "chunks" of symbolic information including factual ('3+4=7'), perceptual ('car 10 m in front'), and goal-related ('driving to the grocery store') information. Procedural knowledge operates through condition-action "production rules" that evaluate the current state of declarative knowledge (e.g., 'if my goal is to pass the lead car') and enact changes on memory and/or the environment accordingly (e.g., 'check that there is sufficient room in the left lane'). Each production rule firing (instantiation and execution) requires 50 ms of cognitive "effort" time, in addition to any time needed to wait for conditions to be met, such as the completion of a memory retrieval. Overall, the ACT-R architecture has a number of built-in functions that enable human-like behavior (e.g., interaction of memory and perceptual-motor processes) as well as built-in limitations on behavior (e.g., forgetting declarative chunks after a period of inactivity). An in-depth discussion of the architecture is beyond the scope of this paper; interested readers may wish to consult Anderson et al. (in press) for more information.

ACT-R and Age Effects

To model age effects, specifically hardware-related effects on cognitive processing, we base our approach on recent work by Meyer et al. (2001). Meyer et al. found that one of the most robust differences between younger and older people arose in the speed of cognitive processing. In particular, they found that, in the context of their EPIC architecture (Meyer & Kieras, 1997), the time for a production-rule firing increases from 50 ms for a younger person to 56.5 ms for an older person — a 13% increase. They offer several pieces of evidence to back their claim. First, for the initial claim of a 50 ms firing time, they argue that this value has a neurological correlate in the average period between zero crossings in the brain's alpha rhythm for younger adults, which has a positive relationship with mean simple response time (see Callaway & Yeager, 1960; Surwillo, 1963; and Woodruff, 1975, as cited by Meyer et al.). For older adults, they argue that mean zero-crossing periods for alpha rhythms is about 10-15% higher for subjects with an age close to 70 when compared to young adults; older subjects' mean simple response times also show a 10-15% increase (see Cerella, 1985; Somberg & Salthouse, 1982, as cited by Meyer et al.). These data lead the authors to conclude that the mean cognitive processor time increases by 13% for older adults and that this is a robust finding independent of task.

The work of Meyer et al. has a straightforward interpretation in the ACT-R architecture. ACT-R, like EPIC, uses a 50 ms cycle time for production rules. To model an older person, we simply incorporate the same cycle-time increase as Meyer et al. — namely, we increase the cycle time for production rules (called "effort" times in ACT-R) by 13%. As we will show, this change impacts performance in non-trivial ways: instead of a 13% impact on performance across measures, the change produces no effects for some measures and large effects for others depending on the emergent interactions between model and task.

In this paper, we focus in particular on the effects of cognitive cycle time and ignore potential changes in the timing of perceptual and motor processes. Meyer et al. also explored how perceptual and motor processes are affected by age; however, the mapping of their results to the ACT-R architecture is not as straightforward as the mapping for cognitive cycle time, and thus we leave this for future work. Nevertheless, we demonstrate in this paper that at least some significant aspects of age-related individual differences in driving can be successfully accounted for simply by incorporating basic differences in cognitive processing.

Driving and Age Effects

Modeling the effects of age on driver performances centers on our use of the ACT-R integrated driver model (Salvucci, Boer, & Liu, 2001). The driver model, as mentioned, incorporates both the lower-level aspects of vehicle control with the higher-level aspects of driver situational awareness and decision making. The model can navigate a variety of highway environments, the most common being a multi-lane highway with automated traffic and realistic vehicle dynamics, as pictured in Figure 1. While driving, the model interacts with the simulated environment through a virtual steering wheel and pedals, producing behavioral protocols completely analogous to those of human drivers in the simulator — recording, for example, steering and pedal depression over time along with eye movements to visual regions. The model has been validated with respect to various aspects of basic driver behavior, such as curve negotiation and lane changing (e.g., Salvucci, Boer, & Liu, 2001), and also with respect to effects of secondary tasks on performance (e.g., Salvucci, 2001).

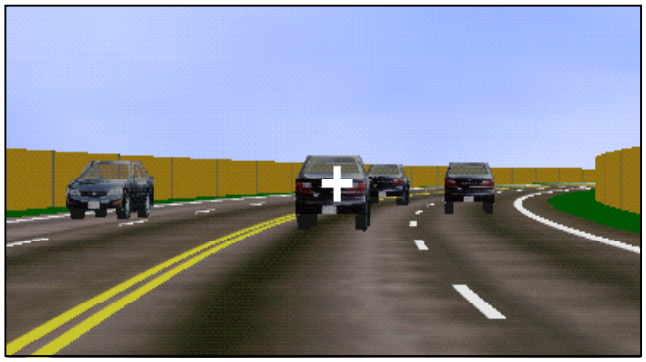

Figure 1: Sample driving simulation environment.

To model the effects of age on driver behavior, we incorporate the 13% cycle-time increase into the driver model. The increase affects all production rules across the model — most importantly, slowing down the iterating control cycle that handles the updates for steering and speed control. As mentioned, this has non-trivial downstream effects on performance rather than a simple 13% effect across measures of performance. The next two studies demonstrate how such a small change at the "hardware" level can result in very interesting emergent behavioral predictions.

Study 1: Age Effects on Lateral Stability

Our first validation study addresses effects of age on drivers' ability to maintain lateral stability — that is, side-to-side stability as measured by lateral velocity. Reed & Green (1999) compared the performance of younger and older human drivers in a simulator and on the road while executing a secondary task (dialing phone numbers). We focus our analysis on their simulator data, comparing the performance of their drivers to the predictions of the driver model in a simulator with the same task.

Human Data

In Reed and Green's (1999) study, drivers navigated a simulated straight road at a constant speed of roughly 60 mph and were occasionally cued verbally to perform a secondary task, namely dialing an 11-digit phone number (including '1' and an area code: e.g., '1-215-555-1212'). On cue, drivers picked up the phone, dialed the 11-digit number presented on a card located at the center console, and pressed a "Call" button to initiate the call. The driver then received a voice confirmation that the number was dialed correctly, and finally the driver pressed "End" to end the call. Reed and Green collected data from a total of twelve drivers, six of whom were older than 60 years of age, six of whom were between the ages of 20 and 30. They measured lateral stability as the mean lateral (side-to-side) velocity of the vehicle both during the secondary task and during normal driving.

Model Simulations

The model for the Reed and Green task was derived in a straightforward manner. The ACT-R driver model was integrated with a task environment analogous to that in the Reed and Green study — that is, a simulated one-lane straight road. The one difference in the model's task environment from that of Reed and Green arose in speed control: because the model has no speedometer with which to monitor speed, the model was given a lead vehicle driving at a constant speed, which it used to monitor its own speed. The model was then extended to include a model for the secondary task of phone dialing. This secondary-task model derived directly from a similar previous model of dialing (Salvucci et al., 2004) specified in the ACT-Simple framework (Salvucci & Lee, 2003), which is essentially a shorthand notation for standard ACT-R production rules. The model, shown in Table 1, differed from the previous model only in that it dialed the prefix "1" before the area code and phone number and that it looked at the cue card for the number rather than recalling it from memory. The "pop" marking in the table denotes commands after which the dialing model passed control to the driving task. Because the control characteristics of the Reed and Green simulator (e.g., steering force feedback) differed from those of the simulator used to validate the original driver model, three parameters[1] of the model that control overall steering were adjusted to produce the best fit in the results below. However, it should be noted that the model immediately produced the desired qualitative fit — this estimation only improved the quantitative fit. The younger and older driver models differed only in the 13% increase in cognitive cycle time for the older driver model. The model data reported below represents roughly 4-5 minutes of driving in which the model performed eight secondary-task trials with a 20 s delay between task trials.

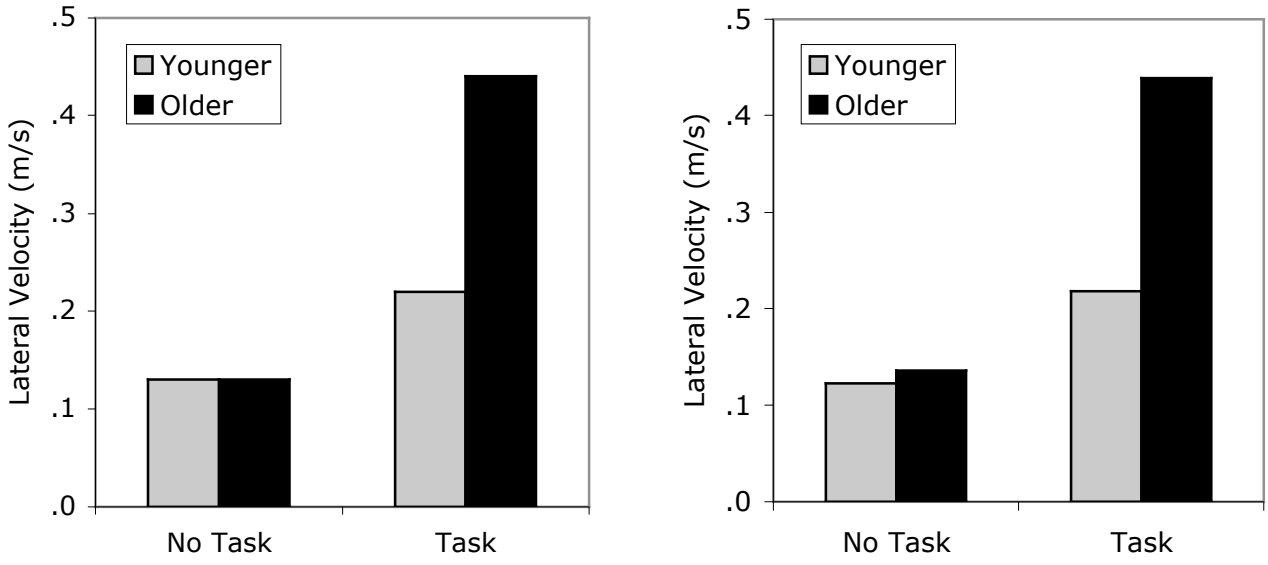

Figure 2: Lateral velocity, (a) human drivers (Reed & Green, 1999) and (b) model predictions.

Results

Figure 2(a) shows the lateral-velocity results taken from the human drivers in the Reed and Green study. In the No-Task condition, the younger and older drivers performed equally and there were no effects of age. In the Task condition, while the performance of both younger and older drivers degraded significantly, the performance of the older drivers was affected far more dramatically, with older drivers exhibiting a mean lateral velocity of .44 m/s and younger drivers a mean lateral velocity of .22 m/s in this condition.

Figure 2(b) shows the models' predictions for the same conditions, R=.99. The models, like human drivers, exhibit no age effect in the No-Task condition. Here the 13% cycle-time increase is not large enough to affect the downstream performance with respect to lateral velocity, effectively adding only tens of milliseconds to the overall control-cycle time: while the younger model updates control every 200 ms, the older model updates every 226 ms, and the extra 26 ms does not affect overall steering performance. However, also like human drivers, the model exhibits differential effects of age and task on performance. The younger model exhibits reduced performance because of less time devoted to control, as we have observed in previous studies (e.g., Salvucci, 2001). The older model exhibits an even greater degradation because of occasional, somewhat severe steering corrections: in situations where the younger model may not update control for, say, 1 s, the 13% increase for the older model would exceed 100 ms — enough time for the vehicle to travel roughly 2.7 m at the given speed and move significantly off-center in the lane. The model, seeing the large offset from lane center, performs a hard steering correction and generates a large lateral velocity. In fact, the younger model also experiences such corrections; however, the corrections are both more frequent and more severe for the older model.

Study 2: Age Effects on Brake Response

Our second validation study addresses effects of age on drivers' ability to respond to sudden external events via braking. Hancock *et al.* (2003) ran an empirical study on younger and older drivers to investigate differential effects of cell-phone distraction on braking performance. We now examine their task and results and show how the same driver model can account for this very different aspect of driver behavior and performance.

Human Data

In Hancock *et al.*'s (2003) study, drivers drove down a test track at approximately 25 mph toward an intersection with a stoplight. During some trials, the driver was cued by tone to perform a secondary task: they looked at a digit on mounted screen and pressed a key to indicate whether or not this digit corresponded to the first digit of a previously-memorized number. Also during these trials, the stoplight turned red 0.5-1 s after the onset of the secondary task, causing the driver to brake in response. During other trials, the driver only responded to the red stoplight without a secondary task. Hancock et al. collected data from 36 drivers — 19 between the ages of 25 and 36, and 16 between the ages of 55 and 65. Overall, they measured brake response time with and without the task as the time delay between the onset of the red stoplight and the initial depression of the brake.

Model Simulations

To model the Hancock et al. task, we took the model from the Reed and Green task and modified only the task components of the model. The driver model does not currently have the ability to encode and monitor stoplights, and thus we modified the environment such that the lead

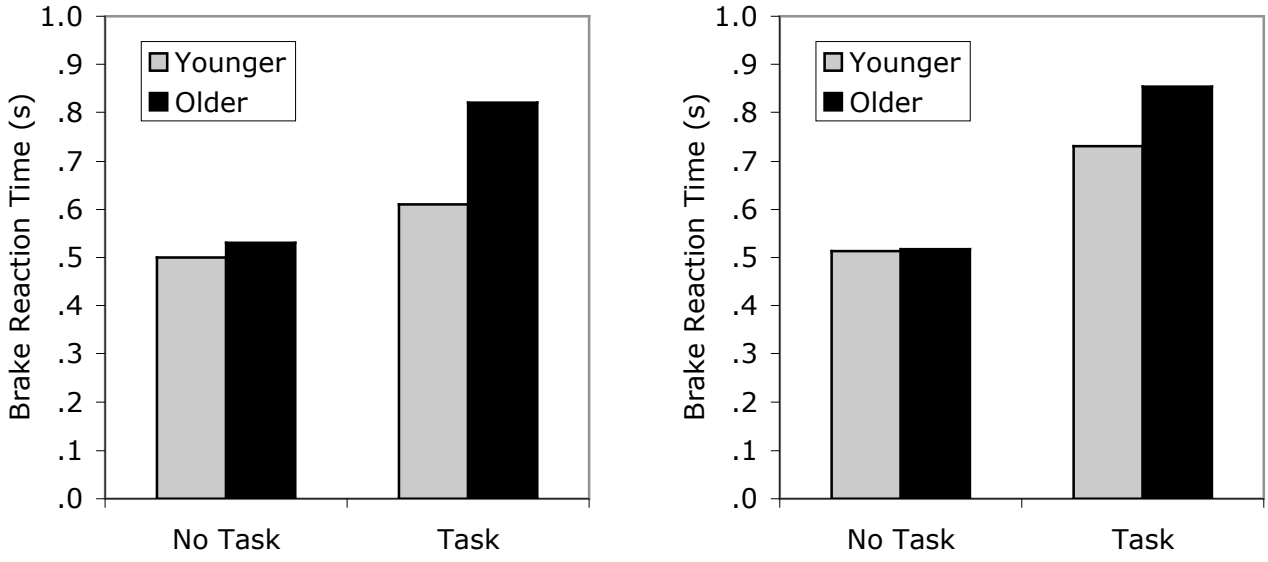

Figure 3: Brake reaction time, (a) human drivers (Hancock et al., 2003), and (b) model predictions.

vehicle's brake lights would turn red 0.5-1 s after the onset of the secondary task, keeping the basic temporal structure of the Hancock et al. task. The secondary-task model was derived by modifying the Reed and Green task model to type only 1 keypress as opposed to 11; the task model is shown in Table 2. All parameter values were taken directly from the model in Study 1. However, we had to modify one braking-related parameter because of the nature of this task: the standard driver model requires 500 ms to move its foot from accelerator to brake, but because of the emergency nature of this task, we instead used a time of 310 ms — recently reported by Lee et al. (2002) as the minimum time for this movement — and eliminated motor preparation time due to the drivers' pre-preparation of the movement as they approached the intersection. Again, the younger and older driver models differed only in the 13% increase in cognitive cycle time for the older driver model. The model data below includes roughly 5 minutes of driving in which the model performed 16 secondary-task trials with a 10 s delay between task trials.

Table 2: Secondary-task model for Study 2.

```
(move-hand device pop)
(look-at device pop)
(think pop)
(press-button key5 pop)
```

Results

Figure 3(a) shows the results for the human drivers. We see a similar pattern emerge in this study as we saw in Study 1. First, younger and older drivers showed no significant difference in the No-Task condition. Second, the secondary task significantly degraded the performance of both groups in the Task condition. Third, the task has a greater effect on the older drivers than the younger drivers. We should note that, although the graphs for Studies 1 and 2 are visually similar, they show very different aspects of behavior; the similarity is rather surprising given that one study examines lateral stability while the other emphasizes response time for longitudinal (braking) behavior.

Figure 3(b) shows the results for the model simulations, R=.94. As in Study 1, the models nicely account for the human drivers' behavior. The younger and older models show equivalent braking response times in the No-Task condition. Again, the slightly longer control update cycle for the older model is not enough to produce a significant effect. At the same time, the models show large effects of task in the Task condition, and the older model shows a significantly larger effect than the younger model. As in Study 1, the 13% cycle-time increase for the secondary task model increases pauses in control by 100 ms or more, thus producing an effect of roughly this size between the younger and older models. One might expect that the age effect for brake response might be heavily tied to differences in motor-movement speeds (from accelerator to brake), and given that the interaction effect in the human data is slightly larger than that for the model, this could indeed be one factor. Nevertheless, these results show that differences in cognitive processing are also a major component of this interaction and accounts for critical aspects of the human data.

General Discussion

In this paper we present a straightforward method of accounting for age-related differences in driver performance, focusing on "hardware" differences in cognitive processing time. While the idea of slowing processing time by 13%

for older people seems simple enough, it should be noted that the resulting predictions are far from trivial. Indeed, one might at first expect the slowdown to result in analogous performance decrements — for instance, a 13% degradation in lateral velocity and braking response. However, for complex dynamic tasks, this situation is much more complicated: the model's behavior is filtered through both the perceptual-motor processes and the vehicle dynamics, resulting in predictions that can only be generated and tested through "embodied" cognitive models that interact directly with realistic task environments. The two validation studies show that the ACT-R driver model, in the context of such a realistic environment, successfully accounts for these complex interactions in the driving domain, namely for both the lack of effects (in the No-Task condition) and larger-than-expected effects (in the Task condition) for lateral and longitudinal measures.

This work also illustrates one of the important advantages to working in the context of a cognitive architecture — namely, the sharing and re-use of ideas and model implementations within an architecture and even across different architectures. Not only does the work of Meyer et al. (2001) have large implications for their own EPIC architecture (Meyer & Kieras, 1997), the work translates well to other architectures such as ACT-R. In addition, this type of foundational work has immediate implications for all models developed in the architectures; for instance, other ACT-R models of complex dynamic tasks (or any tasks general) could incorporate the 13% cycle-time increase to immediately derive age-related predictions, enabling comparison to human data for a host of new measures. Such work would nicely complement recent work on other aspects of individual differences, such as differences in working memory (Lovett, Daily, & Reder, 2000). These studies of individual differences bring to light the predictive power inherent in cognitive architectures and help to make further strides toward Newell's (1990) vision of more "unified theories of cognition."

An Artificial Life Approach to the Study of Basic Emotions

Matthias Scheutz (mscheutz@cse.nd.edu)
Department of Computer Science and Engineering
Notre Dame, ND 46556 USA

Abstract

We propose a methodological framework for the study of emotional control based on extensive computer simulations with arti cial agents implementing emotional control mechanisms and demonstrate the methodology with simulations experiments in an arti cial environment. Speci cally, a biologically plausible schema-based model of basic forms of fear and anger is proposed and tested with respect to a variety of parameter ranges.

Introduction

Emotions are an integrative part of our mentality. At the level of the functional architecture they serve several crucial roles, from fast perceptions of threats, to focusing and redirecting attention, to in uencing memory storage and retrieval, to social regulation through expression and perception of emotions, and many more (Derryberry & Tucker, 1994; Fredrickson, 1998; Bless, Schwarz, & Wieland, 1996; Schwarz, 1990; Blaney, 1986; Kahneman, Wakker, & Sarin, 1997; Clore, Gasper, & Conway, 2001; Frijda, 2000; Cosmides & Tooby, 2000). Several circuits have been hypothesized to be involved in emotional processing in mammalian brains, yet only a few computational models (mostly of fear mechanisms) have been proposed and implemented in an effort to test theoretical predictions about emotion processes and mechanisms. Moreover, these models are limited to very specific processes (e.g., Pavlovian fear conditioning) and do not specify other parts of an architecture that are required for a complete, functional control system (e.g., homeostatic control mechanisms, various forms of perceptual processing, action selection mechanisms, etc.). Hence, they leave out and cannot address many other emotional states that essentially depend on additional processing components (e.g., such as social emotional states that depend on the expression and perception of emotions).

One way to study the effects of emotional control circuits for individual agents as well as groups of agents is to conduct simulations with artificial agents that are controlled by architectures that define emotion models. Such simulation studies have the advantage that the role of emotions and the consequences of emotional disturbances can be analyzed at several different levels at the same time: the *mechanistic level* of the implementation of the model (e.g., a neuronal level), the *individualistic level* (e.g., the control loops between emotion circuits and the agent body), and the *social level* (e.g., the effects of emotional signaling for the well-being or functioning of a group).

In this paper we will (1) propose a methodological framework for the study of emotional control based on extensive computer simulations with artificial agents implementing emotional control mechanisms and (2) demonstrate the methodology with simulations experiments in an artificial environment. Specifically, a biologically plausible schema-based model of basic forms of fear and anger is proposed and tested with respect to a variety of parameter ranges. The results show where emotional control is successful and better than non-emotional strategies, but also where it fails.

Background on Computational Models of Emotions

While several suggestions about the neural and functional organization of emotional circuits exist in the literature, there are currently only a few proposals for computational models that implement and test them. The existing computational models can be categorized into two main classes, based on whether they are aimed at explaining low-level neurological structures and mechanisms, or whether they are intended to model higher-level emotional processes. The low-level models can further be divided into general processing models of brain mechanisms and specific emotion models of particular brain structures.

The most extensively developed low-level models among the first kind are Grossberg's *CogEM* models (e.g., (Grossberg & Schmajuk, 1987)), which are models of learning cognitive, emotional, and motor properties. *CogEM* models can account for several effects in Pavlovian fear conditioning (e.g., secondary conditioning or attentional blocking), but have not been directly applied to empirical data (e.g., data from fear conditioning studies with rats).

Another class of low-level neural models is targeted specifically at modeling the amygdala, which performs several functions in emotion processing (LeDoux, 1996; Rolls, 1995). The lateral amygdala, for example, has been shown to exhibit associative plasticity during fear learning (Blair, Tinkelman, Moita, & LeDoux, 2003) and a preliminary computational model of associative learning in the amygdala has been developed and tested in three associative learning tasks (Balkenius, 2000).

Moreover, recent evidence from studies with rats suggests that the amygdala, in particular, the frontotemporal amygdala, which is taken to integrate sensory information, encodes hedonic values of an unconditioned stimulus as part of the fear memory (Fanselow & Gale, 2003). LeDoux and colleagues have hypothesized a dual pathway model of emotional processing in the amygdala, which they tested in auditory fear conditioning studies (Armony, Servan-Schreiber, Cohen, & LeDoux, 1995). These models have been also used in simulated lesion studies and successfully compared to data from actual lesion studies with rats.

While most research on emotional modeling in low-level models is focused on Pavlovian conditioning and targeted at neural structures and processing mechanisms, higher-level models of emotions are intended to capture the processing sequence involved in emotion processes and are typically concerned with a wider range of emotions. While all low-level models are neural network models, higher-level models comprise both connectionist and symbolic approaches.

An example of a high-level connectionist approach is the ITERA model (Nerb & Sperba, 2001), which is intended to study how media information about environmental problems in uences cognition, emotion, and behavior. Facts, input types, emotions, and behavioral intentions are all represented in terms of individual neural units that are connected via excitatory and inhibitory links and compete for activation.

Most attempts to model emotions at higher levels, especially in artificial intelligence research, are however based on symbolic architectures (e.g., Soar (Newell, 1990) or ACT (Anderson, 1993)). They typically focus on the OCC model (Ortony, Clore, & Collins, 1988), which hypothesizes prototypical "update rules" for changes in emotional state that can be directly implemented in rule-based systems (e.g., (Marsella & Gratch, 2002).

What is common to all the above emotion models is that they have been implemented and tested in isolation from any *body model*. Consequently, it is difficult if not impossible to investigate crucial aspects of emotion processing that need a body for control and thus go beyond functional properties (like the effects of Pavlovian conditioning), which can be tested in stand-alone models (e.g., by applying a stimulus and measuring the output).

While some attempts have been made to implement connectionist emotion models on robots, where different emotions types are represented as connectionist units that compete for activation, which in turn cause the robot to exhibit a particular behavior (e.g., (Michaud & Audet, 2001; Breazeal, 2002; Arkin, Fujita, Takagi, & Hasegawa, 2003)), these architectures do not attempt to model any specific psychological or neurobiological theory of emotions (e.g., in an effort to verify or falsify its predictions). Rather, they are mainly concerned with the applicability of a particular control mechanism from an engineering perspective. Moreover, these models typically lack a systematic evaluation of their performance (an exception is (Breazeal, 2002)). Finally, no experiments have been performed with these robotic architectures to investigate the effects of "emotional malfunctioning".

Probably the most significant restriction of current efforts to model emotions is that they have not been extended to multi-agent environments. Yet, social aspects of emotions (such as signaling emotional states through facial expressions, prosody, gestures, etc.) and the resultant effects at the group level cannot be studied in a single, isolated agent. Rather, multiple interacting agents with emotional control systems are required, especially for arguments about the adaptive role of emotions (e.g., (Cosmides & Tooby, 2000)). To our knowledge only one project (Dulk, Heerebout, & Phaf, 2003) uses an artificial life simulation to study some evolutionary aspects related to emotional processing, specifically, the evolutionary justification for LeDoux's dual-route fear processing proposal (LeDoux, 1996). However, the employed neural network does not and is not intended to implement emotions or model emotional circuits. And while the employed neural network suggests some interesting conclusions about the circumstances under which dual processing routes might be beneficial, it does not capture emotional circuits, and is, therefore, silent about emotional phenomena.

Simulations of Emotional Agents

Over the last few years we have developed an agent-based simulation environment SWAGES to investigate different agent architectures and architectural mechanisms. In particular, two main roles of emotions in agent control systems have been studied in extensive simulations in an effort to evaluate the utility of emotional control (compared to other non-emotional control strategies): *the role of emotions for individual agents* (e.g., the selection of actions) and *the role of emotion for social groups* (e.g., in con icts with conspecifics and individuals from other species).

Results from simulation experiments with agents performing foraging tasks, for example, show that *action selection* based on emotional states can be very effective in the competition for resources in hostile multi-agent environments (e.g., (Scheutz, 2001) and that motivational "hunger" and "thirst" states as well as emotional "fear" and "anger" states are likely to evolve in a variety of competitive multi-agent environments (Scheutz & Sloman, 2001)).

In general, we found that agents with emotional control mechanisms performed much better in a variety of foraging and survival tasks in environments with little to no structure than agents with much more sophisticated cognitive control systems if the "cost of deliberation" is taken into account (e.g., (Scheutz & Schermerhorn, 2002)).

On the social side, we found that expressing emotions and being able to react to emotional expressions of others can have a beneficial regulatory effect in social groups and lead to superior con ict resolution strategies (e.g., (Scheutz & Schermerhorn, 2004)).

In all these studies, we construed emotions as con-

trol processes that initiate, interrupt, suppress, reprioritize, or in general modify behavior or behavioral dispositions. Emotions are implemented in terms of control components (typically, in neural networks) that are connected in appropriate ways to sensors and effectors of agent body models. The underlying assumption is that the level of control components is appropriate for analyzing and understanding the functional organization of emotion mechanisms. In the following we brie y outline our architectural approach to the study of emotions and present some experimental results.

Basic Motivations and Emotions as Control Processes

Motivations may be considered *desire-like states* in that they in uence and bias an agent's behavioral dispositions in such a way as to contribute to the realization of a desired change in the environment and/or agent. We use the term "basic motivations" to refer to motivations that have little to no cognitive involvement and are primarily linked to "basic needs" of an agent (e.g., to maintain a certain energy level). For some of these, the familiar term "drive" is appropriate, namely if the agent is driven in a mostly reactive way to act so as to eliminate the disparity between a desired and an actual state that was the cause for the motivation. For example, a state of an agent's control system qualifies as a "hunger" state if it is caused by lack of energy and results in food-seeking behavior (McFarland, 1981).

It is possible to use control components, whose outputs control gain values of motor controllers, to implement the kind of control system that will be able to instantiate basic motivations. For example, "hunger" could be instantiated by a proportional controller P (Özbay, 2000) such that input to P comes from an internal sensor S that measures the current energy level. P compares a desired equilibrium energy level (i.e. set point), e_{des}, to the actual energy level e_{act} and scales the difference by a gain factor g_e: $P = g_e \cdot (e_{des} \quad e_{act})$. The output then is a measure of the urgency with which the system requires energy. Hence, the intensity of basic motivations is modeled by the magnitude of the control circuits' outputs that can in turn modulate behavior.

Emotions may also be considered to be desire-like in that they in uence and bias an agent's behavior. Again, we use "basic emotion" to refer to states with little or no cognitive involvement. For our purposes, we distinguish *basic emotions* from *basic motivations* in that basic emotions need not be related to a perceived difference between an actual and a desired state. Furthermore, basic emotions themselves can be states that the agent does or does not desire whereas basic motivations are directed towards or away from what the agent desires. "Fear", for example, in and of itself is an undesirable state of an agent in that it is indicative of danger. As such, it causes the agent to behave in such a way as to be prepared for or avoid danger. Hence, while "fear" can be also motivational in the sense that it may move the agent away from the cause of fear it is also emotional as it itself is not a desired state. A fear state with no clearly discernible danger present, which causes an agent to be more cautious and alert, may itself not instantiate a motivational state that is connected to a particular goal such as running away from a particular threat.

"Fear", as discussed above, can be instantiated by a controller C, which integrates over time the frequency of occurrence of fear triggering conditions. Input to C comes from an internal sensor S that is activated by a fear triggering condition. C integrates these inputs over time and outputs a signal that corresponds to the intensity of "fear" and modulates behavior to be more alert and ready for sudden activity. A neural control circuit implementing an appropriate response characteristic (similar to that given by $g(t) = e^{-t}$ to a unit impulse, which is generated by the sensor or the perceptual system detecting a dangerous stimulus), could use an *interactive activation and competition* (IAC) unit (McClelland & Rumelhart, 1988), whose change in activation is given by $\Delta act = S \cdot g_S \cdot act + decay \cdot act$, where act is the current activation level of the control system, g_S is the gain for the sensor input and $decay$ is the discount value for past activations.

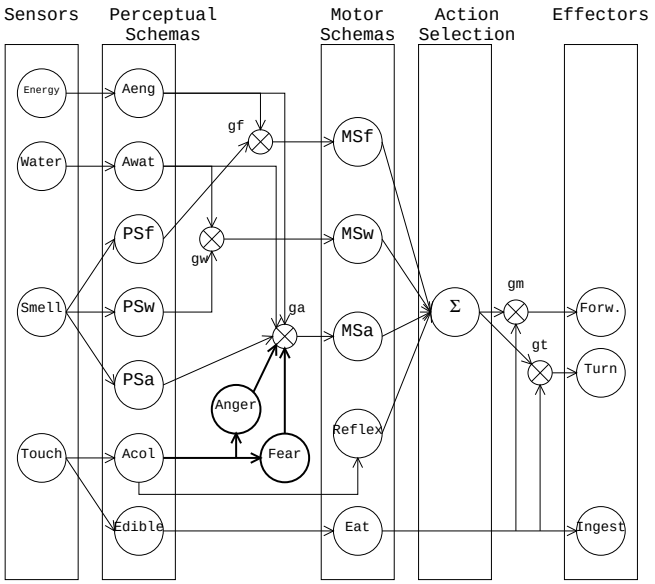

Figure 1: The schema-based architecture for the simulated emotional agents (see the text for details).

To be able to instantiate a fear state, the above controller needs to control the agent's effectors in a way that the positive output from the controller can in uence and bias the agent's behavior towards avoiding or attempting to avoid dangerous objects. As such, the intensity with which the agent avoids or attempts to avoid these objects depends on the magnitude of the output of the controller: the agent's behavior is modulated by its level of fear.

A Schema-Based Agent Architecture

Using the above control elements to implement basic motivations and emotions, we have compared the performance of agents with mechanisms to implement *fear*

and *anger* to that of agents without these mechanisms in a hostile multi-agent environment, where agents need to forage for resources in order to survive and procreate. The employed architecture is a biologically plausible schema-based architecture (Arbib, 1992) for both agent kinds, which allows the agents to forage for food and water. In this architecture, the behavior of an agent depends at any given time on the relative contributions from a variety of motor schemas. While non-emotional agents have fixed behavioral dispositions to deal with competitors for resources, emotional agents use their emotional control circuits to adapt their behaviors based on past encounters.

Figure 1 shows the architecture for the emotional agents (their emotional subsystem is an implementation of the higher-level functional organization of the basic mammalian "fear/anger system" in the terms of the above suggested control units, e.g., (Berkowitz, 2003)). Schemas are depicted by large circles where the names indicated their function.[1] Small crossed circles indicate gains of schemas (i.e., behavioral dispositions) that are taken as architectural parameters to be varied in the experiments: the degree to which an agent is attracted to food (g_f), to water (g_w), and to other agents (g_a). The bold-face circles labeled "Fear" and "Anger" represent the "fear schema" and "anger schema", respectively. They are only present in the architecture of emotional agents. Both emotion schemas are connected to an "alarm schema" (*Acol*), which is triggered if an agent touches other agents. This mechanism changes the agent's propensity to fight other agents or to ee: the higher the output of a controller, the more stronger the behavioral disposition (i.e., to fight for anger, or ee for fear).

More formally, let $Ent = \{f, w, a\}$ be an index set of the three types of objects in the simulation environment: *food*, *water*, and *agents*. For each object type in Ent, a force vector F_i is computed, which is the sum, scaled by $1/|v|^2$, of all vectors v from the agent to the objects of type i within the respective sensory range, where $|v|$ is the length of vector v. These *perceptual schemas* are mapped into motor space by the transformation function $T(x) = \sum_{i \in Ent} g_i \cdot F_i(x)$, where the g_i are the respective gain values of the perceptual schemes. The gain values simply scale the effect of sensory input, providing a means by which to prioritize certain inputs (e.g., if food is especially important, its gain value could be higher than the other gain values, so that sensing food has a greater impact on the direction chosen than sensing other entities).

All feedback controllers are implemented in a feed-forward three-layer interactive activation and competition neural network (with three input units *in*, three hidden units *hid*, and three output units *out*). The input units receive their activations (via appropriate scaling functions) from the $Water$ (in_w) and $Energy$ level sensors (in_f) via the perceptual *Awat* and *Aeng* schemas as well as from the $Touch$ sensor via the *Acol* schema (in_a), respectively.

The output units are connected to the gain values in the motor scheme via individual scaling functions $f_i(x) = x \cdot c_i + b_i$ (where b_i is the *base gain value* and c_i the scaling factor for the activation of out_i).

The activation value $act_i(t)$ of an IAC unit i at time t is defined by

$$act_i(t) = \begin{cases} (max \quad act_i(t \quad 1)) \cdot net_i(t) \quad decay, \\ \qquad\qquad\qquad\qquad net_i(t) \geq 0 \\ (act_i(t \quad 1) \quad min) \cdot net_i(t) \quad decay, \\ \qquad\qquad\qquad\qquad net_i(t) < 0 \end{cases}$$

where min and max are the minimum and maximum activation level, respectively, *decay* is a decay factor defined by $d \cdot (act_i(t) \quad rest)$ (where d is a constant), $rest$ the rest level, and $net_i(t)$ the weighted sum of all inputs to unit i at time t.

The choice of IAC units over standard perceptrons is based on their update rule, which is particularly suited to implement important temporal features of some emotional states in that it (1) takes into account the *previous activation* (hence, can be used to implement "inner states"), and (2) incorporates a *decay term* to raise or lower the activation to a predetermined *base level*.

Non-emotional agents have a constant g_a gain (i.e., their $c_i = 0$), hence their behavioral dispositions towards other agents are fixed. Emotional agents, on the other hand, can adapt their behavior dispositions, i.e., their g_a gain, by virtue of the feedback controllers implemented in the neural net (their $c_i \neq 0$). Depending on whether g_a is positive or negative, they can implement basic "anger" or "fear" states (as argued in (Scheutz, 2001)).

The Utility of Anger and the Limits of Fear

We report results from two classes of experiments studying the role of emotions in foraging and survival tasks.[2] In the first class, the gain g_a is set to a negative value for both agent kinds, thus making them disposed to avoid other agents. For the second class, g_a is positive for both agent kinds, thus making them disposed to be aggressive towards other agents. Performance was measured in terms of the number of surviving agents after 10000 simulation cycles averaged over 40 runs with random initial conditions. The upper and lower parts of Figure 2 show the results from both classes of experiments for both agent kinds for two architectural variations: agent gain and water gain (i.e., 25 sets of 40 experimental runs each). All runs started with 10 agents of each of the two kinds placed at random location in the environment together with 20 randomly placed food and 20 randomly placed water items; new food and water items are generated on every 4 and 6 cycles in random locations, respectively.

While emotional agents in the first set have a performance peak (of 23.625) that is slightly higher than that of non-emotional agents (of 23.35), the difference is not

[1] For space reasons we cannot describe all the details of the architecture here.

[2] For more details about simulation setup and simulation parameters see (Scheutz, 2001).

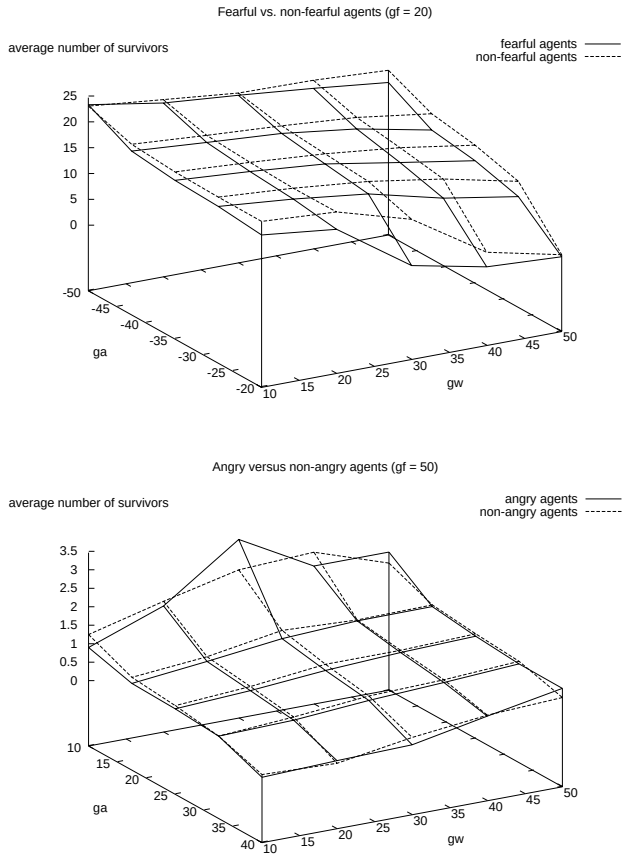

Figure 2: The performance space of the emotional vs. and non-emotional agents (fearful top, angry bottom) based on variations along two architectural dimensions.

significant (t-test, $p > 0.1$). Consequently, being fearful in addition to having the behavioral disposition of avoiding other agents does not increase the overall performance, it may in fact reduce it for some settings of the gain values (e.g., $g_a = \ \ 20$ and $g_w = 30$). For emotional agents in the second class of experiments, however, we find a marginally significant global maximum at $g_a = 10$ and $g_w = 30$. Consequently, in the kinds of environments studied, "anger" does sometimes prove useful for survival.

Discussion

The results reported here are only a very small part of a large set of experiments, in which up to five architectural dimensions were varied in an effort to determine the circumstances in which emotional control is beneficial and where it might be detrimental. The methodology on which they are based consists of a four step process: (1) emotion concepts are analyzed and defined in terms of architectural capacities of agent architectures (Sloman, 2002). (2) Agent architectures with particular emotional control mechanisms (as defined in (1)) are constructed for a given task, for which also a performance measure is defined. (3) Simulations experiments are carried out with the so-defined emotional agents and their performance is determined for a predetermined set of architectural and environmental variations. The outcome then is a *performance space* that corresponds to the varied parameters. The last two steps are repeated with agents implementing non-emotional (or, in general, other) architectures. (4) All resulting performance spaces are then compared with respect to the agents' *performance-cost tradeoffs*, i.e., their performance taken relative to the (computational) cost necessary to maintain and run the instantiated architecture (in the reported experiments the cost for both architectures was taken to be the same). The last point is crucial as it may well be that emotional agents do not perform better than non-emotional ones on a given task in absolute terms, but that they do much better in relative terms, i.e., with fewer resources (which is usually believed to be the case by emotion researchers). Especially from an evolutionary perspective relative performance is the relevant measure.

We believe that the proposed methodology to experiment with agent architectures in an artificial life environment cannot only form the basis for a thorough comparison of the different emotion models that can otherwise not be studied easily (e.g., social emotions and their role in the control of agents), but can also inform emotion researchers interested in clinical aspects of emotions by performing simulated *lesion studies*, where parameters of functional agents are modified or components of the architecture are removed. This, in turn, might help us isolate not only the functional roles of emotions in the control of creatures, but also the ways in which emotional control can fail and how it might be possible to reestablish normal functioning in dysfunctional systems.

Abstract

Based on the theory of conceptual metaphor we investigated the evaluative consequences of a match (or mismatch) of different conceptual relations (good vs. bad; abstract vs. concrete) with their corresponding spatial relation (UP vs. DOWN). Good and bad words that were either abstract or concrete were presented in an up or down spatial location. Words for which the conceptual dimensions matched the spatial dimension were evaluated most favorably. When neither of the two conceptual dimensions matched the spatial dimension, ratings were not as favorable as when the dimensions did match, but were still significantly more favorable than when one conceptual category was matched with the spatial category (e.g., UP and abstract), while the other one was not (e.g., UP and bad). Results suggest that a metacognitive feeling of fluency can produce an additional layer of evaluative information that is independent of actual stimulus valence.

Background

A recent theory of conceptual structure proposes that bodily processes influence and constrain cognitive information processing, and that the resulting knowledge is structured in a largely metaphorical way (Gibbs, 1994; Lakoff & Johnson, 1980, 1999). According to this view, the body is a source of knowledge, and by means of conceptual metaphors, very basic "embodied" concepts are mapped onto more abstract concepts. For instance, the basic orientation of the human body in space (certain things are "up" or "down", relative to the body) is used when conceptualizing abstract categories, such as emotions, when metaphorically talking about "feeling up" or "down". Thus, metaphor, defined as "*understanding and experiencing one kind of thing in terms of another* (Lakoff & Johnson, 1999, p. 5, emphasis in original)," does not merely concern language usage. How we use metaphor to talk about things also has implications for how we act upon, and think about those things.

Central to the theory of conceptual metaphor is the notion of "image schema" (Johnson, 1987, 1999), which describes a pattern of perceptual experience that emerges from very basic bodily activities. For instance, the sensorimotor experience of moving with one's own body through space results in the image schema of VERTICALITY, or the understanding that we usually function in an upright position, with a clear up-down orientation. Indeed, spatial perceptions and spatial language are closely intertwined (Hayward & Tarr, 1995; Miller & Johnson-Laird, 1976; Richardson, Spivey, Barsalou, & McRae, 2003; Tolaas, 1991). Spatial metaphors derived from the concrete concept of VERTICALITY can be used to describe various abstract concepts:

> GOOD IS UP; BAD IS DOWN:
> Things going *downhill*; Feeling *down* in the dumps
> ABSTRACT IS UP; CONCRETE IS DOWN:
> *Higher-order* categories; *sub*-types

Thus, many image schemata are hypothesized to be derived from the basic experience of the body functioning in three-dimensional space: By definition, all human behavior takes place in space. As a consequence, the source domain of space provides a metaphor for multiple target domains (Lakoff & Johnson, 1980, 1999).

Indeed, evidence has been obtained supporting the notion that concrete spatial relations provide opportunities for mapping conceptual relations. For instance, time is often conceptualized as movement through space (Boroditsky, 2000; Boroditsky & Ramscar, 2002; Gentner & Imai, 1992; Gentner, Imai, & Boroditsky, 2002). Graphs are easier to understand when an increase in quantity is represented by an increase in slope, corresponding to the spatial metaphor of MORE IS UP (Gattis & Holyoak, 1996). Inferences about given premises are more accurate when the premises are mapped onto a spatial medium, compared to when they are not (Schnall & Gattis, 1998). Positive words are categorized faster when they are presented in an upward location, whereas negative words are categorized faster whey they are in a downward location (Meier & Robinson, 2004). Thus, when spatial relations can be mapped onto corresponding conceptual relations, cognitive operations are facilitated.

In the current study we investigated the confluence of spatial relations and conceptual relations. As noted earlier, spatial concepts, such as VERTICALITY, serve as the source domain for various target domains, such as goodness/badness, and concreteness/abstractness. Figure 1

describes the relationship between the source domain VERTICALITY and those two target domains. Both target domains have an implicit connection with the source domain. For example, the concept "love" is good and abstract, and both those conceptual categories are conceptualized as UP.

Table 1: Relationship between spatial and conceptual dimensions.

		CONCEPT	
		VALENCE	CONCRETENESS
SPACE	UP	Good	Abstract
	DOWN	Bad	Concrete

The goal of the current study was to investigate the effect of a match (or mismatch) of two different conceptual relations with their corresponding spatial relation. The spatial dimension we investigated was VERTICALITY (UP vs. DOWN), and the two conceptual dimensions were VALENCE (*good* vs. *bad*) and CONCRETENESS (*concrete* vs. *abstract*). The spatial dimension was varied by a simple perceptual manipulation: The stimulus word, which consisted of a good (or bad) word that was either abstract (or concrete) was placed either on top, or on the bottom of the page on which participants evaluated the word.

Table 2 describes the different ways in which the relations can either be matched or mismatched. *Congruent relations* are present when both relations are matched, such as when good, abstract concepts are UP (top panel of Table 2, denoted by "+ +"), but also when both relations are mismatched, such as when bad, concrete concepts are UP (denoted by "- -"). In the latter case neither of the conceptual dimensions matches the spatial dimension, therefore no conflict between the spatial and conceptual relations exists. In contrast, *incongruent relations* are present when only one of the two conceptual dimensions matches the spatial dimension, and the other one does not.

We expected that the extent to which the two conceptual dimensions were in accordance with the spatial dimension would influence the perceived valence of the stimulus words. Specifically, we predicted that when both relationships are matched, as is the case for the congruent "+ +" conditions, stimuli should be rated more favorably. Further, for the congruent "- -" conditions, stimuli should be perceived as less positive than in the congruent "+ +" conditions, but as more positive than in any of the incongruent "+ -" "- +" conditions. This hypothesis regarding the mapping of spatial and conceptual dimensions was tested by presenting participants with strongly positive and strongly negative words that were either abstract or concrete, and thus the content of the words crossed both conceptual dimensions of goodness/badness and abstractness/concreteness. Each word was presented either on top, or on the bottom of a piece of paper, and participants evaluated how good the word was.

Table 2: Congruent (" + +" "- -") and incongruent ("+ -" "- +") relations of spatial and conceptual dimensions.

Stimulus	SPACE	VALENCE Good = UP Bad = DOWN	CONCRETENESS Abstract = UP Concrete = DOWN
Good Abstract e.g., *talent*	UP	+	+
Good Concrete e.g., *palace*	UP	+	−
Bad Abstract e.g., *malice*	UP	−	+
Bad Concrete e.g., *bullet*	UP	−	−
Bad Concrete e.g., *blister*	DOWN	+	+
Bad Abstract e.g., *neglect*	DOWN	+	−
Good Concrete e.g., *circus*	DOWN	−	+
Good Abstract e.g., *passion*	DOWN	−	−

Method

Participants

Participants were 61 undergraduate students from the University of Virginia who received course credit.

Procedure

Participants filled out a survey as part of an experimental session. Instructions specified that the participant's task was to make a judgment about how good or how bad certain words were. It was emphasized to participants that they should go with their first intuition, and that judgments should be made according to what they personally thought, rather than what other people might think.

The word stimuli were presented in the following manner (see Figures 1 and 2). Each stimulus was printed on a separate sheet of paper measuring 4 ¼ by 5 ½ inches. A horizontal line was drawn in the middle of the paper to emphasize up and down locations. The stimulus word was printed either in the space on top of the line (in the upper half of the page), or below the line (in the lower half of the page). Each word was followed by a rating scale on which the participant evaluated the word from 1 (very good) to 7 (very bad). All stimuli were assembled into a booklet that presented the stimuli in a fixed random order. Half of the stimuli were strongly positive words, the other half were strongly negative words. These words were selected from a word list for which normative affective ratings have been established (Bradley & Lang, 1999), and were matched for word length and word frequency. For each valence, half of the words were abstract (e.g., "honor," "greed"), the other half were concrete (e.g., "bouquet," "thief"), thus resulting in eight different experimental conditions. Each stimulus was presented only once, and each participant received all conditions.

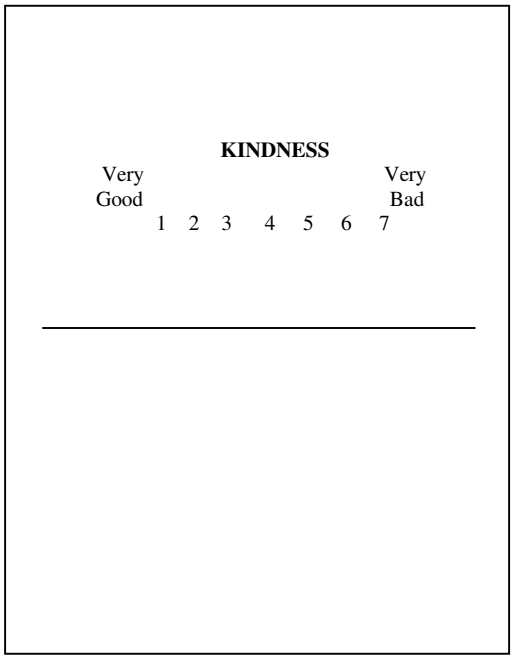

Figure 1: Spatial set-up of survey: "Good"abstract item in upward location.

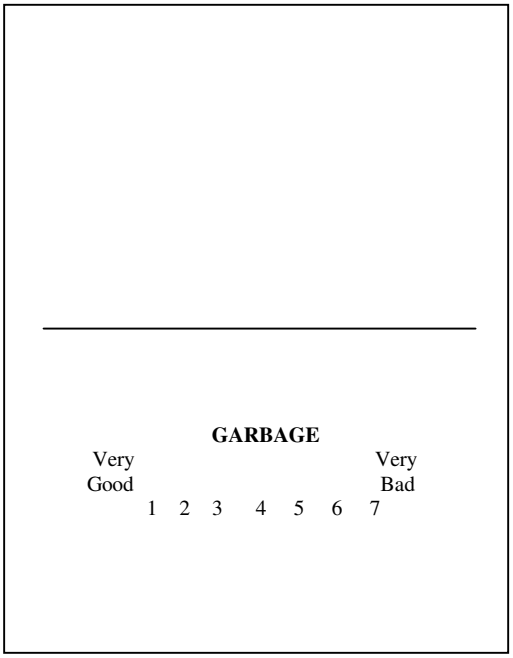

Figure 2: Spatial set-up of survey: "Bad"concrete item in downward location.

Table 3: List of word stimuli.

Good Words		Bad Words	
Abstract	Concrete	Abstract	Concrete
joy	toy	sin	fat
fun	kiss	scorn	tomb
wise	gift	greed	bomb
honor	jewel	upset	thief
brave	dinner	devil	bullet
talent	palace	deceit	prison
fantasy	circus	malice	poison
miracle	delight	misery	blister
passion	sunset	hatred	morgue
kindness	bouquet	failure	garbage
intimate	treasure	neglect	hostage
ambition	sunlight	jealousy	mosquito
affection	butterfly	ignorance	hurricane

Results

Because the valence of the words was strongly positive or strongly negative, and no interaction effect of valence and spatial position was expected (i.e., positive words were not expected to be rated as negative, or negative words as positive depending as a function of their spatial location), separate within-subjects ANOVAs were conducted for positive and negative items. For "good" words, the

interaction of spatial position and level of abstractness was significant, $F(1, 60) = 64.48$, $p < .0001$, with the highest mean for the congruent condition, namely abstract positive words presented in the up location ($M = 5.43$, $SD = .40$)(see Figure 3). Subsequent paired-samples t-tests showed that words in the congruent condition received significantly higher positive ratings than concrete positive words in the up location ($t(60) = -15.95$, $p < .0001$), abstract positive words in the down location ($t(60) = -2.18$, $p < .03$), and concrete positive words in the down location ($t(60) = -7.91$, $p < .0001$). Thus, when the perceptual dimension (UP) was matched with both conceptual dimensions (*good* and *abstract*), evaluations of the positive words became even more positive compared to when they were not.

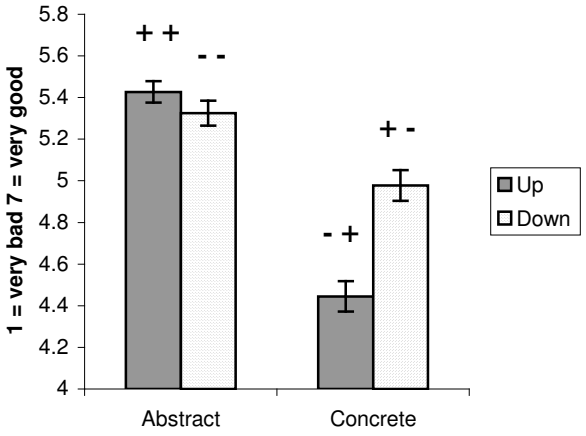

Figure 3: Mean ratings for "good" words.

For the "bad" words, there was also a significant interaction of space and level of abstractness, $F(1, 60) = 54.60$, $p < .0001$. Words in the congruent condition, that is, concrete negative words presented in the down location received the most *positive* ratings ($M = 1.39$, $SD = .39$), and differed significantly from abstract negative words in the down location ($t(60) = 11.06$, $p < .0001$), concrete negative words in the up location ($t(60) = 9.24$, $p < .0001$), and abstract negative words in the up location ($t(60) = 10.68$, $p < .0001$) (see Figure 4). Remarkably, this match between the perceptual dimension and its corresponding two conceptual dimensions did not result in making the negative words more extreme, and thus more negative; rather, as was the case for the positive words, it led to more positive ratings for the negative words.

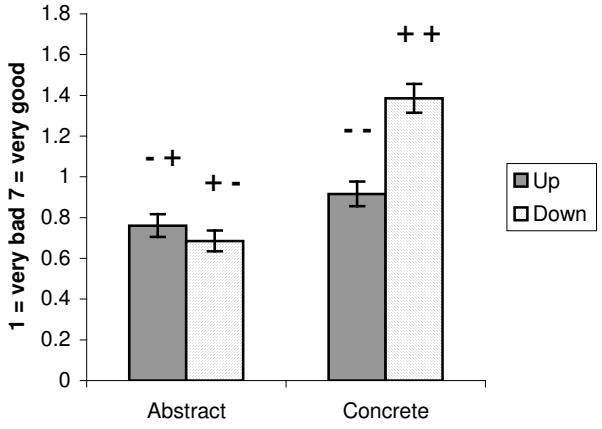

Figure 4: Mean ratings for "bad" words.

The analyses so far have dealt with the "+ +" match conditions of perceptual and conceptual dimension, denoted with two plus signs in Table 2. In addition, more positive ratings were also observed for the " - -" match conditions, denoted with two minus signs in Table 2, where the spatial dimension neither matched the valence, nor the level of abstractness of the words.

To compare specifically the congruent "+ +" with the congruent "- -" conditions, as well as with the incongruent "+ -" "- +" conditions of spatial dimension with the two conceptual dimensions, composite scores were computed. As predicted, the composite average rating for the two congruent "+ +" conditions ($M = 3.41$, $SD = .23$) was significantly more positive than the composite average rating for the two congruent "- -" conditions ($M = 3.12$, $SD = .26$), $t(60) = -8.49$, $p < .0001$ (see Figure 7). In addition, the composite average rating for the two congruent "- -" conditions was significantly more positive than the incongruent "+ -" "- +" conditions ($M = 2.72$, $SD = .23$), $t(60) = -9.83$, $p < .0001$.

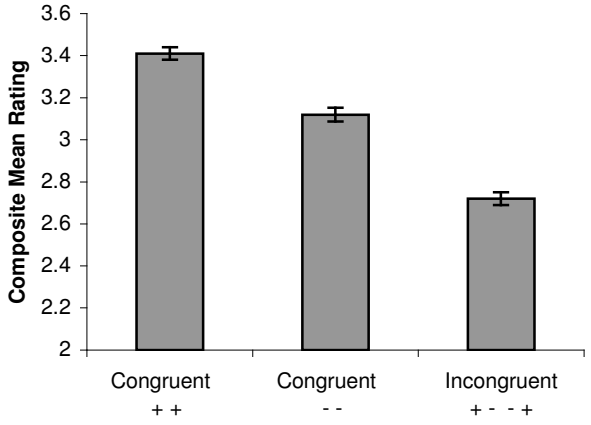

Figure 5: Composite ratings for congruent and incongruent matching conditions.

To summarize, abstract positive words presented in an up location, and concrete negative words presented in a down location were evaluated most favorably. Furthermore, when neither of the two conceptual dimensions matched the spatial dimension, that is when abstract good words were down, or when concrete bad words were up, ratings were not as favorable as when the dimensions did match, but were still significantly more favorable than when one conceptual category was matched with the spatial category (e.g., UP and abstract), while the other one was not (e.g., UP and bad).

Discussion

We found evidence for a connection between a spatial source domain and two conceptual target domains. A match between the source domain of VERTICALITY and the two corresponding target domains of goodness/badness and abstractness/concreteness resulted in more positive evaluations for affectively toned material, regardless of whether this material was positive or negative in valence. Abstract good things were rated as even better when they were presented on top of the page, but concrete bad things were also rated as better when they were presented on the bottom of the page.

The finding regarding the negative words might be considered surprising. A different outcome might have been that the meaning of bad things was intensified with congruent spatial and conceptual dimension, so that bad things became even worse. But this is not what we found. How can this somewhat counterintuitive finding be explained? One possibility is that if conceptual relations are indeed as inherently connected to spatial relations as our findings suggest, then people are more familiar with spatially represented conceptual structure. As a consequence of this familiarity, these mappings are experienced as more pleasant. Indeed, it has been well documented that the repeated presentation of a stimulus is sufficient to increase positive affect toward that stimulus, relative to a stimulus that has not been presented repeatedly. In a classic study originating the work on the so-called mere exposure effect, Zajonc (1968) presented Chinese-looking characters, nonsense words, or yearbook photographs for either 0, 2, 5, 10 or 25 times to participants. Participants subsequently rated how "good" or "bad" the meaning of the Chinese characters, or of the nonsense words was, and how much they liked the person shown in the photographs. For all three kinds of stimuli, participants' ratings became more positive with increased number of presentation. Many studies have since replicated and extended this basic effect, suggesting that the mere exposure effect is a very robust phenomenon (Bornstein, 1989).

Thus, it is possible that external conceptual organization that conforms with one's own representational structure is perceived as more familiar, and therefore, as more pleasing. Perhaps our results may be regarded a *representational mere exposure effect*, where the highest positive valence is assigned to those conceptual organizations that have the highest degree of familiarity. In this regard, it is instructive to review the explanations that have been put forward to explain the mere exposure effect.

Some have proposed that fluency of cognitive operations can explain why people like things better the more often they experience them. Fluency refers to properties of continuous information processing, such as the speed, or ease of processing (Jacoby, Kelley, & Dywan, 1989). These properties emerge as a feature of the *process*, rather than the *content* of cognitive functioning (Winkielman, Schwarz, Fazendeiro, & Reber, 2003). Generally, high fluency, that is, fast and effortless processing of information, signals positive states of the environment, and of one's cognitive processes. As a consequence, fluency can result in positive affect, as well as positive evaluations of target stimuli toward which fluency is experienced. Research on this effect has generated compelling evidence for the fluency hypothesis (Winkielman et al., 2003).

Further, studies involving affective evaluations in particular demonstrate an asymmetric effect, such that only positive evaluations, but not negative evaluations, are influenced by fluency manipulations, regardless of how questions concerning the ratings are worded. For instance, Reber et al. (1998) found that high fluency led to increased judgments of liking and decreased judgments of disliking. Similarly, Winkielman and Cacioppo (2001) instructed half of their participants to report positive affect, and half of the participants to indicate negative affect after a fluency manipulation. Only those reporting on positive affect showed increased positive affect when exposed to high fluency, whereas those reporting negative affect did not show such an effect. Our finding that congruence between spatial and conceptual dimensions led to increased positive ratings even for negative words is consistent with this documented asymmetric effect where only positive evaluations increase as a function of fluency, but not negative evaluations.

An additional finding in the present study was that not only words in the congruent "+ +" conditions, but also words in the congruent "- -" conditions were rated more positively than words in the incongruent "+ -" "- +" conditions. Other data are consistent with the present finding that sometimes two negatives combine to make a positive, so to speak. For instance, according to the *affective certainty* model (Tamir, Robinson and Clore, 2002), when personality traits match with current affective states, people experience facilitated performance on motivationally relevant cognitive tasks. Thus, people who are generally happy, and who found themselves in a happy mood, were more successful at processing affectively valenced information, but the same was true of people who are generally unhappy and found themselves in an unhappy mood, compared with people who are in conflict regarding their beliefs about themselves, and their actual experiences. Similarly, in the present study, more fluency, and therefore higher positive ratings was the result of a lack of representational conflict between the source domain and the

target domain, even if that meant that neither of the target domains could be mapped onto the source domain.

In conclusion, we found that "metaphorical" mappings between inherent spatial and conceptual relations can produce an additional layer of complexity, where the confluence of source domain and target domains has emergent affective properties: Both good and bad things are evaluated as more positive when an explicit spatial representation fits with implicit conceptual structure. In such situations, metacognitive processes involving perceived fluency provide information that goes well beyond representational content itself.

Abstract

A necessary condition for correctly assessing causality is the absence of confounding causes. This set of experiments assesses whether people are sensitive to confounding when they infer causation. Two stories were constructed, one in which two candidate causes and an outcome perfectly covaried (confounded), and one in which one candidate cause occurred independently of a second candidate cause that perfectly covaried with an outcome (unconfounded). If people reason by forming contrast groups that hold alternative causes constant, then in the confounded case, subjects should say that it is impossible to determine causality when two candidate causes are confounded. In the unconfounded case, subjects should be able to say that the candidate is causal. If people are not sensitive to confounding, then they should attribute causality to both candidates in the confounded case, and the results for the target candidate should be the same as those in the unconfounded case. This experiment was conducted with children and adults. Children saw one of the two conditions, while adults saw both conditions. Both children and adults make a distinction between confounded and unconfounded causes when making attributions of causality. Our results show that children are able to state the indeterminacy of confounded causes at an age much earlier than previously documented.

Introduction

One view of how children learn is that they approach the world as scientists and form theories about the world (e.g. Gelman, 1996) using information about variation and covariation to establish causal connections (Gopnik, Sobel & Schulz, 2001). Further, they intervene upon the world in order to discover these relationships (Schulz, 2003). Although children may have misconceptions in their explanations, as when a child states that he thinks God made the sun out of gold and lit it with fire (Siegler, 1998), the presence of such misconceptions does not mean that children are unable to use the data present in the environment to form correct causal attributions. Given that adults have had many more experiences than children, we should not expect children's theories to be the same as adult's theories, especially for complex phenomena. What is important is whether the same process is utilized when determining causality. In particular, this paper seeks to examine whether both children and adults are sensitive to confounding when there are two candidate causes for a novel outcome.

As well as being a potential means of improving science instruction and for examining whether children assess causality in the same manner as adults, assessing children's sensitivity to confounded causes is also important for differentiating between two models of causal attribution: the unconditional ΔP model (Jenkins & Ward, 1965), and the focal sets approach (Cheng and Novick, 1992).

Under the unconditional ΔP model, people compare the frequency of e, an effect of interest, when c, a potential cause, is present, with the frequency of e when the potential cause is not present:

$$\Delta P = P(e|c) - P(e|\sim c)$$

If ΔP = 0, then the candidate is considered noncausal; if ΔP is noticeably greater than 0, then the candidate is thought to cause the outcome, and if ΔP is noticeably less than 0, the candidate is thought to prevent the outcome. In the unconditional version of this model, people ignore confounding and pool over all the information known about the candidate cause. Using this formulation, if both candidate causes perfectly covary with each other and the outcome, then both will be judged as causal. Under the focal sets approach, the same formula can be used, but is evaluated only when comparing across groups where alternative causes are held constant. If people utilize the focal sets approach, they could make a determination when no confounding was present, but would be indeterminate in the case of perfect covariation because no focal set could be formed.

One study looking at third, sixth and ninth graders, as well as non college young adults and undergraduate college students found that before the ninth grade, students were unlikely to state that there was insufficient evidence to determine causality when there is confounding (Kuhn, Amsel, O'Loughlin, 1988). But, these experiments involved causes for which the students were likely to have prior theories, and people interpret ambiguous data in ways that are consistent with their prior beliefs (Darley & Gross, 1983). Kuhn et. al. do not indicate whether students who did not notice the indeterminacy were answering in a manner consistent with their prior theory. Also, this set of studies

focuses on the coordination of theory and evidence, and one of criteria used for assessing student's answers was their ability to justify their responses. If this is an unconscious process, students might be sensitive to the differences between conditions, yet unable to justify their responses. In the present study, the task is made much simpler, by presenting the students with a novel effect and asking for their causal attribution without asking for a justification.

Data from two experiments are presented. Both experiments assess whether people differentiate between confounded and unconfounded causes. In one experiment, the subjects are undergraduates, while in the other experiment the subjects are pre-school age children. In both experiments, participants were presented with two possible causes for a novel event, and were asked to determine the cause of the novel event. In one condition the two possible causes were independently occurring, while in the other conditions, the two candidate causes always occur together. If people are sensitive to confounding they should be able to make a causal attribution in the first condition but not the second.

Methods

These experiments were designed to assess the extent to which people are sensitive to the independent occurrence of potential causes of an effect when making judgments of causality. The first experiment was conducted on adults. Even if adults are able to succeed in this task, it could easily be due to prior training. The second experiment was conducted on children. The similar materials were used for both experiments. Below we describe the methods for both experiments before reporting the results.

Experiment 1

Participants 10 undergraduates at the University of California, Los Angles enrolled in the Introduction to Psychology Course participated in the study. Students receive class credit for participating in the study and were recruited using an on-line bulletin board for this course.

Design This experiment had two conditions and utilized a within subjects design. In one condition, the two possible causes of an unusual event were perfectly correlated (confounded). In the other condition, the same two possible causes occurred independently of one another. Subjects were asked about the causality of the candidate causes in turn. The ordering of the stories, as well as the order in which the subject was asked about each candidate cause, was counterbalanced across subjects.

Materials Two passages of approximately the same length were constructed, (one story was 668 words and the other was 681 words). Both passages tell the story of bunny rabbits that went to two different parties.

In both stories, the parties occur at the same time and on the same day. The day of the party, half of the bunnies ate candy. At one of the parties the bunnies ate cake, while at the other party they did not. In the confounded condition all the bunnies who ate candy also ate cake, in the non-confounded condition half of the bunnies who ate candy also ate cake, and vice versa. All the bunnies at the cake party grew new pink wings; none of the bunnies at the "no cake" party did. Two avoid confusion between the two stories, in one story, the bunnies ate green grass candy and yellow cheesecake; in the other story the bunnies ate blue berry candy and orangey orange cake.

At the end of the story, participants were asked about the causality of each of the causal candidates in the story.

1) Does Yellow Cheese Cake/ Blue Berry Cake all by itself make bunnies grow new pink wings? Yes, No, Impossible to tell.
2) Does Green Grass Candy/ Orangey Orange Candy all by itself make bunnies grow new pink wings? Yes, No, Impossible to tell.

The text of the story was accompanied by illustrations, with an appropriately colored wedge in the bunnies' stomachs representing the cake, and a candy shaped object in the bunnies' stomach representing green grass candy.

Because we were attempting to revise the stimuli in order to make the directions clearer for the children, the stimuli underwent slight modification across the 10 subjects. The conditions remained the same, but there were slight changes in wording and pictorial presentation across groups.

The stories were shown as a power point presentation on a 15" computer screen.

Procedure Participants were randomly assigned to conditions that differed based on the ordering of the stories and assessment questions. Participants were then told that they were going to hear a story about bunny rabbits in two little bunny towns; that something interesting was going to happen to these bunny rabbits, and that they were going to try to figure out what happened.

Participants looked at the illustrations on the screen as the experimenter read the story aloud. At the end of the story, participants were asked about the causality of each of the causal candidates in the story.

The experimenter wrote down their answers on an answer sheet as they progressed through the story.

Experiment 2

Participants 16 pre-school children from the Bellagio day care center at the University of California, Los Angeles participated in the study. Nine male and seven female children between the ages of 4;5 and 5;7, with a mean age of 4;11 participated in the study. One student was excluded from the analysis for answering incorrectly on questions about the facts of the stories presented. The rest of the students answered all of the questions correctly (as explained later).

Design This experiment had two conditions and utilized a between subjects design. In one condition, the two possible causes of an unusual event were perfectly correlated (confounded). In the other condition, the two possible causes of an unusual event occurred independently of one another. The order in which children were asked about each candidate cause was counterbalanced across conditions.

Materials The stories presented to the children had the same content as the stories presented to the adults, with two differences. In both conditions, children saw green grass candy and yellow cheesecake. (This was possible because subjects only saw one story, which ruled out the possibility of carryover between stories.) The children's assessment procedure also differed from that of the adults.

Children were first asked for their spontaneous attribution. "Do you think that it is possible to figure out why the bunnies grew new pink wings?". If the child answered yes then the following questions were asked.

1) Why do you think these bunnies [pointing to those who went to the cake party] grew new pink wings?
2) Why do you think these bunnies [pointing to those who went to the no cake party] did not grow new pink wings? The ordering of these two questions was counterbalanced across conditions.

Because children sometimes do not answer in the free response, do not address both of the causal candidates, or do not address the causal candidates in their responses (i.e. "Bunnies grew wings because they wanted to"), additional probes were added, asking about each of the candidate causes separately. Children were told about statements that other children had made while reading this story. Children were asked to say whether they thought these statements were "definitely right, definitely wrong, or impossible to tell." The statements they were asked to judge were

1) GREEN GRASS candy all by itself makes bunnies grow pink wings.
2) YELLOW CHEESE CAKE all by itself makes bunnies grow pink wings.
3) YELLOW CHEESE CAKE and GREEN GRASS candy together make bunnies grow pink wings.

If the child had previously indicated that the yellow cheesecake was causal, they were not asked about the yellow cheesecake again, (and the same for the other candidates).

Procedure Children were randomly assigned to conditions. Children were video taped during the session. In order to accustom children to the camera, they were first introduced to the camera and allowed to see themselves on the LCD screen. Children were then told that they were going to hear a story about bunny rabbits in two little bunny towns; that something interesting was going to happen to these bunny rabbits, and that they were going to try to figure out what happened.

Participants looked at the illustrations on the screen as the experimenter read the story aloud. At the end of the story, children were asked 4 questions to assess whether they understood and remembered the content of the story. The experimenter pointed to a picture of the bunnies with the candy in their tummies and asked "What did these bunnies eat?", the correct answer being candy (or cake and candy in the confounded case). The experimenter then pointed to the bunnies without candy in their tummies and asked "Did these bunnies eat candy?", the correct answer being no. The experimenter then pointed to a picture of the bunnies at the cake party and asked "What did these bunnies eat at the party?" (this question was omitted in the confounded condition if children answered cake and candy to the first question above), the correct answer being cake. The experimenter then pointed to a picture of the bunnies at the no-cake party and asked "Did these bunnies eat cake?", the correct answer being no. Children who did not correctly answer all questions were excluded from the study.

Results

Experiment 1

Adults subjects were sensitive to confounding when they make causal judgments. In the confounded condition, when asked whether cake caused new pink wings, all 10 subjects said it was impossible to tell. When asked whether candy caused new pink wings, all 10 subjects said it was impossible to tell. In the unconfounded condition, when asked whether cake caused new pink wings, 8 subjects said cake did cause pink wings (the correct answer); 1 subject said it was impossible to tell; and 1 subject said cake did not cause pink wings. When asked whether candy caused pink wings, 6 subjects said candy did not cause pink wings (the correct answer); 4 subjects said it was impossible to tell.

Using McNemar's test for 2-related samples of categorical data, we see that the pattern of responses differed across conditions for both of the causal candidates. Subjects were more likely to say the cake was causal in the unconfounded condition than in the confounded condition, and more likely to say it was impossible to assess causality in the confounded condition than in the confounded condition ($p < 0.05$, exact statistic, binomial distribution used). Subjects were more likely to say that the candy was not causal in the unconfounded condition than in the confounded condition, and were more likely to say it was impossible to tell in the confounded condition than in the unconfounded condition ($p < 0.05$, exact statistic, binomial distribution used).

Using a χ^2 for each set of data, we see that subjects are picking the response that corresponds with the focal set theory reliably better than chance in most cases. Each of following χ^2 analyses uses three cells, corresponding to the three possible responses for the task (yes, no , impossible to time). In the confounded condition, subjects all said that it was impossible to tell if the cake was causal ($\chi^2 = 20$,df=2, $p<0.05$) and it was impossible to tell if the candy was causal ($\chi^2 = 20$,df=2, $p<0.05$). In the unconfounded condition, subjects were more likely to say that the cake was causal

than any other answer choice ($\chi^2 = 9.8$,df=2, $p<0.05$). None of the subjects said the candy was causal ($X^2 = 10$, df=1, $p<0.05$) and were evenly split between saying the candy was not causal or that there was not enough information to assess the relationship.

Experiment 2

Children were also sensitive to confounding when they make causal judgments, but this data has more variability associated with it than the adult version of the experiment.

Children were categorized into one of five causal attribution categories: the cake is causal, the candy is causal, both causal (jointly or independently), it is impossible to tell, and other causal attribution. If children made a spontaneous causal attribution, this was taken as the value for the measure. Otherwise, the value for this measure was taken from the child answers to questions about each individual candidate.

Using a χ^2 analysis for this data, we see that the pattern of responses differed across conditions, ($\chi^2 = 10.18$,df=4, $p<0.05$). In the confounded condition, 3 children said both were causal and 4 children said it was impossible to tell. No other responses were given by children in the confounded condition. In the unconfounded condition, 4 children said cake was causal, 1 child said candy was causal, 2 children said they both were causal, and one child gave an alternate attribution. No children said that it was impossible to establish causality.

Conclusions

Both children and adults make a distinction between confounded and unconfounded candidate causes when making attributions of causality. All adults said that it was impossible to tell whether the cake or the candy alone caused the wings in the confounded conditions. Because the conditions used in this experiment are consistent with examples used in scientific methodology classes, it is possible that the adults have had prior experience in science classes that train them to be able to do this. The same is not true of the children, however.

The child data suggests that children are able to state that is impossible to attribute causality when two candidate causes perfectly covary at a much earlier age than documented by previous studies. Children as young as 4 years old, less than a third as old as previously believed, made such attributions. They were also able to use frequency data to make a causal attribution.

The difficulty in using data to prove that a theory is correct or incorrect may not be due to student's inattention to confounded causes. Instead, it may be that that having to justify their responses, or an interaction with prior knowledge is the problem. When introducing children to the abstract idea of confounding, it may be useful to build of their intuitions of causal attribution by first having them make judgments of potential causes of novel effects. Their answers to these problems could then be used as a basis for discussion about the abstract concept of confounding.

Teaching Structural Knowledge in the Control of Dynamic Systems: Direction of Causality makes a Difference

Wolfgang Schoppek (wolfgang.schoppek@uni-bayreuth.de)
Department of Psychology, University of Bayreuth
D-95440 Bayreuth, Germany

Abstract

Recent publications about humans controlling dynamic systems have emphasized the role of specific rules or exemplar knowledge. Although it has been shown that small systems can be controlled with these types of knowledge, there is evidence that general knowledge about the structure of a system plays an important role, too, particularly when dealing with systems of higher complexity. However, teaching structural knowledge has often failed the expected positive effect. The present work investigates details of acquisition and use of structural knowledge. It is hypothesized that guiding subjects to focus on dependencies rather than effects supports them in applying structural knowledge, especially when the application is practiced in a strategy training. An experiment with N=95 subjects supported the hypothesis of the usefulness of the dependency perspective, but revealed an adverse effect of the strategy training. Differences between subgroups studying different majors have been found that give rise to questions about the relation between prior knowledge and instruction. The results have interesting implications for models of how structural knowledge is represented as well as for methods of teaching system control efficiently.

Humans have to deal with dynamic systems throughout their lives. Especially in industrial environments, people are confronted with new systems such as production lines frequently. Therefore it is worthwhile to study how humans learn to control dynamic systems, and how instruction can support the learning process.

In cognitive psychology, a common paradigm for studying the control of dynamic systems can be characterized by the following features: The systems simulate some fictitious device or environment that most people have no specific experience with (e.g. a tank with sea animals in a biology lab, used by Vollmeyer, Burns, & Holyoak, 1996). This is to ensure an equally low level of prior knowledge. Discrete linear additive equations are used for simulation, one equation per output variable. There is the opportunity to assign values to the input variables in each simulation step, which is referred to as "trial". A number of trials, e.g. six simulated hours, make up a "round". The objective for participants is to attain a specific goal state either at the end of a round, or as soon as possible and to maintain the state. A prominent, yet simple example is the "Sugar Factory" (Berry & Broadbent, 1984) that has been used to investigate questions about implicit vs. explicit knowledge and about rule vs. exemplar learning (e.g. Dienes & Fahey, 1995; Fum & Stocco, 2003; Lebiere, Wallach, & Taatgen, 1998)

Research with this paradigm has shown that subjects largely prefer acquiring and using exemplar knowledge rather than structural knowledge, i.e. subjects memorize specific actions taken in specific situations together with their outcomes. This strategy can be successful under certain conditions: First, when the system has a small problem space like, for example, the Sugar Factory (144 states); second, when the same goal state has to be attained repeatedly (Vollmeyer et al., 1996), which means that only a small fraction of a possibly large problem space is relevant. Simulation studies with the Sugar Factory have shown that it can be successfully controlled by using either declarative representations of specific actions (Lebiere et al., 1998), or learned production rules that also represent specific interventions (Fum & Stocco, 2003). In conditions, however, where subjects have to deal with huge problem spaces (e.g. because the system is more complex and subjects have to attain a number of different goal states), the exemplar strategy is no longer useful[1]. Instead, it is more reasonable to use general knowledge about the causal structure of the system to navigate through the problem space. I will refer to this type of knowledge as "structural knowledge".

In principle, complete structural knowledge is sufficient to control a system even without specific experience. Although correlations between structural knowledge and performance have been reported (Funke, 1993), experiments where structural knowledge was taught, usually failed to demonstrate its superiority (Putz-Osterloh, 1993; Schoppek, 2002). One reason for this is that deriving

[1] The inclination to use exemplar knowledge even when it is inappropriate may explain why subjects generally perform at very low levels when they are asked to control complex dynamic systems that are new to them.

specific actions from structural knowledge is a skill that has to be practiced in addition to learning the structure. This view is corroborated by results from studies where the application of structural knowledge has been practiced extensively (Preussler, 1998). A second reason for the difficulties of applying structural knowledge is that knowledge about causal relations is acquired under a different perspective than it is applied when controlling a system. This issue is elaborated in the following paragraphs.

Verbal protocols of successful system controllers and simulation studies (Schoppek, 2002) have helped identify efficient strategies for acquisition and application of structural knowledge. A good strategy for exploring the causal structure of a system is to vary input variables one at a time to identify the immediate effects of the input variables and the momentum of the system, which is produced by effects of output variables onto each other. For example, a subject could put some lime into the animal tank to observe the effect onto the oxygen content of the water, then set lime input back to zero and observe how the oxygen content changes on its own.

A common application strategy starts with (1) predicting the next state of the system under the assumption of no interventions, continues with (2) calculating the differences between the predicted and the desired state, (3) selecting a free input variable, (4) calculating the input value, and ends with (5) applying the intervention. In the course of this strategy, for each output variable all their dependencies are considered in turn. This consideration of dependencies is a marked difference compared with the focus on effects that is prevalent during acquisition of structural knowledge.

Thus we can distinguish two perspectives on causal relations: One looking for effects of a given cause, the other looking for possible causes of a given effect. The first perspective is prevalent during exploration of a new system, the second is more adaptive during system control. In the following, I will use the word “effects” to characterize constructs related to the first perspective, and “dependencies” to characterize the second perspective.

The distinction of perspectives on causal relations has a number of implications. The first has to do with the question what given information cues the retrieval of what other information. During exploration, when input variables are manipulated and effects are observed, associations from cause to effect are learned, resulting in a structure where representations of input manipulations act as cues for representations of changes in output variables. When the task is to control a system and the dependencies of output variables are considered, output variables should be learned as cues for input variables.

A second implication concerns the mechanism of chunking, which plays an important role in successful problem solving (Newell, 1990, Gobet & Simon, 1996). The effect perspective suggests chunking together single effects of a variable (which can be an input or an output variable), whereas the dependencies perspective suggests chunking together all dependencies of an output variable. Again, the second possibility seems to be more adaptive in system control, because having all dependencies in one chunk relieves the problem solver from extensive memory search, a process that consumes much time, poses high demands on working memory, and is thus error prone.

A second issue in the context of helping humans to use structural knowledge has to do with strategy instruction. Undoubtedly, extensive practice under supervision of experienced operators is effective, but also very costly. Thus it is important to find ways of leveraging structural knowledge efficiently. The way followed here was to base a training program on a strategy that has proven successful in a computer simulated cognitive model of controlling a system similar to the present one (Schoppek, 2002).

To summarize, the aim of the present work is to investigate ways of teaching structural knowledge about dynamic systems, either indirectly by manipulating the perspective on causal relations, or directly by practicing the application of structural knowledge. Specifically, I tested the hypothesis that guiding subjects to focus on dependencies rather than effects enhances performance. By measuring access to causal knowledge with a speeded judgment task I investigated if the different perspectives are also reflected in the representation of structural knowledge. The results may show new ways of teaching structural knowledge and extend our understanding of the use of this type of knowledge.

Experiment

The system I used in this experiment is a simulation of the influences of three fictitious medicines onto the levels of three fictitious peptides in the blood. The medicines are called MedA, MedB, and MedC; the peptides are called Muron, Fontin, and Sugon. The effects of the substances onto each other are simulated with the following discrete linear equations:

(1) $\text{Muron}_t = 0.1\ \text{Muron}_{t-1} + 2\ \text{MedA}_t$

(2) $\text{Fontin}_t = \text{Fontin}_{t-1} + 0.5\ \text{Muron}_{t-1} - 0.2\ \text{Sugon}_{t-1} + \text{MedB}_t$

(3) $\text{Sugon}_t = 0.9\ \text{Sugon}_{t-1} + \text{MedC}_t$

In a neutral state with Muron = Sugon = 0 and Fontin = x, the system is stable. Once some of the medicines are administered, the system gains momentum. Note that the

amount of Fontin in the blood can only be reduced through Sugon, which depends on MedC. Since Sugon decomposes slowly, large time delays of changes in medication have to be dealt with. Subjects interacted with the system through an interface consisting of two tables showing the states of the variables in all trials, and input boxes where they could enter values for the medicines. One round comprised six trials, introduced to the subjects as "simulated hours".

Structural knowledge was tested with a speeded causal relation judgment task. All names of input and output variables were shown on a screen in a spatial arrangement that matched that of the simulation interface. This was done to assure that variables could be identified by both, their names and their locations. Then the name of an output variable was highlighted on the right side of the screen, followed by the highlighting of another variable name on the left side with an ISI of 500 ms. The subject was asked to respond with pressing one of two keys as quickly and accurately as possible to indicate her judgment if there was a causal relation between the highlighted variables or not. All 18 possible input-output and output-output relations were shown in one test. Eight of these relations had to be answered with yes, 10 with no. The procedure was arranged such that knowledge of dependencies should result in faster judgments compared with pure knowledge of effects. This is expected because the variable that was highlighted first (the effect) is assumed to act as a prime for the variable highlighted second (the cause) only when causal relations have been memorized under the perspective of dependencies.

Subjects and Design

N=95 subjects, studying different majors at the University of Bayreuth, participated in the experiment. Subjects were paid 10 € for their participation.

The factor "type of knowledge" with the levels "knowledge of effects" (Eff) and "knowledge of dependencies" (Dep), and the factor "strategy training" with the levels "no training" and "training" were varied between subjects. A third, quasi-experimental factor "field of study" with the three levels arts/humanities, law/economy, and science was also analyzed. In principle, subjects were randomly assigned to one of the four conditions. A few exceptions from complete randomization were due to the objective to have approximately equal distributions of field of study in each condition.

Procedure

The experiment began with a general instruction about the system. All subjects went through a standardized exploration phase guided by the experimenter. The exploration was designed to demonstrate all causal relations between the variables of the system. Subjects were guided to analyze the observed effects and asked to enter them in cards provided by the experimenter. The procedure in this phase was different for the two knowledge conditions: In the Dep condition, the experimenter consistently asked for dependencies, and the cards were sorted by the "dependent" variables Muron, Fontin, and Sugon. In the Eff condition, the experimenter consistently asked for effects, and the cards were sorted by the "independent" variables MedA, MedB, and MedC. At the end of this phase, the experimenter examined the knowledge of the subject orally, again consistently asking either for dependencies or for effects. Subjects had to recall all possible relations with the respective numeric weights before moving on to the next phase (all subjects achieved that).

Subjects in the "no strategy training" condition could then explore the system for one round (six simulated hours) on their own. Subjects in the "strategy training" condition went through a number of exercises where they practiced a method of predicting future states of the system. As mentioned above, this was the first part of a strategy tested earlier in a cognitive model. Only a part of the complete strategy was selected to keep the training short. Nevertheless, all effects (condition Eff) or dependencies (condition Dep) were needed and rehearsed in these exercises.

Next, all subjects were given the control problems. All problems comprised six simulated hours and were given with the objective that the goal states had to be reached as soon as possible, and to be maintained. Table 1 shows the initial states and the goal states for the four control problems. Initially, all variables except Fontin were zero. In order for the subjects to familiarize themselves with the control task, they were given two rounds for Problem 1.

Table 1: The four control problems given to the subjects

Problem 1: Fontin = 50	→	Muron = 200 , Fontin = 1000
Problem 2: Fontin = 900	→	Muron = 100
Problem 3: Fontin = 2000	→	Fontin = 1000
Problem 4: Fontin = 50	→	Muron = 400 , Fontin = 900

Results

To measure control performance, the solution error was calculated by summing the natural logs of the absolute differences between the goal values and the actual values for each time step of a round (Müller, 1993). A perfect solution is indicated by a solution error of zero. Since the results of Problem 2 were close to ceiling, they were excluded from the analysis. I analyzed the mean solution error of the remaining problems as dependent variable in

an ANOVA with the factors "type of knowledge" (knowledge about effects, "Eff" vs. knowledge about dependencies, "Dep"), "strategy training" (with vs. without training), and the quasi-experimental factor "field of study" of the participant (arts/humanities, law/economy, science). The means aggregated across all fields of study are listed in Table 2.

The ANOVA yielded significant main effects of all three factors, "type of knowledge" ($F = 3.94$, $df = 1$, $MSE = 5.57$, $p = .05$), "strategy training" ($F = 5.97$, $df = 1$, $MSE = 8.45$, $p < .05$), and "field of study" ($F = 13.24$, $df = 2$, $MSE = 18.75$, $p < .01$). As expected, subjects who were guided to acquire knowledge of dependencies were more successful in controlling the system (mean solution error = 2.1, SD = 1.3) than subjects who were guided to acquire knowledge of effects (M = 2.6, SD = 1.5). Contrary to expectation, subjects who underwent the strategy training performed lower (M = 2.6, SD = 1.5) than those without strategy training (M = 2.0, SD = 1.3). Subjects studying arts or humanities performed worst (M = 3.2, SD = 1.4, n = 33), followed by subjects studying law or economy (M = 2.3, SD = 1.2, n = 30). Most successful in controlling the system were science students (M = 1.6, SD = 1.1, n = 32).

There is a significant interaction between "field of study" and "type of knowledge" ($F = 3.29$, $df = 2$, $MSE = 4.65$, $p < .05$). Detailed analyses revealed that a strong effect of "type of knowledge" was only present in the group of subjects who studied arts/humanities (see Figure 1). No other effects reached statistical significance (all $p > .05$).

Table 2: Solution error of system control in the various conditions of the experiment

		Eff	Dep	
Strategy training	yes	**2.9** (1.5) n = 24	**2.4** (1.5) n = 26	**2.6** (1.5) n = 50
	no	**2.4** (1.5) n = 22	**1.7** (0.9) n = 23	**2.0** (1.3) n = 45
		2.6 (1.5) n = 46	**2.1** (1.3) n = 49	**2.4** (1.4) n = 95

To test the expectation that knowledge of dependencies results in faster response times in the speeded structural knowledge test, I calculated an ANOVA with the same factors as described above and the mean response times for hits in the first test as dependent variable. (Three subjects with mean response times of greater than 3800 ms were excluded from the analysis. Raw values were ln-transformed for the ANOVA). The expected effect of

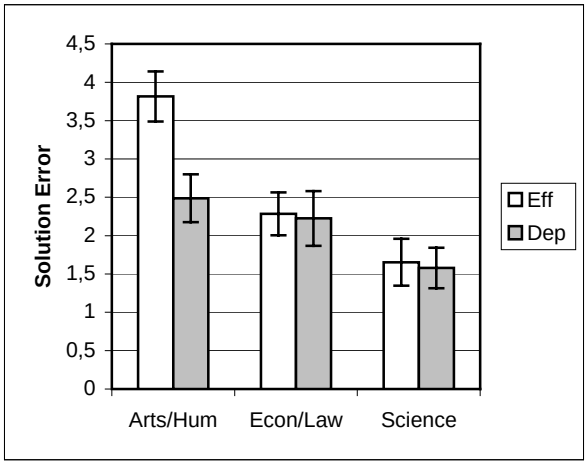

Figure 1: Means and standard errors of solution error of controlling the system (smaller values indicating better performance)

"type of knowledge" was confirmed by the analysis ($F = 7.83$, $df = 1$, $p < .01$), (1559 ms vs. 1237 ms, Dep faster). However unexpectedly, there was also a main effect of "strategy training" ($F = 11.24$, $df = 1$, $p < .01$), (1576 ms vs. 1236 ms, with training faster). No other effects were significant at the level of $\alpha = .05$. The results of the second structural knowledge test were analogous to the first test.

Similar analyses with the discrimination index (an index of how well subjects can discriminate between relations and no relations, cf. Snodgrass & Corvin, 1988) as dependent variable yielded no significant effects. Discrimination indices were relatively high in all conditions (di = 0.89).

Discussion

The experiment has confirmed the hypothesis that guiding subjects to focus on dependencies of output variables rather than on effects of input variables can enhance performance in controlling a complex dynamic system. Although there is an effect in the complete sample, the major contribution came from the subjects studying arts/humanities. Presumably, this group has the least experience with abstract representations of dynamic systems and thus learned something new when focusing on dependencies instead of effects. If the other groups did not benefit from the manipulation because they take the dependencies perspective on their own, or because of some other strategy cannot be told with the present data.

The results of the speeded causal judgment task indicate that focusing on dependencies vs. effects affects the

mental representation of causal relations. The task was arranged to enable priming from output to input variables, but not the other way round. Subjects in the Dep condition were significantly faster in judging the relations, supporting the assumption that they have established stronger associations between output to input variables than subjects in the Eff condition.

The two findings are raising the question about their relation. Are these stronger associations a cause for better performance or are they just a side effect of the experimental manipulation? If the relation was causal, there should be a substantial (negative) correlation between response time in the causal judgment task and solution error in the control problems. The respective correlation is r=.05 in the whole sample. Hence, the faster reaction times in the Dep condition are probably a side effect of the manipulation. This, in turn, supports the hypothesis that the positive effect of knowledge of dependencies on performance is based on the chunking aspect, i.e. the integration of single effect representations according to output variables. It is possible that especially science students have built such chunks on their own, even in the Eff condition. (Note that subjects in the Eff condition were not prevented from gaining knowledge of dependencies). Figure 2 shows a sketch of the hypothetical structure of a dependency chunk "Dep01" (the causal weights are omitted for clarity). The shaded substructure "Eff01" is a chunk that represents the single causal relation between MedC and Sripon. The structure, whose construction in a learning process appears straightforward, mirrors the equations defining the behavior of the system remarkably. The solid lines indicate slot-value relations. Dotted lines indicate the associations between the name of the dependent variable and names of influencing variables, which may have been learned under the Dep condition. These associations can explain the effects in the speeded judgment task, but are not necessary for the usefulness of dependency chunks in control tasks. This interpretation is in line with the assumption of Boucher & Dienes (2003) that there are two ways of learning associations, one resulting in activating relations, the other resulting in chunks that combine the associated information. Baker, Murphy and Vallée-Tourangeau (1996) suppose that these two ways may be attributed to different modules of the mind. Research on causal reasoning has discovered many other cases where concept-driven symbolic processing must be assumed in addition to pure associative learning to explain the phenomena (Waldmann, 1996).

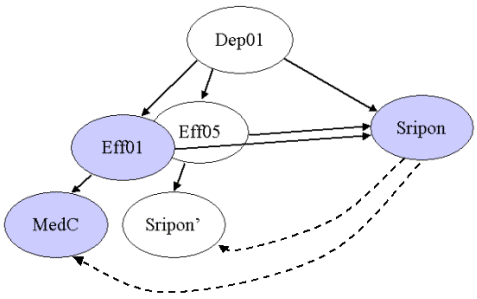

Figure 2: Hypothetical structure of a dependency chunk; solid lines indicate slot-value relations, dotted lines indicate associations.

Unexpectedly, the strategy training had an effect on answering speed in the causal judgment task (with training faster). According to the above interpretation subjects must have rehearsed relations between each output variable y and the variables affecting y during the training. In the Dep condition, this is obvious. Since in the Eff condition subjects were asked for all variables that had an effect on the output variable in question, they had to search memory for names of input variables while the name of the output variable was present in working memory. Thus, subjects have learned associations from output to input in that condition, too.

The adverse effect of the strategy training was also unexpected. The training had been inspired by results from cognitive tutoring that subskills can effectively be trained based on single production rules (Anderson, 1993), and thus, practicing only the most difficult part of a larger strategy appeared reasonable. However, the success of this kind of training depends on the compatibility of the practiced subskills with the subjects' own strategies. This condition seemed to be hurt in the present case. Subjects might have applied the practiced method of predicting the next state, and after successful completion were unclear about what to do next and how to use the result. An alternative explanation is that the practiced strategy has interfered with the subjects' own strategies, resulting in mixtures of incompatible strategy fragments. (see e.g. Vosniadou, 1997 for the difficulties of integrating new knowledge with prior knowledge).

In future efforts to train the application of structural knowledge it should be assured that subjects have at least an idea of the whole strategy. This could be achieved by introducing abstract labels for all subgoals and practicing the whole strategy at least once before possibly focusing on the most difficult part of it (Catrambone, 1998).

In general, the results of the experiment show that variations of structural knowledge do affect performance in the control of dynamic systems. This extends the view that mainly exemplar knowledge or very specific rules are used for controlling systems (Dienes & Fahey, 1995; Fum & Stocco, 2003; Lebiere et al., 1998). It is important to note that not knowledge about single causal relations as measured by the discrimination index of the causal judgment task makes the difference (there were no effects of the experimental factors on di), but rather the way of using it, obviously depending on prior knowledge, and the way of chunking it into larger units.

Acknowledgments

The research reported here was supported by the University of Bayreuth. I would like to thank the anonymous reviewers for valuable hints and Lucie Necasova, Tereza Kvetnova, and Nha-Yong Au for collecting the data.

Deductive rationality in human reasoning: Speed, validity and the assumption of truth in conditional reasoning

Walter J. Schroyens (Walter.Schroyens@psy.kuleuven.ac.be)
Laboratory of Experimental Psychology, University of Leuven

Abstract

We proffer the thesis that, in the process of defeating an inference on the basis of a factual truth that falsifies it, people move from a hypothetical truth-value to a factual truth-value of the conclusion. We will present evidence that shows (a) that some people spontaneously make a truth assumption and constrain their inferences to logically valid inferences, (b) that people tend to abandon the truth-assumption when they have factual evidence to the contrary, (c) that people, however, can and do in fact reason logically when they are informed about the rules of the language game (i.e., the truth-assumption) and (d) that adhering to the truth-assumption in the face of conflicting evidence to the contrary requires an investment of time and effort. The findings are discussed in relation to contemporary theories of human reasoning.

General Introduction

We all reason: We draw inferences from the multiple sources of information we are confronted with and make decisions based on them. This allows us to move around in a changing world where the capability to comprehend the contingent nature of our environment determines for a large part our successes as an individual, as well as a species. The study of human reasoning is therefore important to advance our understanding of the general mechanisms of thought.

The turn of the century has provided the stage of a paradigm shift in human reasoning research. The nineties provided the scene for polemical debates as regards basic human reasoning competence. This basic reasoning competence (i.e., the basic machinery that allows us to draw inferences) was mostly studied by means of abstract knowledge-lean inference problem. By using arbitrary relations (e.g., 'if the letter is an A, then the number is a 2") no content-specific background knowledge would be triggered to influence the reasoning process towards accepting or rejecting the conclusion. Abstraction was made of the specific content of that about which people were reasoning. It is within this research milieu that theories became specified as regards human deduction. In the study of human deduction one studies necessary inferences derived from certain premises. One asks people to draw logically valid inferences, and these are defined as inferences that must be necessarily true if the premises are true. Presently there is an increasingly prominent body of evidence that shows the pervasive influence of content and belief (Cummins et al., 1991). Our beliefs are uncertain (i.e., they are true to a certain degree: e.g., even Newton's mechanics are not universally applicable). This observation induced a shift towards the study of the subjective probabilistic properties of that about which we are reasoning as well as commonsense reasoning or reasoning under uncertainty.

The present research is situated within this timely clash between experimental paradigms and associated theoretical approaches. Theorists sometimes like to boost the polemics between dichotomized opposites (it does make for simpler, and hence more easily publishable reading). For instance, it is claimed that theories that have focused on reasoning under certainty (i.e., deductive reasoning) are incapable of being extended to reasoning under uncertainty (i.e., probabilistic reasoning). The 'core argument' (Oaksford & Chater, 1998) is that common-sense reasoning is non-monotonic, whereas logic systems are monotonic: valid inferences cannot be invalidated; they remain valid. The validity of everyday inferences however would be revisable. For instance, when being given the argument:

'If it is a bird, then it flies;
Tweety is a bird who, thus, can fly"
almost everybody will accept it. At the same time, when subsequently being told that Tweety is an ostrich, almost everybody will reject the original inference and will state that Tweety cannot fly.

The rationality debate in the cognitive science of human reasoning is partly muddled by a failure to distinguish the defeasibility of a conclusion from the non-monotonicity of an inference. For instance, Oaksford and Chater's (1998) core argument is subverted when taking count of the distinction between truth and validity. Monotonicity concerns the validity of inferences; defeasibility concerns the truth of conclusions and this "distinction between *validity* and *truth* … is basic to deductive logic [and] many people find the distinction difficult to grasp" (Glass & Holyoak, 1986, p. 338). The abovementioned definition of logical validity use the notion of truth but the truth of a valid conclusion is always hypothetical (*if* the premises are true, then the conclusion must also be true). The truth-value of a defeated inference however is not hypothetical. It is factual: it hinges on a factual truth (i.e., our belief, at a particular moment in time and space that something is true in the 'real' world).

The present study intends to show the importance of the truth-assumption and by consequence the hypothetical nature of the truth of logically valid inferences. We proffer the thesis that in the process of defeating an inference people move from a hypothetical to a factual truth-value of this conclusion. I present evidence showing (a) that at least some people make the truth-assumption and spontaneously constrain their inferences to logically valid inferences, (b) that people abandon a truth-assumption when they have factual evidence to the contrary, (c) that people, however, can and do in fact reason logically when they are informed about the rules of the language game (i.e., the truth-assumption) and (d) that adhering to the truth-assumption in

the face of conflicting evidence to the contrary requires an investment of time and effort. In the general discussion we will then return to the theoretical and conceptual issues that are touched by the evidence for people's propensity to exhibit deductive rationality in reasoning hypothetically on the basis of a truth-assumption.

Table 1
Formal representation and standard nomenclature of the four basic conditional inference problems and their default conclusions.

	Logically valid		Logically Invalid	
	Affirmation	Denial	Affirmation	Denial
Premises	Modus Ponens:MP	Modus Tollens:MT	Affirm consequent: AC	Denial Antecedent: DA
Major	[If p then q]	[if p then q]	[if p then q]	[if p then q]
Minor	[p]	[not-q]	[q]	[not-p]
Conclusion	[q]	[not-p]	[p]	[not-q]

Experiment

To investigate the truth-assumption in representing the information with which we are confronted and about which we reason, and its import apropos validity and deductive rationality in human reasoning we will make use of well-known content effects in conditional reasoning. In the following I first introduce these effects. Next, I present them within a dual-processing framework. This yields some additional predictions concerning the functional and temporal relations of two conceptually distinct types of reasoning (and the corresponding distinction between hypothetical versus factual truth).

Content Effects. Table 1 presents the most commonly studied conditional inference problems. These problems are formed by an affirmation or denial of the antecedent [p] or consequent [q] of a conditional of the form [if p then q]. The content of the conditional utterance can be almost anything, e.g.:

(1) If you turn the key, then the car will start.
(2) If you heat water to 100°C, then it will boil.
(3) If you push the brake, then the car will stop.
(4) If you jump into the swimming pool, then you'll get wet.

The content effects that are observed with such realistic conditional-inference problems show that the reasoning process is strongly affected by the factual truth of the premises and/or conclusion (Politzer & Bourmaud, 2002).

At a general level the content effects are summarized as an effect of the number of factual counter-examples. For instance, the conclusions for AC and DA are falsified by situations that reflect the possibility that the antecedent is false [not-p] while the consequent is nonetheless observed [p]. When the conditional captures a causal statement, such [not-p and q]-cases reflect *alternative causes*. For instance, when we ask people to generate alternative causes for conditionals (1) and (2), they generally come up with relatively few as compared to the number of alternative causes they can generate for conditionals (3) and (4). The conclusions of MP and MT are countered by situations that represent the contingency where [p] is satisfied whereas [q] is not satisfied. When the conditional enunciates a causal statement, such [p and not-q]-cases reflect *disabling conditions*. For instance, when we ask people to generate alternative causes for conditionals (1) and (3), they generally have little difficulty coming up with a relatively high number of factors that might prevent the effect from occurring. For conditionals (2) and (4) people can only come up with few disabling conditions. The most robust finding in reasoning with conditionals like (1), (2), (3) and (4) above, is that people are less likely to accept MP/MT when there are many (vs. few) disablers and are less likely to accept AC/DA when there are many (vs. few) alternatives.

We proffer the thesis that belief effects in conditional reasoning and the presumed problematical nature of these effects for systems of deduction are due to a failure to play the language game of deduction. When one does not ask people to assume that the premises are true, people are not asked to reason deductively. Studies that investigate content-effects in conditional reasoning often do not even mention the truth-assumption. This implies that no implications can be drawn as regards people's deductive rationality (i.e., their propensity or capability to infer logically valid inferences). To demonstrate the importance of the truth-assumption in deduction reasoning, we decided to stress the truth-assumption and its implication that any inference made under this assumption is hypothetically true. The experiment was set up so we could compare performance on problems that did not stress the truth-assumption with problems that did stress the truth-assumption.

Expectations are relatively straightforward. When people are reasoning on the basis of the truth-assumption they will exhibit more deductive rationality as compared to situations where they reason in an unconstraint context. Deductive rationality in the present study is measured by the proportion of inferences that are valid relative to the norm of classic logic. That is, when people reason in a stressed truth-assumption context, they will endorse more logically valid MP and MT inferences. The logically invalid AC/DA arguments would not be affected by an increased impetus the hypothetical nature of inferences made under the truth assumption. Indeed, the counterexamples to MP/MT would be excluded or impossible, if the conditional were true. However, the counter-examples to AC/DA (i.e., alternative causes) are consistent with a conditional utterance of the form [if p then q]. Indeed, the utterance "If you jump into

the swimming pool, then you'll get wet" does not say '*if and only if* you jump into the swimming pool, then you'll get wet". In sum, there should be an interaction between the logical-validity of the inference and the impetus that is placed on the truth-assumption.

Dual Processing. We noted that the present research is situated within the timely clash between experimental paradigms and associated theoretical approaches. Being faced with the task of reconciling the 'old' (deductive certainty) and the new (probabilistic uncertainty), there is an increasing popularity of so-called dual processing frameworks. There presently seems to be a growing consensus that a distinction can be made between two types of rationality, or systems of reasoning (see, e.g., Evans & Over, 1996; Johnson-Laird, 1983; Stanovich & West, 2000). Dual-process theories of reasoning draw on the distinction between, on the one hand, highly contextualized associative, heuristic, tacit, intuitive or implicit processes that are holistic, automatic, experiential in nature, and relatively undemanding of cognitive capacity and, on the other hand, de-contextualised, rule-based, analytic, explicit processes that are relatively slow, and demanding of cognitive capacity.

There is a commonality in almost all dual-processing theories. About the functional relation between the two reasoning systems it has been argued that there is a primacy of System 1 processes (Stanovich & West, 2000). Evans and Over (1996) similarly discussed the override function of System 2 (Explicit, Rationality-2 in their terminology). This functional relation parallels the distinction and relation between generate and test procedures (Chater & Oaksford, 1999) or, analogously, the conclusion formulation and validation stages proffered in the highly influential mental models approach to reasoning (Johnson-Laird, 1983; Johnson-Laird & Byrne, 1991, 2002). We can associate factual/probabilistic reasoning and hypothetical/deductive reasoning with respectively System-1 and System-2 thinking. The override function of System-2 as regards the output of System-1 consequently allows us to specify some additional expectations concerning the potential effect of stressing the truth-assumption.

In the dual-processing framework it is assumed that System-2 processes are secondary to the workings of System-1 processes. This implies that if we can inhibit system-2 thinking, the effects of its functionality will be reduced. That is, we would expect the effect of stressing the truth-assumption to be reduced under conditions that are not conducive to system-2 thinking. We can expect, the other way round, that when we can instigate system-2 thinking, the effect of its potential override function would be increased. This means that the effect of stressing the truth-assumption would be strongest under conditions that allow people to engage in the resource-dependent and time-consuming system-2 type of thinking.

We asked one group to reason as quickly as possible, thereby reducing the potential import of the system-2 thinking (see Schroyens, Schaeken, & Handley, 2003) and the expected effect of stressing the truth-assumption. A second group was asked to think carefully. Given that people are less likely to engage in system-2 thinking under speeded inference conditions (as compared to the standard-inference conditions), we can expect that the inhibitory effect of stressing the truth-assumption will be annulled. That is, the other way around, only people who have the time and motivation to engage in system-2 type thinking will exhibit the effect of stressing the truth-assumption.

Method

Design. Participants served as their own control as regards inference type (logically valid: MP/MT vs. logically invalid: AC/DA), the number of alternative causes (few vs. many), the number of disabling conditions (few vs. many), and the impetus that was placed on the truth-assumption (no vs. strong). A between-groups factor was formed by the impetus that was placed on speed vs. accuracy.

Materials. We collected 16 conditionals utterances for which people in a pre-test were able to generate few or many alternatives and few or many disablers (see, e.g., items 1-4 presented above). The set contained four items for each of these four types of conditionals with few/many alternatives/disablers. Each conditional served as the major premise for each of the four types of inference problems (MP/MT/AC/DA, see Table 1).

The inference problems were cast into two booklets. A first booklet contained the 32 items that did not mention the truth-assumption and a second booklet with 32 other items that stressed the truth-assumption. (The specific item content was counter-balanced across the two truth-assumption conditions). Each counterbalancing set contained two items of an MP/AC/DA/MT argument about a conditional with few/many alternatives/disablers (2x4x2x2=32). The non-stressed condition presented the problems as follows.

If you turn the key, then the car will start.
You turn the key.
It follows:
The car will start.

Participants marked their evaluation of this conclusion on a 7-point scale ranging from (1) very uncertain that the conclusion follows to (7) very certain that the conclusion follows. In the stressed truth-assumption condition the problem was presented in the following format:

If you assume that it would always be true that:
If you turn the key, then the car will start.
And you know for sure:
You turn the key.
Then it would follow:
The car will start.

Participants marked their evaluation of this conclusion on a 7-point scale ranging from (1) very uncertain that the conclusion follows if one assumes that the rule is true to (7) very certain that the conclusion follows if one assumes that the rule is true.

The instructions to the speeded inference conditions mentioned that they were to evaluate the problems fast and should not stay too long with any particular problem. After the 3rd and the 6th sheet of paper, with four problems per page, an extra page was inserted which reminded them that

they were to make their judgment 'as quickly as possible'. In the accuracy conditions this reminder said that they were to 'think carefully' and that their evaluations of the conclusions should be 'as accurate as possible'.

Procedure. Participants received both problem booklets at the beginning of the session (the standard problems first; the truth-assumption problems second). About half the students in each of two 11th and two 12th grade classes received the problems with speeded-inference instructions, whereas the other half received the accuracy instructions. The students in accuracy groups were told that the one who generated the most correct conclusions of a predetermined subset would receive 10 Euro. To the speeded groups it was said that the person who solved the problems fastest (at a minimum accuracy level) would also receive 10 Euro.

Participants. Participants were 72 11th and 12th grade student from a Belgian, Flemish high school. Thirty-four students received the speeded-inference instructions; the remaining 38 pupils ended up in the accuracy conditions.

Results

Certainty ratings (1-7) were transformed to the [0,1] probability interval and submitted to analyses of variance. Figure 1 presents the effect of alternatives on the logically invalid inferences (AC/DA), and the effect of disablers on the logically valid inferences (MP/MT) in the standard conditions that do not mention the truth assumption. These standard problems replicate the standard findings. First, the number of disablers affected the certainty ratings of the logically valid inferences: Participants are more certain that the conclusion follows when there are few counterexamples, .81 vs. .69; $F(1,70) = 53.06$, $p < .01$. Second, the invalid inferences also showed the standard counterexample effect of few vs. many alternatives: Participants rate the conclusions less certain when more counterexamples can be found for it, .81 vs. .60; $F(1,70) = 153.75$, $p < .01$. Figure 1 also shows that the counterexample effect is larger on the logically invalid inference, as compared to the logically valid inferences; $F(1,70) = 21.38$ $p < .01$.

Figure 2 shows the size of the counterexample effect (few vs. many) as a function of the timing constraint, logically validity and the assumption of truth. Figure 2 clearly shows that the counterexample effect on the logically valid inferences is reduced when people make the truth-assumption, $F(1,70) = 14.21$, $p < .001$, but only so when individuals reason without a timing constraint and focus on accuracy, $F(1,70) = 19.67$, $p < .01$. The counterexample effect does not approach significance in this condition, .866 vs. .853. The interaction between speed and truth at the level of the valid inferences was significant, $F(1,70) = 5.41$, $p < .05$. No such interaction was observed at the level of the invalid inferences ($F = .003$), and the third-level interaction indeed tended to approach statistical significance, $F(1,70) = 2.85$, $p < .10$. Specific comparisons showed that, as expected, the counterexample effect on the valid inferences re-appears when people evaluate the conclusions as fast as possible, .873 vs. .808: $F(1,70) = 9.66$, $p < .01$. That is, stressing the truth-assumption does not reduce the counterexample effect on the logically valid inferences when people are reasoning under a timing constraint ($F < 1$). At the level of the logically invalid inferences, we see an overall reduction of the counterexample effects, $F(1,70) = 13.22$, $p < .01$. This might suggest that stressing the truth-assumption tends to

Figure 1

Certainty ratings of the logically valid and invalid arguments under standard conditions that do not mention the truth assumption.

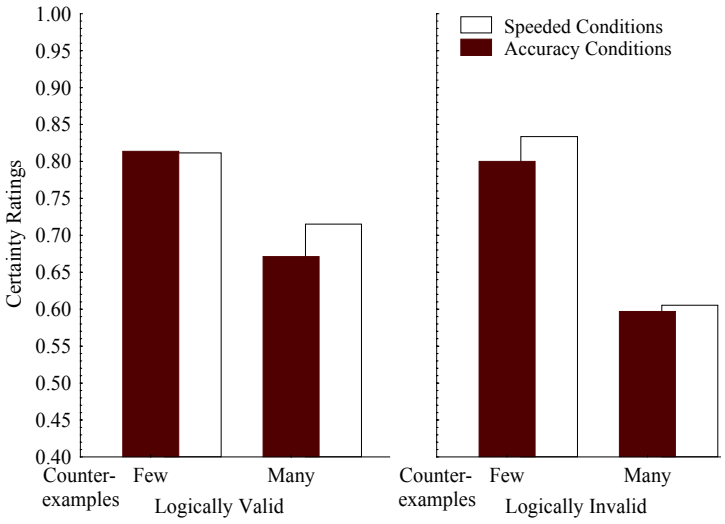

Figure 2

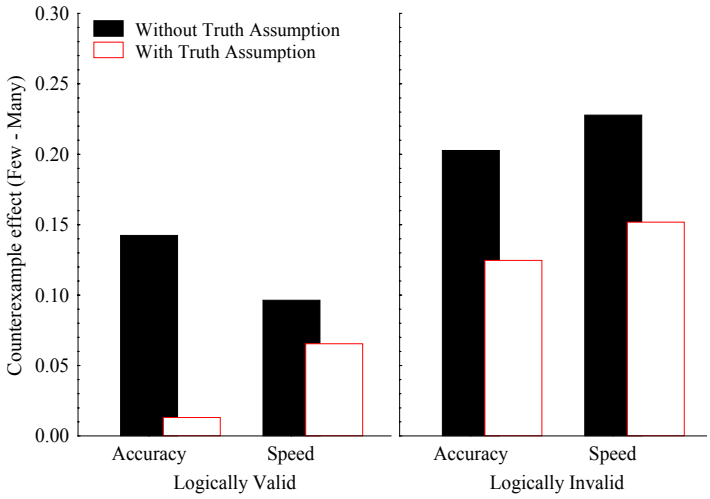
Counterexample effects on the logically valid and invalid arguments as a function of a timing constraint and the explicit presence of the truth assumption.



induce an overall inhibition of background knowledge. The fact that the truth-assumption effect on the valid inferences depends on the timing constraint tells us that this is not the entire story. Also, as noted before, the counterexample effects on the valid inferences are completely annulled when the truth-assumption is stressed (under accuracy conditions), whereas Figure 2 shows that they are still very much present on the invalid inferences under the same conditions. The reduced counterexample effects on the invalid inferences presented under truth conditions concurs with the idea that some people adopt a bi-conditional interpretation of 'if'. The alternative causes are then theoretically or hypothetically (i.e., under the assumption of the truth of the utterance) impossible.

Discussion

Our findings corroborate several of the claims we have made regarding deductive rationality in human reasoning. First, in order to reason deductively one has to make and adhere to the truth-assumption. We observed that the counter-example effect on the logically valid inferences is indeed smaller than that on the logically invalid inferences. The counter-examples to logically valid inferences are indeed (hypothetically) impossible – this is actually why these inferences are logically valid. Second, though we have evidence that some people spontaneously exhibit deductive rationality in adhering to the truth-assumption, other people clearly abandon the truth-assumption in the light of factual evidence to the contrary. The probabilistic counterexample effects on the logically valid inferences attest to this.

The speed/accuracy manipulation and the effects of stressing the truth-assumption provide strong support to our analyses of deductive rationality within a dual processing scheme. First, the overall increase in deductive rationality (as measured by the increase in the certainty ratings of the logically valid inferences) under conditions that stress the truth-assumption lends support the centrality of the truth-assumption in the notion of logically validity and human deductive reasoning. Second, the annulment of the counter-example effects on the logically valid inferences under conditions that make it clear that the truth of inferences about factually false utterances is a hypothetical truth, is also in agreement with the thesis that people inhibit factual knowledge that conflicts with the hypothetical truth of the utterances people reason about. Third, the dependency of the counter-example effect annulment on the time and effort people take to provide an evaluation of the conditional inferences, concurs with (and was predicted on the basis of) the thesis that probabilistic content-driven reasoning is primary to the effortful abstract, analytic hypothetical reasoning processes that can serve to override the output of the fast and frugal heuristic processes.

General Discussion

Our study shows the import and importance of the truth-assumption as regards deductive rationality in human reasoning. In the current general discussion we will touch upon some wider theoretical and conceptual issues. We will first consider the rational basis for the truth-assumption. Next, we will consider the import and importance of the truth-assumption as regards arguments that have been made in discussions of the non-monotonic and/or defeasible nature of human reasoning.

An Implicit vs. Explicit Truth-Assumption. We found support for thesis that at least some people make the truth-assumption and actually stick to it. It remains the case, however, that the majority of people will abandon the truth-assumption. The sizable counterexample effects on the logically valid inferences evidence this. One can only claim that the truth-assumption is abandoned when it is made in the first place. The question that then arises is whether those people who do not follow the truth-assumption (by taking count of factual knowledge to the contrary) actually made it in the first place.

It is our contention that when people form a representation of the utterances they are confronted with, they initially and implicitly make the assumption that the proposition expressed by it is true. This is in accordance with the Gricean maxims of conversation (which by themselves are related to Kant's four a priori categories of quantity, quality, relevance and modality): we generally assume/ensure that our or the speaker's contribution is truthful, relevant and as informative as possible, though not more detailed than required by the context (Grice, 1975). The truth-assumption is an implicit assumption (see, e.g., Schroyens, Schaeken, & d'Ydewalle, 1999). It is partly because it is an implicit assumption (at least to start with) that it is easily abandoned. The rational basis of the truth-assumption can be found in the idea of bounded rationality or cognitive economy. There is a representational cost attached to considering all possibilities, both true and false.

Most current theories presume the truth-assumption. This is not very surprising when one considers that truth is ontologically primordial to falsity: Non-truth presumes truth – as non-being presumes being. The mental-models theory (Johnson-Laird & Byrne, 2002) is the single one theory that is most explicit in invoking the truth-assumption. Indeed, it forms the basis of the truth-principle as regards the representation of the meaning of conditionals of the form [if p then q]. This principle states that people initially represent only represent true possibilities. Oaksford, Chater, & Larkin (2000) seems to have the only theory for which it is difficult to see whether it incorporates the truth-assumption. They do not seem to distinguish true from false utterances. There are only degrees of truth (i.e., probabilities). This restriction to factual truth (verisimilitude) is problematical because there is plenty of evidence that shows that people can reason hypothetically and deductively.

Truth, Validity and Non-Monotonic Reasoning. We situated the present study within the timely clash between paradigms focusing on deductive or probabilistic reasoning and presented the core argument that is made against logic theories. Theories of human deduction would not be capable to cope with the defeasible nature of human reasoning.

Our introductory analyses of the core argument against mental logic have shown that the issues are more complex: The defeasibility of a conclusion does not necessarily imply the non-monotonicity of an inference. Let us reiterate our

arguments against the claim that logic is in trouble because it is monotonic, while commonsense reasoning would not be Indeed, we have come to the somewhat controversial conclusion that it remains an open question whether commonsense reasoning is non-monotonic (even though we know it is defeasible).

We know that the counterexamples to the Modus Ponens argument (MP: if p then q, p, therefore q) are cases that naive reasoners (as opposed to logicians) consider impossible if the conditional utterance is true (Evans, Ellis, & Newstead, 1996). When they assume that [if p then q] is true, most people generally judge that it would be impossible that there are [p and not-q]-contingencies: situations wherein the consequent does not follow from the antecedent. In short, when people defeat a logically valid inference this simply indicates that peoples' intuitive notion of validity does not match that of logical validity. The pervasive 'belief effects' show that reasoners are much more concerned with the factual truth of a conclusion (Tweety the ostrich does not fly), as compared to the hypothetical truth of such conclusions (if it were true that all birds fly then Tweety the ostrich would fly).

Since logical validity encompasses the truth assumption, defeating a necessary inference marks the abandonment of this truth-assumption. By consequence it remains undetermined whether people have reasoned non-monotonically (i.e., revised a judgment of logical validity into a judgment of logical invalidity). When we assume, for arguments sake, that people actually aim to derive logically valid inferences, the defeasibility of inferred inferences shows that people shift from one notion of validity (i.e., logical validity, which includes the truth-assumption) to another notion of validity (let us call it 'psychological validity', which gives more weight to factual truth and allows a truth-assumption to be annulled). It seems one succumbs to the fallacy of equivocating two distinct concepts (logical and psychological validity), when defeasibility of an inference is taken to indicate non-monotonicity of human reasoning.

Because classic logic is monotonic while everyday reasoning is presumably non-monotonic (or at least defeasible), it has been stated that neither mental-models theories nor mental-logic theories are capable of explaining common-sense reasoning. It is hard to see why polemics have been created when defeating inferences is actually at the heart of mental models theory. Mental-models theory holds to a three-stage processing scheme. People first generate initial (incomplete) representations of what they think is possible if the premise are true (model-construction); they then integrate the representation of the multiple source of information that form a reasoning problem (model-integration). This allows them to generate a putative conclusion, which, third and most importantly, at least some people at least sometimes attempt to test by looking for a counterexample. A conclusion is rejected and/or modified in the light of conflicting information. That is, defeasible reasoning is in no way beyond the reach of mental-models theory, quite on the contrary:

"It is worth given up, not the thesis that human beings are capable of rational thought, but the idea that what underlies this ability is a mental logic. There can be reasoning without logic. More surprisingly, perhaps, there can be valid reasoning without logic" (Johnson-Laird, 1983, p. 40).

Acknowledgments

The present research was done with the support of the Flanders (Belgium) Fund for Scientific Research and the Research Council of the University of Leuven. We also like to express our grateful acknowledgments to Sunile Maes and Lieven Brebels for their help in collecting the data.

Abstract

In previous research, Gerjets, Scheiter, and Tack (2000) demonstrated that learners experience serious difficulties in utilizing instructional examples according to their profitability when interacting with a hypertext-based learning environment. In this paper we focus on possible causes of these difficulties and on different instructional methods for improving learners' utilization of worked-out examples in hypertext environments. The results of two experimental studies are reported.

Learning from Worked-Out Examples: The Role of Example Processing Strategies and Example Design

Research over the last 15 years in the domain of learning and problem solving has demonstrated that instructional examples play an important role for knowledge acquisition in domains like mathematics, physics, or programming (Chi, Bassok, Lewis, Reimann, & Glaser, 1989). In particular for initial skill acquisition, learning from worked-out examples seems to be superior to actively solving training problems (Sweller, van Merriënboer, & Paas, 1998). However, numerous findings also indicate major drawbacks of example-based learning. In particular, poor learners tend to overuse examples during problem solving without reflecting on their appropriateness (VanLehn & Jones, 1993). In addition, learners have difficulties identifying relevant information in worked-out examples and are often distracted by examples' surface features (Ross, 1989). Furthermore, Renkl (1999) assumes that students often suffer from illusions of understanding when learning from worked-out examples. I.e., they may have the false impression of having grasped the solution rationale of an example problem. Finally, learners have difficulties generalizing solutions from examples to novel problems (Catrambone & Holyoak, 1989; Reed, Dempster, & Ettinger, 1985).

A number of empirical studies have identified features of *example processing strategies* and *example design* that are efficient for successful knowledge acquisition (cf. Atkinson, Derry, Renkl, & Wortham, 2000).

Important *strategical aspects* mainly concern the *adequate selection and elaboration* of instructional examples. Reed, Ackinclose, and Voss (1990) showed that learners failed to select sufficiently complex instructional examples for learning although the profitability of these examples for *subsequently solving test problems* could be demonstrated. However, Reed, Willis, and Guarino (1994) found that learners who were allowed to select worked-out examples *while solving test problems* were able to select suitable examples. Additionally, it has been shown that *self-explanations* are an important aspect of good learners' example processing (Chi et al., 1989; Pirolli & Recker, 1994; Renkl, 1997). In particular, anticipations of solution steps and inferences with regard to the relations between solution steps, goals, and abstract principles have been proven useful for knowledge acquisition.

With respect to *design issues* it could be shown that *multiple examples* can support schema induction which helps learners to solve novel problems (Cummins, 1992). Providing multiple examples with *different surface features* might further improve this process of abstraction (Quilici & Mayer, 1996). Additionally, it has been proposed that the provision of *completion problems* - where learners have to fill in some details of worked-out examples' solution steps - is a helpful instructional device as it fosters self-explanations (Van Merrienboer, 1990). In particular, presenting completion problems along with evaluative feedback on subjects' gap-filling performance seems to improve learning outcomes. For instance, Stark (1999) showed that learners benefit from such a combination of completion problems and feedback and stresses the point that completion problems foster example elaboration whereas giving feedback on the learning success might prevent learners from *illusions of understanding*.

From these findings on learning from examples it can be argued that *strategies of example selection and processing* as well as *features of example design* have to be taken into account to improve learning outcomes.

The aspect of adopting suitable strategies gains increasing importance the more the control of the learning process is left up to the learner. In learning situations where the learner can *select* instructional material as well as determine the *sequence* and the *pace* of presentation, the importance of strategies increases (Gerjets, Scheiter, & Tack, 2000). Therefore, an identification of suitable strategies of information utilization and an examination of whether learners can adopt these strategies is highly relevant when more focus is put on self-regulated learning in the field of instruction.

Example-Based Hypertext Environments

One domain in which these issues of learner control are stressed is the field of hypertext-based learning where the user can select among different kinds of information and where he can choose according to his goals when the information is to be presented and in which order (Rouet & Levonen, 1996).

On the one hand, this allows for great flexibility and adaptivity of learning and problem solving. Generally, it is assumed that the nonlinear structure of hypertext environments improves learners' ability to use knowledge in a flexible way, so that they learn to apply one information unit to serve different purposes in a variety of situations. Non-linearity also enables learners to utilize information units according to their goals and to their prior knowledge. With regard to example-based learning, providing multiple examples with different surface features in a nonlinear hypertext environment allows the learner to compare examples within one problem category as well as to compare examples between different problem categories. These comparisons are fundamental for processes of abstraction in that they allow learners to identify structural features that define different problem categories. Therefore, non-linearity and the resulting opportunities of flexible information utilization may be especially suitable when learning from examples.

On the other hand, learners can "face new problems in selecting and accessing relevant information" (Rouet, Levonen, Dillon, & Spiro, 1996, p. 3). Problems can arise if learners do not possess the necessary prerequisites to cope with the demands that have been imposed to them by redirecting control over the learning process to them (Rouet & Levonen, 1996). Learning with a nonlinear hypertext increases the amount of control demands by making it necessary that learners permanently make decisions about the profitability of individual information units with regard to their current learning tasks. Even if all information provided is relevant to the current task, the information items may differ with respect to their profitability in terms of their processing costs and their contribution to improving the learning outcome (cf. Pirolli & Card, 1999). Therefore, learners may have to develop adequate strategies of information selection and processing in order to make use of the potential benefits of hypertext-based information presentation.

Based on these considerations a question of central importance in example-based learning with hypertext is whether learners are capable of utilizing examples according to their profitability, i.e., select, sequence, and compare them in a suitable way. Most research on learning from examples up to now has focused on learning situations where learners have been forced to process the examples provided in a predefined sequence and, in some studies, even for a fixed amount of learning time. However, it is not clear whether these findings can be easily transferred to more natural learning situations that allow subjects to select information in different sequences and to control their own pace of studying.

Results of Previous Experiments

In a series of previous experiments Gerjets, Scheiter, and Tack (2000) demonstrated that learners experience difficulties in hypertext environments with regard to their ability to utilize examples according to their profitability. These experiments were conducted using a web-based hypertext environment for training and testing in the domain of combinatorics (HYPERCOMB). During the learning phase subjects could retrieve abstract information on six problem categories from the domain of combinatorics. Depending on the experimental condition, this abstract information was either not augmented by any additional instructional information or was augmented by one or three worked-out examples that illustrated the six problem categories. Learners could retrieve the information they wanted to study and could determine the pace and sequence of information presentation. When they had the impression that they had learned sufficiently well learners could switch to a test phase where they had to solve three test problems. Automated logfile analyses were used to track subjects' strategic navigation behavior. Additionally, subjects' problem-solving performance was registered.

In order to investigate strategic adaptation to different instructional situation Gerjets et al. (2000) studied learners with either *low or high domain-specific prior knowledge* using different instructional versions of HYPERCOMB (no or one example or three examples per problem category) *with or without time pressure*.

As a result of their experiments Gerjets et al. (2000) showed that learners have difficulties in selecting the most profitable information in a specific instructional situation.

A comparison among the three instructional conditions yielded no beneficial effects of *merely providing* examples compared to providing only abstract information. However, if subjects *made use* of the examples in a suitable way (e.g. by comparing different examples) this clearly improved their learning and problem solving performance compared to subjects who made insufficient use of the instructional material. These findings on information profitability were contrasted with learners' actual information utilization behavior. Despite the fact that example processing proved to be useful, about half of the subjects demonstrated poor example processing strategies as they neither processed each example in the one-example condition more than once nor did they study more than one example per problem category in the three-example condition.

Hypotheses: Possible Explanations for Learners' Problems to utilize instructional examples according to their profitability

There might be two different explanations for learners' problems to utilize instructional examples according to their profitability, which will be described in the following paragraphs. Furthermore, two experimental conditions will be outlined that were designed to counteract these hypothesized causes of subjects' failures in using examples adequately.

Non-linearity

A first explanation is related to the fact that the experimental material is designed as a nonlinear hypertext environment. According to Niederhauser, Reynolds, Salmen, and Skolmoski (2000) additional control demands caused by non-linearity may result in extraneous cognitive load (cf. Sweller, Van Merrienboer, & Paas, 1998), which in turn impedes learning activities. Learners may suffer from

cognitive overload due to additional control and navigational demands caused by the nonlinear environment.

Additionally, learners may be in general overwhelmed by the need to *decide which information is profitable to select in which situation* (cf. Rouet et al., 1996). As a result subjects may be unable to utilize examples according to their profitability, either because of cognitive overload or because of inadequate navigational decisions. In order to counteract these problems of cognitive overload and of information selection we introduced a *linear-hypertext condition* of HYPERCOMB that contained exactly the same information as the *nonlinear-hypertext condition* and that forced learners to recognize every information available in a predefined order. Thereby, only pacing was left up to the learner. Eliminating the need to select and sequence information should reduce extraneous cognitive load and should free cognitive resources for processing instructional examples adequately. Furthermore, profitability judgements are less critical in a linear-hypertext condition.

Illusions of understanding

A second explanation for the insufficient use of the examples provided in HYPERCOMB is not related to the non-linearity of the information presentation but is related to the fact that learners may suffer from *illusions of understanding* when learning from worked-out examples (Renkl, 1999). To prevent learners from such illusions we introduced an instructional condition with incomplete examples and feedback where we presented fragmentized example solutions and asked the learners to complete these gaps by selecting one of two possible multiple-choice answers. After the completion, learners were provided with feedback concerning the correctness of their answers. This procedure may improve intensive example processing as it may help learners to realize that they are far away from an in-depth understanding of the example solutions. As a result, learners may notice that examples proved a profitable source of information and are helpful in order to overcome these comprehension failures.

In experiment 1 a nonlinear version of HYPERCOMB with three complete worked-out examples per problem category (baseline condition) was compared to a linear version in order to test the first hypothesis that subjects' inadequate use of examples results from additional navigational and control demands in nonlinear hypertext.

In experiment 2 the baseline condition was compared to a condition with three incomplete examples with feedback in order to test the second hypothesis that subjects' failures in using examples adequately results from an illusion of understanding.

We expected that both instructional manipulations should increase the time spent on processing examples and thereby improve learning outcomes. Additionally, we assumed that the instructional devices would especially foster learning outcomes of subjects with low prior knowledge who may suffer from control demands as well as from illusions of understanding to a greater extent that learners with high prior knowledge.

Experiment 1: Linear Hypertext

Method

Participants Subjects were 80 students of the Saarland University, Germany, who either participated for course credit or for payment. Average age was 23.4.

Materials and procedure Subjects used the HYPERCOMB environment for learning and problem solving. First, a short introduction to the domain of combinatorics was presented. During the subsequent learning phase subjects could retrieve abstract information on six problem categories (defined by their associated formula) from the domain of combinatorics. Additionally, three worked-out examples that varied with regard to their complexity and their cover story were provided for each problem category. In the test phase subjects were instructed to solve three probability word problems. Neither the abstract information nor the worked-out examples of the learning phase were available during the test phase.

Design and dependent measures As a first independent variable two levels of domain-specific prior knowledge were introduced. Additionally, two different instructional conditions were implemented (2 x 2 design):

In the *nonlinear-hypertext condition (baseline)* learners could choose by themselves which information to retrieve (i.e., abstract information and three different examples per problem category) and in which sequence to pursue. Learners could retrieve all information pages as often as they wanted and they could study them as long as they wanted. The learners themselves controlled the learning process so they could as well neglect all the provided information as study them very carefully. This condition served as baseline condition.

In the *linear-hypertext condition* the same instructional material as in the first condition was presented in a linear fashion. Learners had to follow a so-called *guided tour* through the hypertext environment by using "next"-buttons to get from one page to another. All problem categories were explained successively. For each problem category, first the abstract information page was displayed followed by three example pages. Every information page was presented only once, learners could not look back to information already seen and they could not skip any of the information. Therefore, selection and sequencing of the information pages were controlled by the system and only pacing was left up to the learner.

In the test phase subjects had to solve three word problems by marking the appropriate solution principle and the values of two variables for each of the test problems in a multiple-choice form. No calculations had to be made. One error was assigned for each wrong answer (i.e., subjects could obtain overall error rates between 0 and 9). Problem-solving time as well as learning time on example pages and on abstract pages was recorded by using logfiles. Following the test phase subjects had to pass a knowledge test with multiple-choice questions related to abstract concepts from the domain of combinatorics. Similar questions were posed as a pretest at the beginning of the experiment to register subjects' domain-specific prior knowledge. Subjects were

assigned to high and low prior knowledge groups by means of a median splits according to their pretest results.

Results and Discussion

First, we compared high and low prior-knowledge subjects learning either in the nonlinear or in the linear-hypertext condition within the two levels of prior knowledge with regard to their pretest errors (table 1). An overall ANOVA (instructional condition x prior knowledge) yielded no differences between the instructional conditions (F < 1).

Table 1: Time data (in sec) and error rates (in %) as a function of prior knowledge and instructional condition

Instructional condition	**Nonlinear**		**Linear**	
Prior knowledge	**High**	**Low**	**High**	**Low**
Pretest errors	28.6	63.2	30.3	64.3
Time on example pages	608	465	948	1069
Problem-solving time	602	550	617	606
Problem-solving errors	33.3	42.2	27.2	39.4
Knowledge-test errors	11.0	32.0	18.5	26.5

Time data With regard to example-processing time, an overall ANOVA (instructional condition x prior knowledge) yielded a significant main effect of instructional condition. Subjects in the linear-hypertext condition spent more time on example pages than subjects in the nonlinear-hypertext condition ($F(1,76) = 36.39$; $MS_E = 122363.7$; $p < .001$). Additionally, it could be shown that there was no difference between subjects with high and low prior knowledge concerning example processing time ($F < 1$). The interaction between instructional condition and prior knowledge was marginally significant ($F(1,76) = 2.84$; $MS_E = 122363.7$; $p < .10$). The increase of example-processing time due to the linear information presentation was slightly more pronounced for subjects with low prior knowledge ($t(38) = 5.37$; $p < .001$) than for subjects with high prior knowledge ($t(38) = 3.13$; $p < .01$).

Furthermore, we analyzed whether there was a *trade-off* between example-processing time and problem-solving time, in that learners in the nonlinear hypertext-condition might need less time for studying the examples but more time for later problem solving. However, an ANOVA for problem-solving time yielded no significant results (all Fs < 1).

Performance data In order to test the assumption that an increase in example-processing time leads to better problem-solving performance, we conducted an overall ANOVA (instructional condition x prior knowledge) that, however, only yielded a significant main effect for prior knowledge ($F(1,76) = 5.59$; $MS_E = 399$; $p < .05$). There neither was a main effect for instructional condition nor was there an interaction between instructional condition and prior knowledge (both Fs < 1).

Besides problem-solving performance we also analyzed knowledge-test performance as an indicator of learning success. An overall ANOVA (instructional condition x prior knowledge) for knowledge-test errors yielded a main effect for prior knowledge ($F(1,76) = 10.51$; $MS_E = 400.1$; $p < .01$) which was due to the high degree of item overlap between the pretest and the knowledge test at the end of the experiment. There was, however, no main effect for instructional condition as well as no interaction (both Fs < 1).

To conclude, providing subjects with linear hypertext increased example-processing time to a large extent as expected. However, this increase in time spent on examples was not accompanied by the expected gains in performance. Furthermore, it could be shown that learning in the nonlinear-hypertext condition was even more efficient because subjects needed less example-processing time for achieving the same level of performance without increases in problem-solving time. Therefore, our first explanation that subjects shallow example processing in hypertext environments observed in previous experiments (Gerjets et al., 2000) can not be traced back to additional control and navigational demands caused by nonlinear information presentation: Reducing these demands does not result in improved performance although example utilization behavior is intensified.

Thus, it seems that merely quantitative increases in example-processing time are not sufficient to ensure successful learning. Therefore, in experiment 2 we implemented incomplete examples with feedback as an instructional method that focuses on more qualitative improvements of example processing instead of only increasing example-processing time. This is in accordance with our second hypothesis that superficial example processing can be traced back to illusions of understanding when learning from worked-out examples.

Experiment 2: Incomplete Examples with Feedback

Method

Participants Subjects were 80 students of the Saarland University, Germany who either participated for course credit or payment. Average age was 23.7 years.

Materials and procedure Subjects used the same HYPERCOMB environment for learning and problem solving as the subjects in the nonlinear-hypertext condition in experiment 1. It consisted in a short introduction to combinatorics, a learning phase with abstract information and three worked-out examples per problem category, and finally a subsequent test phase with three probability word problems.

Design and dependent measures As a first independent variable two levels of domain-specific prior knowledge were introduced. Additionally, two instructional conditions were implemented (2 x 2 design):

As a *baseline condition* we used the nonlinear-hypertext condition from experiment 1 where subjects could decide by themselves which information to review (abstract information and three fully worked-out examples per problem category) and in which sequence to pursue.

In the *feedback condition* the solution steps of the worked-out examples where fragmentized and subjects where asked to fill these gaps by choosing among two multiple-choice answers. It is, however, important to note that subjects could decide by themselves whether they filled in the gaps and used the opportunity to receive feedback or not. Every

example solution was fragmentized two or three times and the gaps were related to structural features of the problem categories. After having determined the gap-filling answer subjects automatically received feedback on whether their answer was right or not. In case of choosing the wrong alternative the right answer was presented.

The subsequent test phase was identical to experiment 1. As dependent measures error rates and time date were recorded. In the feedback condition the frequency of feedback utilization was additionally registered. As in experiment 1 subjects had to pass a knowledge test with multiple-choice questions related to abstract concepts from the domain of combinatorics after the test phase. Subjects' answers to similar questions at the beginning of the experiment were used to distinguish between low and high prior-knowledge subjects.

Results and Discussion

The results of experiment 2 are shown in table 2. A first comparison revealed that there were no differences between the instructional conditions with respect to pretest errors ($F < 1$). (cf. table2).

Table 2: Time data (in sec) and error rates (in %) as a function of prior knowledge and instructional condition

Instructional condition	**Baseline**		**Feedback**	
Prior knowledge	**High**	**Low**	**High**	**Low**
Pretest errors	28.6	63.2	33.6	63.7
Time on example pages	608	465	692	785
Problem-solving errors	33.3	42.2	36.4	46.1
Knowledge test errors	11.0	32.0	21.5	27.0

Time data In order to test the hypothesis that subjects in the feedback condition process the examples more intensively than subjects in the baseline condition, we conducted an overall ANOVA (instructional condition x prior knowledge) for the time spent on example pages. However, this ANOVA only yielded a marginally significant main effect for instructional condition ($F(1,76) = 3.67$; $MS_E = 222102.5$; $p < .10$) with subjects in the feedback condition spending more time on studying example pages than subjects in the baseline condition. There was neither a main effect for prior knowledge ($F < 1$) nor an interaction ($F(1,76) = 1.25$; $MS_E = 222102.5$; $p > .40$).

Performance data With regard to problem-solving errors an overall ANOVA (instructional condition x prior knowledge) yielded no main effect for the instructional condition ($F < 1$). Thus, although there was a slight increase in example-processing time in the feedback condition this increase was not accompanied by respective improvements in problem-solving performance. For prior knowledge, the analysis yielded a main effect ($F(1,76) = 4,08$; $MS_E = 658.8$; $p < .05$). No interaction between the two factors could be demonstrated ($F < 1$).

Additionally, we conducted an ANOVA (instructional condition x prior knowledge) for knowledge-test errors, which yielded no significant main effect for the knowledge test errors ($F < 1$). The interaction between these two factors was marginally significant ($F(1,76) = 3.56$; $MS_E = 381.3$; $p < .10$).

To conclude, at first sight asking subjects to fill in gaps and providing feedback on these gap-filling activities does not seem to be an effective way of improving subjects' learning outcomes in example-based hypertext environments. However - because the use of feedback was not obligatory - it can be expected that only subjects who retrieved feedback sufficiently would often show better learning outcomes.

Therefore we calculated the correlation between the number of times subjects used feedback and the resulting learning outcomes in the feedback condition for high and low prior-knowledge subjects separately. These analyses show that subjects with low prior knowledge indeed benefited from an extended use of feedback (correlation between frequency of feedback utilization and problem-solving errors: $r = -.45$; $p < .05$; knowledge-test errors: $r = -.44$; $p < .05$, one-tailed test) whereas there were no or only weak associations between frequency of feedback utilization and learning outcomes for high prior-knowledge subjects (problem-solving errors: $r = -.12$; $p > .30$; knowledge-test errors: $r = -.31$; $p < .10$).

To sum up, subjects with low prior knowledge who made sufficient use of feedback clearly improved their problem-solving performance compared to subjects with low prior knowledge who made insufficient use of the instructional material. This is in line with our second hypothesis that the provision of incomplete examples with feedback may be useful to reduce illusions of understanding. These findings on the profitability of feedback information for learners with low prior knowledge were contrasted with their actual information utilization behavior in a next step of analysis: Despite the fact that the use of feedback proved useful for learners with low prior knowledge, they did not retrieve feedback more often than learners with high prior knowledge ($t(38) = -.42$; $p > .60$; 2-tailed test). To conclude, although the use of feedback fostered problem-solving and knowledge-test performance of low prior-knowledge subjects they did not use it more extensively. Thus, similar to the findings of example utilization it could be demonstrated again that subjects may experience serious difficulties in utilizing beneficial information provided in hypertext-environments according to its profitability.

Conclusions

With regard to the impact of two different instructional manipulations reported in this paper the following conclusion can be drawn. Although a linear information presentation increases example-processing time this does not automatically lead to improvements in learning outcomes. Linear presentation might reduce extraneous cognitive load due to control and navigational demands in nonlinear hypertext environments, however, this may also imply that learning advantages of nonlinear environments are neutralized. I.e., learners in a linear environment no longer have the opportunity to select and sequence information according to their needs. This lack of opportunity to self-control information utilization also may impair important processes of example comparison. Therefore, there may be a trade-off between the benefits and the drawbacks of non-linearity.

With regard to the provision of incomplete examples with feedback it could be demonstrated that this

instructional device was beneficial for subjects with low prior knowledge but that these subjects often made insufficient use of it.

Therefore, learners do not only have problems in utilizing worked-out examples according to their profitability for learning but also in using feedback extensively when learning in nonlinear environments. On the one hand, learners skip helpful information like feedback if they can control their learning process by themselves. On the other hand, when restricting learner control by presenting information in a linear environment learning becomes less efficient.

Therefore, the development of a learning environment where both of these findings are combined might be most successful. It can be assumed that learning in a nonlinear hypertext environment might be improved by forcing subjects to recognize information units of crucial importance for learning - like a minimal number of examples or the use of feedback on example completions. When developing learning environments, the specific learning situation must be considered to guarantee the advantages of non-linearity and at the same time to reduce the drawbacks by forcing the user to recognize profitable information. There must be a balance between the control that is given to the learner and the system control.

Abstract

Humans and animals use imitation as a mechanism for acquiring knowledge. Recently, several algorithms and models have been proposed for imitation learning in robots and humans. However, few proposals o er a framework for imitation learning in a stochastic environment where the imitator must learn and act under real-time performance constraints. We present a probabilistic framework for imitation learning in stochastic environments with unreliable sensors. We develop Bayesian algorithms, based on Meltzo and Moore's AIM hypothesis for infant imitation, that implement the core of an imitation learning framework, and sketch basic proposals for the other components. Our algorithms are computationally efficient, allowing real-time learning and imitation in an active stereo vision robotic head. We present results of both software simulations and our algorithms running on the head, demonstrating the validity of our approach.

Imitation learning in animals and machines

Imitation is a common mechanism for transferring knowledge from a skilled agent (the *instructor*) to an unskilled agent (or *observer*) using direct demonstration rather than manipulating symbols. Various forms of imitation have been studied in apes [Visalberghy and Fragaszy, 1990, Byrne and Russon, 2003], in children (including infants only 42 minutes old) [Meltzoff and Moore, 1977, Meltzoff and Moore, 1997], and in an increasingly diverse selection of machines [Fong et al., 2002, Lungarella and Metta, 2003]. The attraction for machine learning is obvious: a machine with the ability to imitate has a drastically lower cost of reprogramming than one which requires programming by an expert. Imitative robots also offer testbeds for cognitive researchers to test computational theories, and provide modifiable agents for contingent interaction with humans in psychological experiments.

Few previous efforts have presented biologically plausible frameworks for imitation learning. Bayesian imitation learning has been proposed to accelerate Markov decision process (MDP) learning for reinforcement learning agents [Price, 2003]; however, this framework chiefly addresses the problem of learning a forward model of the environment [Jordan and Rumelhart, 1992] via imitation (see below), and the correspondence with cognitive findings in humans is unclear. Other frameworks have been proposed for imitation learning in machines [Breazeal, 1999, Scassellati, 1999, Billard and Mataric, 2000], but most of these are not designed around a coherent probabilistic formalism such as Bayesian inference. Probabilistic methods, and Bayesian inference in particular, are attractive because they handle noisy, incomplete data, can be tuned to handle realistically large problem sizes, and provide a unifying mathematical framework for reasoning and learning. Our approach is unique in combining a biologically inspired approach to imitation with a Bayesian framework for goal-directed learning. Unlike many imitation systems, which implement only software simulations, this paper demonstrates the value of our framework through both simulation results and a real-time robotic implementation.

Components of an imitation learning system

The observer must surmount a number of problems in attempting to replicate the behavior of the instructor. Although described elsewhere [Schaal et al., 2003, Rao and Meltzoff, 2003], we briefly reformulate them as follows:

1. **State identification:** Ability to classify high-dimensional sensor data into a lower-dimensional, relevant state robust to sensor noise. State identification should differentiate between the internal state of the observer (proprioceptive feedback, etc.) and the state of the environment, including the states of other agents, particularly the instructor.
2. **Action identification:** Ability to classify sequences of states in time.
3. **State mapping:** Transformation from the egocentric coordinate system of the instructor to the egocentric coordinate system of the observer.
4. **Model learning:** Learning forward and inverse models [Blakemore et al., 1998] to facilitate interaction with the environment.
5. **Policy learning:** Learning action choices that maximize a reward function, as observed from the actions selected by the instructor in each given state.
6. **Sequence learning and segmentation:** Ability to memorize sequences of key states needed to complete

an imitation task; ability to segment imitation tasks, and to divide tasks into subtasks with particular subgoal states.

A Bayesian framework for goal-directed imitation learning

Imitation learning systems that learn only state and action mappings (without modeling the environment or the instructor's goals) ignore the separability of the instructor's intent from the actions needed to accomplish that intent. Systems that use deterministic models rather than probabilistic ones ignore the stochastic nature of realistic environments. We propose a goal-directed Bayesian formalism that overcomes both of these problems. The notation s_t denotes the state (both internal and external to an agent) at time t, and a_t denotes the action taken by an agent at time t. s_G denotes a special "goal state" that is the desired end result of the imitative behavior. The key to viewing imitation learning as a model-based, goal-directed Bayesian task is to identify:

Forward model: Predicts a distribution over future states given current state(s), action(s), and goal(s)—$P(s_{t+1}|a_t, s_t, s_G)$. Models how different actions affect environmental state.

Inverse model: Infers a distribution over actions given current state(s), future state(s), and goal(s)—$P(a_t|s_t, s_{t+1}, s_G)$. Models which action(s) should be selected to transition from one environmental state to another.

Prior model: Infers a distribution over actions given current state(s) and goal(s)—$P(a_t|s_t, s_G)$. Models the policy (or preferences) followed by a particular instructor in transitioning through the environment to achieve a particular goal.

Thus the prior model involves learning an MDP (or a partially observable MDP), while the forward model involves learning a "simulator" of how the environment (possibly including other agents) reacts to actions performed within it. Learning inverse models is a notoriously difficult task [Jordan and Rumelhart, 1992], not least because multiple actions could have mapped from s_t to s_{t+1}. However, using Bayes' rule, we can infer the distribution returned by the inverse model using the forward and prior models:

$$P(a_t|s_t, s_{t+1}, s_G) \propto P(s_{t+1}|a_t, s_t, s_G) \Pr(a_t|s_t, s_G) \qquad (1)$$

Equation 1 can be used to either select the maximum a posteriori action to complete a state transition, or to sample over a distribution of alternatives, refining the model (and representing an exploration- exploitation tradeoff reminiscent of reinforcement learning). Sampling from the distribution over actions is also called *probability matching*. Evidence exists that the brain employs probability matching in at least some cases [Herrnstein, 1961, Krebs and Kacelnik, 1991].

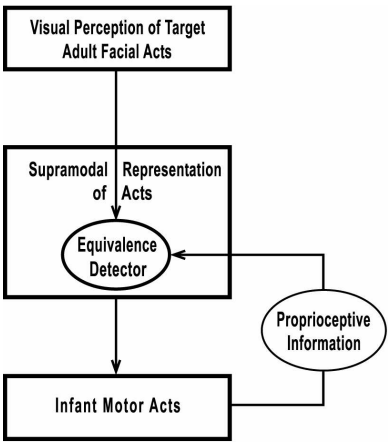

Figure 1: **AIM hypothesis model for infant imitation:** The AIM hypothesis of Meltzo and Moore [Meltzo and Moore, 1997] argues that infants match observations of adults with their own proprioceptions using a modality-independent representation of state. Our computational framework suggests an efficient, probabilistic implementation for this hypothesis.

Fig. 1 graphically represents Meltzoff and Moore's Active Intermodal Mapping (AIM) hypothesis [Meltzoff and Moore, 1997]. According to this cognitive model, imitation begins with an infant (or other agent) forming a representation of features in the outside world. Next, this representation is transformed into a "supra-modal," or modality-independent, representation of those features. An equivalence detector matches the current modality-independent representation of the instructor's state with a modality-independent representation of the infant observer's state. Proprioceptive feedback guides the infant's motor output toward matching the instructor's state. Our framework for Bayesian action selection using learned models captures this idea of imitation as a "matching-to-target" process.

Fig. 2 depicts a block diagram of our architecture. Like AIM, our system begins by running several feature detectors (skin detectors, face trackers, etc.) on sensor inputs from the environment. Detected features are monitored over time to produce state sequences. In turn, these sequences define actions. The next step is to transform state and action observations into instructor-centric values, then map from instructor-centric to observer-centric coordinates. Observer-centric values are employed to update probabilistic forward and prior models in our Bayesian inference framework. Finally, combining distributions from the forward and prior models as in Eqn. 1 yields a distribution over actions. The resulting distribution over actions is converted into a single motor action the observer should take next, with an efference copy conveyed to the feature detectors to cancel out the effects of self-motion.

State and action identification

Deriving state and action identity from sensor data involves task- and sensor-specific functions. Although it is impossible to summarize the extensive

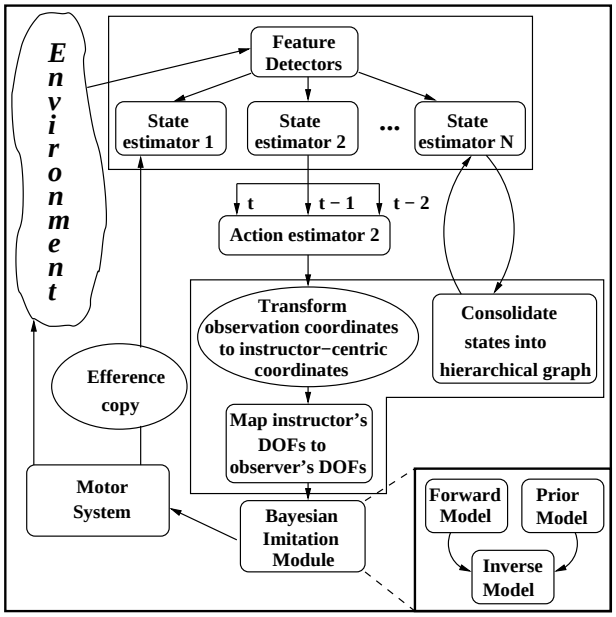

Figure 2: **Overview of model-based Bayesian imitation learning architecture:** As in AIM, the initial stages of our model correspond to the formation of a modality-independent representation of world state. Mappings from instructor-centric to observer-centric coordinates and from the instructor's motor degrees of freedom (DOFs) to the observer's motor DOFs play the role of equivalence detector in our framework, matching the instructor's motor output to the motor commands of the observer. E erence copy provides proprioceptive feedback to close the motor control loop.

body of work in action and state identification here, we note recent progress in extracting actions from laser rangefinder and radio [Fox et al., 2003] and visual [Efros et al., 2003] data. In most cases, computational expediency necessitates employment of dimensionality reduction techniques such as principal components analysis, Isomap [Tenenbaum et al., 2000], or locally linear embedding [Roweis and Saul, 2000]. Saliency detection algorithms [Itti et al., 1998] may also help reduce high-dimensional visual state data to tractable size.

Learning state mappings

A prerequisite for any robotic imitation task is to determine a mapping from the instructor's state to the observer's [Nehaniv and Dautenhahn, 2002]. We view this state mapping problem as an instance of subgraph isomorphism, where the goal is to match subgraphs from the instructor (corresponding to effectors, e.g. limbs) to their corresponding graphs in the observer. In the simulation and robotic head results shown below, the mappings are trivial; developing detailed graph-theoretic approaches to mapping from instructor states to observer states remains an ongoing topic of investigation.

Learning forward models

Numerous supervised and unsupervised approaches (see e.g. [Jordan and Rumelhart, 1992, Todorov and Ghahramani, 2003]) have been proposed to learn models of the environment, and to discover policies to maximize rewards obtained from the environment. Evidence demonstrates that infants learn forward models of how their limbs, facial muscles, and other body parts react to motor commands, a process referred to by Meltzoff and Moore [Meltzoff and Moore, 1997] as "body babbling." Such forward model learning could occur both prenatally and during infancy. We anticipate using well-established supervised algorithms to acquire forward models of environmental dynamics. Unsupervised learning of forward and inverse models to generate motor policies is a well-known problem in the reinforcement learning community (see [Kaelbling et al., 1996] for a survey). In reinforcement learning, an agent's internal reward signal alone is used to learn models of the environment, rather than relying on examples provided by a teacher as in imitation learning.

Sequence learning and segmentation

Realistic imitation learning systems must be able to learn sequences of states that define actions, and to segment these sequences into meaningful chunks for later recall or replay. Part of our ongoing work is to define how semantically meaningful chunks can be defined and recalled in real time. Recent developments in concept learning (e.g., [Tenenbaum, 1999]) suggest how similar environmental states might be grouped together, enabling development of hierarchical state and action representations in machine systems.

A Bayesian algorithm for inferring intent

Being able to determine the intention of others is a crucial requirement for any social agent, particularly an agent that learns by watching the actions of others. Recent studies have revealed the presence of "mirror neurons" in monkey cortex that fire both when an animal executes an action and when it observes others performing similar actions. These findings suggest a neurological substrate for intent inference in primates [Rizzolatti et al., 2000]. One appealing aspect of our framework is that it suggests a probabilistic algorithm for determining the intent of the instructor. That is, an observer can determine a distribution over goal states based on watching what actions the instructor executes over some period of time. This could have applications in machine learning systems that predict what goal state the user is attempting to achieve, then offer suggestions or assist in performing actions that help the user reach that state. The theory could lead to quantitative predictions for future cognitive studies to determine how humans infer intent in other intelligent agents.

Our algorithm for inferring intent uses applications of Bayes' rule to compute the probability over goal states given a current state, action, and next state obtained by the instructor, $P(s_G|s_{t+1}, a_t, s_t)$. This probability distribution over goal states represents the instructor's intent. One point of note is that $P(s_{t+1}|a_t, s_t, s_G) \equiv P(s_{t+1}|a_t, s_t)$; i.e., the forward model does not depend on the goal state s_G, since the environment is indifferent

to the desired goal. Our derivation proceeds as follows:

$$P(s_{t+1}|a_t, s_t, s_G) = \frac{P(s_{t+1}, s_t, a_t, s_G)}{P(a_t, s_t, s_G)} \quad (2)$$

$$P(s_{t+1}|a_t, s_t, s_G) = \frac{P(s_G|s_{t+1}, a_t, s_t)}{P(s_G|a_t, s_t)} \frac{P(s_{t+1}, a_t, s_t)}{P(a_t, s_t)} \quad (3)$$

Because $P(s_{t+1}|a_t, s_t, s_G) \equiv P(s_{t+1}|a_t, s_t)$, and since $\frac{P(a_t,s_t)}{P(s_{t+1},a_t,s_t)} = \frac{1}{P(s_{t+1}|a_t,s_t)}$:

$$P(s_G|a_t, s_t) = P(s_G|s_{t+1}, a_t, s_t) \quad (4)$$

$$\frac{P(s_G, a_t, s_t)}{P(a_t, s_t)} = P(s_G|s_{t+1}, a_t, s_t) \quad (5)$$

$$\frac{P(a_t|s_G, s_t) P(s_G, s_t)}{P(a_t, s_t)} = P(s_G|s_{t+1}, a_t, s_t) \quad (6)$$

$$P(a_t|s_G, s_t) P(s_G, s_t) \propto P(s_G|s_{t+1}, a_t, s_t) \quad (7)$$

$$P(s_G|s_{t+1}, a_t, s_t) \propto P(a_t|s_G, s_t) P(s_t|s_G) P(s_G) \quad (8)$$

The first of the terms in Eqn. 8 represents the prior model. The second term represents a distribution over states at time t, given a goal state s_G. This could be learned by, e.g., observing the instructor manipulate an object, with a known intent, and recording how often the object is in each state. Alternatively, the observer could itself "play with" or "experiment with" the object, bearing in mind a particular goal state, and record how often each object state is observed. The third term is a prior over goal states; it can be derived by modeling the reward model of the instructor. If the observer can either assume that the instructor has a similar reward model to itself (the "like-me" hypothesis [Meltzoff, 2002]), or model the instructor's desired states in some other way, it can infer $P(s_G)$.

Interestingly, these three terms roughly match the three developmental stages laid out by Meltzoff [Meltzoff, 2002]. According to our hypothesis, the first term in Eqn. 8 corresponds to a distribution over actions as learned during imitation and goal-directed actions. This distribution can be used if all the observer wants to do is imitate body movements (the first step in imitation that infants learn to perform according to Meltzoff's theory of development). The second term in Eqn. 8 refers to distributions over states of objects given a goal state. Because the space of actions an agent's body can execute is presumably much less than the number of state configurations objects in the environment can assume, this distribution requires collecting much more data than the first. Once this second term is learned, however, it becomes easier to manipulate objects to a particular end—an observer that has learned $P(s_t|s_G)$ has learned which states of an object or situation "look right" given a particular goal. The complexity of this second term could explain why it takes babies much longer to learn to imitate goal-directed actions on objects than it does to perform simple imitation of body movements (as claimed in Meltzoff's theory). Finally, the third term, $P(s_G)$, is the most complex term to learn. This is both because the number of possible goal states s_G is huge, and the fact that the observer must model the instructor's distribution over goals indirectly (the observer obviously cannot directly access the instructor's reward model). The observer must rely on features of its own reward model, as well as telltale signs of desired states (e.g., states that the instructor tends to act to remain in, or that cause the instructor to change the context of its actions, could be potential goal states) to infer this prior distribution. The difficulty of learning this distribution could explain why it takes so long for infants to acquire the final piece of the imitation puzzle, determining the intent of others. We did not explicitly design the terms in our intent inference algorithm to match childhood developmental stages; rather, the derivation follows from the inverse model formulation in Eqn. 1 and straightforward applications of Bayes' rule.

Simulation results

Fig. 3 demonstrates imitation results in a purely simulated environment. The task is to reproduce observed trajectories through a maze containing three different goal states (maze locations marked with ovals). This simulated environment simplifies a number of the issues mentioned above: the location and value of each goal state is known by the observer a priori; the movements of the instructor are observed free from noise; the forward model is restricted so that only moves to adjacent maze locations are possible; and the observer can detect when it is next to a wall (although it does not know a priori that it cannot move through walls).

The observer first learns a forward model by interacting with the simulated environment for 500 simulation steps. The instructor then demonstrates 4 different trajectories to the observer (1 to the white goal, 2 to the light gray goal, 1 to the dark gray goal), allowing the observer to learn a prior model. Fig. 3(a) shows the maze environment used in our simulations. Fig. 3(b) shows a sample training trajectory (black arrows) where the instructor moves from location (1,1) to the goal state at (3,3). The solid white line (over arrows) demonstrates the observer reproducing the same trajectory after learning. The observer's trajectory varies somewhat from the instructor's due to the stochastic nature of the environment. Fig. 3(c) shows another training trajectory, comprising 47 steps, where the instructor moves toward the white goal (goal 1). The observer's task for this trajectory is to estimate, at each time step of the trajectory, a distribution over which goal state the instructor is headed toward. During the inference process, the observer does not have direct knowledge of the actions selected by the instructor; it must infer these by monitoring state changes in the environment. The graph in Fig. 3(d) shows this distribution over goals, where data points represent inferred intent averaged over epochs of 8 simulation steps each (i.e., the first data point on the graph represents inferred intent averaged over simulation steps 1-8, the second data point spans simulation steps 9-17, etc., with the last epoch spanning 7 simulation steps). Note that the estimate of the goal is correct over all epochs. The algorithm is particularly confident once the ambiguous section of the trajectory, where the instructor could be moving toward the dark gray or the light gray goal, is passed. Performance of the algorithm would be enhanced by more training; only 4 sample tra-

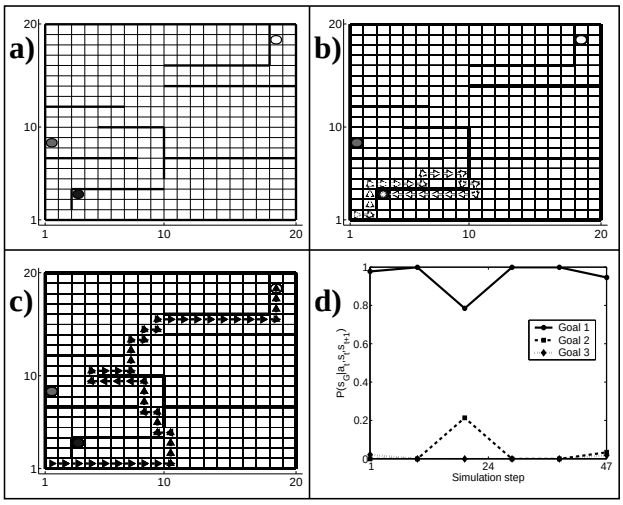

Figure 3: **Simulated environment for imitation learning:** (a) Maze environment used to train observer. Thick black lines denote walls; ovals represent goal states. Lightness of ovals is proportional to the probability of the instructor selecting each goal state (re ecting, e.g., relative reward value experienced at each state). (b) Example trajectory (black arrows) from the instructor, ending at the second goal. Reproduction of the trajectory by the observer is shown as a solid white line overlying the arrows; inference is performed as in Eqn. 1. The instructor required 23 steps to reach the goal; the observer required a slightly larger number of steps due to both the stochastic nature of the environment and imperfect learning of the forward and prior models. (c) Instructor's trajectory in the intention inference task. (d) Graph showing a distribution over instructor's goal states, as inferred by the observer at di erent time points in the simulation. Note how the actual goal state, goal 1, maintains a high probability relative to the other goal states throughout the simulation. Goal 2 brie y takes on a higher probability due to limited number of training trajectories.

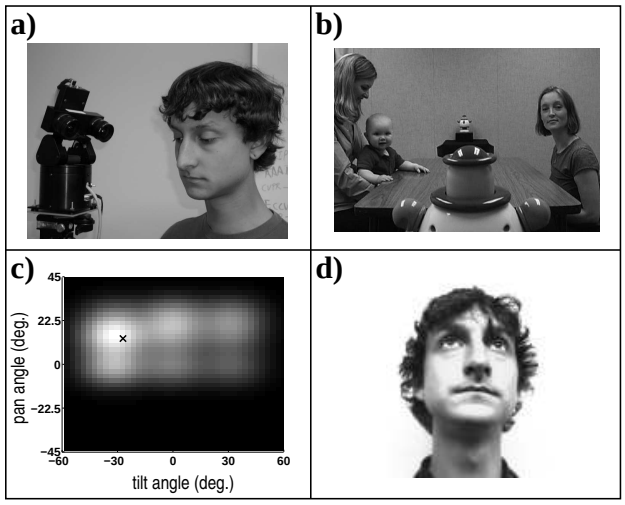

Figure 4: **Gaze tracking in a robotic head:** (a) Biclops active stereo vision head from Metrica, Inc. (b) Infants as young as 9 months can detect gaze based on head direction; older infants ($\geq$ 12 months) use opened eyes as a cue to detect whether they should perform gaze tracking (from [Brooks and Meltzo , 2002]). (c) Likelihood surface for the face shown in (d), depicting the likelihood over pan and tilt angles of the subject's head. The region of highest likelihood (the brightest region) matches the actual pan and tilt angles (black X) of the subject's face shown in (d).

jectories were presented to the algorithm, meaning that its estimates of the distributions on the right hand side of Eqn. 8 were extremely biased.

Real-time application in a robotic head

We have also implemented our probabilistic approach in a Biclops active stereo vision head (Fig. 4(a)). The head follows the gaze of a human instructor, and tracks the orientation of the instructor's head to determine where to look next. Gaze following [Brooks and Meltzoff, 2002, Scassellati, 1999] (Fig. 4(b)) represents a key step in the development of shared attention, in turn bootstrapping more complicated imitation tasks. Our system begins by identifying an image region likely to contain a face (based on detecting skin tones and bounding box aspect ratio). We employ a Bayesian pose detection algorithm [Wu et al., 2000] that matches an elliptical model of the head to the human instructor's face. Our algorithm then transforms the estimated gaze into the Biclops' egocentric coordinate frame, causing the Biclops to look toward the same point in space as the human instructor. We trained the pose detector on a total of 13 faces, with each training subject looking at 36 different targets; each target was associated with a different pan and tilt angle relative to pan 0, tilt 0 (with the subject looking straight ahead).

Fig. 4(c) depicts a likelihood surface over pan and tilt angles of the instructor's head in the pose shown in Fig. 4(d). Our system generates pan and tilt motor commands by selecting the maximum a posteriori estimate of the instructor's pan and tilt, and performing a simple linear transform from instructor-centric to egocentric coordinates. Out of 27 out-of-sample testing images using leave-one-out cross-validation, our system is able to track the angle of the instructor's head to a mean error of $\pm$4.6 degrees. [1] Our previous efforts [Shon et al., 2003] demonstrated the ability of our system to track the gaze of an instructor; ongoing robotics work involves learning policy models specific to each instructor, and inferring instructor intent based on object saliency.

Conclusion

This paper describes a Bayesian framework for imitation learning, based on the AIM model of imitation learning by Meltzoff and Moore. The framework emphasizes imitation as a "match-to-target" task, and promotes separation between the dynamics of the environment and the policy a particular teacher chooses to employ in reaching a goal. We have sketched the basic components for any imitation learning system operating in realistically large-scale environments with stochastic dynamics and noisy sensor observations. Our model naturally leads to a Bayesian algorithm for inferring the intent of other

[1] We de ne error as:
$$\mathcal{E} = \sqrt{\left(\theta_{pan} \quad \hat{\theta}_{pan}\right)^2 + \left(\theta_{tilt} \quad \hat{\theta}_{tilt}\right)^2}$$
where θ is the true angle, and $\hat{\theta}$ is our system's estimate of the angle.

agents. We presented preliminary results of applying our framework to a simulated maze task and to gaze following in an active stereo vision robotic head. We are currently investigating the ability of the framework to scale up to more complex robotic imitation tasks in real-world environments. We are also exploring the connections between our probabilistic framework and findings from developmental psychology.

Abstract

A modular connectionist model covers all six established phenomena in transitivity development in children and predicts a new effect. In contrast, a symbolic-rule hypothesis based on logic captures none of these effects and is directly contradicted by one of them. In the model a constraint-satisfaction network generates a response based on input from a feed-forward comparison module and the particular question asked. Cycles to saturate the response module implement response times.

Psychology of Transitivity

Piaget and his colleagues (Inhelder & Piaget, 1964; Piaget, 1969) designed the transitivity problem to assess the development of children's logical-inference abilities. This problem often employs sticks (or times) of different length, as shown in Figure 1. Given, for example, that a child learns that stick 2 is longer than stick 1, and that stick 3 is longer than stick 2, can the child infer that stick 3 must be longer than stick 1? This is not a perceptual problem in that the child only identifies a stick by its unique color, never seeing the actual stick lengths. Piaget's evidence suggested that correct untrained inferences, such as comparing sticks 1 and 3, did not emerge until around seven years of age, thus providing an index of the child's entry into the stage of concrete operations.

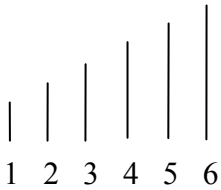

Figure 1: A six-stick version of the transitivity task.

Piaget's long-dominant view of the transitivity task as being solved by logic was ultimately contradicted in an experiment measuring the time it took for people of different ages to make various inferences (Trabasso, Riley, & Wilson, 1975). Using a six-item version of the task like that in Figure 1, Trabasso et al. trained 6-year-olds, 9-year-olds, and university students on all adjacent pairs of sticks and then asked about all possible pairs of sticks, varying the question between *Which stick is longer*? and *Which stick is shorter*? Five different effects were reported.

1. A serial-position effect: learning the adjacent pairs near the ends of the array before the pairs near the middle.
2. A distance effect: faster inferences about pairs that are farther apart in length than for pairs close together in length.
3. An anchor effect: faster inferences about pairs involving an end anchor (sticks 1 or 6) than for pairs not involving an end anchor.
4. A congruity effect: faster inferences when the term used in the question (e.g., longer) is compatible with an end anchor (e.g., the longest stick) in the pair being compared than when the question term (e.g., longer) is incompatible with an end anchor in the pair being compared (e.g., the shortest stick).
5. An age effect: older participants learned the adjacent pairs faster and made inference comparisons faster and more accurately than did younger participants.
6. Other experiments with different comparison tasks found that the distance effect diminished with increasing age (Duncan & McFarland, 1980; Sekuler & Mierkiewicz, 1977).

The first four of these effects have been replicated in a wide range of tasks involving symbolic comparisons along a dimension, e.g., numerical comparisons (Banks, 1977; Duncan & McFarland, 1980; Leth-Steenson & Marley, 2000; Sekuler & Mierkiewicz, 1977).

The distance effect was particularly damaging to Piaget's logical-inference interpretation because it is precisely opposite to what Piaget would presumably predict. Assuming that each inference takes some constant time, Piaget would have to predict that the more inferences required to make a comparison, the longer the comparison would take. For example, comparing sticks 2 and 3 requires no inference at all because participants are trained on such adjacent pairs. In contrast, comparing sticks 2 and 4 requires a single inference from two premises ($S2 < S3$ and $S3 < S4$, therefore $S2 < S4$). And comparing sticks 2 and 5 requires two inferences (the previous inference plus this one: $S2 < S4$ and $S4 < S5$, therefore $S2 < S5$). The larger the split (or difference) between sticks, the more inferences would be required. The splits are conventionally termed 1, 2, and 3 in these three comparisons, respectively.

Because of the distance effect in their response-time data, Trabasso et al. concluded that people don't use logical inference per se to solve this task. They argued instead that participants construct a spatial image of the sticks while being trained on adjacent pairs and then consult this image when asked to make another comparison. The farther the sticks are apart within this spatial image, the easier it is to make a correct comparison. Despite a recent resurgence of interest in studying and modeling transitivity, there has been no computational model that covers all six of these effects. It is, in fact, computationally unclear how the brain might construct and consult spatial images in this way.

The purpose of the present work is to build such a model with cascade-correlation (CC), a neural-network learning algorithm that has been used to simulate many other phenomena in cognitive development (Shultz, 2003). Another reason to use CC is that it searches in topology space, building the network, as well as in weight space.

Like other feed-forward neural algorithms, CC produces responses in more or less constant time, and thus is not naturally suitable for covering response-time effects. To add this capability, we used a modular system of two networks, which we call constraint-satisfaction cascade-correlation (CSCC). A CC network learned to judge the relative lengths of adjacent sticks and a constraint-satisfaction (CS) network used that information plus information contained in the question to generate a response. The number of update cycles that the response module required to settle into a steady state was taken as an index of response time.

Method

The CSCC modular network system is shown schematically in Figure 2.

Comparison Module

The CC comparison module is on the left side of Figure 2. Inputs to the comparison module describe the colors of the two sticks being compared and were coded in a binary *n*th-unit fashion (1 for the color of a stick and 0s elsewhere for colors that are not involved). The 12 inputs (the same 6 colors for each of two sticks) were fully connected to a single output unit having a sigmoid activation function, which coded a length comparison with targets of -0.5 if the left (L) stick is longer and 0.5 if the right (R) stick is longer. Comparison networks were trained on all ten adjacent pairs of sticks until all output values were within score threshold of their targets on all of these ten training pairs. Order of the two sticks being compared is counterbalanced across comparisons.

We implemented age differences by using different values of score threshold: 0.5 for adults, 0.55 for 9-year-olds, and 0.6 for 6-year-olds. This is consistent with finding that older people learn more from the same experiences than young children do (Case, Kurland, & Goldberg, 1982), a principle that has been successfully used to simulate age differences in learning in several other CC simulations (Shultz, 2003). Different score thresholds would also work for capturing developmental effects here, but these particular values produced overall proportions correct that were very close to those reported by Trabasso et al. (1975) for their different age groups. We ran 12 networks at each of the three score-threshold levels, matching the *n*s at each age level in the Trabasso et al. experiment. Full details of the CC algorithm are discussed elsewhere (Shultz, 2003).

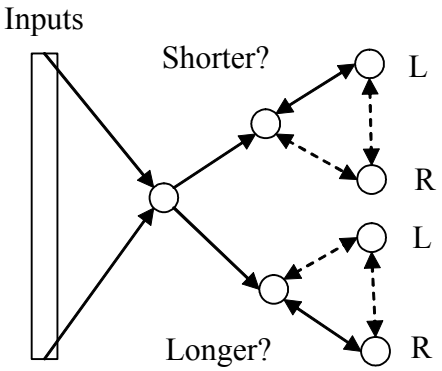

Figure 2: CSCC modular networks for transitivity.

Response Module

After training, output from the comparison module served as input to a three-unit response network. Activation on the other two units in this CS network represented the left or right sticks as being the correct response to the question being asked. As shown on the right side of Figure 2, the precise form of this response network varied according to the question being asked. Recall that the target output of the comparison network was 0.5 when the right stick was longer, and -0.5 when the left stick was longer. Consequently, if the question was *Which stick is longer*?, then there were positive weights (0.5, signified by a solid line) between the comparison unit and the right (R) unit and negative weights (-0.5, signified by a dashed line) between the comparison unit and the left (L) unit. If the question was *Which stick is shorter*?, then the signs of these weights were reversed; there were positive weights between the comparison unit and the left unit and negative weights between the comparison unit and the right unit. The basic principle underlying these weight settings is to enhance the activation value of the side unit corresponding to the stick that is longer when the question term is *longer*, and to enhance the activation value of the side unit corresponding to the stick that is shorter when the question term is *shorter*. More generally the idea is to activate the correct response and inhibit an incorrect response.

Connections between the left and right units were always negative to reflect the idea that these two units are competing with each other. Unlike the comparison unit, these two side units had no external inputs; all of their input came from inside the response network.

As is typical with CS networks, weights in this response module were bidirectional, with one weight going in each direction between any two units. As in other CS simulations (Kunda & Thagard, 1996; Shultz & Lepper, 1996), we assume here that these networks are constructed on the fly

by participants in response to their particular experimental setting and the question being posed to them. There is no assumption that participants are conscious of this construction. It is rather that the design of a response module is strongly constrained by the participant's understanding of the experimental situation and question.

All three units in a response module started out with an initial activation value of 0. At every cycle, three units were randomly selected, with replacement, to have their activations updated. In each such update, net input to the updated unit *i* was computed as:

$$net_i = in\left(\sum_j w_{ij} a_j\right) + ex(input_i) \quad (1)$$

where a_j is the activation of each sending unit *j*, w_{ij} is the relevant connection weight, $input_i$ is any external input to the receiving unit, and *in* and *ex* are parameters scaling influences internal or external, respectively, to the network. These last two parameters were both set to 0.1 in our simulations, but a wide range of values work equally well.

If this net input was positive, it was added to the receiving unit's current activation $a_i(t)$ after being scaled by the distance of that current activation from the activation ceiling of 1.0:

$$a_i(t+1) = a_i(t) + net_i(ceiling - a_i(t)) \quad (2)$$

Alternatively, if the net input was negative, it was added to the receiving unit's current activation $a_i(t)$ after being scaled by the distance of that current activation from the activation floor of -1.0:

$$a_i(t+1) = a_i(t) + net_i(a_i(t) - floor) \quad (3)$$

An overall measure of the degree to which a CS network has settled into a stable state is its *goodness*, computed as the sum of triple products of unit activation values and the relevant connection weight plus the sum of the products of external inputs and activation values:

$$goodness = \sum_{ij} w_{ij} a_i a_j + \sum_i input_i a_i \quad (4)$$

Equations 1-4 are fairly standard in the CS-network literature (Shultz, 2001). In this kind of scheme, goodness rises as units have their activations updated and eventually levels off as activations stop changing. Examples are provided in Figure 3 in terms of goodness changes over update cycles for networks with three different levels of comparison inputs. We identified the cycle at which goodness starts to reach asymptote as no goodness change greater than .02 (asymptote-threshold parameter) for 8 consecutive cycles (asymptote-patience parameter). These parameter values were selected because they correspond to our visual impressions of when goodness values approach asymptote. A range of different threshold and patience values works equally well, although sufficiently extreme parameter values can blur differences between sticks and between conditions. Figure 3 shows that networks settle quicker with higher, and more decisive, comparison activations.

To cover the congruity effect, we multiplied comparison inputs by 0.8 whenever there was an anchor stick that was incompatible with the term used in the question. This is a computational shortcut consistent with the idea that the congruity effect is based on semantic interference between incompatible terms, some of which have to be translated to a compatible form to answer the question (Banks, 1977). When asymptote was reached, the comparison unit, left or right, with the higher activation was taken as the response module's answer to the question that was posed.

Before activation-update cycles began, all the connection weights and external inputs had their initial values randomized a bit by adding or subtracting up to 10% of their initial values in a uniform distribution. This is to reflect the fact that not all participants interpret the experimental procedures and questions in exactly the same way. A wide variety of randomization values work equally well to implement such individual differences.

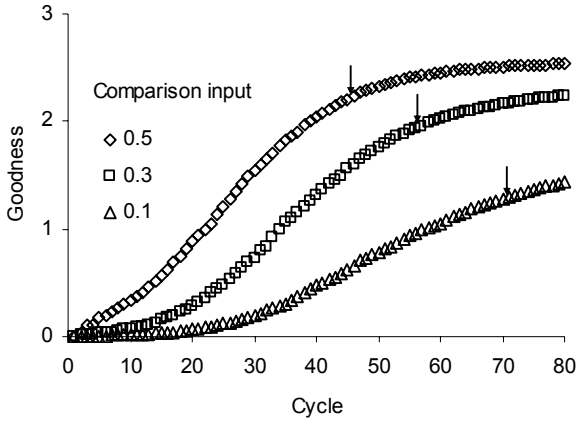

Figure 3: Increasing goodness over activation-update cycles in a CS response network at three levels of comparison input. Arrows indicate the cycle at which a goodness asymptote was reached.

Results

Learning

Although CC networks are capable of recruiting new hidden units if they are needed, none of our networks did so. This indicates that the problem of learning *n*th-unit, binary-coded, adjacent stimulus pairs is a rather simple linearly-separable problem. The mean number of epochs taken to learn the training patterns was 7.2 for score threshold of 0.6, 7.7 for score threshold of 0.55, and 10.2 for score threshold of 0.5.

The serial-position effect for training is evident in Figure 4. A score-threshold x training-pair mixed ANOVA of comparison-network error yielded a quadratic trend for training pair, $F(1, 33) = 279$, $p < .001$. With no interaction with score-threshold, this shows the serial position effect at each age: better learning of training pairs at the ends of the array than in the middle. There was also a main effect of score-threshold, $F(2, 33) = 19.59$, $p < .001$, capturing the superiority of older, deeper learners.

Inference

The theoretically-important distance effect is shown in Figure 5. In a score-threshold x split ANOVA of cycles to settle, the largest effect is a linear trend for split, $F(1, 33) = 582$, $p < .001$, confirming a strong distance effect at every score threshold, representing the three different ages. Network responses were faster the larger the split between the sticks being compared. It is also evident that the distance effect diminished a bit with decreasing score threshold, representing increasing age.

In Figure 6, a score-threshold x end-anchor ANOVA of cycles to settle reveals a main effect of anchor, $F(1, 33) = 166$, $p < .001$, simulating the finding that performance is quicker when an end anchor is present. A score-threshold x end-anchor interaction, $F(2, 33) = 6.73$, $p < .01$, predicts that the anchor effect may also diminish with increasing age.

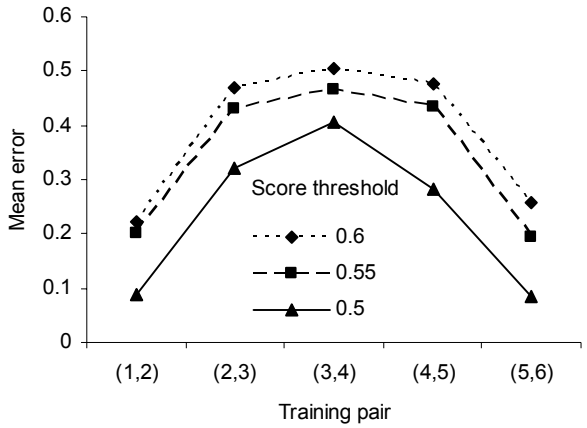

Figure 4: The serial-position effect: mean error for different training pairs and score thresholds.

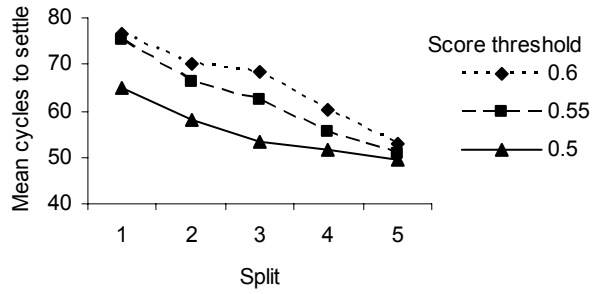

Figure 5: The distance effect: mean cycles to settle for different splits and score thresholds.

The congruity effect is plotted in Figure 7, in the form of an end-anchor x question interaction, $F(1, 33) = 288$, $p < .001$. This shows faster responding when there is compatibility between question and end anchor.

Knowledge-representation Analysis

Mean weights across 12 networks at each score-threshold level are plotted in Figure 8 in order to understand the knowledge representations acquired by the comparison networks. Recall that target output activation is negative when the left stick is longer, and positive when the right stick is longer.

Correct performance by a network can be understood by considering a few example weights. A large positive weight from the R6 input ensures positive output compared to any shorter comparison stick L1 to L5. A somewhat less positive weight from the R5 input produces positive output except when compared to the longer stick L6, in which case the stronger negative weight from the L6 input produces a negative output, signaling that the left stick is longer.

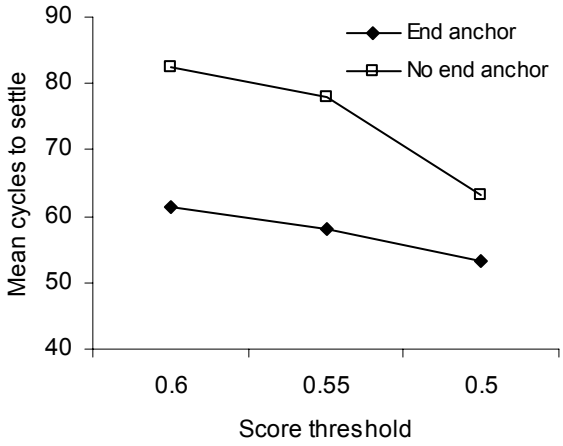

Figure 6: The anchor effect: mean cycles to settle for different score thresholds and the presence of an end anchor.

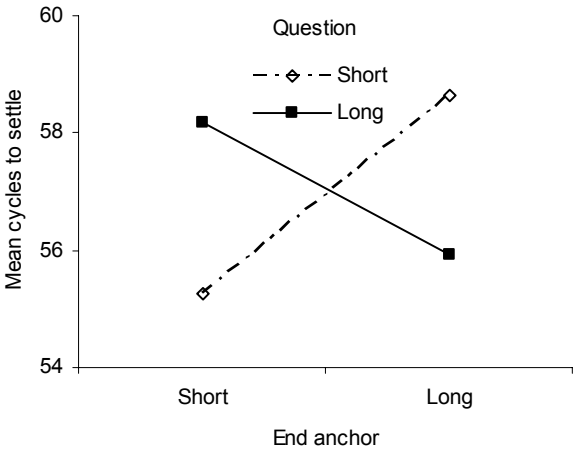

Figure 7. The congruity effect: mean cycles to settle for different size anchors and question phrasing.

The overall pattern of weights is V-shaped, seen most clearly at the lowest score-threshold of 0.5, representing adults. For the right sticks, weights are larger with increasing stick size; for the left sticks, weights are smaller with increasing stick size because the target output is negative when a left stick is longer. Fairly precise left-right

symmetry in weight values on each branch of the V is important to enable accurate judgment of pairs that are close together (e.g., L2 vs. R3).

Serial-position Effect The fact that connection weights have a steeper slope near the ends of the array than in the middle explains the serial-position effect. More distinctive weights produce larger absolute comparison outputs, which are closer to their target values, yielding less network error.

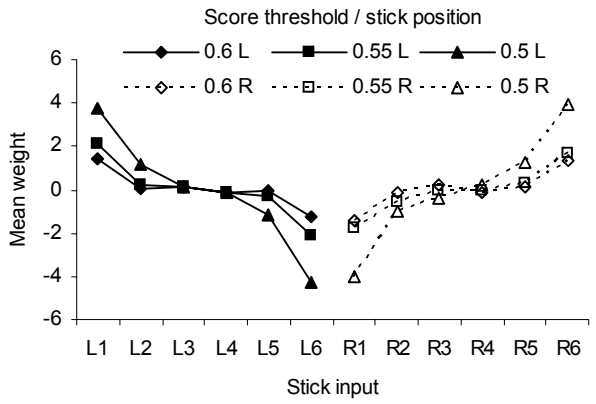

Figure 8: Mean weights in comparison networks from various input units at different score thresholds.

Distance Effect The manner in which this knowledge representation produces the distance effect is evident from the weight plot. Sticks close in size are more likely to have similar weights, producing small absolute comparison values, thus requiring more cycles to reach asymptote in the response module. In contrast, sticks that are farther apart in size are more likely to have larger differences in weight values, producing larger absolute comparison outputs, and thus requiring fewer response-module cycles.

Anchor Effect The manner in which this knowledge representation produces the anchor effect is also evident. Weights for the end anchor sticks (1, 6) have more extreme values than do weights for the other sticks, ensuring larger absolute comparison values and thus quicker responses when end-anchor sticks are involved in a comparison.

Developmental Effects The origin of developmental effects is also apparent from these knowledge representations. The lowest score-threshold of 0.5 (representing adults) produces the steepest V shape with the most easily distinguishable weights. The higher score-thresholds of 0.55 and 0.6 (representing 9- and 6-year-olds, respectively) produce progressively shallower V shapes with weights that are closer in size. The less distinctive the weights, the smaller the absolute output of the comparison module and the more cycles required to reach asymptote in the response module.

Discussion

Our model is a hybrid modular system, with a feed-forward CC network making a length comparison and a CS network using this comparison information along with question information to generate a response. This CSCC model simulated all of the established psychological effects in the development of transitivity in humans. Captured phenomena include the serial-position, distance, anchor, congruity, age-related improvement, and diminishing distance effects.

All of these effects followed naturally from the modular-networks model without any parameter tweaking or special manipulation of training patterns. In general, these effects were produced by the comparison network's natural tendency to learn to order the stimuli by length on its connection weights. The serial-position and anchor effects were due to the fact that these weights were more distinct near the ends of the array than in the middle. The distance effect arose from the fact that the relevant connection weights (those with non-zero inputs) were more distinct with sticks of more distinct size. The congruity effect arose from incompatibility between an anchor and the term used in the questioning, which was made to cause a small degradation of the comparison signal. The age-related improvement and diminishing distance effects were simulated by the familiar phenomenon of older individuals learning the problem more deeply than younger ones do.

Similar interpretations of the serial-position, distance, and anchor effects have been offered by other connectionist modelers (Leth-Steenson & Marley, 2000). But ours is the first model to capture all six effects and to offer novel connectionist interpretations of the congruity and developmental effects. Together these models show how transitivity phenomena can be explained in a neural fashion. We plan to review all of the recent simulations of human and animal data on transitivity in a fuller publication. Different models typically focus on somewhat different phenomena.

Does our model confirm Trabasso et al.'s (1975) hypothesis that people consult a visual image of an ordered spatial array of sticks to answer inference questions? The knowledge representation learned by comparison-module networks certainly does order the array of sticks by length. This learning is based merely on information about the relative lengths of adjacent pairs, without any information on how long the sticks actually are. Whether this knowledge representation constitutes a *visual* image, either in artificial networks or in real brains, is debatable. One way to investigate this issue in real brains might be to see if visual cortex becomes particularly active in brain images of people learning and solving transitivity tasks (Behrmann, Kosslyn, & Jeannerod, 1996). In any case, the simulation presented here demonstrates a fully specified functional account of transitivity development, whether assumed to be located in visual cortex, hippocampus, or other brain regions.

In contrast to these neural-network simulations, Piaget's original logical-inference view cannot account for any of these transitivity phenomena. Indeed its predictions for the effect of distance on response time are precisely the opposite of what actually occurs. Because Piaget's

hypothesis can be naturally framed in terms of a recursively-applied symbolic transitivity rule, this issue can be viewed as another instance of the symbolic rules vs. subsymbolic connections debate that has dominated cognitive science for the past 18 years. As far as psychological development is concerned, results have consistently favored the connectionist approach because it typically covers a wider range of phenomena in a more principled fashion than does the symbolic rule-based approach (Shultz, 2003).

In a more detailed publication, we will present data and analyses of correct inferences by our networks. In general these data also mirror the performance of participants in Trabasso et al.'s (1975) experiment. There is no problem with speed-accuracy tradeoffs in our simulations because response times and errors are positively related.

Although it is beyond the scope of this paper to fully evaluate the various alternative psychological theories of transitivity, these theories do not seem capable of accounting for all the phenomena treated here.

Results indicated that age effects on transitivity tasks can reflect rather small quantitative differences in depth of learning, rather than major qualitative differences in type of processing. Similar results have been found in simulations of a number of other developmental phenomena, including seriation (Mareschal & Shultz, 1999), discrimination shift learning (Sirois & Shultz, 1998), and concept learning (Shultz & Cohen, 2004). Our explanation represents a radical departure from previous interpretations of these phenomena, which have tended to suggest that older children are doing something qualitatively different than are younger children. Because of its capacity for network growth, the CC algorithm is particularly well suited to discovering whether qualitative changes are necessary for capturing developmental change. Some developmental phenomena require such qualitative growth, while other developmental phenomena do not (Shultz, 2003). In addition, our model predicted a diminishing anchor effect with increasing age that could be tested with children.

To capture the heretofore elusive congruity effect we implemented a (shortcut) neural version of the idea that semantic incompatibility between an anchor and question term can slow performance. We also plan to implement an alternative hypothesis based on the notion that particular combinations of question and items serve to bias the participant's response at the start of a random walk towards one or another decision boundary (Link, 1990). Our current response module, with its random selection of units to update, might be adapted to implement the basic features of Link's hypothesis. Comparing results across the two techniques could indicate which hypothesis provides a better explanation.

Abstract

Two models are presented that compute a quasi-regular mapping. One was based on localist representations of items in the quasi-regular domain, the other was based on distributed representations. In each model, a control parameter termed *input gain* was modulated over the one and only level of representation that mapped inputs to outputs. Input gain caused both models to shift between regularity-based and item-based modes of processing. Performance on irregular items was selectively impaired in the regularity-based modes, whereas performance on novel items was selectively impaired in the item-based modes. Thus, each model exhibited a double dissociation without separable processing components. These results are discussed in the context of analogous dissociations found in language domains such as word reading and inflectional morphology.

Introduction

The quasi-regular nature of language has played a central role in theories of language processing in the mind and brain. On the one hand, language processes must be able to handle novel inputs, e.g., skilled readers can give reasonable pronunciations and conjugations to verbs that they have never encountered before. These abilities demonstrate how language usage can be generative on the basis of regularities. On the other hand, irregular items often exist for which the regularities do not apply. Thus, language processes must be able to override the regularities, when appropriate, with knowledge that is applicable to only a few items, or even to just one. How are language processes structured to handle both regularities, and the exceptions to those regularities?

One answer to this question is that any given quasi-regular domain is processed by two complementary routes. A *regularity-based* route is specialized to capture the regularities that span across linguistic items in the domain, and an *item-based* route is specialized to capture knowledge that is specific to items in the domain. For instance, in the words-and-rules theory (Pinker, 1999), rules are used to process regular inflectional morphologys (e.g., WALK-WALKED), and a lexicon is used to process irregular inflections (e.g., GO-WENT). In the dual-route cascaded (DRC) theory of word reading (Coltheart, Curtis, Atkins, & Haller, 93; Coltheart et al., 2001), a set of grapheme-to-phoneme correspondence rules is used to capture regularities between the spellings and sounds of words, and a system of lexical knowledge serves to override the rules when necessary (e.g., PINT does not rhyme with MINT).

Alternatively, *single-route* theories have been proposed in which the mechanisms and representations for handling regularities and irregularities are inseparable. For instance, Rumelhart and McClelland (1986) proposed a theory in which a single route of processing was used to generate the past tense of both regular and irregular verbs (also see, e.g., Joanisse & Seidenberg, 1999). Kello and Plaut (2003) proposed a theory of word reading in which the mapping from spelling to sound is mediated by a single level of learned representations (also see Plaut & Gonnerman, 2000).

A wide variety of evidence has been brought to bear on dual-route and single-route theories of language processing (for reviews, see Coltheart et al., 2001; McClelland & Patterson, 2002; Pinker, 1999; Pinker & Ullman, 2002; Plaut, McClelland, Seidenberg, & Patterson, 1996). Much of this evidence speaks to one or another particularity of a given theory. Every piece of evidence contributes to the overall debate, but here we focus on one kind of evidence that is relevant to all theories in question: dissociations between regularity-based and item-based processing.

Double dissociations have been observed in language processing, and some have been interpreted as evidence for separable regularity-based and item-based components of the language system. In the area of inflectional morphology, Ullman and his colleagues (Ullman et al., 1997) reported evidence for a dissociation between the past tense formation of regular and irregular verbs in English. They found that Alzheimer's patients, as well as aphasics with posterior lesions, were poor at generating the past tense of verbs with irregular inflections, but relatively normal with regular inflections. They found the opposite pattern for Parkinson's patients and aphasics with anterior lesions. Marslen-Wilson and Tyler (1997; 1998) found a similar dissociation in a priming paradigm with language-impaired patients.

In the area of word reading, deficits found in surface and phonological dyslexia have been interpreted analogously to those found in posterior versus anterior aphasics. For instance, Berhmann and Bub (1992) reported on a surface dyslexic patient MP for whom the ability to read exception words (particularly of low frequency) was greatly impaired,

whereas the ability to read both regular words and nonwords was mostly intact. By contrast, Funnell (1983) reported on a phonological dyslexic patient WB for whom the ability to read nonwords (even simple CVC nonwords) was greatly impaired, whereas the ability to read both easy and difficult words was mostly intact.

The impairments of these and other patients have a straightforward explanation in terms of separable item-based and regularity-based processing components. The deficits in Alzheimer's patients, posterior aphasics, and surface dyslexics all reflect damage to an item-based component of processing (e.g., a lexicon) that is responsible for irregular items (not necessarily the same component across types of deficits). The deficits in Parkinson's patients, anterior aphasics, and phonological dyslexics all reflect damage to a regularity-based component of processing (e.g., rules) that is responsible for novel items.

These double dissociations appear to challenge single-route theories because item-based and regularity-based processes are not separable in single-route theories. Proponents of single-route theories have responded to this evidence in a number of ways. In some cases, methodologies or interpretations of data have been called into question (e.g., McClelland & Patterson, 2002). In other cases, the data have been explained in terms of dissociations between semantic and phonological components of processing, rather than item-based and regularity-based components (e.g., Joanisse & Seidenberg, 1999). The research to date has left open the question of whether dissociations between the processing of novel and irregular items can be explained without reference to an architectural dichotomy in the language system.

Current Work

The primary aim of the current study was to demonstrate how a dissociation between item-based and regularity-based processing can occur in a single-route architecture without any manipulation of separable processing components, i.e., without reference to separable semantic and phonological contributions to processing. The basic idea is that a single component of processing can shift between two qualitatively different "modes" of processing as a function of one control parameter. Specifically, we present two different kinds of connectionist models that possess a control parameter termed *input gain*. We show that, in both types of models, input gain can cause a shift in processing between an item-based mode and a regularity-based mode. Furthermore, we show how this shift can give rise to a double dissociation in performance on irregular versus novel inputs.

The models were built to process an abstract, quasi-regular mapping. Properties of the mapping were analogous to basic properties of quasi-regularity in language domains. However, items did not correspond to any particular words in a particular language domain. The mapping was created primarily to facilitate analysis of the models, rather than to simulate a particular language phenomenon such as the past tense formation in English. Therefore, the models are intended and reported only as proofs-of-concept.

The first model used a single level of localist nodes to map input patterns onto output patterns. Each node represented one item in the training corpus, and the activation of each node was a function of the similarity between the item it represented, and the current input to the model. Thus, this model could be considered as *analogy-based* because both known and novel inputs were explicitly processed in terms of the similarity of their input patterns to that of all items in the corpus (see Albright & Hayes, 2003; Nakisa, Plunkett, & Hahn, 2000).

The second model used a *distributed* level of representation to map input patterns onto output patterns. Hidden representations were learned via backpropagation (Rumelhart, Hinton, & Williams, 1985), and each hidden unit contributed to the processing of many, if not all, items in the training corpus. Representations learned through backpropagation tend to map similar inputs onto similar outputs (Rumelhart et al., 1995). Thus, as in the analogy model, the distributed model processed both known and novel inputs in terms of their similarity to items in the corpus. But unlike the analogy model, hidden representations were shaped by similarities among both input and output patterns in the corpus, as well as the relationships between inputs and outputs.

In both models, input gain is a multiplicative scaling parameter on the net inputs to units, be they localist nodes or hidden units. The current simulation results show that the modulation of input gain at testing caused similar effects in both models. At low levels of input gain, both models failed to map irregular items to their appropriate outputs, but succeeded in mapping regular items and novel inputs. At high levels of input gain, both models succeeded at mapping both regular and irregular items, but performed poorly with novel inputs.

The reason why input gain caused this double dissociation was different for each model. In the analogy model, input gain modulated the intensity of competition for activation among localist nodes. Low levels of competition caused outputs to be based on the summed contributions from many partially activated nodes. Regularities across nodes were extracted in these summations to the point of overriding any exceptions to the regularities. By contrast, high levels of competition caused a winner-take-all mode of processing in which a known input correctly activated its corresponding node, whereas a novel input incorrectly activated a node corresponding to a similar, known item.

In the distributed model, input gain modulated the sharpness of a sigmoidal activation function. Low levels of input gain caused hidden units to operate mostly in their linear range, thereby emphasizing the componential (i.e., regular) relationships that were learned between inputs and outputs. High levels of input gain caused hidden units to operate mostly in their asymptotic range, thereby emphasizing the conjunctive relationships that were learned between inputs and outputs (for a discussion of

componential and conjunctive coding, see O'Reilly, 2001). Componential relationships supported only the processing of regular and novel items, whereas conjunctive relationships supported only the processing of known items.

Simulation Methods

Input and Output Representations were constructed from a 12 dimensional binary space. Out of $2^{12} = 4096$ possible input patterns, one fourth (1024) were chosen at random to constitute the corpus of items. Each chosen input pattern was associated with one output pattern. Output patterns were created in two steps. First, each input pattern was copied to its corresponding output pattern (i.e., the identity mapping. Note, however, that the results apply to all linearly separable mappings). Second, the bit value of each dimension, for each output pattern, was flipped with a 5% probability. Thus, the identity mapping was a regularity, and flipped values were exceptions to that regularity. This procedure resulted in 563 fully regular items (no flipped bits), and 461 irregular items with one to four flipped bits per item. The 3072 remaining patterns served as novel items during testing.

For the analogy model, there were 12 input units corresponding to the 12 input dimensions, and dimension values were coded as activations of ±1 on the inputs. For the distributed model, there were 24 input units, half of which coded the 12 dimension values as activations of 0 or 1. The other half were activated as flipped values of the first half, i.e., $1–x$, where x was each of the first 12 activations. The $x|1–x$ coding scheme was used because the distributed model was trained via backpropagation (this scheme was not necessary in the analogy model because it was not trained; see next two sections). In backpropagation, no learning will occur on a unit's sending weights when the activation value of that unit is zero. Therefore, the $x|1–x$ coding scheme ensured that weight derivatives were generated for every input dimension, on every training episode.

For both models, there were 12 output units corresponding to the 12 output dimensions, and dimension values were coded as targets of 0 or 1 on the outputs.

Analogy Model Architecture. In the analogy model, input units were fully connected to 1024 "logogen" units. Each logogen represented one item in the corpus, and the weights on incoming connections from input units were set according to each logogen's input pattern, i.e., +1 weights for positive input dimensions, and -1 weights for negative dimensions. Each logogen projected outgoing connections to all 12 output units, and the weights on outgoing connections were set according to each logogen's output pattern (as for incoming connections).

To process a given item, input units were first set to the item's input pattern. Logogen activations were then calculated with the normalized exponential function (see Nosofsky, 1990),

$$a_j = e^{\gamma \varepsilon I_j} \Big/ \sum_i e^{\gamma \varepsilon I_i},$$

where I was the net input to a unit, calculated as the dot product between the input vector and the incoming weight vector, γ was input gain, ε was noise sampled evenly in the range ±0.1, and i spanned all logogens. Each output unit was then calculated as the sigmoid of the dot product between the logogen vector and its incoming weight vector. Noise was included to break perfect ties between very small (e.g., two or three) numbers of activated logogens. Such ties occurred more often at high levels of input gain.

Distributed Model Architecture. In the distributed model, the input units were fully connected to 200 hidden units, and the hidden units were fully connected to the output units The number of hidden units was determined through pilot testing to be about 50 units more than the minimum needed to learn the mapping. However, results were very similar over a range of hidden unit numbers. Hidden units were calculated with the hyperbolic tangent function,

$$a_j = \tanh\left(\gamma \varepsilon I_j\right),$$

which is analogous to the logistic, except it has asymptotes at ±1 instead of 0 and 1. Input gain (γ) was fixed at 1 during training, and varied during testing (see next section). Noise (ε) was fixed at 0.1 (as in the analogy model) during both training and testing. Output units were calculated as in the analogy model.

Connection weights were initialized to random values in the range ±0.1, and weights were learned by gradient descent,

$$\Delta w_{ij} = \eta\left(\partial E / \partial w_{ij}\right),$$

where w_{ij} was the connection weight from unit j to i, η was the learning rate (fixed at 0.001), and E was cross-entropy error (Rumelhart et al., 1995). Weight changes were made each time after weight derivatives had been accumulated over all 1024 items in the corpus. Weight derivatives were calculated for each item as follows: input units were set to the item's input pattern, activation was propagated forward through the network, an error signal was calculated from the difference between actual and target outputs, and the error signal was backpropagated to generate the weight derivatives. Weight updates were repeated until every output unit was with 0.1 of its target for every item in the training corpus. This criterion was reached after 3000 passes through the corpus.

Testing Procedure. For both models, performance was assessed on each test item by setting the input units to the item's input pattern, and then determining whether the activation of each output unit was within 0.5 of its target (which was either 0 or 1). Model outputs were correct only when the activations of all 12 output units were within range. Targets for items in the corpus were set according to each item's output pattern. Targets for the 3072 novel items were set according to each item's input pattern, i.e., the identity mapping.

To dissociate item-based and regularity-based processing, input gain was varied as a single control parameter over the logogen units in the analogy model and over the hidden units in the distributed model. The reported levels of input gain were between 0.5 and 3 for the analogy model, and 0.333 and 3 for the distributed model. These ranges were chosen to show asymptotic performance at the lower and upper ends, i.e., the patterns of behavior did not change substantially beyond these ranges.

Simulation Results

Mean accuracies for the analogy model are graphed in Figure 1 as a function of input gain and item type (regular, irregular, or novel). The same are graphed for the distributed model in Figure 2.

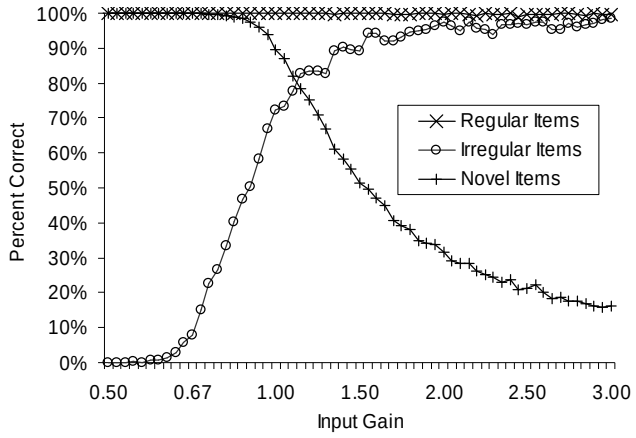

Figure 1: Mean accuracies for the analogy model

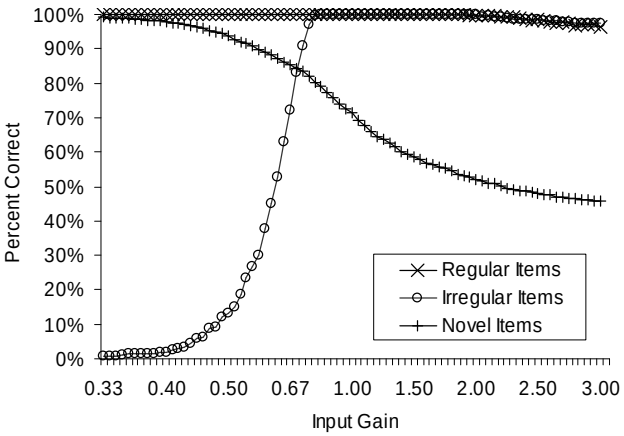

Figure 2: Mean accuracies for the distributed model

Figures 1 and 2 show that both models exhibited a clear dissociation in performance on irregular items compared with novel items. At low levels of input gain, generalization of the identity mapping to novel inputs was essentially perfect, as was performance on regular items. By contrast, performance on irregular items dropped to 0%, at which point all inputs resulted in the identity mapping. For irregular items, application of the identity mapping can be considered as a *regularization* error because, for the quasi-regular domain constructed here, the identity mapping is the regular mapping.

At high levels of input gain, performance on all items in the corpus was near perfect in both models. By contrast, mean accuracies for the novel items dropped to as low as 16% for the analogy model, and 46% for the distributed model. Of all the analogy model's erroneous responses to novel items at the highest level of input gain, 97% were output patterns that corresponded to output patterns in the training corpus. These responses can be considered as *lexicalization* errors because they are responses for other items in the model's "lexicon". The same analysis of errors made by the distributed model showed only 27% lexicalization errors (where the chance rate was 25%).

These results show that the manipulation of input gain as a single control parameter, over a single level of representation, caused a clear double dissociation in both models. To better understand the similarities and differences in processing between these models, three visualizations of the input-output mappings for each model are shown in Figure 3.

In each visualization, all 4096 points in the 12 dimensional input space are arranged on a grid such that all adjacent vertices differ by only one bit. To illustrate, near the lower left-hand corner of each plot is the vertex where all 12 input dimensions are negative. The next vertex up and the next vertex to the right each have one positive input dimension, and so on. Each grid "wraps around" such that vertices on the left edge are adjacent to the corresponding vertices on the right edge, and likewise for the top and bottom edges. Thus, the 2D space of each grid represents a portion of the similarity structure in the 12D input space. In addition, 10 evenly spaced points are interpolated in each space between each pair of vertices. Given that each side has 64 vertices ($64^2 = 4096$), there are $640^2 = 409{,}600$ points of the input space represented in each plot.

At each point, a gray scale value is plotted that represents the summed activation of four output units for the corresponding input pattern. The same four output units (chosen arbitrarily) are shown at all points in all plots. The gray scale values are calculated such that, the darker the point, the closer the outputs were to 0.5. Conversely, whiter points indicate where the outputs were at their asymptotes (0 or 1). Thus, the dark borders in each plot represent the decision boundaries in each model, that is, where one or more of the four outputs crossed the middle point between asymptotes as a function of change in the input space.

Plots are shown for each model, at three different levels of input gain: the low end (0.5 in the analogy model and 0.333 in the distributed model; top row), the high end (3 in both models; bottom row), and the point at which accuracies for irregular items and novel items are equal (1.1 in the analogy model and 0.8 in the distributed model; middle row). Overall differences in plot densities for the analogy model, compared with plot densities for the distributed model, were due to differences in the polarity of the output

units: outputs in the distributed model tended to be closer to 0 or 1, i.e., values that corresponded to white points on the plots.

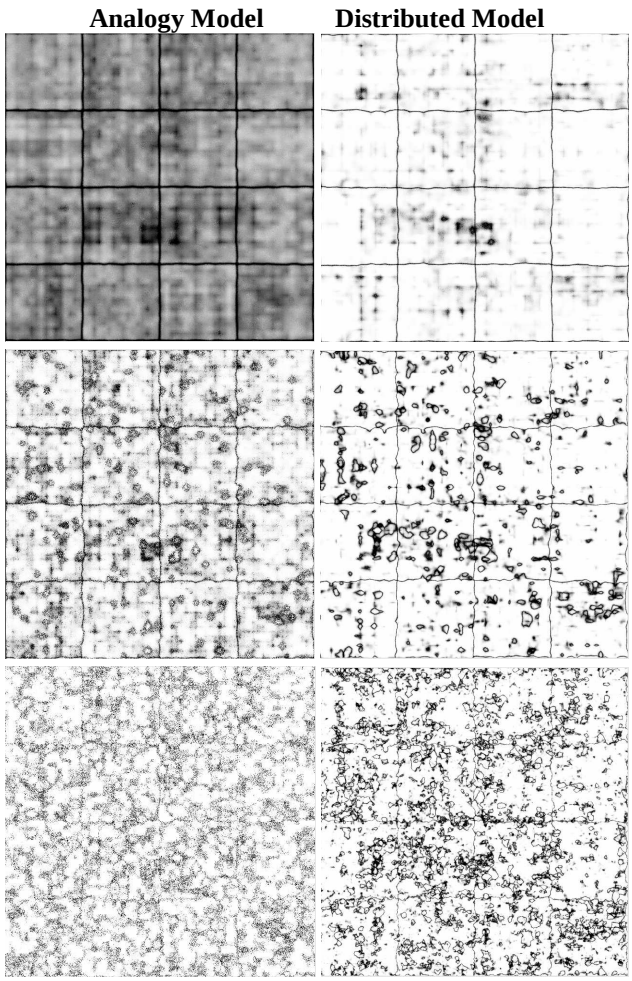

Figure 3. Visualizations for each model at low (top), medium (middle), and high (bottom) levels of input gain

The grid patterns seen in the top two plots of Figure 3 show that both models processed the identity mapping at the low end of input gain. In fact, if all 12 outputs had been represented, each plot would show a 64 by 64 grid pattern, where the grid lines fall exactly between the vertices. Thus, the grid reflects the finding that, at low input gain, the identity mapping was generalized to all inputs, including those for novel and irregular items. The grid is a depiction of regularity-based processing in each model because the identity mapping was the regularity in our quasi-regular domain.

The middle two plots show that the grid pattern became distorted for both models at moderate levels of input gain, and "pockets" of decision boundaries began to appear. Given that mean accuracies were about 80% for irregular items at these levels of input gain, one can infer that the distortions and pockets reflect the "warping" of the identity mapping that was necessary to process the irregular items. Moreover, given that mean accuracies were about 80% for novel items as well, one can infer that these distortions and pockets were mostly isolated to the irregular items. These plots show that a balance was struck at moderate levels of input gain between item-based and regularity-based processing.

The bottom two plots show that, for each model, the grid pattern was mostly replaced by pockets of decision boundaries at the high end of input gain. These pockets have a fairly simple interpretation for the analogy model. Recall that, at the high end of input gain, 97% of the errors for novel items were lexicalizations. What this means is that the pockets show where known inputs were mapped correctly, and where novel items were mapped incorrectly to similar known items. These "item pockets" are a depiction of item-based processing in the analogy model.

In the distributed model, the pockets cannot be readily interpreted as item pockets because a substantial number of novel items were mapped correctly at the high end of input gain (46%), and the proportion of lexicalization errors for novel items was not much above chance (27%). It appears that the distortions needed for accurate mappings of irregular items had "spread out" at high levels of input gain. Because the mapping of regular items is mostly correct at the high end of input gain, one can infer that the decision boundaries spread out over untrained (novel) regions of the space more than they did over trained (known) regions. It is this selective spread of decision boundaries that indicates item-based processing at the high end of input gain.

Conclusions

The current simulations provide a new demonstration of how double dissociations can occur without separable processing components (see also Devlin & Gonnerman, 1998; Juola, 2000). Performance on novel versus irregular stimuli was dissociated by shifting between regularity-based and item-based modes of processing. Unlike previous demonstrations, these modes existed at the ends of a continuum created by one control parameter.

It is important to acknowledge that the current work only opens the door to an alternative to the rules/lexicon and phonology/semantics explanations of double dissociations. It is unclear whether input gain would provide a satisfying account of specific empirical results. For instance, input gain would not appear to handle dissociations in which all regular items, both novel and known, are impaired (Marslen-Wilson & Tyler, 1997, 1998; Ullman et al., 1997). Also, the current simulations did not include subregularities or variations in the frequency of items. These factors have been simulated successfully (Kello, Sibley, & Plaut, submitted), but only as demonstrations. Subregularities allowed for model errors that were more like patient errors, but further work is necessary to test the simulated errors.

The current simulations also raise a number of larger questions, such as: Are there any testable differences between the analogy and distributed models presented here? Do these simulation results have implications for current

theories of word reading and inflectional morphology? Are the reported models consistent with the localization of regularity-based and item-based processing in the brain, to the extent that evidence exists for such localization? What might be the neural bases of input gain? These and other questions await further research.

Acknowledgments

This work was funded in part by NIH Grant MH55628, and NSF Grant 0239595. The computational simulations were run using the Lens network simulator (version 2.6), written by Doug Rohde (http://tedlab.mit.edu/~dr/Lens). We thank David Plaut for his input on precursors to this work.

Fodor's 'Guilty Passions': Representation as Hume's Ideas.

Peter Slezak (p.slezak@unsw.edu.au)
Program in Cognitive Science, School of History & Philosophy of Science
University of New South Wales, NSW 2052 AUSTRALIA

Abstract

Jerry Fodor (1985) has joked that philosophers have always been prone to eccentric worries such as an anxiety about the existence of tables and chairs, but with the issue of mental representation they have found a problem that is real and crucial for progress in the cognitive sciences. However, given Fodor's 'methodological solipsism' of computational symbols and their 'formality condition', Jackendoff (1992) has facetiously asked "Why, if our understanding has no direct access to the real world, aren't we always bumping into things?" It is no accident that Jackendoff's parody recalls Samuel Johnson's famous retort to Berkeley's "ingenious sophistry" by kicking a stone. There is an acute irony in the fact that cognitive science has simply rediscovered the philosophers' traditional worry about tables and chairs. Accordingly, it is not surprising that Fodor's latest book *Hume Variations* endorses the classical Empiricist 'idea' idea of Locke, Berkeley and Hume. The paper explores Fodor's concept of ideas as mental objects in relation to its historical antecedents.

Precursors

For some time, Fodor (1978, 1998) has been making hints *en passant* comparing his favored theory of mind with that of early modern Empiricist philosophers. For example, in his *Concepts*, he said "To a first approximation ... the idea that there are mental representations is the idea that there are Ideas *minus* the idea that Ideas are images." "Hume taught that mental states are relations to mental representations, and so too does RTM" (Fodor 1998, p. 8,9). In this light, it is hardly surprising that modern problems might be simply the reinvention of old problems in a new guise. Now, with his *Hume Variations* (2003), Fodor has come out of the closet, admitting to having harbored something like a "guilty passion" for Hume's *Treatise of Human Nature*. Fodor's enthusiasm for Hume is based on his view that Hume's account of the mind "seems, in a number of respects, to anticipate the one that informs current work in cognitive science" (p. 2). Indeed, Fodor suggests "Hume's *Treatise* is the foundational document of cognitive science: it made explicit, for the first time, the project of constructing an empirical psychology on the basis of a representational theory of the mind; in effect, on the basis of the Theory of Ideas" (p. 134). More specifically, Fodor says, "it remains fully plausible that cognitive processes are constituted by causal interactions among mental representations, that is, among semantically evaluable mental particulars" (p. 135). Translated, this means an 'atomistic' account of concepts, of which he says, "To be sure, on this view, we're not after all so far from billiard balls" (p. 137). Fodor adds, "Either that, or we really are entirely in the dark". Indeed, there are ample grounds to wonder about both the degree of current illumination and also Fodor's history.

Independently of his earlier *obiter dicta*, Fodor's formulations have always been evocative of traditional accounts of 'ideas' as the 'direct objects' of perception and understanding. This is the compelling conception according to which we don't perceive the objects of the world directly, but only indirectly as mediated by our mental representations or ideas of them. Fodor's analysis of 'propositional attitudes' as "relations between organisms and internal representations" has always suggested a tri-partite, 'object' conception of concepts common to traditional and contemporary representative theories (Bechtel 1998, Slezak 2002):

$$\text{world} \leftrightarrow \text{representation} \leftrightarrow \text{mind}$$

Fodor protests that his view is a minority opinion but the problematic tripartite structure has always been dominant (see von Eckardt 1993, Slezak 2002), despite the periodic complaints of 'pragmatists', and 'direct perception' advocates such as Hume's critic Thomas Reid and his more recent counterparts such as Hilary Putnam (2000).

Fodor suggests that Hume's account not only anticipates current work in cognitive science but "thinking seriously about our theory of mind in relation to Hume's might help with the project" (p.2). Thus, Fodor's small book may be seen as an extended historical footnote or appendix to earlier work, particularly his *Concepts* (1998). By 'outing' himself as adherent of the classical 'idea' idea, Fodor illustrates an important approach to theorizing in cognitive science.

With some important differences, Fodor's enterprise shares its approach and purpose with Chomsky's (1966) neglected *Cartesian Linguistics* which sought to understand the body of theoretical insight of the premodern period, to appraise their contemporary relevance and to find ways to exploit them for advancing contemporary inquiry. For his part, Chomsky offered no explicit analysis of the relation of Cartesian linguistics to current work on the grounds that the modern reader should have little difficulty in drawing these connections for himself (1966, p. 2). Chomsky was undoubtedly too optimistic in this regard, perhaps contributing to the neglect of this important contribution to both classical scholarship and contemporary cognitive science. By contrast, Fodor's book is weighted in the opposite direction with primary focus upon current theories of the mind.

As Fodor points out, Hume has suffered from a procrustean hindsight according to which most of what he

took to be important about his own philosophy has been dismissed as not philosophy at all, but empirical psychology (p. 5). As Fodor notes wryly, "Mastering the science of human nature doesn't sound a lot like analyzing concepts" (p. 5). The changed philosophical climate today has more or less effaced the distinction between philosophical inquiry and science, thereby permitting us to see Hume in a clearer light.

Of course, Fodor chooses Hume for this exercise because Hume "holds a fairly rudimentary and straightforward version of the sort of cognitive psychology that interests me" (p. 2). That is, Fodor has a partisan rather than purely exegetical purpose - namely, to use Hume as a vehicle for advertising the virtues of his own theory of mental representation. As far as it goes, this is an important and interesting exercise - not least, because the parallels and divergences help us to get a clearer picture of Fodor's own significant position on issues central to cognitive science today.

Fodor's book reveals something of the mutually illuminating connections between the disjoint literatures of cognitive science and the history of early modern philosophy. However, Fodor is not vindicated simply because he was anticipated by Hume. The 'Whig' approach to history cuts both ways, and Hume's neglected critic Reid derives a renewed interest precisely because of Fodor's project and its partisanship. Reid gets short shrift from Fodor, relegated with other 'pragmatists', direct-realists and Wittgensteinians to dismissive footnotes. However, a *Reid Variations* would tell a more compelling alternative story than Fodor allows.

As Fodor notes, Hume's representative Theory of Ideas (TOI) was itself derived from Descartes. Consequently, throughout the book Fodor refers to the doctrine he defends as 'Cartesian' though in this case the adjective is intended to modify 'representationalism' and not the more usual 'dualism'. However, Hume's conception of this representationalism was, in fact, closer to Malebranche's version than Descartes's own. Though a follower of Descartes, Malebranche held a distinctive and highly problematic conception of ideas as objects in the mind of God. Indeed, Descartes shared the 'pragmatism' and 'direct realism' of Malebranche's critic Arnauld and later Reid - the very doctrine that Fodor combats as "a main concern throughout this book" (p. 12). Fodor characterizes this pragmatist doctrine as "the defining catastrophe of analytic philosophy of language and philosophy of mind in the last half of the twentieth century" (p. 73,4). Accordingly, insisting on such issues of provenance and tracing the genealogy of ideas is no mere antiquarian pedantry or exegetical nicety. If we take Fodor's enterprise seriously, on his own account and example, the historical parallels can be very instructive about our current theoretical problems. In particular, the celebrated Malebranche-Arnauld debate and its subsequent re-enactments were anticipations of Fodor's polemic with his critics today. By focusing on Hume alone, Fodor obscures this broader picture, but the pattern of recurrence is a striking fact whose significance deserves to be understood.

Curious & Melancholy Fact?

Despite Fodor's unfailing optimism, there is a kind of recurrence which deserves attention because it is a manifestation of deeper, and therefore specially illuminating, causes, - a chronic malaise that is symptomatic of deep pathology. Thus, Yolton (1984, p. 6) has noted that the burning question among philosophers in the seventeenth and eighteenth centuries is that of "objects present to the mind" - precisely Fodor's question of "concept possession" central to the recent book and his earlier *Concepts* (1998). Fodor suggests that in the intervening period since Hume the theory of ideas "seems to have made some modest progress" while acknowledging that it is, "to be sure, more modest than some have advertised" (p. 157). Although relegated to footnotes in Fodor's book, modern counterparts of Hume's critics are also prominent among leading theorists today. This looks alot less like progress, however modest, than Fodor suggests. Thus, Putnam (2000) has recently defended Reid's "natural realism" and he also cites John Austin who, significantly, invokes yet earlier writers saying: "It is a curious and in some ways rather melancholy fact that the relative positions of Price and Ayer at this point turn out to be exactly the same as the relative positions of Locke and Berkeley, or Hume and Kant." (Austin 1962, p. 61)

In a riposte to Putnam (2000), Fodor (2000) asserts bluntly, "In fact, there is no direct realist theory of perception (or of anything else that's mental)". However, Fodor ignores Putnam's concern about representations as "interface" between mind and world, though this has been the classical source of discomfort about the 'veil of ideas' central to the Humean conception. Thus, Putnam and Reid are grouped with Gibson and McDowell as among those who "reject RTM entirely" in the sense that they hold "perception isn't mediated by mental representations." Fodor adds that this flies in the face of the evidence from the success of modern psychology. Referring specifically to Reid, Fodor suggests "but for the notion of mental representation, much of what the mind does would be miraculous. The miracle theory of mind is the natural alternative to the representational theory of mind" (Fodor 2000). Fodor's extravagant humour makes it hard to tell whether he is just exaggerating for effect or plain wrong in this characterization of the Reid/Putnam view. Of course, there have been accounts purporting to deny representations altogether (Brooks 1991, Freeman and Skarda 1990, Clark and Toribio 1994, Greeno 1989, van Gelder, 1998). However, even these views are not plausibly seen as a return to something like behaviorism since, strictly speaking, they do not reject internal representations at all (see Markman and Dietrich 2000). For his part, Putnam makes the point explicitly, seeking "to distinguish carefully between the activity of "representation" (as something in which we engage) and the idea of a "representation" as an *interface* between ourselves and what we think about, and to

understand that giving up the idea of representations as interfaces requiring a "semantics" is not the same thing as giving up on the whole idea of representation" (Putnam 2000, p. 59). Thus, Fodor's appears to miss the more subtle views (not to mention explicit texts) which do not deny representations as such but only a certain notoriously problematic conception of them as mental objects with truth values. Futhermore, as Greco (1995) notes, "it is clear that Reid does not deny the existence of ideas if ideas are thought of as operations or acts of thought. Rather, Reid objects only to ideas as mental entities distinct from any operation or act" (1995, p. 283).

Jerry-mandering?

Fodor reproaches Putnam and cites Marr's (1982) research as exemplary proof of the representational pudding. However, Marr's differential equations, zero crossings and other formalisms are not obviously the widely individuated, semantically evaluable mental particulars that Fodor takes to be characteristic of representations. Marr is undoubtedly a counter-example to any theory that would deny representations altogether, but fails to address the concern with 'object' theories of Hume and Fodor. Thus, Fodor's animadversions against miraculous theories are beside the point since the "direct" theories of interest are also "indirect" in Fodor's uncontroversial sense, namely, in positing some internal, causal processes which are responsible for, and in this sense 'mediate', perception, belief and action. This way of putting the point will be agreed on all sides. Neither Putnam nor Reid would demur from this way of 'jerry-mandering' the issue since everyone is an indirect representationalist in this sense.

Granny & the Golden Mountain

Fodor's hard-core *Malebranchisme* is further confirmed and illuminated by his un-selfconscious use of the most venerable argument for ideas as mediating objects of perception: Fodor asks how he could think about his Granny if he is in New York and she is in Ohio. Or, "How can I be in an unmediated relation to Ebbets Field (alas long since demolished); or to my erstwhile dentist, who passed away a year ago in August?" (Fodor 2000). This is, of course, just the notorious Argument from Illusion, and the rhetorical force of Fodor's question relies upon the remoteness or non-existence of things we are supposed to be in a problematic "direct" relation to. Malebranche, too, remarks "it often happens that we perceive things that do not exist, and that even have never existed - thus our mind often has real ideas of things that have never existed. When, for example, a man imagines a golden mountain, it is absolutely necessary that the idea of this mountain really be present to his mind" (1712, p. 217). The classical conclusion, of course, is that we must be in a direct relation with something else - namely, an image, sense datum or 'idea'. However, the "directness" of veridical perception (or memory) is not so easily defeated in this manner, since it need not rely on some occult relation to its objects as Fodor suggests. Of course, it is not obvious that Fodor's causal theory is any better able to deal with distant or non-existent objects of thought, as Putnam has pointed out. Conceptual or inferential role theories offer an alternative conception in the spirit of Arnauld and Reid. Moreover, as just noted, both direct and indirect theories of perception are equally committed to causal intermediaries which will explain Fodor's relation to Ebbets Field, his granny and his late dentist.

Fodor's deployment of what is in effect the Argument from Illusion suggests that he may be open to the kind of charge Putnam makes against Dummett, namely, "that his picture ... is closer to the 'cognitive science' version of the Cartesian cum materialist picture than he himself may realize" (Putnam 2000, p. 58). By this Putnam means the 'Cartesian Theatre' conception minus dualism that Dennett, too, has characterized as 'Cartesian Materialism'. Despite its centrality in the tradition of ideas, Fodor nowhere attempts to escape or even address this potential difficulty, perhaps on the grounds that modern computational, symbolic accounts of representation are automatically immune from the objection. On the contrary, however, statements by Newell (1986, p.33) and others articulating the foundational symbol-system paradigm characteristically assimilate external and internal symbols in such a way as to encourage just such suspicions (see also Bechtel 1998, Lloyd 2003). It is striking that the earliest complaints in the 17th century were precisely about taking things outside the mind as a model for the things inside (Slezak 2002).

Why God Bothered

There is particular irony in the fact that the problem for resembling ideas may be, at a deeper level, the problem shared by Fodor's RTM as well. It is not only resemblance that creates difficulties for ideas or representations. Another manifestation of the same problem may be an 'externalist' conception of representations as semantically evaluable - the claim that mental processes tend to preserve semantic properties like truth. Fodor (1994, p. 9) has said that this is "the most important fact we know about minds; no doubt it's why God bothered to give us any" (1994, p. 9). However, Fodor has seen a dilemma arising from the fact that mental content doesn't appear to supervene on mental processes and, therefore, perhaps "semantics isn't part of psychology" (Fodor 1994, p. 38). This dilemma seems to arise from the fact that semantic evaluability of representations, or old-fashioned 'veridicality' of ideas, like resemblance, depends on being able to make a comparison between ideas and what they purportedly refer to. In Berkeley's idealist response to this problem we can see the precursor and analog to Fodor's (1980) methodological solipsism. In view of these parallels, it is striking, though perhaps not surprising, that Fodor (1994) sees a deep puzzle about how misrepresentation could arise if any causal or correlational theory were true. I have suggested (Slezak 2002, 2004) that the modern problem of misrepresentation is a unnoticed variant of the classical 'Argument from Illusion' and so it should not be surprising that we saw Fodor give an explicit endorsement to just this form of

argument. Fodor argues that if ideas are caused directly by external objects, we can't have misrepresentations (i.e. illusions), whereas the classical argument concludes from the fact that we have illusions, our ideas can't be directly caused by external objects.

In this regard, Fodor's latest discussions raise questions that were central to his seminal book *The Language of Thought* (1975). Dennett (1977) noted:

> Hume wisely shunned the notion of an inner self that would intelligently manipulate the ideas and impressions, but this left him with the necessity of getting the ideas to 'think for themselves'. ... Fodor's analogous problem is to get the internal representations to 'understand themselves' ... If there is any future for internal systems of representation it will not be for languages of thought that 'represent our beliefs to us', except in the most strained sense. (Dennett 1977, p. 274, 5)

Fodor acknowledges that Putnam is aware that nowadays representational theories are formulated so that there is no "user" or exempt agent as undischarged homunculus, but suggests that he fails to acknowledge that perception is direct under these accounts. Fodor asserts that, like telephone conversations with his wife, perception is mediated in all sorts of ways, but "still, it is my wife that I talk to". However, it is here that we see where the debate seems to have become derailed. Direct realists would entirely agree with Fodor's way of making this last point. It is emphatically not the "mediation" of causal processes in all sorts of ways that constitutes the potential problem for representational theories. The problem arises only from *some* of the ways that the mediating causal processes may be conceived. For example, it is not their mediation as such that makes pictures problematic as internal representations subserving imagery. Fodor's account of what makes perception (or talking on the telephone) "direct" is exactly the kind that Putnam, Austin and Reid, inter alia, would endorse.

Gallstones or Headaches?

Fodor suggests that until recently it was generally supposed that explaining having a concept is dependent on explaining what a concept is. That is, the explanation of concept possession should be parasitic on the explanation of concept individuation (Fodor 1998, p. 2). Fodor laments the reversal of this assumption about priority and the direction of explanatory dependence. Fodor's particular target in *Hume Variations* is the one identified in *Concepts*, namely, pragmatists and dispositionalists who hold that having a concept is a matter of some kind of capacity, a matter of what you are able to do as a kind of epistemic 'know how' (Fodor 1998, p. 3). Of particular concern for Fodor, and the reason for Hume's appeal, is their shared opposition to such theories:

> ... an account that renders having concepts as having capacities is intended to preclude and account that renders concepts as species of mental particulars: capacities aren't kinds of *things*; a fortiori, they aren't kinds of *mental* things. (Fodor 1998, p. 3)

Thus, Fodor insisted that "understanding what a thing is, is invariably prior to understanding how we know what it is" (1998, p. 5). He says "epistemic capacities don't *constitute* concepts, but merely *presuppose* them." (p. 20).

It is worth remarking that Yolton (2000) notes that the "pervasive notion" throughout the seventeenth and eighteenth centuries has been that of "presence to the mind" - precisely Fodor's question of concept possession.

Thus, Fodor takes it to be a truism about the possession conditions for concepts that "If concept tokens are mental particulars, then having a concept is being in a relation to a mental particular" (1998, p. 3 fn 1). However, such talk of "possession conditions" is a framework that biases our theory towards an object-account of concepts since "possession" is itself, like "mental object" a metaphor with misleading connotations when we are concerned with states of the mind-brain. The old-fashioned term 'presence to the mind' is preferable in this regard. Colloquially, we may speak of "having a headache", or "having little patience", but talk of "possession conditions" in such cases is not obviously as appropriate as for tables and chairs. For example, having a headache is more like having indigestion or being sunburnt than owning something. By contrast, having gallstones is undeniably object possession but likely to be a poor model for psychological states. Less figuratively, the question is whether we should adopt a Malebranchean-Lockean-Humean object theory or an Arnauldian-Cartesian-Reidian process, act theory. At the very least, object implications of colloquial idioms in folk-psychology propositional attitude talk should not prejudge the issue.

These foregoing remarks have a distinctly Rylean flavour, and it is perhaps not surprising that Ryle is among the culprits in Fodor's plot. Fodor suggests that "Mid-century philosophy of mind consisted largely of confusing these issues by endorsing pragmatism as a remedy for dualism" (p. 24) and Fodor regards Ryle's (1949) *Concept of Mind* is the *locus classicus* for this confusion.

However, this analysis is to misread Ryle in a revealing manner. Ryle was concerned, in the first instance, to give a remedy for certain spurious views about our mental life. That is, the conceptual confusions of interest may encourage dualism but are independent of it. For Ryle, dualism is a *consequence* of holding certain mistaken views about our mental life and not identical with these views. Thus, Ryle's criticism of the "intellectualist legend" and the distinction between 'knowing how' and 'knowing that' have nothing to do with dualism. Further, Ryle's criticism of the doctrine of the 'mind's eye' anticipates Pylyshyn's polemic against pictorial theories concluding that "imaging occurs, but images are not seen" (1949, p. 247). Exactly as Pylyshyn would argue a generation later, Ryle said that someone imagining a scene "is not being a spectator of resemblance ... but he is resembling a spectator" (1949, p. 248). Thus, for Ryle pragmatism was primarily a remedy for certain

doctrines that may lead to dualism, but may equally lead to bad theories within a purely physicalist framework.

In Fodor we see the preference for a conception of representation which reverses the trend discernable in the seventeenth century. Yolton points out:

> ... in the writings of the main figures (Descartes, Arnauld, Malebranche, Locke, Berkeley, Hume and Kant), we can follow a gradual emergence of a clear translation or transformation of the old ontological language of presence to the mind into an epistemic presence. (Yolton 2000)

Propositional attitudes are explicated in a now-standard fashion by means of the inner box metaphor. In case anyone had doubts, Fodor (1998, p. 8) makes it clear that talk of belief boxes is a little joke which can be translated into harmless functional terms. However, even when stripped of its whimsical features, the metaphor and its implications are by no means so innocent as generally assumed. Specifically, the locution encourages Fodor's objectified ontological analysis and the priority he gives to questions of what concepts *are* as opposed to how they might be "possessed" or known. Arnauld's book *On True and False Ideas* was precisely a response to this conception in Malebranche's *The Search for Truth*. Given such a conception, it is not surprising that Fodor prefers an atomistic rather than holistic account of meaning, though he notes that the two issues are strictly distinct, since he says current fashion "tends to favor mental objects that are defined by (perhaps all) of their interrelations (p. 12). Nevertheless, propositions conceived as mental atoms are more readily seen as objects having their meanings individually and a holism of a more radical variety would dispense with mental objects altogether in favour of acts, processes or dispositions. It is perhaps not implausible to see a relevant parallel with Locke's project in his *Essay* which Jolley (1999, p. 39) suggests is "self-consciously modeled on the corpuscularian theory of matter". It may be helpful to see that Fodor is true to his avowed Empiricist progenitors even to the extent of such analogous commitments. Remarkably and more directly relevant, Reid, too, captures Fodor's corpuscularism in his attack on Hume's 'ideas' "which, like Epicurus's atoms, dance about in emptiness" (Reid 1985/1997, p. 22).

Fodor considers Stroud's (1977) criticism of Hume's mental atomism and quotes the following passage:

> The Theory of Ideas restricts [Hume] because it represents thinking of having an idea as fundamentally a matter of contemplating or viewing an 'object' - a mental atom that can come and go in the mind ... (Stroud 1977, p. 225,6; quoted in Fodor 2003, p. 11).

What is remarkable about this passage is what Fodor *fails* to comment upon (though the same remarks are quoted again at p. 21), namely, Stroud's concern with having an idea as *contemplating or viewing* an object. Fodor's complete neglect of this point is especially surprising because, as already noted, it has been central to the long tradition of criticism of the 'idea' idea. Of course, Fodor (2000) is right that the causal mediation of representational theories doesn't mean that we perceive the representations themselves, but this is only to identify the problem and not to show that particular accounts actually avoid it. In his new book, Fodor's off-hand treatment of critics of representationalism suggests an insensitivity to this concern explicitly raised by Stroud which, like Putnam's concern, arises from the inherent features of a classical tri-partite conception of ideas. Rorty (1980) too was centrally concerned with what he describes as "the original sin of epistemology" (1980, p. 60), namely, the kind of representationalism originating with Descartes. Rorty describes this as "the Cartesian image of the Eye of the Mind - the very image which has often been accused of leading to the 'veil of ideas' and to solipsism" (1980, p. 94). Fodor's new book does not address such concerns although, of course, he appreciates the way that traditional scepticism arose for the reasons just noted, and he says with mild sarcasm that it led "either to the view that 'strictly speaking' nobody ever saw a piano, or to the view that 'strictly speaking' pianos are mental" (Fodor 2000). With this oblique allusion to Berkeleyan idealism, Fodor suggests that, by contrast, the representational theory "doesn't need to say anything like that now" since it has abandoned its pretensions to being epistemology, content with being only a psychology of perception. In this form representational theories hold that "Causal processes involving mental representations mediate these perceptual relations, but you don't (typically) perceive the representations themselves either directly or otherwise" (Fodor 2000).

First, it is undeniable that an explanatory scientific psychology "doesn't need to say anything like that now", but requiring mental particulars to be semantically evaluable seems to invoke precisely the sorts of problems of veridicality arising for an epistemology concerned with knowledge as true belief. However, be that as it may, the problems of concern do not arise only if the enterprise is conceived as epistemology, as the imagery debate has amply demonstrated. The problem may arise as an unnoticed consequence of certain ways of conceiving the representations, typically when they are modeled too closely on externally perceivable objects. Thus, in a frequently cited overview of the traditional theory of ideas, McRae (1965) pointed to the central notion of an idea as the immediate object of perception or thought that can be traced back to Descartes. McRae suggests that ideas make their appearance in Descartes as immediately present objects for looking at or "contemplating".

> What remains basic for the earlier Descartes, for the later Descartes, for Malebranche and for Locke, is that ideas are the immediate objects of perception, that all knowing reduces to seeing, and that seeing (however intellectual it may be) is the sole operation of which the understanding is capable. It is of secondary importance for their conceptions of what knowing is whether these immediate objects or ideas are in the brain, in the mind, or in God. (McRae 1965, p. 179)

We may add that it is of secondary importance whether these immediate objects are pictures, propositions or other mental particulars *à la* Fodor. He writes:

> ... the questions with which theories of meaning are primarily concerned are metaphysical rather than epistemic. This is as it should be; understanding what a thing is, is invariably prior to understanding how we know what it is. (1998, p. 5)

However, Fodor's impeccable principle giving priority to the question of "what a thing is" rather than "how we know what it is" does not obviously apply as well to *knowledge* as to tables and chairs. Arguably, it is exactly in the case of forms of knowledge that the epistemic questions must take precedence. Take the case of grammar which Chomsky insists has no other reality than the knowledge of a speaker-hearer: Here the question of "what a thing is" collapses into the question of "how we know what it is". Grammar is *constituted* by being a form of knowledge and, therefore, *how we know it* counts as an answer to the question of *what it is*. Similarly, in the case of meanings and concepts, unlike the case of tables and chairs, the question of "what a thing is" is plausibly construed as the question of what we know.

These critics represent the various pragmatic or dispositional views that Fodor excoriates. It is no accident that Gibson's similarly motivated 'ecological' approach dismissed by Fodor, like the closely related 'situated cognition', are theories of direct realism which have been proposed as alternatives to the representationalism of modern computational theories. This is merely one form in which the Malebranche-Arnauld (or Hume-Reid) debate is being rehearsed today.

Le plus séduisant cartésien?

We may better understand Fodor and Hume through their antecedents and their critics. Thus, I have emphasized Malebranche here in part to correct Fodor's misleading allusions to 'Cartesianism' as the provenance of Humean views of representation. Fodor's reference to Hume's Cartesianism needs to be qualified to reflect these nuances and is correct only if we understand it as reference to Malebranche's version of *la pensée cartésienne* and not that of Arnauld or Descartes himself who shared precisely the pragmatism that Fodor is battling. If the interest and relevance of Malebranche's theory today is surprising, this is because its theological trappings and overtones of mysticism have, in Nicolas Jolley's words, "so effectively concealed the seventeenth-century debate from the view of contemporary philosophers" (Jolley 1990, p. 201). Nevertheless, it is not without reason that Malebranche was characterised by a 17th Century author, as we might say of Fodor too, *En un mot, c'est le plus séduisant cartésien que je connaisse* - in a word, the most seductive Cartesian that I know (quoted in Moreau 1999, p.9).

Abstract

This research examines mechanisms underlying the primacy in processing of elements over relations. It is hypothesized that elements are detected atomatically even when the task is to ignore them, and this automatic detection may interfere with the processing of relations. In Experiment 1, 4 year-olds and adults were asked to ignore elemental features and to match a test item to a target by detecting the numerical equivalence beween the test and the target. Results indicate that only children, but not adults, cannot ignore elements, thus suggesting that elements could be processed automatically. In Experiment 2, the same task was presented again, except that elements were perceptually-rich. This time, both children and adults exhibited difficulty ignoring elements. These findings point to two important regularities. First, attention is automatically attracted to elements, interfering with processing of relations, and this interference may make relational processing more difficult. And second, perceptual richness of elements amplifies this effect.

Introduction

Humans live in a structured environment: we encounter entities that are interconnected spatially, temporally, or conceptually into larger arrangements. Those components of structure that are entities or separable properties of these entities can be considered elements, whereas the manner in which elements are arranged can be considered relations.

However, it is not self-evident as to what constitutes an element or a relation. For example, a letter may constitute a relational entity in a letter recognition task, but it constitutes an element in a lexical decision task. Similarly, a word may constitute a relational entity in lexical decision, but (as demonstrated by Ratcliff and McKoon, 1989) it constitutes an element in a sentence comprehension task.). Because there is evidence that stimulus familiarity is established early in the course of processing and familiar stimuli are processed by dedicated circuits (Hölscher, Rolls, & Xiang, 2003; Xiang & Brown, 1998), it seems that familiar objects are good candidates for being considered elements.

Processing of structure requires processing of both elements and relations because both elements and relations carry important information: changing a relation (e.g., *the ball is under the table* instead of *the ball is on the table*) as well as changing an element (e.g., *the book is under the table* instead of *the ball is under the table*) can radically change the nature of the information. Processing of structure and the ability to recognize the processed structure at a later time is critically important for both cognition and learning.

There is multiple evidence that pointing to a primacy of processing of elements over relations in terms of processing time, as well as phylogenetic, ontogenetic, and microgenetic time. First, researchers have found that, across a broad array of tasks, elements are processed prior to (or faster than) relations (Goldstone & Medin, 1994; Ratcliff & McKoon, 1989). Second, there is evidence that processing of some relations (e.g., numeric equivalence) is available to great primates, but even for great primates this processing requires much more substantial training than processing of elements (Thompson, Oden, & Boysen, 1997). Third, there are developmental differences in processing of elements and relations, with younger children being less likely to process relations than older children and with greater age differences in the processing of relations than elements (Gentner & Toupin, 1986; Kotovsky & Gentner, 1996). Finally, there is also a large body of evidence indicating that in knowledge rich domains, novices are more likely to process elements (i.e., individual pieces of a chess position, or entities in a problem description) more ably then relations (i.e., the arrangements of pieces in the position, or equations that underlie the solution to the problem), although experts often process relations as well as elements (Chase & Simon, 1973; Chi, Feltovich, & Glaser, 1981; Larkin, 1983; Reed, Ackinclose, & Voss, 1990; Reingold, Charness, Schultetus, & Stampe, 2001).

Taken together, these findings suggest that elements and relations are psychologically distinct. We further contend that there might be an attentional mechanism underlying the differential processing of elements and relations: elements may be detected automatically, and this automatic detection may interfere with processing of relations.

The idea of such a mechanism has been supported by several sets of findings. First, it has been found that the likelihood of processing of relations often varies with the salience of elements. For example, when Structures 1 and 2 (e.g., two sequence of triangles monotonically increasing in

size) differ in elemental and relational correspondences (i.e., the leftmost triangle in Structure 1 has the same size as the rightmost triangle in Structure 2 in terms of an elemental match, whereas it corresponds to the leftmost triangle in Structure 2 in terms of its position), participants focused on relational matches when objects were perceptually impoverished. At the same time, they were more likely to focus on the elemental matches when objects were perceptually elaborated (see Gentner & Medina, 1998 for a review). Second, introduction of a simple warm-up task, which attracts attention to either to relations or to elements, markedly increases processing of relations, but not elements in a target task (Sloutsky & Yarlas, under review), thus indicating that processing of elements is at ceiling. Both sets of findings suggest that elements may be processed in an automatic and obligatory manner.

If this is the case, then elements should be detected even when the task is to ignore them, and these automatically detected elements may interfere with processing of relations. Furthermore, because young children may have difficulty deliberately directing their attention to some properties of stimuli, while ignoring others, it seems likely that children would exhibit these effects under a wider range of conditions than adults.

To test these hypotheses, we created a task, in which participants were asked to focus on a simple relation of numeric equivalence. We selected this relation because previous research demonstrated that even primates could match items having equivalent number of elements, regardless of what these elements were (Thompson, et al., 1997). We deemed it reasonable, therefore, that the relation of numeric equivalence should be available to 4-to-5 year-olds. The task (a variant of Garner's interference task) was presented as a "matching game," in which participants were presented with a Target having a particular number of identical elements (e.g., two identical shapes), and a Test item. If the Test item had the same number of elements, participants should identify it as a match, otherwise they should identify an item as a mismatch. The items were presented under three conditions. First, there was a "fixed" condition, in which the Target and Test items had identical elements, and matching or mismatching relation was the only source of variance. Second, there was a "correlated" condition, in which elements and relations varied together: a relational match accompanied an elemental match, and a relational mismatch accompanied an elemental mismatch. Finally, there was an "orthogonal" condition, in which relations and elements varied independently. Examples of items across the three conditions are presented in Figure 1.

If elements are not attended to in the course of relational processing, there would be no difference in speed and accuracy of matching across the three conditions. If, however, elements are processed automatically, there should be a difference in speed or accuracy between the orthogonal condition and the correlated conditions. Such a decrease would be a strong evidence for automatic processing of elements and fro interference of automatically detected elements in processing of relations. As mentioned above, we expect that even young children process elements automatically, and, therefore, we expect that even young participants would exhibit these effects.

Experiment 1

Method

The goal of this Experiment was to test the hypothesis that even early in development, elements are processed automatically, and this automatic processing of elements may interfere with processing of relations.

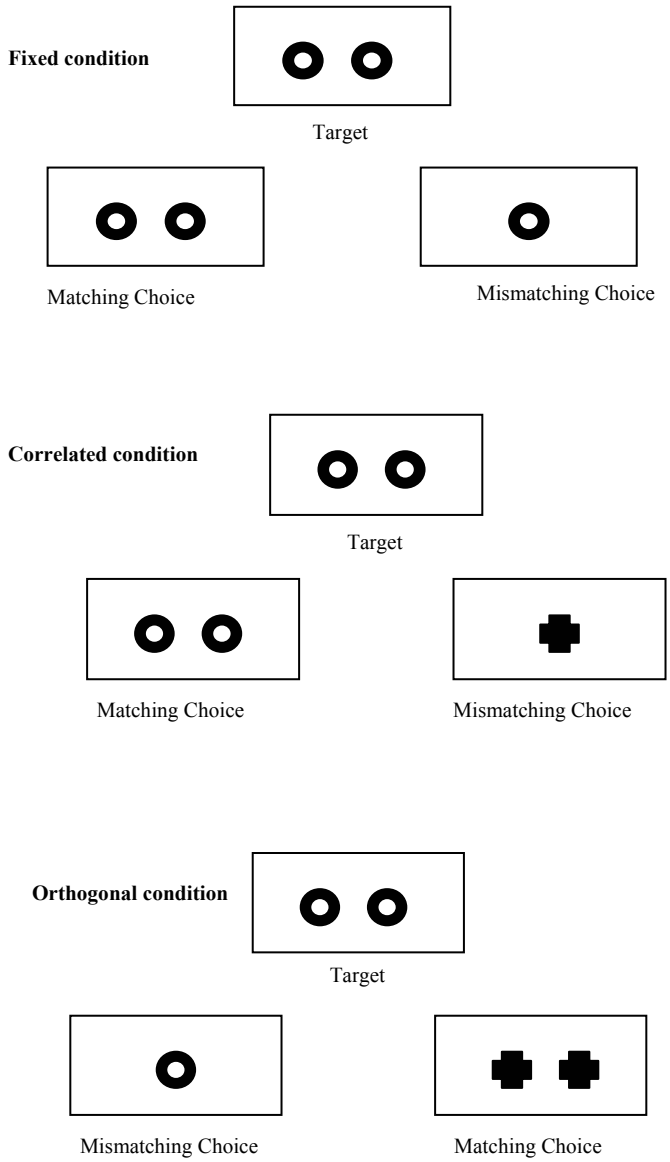

Figure 1: Example of stimuli across the three conditions.

Participants

Participants were 44 young children (Mean Age = 4.41 years, *SD* = 0.346 years; 24 girls and 20 boys) recruited from childcare centers located in middle class suburbs of the Columbus, Ohio area, with approximately equal numbers of participants in the fixed, correlated and orthogonal conditions. There was another group of 37 college undergraduates (13 women and 24 men) participating in the experiment for course credit. There was also approximately equal numbers of participants in the fixed, correlated and orthogonal conditions.

Materials

Materials were stimuli sets, each consisting of three panels. Two of these panels were Target and Choice items and these depicted simple geometric shapes (e.g., circle, triangle, cross). The third panel depicted a Trash can. Stimuli set were presented on screen with the Target and Trash can above each Choice item, with the latter one placed equidistantly to the former two. Participants were told there that if the Choice item has exactly the same number of shapes as the Target, there is a match, and they should point to the Target, whereas if the number is different, there is a mismatch, and they should point to the Trash can. There were a total of 24 trials with 12 matching and 12 mismatching trials. As mentioned above, there were three between-subjects conditions: fixed, correlated, and orthogonal.

There were exactly the same elements employed across trials in these conditions. However, within the trials, there were identical elements in all three panels in the fixed condition, elements covaried with the relation of equivalence in the correlated condition, and elements and the relation of equivalence varied independently in the orthogonal condition.

Design and Procedure

The design included two between subject factors, Condition (fixed, correlated, and orthogonal) and Age (young children and adults). Participants were randomly assigned either fixed, correlated, or orthogonal condition. The dependent variables were accuracy and latency of responses. Young children were given brief training, in which real three-dimensional objects were used to explain the rules of the "matching game." The training was identical across the three conditions.

The child participants were tested individually by a female researcher in a quiet room in their schools, whereas adult participants were tested in a lab room on campus. First, the child participants were trained on a real-object version of the computer task (this training was not used with adult participants). The researcher showed the participants two clear plastic shoeboxes. The instructions said: *This is a toy box* (pointed to box with two stars on the front) *and this is a trash can* (pointed to plain box). *There are two stars on this toy box, so this is the "two-toy" toy box. If I give you two toys, you put them in here. If I don't give you two toys, you put them in the trash can*. Then the researcher set one, two, or three toys in front of the participants and asked, "Should these go in the toy box or the trash can?" The toys were small, colorful, plastic toys (i.e. sunglasses, cars, tops). The participant was given feedback for these training trials. The participant had four trials with the two-toy toy box, after which the researcher replaced it with a one- or three-toy toy box (designated by stars on the front) and restated the instructions. Each participant had four trials with each toy box, totaling 12 training trials. If the participants were successful on the last three trials, they proceeded to the computer task. If a participant was not successful, the experiment was terminated because the participant did not demonstrate understanding of the task.

The computer task was the same as the training, except that the child participants responded by pointing to the Target or Trash can or naming them. Children's responses were entered by the experimenter. Adult participants entered their choices by pressing appropriate buttons on the keyboard. The experiment was administered on computer and was controlled by SuperLab Pro 2.0 software.

The screen was divided by a horizontal line, with the Target and Trash can above the line and the "toys" to be moved below. The toys were actually two-dimensional shapes (square, triangle, cross, circle, heart, and diamond). The researcher said to the child participants: *Now we are going to do the same thing, but on the computer. Here is the toy box (i.e., the Target) and here is the Trash can and here are the toys* (pointed to each as they were mentioned). *If the number of toys on the toy box is the same as the number of toys down here, then you tell me to put them in the box. If the number of toys on the toy box is different than the number of toys down here, then you tell me to put them in the trash.* The researcher then pressed "1" for box and "0" for trash, according to the participants' responses. The adults had similar instructions on the computer screen and two examples (one match and one mismatch). There were four warm-up trials on the computer and 24 test trials. Warm-up trials were exactly as the test trials, except that the former were accompanied by feedback.

Results and Discussion

Because procedures for children and adults differed slightly, we present their data separately. Recall that children's responses were entered by the researcher, which added time to their latencies. To adjust for this added time, we conducted a separate experiment, in which we used measured the speed of pressing buttons by the researcher. We then averaged this time across trials, and subtracted it from each child participant response.

Children. Overall child participants exhibited high accuracy of responding with 91% correct in the fixed condition, 97% correct responses in the correlated condition, and 88% correct in the orthogonal condition. There was an approaching significance difference in accuracy between the orthogonal and the correlated condition, with greater

accuracy in the correlated condition, t (27) = 1.81, p = .08. Latencies across the three conditions are presented in Figure 2.

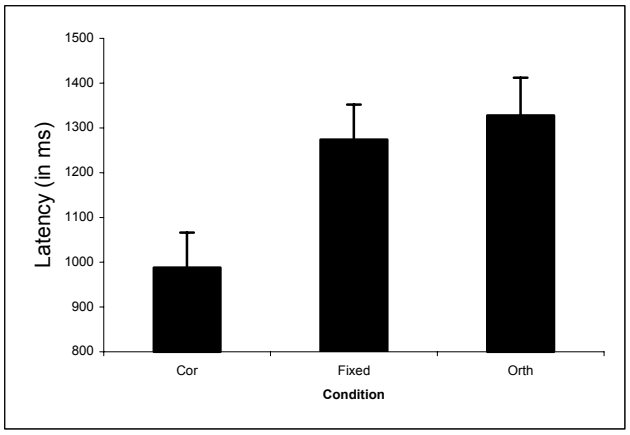

Figure 2. Children's latencies by condition. Error bars represent Standard Errors of the Mean.

These latencies were subjected to a one-way ANOVA. The analysis pointed to significant differences across the three conditions, F (2, 41) = 5, 21, p = .01. Post-hoc Tukey tests indicated that responses in the fixed and the orthogonal condition were slower than responses in the correlated condition, ps < .05. These results indicate that there was a significant speed up in the correlated condition, pointing to an automatic processing of elements.

Adults. Adults' data differed from those of young children in that there was little evidence of elements interfering with processing of relations. Adults exhibited comparable accuracy across the conditions, with 97% correct in the fixed condition, 97% correct in the correlated condition, and 95% correct in the orthogonal condition, ns, p > .3. Similarly, they exhibited comparable latencies across the conditions, 1017 ms in the fixed condition, 987 ms in the correlated condition, and 988 ms in the orthogonal condition, ns, p > .8.

Results of this experiment indicate that children, but not adults exhibit automatically processing of elements even when instructed to focus on relations.

Experiment 2

The goal of this experiment was to test the second hypothesis that perceptual richness of elements may amplfy the effects of automatic detection of elements found in Experiment 1.

Participants

Participants were 40 young children (Mean Age = 4.49 years, SD = 0.33 years; 24 girls and 16 boys). They were recruited in the same manner as in Experiment 1 and there were approximately equal numbers of participants in the fixed, correlated and orthogonal conditions. There were also 70 college undergraduates (17 women and 53 men) participating in the experiment for course credit. There was also approximately equal numbers of participants in the fixed, correlated and orthogonal conditions.

Materials

The task was set up identically to the task in Experiment 1 expect for the nature of the stimuli. Instead of the simple geometric shapes, the stimuli were perceptually rich images of common animals (e.g., bird, dog, turtle). An example of stimuli is presented in Figure 3. Again, participants were told there that if the Choice item has exactly the same number of shapes as the Target, there is a match, and they should point to the Target, whereas if the number is different, there is a mismatch, and they should point to the Trash can. There were a total of 24 trials with 12 matching and 12 mismatching trials. Again, there were three between-subjects conditions: fixed, correlated, and orthogonal.

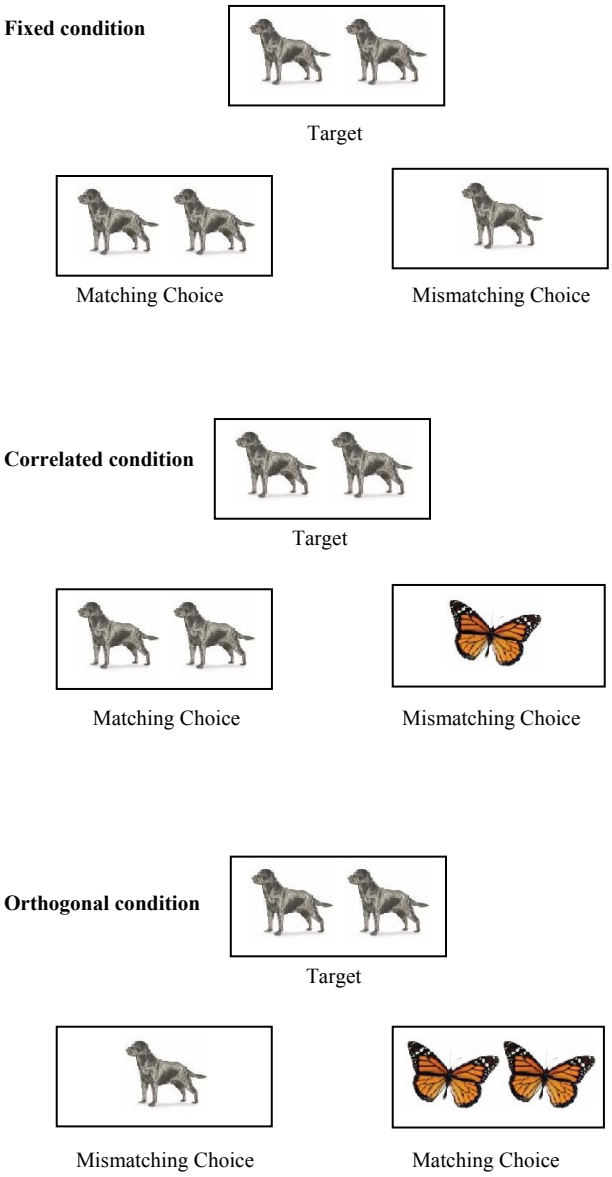

Figure 3: Example of perceptually rich stimuli across the three conditions.

Design and Procedure

The design of this experiment is identical to the design of Experiment 1. The design included two between subject factors, Condition (fixed, correlated, and orthogonal) and Age (young children and adults). Participants were randomly assigned to each level of the Condition. The dependent variables were accuracy and latency of responses. Again, young children were given brief training, identical to the training in Experiment 1 and using the same three-dimensional objects.

Results and Discussion

Data was entered and analyzed in the same manner as in Experiment 1.

Children. Similar to Experiment 1, the child participants exhibited high accuracy of responding with 94% correct in the fixed condition, 97% correct responses in the correlated condition, and 94% correct in the orthogonal condition. There were no significant differences between the accuracies of the three conditions. Latencies across the three conditions are presented in Figure 4.

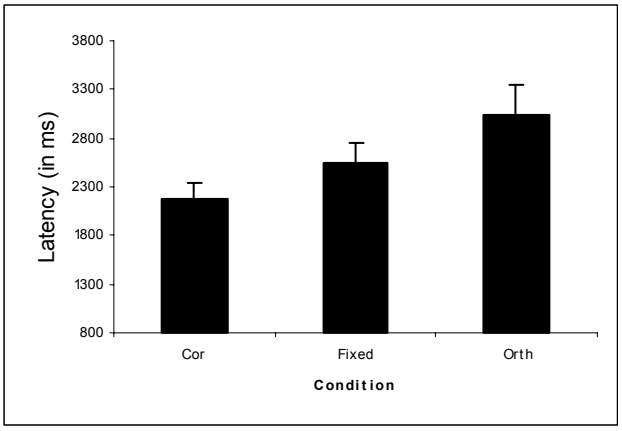

Figure 4. Perceptually rich stimuli. Children's latencies by condition. Error bars represent Standard Errors of the Mean.

These latencies were subjected to a one-way ANOVA. The analysis pointed to significant differences across the three conditions, F (2, 36) = 3.60, p = .038. Post-hoc Tukey tests indicated that responses in the orthogonal condition were slower than responses in the correlational condition, p = .03. These results indicate that there was a significant slow down in the orthogonal condition, pointing to an interference on the part of perceptually rich elements.

Adults. Adults exhibited interference effects showing somewhat lower accuracy in the orthogonal condition with 97% correct in the fixed condition, 97% correct in the correlated condition, and 92% correct in the orthogonal condition. The one-way ANOVA pointed to significant differences across the three conditions, F (2, 67) = 3.41, p = .04. Post-hoc Tukey tests indicated a significant difference in accuracy between the orthogonal and the correlated condition, with greater accuracy in the correlated condition, p = .05, and an approaching significance difference in accuracy between the orthogonal and the fixed condition, with greater accuracy in the fixed condition, p = .08. They exhibited comparable latencies to the children across the conditions, 911 ms in the fixed condition, 943 ms in the correlated condition, and 1017 ms in the orthogonal condition, ns, p > .8.

Results of this experiment indicate that increasing the perceptual richness of the elements produces more interference of automatically detected elements with processing of relations not only in children, but also in adults.

General Discussion

Two important findings stem from the reported experiments. First, when elements are perceptually impoverished, and the task is to focus on relations, young children automatically attend to elements. And second, perceptual richness of elements amplifies this effect in children, and it reveals the effect in adults.

Findings that elements are attended to automatically, even when the task is to ignore them, may explain the earlier found primacy in processing of elements. As mentioned above, elements are processed prior to (or faster than) relations (Goldstone & Medin, 1994; Ratcliff & McKoon, 1989), younger children are less likely to process relations than older children (Gentner & Toupin, 1986; Kotovsky & Gentner, 1996), and experts in a domain are more likely to process domain-important relations than novices (Chase & Simon, 1973; Chi, Feltovich, & Glaser, 1981). These findings suggest that the difficulty of processing relations may often stem from participants inability to ignore irrelevant elements.

This attentional mechanism is capable of explaining several existing findings. In particular, there is evidence (see Gentner & Medina, 1998; Markman & Gentner, 1993) that when elements are perceptually-rich, participants are more likely to focus on matching elements than when elements are perceptually-impoverished. Because perceptually-rich stimuli are more likely to engage attention than perceptually-impoverished stimuli, it seems that differences reported by Gentner & Medina (1998) may stem from greater attention automatically attracted to perceptually-rich elements.

Finally, there is evidence that although young children have difficulty processing relations under regular conditions, they are significantly more likely to process relations when relations are labeled (Gentner &

Loewenstein, 2002; Kotovsky & Gentner, 1996). Again, it seem that labels attract attention to relations thus making it easier to ignore elements.

It seems that these examples demonstrate that, unless attention is attracted to relations and away from elements, participants are more likely to automatically attend to elements, and attention to elements may interfere with their processing of relations. Recall that current research used a highly familiar relation of numerical equivalence, and interference effects manifested themselves in a decresed latency or accuracy. However, it is possible that when relations are less familiar, interference may result in a failure to detect a relation.

In short, reported results indicate that elements are detected automatically. The results also indicate that perceptual richness of elements amplifies the effect of automatic detections of elements. It is possible that automatic detection of elements may interfere with processing of relations, especially when the task is to ignore elements.

Abstract

The problem of whether human causal judgments could be better explained by associationistic or probabilistic accounts is dealt with in the paper that reviews the basic tenets of the power PC theory (Cheng, 1997), the most famous of the probabilistic explanations, and discusses some results obtained by Fum & Stocco (2003) that are at odds with power PC predictions. An integrated model is described that is capable of explaining those findings, and a new experiment is presented in which the predictions of the model and of the power PC theory are contrasted in the case in which the causal power of a compound cue is equal to one of its components. The results clearly corroborate the model that provides, moreover, an explanation for some data that lie outside the scope of the power PC theory.

Introduction

Recent research on adult causal cognition has been focusing on two main kinds of theoretical explanations that capture many of the central findings in the field.

Associative accounts (Shanks, 1995) consider the causal reasoning performed by humans as similar to the classical conditioning happening in animals and claim that, because both processes involve the detection of the same predictive relations, they may use a common mechanism. The most famous model in this class is that of Rescorla & Wagner (1972)—henceforth R&W—that has been successfully applied to account for a series of phenomena—like blocking (Kamin, 1969), overshadowing (Price & Yates, 1993), conditioned inhibition (Chapman & Robbins, 1990), and contingency effects (Dickinson, Shanks, & Evenden, 1984), to name only a few—that were originally discovered in animals, and that have been demonstrated to play a critical role in human causal learning, too.

Probabilistic theories, on the other hand, rely essentially on the analysis of the contingencies that organisms are supposed to acquire by interacting with their environment, and try to estimate the extent to which a cue (or potential cause) can determine a given outcome. The most famous among these accounts is constituted by Cheng's power PC theory (Cheng, 1997), an extension of the probabilistic contrast model developed by Cheng & Novick (1990).

Fum & Stocco (2003) argued that associative and probabilistic models possibly cover distinct steps in human causal induction, with associative accounts describing the processes by which people (and animals) notice and extract statistical connections between events, and probabilistic models capturing the reasoning skills brought to bear in causal cognition. Investigating the role of compound cues in causal judgments, however, they obtained experimental findings that could not be explained, in their entirety, by either group of theories.

In the paper we review the power PC theory and illustrate some results obtained in Fum & Stocco (2003) that seem to falsify it. We present a new model that, while being compatible with previous data, is able to explain those puzzling results. We describe an experiment in which our model and the power PC make contrasting predictions, and we present findings that corroborate our hypothesis. We discuss some further data that, while implied by our model, are out of the scope of the power PC theory. We conclude the paper by summarizing the features of our account of human causal cognition and by outlining some possible developments.

A Probabilistic Account

Perhaps the simplest of the probabilistic models of causation is given by the ΔP rule (Jenkins & Ward, 1965) that formalizes the idea that people mentally compare the frequency of an outcome O in presence and in absence of a given cue C: $\Delta P_c = P(O|C) - P(O|\neg C)$. If the difference is around 0, the outcome is just as likely when the cue is present as when it is absent; if it approaches 1, C is perceived as producing O; if it approaches -1, the cue is seen as preventing the outcome.

Relying on this idea, Cheng & Novick (1990) developed their probabilistic contrast model assuming that, in presence of a set of possible causes for an effect, the ΔP for each cause is computed on the so-called *focal set*, defined as "a contextually determined set of events that the reasoner uses as input to the covariation process" (Cheng, 1997, p. 371). When a putative cause is taken into account, all other causal factors are kept constant within the focal set, and ΔP is computed on a background of constant alternative causes.

The transition from the probabilistic contrast model to the power PC theory was motivated by a series of problems that could not be adequately explained by the former nor by alternative associative accounts like the R&W. The power PC theory essentially computes how much a ΔP judgment should be discounted for providing an estimate of the causal power of a cue. It also detects special conditions in which the causal power cannot be deduced from ΔP.

One of the tenets of the theory is that, whenever the possible alternatives to a candidate cause C are kept under control and ΔP is non negative, $\mathbf{C}$ (i.e., the causal power of C to generate the outcome O) is given by:

$$\mathbf{C} = \frac{\Delta P_c}{1 - P(O|\neg C)}$$

According to the power PC theory, identical values of ΔP associated with different values of $P(O|\neg C)$, the *base rate*, will lead to different causal judgments. When the alternative causes are controlled, the theory predicts that, with ΔP kept constant, the causal power increases with an increase in the value of the base rate. As a special case, if the base rate is equal to 1, the causal power remains undefined, because the denominator becomes 0. If the base rate is equal to 0, the power PC reduces to the probabilistic contrast model, and the causal power depends exclusively on ΔP. Finally, if ΔP is 0, the causal power of C is 0, too.

Fum & Stocco (2003) focused on some interesting consequences of Cheng's theory concerning the role of compound cues, and set up an experiment to test them. To reduce the complexity of the theoretical framework, and to establish a clear experimental paradigm, four assumptions were made. First, the causal power of a generic cue A was defined as the probability that, all other things being equal, the cue would produce the outcome O: $\mathbf{A} = P(O|A)$. Second, a given outcome had a null probability of being obtained in absence of the cue: $P(O|\neg A) = 0$. Third, all cues were considered as independent. Fourth, all the cues were pure causes: none of them was an enabling condition (Cheng & Novick, 1991) nor needed any enabling conditions to produce its effect.

Given these assumptions, it is possible to deduce[1] some important consequences from the power PC theory. We focus here on two of them:

Irrelevance of Compound Previous experience with a cue presented in a compound form should be irrelevant to the judgment of its causal power, given that there are trials in which the cue appears alone. It is a tenet of both the power PC theory and of the probabilistic contrast model that only items in the focal set—where everything, but the candidate cause whose causal power is being evaluated, is kept constant—are taken into account to compute ΔP. Let us consider, for instance, the classical backward blocking paradigm (Chapman, 1991; Dickinson & Burke, 1996; Shanks, 1985), where compound trials of the form $(A, B \rightarrow O)$ are followed by a set of trials of the form $(A \rightarrow B)$. In this context, an adequate focal set to evaluate the causal power of the blocking cue A is constituted by trials $(A \rightarrow O)$ only, because by including $(A, B \rightarrow O)$ in the set, the cue B would also vary. The power PC theory therefore predicts that a previous presentation of a compound cue $(A, B \rightarrow O)$ should not influence the following judgment for cue A.

Equalization to Compound Sometimes it could be necessary to estimate the causal power of a cue over an inadequate focal set. Taking the example of backward blocking again into account, it should be noted that the trials $(A, B \rightarrow O)$ constitute an inadequate focal set for evaluating the causal powers of A and of B because both cues are covariant within the same set. However, this is exactly what participants in the control group of that paradigm are requested to do, and what a theory is supposed to provide an explanation for. When participants are forced to make a judgment, they should adopt the trials $(A, B \rightarrow O)$ as a focal set, and this would lead them to assign both cues the same causal power of the compound. Given the fact that the effect is never obtained without the cause, and that each possible cause appears in the set of trials $(A, B \rightarrow O)$, it is possible to demonstrate that $\mathbf{A} = P(O|A, B)$ i.e. the causal power of cue A should be equal to the probability of obtaining the outcome given the compound. The same should be true for B.

The experiment carried out in Fum & Stocco (2003) obtained findings that falsified these predictions. More precisely, contrary to the irrelevance of compound hypothesis, judgments concerning a cue A, experienced only in a compound form (i.e. together with another cue B), were significantly *higher* than judgments for the same cue experienced alone. In a similar vein, and contrary to the equalization to compound prediction, the judgments for a cue A, experienced only in a compound form, were significantly *lower* than judgments given to the compound cue embedding A.

While no theoretical explanation for these results was provided in the paper, the findings clearly suggested the existence of important factors determining causal judgements that lie beyond the scope of the power PC theory.

An Integrated Model

Trying to find an explanation for the results reported in Fum & Stocco (2003), we assume that people are able to acquire some knowledge about the contingencies that exist between cues and outcomes. A significant role is played in this phase by associative processes that contribute to the construction of an internal representation for the magnitude of the (single and compound) cues that were directly experienced. There is evidence that it is possible to spontaneously learn such knowledge by interacting with the environment (e.g., Hasher & Zacks, 1984), and we assume that people rely on this information in providing the judgments for those situations they actually encountered.

When a judgment about the causal power of a cue experienced only in compound form is required, the information about the stored magnitudes is used to infer the causal power of the individual novel stimuli, too. This process resembles reverse engineering, because people are supposed to figure out a conceivable distribution for the magnitudes of the single cues that could originate the magnitude of the compound representation.

Let us consider the top panel of Figure 1, that depicts the situation typically encountered in a blocking paradigm. The model assumes that, by interacting with the environment and by noticing the contingencies between cues and outcomes, people are able to construct an internal representation for the causal power of the cues they experience directly—for instance, A, (A, B), and others, like C. The stored magnitude could be a more or less faithful representation of the actual causal power of a given cue but, in any case, it constitutes the basis for causal judgments. To estimate the causal power of an experienced cue, people rely on its magnitude representation, and translate it into the required numerical scale.

When requested to provide an estimate for a cue that was experienced only in compound form (B, in our example), they try to figure out a sensible value for it—in our case, a magnitude for B compatible with the magnitude of both A and the compound (A, B). This process involves a comparison only between those cues that are relevant for deriving the causal

[1] We refer to the original paper for the mathematical derivations.

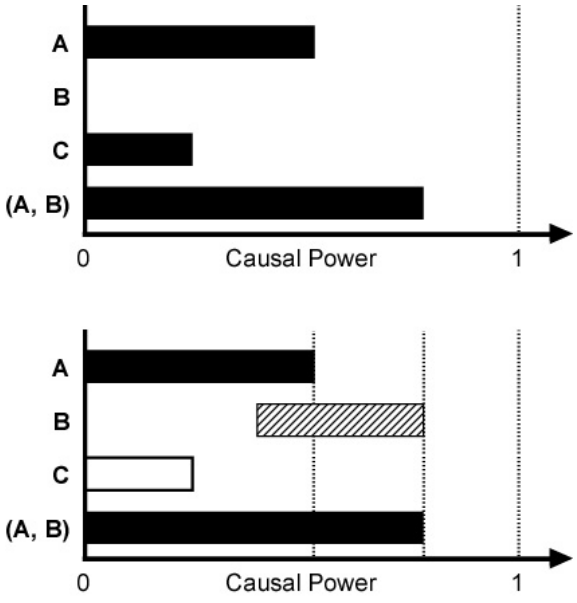

Figure 1: Phases of causal judgement. *Top (associative)*: Causal powers for cues represented as inner magnitudes. *Bottom (probabilistic)*: Inferring the value of cue *B*, that has not been experienced.

power of B (in our example A and (A,B)) and excludes the others (in our case, C). The set of cues taken into consideration conforms to the notion of focal set.

First, we shall observe that the causal power of B, which we denote through its boldface name $\mathbf{B}$, cannot be smaller than the difference between $(\mathbf{A},\mathbf{B})$, the causal power of the compound, and $\mathbf{A}$: if it were so, a certain part of the overall compound effect would remain unexplained: a "rod" shorter than $(\mathbf{A},\mathbf{B})-\mathbf{A}$ could not cover the whole length of the rod representing $(\mathbf{A},\mathbf{B})$. Therefore, $\mathbf{B}_{min}=(\mathbf{A},\mathbf{B})-\mathbf{A}$. Generally, some part of the causal power of B will be shadowed by A: if we simply subtract $\mathbf{A}$ from the compound $(\mathbf{A},\mathbf{B})$, we would in fact grossly underestimate the causal power of B. On the other hand, $\mathbf{B}$ cannot be greater than $(\mathbf{A},\mathbf{B})$, so that, $\mathbf{B}_{max}=(\mathbf{A},\mathbf{B})$.

The model therefore assumes that is "rational" to provide as a judgment for the causal power of B a value lying between $\mathbf{B}_{min}$ and $\mathbf{B}_{max}$. All the values between this range are plausible and coherent with the magnitude of the associatively experienced contingencies. The particular judgments provided by participants vary stochastically between this range. The mean expected value for $\mathbf{B}$ is therefore obtained by weighting each possible $\mathbf{B}$ by its probability $P(\mathbf{B})$:

$$\overline{\mathbf{B}}=\int_{\mathbf{B}_{min}}^{\mathbf{B}_{max}}\mathbf{B}\,P(\mathbf{B})\,\mathrm{d}\mathbf{B}$$

For any symmetrically distributed probability function $P(\mathbf{B})$, the previous equation reduces to the average between $\mathbf{B}_{min}$ and $\mathbf{B}_{max}$:

$$\overline{\mathbf{B}}=(\mathbf{A},\mathbf{B})-\frac{1}{2}\mathbf{A}$$

Explaining Previous Results

Not surprisingly, the model can accommodate the results obtained by Fum & Stocco (2003). Two main findings were reported in that paper. First, some associative effects resulted in a systematic distortion of the causal judgments provided by the participants. The model assumes that these effects are confined to the first phase of the process leading to causal judgments, where inner magnitudes of contingencies are supposed to be acquired.

The second result is more interesting, and it seems critical for the power PC theory. In order to account for backward blocking—one of the most robust and popular contingency learning phenomena—a theory should be able to explain how people make a causal judgment about a cue that has been experienced only in compound form. As previously noted, power PC either should exclude taking into account the inadequate focal set $(A,B\rightarrow O)$, denying thus itself the possibility to account for backward blocking, or should predict, by using only that available set, that the judgments about the causal power of A and B will be equal that of the compound (A,B).

Our model makes a different prediction. According to it, participants are supposed to construct a mental representation of the causal power of A and B such that, by joining (and possibly overlapping) them, they will cover that of the compound (A,B). Because the magnitude of the causal power of one of the cues, let us say $\mathbf{A}$, should be obviously comprised between 0 and $(\mathbf{A},\mathbf{B})$, the estimate for the mean causal power $\overline{\mathbf{B}}$ could be computed by averaging on the predicted values of $\mathbf{B}$, computed on all the values for $\mathbf{A}$ comprised between these extremes:

$$\overline{\mathbf{B}}=\int_0^{(\mathbf{A},\mathbf{B})}\left((\mathbf{A},\mathbf{B})-\frac{1}{2}\mathbf{A}\right)\mathrm{d}\mathbf{A}\Big/\,(\mathbf{A},\mathbf{B})$$

By solving this equation we obtain:

$$\overline{\mathbf{B}}=\frac{3}{4}(\mathbf{A},\mathbf{B})$$

The same result will hold, of course, for $\overline{\mathbf{A}}$.

In the experiment of Fum & Stocco (2003) the value for $(\mathbf{A},\mathbf{B})$ was set to 0.80. Under this condition, the model predicts that $\mathbf{A}=\mathbf{B}=0.60$. The judgments provided by participants were $\mathbf{A}=0.62$ and $\mathbf{B}=0.61$, respectively, with the difference being not statistically significant. It is useful to remind that, according to the power PC theory $\mathbf{A}=\mathbf{B}=(\mathbf{A},\mathbf{B})=0.80$.

Some New Predictions

A model should be considered as good not because it is able to explain previous data but because it allows making bold predictions about future events. For most of the cases, our model produces estimates of the causal power that are close to those provided by the power PC theory. It makes, however, a completely different prediction when, in an extreme blocking situation, the causal power of the compound is equal to the causal power of one of its components: $(\mathbf{A},\mathbf{B})=\mathbf{A}$.

Causal Judgments Under this condition, the power PC theory predicts that, independently of the values assumed by (A,B) and A, the cue B will be perceived as having a null

causal power. In this case, B is the candidate cause, and A is a background cause, as assumed in Cheng's framework. The focal set for B is constituted by all of the trials $(A, B \rightarrow O)$ and $(A \rightarrow O)$. In this set, $P(O|B)$ may be estimated as $P(O|A,B)$, and $P(O|\neg B)$ is given by $P(O|A)$. Given that, we can apply the standard equation for the causal power:

$$\mathbf{B} = \frac{P(O|A,B) - P(O|A)}{1 - P(O|A)}$$

Since $P(O|A,B) = P(O|A)$, it follows that $\mathbf{B} = 0$.[2]

On the contrary, according to our model, **B** will be given a value equal to $(\mathbf{A},\mathbf{B}) - \mathbf{A}/2$. Because, $(\mathbf{A},\mathbf{B})$ has been supposed equal to **A**, it follows that $\mathbf{B} = \mathbf{A}/2$, i.e, we expect that the causal power of B will be judged to be about half of the value of the causal power of A.

Because the model provides some details about the processes underlying causal judgment, it allows making some predictions that lie outside the scope of competitive accounts. More particularly, it predicts the following:

Confidence Ratings According to the model, trying to provide a judgment about the causal power of an experienced cue (e.g. A in the backward blocking paradigm), participants rely on an existing stored representation. On the other hand, when requested to assess the causal power of a cue that has been experienced only in a compound form (e.g., B, in the same paradigm) they cannot access a similar representation to assign a reliable value to **B**, and that constitutes an important source of uncertainty. When requested to estimate the confidence according to which they provide their causal judgments, participants should therefore trust their judgment for cue A more than that provided for B.

Latencies In the backward blocking paradigm—in which the presentation of a compound stimulus $(A, B \rightarrow O)$ is followed by the presentation of one of the its components, e.g., $(A \rightarrow O)$—the judgment concerning the causal power of A could be produced by reading off the value of its internal representation built according to associational principles. To provide a judgment for B, on the other hand, it is necessary to take into account the range of possible values that a coherent judgment could assume, i.e., it is necessary to resort to the second phase hypothesized by the model. As a consequence, the time need to provide a judgment for **B** should be longer than that spent in trying to assess the value for **A**.

The Experiment

To put these ideas under empirical testing, we carried out an experiment, using the Tanks paradigm introduced by Shanks (1985), in which the predictions of our model were directly compared with those deriving from the power PC theory.

Method

Participants The participants were 111 college students (28 males and 83 females) aged between 18 and 36 years (mean and median = 20) enrolled in an introductory Psychology course.

Design and Procedure Participants saw a series of trials in which a picture of an army tank moved across a computer screen. On every trial a weapon system fired, and the tank was hit by one or two projectiles; in some trials the tank was destroyed, in others it remained undamaged. At the moment the weapon fired, one or two colored lights went on in the lower part of the computer screen. The color of the light indicated the kind of projectile that was used. Conceptually, each light could be considered as a separate cue, and the explosion of the tank could be regarded as the outcome.

The experimental session consisted of two sets of 20 trials each. In every trial from the first set two projectiles were contemporaneously fired—this phase could be indicated by $(A, B \rightarrow O)$. In each trial from the second set one of the projectiles was fired alone $(A \rightarrow O)$. Three experimental conditions were set up, each condition differing in the probability of the tank being distroyed by the projectiles. The probabilities were equal to 0.2 (Low), 0.5 (Medium) and 0.8 (High). In the Low condition, therefore, the tank was (randomly) destroyed 4 times in 20 trials, while in the Medium and High condition it was destroyed 10 and 16 times, respectively. The probability of the tank being destroyed by two projectiles in trials from the first set was the same as the probability of being destroyed by a single projectile in the others, i.e., $P(A, B \rightarrow O) = P(A \rightarrow O)$. Finally, trials from the two sets were randomly interleaved for each participant, and participants were randomly assigned to an experimental condition.

Participants were requested to judge the efficacy of each kind of projectile on a scale ranging from 0 to 100, where 0 indicated null efficacy (i.e., the projectile never destroyed the tank) and 100 maximum efficacy (i.e., the projectile always destroyed the tank). They were also asked to indicate, on a seven point scale, the confidence with which they formulated their judgments about the causal power of each projectile. The last main dependent variable that was recorded was constituted by time needed to provide each causal judgment.

At the beginning, participants read an instructions sheet, written in Italian, that explained the task. After that, they saw four practice trials. The tank was randomly destroyed in two of the trials, and in the remaining two it was left undamaged.

At this point the experiment could start. Two colors (chosen in a set that comprised red, yellow, green, and blue) were randomly assigned to the two projectiles used in each experiment session, and the participants were exposed to the 20 trials of the first phase and 20 trials of the second one. To ensure that participants paid attention to the presentation trials, during the experiment four "control" screens appeared at randomly chosen times asking participants to indicate what they had just seen, i.e. which projectile/s was/were fired and whether the tank had been destroyed.

At the end of the presentation trials, participants were asked to provide their judgment about the efficacy of each of the two projectiles they had experienced. After that, they were requested to rate their causal judgments, i.e., to indicate how confident they were about the correctness of their answers.

Stimuli and Apparatus The experiment was performed on a PC equipped with a 15" LCD flat screen and headphones. A

[2] Cheng (1997) derived a computational analysis of the R&W model showing that, under particular conditions—that were met by our experiment—it asymptotically computes a probabilistic contrast over a focal set. It is therefore possible to conclude that, the R&W model makes here the same prediction of the power PC, i.e., $\mathbf{B} = 0$.

custom-made program written in Java was utilized to present the stimuli and to record the participants' judgments. During the presentation trials, the picture of a tank (120 x 45 pixels) moved at constant speed crossing the screen from right to left. A disk (with a diameter of 300 pixel) in the center of the screen simulated the view finder of the weapon system and displayed a desert landscape. The area of the screen outside the disk was kept blank. The tank was visible only when it crossed the disk (employing 3300 ms to cover its diameter), in the remaining time participants could only hear the engine sound through the headphones.

When the tank was approximately at half of its path, completely visible within the view finder, the weapon fired: one or two gunfire sounds were heard and one or two lights, represented by round LEDs (with diameter of 150 pixels) were lit up with the color of the projectile that had been shot.

The tank was always hit, and 1000 ms after the LEDs were brightened, it flashed for 300 ms to simulate the projectile impact. In the trials in which the tank was destroyed, an explosion sound was heard, and the tank was covered by a dust cloud that, after it dissolved, left visible only the wreck. In the trials in which the tank was left undamaged it continued its course until disappearing from the view. In both cases the LEDs remained lit. Each trial lasted approximately 7.5 s; after that, with a shutter effect, the view finder was closed and opened again, and a new trial began.

The control screen utilized to monitor the participants' attention had four LEDs placed at the vertices of an imaginary rectangle positioned at the center of the monitor, each LED associated with two radio button labeled "Yes" and "No", respectively. Participants were asked to indicate which LEDs were lit (and which projectiles were fired) in the very last trial. Moreover, they had to indicate whether the tank had been destroyed or not by choosing between two more yes/no buttons.

The judgments about the efficacy of each projectile were collected through separate screens. In each screen a colored LED was presented together with a request to provide a judgment about the projectile by setting a slider. The mark was positioned at the middle of the slider and the value for the judgment was set to "unassigned". As soon as the participant started moving the mark, an integer value appeared on screen indicating the mark position on a scale ranging from 0 to 100. The confidence rating were collected by having participants check one of seven radio buttons. The buttons at the extremes were labeled with the Italian equivalents of "No Confidence" and "Complete Confidence", respectively.

Results

To avoid considering data that did not accurately reflect the phenomena under investigation, participants that made four or more errors (over a total of 20 possible answers) in the control task were excluded from the sample.[3] The data of 19 (out of 111) participants were thus discarded, and the following analyses were carried out on the remaining ones: 28 participants in the Low condition, 30 in the Medium, and 34 in the High condition, respectively.

[3]The same criterion had been adopted in Fum & Stocco (2003).

Table 1: Mean causal judgments for **A** and **B**

	Low	Medium	High
Judgment for **A**	41.32	64.53	75.44
Judgment for **B**	23.48	39.83	48.53

Causal Judgments The causal judgments provided by participants are reported in Table 1 and illustrated in the top panel of Figure 2. A mixed-design ANOVA was carried out having Condition (Low vs Medium vs High) as a between-subjects and Judgment (A vs B) as a within-subjects variable.

The analysis showed as significant the main effects of the Condition ($F(2,89) = 34.44$, $MSE = 1125.90$, $p < .0001$) and of the Judgment ($F(2,89) = 55.29, MSE = 24357, p < .0001$) but not their interaction. Contrary to the power PC predictions, participants provided judgments for the causal power of B that were completely different from the expected zero value ($t(88) = 14.50, p < .0001$). In accordance with the predictions of our model, their judgments for the causal power of A and B differed significantly, and the value of the judgments increased with an increase in causal power of the compound stimulus (A,B). The model, however, makes a stronger prediction, i.e., that the ratio between the two stimuli should be constant. We calculated this ratio for each participant, and then computed the mean of the ratios for each condition. Results are reported in the bottom part of Figure 2: ratios remained constant across conditions, with only slight and insignificant differences among them. Values of the ratios were around 0.6, close to our estimate, i.e. 0.5. This result could be considered more than satisfactory being our model completely parameter-free.

Confidence Ratings In analyzing confidence ratings and latencies, we pooled the data of all the participants because

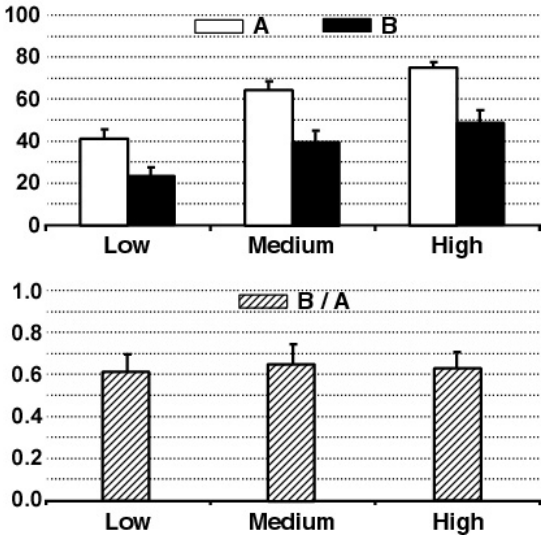

Figure 2: Mean causal judgments (*top*) and mean ratios between **B** and **A** (*bottom*) in the experimental conditions.

our model does not discriminate, under these aspects, among the different conditions.

We found that the confidence ratings for **A** (mean = 3.85) were indeed greater than those for **B** (mean = 3.52), the difference—as revealed by a two-tailed, paired *t*-test—being statistically significant ($t(91) = 2.48$, $p = 0.01$). However, to take into account the possibility that the confidence ratings—collected through a seven point Likert scale—did not conform to a normal distribution, we conducted also a Wilcoxon Matched-Paired test that confirmed the existence of the effect ($T = 676.00$, $N = 92$, $p = 0.04$).

Latencies An even strongest corroboration for our model came from the analysis of latencies. As predicted, the mean time needed to express a jugdment for *A* (17.18 s) resulted smaller than the time needed for *B* (21.31 s). A *t*-test confirmed that the difference was significant ($t(90) = 2.14$, $p = 0.04$). The difference remained significant taking into account the square root ($t(90) = -2.11$, $p = 0.03$) and the logarithm ($t(90) = 2.07$, $p = 0.04$) of the latencies. Causal induction processes seem to respect the time course we hypothesized.

Conclusions

In the paper we presented a model of high level cognitive processes in causal induction that is able to explain previous findings that resulted antithetical to some predictions of the power PC theory, and that can take into account new data that are at odds with, or beyond the scope of, that theory. The model assumes that, when required to provide a causal judgment, people recur to both associative and probabilistic processes. These processes play, however, a different role in causal cognition: associative processes contribute to the construction of an internal representation of the power of directly experienced cues, while probabilistic reasoning is required to estimate the magnitude of the non directly perceived ones.

In the paper we have gone one step further in the description of the cognitive processes underlying such judgments, and we have extended the set of data that may be taken into consideration to discriminate between different accounts. We find particularly important the fact that participants were able to express faithful subjective confidence about their own ability to estimate the causal power of different cues, an indication that these estimates lie above the subjective threshold (Dienes & Perner, 1999) and, therefore, that some kind of explicit knowledge is required to provide these judgments.

We are currently working to extend the model on paradigms other than blocking, and to provide finer estimates of human causal judgment. In particular we think that associative effects, probably reflecting an evolutionarily older, non-specific learning system, shall be further investigated. Our model might be of guidance in determing under which conditions such effects may overcome the explicit processes we described.

Acknowledgements

We thank Fabio Del Missier for some helpful suggestions and the fruitful discussions. We would also like to thank an anonymous reviewer for the inspiring comments.

Inferring knowledge of properties from judgments of similarity and argument strength

Sean Stromsten (sean_s@mit.edu)
Department of Brain and Cognitive Sciences
Massachusetts Institute of Technology
Cambridge, MA 02139-4307 USA

Abstract

Psychological similarity has been invoked to explain many phenomena, including judgments of the strength of inductive arguments (Osherson et al., 1990). The present work follows the suggestion of Tenenbaum and Griffiths (2001) that judgments of similarity and judgments of argument strength cohere because they are essentially judgments of the same kind, which consult the same knowledge of properties of objects or classes. I work backward from people's judgments of argument strength and similarity to the knowledge of properties–specifically, knowledge of probable property extensions–that might explain the coherence among those judgments. I show that the knowledge inferred can be used to predict other such judgments. I then examine this knowledge for structural properties such as taxonomic organization.

Induction, or generalization from examples, is a central cognitive capacity in need of two kinds of explanation: (1) What representations and processes underly induction? (2) Why do we have those representations, and carry out those processes? That is, to the degree that they work, what relation to right reason explains their success? I focus here on the second question, and with respect to just one much-studied inductive task, category-based induction.

To illustrate this task, consider the following inductive argument (after Osherson, et al. , 1990)

Chimpanzees require biotin for hemoglobin synthesis.
Gorillas require biotin for hemoglobin synthesis.

Mammals require biotin for hemoglobin synthesis. (1)

Horizontal lines separate conclusions from their premises. The premises assert facts about categories of objects, and the conclusions do not (in general) follow deductively.

Osherson et al. collected extensive judgments of the strength of such arguments–that is, the subjective probability of the conclusions, given the premises. The arguments contained various mixtures of ten species of mammals in the premises, but all conclusions were about either 'horses' or 'all mammals' (the set of all mammals is approximated, in all models discussed here, by the set of ten mammals used in the arguments)[1].

In order to study argument strength, rather than particular knowledge of predicates, the premises and conclusion assert so-called 'blank' predicates of species, about which experimental participants will not have direct knowledge. The biological sound of the predicates, and the fact that they are asserted to be true of all members of one or more species, are clues that they are biological properties. The intention, then, is that participants have no choice but to fall back on categorical biological knowledge.

Osherson et al. propose the *similarity-coverage* model, which predicts the judged strength of these arguments as a function of judgments of pairwise similarity among the species of animals in them. The strength $g(X, Y)$ of a conclusion, according to this model, is a weighted sum of (1) the similarity of the premise categories X to the conclusion category Y, and (2) the degree to which the diversity of the premise categories 'covers' the lowest superordinate category S including both the premise categories and the conclusion category:

$$g(X,Y) = \alpha \max_i sim(X_i, Y) + (1-\alpha) \sum_j \max_i sim(X_i, S_j).$$

[1] In what follows, in addition to the 81 judgments studied by Osherson et al. , I use data on 28 additional judgments, collected by Sanjana and Tenenbaum (2003). They designed these additional generalization judgments to demonstrate effects which their Bayesian model could explain, but which the Osherson et al. model could not. Again, 'horse' was the only species in the conclusions. The innovation was repeated examples of the same species, which required a cover story that makes such examples reasonable. Participants observed a set of example animals–individual animals–with a particular disease, and were then asked to judge the probability that horses could get the disease. Trusting that participants assume that disease susceptibility is a species property, I aggregate these data with the Osherson et al. data.

Osherson et al. test their model against a number of robust qualitative patterns in the way the plausibilities people assign to such arguments relate to the similarities of the categories used. A few examples of these patterns will illustrate the utility of the similarity and coverage terms. The argument

Chimpanzees require biotin for hemoglobin synthesis.

Gorillas require biotin for hemoglobin synthesis. (2)

is stronger than the argument

Chimpanzees require biotin for hemoglobin synthesis.

Dolphins require biotin for hemoglobin synthesis. (3)

because gorillas are more like chimpanzees than dolphins are. The argument

Chimpanzees require biotin for hemoglobin synthesis.
Dolphins require biotin for hemoglobin synthesis.

Mammals require biotin for hemoglobin synthesis. (4)

is stronger than argument (1), which may be explained by the greater 'coverage' of the set of mammals by 'chimpanzees and dolphins' than by 'chimpanzees and gorillas'.

It may strike the reader that these intuitions require more than purely psychological, *ad hoc* explanations, for surely they are *correct*. If so, they require normative (Bayesian) explanation. This point has been addressed by several authors, beginning with Heit (1998).

There are a number of other reasons for dissatisfaction with an explanation of judgments of argument strength in terms of judgments of similarity, having nothing to do with the degree of predictive success of the similarity-coverage model. The most obvious, perhaps, is that similarity and argument strength are judgments of equal status, equally in need of explanation. Another objection is that the judged similarity of x to y is not a stable, context-free property of the pair (Tversky, 1977). If judgments of similarity must be computed on-the-fly, as judgments of the strength of arguments presumably are, then whatever knowledge is consulted when computing similarities could be consulted when computing argument strengths, without computing similarity as an intermediary. This is, in essence, the kind of explanation proposed in the Bayesian models of Sanjana and Tenenbaum (2003) and Kemp and Tenenbaum (2003). For purposes of direct comparison, they predicted argument strengths from similarities, just as Osherson, et al. did, but did so by way of inferring taxonomic knowledge presumed to underly both similarity and argument strength judgments.

Bayesian generalization

Before discussing the details of particular proposals, I will briefly review the notion of category-based induction as Bayesian generalization, as formulated by Tenenbaum and colleagues. We assume that:

- The premise categories are random samples from the set c of categories having the target 'blank' property.
- Prior to receipt of any examples, the generalizer has a hypothesis space H, where each hypothesis $h \in H$ is a possible extension for the target property. The generalizer also has a probability distribution over H, which represents the prior degree of belief that each candidate is the extension of the target property. This prior distribution may itself be sensitive to (conditional on) other information, for instance, about the *kind* of property being generalized.

The probability that a category y is a member of the set c, given a set of n examples $\mathbf{x}$ drawn at random from c , can be found by summing over hypotheses:

$$P(y \in c|\mathbf{x} \sim c, \xi) = \sum_h P(y \in c|c = h)P(c = h|\mathbf{x} \sim c, \xi).$$

Here $\mathbf{x} \sim c$ means that the examples $\mathbf{x}$ are random draws from c, and ξ represents background information. The first term is 1 if $y \in h$, and 0 otherwise. The second term can be re-written in an enlightening form by Bayes rule:

$$P(y \in c|\mathbf{x} \sim c, \xi) = \frac{\sum_{h \ni y} P(\mathbf{x} \sim c|c = h)P(c = h|\xi)}{\sum_{h'} P(\mathbf{x} \sim c|c = h')P(c = h'|\xi)}.$$

The terms $P(\mathbf{x} \sim c|c = h)$ represent the probability of seeing just the examples $\mathbf{x}$ in n draws from h. Assuming that items in h are drawn with equal probability, then the probability of drawing any particular item in a single draw is $1/|h|$. Then $P(\mathbf{x} \sim c|c = h)$ is $|h|^{-n}$, if h contains all the examples in $\mathbf{x}$, and zero otherwise. The likelihood term $P(\mathbf{x} \sim c|c = h)$ depends only on the examples and the contents of h, so we see now that ξ represents information we may have, prior to seeing the examples, about the probability of the various possible extensions. In what follows, I suppress this term to make the notation simpler.

Further abbreviating $P(c = h)$ to $P(h)$, we can re-write the above as

$$P(y \in c|\mathbf{x} \sim c) = \frac{\sum_{h \supset y \cup \mathbf{x}} |h|^{-n} P(h)}{\sum_{h' \supset \mathbf{x}} |h'|^{-n} P(h')}. \quad (1)$$

Note that the sum in the denominator can be broken into two sums: one is the same as that in the numerator, and the other is over those hypotheses that contain the $\mathbf{x}$ but *not* y. Generalization, then, depends on two weighted sums: one over the properties common to both $\mathbf{x}$ and y, and another over those distinctive to $\mathbf{x}$. Each summand is weighted by both its prior plausibility and its likelihood or 'fit' to the examples.

The two terms have different jobs to do. The fit for extension h–that is, $|h|^{-n}$–gives an advantage to smaller extensions, which is exponential in the number of examples. Without a likelihood term sensitive to the number of examples, we miss an important phenomenon: given that examples are consistent with two extensions, increasing the number of examples ought to shift weight to the more specific extension. For instance, suppose our prior gives high weight to the classes 'mammal' and 'rodent'. Then, given 'mouse' as an example of a species with property P, either class is quite plausible. But adding the further examples 'gerbil' and 'hamster' ought, intuitively, to give a strong advantage to 'rodent', because the selection of three rodents from the larger class is highly coincidental. The likelihood term captures this focusing effect.

Without prior preferences for some extensions over others, the likelihood or 'fit' term will always favor the extension consisting of just the examples, and will have no preference among larger extensions of the same size. For example, given 'mouse' and 'gerbil' as examples of species with some property, generalization to 'turtle' will be just as strong as that to 'hamster'. A prior favoring the natural class 'rodents' over 'rodents minus hamsters, plus turtles' prevents this bizarre behavior.

Similarity as a function of generalization probabilities Tenenbaum and Griffiths (2001) have argued that the similarity of x to y is a function of the probability of generalizing from x to y, or vice-versa, or both. This move gives the infamously slippery notion of similarity some solid footing on the ground of reason, because generalization has a normative foundation in Bayesian statistics. They also show how this view rationalizes earlier work on formalizing similarity and generalization.

For present purposes, we need not delve deeply into the question of just how generalization probabilities determine similarities. I assume, as Osherson et al. do, that similarity is symmetrical, and, further, that it has this particularly simple form:

$$sim(x, y) \equiv \frac{P(y \in c|x \sim c) + P(x \in c|y \sim c)}{2}. \quad (2)$$

Intuitively, this definition says that two items are similar to the degree that one is likely to have a property that the other exemplifies.

Previous work on Bayesian modeling of category-based induction

Various restrictions on the form of the prior could be entertained. For instance, each species might correspond to a location in a low-dimensional Euclidean 'psychological space', with higher priors assigned to sets contained by convex or connected regions. The restricted families of priors investigated by Tenenbaum and colleagues are based on binary trees, with species at the leaves. The sets with highest priors are those corresponding to single subtrees, but some probability is assigned to sets picked out by multiple subtrees. Sanjana and Tenenbaum use a generic method for assigning probabilities to disjunctions of a basis set of hypotheses (in this case, single subtrees), while Kemp and Tenenbaum define a simple 'mutation' process that can generate arbitrary hypotheses, but assigns lower probability to those that require many mutations, or mutations over short branches.

The proponents of these tree-based priors stress that taxonomic trees are not just another restricted family of priors; they are also an independently-motivated *theory* of the domain. People around the world seem to organize creatures into 'folk taxonomies' (Atran, 1995), and the geneology of species does, indeed, form a tree. This kind of theory may be applicable in domains besides biology: even artifact kinds are often the result of a process of copying and modifying earlier designs.

One obvious way to compare various proposed families of priors is to compare predictive accuracies: fit the parameters (for instance, the locations of the points in a metric-space model, or the topology and branch lengths of a tree) to subsets of the judgments and see how well each model predicts the rest.

Rather than competing with previous models on data fit, I take a complementary, 'empirical Bayes' approach (see, for instance, Gelman, et al. , 1995): I place *no* constraints on the form of the prior, find priors that do a good job predicting the data, and then examine those priors for structural properties.

This strategy has an obvious pitfall: an unrestricted search for a prior that makes the data probable may over-fit the accidental properties of the training data, especially, as in this case, when there are many more parameters than data points. Before examining the prior for interesting structural properties, therefore, I demonstrate that the model is not over-fitting so badly as to be uninformative.

Computing a prior from judgments

For any given hypothesis space and prior, Bayesian generalization yields point estimates for a set of similarities and/or argument strengths. To accommodate noisy human data, I take these point estimates to be central tendencies.

In what follows, I refer to the model's prediction of the ith judgment, given a prior, θ, as $j_i^m(\theta)$ (this is given by either equation 1 or equation 2, above). The actual human judgment I denote j_i^h. A simple noise model that respects the constraint that both generalization probabilities and similarities must be between 0 and 1 assumes that

$$log\left(\frac{j_i^h}{1-j_i^h}\right) \sim N\left(log\left(\frac{j_i^h}{1-j_i^h}\right), \sigma^2\right).$$

In words, we apply a transform to each model prediction that may (conveniently) take on any real value, and assume that the similarly-transformed human judgment is normally distributed around this transformed prediction.

A bit of work (omitted here) reveals that the log-likelihood (up to an additive constant) of a set of judgments $\mathbf{j}$ is

$$P(\mathbf{j}|\theta) = \sum_i \log\left(\frac{j_i^h}{1-j_i^h} + \frac{1-j_i^h}{j_i^h} + 2\right) + \frac{1}{2\sigma^2}\left(\log\left(\frac{j_i^h}{1-j_i^h}\right) - \log\left(\frac{j_i^m(\theta)}{1-j_i^m(\theta)}\right)\right)^2. \quad (3)$$

The log likelihood of a set of judgments has a complicated but readily-computed gradient with respect to the prior, involving only the second term in equation 3, which can therefore be optimized by off-the-shelf techniques. I used the method of conjugate gradients, stopping whenever several iterations produced less than a set increase in the log likelihood of the training data. The model was parameterized by 'soft-max' parameters z, where the prior probability of extension i is given by $\theta_i = \frac{e^{z_i}}{\sum_j e^{z_j}}$. On each run, the z were randomly initialized such that the θ were nearly uniform.

Table 1: Predictions of held-out data given various training data. All rows show averages of ten runs, with associated standard errors.

Predicting held-out judgments

Remarkably, this rather lavishly parameterized model does a reasonable job of predicting randomly held-out judgments when fit to the rest.

Tuned to the judgments of argument strength, the model's predictions of pair-wise similarity agree strongly with the actual judgments, approaching a correlation of 0.9. A number of experiments, using various proportions of each kind of judgment as training data, are reported in table 1.

This model does relatively poorly on the task that has been the focus of the previous work–predicting the argument strengths, given the similarities. A possible explanation for the deficit relative to the other published fits is that the assumptions about the form of the prior made explicitly by using a tree with mutations (and perhaps implicitly in the similarity-coverage model) are essentially correct, in which case opening up the space of priors, as I have done, can only reduce predictive accuracy. As further evidence of over-fitting, early stopping would usually have yielded better predictions, although I could not find a single stopping rule that consistently did so.

Given these results, we can expect that the priors converged to will reflect both the underlying structure of people's knowledge and, to some degree, peculiarities of the data set fit by the over-parameterized model. In the next section, I examine the priors converged on for taxonomic structure.

The 'shape' of the prior

For the purpose of examining the structure of the prior that best explains the data, I focus on results obtained by optimizing the prior over the entire set of judgments.

If we examine the hypotheses with highest priors, certain patterns can be found by eye or statistical

test. Table 2 lists the 10 sets with the highest average prior probability in a typical optimization run.

If the most probable sets are those corresponding to sub-trees of a taxonomic tree, then we should expect that most pairs of such sets will obey taxonomic constraints: either one will contain the other, or they will be disjoint. There are a suspiciously large number of these containment relations among the top-ranked sets–randomly generated collections of sets have as many containment relations between pairs as the top-ranked 100 sets only about 40 out of 1000 times. There is an even more extreme number of disjoint pairs–exceeded not even once in 1000 random sets. Forcing the random sets to match the top-ranked 100 in number of members makes no difference to these results.

However, there are also quite a few partially overlapping sets, which is not what we would expect from a single, strictly-observed tree. The overlap is notably non-arbitrary, however. For instance, the sets 'chimp, gorilla, mouse, squirrel', 'chimp, gorilla, dolphin, seal', and 'mouse, squirrel, dolphin, seal' are composed of just the three pair 'dolphin, seal', 'chimp, gorilla', and 'mouse, squirrel' ('Mouse, squirrel' is not shown here, but ranked 14th in this solution. 'Horse, cow', another pair one might expect, is not far behind.).

What this might point to is a 'mutation' process, as suggested by Kemp and Tenenbaum (2003). While there are sets above that could only be explained by mutations, if a single tree is assumed, they seem to be restricted to cases where the mutations could occur over relatively long branches; members of the very short subtrees, such as 'dolphin, seal', seem to be present or absent in tandem, as predicted by the mutation process.

Another possibility is that the prior reflects uncertainty over *several* taxonomies. Uncertainty about just which taxonomy to consult may be of two kinds: uncertainty about which taxonomy is *correct*; and uncertainty about which taxonomy is *relevant* to the property under consideration. The first is a commonplace of probabilistic modeling, and quite intuitively understandable, in this case. If I perform bottom-up, agglomerative clustering by eye, using the two-dimensional multidimensional scaling solution in figure 1, I come up with the tree topology used in both the Sanjana and Tenenbaum and the Kemp and Tenenbaum papers. But only the lowest-level clusterings are obvious. Is the 'seal, dolphin' cluster closer to the 'gorilla, chimp' cluster than the 'mouse, squirrel' cluster is? It is hard to tell.

The second kind of uncertainty is about which of several trees is relevant. Even if some properties are

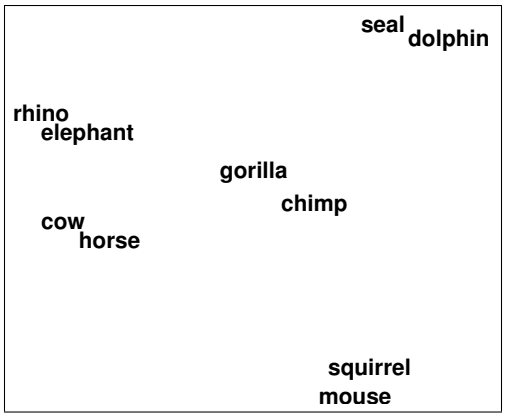

Figure 1: A two-dimensional MDS solution for the similarities of the ten mammals (Euclidean metric, variance accounted for = .81)

distributed according to a particular tree/mutation process, others are likely not to be. This is true even if we restrict attention to biological properties of the kind that are likely to be universal across a species (and which therefore are sensible fodder for the kinds of judgments we consider here). 'Deep' biological properties, such as having a certain organ or metabolic process, are quite likely to respect the 'tree of life'–that representing the genealogy of species. The distribution of other species properties, such as what and how members eat, may be quite random with respect to this tree, but might still respect a different tree.

How might people come to have these priors?

I proceeded above with no constraints on the form of the prior over possible extensions of a new predicate. People or machines asked to make these judgments, however, have no such luxury. They must assume that the extension of the new predicate is systematically related to some known predicate or predicates (and, more generally, that predicates are likely to have systematically related extensions), or have no basis for generalization.

In addition to positing coherence among new properties and old ones, real learners must learn from the kind of data available in the real world. Similarity-like data may sometimes be available, but they are not necessary; people can observe objects and their properties–for instance, that cows, horses, elephants and rhinos all eat grass. Lists of such properties are standard fodder for machine-learning methods, including agglomerative clustering or more sophisticated tree-finding methods. Several strate-

Table 2: The 10 sets with the highest prior probability, on a single optimization over all judgments. There are many instances of nesting, but they are not strictly compatible with any single taxonomic tree.

gies of tree-learning from such data have been applied to a number of standard machine-learning datasets in Kemp et al. (2003).

Summary and discussion

I have suggested a novel technique of general utility for fitting a Bayesian model to a set of judgments. I applied this technique to a large collection of human judgments. Without imposing a taxonomic form on the prior, the prior of a Bayesian model optimized to fit human judgments nevertheless shows significant conformity to taxonomic constraints. It seems that either participants have a bias, in the domain of animals, toward priors that respect the taxonomic constraints, or the raw facts about mammals have this structure (which would, in turn, *justify* a taxonomic bias).

The technique is not limited to the case of a structureless prior over a small set of possible extensions. Any prior that has tractable derivatives with respect to its parameters could be so optimized. In the case of a larger number of categories, whose power set is too large for enumeration, an approximate gradient could be computed using a sample from the current estimate of the prior.

A principled alternative to using held-out data to check models, and to using null-distribution hypothesis tests to look for structure in the prior, is Bayesian model comparison: compare the marginal likelihoods of various structures. For most interesting structure classes, the sums or integrals involved are intractable, but they can be approximated by Markov Chain Monte Carlo or other methods.

Acknowledgments

This work grows out of many conversations with several members of the Computational Cognitive Science lab at MIT: Charles Kemp, Tom Griffiths, and Joshua Tenenbaum. For helpful discussion, I also thank Amy Hoff, Steven Sloman, and David Sobel. This work was supported in part by NSF IGERT grant 9870676 at Brown University.

Detecting the Hot Hand: An Alternative Model

Yanlong Sun (Yanlong.Sun@uth.tmc.edu)

University of Texas Health Science Center at Houston
School of Health Information Sciences, 7000 Fannin Suite 600
Houston, TX 77030 USA

Abstract

The belief in the hot hand was suggested to be a "cognitive illusion" since no significant evidence was found in the basketball-shooting data to reject the simple binomial model (Gilovich, Vallone & Tversky, 1985). The present study argues that in order to evaluate the validity of human perception and cognition such as the hot hand belief, a data-driven approach is needed to compare multiple alternative models. A hot hand model with nonstationary shooting accuracy was tested and showed significantly better approximation to the data than the binomial model, indicating that the simple binomial model may not be accurate enough to serve as a normative model. This finding suggests that the hot hand might indeed have existed, and weakens the argument that the hot hand belief might be "seeing patterns out of randomness."

The Hot Hand and the Perception of Randomness

The "hot hand" in the game of basketball has received much attention in cognitive psychology because it touches an interesting topic about human perception and cognition of random and non-random events outside the psychological laboratory. A long-lasting debate about whether the hot hand exists, hence, whether the hot hand belief is a valid cognitive activity, was triggered by three articles by Gilovich, Vallone and Tversky (1985), and Tversky and Gilovich (1989a, 1989b) (later "GVT" refers to these three articles as a group, unless specified otherwise). The researchers interpreted the hot hand belief as a manifestation about statistically significant deviations from what is expected by the simple binomial model, namely, nonstationary shooting accuracy or positive dependence in basketball shooting sequences. However, no statistical evidence was found to support such belief. After a number of statistical analyses on a large set of data, the researchers found that actual basketball shooting sequences were "indistinguishable from that produced by a simple binomial model" (Gilovich et al., 1985, p. 297). They concluded, "perhaps, then, the belief in the hot hand is *merely* [italics added] one manifestation of this fundamental misconception of the laws of chance" (Tversky & Gilovich, 1989a, p. 16).

Since GVT, many studies have been carried out to investigate the hot hand in basketball or other sports such as baseball. These studies roughly fell into four categories: a) studies that conducted null hypothesis tests but failed to reject the binomial model (e.g., Adams, 1992; Albright, 1993; Chatterjee, Yilmaz, Habibullah, & Laudato, 2000), (b) studies that raised concerns about the power of significance tests conducted by Gilovich et al. (1985) and Albright (1993) (e.g., Miyoshi, 2000; Stern & Morris, 1993; Sun, 2001, 2003; Wardrop, 1999), (c) studies that proposed alternative models that may support the hot hand belief (e.g., Albert, 1993; Albert & Bennett, 2001; Larkey, Smith, & Kadane, 1989), (d) a study that addressed the adaptive value of the hot hand belief, assuming the accuracy of the binomial model (Burns, 2001).

The present paper takes a step further and examines the accuracy of the simple binomial model in a side-by-side comparison with an alternative model that assumes the existence of the hot hand. The importance of such a comparison is obvious since which model is more accurate would inevitably affect researchers' opinion about the validity of the hot hand belief. As Brunswik (1956) and Simon (1982) suggested, the environment in which human perception and cognition originate and operate must be carefully studied. On one hand, it is possible that the hot hand does not exist and the hot hand belief is another example of misperceptions of randomness outside the psychological laboratory, in addition to many previous findings when random events were clearly defined (e.g., Falk, 1981; Kahneman and Tversky, 1972; Tversky & Kahneman, 1971, 1974; Wagenaar, 1972). On the other hand, it is possible that the hot hand does exist, even with a substantial effect size (e.g., substantial changes in shooting accuracy), and traditional statistical tests are generally low in power thus not capable of detecting the effect. The fact is that a truly random process can produce seemingly non-random "patterns," but a truly non-random process can produce seemingly random events as well. Lopes and Oden (1987) demonstrated that although human subjects sometimes misidentified random events as nonrandom (i.e., false alarms), they could also correctly detect truly nonrandom signals (i.e., correct hits). Thus, it is important to find out whether the simple binomial model is accurate enough to serve as a normative model. Then, researchers might be able to answer the question whether the hot hand belief is more about signal detections, or, just "seeing something out of randomness."

Model-driven vs. Data-driven

GVT concluded that actual basketball-shooting records "may be *adequately* [italics added] described by a simple binomial model" (Gilovich et al., 1985, p. 313). However, such a conclusion was solely based on the non-significant *p* values in null hypothesis tests under the binomial model. Sun (2003) and Wardrop (1999) pointed out that GVT's statistical tests were largely redundant and generally low in power, and in many cases, GVT failed to report large deviations from the binomial process or misinterpreted the test results. In the present paper, I only address the importance of comparing multiple models and why non-significant *p* values do not necessarily suggest the accuracy of the simple binomial model.

Criticisms of null hypothesis significance testing (NHST) have been leveled for decades. Many researchers warned that when alternative hypotheses abound, misinterpretations of statistical significance could easily arise (e.g., Cohen, 1994; Lykken, 1991; Oakes, 1986). Nevertheless, many researchers tend to ignore the fact that NHST only estimates $p(D \mid H_0)$, the probability that data D could have arisen if the null hypothesis H_0 were true, not $p(H_0 \mid D)$, the probability that H_0 is true, given D. In modeling basketball shooting, the fact that no significant deviation was found to reject the binomial model, namely, $p(D \mid H_{\text{Binomial}}) > .05$, only indicates that the binomial model may not be terribly erroneous. However, not being terribly erroneous is not the same thing as being accurate or being unique. A *p* value greater than .05 only prompts researchers to retain the null, not to accept the null as if it were true or even likely to be true.

Let H_{Binomial} denote the event that the binomial model is true, $H_{\text{Hot Hand}}$ denote the event that the hot hand theory is true, and D denote the event that a certain statistic from the shooting data reaches a certain level. In order to demonstrate the adequacy of binomial model or the invalidity of the hot hand theory, given the available data, one needs to find out which hypothesis the data are in favor of, namely, to compare $p(H_{\text{Binomial}} \mid D)$ and $p(H_{\text{Hot Hand}} \mid D)$. In Bayes' theorem,

$$\frac{p(H_{Binomial} \mid D)}{p(H_{Hot\ Hand} \mid D)} = \frac{p(H_{Binomial})\,p(D \mid H_{Binomial})}{p(H_{Hot\ Hand})\,p(D \mid H_{Hot\ Hand})}. \quad (1)$$

If one is not biased toward either one of the two hypotheses before examining the data, it is reasonable to assign equal prior probabilities to both models, $p(H_{\text{Binomial}}) = p(H_{\text{Hot Hand}}) = .50$. Then, the comparison between $p(H_{\text{Binomial}} \mid D)$ and $p(H_{\text{Hot Hand}} \mid D)$ comes down to the comparison between $p(D \mid H_{\text{Binomial}})$ and $p(D \mid H_{\text{Hot Hand}})$. GVT's statistical analyses showed that in a number of statistical tests,[1] $p(D \mid H_{\text{Binomial}})$ was not significantly small. Nevertheless, such information alone cannot invalidate the hot hand theory, another piece of information, $p(D \mid H_{\text{Hot Hand}})$ is still missing.

The argument here actually calls for a data-driven approach that compares at least two rival models, rather than a model-driven approach that conducts null hypothesis tests only on one model. The distinction between these two approaches is not a clear cut but rather a difference in emphasis. The data-driven approach eventually has to come down to evaluations of a limited number of models one by one. If a certain model superior to others arises, it will be tested against further data for a need to abandon or modify the model. In this sense, the distinction between two rival models often is not an absolute dichotomy. It is true that in hypothesis testing, such as in Equation 1, two hypotheses have to be exclusive to each other. Nevertheless, in data modeling, two models might only differ in the degrees they approximate the actual process. Which model is selected would be based on which model provides a better approximation of the data, rather than some "mechanical dichotomous decisions around a sacred .05 criterion" (Cohen, 1994, p. 997).

Extracting Relevant Statistics from the Data

To compare multiple models by a data-driven approach, it is essential to extract relevant statistics from the available data. Sun (2003) pointed out that the statistical tests conducted by GVT, such as the test of serial correlation (compared to zero) and runs test were largely focused on the first moment estimate of the time series, namely, the *hit rate* (i.e., observed hitting percentage in a sequence of a certain length) as an estimate of *shooting accuracy* (i.e., the probability for any given shot to be a hit). However, by the law of large numbers, *hit rate* only provides a good approximation of *shooting accuracy* when shooting accuracy remains constant and the sample size is considerably large. Thus, assuming the hot hand is about the nonstationarity of the shooting accuracy, fluctuations of shooting accuracy would not be easily detected by fluctuations of hit rate, when a player only took a limited number of shots in each game. For instance, given a result of 5 hits in a sequence of 10 shots, a null hypothesis test *alone* cannot distinguish whether the hit rate of 50% is a result of a shooting accuracy of 40% or a shooting accuracy of 60%.

By focusing on higher moments of the shooting sequences, Sun (2003) found significant fluctuations of serial correlations in the field goal data that were originally reported by Gilovich et al. (1985). That is, a player sometimes shot in streaks (i.e., successive hits or misses), such as in {1, 1, 1, 1, 0, 0, 0, 0}, yielding a positive serial correlation, and sometimes shot alternatively (hits and misses alternated very often), such as in {1, 0, 1, 0, 1, 0, 1, 0}, yielding a negative serial correlation. The observed changes in serial correlations were unlikely to be accounted for by the simple binomial model, namely, $p(D \mid H_{\text{Binomial}}) < .05$, where D represents the event that the serial correlations changed significantly. Only when the data were *aggregated* across all periods, the *overall averaged* serial correlation was close to zero (e.g., comparing the overall

[1] Note that most of GVT's tests were mathematically redundant (see Wardrop, 1999).

serial correlation with zero, $p > .05$). This finding has at least two indications. First, the actual basketball shooting might not be a stationary process since hits and misses are *not evenly* distributed in the observed shooting sequence. Second, fluctuations of hit rates and the overall serial correlation are not sensitive enough to capture such nonstationarity. In the following, I will present an alternative model that can be distinguished from the simple binomial model by examining the fluctuations of serial correlations. Furthermore, this model may provide a better approximation to the observed data.

A Model of the Hot Hand

Model and Parameter Settings

In real basketball games, it is very possible that potentially high or low shooting accuracy ("hot hand" or "cold hand") might exist but were *interrupted* by other activities such as shot selection and defensive pressure. For example, after making one or two shots, a player may become confident and try more difficult shots, or the opposing team may intensify their defensive pressure on that player. Less frequent interruptions tend to produce shooting sequences with positive serial correlations, since the player's shooting accuracy, either high or low, remains comparatively unchanged, for example, an extreme case would be something like {1, 1, 1, 1, 1, 0, 0, 0, 0, 0}. And vice versa, more frequent interruptions tend to produce shooting sequences with negative serial correlations, for example, a resulting sequence like {1, 0, 1, 0, 1, 0, 1, 0, 1, 0}.

Figure 1 represents a Markov switching model (hence referred to as "the hot hand model"). Similar models have been used by Lopes and Oden (1987) in studying human subjects' ability of distinguishing between random and nonrandom events, and by Albert and Bennett (2001) in modeling the "streakiness" in baseball.

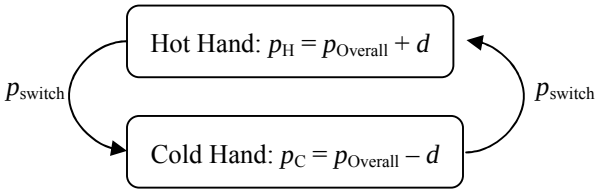

Figure 1. A Markov Model of the Hot Hand

To accommodate the hot hand theory, the major characteristic of this model is that it has two states, "hot hand" and "cold hand," representing two different levels of shooting accuracies, p_H and p_C, respectively. If a player's overall shooting percentage in the entire season was $p_{Overall}$, p_H and p_C were shifted higher or lower in the same amount of d from $p_{Overall}$. Then, this player's simulated shooting sequence will be generated as the player switches between the "hot hand" and the "cold hand." How often the player makes the switch depends on the switching probability, p_{switch}. A high p_{switch} value (e.g., $p_{switch} > .50$) means the player switches between two states very often. In an actual basketball game, this would represent the situation in which a hot hand or a cold hand is detected and a real-time adjustment is immediately deployed by either the player or the opposing team. And vice versa, a low p_{switch} value (e.g., $p_{switch} < .50$) means that the player rarely switches between two states. This would represent the situation in which a hot hand or a cold hand remained uninterrupted or real-time adjustments rarely occurred.

Actually, when $p_H = p_C = p_{Overall}$ ($d = 0$) and $p_{switch} = .50$, the hot hand model is in effect equivalent to the binomial model. If the binomial model were truly adequate and unique, one would expect that a model with dramatically different parameter settings would be less capable of describing the observed data. For this reason, I chose a set of extreme values to represent the hot hand model, in which $d = .30$ (i.e., $p_H - p_C = .60$) and p_{switch} was randomly selected from (.95 and .05) with a 50-50 percent chance for every 10 shots, whereas the binomial model only took a constant shooting accuracy $p_{Overall}$. Figure 2 illustrates the difference between two models in terms of the shooting accuracy along the time line.

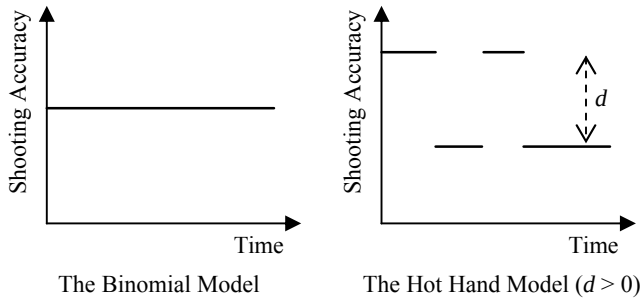

Figure 2. Two Possible Models of Basketball Shooting

Simulation Procedure

Gilovich has kindly provided the field goal data that were reported in Gilovich et al. (1985). There were 18 players in the data set, and 16 of them were included in the simulation (2 players were excluded because their shooting sequences were too short).

For each player in the simulation, I computed a statistic called "MMAC" (Max-Min Moving Autocorrelation) from his actual shooting sequence, whereas MMAC was defined as the absolute difference between the largest and smallest moving serial correlations, where the moving serial correlations were calculated as the serial correlations within a window of 100 shots, starting from the first shot then each time moving 1 shot further until the end of the sequence. The purpose for choosing such specific statistic is to capture the fluctuations of the serial correlations. In the meantime, to reduce chance errors, a large sample size is needed so that the window width of 100 shots was chosen.

For each of the 16 players, I ran 10,000 simulations with the binomial model and another 10,000 simulations with the hot hand model, each simulation generating one shooting

sequence in the same length of the player's actual shooting sequence and with the same overall shooting accuracy. The statistic MMAC was calculated from each simulated sequence, then compared to the observed MMAC from the player's actual shooting record. The probabilities for each model's simulated MMAC to include the observed MMAC were computed as $p(D \mid H_{\text{Binomial}})$ and $p(D \mid H_{\text{Hot Hand}})$. Then, given equal prior probabilities $p(H_{\text{Binomial}}) = p(H_{\text{Hot Hand}}) = .50$, posterior probabilities $p(H_{\text{Binomial}} \mid D)$ and $p(H_{\text{Hot Hand}} \mid D)$ were calculated by Equation 1. Since there were only two hypotheses considered, $p(H_{\text{Binomial}} \mid D) + p(H_{\text{Hot Hand}} \mid D) = 1$.

Simulation Results

The simulation results are listed in Table 1. Columns 2 to 5 list the probabilities $p(D \mid H_{\text{Binomial}})$, $p(D \mid H_{\text{Hot Hand}})$, $p(H_{\text{Binomial}} \mid D)$, and $p(H_{\text{Hot Hand}} \mid D)$, respectively. Column 6 lists the probabilities of detecting significance ($a = .05$, two-tailed) by runs test (Siegel, 1956) on the sequences generated by the hot hand model. The table is ordered in the ascending order of $p(D \mid H_{\text{Binomial}})$.

Considered separately, the probabilities $p(D \mid H_{\text{Binomial}})$ and $p(D \mid H_{\text{Hot Hand}})$ (Columns 2 and 3) in effect provided p values for null hypothesis significance testing, assuming either of the two models as the ture hypothesis ($a = .05$, two-tailed). For players 24, 10, and 3, the simulation results $p(D \mid H_{\text{Binomial}}) < .05$ actually provided significant p values to reject the binomial model. For players 18 and 50, $p(D \mid H_{\text{Binomial}})$ were only slightly greater than .05. (Considering the fact that there were 16 players tested, the probability of family-wise Type I errors needs to be calculated, which was found to be less than .05. see Sun, 2003) On the other hand, none of the p values in $p(D \mid H_{\text{Hot Hand}})$ reached the significance level of .05.

Assuming one is unbiased toward either of the two models prior to examining the data, so that $p(H_{\text{Binomial}}) = p(H_{\text{Hot Hand}}) = .50$, the comparisons between $p(H_{\text{Binomial}} \mid D)$ and $p(H_{\text{Hot Hand}} \mid D)$ (Columns 4 and 5) would reveal which model obtains more support from the observed data in terms of the MMAC statistic.

Table 1. Comparisons between the binomial model and the hot hand model

Player	$p(D \mid H_{\text{Binomial}})$	$p(D \mid H_{\text{Hot Hand}})$	$p(H_{\text{Binomial}} \mid D)$	$p(H_{\text{Hot Hand}} \mid D)$	Power (runs test)
24	.0178	.3380	.0500	.9500	.1911
10	.0223	.3127	.0666	.9334	.1909
3	.0232	.4116	.0534	.9466	.1891
18	.0508	.1299	.2811	.7189	.1836
50	.0690	.4709	.1278	.8722	.1824
7	.1517	.5929	.2037	.7963	.1854
25	.4084	.6539	.3844	.6156	.1836
2	.5343	.9610	.3573	.6427	.1951
11	.5446	.8983	.3774	.6226	.1795
22	.6472	.9640	.4017	.5983	.1769
53	.7094	.9766	.4208	.5792	.1936
5	.7370	.9855	.4279	.5721	.1928
4	.7625	.9953	.4338	.5662	.1918
6	.8004	.9993	.4447	.5553	.1872
1	.9393	.9993	.4845	.5155	.1871
9	.9886	.9999	.4972	.5028	.1845
Mean	.4632	.7297	.3161	.6839	.1872

Note: D represents the event that the simulated MMAC is greater than or equal to the observed MMAC calculated from each player's shooting record. Column 6 is the estimated power of runs test based on detections of significance ($a = .05$, two-tailed) on the simulated sequences by the hot hand model.

For individual cases, MMAC appeared to be substantially in favor of the hot hand model rather than the binomial model for a certain number of players (e.g., players 24, 10, 3, 18, 50, 7, 25, 2, and 11), as $p(H_{\text{Binomial}} \mid D)$ was much smaller than $p(H_{\text{Hot Hand}} \mid D)$ (see Table 1, Columns 4 and 5). One may calculate a c^2 statistic for each player to test the null hypothesis that MMAC is indifferent to either of the binomial model or the hot hand model. However, c^2 statistics tend to be over-sensitive when the expected frequency in a certain cell is too low (for example, the players 6, 1, and 9). The result that all c^2 were significant ($df = 1$, $p < .01$) for all of the 16 players might have overestimated the superiority of the hot hand model.

Taking all 16 players together, the hot hand model appeared to be substantially superior to the binomial model in accounting for the observed MMAC. On the average, $p(D \mid H_{\text{Binomial}}) = .4632$, and $p(D \mid H_{\text{Hot Hand}}) = .7297$. By the criterion of maximum likelihood, given equal priors $p(H_{\text{Binomial}}) = p(H_{\text{Hot Hand}}) = .50$, the observed data seemed to support the hot hand model rather than the binomial model: on the average, the posterior probabilities are $p(H_{\text{Binomial}} \mid D) = .3161$ and $p(H_{\text{Hot Hand}} \mid D) = .6839$.

It may be possible that the hot hand model appeared to be superior to the binomial model only in terms of the statistics of MMAC. To see whether the hot hand model was "truthful" to other observed statistics such as the number of runs, I also conducted a runs test for each simulated sequence by the hot hand model, since out of those 16 players, runs test only detected one significance at the .05 level in the observed shooting sequence (player 53, see Gilovich et al., 1985). (Note that because of the symmetrical setting of the model, there is no need to check the hitting percentage.) The results of runs test suggested that the hot hand model was largely truthful to the observed shooting sequence in the statistic of number of runs, since on the average, only 18.72% of the simulated sequences were detected as significant deviations from what is expected by the binomial model (see Table 4, last column). A further check found that during 10,000 simulations for each player with the hot hand model, the *overall* serial correlations were symmetrically distributed around the mean of zero, with a standard deviation slightly larger than the expected value ($1/\sqrt{N-3}$) assuming binomial process (N is the number of shots in each sequence). Together, these observations provided confirmations to my previous claims. That is, a nonrandom process (such as the hot hand model) can produce seemingly random sequences and may not be easily detected by traditional statistical methods (such as the runs test, or, comparing the overall serial correlation with zero).

Discussion

One might argue that the "hot hand model" fitted the data better than the binomial model simply because the former has more parameters than the latter. I have three reasons to counter this argument. First, basketball shooting is a complex process. It is very reasonable to believe that a useful model needs more parameters than just a single constant shooting accuracy. Second, the extra parameters in the hot hand model may not be counted as "free parameters" because they feasibly represent actual situations in which a player's shooting accuracy may change and real-time adjustments take place quickly (or slowly). Lastly and most importantly, as mentioned before, the hot hand model actually took parameter values that were substantially different from the simple binomial model. Yet, it provided more accurate descriptions of the observed data. This would have seriously challenged the accuracy of the simple binomial model.

It should be pointed out that the primary purpose for building the hot hand model is not to argue about its uniqueness. Nevertheless, such model may prompt researchers to consider the possibility that non-random process may easily produce seemingly random sequences and the possibility that the hot hand belief is indeed a valid cognitive activity in detecting non-random events. It is important to notice that particular statistics such as number of runs, serial correlations, including the MMAC statistic I used in this study, may not be sensitive enough to tell the difference between two different processes. Nevertheless, researchers need to consider multiple models in evaluating the validity of human perceptions, since multiple models can co-exist and provide different levels of approximations to the actual underlying process.

The simulation has shown that for a certain number of players, the hot hand model is substantially superior to the binomial model. For the other players, these two models are not easily distinguishable. By Bayes' theorem in Equation 1, if both models account for the data with the same capability so that $p(D \mid H_{\text{Binomial}}) \approx p(D \mid H_{\text{Hot Hand}})$, which model is more likely to be "perceived" from the data, namely, $p(H_{\text{Binomial}} \mid D)$ and $p(H_{\text{Hot Hand}} \mid D)$, then, is entirely determined by personal beliefs, $p(H_{\text{Binomial}})$ and $p(H_{\text{Hot Hand}})$. There is no prior reason why basketball fans and players should agree with researchers on such personal belief. In other words, the hot hand belief may not be readily dismissed as merely a misperception of randomness simply because the researchers failed to reject the binomial model by null hypothesis significance testing.

General Conclusion

The primary purpose of the present paper is not to dispute whether ordinary people misperceive probabilistic events in basketball, but to prompt further investigations of the actual process of basketball shooting. Lacking normative knowledge such as probability theory and theories of stochastic processes, ordinary people are often prone to mistakes. However, it is also possible that the hot hand belief was describing a true anomaly that was not detected by traditional statistical methods. The present study presented a case when statistical methods are applied objectively rather than subjectively toward the plausible

models, how a different point of view, regarding the validity of human perceptions of the environment, could be obtained. That is, comparing to a model-driven approach that only conducts null hypothesis testing on a single model, a data-driven approach can be more revealing by comparing multiple models. Then, it was suggested that the simple binomial model might not be accurate enough to serve as a normative model in evaluating the validity of the hot hand belief. From Brunswik's (1956) point of view, an organism and the environment in which the organism was embedded should receive equal emphasis in psychological theory and research. In this sense, the primary purpose of the present study is to serve as "a propaedeutic to functional psychology" (Brunswik, 1956, p. 119), a necessary step before psychologists can fully understand the belief in the hot hand.

Spatial Updating in Intrinsic Frames of Reference

Abstract

The present study investigates the properties of the spatial updating in terms of intrinsic frames of reference. We hypothesize that the efficiency of dynamically updating object-to-object relations is based on two main factors, a relatively stable frame of reference provided by the orienting object (or object array), and the behavioral significance (salience) level of the target objects. Three experiments were conducted using tasks of direction pointing. It was found that responses were significantly slower when the orienting object was constantly rotating. Given a relatively stable frame of reference, responses to the salient objects were faster than those to the non-salient objects when the number of salient objects was limited. The salience effect disappeared and re-appeared in the absence and presence of a stable frame of reference, respectively. These findings indicated that spatial updating in intrinsic frame of reference is not automatic and is limited by the number of target objects.

Introduction

As people move through an environment, they continuously update the spatial relations between themselves and the environment and the relations between the objects in the environment. For instance, a pedestrian who is waving on a taxi may also notice that a dog is chasing the taxi from behind. In this scenario, two kinds of information have to be encoded by the pedestrian, the relation between his body and the taxi, and the relation between the taxi and the dog. In fact, this example illustrates the distinction between an egocentric reference system (body-centered) and an allocentric reference system (more specifically in this scenario, an object-centered intrinsic system). It has been generally agreed that in encoding spatial information, different reference systems can be involved. Many researchers adopted the distinction between egocentric and allocentric reference systems and conjectured that participants in their experiments used either one of such systems (e.g, Bryant & Tversky, 1999; Diwadkar & McNamara, 1997; Franklin & Tversky, 1990; Shelton & McNamara, 1997; Sholl & Nolin, 1997; Simons & R. Wang, 1998. For a recent treatment, see McNamara, 2003, and Mou & McNamara, 2002).

A large body of research has been focusing on spatial updating with respect to the egocentric system. It has been indicated that spatial memories are primarily egocentric and updating by the egocentric system is of high fidelity and automatic (e.g., Rieser, 1989; Shelton & McNamara, 1997; Simons & R. Wang, 1998; R. Wang, 1999). Nevertheless, Mou and McNamara (2002) and McNamara (2003) recently proposed that spatial information is encoded primarily of object-to-object spatial relations, and therefore is allocentric. This new theoretical framework calls for a systematic study on properties of spatial updating in intrinsic systems in dynamic situations, as compared to updating in egocentric systems. For example, Sholl and Nolin (1997) and R. Wang (1999) have suggested that egocentric self-to-object spatial relations are updated automatically as people move through an environment. It remains unclear whether updating in intrinsic frame of reference is also automatic. Furthermore, what kind of information is to be updated in intrinsic systems? Are all objects in the environment being updated with equal priorities? The present paper attempts to answer these questions by reporting three experiments.

Our working hypothesis on spatial updating in intrinsic frame of reference is that such a process involves paying attention to both the orienting objects that anchor the intrinsic frame of reference and the target objects in their relations to the orienting objects. In other words, there are two sequential components in such a process: establishing and maintaining a frame of reference, then, updating the object-to-object relations. Thus, we hypothesize that updating in intrinsic systems can be achieved dynamically only when a relatively stable frame of reference can be maintained. In the taxi example above, in order to update the relations between the taxi and the dog, the pedestrian first needs to identify the orientation of the taxi. Second, we hypothesize that updating of object-to-object relations is affected by the behavioral significance of the target objects. This hypothesis is based on previous findings that visual selection can be prioritized by the object's properties, by its specific location and background (e.g., Duncan, 1984; Wolfe, 1994), or even by cues in time (e.g., Watson, Humphreys, & Olivers, 2003). In the taxi example, a dog chasing the taxi probably is more salient than other objects on the street (say, a post stand), thus it is more likely to be

attended to continuously by the pedestrian. We will refer to this effect as the "salience effect" throughout this paper.

We conducted three experiments to test our hypotheses. The task we used was similar to the direction pointing task in the visual map condition in Hintzman, O'Dell, and Arndt (1981). Two major modifications were made to fit our specific needs. First, we added settings to test the salience effect. That is, the target objects had two different salience levels, determined by both behavioral and perceptual significance. Second, to test real-time updating, our experiments were implemented in dynamic settings, which involved continuous relative movement between the orienting object (intrinsic frame of reference) and the target objects. We tested three different movements: the translation-only movement (Experiment 1), the movement in which the orienting object rotated while the target objects remained still (Experiment 2), and the movement in which the orienting object remained still but the target objects rotated (Experiment 3).

General Method

Since all three experiments reported here shared similar settings and procedures, we summarize the common aspects of the experimental settings and data analyses in this section. The experiments were conducted on a Pentium II computer, and the stimuli were presented on a 19-inch CRT monitor. The stimuli consisted of one blue submarine image (bird's eye view) and a certain number of white dots (non-salient objects) and red dots (salient-objects) on a grey background. All three experiments used a 2x8x8x2 within-subjects design, in which there were two salience levels (salient vs. non-salient), eight submarine orientations, eight target directions, and two levels for the number of salient objects. Each participant completed 256 trials, with each trial representing one combination of all levels of all factors. The order of the 256 trials was randomly shuffled. A trial consisted of three steps. First, the submarine and the surrounding dots were presented and the submarine flashed three times to help participants identify its location and orientation. Then, depending on the specific experiment, either the submarine or the surrounding dots started to move (translating or rotating). Finally, the relative movements stopped and at the same time one of the surrounding dots flashed as the target. The instruction for all three experiments was the same. Participants were instructed to imagine being on the submarine and an enemy submarine (the target) was hiding at the location of one of those surrounding dots. The red dots were more likely to be enemy positions thus participants should pay particular attention to them. When the target flashed, participants were told to indicate the direction of the target relative to the orientation of the submarine.

The responses were made with a number keypad on a standard PC keyboard. On the keypad, the number keys 1, 2, 3, 4, 6, 7, 8, and 9 were used as response keys, with each representing one of the eight directions relative to key 5. These keys were re-labeled with drawings of arrows pointing to the corresponding directions. All other keys were removed and the key for number 5 (which was in the center of all eight response keys) was replaced with a stud that could not be pressed. Participants were instructed to use only one finger to press the response keys. At the beginning of each trial, they were told to rest the finger on the stud, and after they made the response, to put the finger back on the stud.

The primary dependent measure was the reaction times (RT) measured in milliseconds. To avoid confusion, we adopted the same labeling scheme as used in Hintzman et al. (1981). Descriptive names were used for responses (target direction relative to the submarine's orientation), such as front, right-front, right, right-back, back, left-back, left, and left-front. For submarine orientation (equivalent to the arrow orientation in Hintzman et al.'s experiment 1 and 2), we used digits 0 through 7, representing the number of steps by 45° clockwise from upright (e.g., digit 0 for the upright submarine orientation, and digit 4 represents the downright orientation).

Experiment 1

Participants Twelve college students and graduate students in the Houston medical center area participated in Experiment 1 (six males and six females, and the average age was 29.3 years with an SD of 4.81 years). Participants were paid for participation.

Procedure Figure 1 shows a typical display in Experiment 1. At the beginning of each trial, one blue submarine image and 400 dots (in which 2 or 4 of them were red and the rest were white) arranged in a 20 x 20 array were presented simultaneously. Red and white dots were the same size, with a diameter of approximately 0.40 cm. The horizontal and vertical distance between every adjacent two dots (hence referred to as one unit) was approximately 0.85 cm, and the submarine image, when upright, was approximately 0.80 cm high and 0.44cm wide. The salient objects were randomly plotted (without overlapping with each other) within a 5 by 5 array in the center of the entire array. The initial position of the submarine was 4, 5 or 6 units (randomly selected) away from the center of the array, randomly taking one of the 8 possible orientations but always approximately pointing to the center of the dot array.

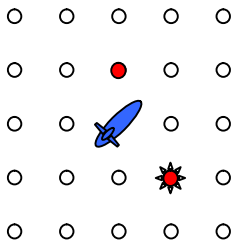

Figure 1

At the beginning of each trial, the submarine flashed three times and then started to move (translation without rotation)

toward the center of the array. The moving speed was constant for all trials, which was approximately 2136 ms per unit (0.47 units per second). When the submarine reached approximately the center of the array, it would stop and at the same time, one of the eight dots in the 3 by 3 square where the submarine was located would flash (the submarine image covered the dot in the center of the square). Participants pressed the response key to respond to the target direction relative to the submarine. The accuracy and reaction times were recorded. A regular experimental session took approximately one and a half hour (in which the training session took approximately 20 minutes).

Results The mean RT for the 12 participants was 1247.4ms with a standard deviation of 542.40ms. The mean accuracy rate was 93.5% with a standard deviation of 4.56%. RT as a function of the target direction is shown in Figure 2, and RT as a function of the submarine orientation is shown in Figure 3, with RT broken down by two salience levels, where error bars represent standard errors. The target names in Figure 2 are abbreviated (F for Front, FR for Right Front, etc.). To emphasize the symmetry and continuity, the direction F in Figure 2 and the orientation 0 in Figure 3 were represented twice. This convention is used in other similar figures throughout this paper.

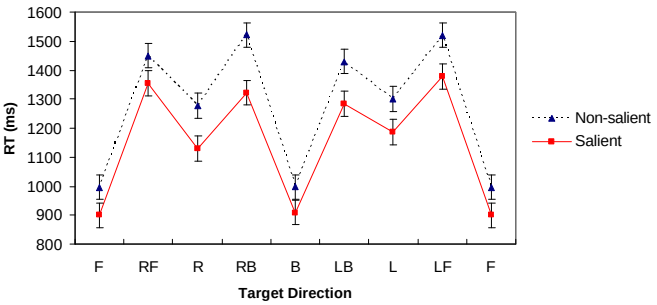

Figure 2. Experiment 1, RT as a function of target direction.

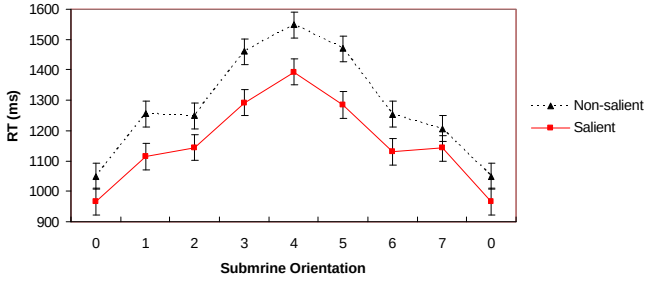

Figure 3. Experiment 1, RT as a function of submarine orientation.

A significant orientation effect was observed. RT as a function of the target direction showed an "M" shaped profile, fastest on the front and back directions and slowest on the right-back and left-back directions ($F_{7, 77}$ = 16.14, p < .001, estimated effect size = .595). As a function of submarine orientation, RT was fastest when the submarine was upright (orientation 0), and slowest when the submarine was pointed down (orientation 4) ($F_{7, 77}$ = 16.74, p < .001, estimated effect size = .603).

Of primary interests to us was the salience effect. It is clear from both Figures 2 and 3 that the salience level had a significant effect on RT. In all target directions and submarine orientations, responses to salient objects were faster than that of non-salient objects, with an average difference of 128.6 ms ($F_{1, 11}$ = 27.95, p < .001, estimated effect size = .718). Moreover, the salience effect appeared to be very stable in size across all target directions and submarine orientations: the two curves in each figure are essentially parallel, and both interactions (salience by target direction, and salience by submarine orientation) were not significant ($F_{7, 77}$ = 1.185, p = .321; and $F_{7, 77}$ = 1.471, p = .190, respectively).

The number of salient objects (hence abbreviated as NOS) appeared to have a small effect on RT. On average, RT was faster when NOS = 2 than when NOS = 4 (mean difference = 26.5 ms), which was marginally significant ($F_{1, 11}$ = 4.57, p = .056). The effect of NOS would be observed more clearly through the interaction between NOS and salience, which was statistically significant ($F_{1, 11}$ = 6.09, p = .031, estimated effect size = .356). It appeared that NOS had little effect on RT when the target was a non-salient object (1314.9 ms when NOS = 2, compared to 1308.3 ms when NOS = 4), but the effect was considerably larger when the target was a salient object (1153.3 ms when NOS = 2, compared to 1212.9 ms when NOS = 4, mean difference = 59.6 ms).

Other factors remaining constant, faster RT for the salient objects in Experiment 1 suggests that spatial information about salient objects was updated with a higher priority thus retrieved more quickly than the information about the non-salient objects. Moreover, the orientation dependence was presented in responses to both salient objects and non-salient objects: both main effects of target direction and submarine orientation were significant but none of the interactions (target direction and salience, submarine orientation and salience, respectively) reached significance, implying the important role the orientation plays in spatial updating.

Furthermore, it is interesting to note that the salience effect remained but reduced in size when the number of salient objects increased (from 161.6 ms when NOS = 2, to 95.4 ms when NOS = 4). One explanation is that more than four salient objects were prioritized but the retrieval of the corresponding information was achieved in a serial fashion. Another explanation is that the capacity of such prioritization was already exceeded when there were four salient objects. Then, participants might randomly choose, say, two of the salient objects for particular attention. As a result, the averaged salience effect in the four salient objects condition was reduced, compared to the two salient objects condition. In either case, it appears the salience effect would eventually disappear when the number of salient objects exceeds a certain level. It would be interesting to conduct

experiments to further investigate the capacity of such a "salience buffer."

Experiment 2

Participants Twelve college students and graduate students in the Houston medical center area participated in Experiment 2 (four males and eight females, and the average age was 26.3 years with an SD of 4.49 years). Participants were paid for participation.

Procedure The procedure was essentially the same as in Experiment 1. The following were the major differences. The potential targets were 8 dots aligned on a circle at 45° intervals, with the submarine located in the center. When the submarine is aligned upright, these eight dots are on the front, right-front, right, right-back, back, left-back, left, and left-front, respectively (see Figure 4). For the two levels of the number of salient objects, instead of 2 salient objects vs. 4 salient objects, Experiment 2 compared the conditions of 1 salient object vs. 2 salient objects.

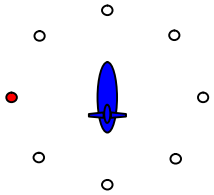

Figure 4

At the beginning of each trial, one blue submarine image and 8 dots (in which 1 or 2 of them were red and the rest were white, on a circle with a diameter approximately of 5.93 cm) were presented simultaneously. All dots were in the same size with a diameter approximately of 0.80 cm. The submarine image, when upright, was approximately 1.98 cm high and 0.88 cm wide. The positions of salient objects were randomly selected (without overlapping with each other). The initial orientation of the submarine was always upright. After flashing 3 times, the submarine started to rotate around the center of the circle. The rotation speed was constant for all trials, which was approximately 0.033° per ms (approximately 2763ms for every 90°). When the submarine reached a certain orientation, it would stop and at the same time one of the eight dots would flash. The rotating distance was determined by the trial settings on the submarine orientation, with a minimum of 45° and a maximum of 360°. Among 256 trials, each 32 trials had the same rotating angle ranging from 45° to 360° in the step of 45°. The order of the trials was randomly shuffled before presentation.

Results The mean RT for the 12 participants was 1772.7 ms with a standard deviation of 663.54ms. The mean accuracy rate was 94.7% with a standard deviation of 6.13%. RT as a function of the target direction is shown in Figure 5, with RT broken down by two salience levels. (RT as a function of the submarine orientation showed the same overlapping pattern. The figure is omitted here to save space.)

The most obvious observation in Figure 5 is the absence of the salience effect: RT for the salient objects was almost identical to that for the non-salient objects. Overall, there was little difference between RT for salient objects and RT for non-salient objects (mean difference = 18.4 ms, $F_{1, 11} = 0.841$, $p = .379$). Moreover, both the main effect of NOS and the interaction of salience and NOS were not significant ($F_{1, 11} = 0.436$, $p = .522$; $F_{1, 11} = 4.190$, $p = .065$, respectively). Though statistically it is impossible to prove the null hypothesis (i.e., the salience effect did not exist), compared to the magnitude of the salience effect observed in Experiment 1, we are confident that the salience effect was at least largely reduced in Experiment 2.

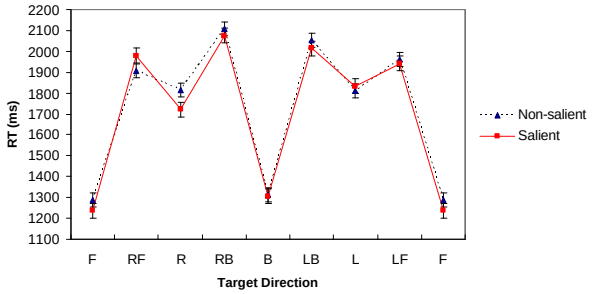

Figure 5. Experiment 2, RT as a function of target direction

Another interesting finding was that RT in Experiment 2 was much slower than that in Experiment 1 for all target directions and submarine orientations. (Figure 6 shows the comparison between all three experiments.) The average difference in RT between Experiment 1 and Experiment 2 was 525.3ms. We suspect that the absence of a stable frame of reference played a major role. Compared to Experiment 1, the major difference in Experiment 2 was that the submarine was rotating constantly before the target was presented. As a result, no stable frame of reference was provided in terms of a fixed submarine orientation. In such a situation, there were two possible strategies of establishing and maintaining a frame of reference. One was that participants could first establish a frame of reference as the submarine was initially presented, then update (i.e., rotate) that frame of reference along with the submarine as it rotated. The other was that participants just waited until the submarine stopped then re-established a frame of reference. We had two reasons to believe that the second strategy was preferred and actually utilized by participants. First, it would take much less effort to re-establish a frame of reference when the submarine stopped rotating, than to maintain a frame of reference by constantly updating it with the rotating submarine. In extreme cases, the submarine would have rotated 360° before it stopped. It would make little sense to update the frame of reference if it would return to its initial position. Second, if the first strategy was actually applied and our participants indeed were updating a frame of reference along with the rotating submarine, Experiment 2 would have had similar RTs as in Experiment 1.

Nevertheless, one may raise the question whether RTs in Experiment 1 and Experiment 2 were directly comparable

since there were confounding factors such as the size of the stimuli and the difference between translation and rotation. For example, it was found that imagined rotation was more difficult than imagined translation (e.g., Presson & Montello, 1994). Due to this consideration, we conducted Experiment 3 with these factors controlled.

Experiment 3

Participants Twelve college students and graduate students in the Houston medical center area participated in Experiment 1 (four males and eight females, and the averaged age was 27.7 years with an SD of 5.55 years). Participants were paid for participation.

Procedure The procedure and device was essentially the same as in Experiment 2. The only difference was that in Experiment 3, the eight surrounding dots were rotating simultaneously while the submarine remained still. Other factors such as the image sizes, the arrangement of the display, and the relative rotation speed, remained the same. The initial orientation of the submarine was randomly selected as one of eight possible orientations. After flashing the submarine three times, the surrounding dots started to rotate around the center of the circle. When they reached a certain location (determined by the trial settings), they would stop and at the same time one of the eight dots would flash.

Results The mean RT for the 12 participants was 1373.1 ms with a standard deviation of 401.68ms. The mean accuracy rate was 93.8% with a standard deviation of 4.52%.

Similar to in Experiments 1 and 2, we observed significant effects of target direction and submarine orientation in Experiment 3 ($F_{7, 77} = 31.590$, $p < .001$, estimated effect size = .742; $F_{7, 77} = 41.075$, $p < .001$, estimated effect size = .789, respectively). Similar to Experiment 1, we observed a significant salience effect. Through all target directions and submarine orientations, responses to salient objects were faster than that to non-salient objects. The average difference in RT for salient objects and non-salient objects was 88.8ms, which was statistically significant ($F_{1, 11} = 16.546$, $p < 0.01$, estimated effect size = .601). (RT as a function of the target direction and a function of the submarine orientation showed the similar split patterns as in Figures 2 and 3. The figures are not shown here.) The salience effect appeared to be very stable across all target directions and submarine orientations: both interactions (salience by target direction, and salience by submarine orientation) were not significant ($F_{7, 77} = 1.123$, $p = .358$; and $F_{7, 77} = 0.999$, $p = .439$, respectively).

The number of salient objects (NOS) showed significant effect on RT. On average, RT was faster when NOS = 1 than when NOS = 2 (mean difference = 79.4 ms, $F_{1, 11} = 32.588$, $p < .001$, estimated effect size = .748). The interaction between NOS and salience was statistically significant ($F_{1, 11} = 42.025$, $p < .001$, estimated effect size = .793). As a result, it appeared that NOS had little effect on RT when the target was a non-salient object (1415.8 ms when NOS = 1, compared to 1419.2 ms when NOS = 2), but the effect was considerably large when the target was a salient object (1251.1 ms when NOS = 1, compared to 1406.4 ms when NOS = 2, mean difference = 155.3 ms). In addition, the salience effect here was larger when there was only one salient object (1415.8 ms compared to 1251.1 ms, with a difference of 164.7 ms), but essentially disappeared when there were two salient objects (1419.2 ms compared to 1406.4 ms, with a difference of 12.8 ms). The diminished salience effect could be due to participants' limited capacity in prioritizing salient objects, or due to the conflicting relations between the two target objects and the orienting submarine (for example, the two salient objects could be on the opposite sides of the submarine). We will leave this question to future investigations.

On average, RT in Experiment 3 was faster than in Experiment 2 (average difference was 399.6ms), but still slower than in Experiment 1 (average difference was 125.7ms) (see Figure 6). This observation confirmed the previous hypothesis that rotation was indeed more difficult than translation. However, it also confirmed the hypothesis that faster reaction times can be produced by a relatively stable frame of reference.

General Discussion

We summarize the general findings in the present study by comparing all three experiments. The experiments had similar task instructions (direction pointing by paying specific attentions to the salient objects), but differed mainly in the forms of relative movements between the orienting object and the target objects. By manipulating the relative movement, we obtained different response times. Figure 6 shows the comparison.

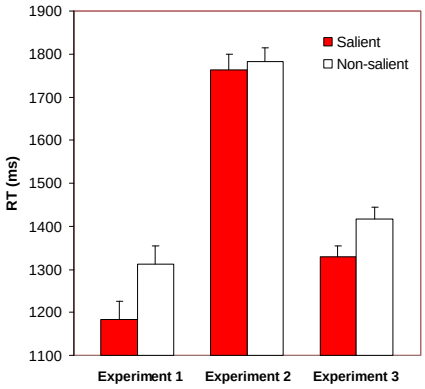

Figure 6. Comparison of RT among three experiments

From a computational point of view, updating of the object-to-object relations in intrinsic frame of reference depends mainly upon two factors: a frame of reference, and a potential target. The different reaction times in the three experiments suggest that a stable frame of reference is critical when the object-to-object relations are to be updated. When the orienting object was rotating, it appeared that the intrinsic frame of reference based on that object was not continuously updated: responses tended to take longer as if a frame of reference had to be re-established. Previous

studies have suggested that egocentric self-to-object spatial relations are updated continuously as people move through an environment (e.g., Sholl & Nolin, 1997; R. Wang, 1999). Our results indicate that maintaining an intrinsic frame of reference is not automatic. The difference might be due to the fact that an egocentric system is relatively easier to be maintained.

Furthermore, we found that given a relatively stable frame of reference, responses for salient objects were significantly faster than those for non-salient objects (Experiments 1 and 3). In addition, the salience effect was largely reduced when a fixed frame of reference was removed (Experiment 2), and re-appeared when a fixed frame of reference was provided (Experiment 3). This observation confirmed our hypothesis that updating of spatial relations can take place dynamically with different priorities when a relatively stable frame of reference is maintained.

Responses to both salient objects and non-salient objects manifested the same orientation dependence in all three experiments, similar to the orientation dependence found in the experiments where egocentric systems were used (e.g., Hinzman, et al.). This similarity might provide an interesting link between the egocentric systems and intrinsic systems. Either participants were imposing an egocentric frame of reference on an external object (e.g., imagine themselves on the orienting submarine), or, as suggested by McNamara (2003), people could in effect treat their bodies as just another object in the space.

Overall, the present study identified several properties of spatial updating in intrinsic frames of reference. In the real world situations, the surrounding environment is constantly changing and people have to adaptively and efficiently prioritize and organize necessary spatial information. Therefore, salient spatial entities, determined by both behavioral and perceptual significance, would receive higher priorities in processing and updating. Furthermore, the current study supports the general claim that multiple reference systems can co-exist in the brain and in the mind to represent space, with each supporting a different class of spatial tasks (H. Wang, Johnson, and Zhang, 2001). For example, while egocentric systems (body-centered) are more convenient for directly supporting motor actions, allocentric systems are more important for representing object-to-object relations in the environment. When a stable allocentric frame of reference is not available, the spatial information will have to be inferred from egocentric information.

Acknowledgements

This study was supported in part by the postdoctoral fellowship from the W. M. Keck Center for Computational and Structural Biology of the Gulf Coast Consortia for the first author and the Grant N00014-01-1-0074 from the Office of Naval Research Cognitive Science Program for the second author. Abstract

We hypothesize that statistically unsophisticated people perceive event likelihood with a coarser scale with a limited number of categories, before they report exact numerical probability values. Refinement of the scale beyond a certain level would therefore not improve overall judgmental accuracy and consistency but just impose a heavier burden on their limited computational capacity. An experiment of probabilistic judgment was conducted to test this hypothesis. Results from both behavioral data and event-related potentials in EEG recordings supported our hypothesis.

Introduction

Assessing the likelihood of uncertain events is an essential aspect of human reasoning and decision-making. In the absence of adequate formal models for computing the probabilities, people often rely on intuitions and heuristics to assess uncertainty. The question of how lay people and experts evaluate the probabilities of uncertain events has attracted enormous research interest. (For a historical review, see, e.g., Goldstein & Hogarth, 1996). Proponents of the "heuristics and biases" program argued that intuitive probabilistic judgment is often systematically biased and error-prone (Kahneman, Slovic, & Teversky, 1982). Various violations of normative models, including overconfidence, base-rate neglect, and the conjunction fallacy, have been attributed to applications of a small number of distinctive judgmental heuristics. However, others argued that the human mind has evolved to deal with the structure of the social and physical environment rather than to solve abstract probability problems (Chase, Hertwig, & Gigerenzer, 1998; Gigerenzer et al., 1999; Wang, Johnson, & Zhang, in press). When external information is presented effectively, people can be good intuitive statisticians (e.g., Cosmides & Tobby, 1996). For instance, Gigerenzer and colleagues found that when problems were stated in terms of frequencies instead of probabilities, the stable errors of judgments disappeared (Gigerenzer, 1991; Sedlmeier & Gigerenzer, 2001). For a recent collection of different perspectives on interpreting human intuitive probabilistic judgment, see Gilovich, Griffin, & Kahneman, 2002.

The theoretical claim that the human mind is not adapted to process probabilities has been a magnet for controversy (e.g., Gigerenzer, 1994; Gigerenzer & Hoffrage, 1995; Kahneman & Tversky, 1996). In spite of the centrality of the question, the internal representations and functional neural foundations underlying human probabilistic judgment are poorly understood. Until recently, most research has relied on observations and interpretations of behavioral experiments. In this paper we report a study that investigates the internal representations of human intuitive probabilistic assessment, from both behavioral and neurological perspectives.

Uncertainty Assessment by Approximation

A common scheme in psychological experiments of probabilistic judgment is to ask participants to report probabilities in numerical values, such as the chance of breast cancer in percentage given a positive test result (e.g., Sedlmeier & Gigerenzer, 2001). One question with this scheme, however, is that participants' response of numerical probability values may not genuinely reflect the true internal representation of their likelihood assessment. The following example illustrates this point. When asked to give a numerical estimate of the probability of a certain event provided with probabilities of other events, people often give incoherent answers (e.g., Osherson et al., 2001):

(a) Prob (Clinton is re-elected to the Senate in 2006) = .75
(b) Prob (Giuliani runs for the Senate in 2006) = .5

Participants' response:
(c) Prob (Clinton is re-elected to the Senate in 2006 and Giuliani runs for the Senate in 2006) = .1

Apparently, the numerical estimate of .1 is incoherent with the other two given probabilities, and the correct answer should be at least .25. However, it is possible that participants did not distinguish small increments on the continuous scale of probabilities. The estimate of .1 probably is only an approximation by the idea that the chance for Clinton may drop dramatically if Giuliani joins in the competition, rather than the result of exact

calculations. In other words, the incoherence is likely to be produced by the application of a coarser scale, rather than by some systematically biased heuristic.

We propose two hypotheses on the internal representations when people intuitively assess the event likelihood without exact calculations. First, the task of judgment of probabilities can be partitioned into two separate phases: the internal representation and the response (see Figure 1). The internal representation of event likelihood is the result of an approximate estimation of presented information (cues) on a coarser scale (internal scale). Only when subjects need to report probability values (e.g., in a typical psychological experiment), the internal scale is projected onto a finer continuous scale (response scale). Second, the internal scale has only a limited number of categories that represent different magnitudes of the perceived event likelihood. Together, these two hypotheses allow us to distinguish two fundamentally distinctive types of internal representations underlying human probabilistic judgment. We illustrate each of them in detail next.

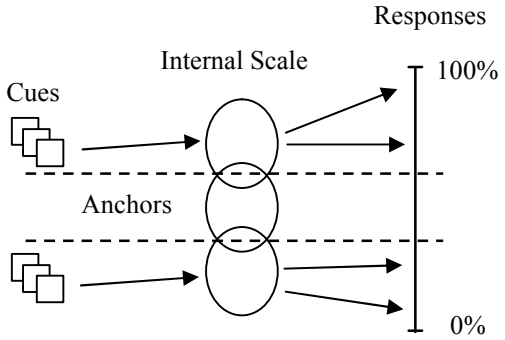

Figure 1. Internal representation on a coarser scale

Internalization by Anchoring and Adjustment

The hypothesis that people's perception of the event likelihood may not be infinitely refined is based on the notion that human beings have limited computational capacity. Miller (1956) suggested that the number of levels of any variable that can be internalized is not only finite but also small. Miller's finding has been widely cited in psychometric research on whether there is an optimal number of response alternatives in designing a scale. Many researchers believe that a further refinement of scales is meaningless if it is beyond human information processing capacity (for a review, see Cox, 1980).

In assessing the event likelihood, the number of categories on the internal scale is determined by the way these categories are formed. Previous studies show that people often use the "anchoring and adjustment" heuristic in judgments of belief and value (Tversky & Kahneman, 1974). Tversky and Kahneman presented anchoring as a process in which "people make estimates by starting from an initial value that is adjusted to yield a final answer" (1974, p. 1128). Chapman & Johnson (2002) provided a review on recent development in understanding the mechanisms of anchoring. One important implication of anchoring is that the number of categories on the internal scale is limited, rather than infinitely refined, since there are only a limited number of anchors that can be processed at the same time (see Figure 1). Note that it is not to suggest that people can not distinguish two very alike events with subtle difference. However, such distinction can only be achieved based on a side-by-side comparison, as one of the two events serves as an anchor.

The anchors can be directly provided by external cues, predefined action thresholds, or by knowledge retrieved from memory (for example, availability heuristic, Tversky & Kahneman, 1974). In the example of incoherent estimate mentioned before, the anchors would be likely provided by the probabilities stated in the first two statements, .75 and .5. Thus, there would be only three categories of likelihood divided by these two numbers, more likely than .75, less likely than .5, and a category in the between. When asked to report a numerical probability estimate to the third statement, the category of the lowest possibility was projected onto a continuous scale As a result, a small number such as .1 was likely to be generated. It is very conceivable, however, that in a different occasion the same person would give an answer of .2 instead of .1 to the same question without changing his or her perception of the event.

In everyday life situations, it is often the case that one of a few options is chosen based on predefined action thresholds rather than on exact probability values. It was found that physicians often significantly overestimated the probability of disease given a positive test result. In one study, 95 out of 100 physicians estimated the probability of breast cancer between 70% and 80% given a positive mammography while the correct answer is merely 7.8% (Eddy, 1982). Nevertheless, such large deviations do not necessarily mean that they are poor physicians. Probably to a physician, what matters most is a dichotomy whether a test result is positive. Consequently, a two-category internal representation (for example, "more likely" and "less likely") would be adopted until further diagnosis is conducted. When the physicians were asked to report an exact numerical value, they simply just obtained a number that would represent the category of the highest likelihood on the internal scale. Thus, a large number was likely to be reported.

Coarser Scales versus Finer Scales

The above argument actually suggests the need to partition the errors of intuitive probabilistic judgment. By distinguishing the internal representation from the numerical responses, we in effect partition the errors into two sources: systematic errors when the external information is internalized onto a coarser scale, such as overconfidence, availability bias, and conjunction fallacy (e.g., Kahneman, Slovic, & Teversky, 1982), and "random errors" when the internal representation are projected onto the continuous scale of numerical values. From Figure 1, it can be seen that a large portion of errors is elicited by the projection of a

coarser scale onto a continuous scale. Thus, a direct comparison between human perception of event likelihood and criteria derived from a normative model very likely has exaggerated the irrationality of human intuitive judgment. In the previous example of incoherent estimate, incoherence would be greatly reduced if a coarser scale is used to evaluate participants' responses.

We reason that in assessing uncertainty, people prefer a coarser scale (e.g., fewer categories) to a finer scale (e.g., more categories) as the internal representation, since the former may function effectively and demand less computational load in a variety of cognitive tasks. People assess the event likelihood only to the extent that it is adequate to reach a conclusion or choose an action. For example, when a person needs to decide whether or not to bring an umbrella to work based on the chance of rain, a chance of 70% and a chance of 80% probably would not make much difference in such a decision. Sometimes a finer judgment can be obtained but such refinement might have little effect to improve the choice. For example, Kareev and colleagues suggested that the limited capacity of working memory could actually help the early detection of covariation (Kareev, 1995; Kareev, Lieberman & Lev, 1997). In Sun & Tweney (2002), researchers found that participants chose their actions based on a heuristic of using small samples, and their performance in the task was very close to that obtained by the optimal strategy.

Our hypothesis that there exists a coarse representation of uncertainty for intuitive probabilistic judgment is consistent with the large body of literature on mental presentations of quantity and numbers. Dehaene and colleagues (Dehaene, 1997; Dehaene et al, 1998) have suggested that there is a coarse and analog mental number line, which is the foundation of a "number sense" and shared by humans and animals. Recent studies using brain-imaging techniques have provided further support for the existence of such coarse scale representations. It has been found that the approximation and exact calculation tasks of large numbers (as compared to rote arithmetic operations) put heavy emphasis on the left and right parietal cortices, which may encode numbers in a non-verbal quantity format (e.g., Dehaene et al., 1999; Pesenti et al., 2000; Stanescu-Cosson et al., 2000).

To test our hypotheses, we conducted an experiment in which participants performed a task of probability estimation. The task was to estimate the winning probabilities of poker hands in a standard "draw poker" game when presented with the highest two cards out of the five cards on a hand. The reason we selected this task is that it provides an objective criterion for evaluating participants' estimates. Most importantly, this task offers a distribution of probabilities ranging from zero to close to 100% with extremely small increments. This feature allows us to look into the refinement of the internal scale when people need to make estimates intuitively. We compared two conditions in the experiment. The coarser-scale condition required probability estimation within an increment of 30% (e.g., less than 30%, 30% ~ 60%, and greater than 60%). The finer-scale condition required probability estimation within an increment of 10%. Both behavioral data and the event related potentials (ERP) in EEG recordings were collected. The experiment results supported our hypotheses. First, estimates by the finer scale showed significantly worse performance in terms of overall accuracy and consistency. Second, significant ERP difference was found over the parietal area between two conditions, indicating that different levels of effort were involved in the application of different internal scales.

Method

Participants Six graduate students in the Houston medical center area participated in the experiment. All participants were right-handed males. The averaged age was 27 years old. None of the participants reported having any in-depth knowledge of probabilistic theories. All participants reported having some experience of playing poker games but only at a novice level.

Procedure The stimuli in the experiment (two-card poker hands) consisted of 18 levels of winning probabilities, ranging from 5% to 90% with a step of approximately 5% (as in a one-deck and two-person game). With suit variations, there were 36 different hands used in the experiment. (Note that in this experiment, the suit variation does not change the winning probability since the highest hand is a one-pair of aces.) Participants were introduced with the rules of hand ranking before the experiment (e.g., a pair is higher than single cards; the Ace is higher than the King, and etc.) without being informed of the corresponding probability values.

Figure 2 shows the procedure of the experiment. Stimuli were displayed on a 17-inch CRT monitor. To reduce eye movements, the viewing angle of the displays on the screen was limited to 2%. After the fixation display, two poker cards were presented. Participants were instructed to form an estimate of winning probability in their mind immediately. After the second fixation, a number was displayed and the participants needed to compare their estimate to the displayed number as quickly as possible. A Microsoft PC mouse was used to collect the responses (the left button for "less than," and the right button for "greater than").

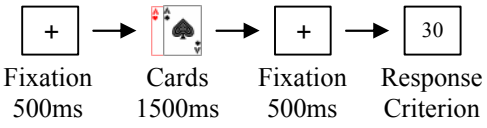

Figure 2. Experiment Procedure

There were two experimental conditions: the coarser-scale condition and the finer-scale condition. In the coarser-scale condition, participants were instructed to estimate probabilities in three categories (less than 30%, 30% ~ 60%, and more than 60%). The number displayed as the

comparison criterion is either 30 or 60, randomly selected. In the finer-scale condition, participants were instructed to form the estimate accurate to the single digit. The comparison criterion was either 5% plus or 5% minus (randomly selected) the true winning probability. For example, a pair of aces has a winning probability of 90%. Then, participants needed to compare their estimates with either 85% or 95%, depending on which number was displayed. Each participant completed both conditions. The order of two conditions was balanced among participants. Each condition consisted of 72 trials in 2 trial list cycles, and each of the 36 poker hands was displayed once in each cycle. The order of trials was randomly shuffled. Response time was recorded as the latency after the onset of comparison criterion. During the experiment, ERPs were sampled at 250 Hz with a 128-electrode geodesic sensor net (GSN) reference to the vertex (Tucker, 1993).

Results

Behavioral Results Table 1 shows the comparison between two experimental conditions on participants' probabilistic estimates in three categories, accuracy, consistency, and response time. Accuracy was calculated as the percentage when participants made the comparison correctly. For example, if the true winning probability was 70 percent, and the number displayed as the comparison criterion was 60, the correct response should be "greater than." (In case of identical numbers, either response was counted as correct.) All participants showed higher levels of accuracy in the coarser-scale than in the finer-scale condition. On average, the accuracy was 76.4% in the coarser-scale condition, and 56.0% in the finer-scale condition, with a difference of 20.4% ($t(5) = 4.576$, $p < 0.01$, two-tailed). Furthermore, we compared participants' accuracy in two trial list cycles in each condition and found little improvement in accuracy over the trials. The low accuracy level in the finer-scale condition was not significantly different from random guess (comparing to the expected value of 50%, $t(5) = 1.836$, $p = .12$, two-tailed), indicating that participants were not able to distinguish winning probabilities of poker hands in the increment of 10%.

To evaluate participants' judgmental consistency, we calculated Pearson correlations in their responses over two identical sets of stimuli (36 poker hands in each set) in each condition. All six participants in the coarser-scale condition and only one participant in the finer-scale condition showed correlations significantly different from zero ($n = 36$). The averaged correlation was .472 in the coarser-scale condition, and .076 in the finer-scale condition, with a difference of .396 ($t(5) = 7.906$, $p = .001$, two-tailed). This finding was consistent with the difference in accuracy between two conditions, supporting the speculation that participants were more likely to make a random guess in the finer-scale condition.

Table 2 Comparing Coarser-scale and Finer-scale

	Coarser-scale	Finer-scale	Difference
Accuracy	76.4% (8.61)	56.0% (8.05)	20.4%
Consistency	.472 (.060)	.076 (.094)	.396
RT	664.1ms (233.75)	798.4ms (298.93)	-123.2ms

N = 6. Standard deviations were listed in parentheses. All three comparisons were significant $p < .05$ (two-tailed).

The response time was also significantly different between two conditions. The averaged RT was 664.1ms in the coarser-scale condition and 798.4ms in the finer-scale condition, and the former was 123.2ms faster that the latter ($t(5) = -3.118$, $p < 0.05$, two-tailed). Since the response time was recorded as the latency after the onset of comparison numbers rather than the onset of poker cards, it is not clear whether probability estimation or number comparison, or both, produced the difference. Previous studies found that the time to make magnitude comparisons decreases linearly as the numerical distance between two numbers (e.g., Moyer & Landauer, 1967). Nevertheless, the large RT difference in our experiment indicated that the task of probability estimation and comparison as a whole might take more efforts in the finer-scale condition than in the coarser-scale condition.

ERP Results We rejected trials with voltages exceeding ± 100 μV. The remaining trials were segmented then averaged in synchrony with stimulus onset (display of poker cards) in a window of 1100ms (100ms before and 1000ms after stimulus onset), digitally transformed to an average reference, band-pass filtered (0.5 to 20 Hz), and corrected for baseline over 100ms before stimulus onset. Experimental conditions (Coarser vs. Finer) were compared on the 10 central-parietal electrodes by a repeated-measure ANOVA. We found significant ERP difference between two conditions at 400 ± 20ms (peak values) following stimulus onset (Greenhouse-Geisser $F(1,5) = 12.511$, $p <0.05$), where the finer-scale condition yielded more positive voltages over parietal electrodes. Figure 3 shows the wave forms of electrode CP1 (GSN 38) and the voltage difference map (finer-scale minus coarser scale) by spherical spline interpolation. The comparison between the left and right hemispheres over the parietal area was not significant (Greenhouse-Geisser $F(1,5) = 5.339$, $p = .127$). At the current stage of the study, we have not found significant voltage differences over other brain areas. Furthermore, examinations on latency did not reveal any significant differences between two experimental conditions.

Examination of the waveforms showed that the ERP difference occurred after the P300 component, when participants were viewing identical displays and had not yet received the comparison stimuli. The P300 and its sub-components p3a and p3b have been considered as a process that indexes the ensuing memory storage operations, as

P300 amplitudes were found related to memory of previous stimulus presentations (e.g., Fabiani, Karis, & Donchin, 1990; Johnson, 1995; Paller, McCarthy, & Wood, 1988; for a recent review, see Polich, 2003). Our results are also consistent with those of Dehaene and colleagues (Dehaene et al., 1999; Naccache & Dehaene, 2001), who showed that 200-400ms after the stimulus onset is critical to distinguish among different numerical operations with distinctive semantic implications. Based on this observation, we speculate that the difference in ERPs in our experiment probably was due to different working memory load. Specifically, when judging the winning chance of a certain poker hand, other poker hands (either from previous trials or by temporary construction) were used as anchors to build categories on the internal representation. Fewer anchors were needed in the coarser-scale condition. On the contrary, the finer-scale condition demanded more effort because more hands needed to be considered at the same time. This speculation is consistent with the participants' oral report after the experiment. For example, one participant reported that he had to think of more hands with "nearby" rankings in the finer-scale condition.

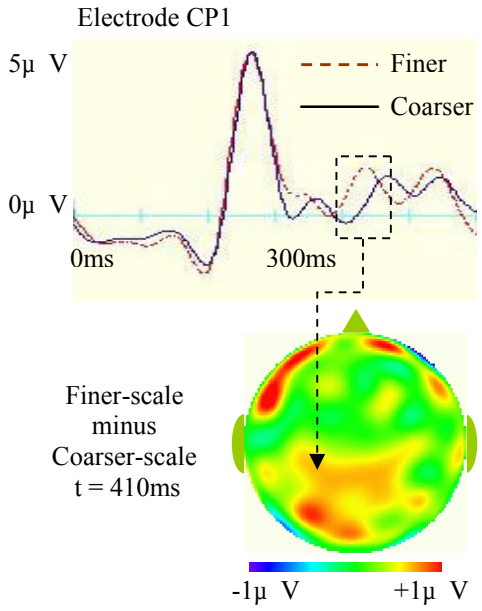

Figure 3

General Discussion

In sum, the findings in our experiment were consistent with our hypotheses of the internal representation of a coarser scale in intuitive judgment of event likelihood. The analyses of behavioral data suggested that if participants were only able to distinguish event likelihood with a coarser scale, a large portion of errors would be produced when they were forced to estimate probabilities with a finer scale. This kind of errors was manifested in both judgmental accuracy and consistency. The low accuracy level (close to random guess) and the low consistency level (close to zero) in the finer-scale condition indicated that participants were not able to distinguish winning probabilities of poker hands in the increment of 10%. Therefore, if the internal scale indeed had a limited number of categories, most likely this number was not greater than 10. It is interesting to point out that in our experiment, there were 36 different hands at 18 equally distributed levels of winning probabilities. If these hands were presented *externally* at the same time in the order of their rankings, it is reasonable to assume that any participant can report probability values accurate to the 5% increment by anchoring and adjustment. Nevertheless, their poor performance in the finer-scale condition indicated that the number of anchors that can be processed *internally* was quite limited. Furthermore, the ERP difference occurred when participants were viewing identical displays, indicating that participants followed the experimental instruction in forming their estimates at different levels of refinement. And estimating by a finer scale appeared to require more computational effort.

Note that the present study is still at its preliminary stage and there are many questions left to be answered. For example, more replications are needed and the ERP analyses can be extended such as comparisons over other brain areas and source localization. It would also be interesting to test someone who is an expert at poker and to see whether the performance would be better, especially in the finer-scale condition. Another example is that the model of a coarser internal scale can be further examined by manipulating the external representations, as previous studies indicated the important roles of the interaction between internal and external representations in human numerical cognition (e.g., Zhang & Norman, 1995; Zhang & Wang, in press). Upon further experiments and analyses, we believe that the present study will provide a better understanding of human intuitive probabilistic judgment.

Abstract

This work explores the importance of similarity-based processes in human everyday reasoning, beyond purely rule-based processes prevalent in AI and cognitive science. A unified framework encompassing both rule-based and similarity-based reasoning may provide explanations for a variety of human reasoning data.

The paper implements this analysis in a cognitive architecture CLARION, which has previously succeeded in capturing a variety of human learning data in simulations. The exploration of similarity-based reasoning in this architecture leads to a more complete and more comprehensive framework of human reasoning and learning. The simulation within this architecture accurately captures human reasoning data, including numerical measures and verbal protocols. This work demonstrates the significant role played by similarity-based reasoning. Furthermore, it demonstrates how such a reasoning process falls out of the existing structure in the cognitive architecture CLARION.

Introduction

What is human everyday reasoning like? Is it suitably captured by formal models developed by logicians and AI researchers? Or is it different? What are its similarities and differences to these models? After all, computationally speaking, what are the essential patterns in such reasoning?

In this paper, we will attempt to describe some data of human everyday (i.e., mundane or "commonsense") reasoning in computational terms. We will instantiate our analysis in the form of a computational model implemented in a generic cognitive architecture — CLARION (Sun 2002).

A little background is in order here. Sun (1991) proposed a theory of human everyday reasoning based on a combination of rule-based reasoning and similarity-based reasoning, implemented with a mixture of localist and distributed connectionist models. This theory was further developed and elaborated in Sun (1995). The basic tenet of this theory is that, to a significant extent, human everyday reasoning may be described by a combination of rule-based and similarity-based reasoning. Human everyday reasoning may be reduced to these two types of processes. The intermixing of rule-based and similarity-based reasoning can lead to complex patterns of inferences as commonly observed in human everyday reasoning. And these two types of processes may be captured within a unified connectionist model; that is, they fall out of the very same model (albeit with a combination of localist and distributed representations).

The theory was backed up by psychological evidence in the form of verbal protocols as in Collins (1978) and Collins and Michalski (1989). In Sun (1995), these protocols were analyzed based on two mechanisms: rules and similarity (Tversky 1977, Hahn and Chater 1998). The analysis showed that vast majority of the protocol data might be easily captured by the intermixing of these two mechanisms. This theory was crystallized into a two-component model whereby rule-based reasoning was carried out in one component with localist representation, and similarity-based reasoning in another with distributed representation (Sun 1995). Relevant to this approach, Sloman (1993) published a set of experiments, which provided support to the hypothesis of Sun (1991) (see also Sun 1995). He found that similarity played a significant role in determining outcomes of inductive reasoning and similarity might be characterized by feature overlapping (as in Sun 1991). Five years later, Sloman (1998) described further experiments that again supported the hypothesis that there were two parallel mechanisms at work in human everyday reasoning (Sun 1991).

In the remainder of this paper, we first describe the three pertinent experiments of Sloman (1998), which were consistent with the theory advanced in Sun (1991) and Sun (1995). We then describe the generic cognitive architecture, CLARION, used in capturing human everyday reasoning. Next, the particular setup of the architecture for capturing this set of human experiments is described. We then describe the results from simulating the experiments of Sloman (1998) using CLARION. Finally, some general discussion completes the paper.

The Categorical Inference Task

Let us examine some human reasoning data that illustrates combinations of similarity-based and rule-based reasoning (SBR and RBR, respectively). We will look into the data from experiments 1, 2, 4, and 5 of Sloman (1998), which are most relevant to this issue.

Among them, according to our interpretation, although experiment 1 used forced choice while experiment 2 used rating of argument strength, both involved SBR to a very significant extent. Experiment 4 involved explicit use of categorical relations, and thus mainly RBR. Experiment 5 involved more of SBR, as well as RBR.

Specifically, in experiment 1, subjects were given pairs of arguments, either in the form of *premise specificity*:

a. All flowers are susceptible to thrips. $\Longrightarrow$ All roses are susceptible to thrips.

b. All plants are susceptible to thrips. $\Longrightarrow$ All roses are susceptible to thrips.

or in the form of *inclusion similarity*:

a. All plants contain bryophytes. $\Longrightarrow$ All flowers contain bryophytes.

b. All plants contain bryophytes. $\Longrightarrow$ All mosses contain bryophytes.

Subjects were to pick the stronger of the two arguments from each pair. 73 subjects were tested and each was given 18 pairs of arguments (among other things not related to this task).

The results showed that the more similar argument from each pair of arguments was chosen 82% of times (for inclusion similarity) and 91% of times (for premise specificity). t tests showed that these percentages were significantly above chance, either by subjects ($t(72) = 18.64$ and $t(72) = 33.09$ for premise specificity and inclusion similarity, respectively; $p < 0.0001$) or by argument pairs ($t(8) = 6.97$ and $t(8) = 15.61$ respectively; $p < 0.0001$). We note that, if only RBR had been used, then similarity should not have made a difference, because the conclusion category was contained in the premise category and thus both arguments in each pair should have been equally, perfectly strong. Therefore, the data suggest that SBR was involved to a significant extent.

In experiment 2, subjects were instead asked to rate the likelihood ("conditional probability") of each argument. Ratings could range from 0 to 1. 18 subjects were tested.

The mean rating was 0.89 for inclusion similarity and 0.86 for premise specificity. Both were significantly below 1, both by subjects ($t(17) = 2.75$ and $t(17) = 3.23$ respectively; $p < 0.01$), and by arguments ($t(17) = 8.87$ and $t(17) = 6.14$ respectively; $p < 0.0001$). Again we note that it would have been the case that the outcome was 1 if only RBR had been used (because the conclusion category was contained in the premise category). Thus, SBR was significantly present here too. Indeed, ANOVA showed that across subjects, there was a significant main effect of similarity (low vs. high; $F(1, 17) = 18.90, p < 0.001$). So was the case across argument pairs ($F(1, 16) = 12.64, p < 0.001$).

In experiment 4, subjects were asked to rate the likelihood of each argument. Ratings could range from 0 to 1. However, in this case, each category inclusion relation was specifically presented as part of each argument. For example,

All plants contain bryophytes. All mosses are plants. $\Longrightarrow$ All mosses contain bryophytes.

The results showed that the mean judgment was 0.99. 23 out of 27 subjects gave all 1's. 32 out of 36 arguments received judgments of all 1's (excluding one individual who gave 0.99 throughout). In other words, the similarity-based phenomena almost disappeared. Instead, an explicit RBR mode based on category inclusion relations was used.

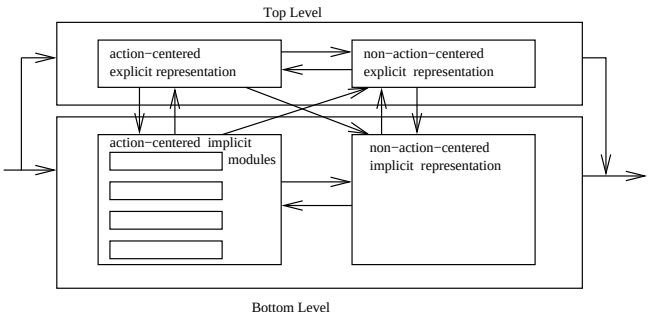

Figure 1: The CLARION architecture.

Experiment 5 was similar to experiment 2, in that ratings were obtained. However, before any ratings were done, subjects were asked to make category inclusion decisions. Thus, in this case, subjects were reminded of rule-based reasoning explicitly involving category inclusion relations. Therefore, they were more likely to use RBR, although probably not as much as in experiment 4, due to the separation of category inclusion judgment and argument likelihood rating in the experiment procedure (unlike that of experiment 4).

The results showed that no one of the 18 subjects gave a likelihood judgment of 1 for every argument, indicating SBR was probably at work. Compared with experiment 2, having subjects make category inclusion judgments increased the likelihood ratings. The mean judgment for experiment 5 was 0.92 as opposed to 0.87 for experiment 2. [1] This increase might reflect the increased involvement of RBR. Nevertheless, ANOVA showed a significant effect of similarity (low vs. high), across subjects ($F(1, 17) = 9.33, p < 0.01$), and across argument pairs ($F(1, 16) = 11.42, p < 0.01$).

Below, we will utilize this task of categorical inference for the further testing of cognitive architecture CLARION. The simulation shows indications of the significance of similarity-based reasoning (as opposed to probabilistic or Bayesian reasoning; cf. Anderson and Lebiere 1998).

The CLARION Model

CLARION is an integrative model with a dual representational structure (Sun et al 2001, Sun 2002). It consists of two levels: the top level captures *explicit* processes and the bottom level captures *implicit* processes. See Figure 1.

First, the inaccessible nature of implicit knowledge is suitably captured by subsymbolic distributed representations provided by a backpropagation network. This is because representational units in a distributed representation are capable of accomplishing tasks but are

[1] However, the difference was not statistically significant by subjects, although significant by arguments ($t(35) = 3.81, p < 0.0001$).

subsymbolic and generally not individually meaningful (see Smolensky 1988, Sun 1995). This characteristic of distributed representation accords well with the (direct) inaccessibility of implicit knowledge.

In contrast, explicit knowledge may be captured in computational modeling by a symbolic or localist representation (Clark and Karmiloff-Smith 1993), in which each unit is more easily interpretable and has a clearer conceptual meaning. This characteristic captures the property of explicit knowledge being (directly) more accessible and more manipulable (Smolensky 1988, Sun 1995).

This radical difference in the representations of the two types of knowledge leads to a two-level model whereby each level using one kind of representation captures one corresponding type of process, either implicit or explicit. The model may select to use one level or the other, based on current circumstances (e.g., experimental conditions; see Sun 2002 for details). When both levels are used, the outcome from the two levels may be combined in some ways, which may be partially domain specific (Sun 2002).

At each level of the model, there may be multiple modules, both *action-centered* modules and *non-action-centered* modules (Schacter 1990, Moscovitch and Umilta 1991). The reason for having both action-centered and non-action-centered modules (at each level) is because, as it should be obvious, action-centered knowledge (roughly, procedural knowledge) is not necessarily inaccessible (directly), and non-action-centered knowledge (roughly, declarative knowledge) is not necessarily accessible (directly). Although it was argued by some that all procedural knowledge is inaccessible directly and all declarative knowledge is directly accessible, such a clean mapping of the two dichotomies is untenable in our view. We will refer to these two sets of modules as the *action-centered subsystem* (the ACS) and the *non-action-centered subsystem* (the NACS), respectively. There are also other components, such as working memory, episodic memory, etc., which are not important to this work.

In this work, we will focus on the NACS, due to the declarative nature of the task. This subsystem, as stated earlier, consists of (1) a top level (known as the GKS, or the general knowledge store), which is made up of a set of chunks and a set of explicit associative rules linking chunks, and (2) a bottom level (known as the AMNs, or the associative memory networks), which is made up of implicit associative memories (Sun 2002).

At the top level of the NACS, the essential elements are *chunks*, each of which is specified by a set of dimension-value pairs (i.e., attribute-value pairs) that describes an entity (or an object), along with a chunk label. Each chunk is represented by a chunk node, which is linked to the nodes at the bottom level (the AMNs) representing the individual dimension-value pairs involved.

The support for the conclusion of an associative rule, which is a chunk, is calculated as follows (Sun 1994):

$$S_j^a = \sum_i S_i^c * W_i^a \qquad (1)$$

where j indicates the jth rule at the top level, S_j^a is the support for associative rule j, S_i^c is the strength of the ith chunk in the condition of the rule, i ranges over all the chunks in the condition of rule j, W_i^a is the weight of the ith chunk in the condition of rule j (which, by default, is $W_i^a = 1/n$, where n is the number of chunks in the condition of the rule).

The conclusion chunk has a strength level that is determined by the maximum of all the support from all the relevant rules:

$$S_{c_k}^c = \max_{j:\text{all associative rules leading to } c_k} S_j^a \qquad (2)$$

where $S_{c_k}^c$ is the strength of chunk c_k (resulting from associative rules), and j ranges over all the associative rules pointing to c_k.

In addition, similarity-based reasoning falls out of knowledge encoding with chunks (i.e., with sets of dimension-value pairs). A known (given or inferred) chunk is automatically compared with another chunk. If their similarity is high enough, then the other chunk is inferred. The strength of a chunk c_i as the result of similarity-based reasoning is:

$$S_{c_i}^c = \max_j (S_{c_j \sim c_i} \times S_{c_j}^c)$$

where $S_{c_j \sim c_i}$ measures the similarity from c_j to c_i (Tversky 1977), $S_{c_j \sim c_i} \times S_{c_j}^c$ measures the support to c_i from the similarity, and j ranges over all the chunks.

The default similarity measure (Sun 1995, Tversky 1977) is:

$$S_{c_1 \sim c_2} = \frac{N_{c_1 \cap c_2}}{f(N_{c_2})}$$

where $S_{c_1 \sim c_2}$ denotes the similarity from c_1 to c_2. $N_{c_1 \cap c_2}$ is the weighted sum of the identically valued dimensions in c_1 and c_2 (among all the specified dimensions of c_2 — the dimensions that have specified values). That is, $N_{c_1 \cap c_2} = \sum_{i \in c_2 \cap c_1} W_i^{c_2} \times A_i$, where A_i is the strength of the value of dimension i in chunk c_1, which is normally 1 (representing full strengths). The weights ($W_i^{c_2}$) in the weighted sum are specified with respect to c_2 (the target of similarity, not the source of it). Normally, these weights are the same and equal to 1. N_{c_2} is the weighted sum of the specified dimensions (the dimensions that have specified values) of c_2. That is, $N_{c_2} = \sum_{i \in c_2} W_i^{c_2} \times A_i$, where normally $A_i = 1$ and $W_i^{c_2} = 1$. f is a super-linear, but close to linear, function (such as $f(x) = x^{1.0001}$ as in our simulation of this task). [2] For further details, see Sun (1995).

Similarity is automatically computed whenever reasoning involves multiple chunks that are similar to one another. Therefore, there is no dedicated representation of similarity between any two chunks.

Similarity-based and rule-based reasoning can be inter-mixed. When both SBR and RBR are employed, we have:

$$S_{c_i}^c = \max(c_{14} \times \max_{j:\text{all rules leading to } c_i} S_j^a,$$

[2] Similarity is thus limited to $[0, 1)$.

$$c_{15} \times \max_{j:\text{all chunks similar to } c_i} (S_{c_j \sim c_i} \times S^c_{c_j}))$$

where c_{14} and c_{15} are two constants that balance the two measures (rule versus similarity), and $S_{c_j \sim c_i}$ is the similarity measure.

As a result of mixing SBR and RBR, complex patterns of reasoning can emerge. As explicated in Sun (1995), the conclusion from one step of reasoning can be used as the starting point of the next step. The iterative process of combined rule-based and similarity-based reasoning allows all possible conclusions to be reached (including "inheritance" reasoning; Sun 1995). These different sequences together capture essential patterns of human everyday reasoning (see Sun 1995 for details).

Note that all of the operations of the non-action-centered subsystem are under the control of the action-centered subsystem, which makes action decisions each step of the way. To do so, the top level of the ACS consists of a set of explicit action rules, either externally given or extracted from the bottom level (from implicit knowledge), while the bottom level consists of implicit decision networks (trained with reinforcement learning algorithms, negligible in this task). For details regarding the ACS and its parameters, see Sun et al (2001) and Sun (2002). We will not get into these details here, as they are not directly relevant to this work.

It is worth noting that CLARION has been successful in simulating a variety of cognitive tasks. These tasks include serial reaction time tasks, artificial grammar learning tasks, process control tasks, alphabetical arithmetic tasks, and the Tower of Hanoi task (Sun 2002, Sun and Zhang 2004). In addition, we have done extensive work on a complex minefield navigation task (Sun et al 2001, Sun and Peterson 1998). We are now in a good position to extend the effort to the capturing of a wide range of human reasoning and memory processes, through simulating reasoning and memory task data. This paper is but one aspect of this effort.

Simulation Setup

At the top level of the NACS (i.e., the GKS), all relevant category inclusion relations, such as "flowers are plants" or "mosses are plants", were encoded as associative rules. Chunk nodes in the GKS were used to represent the concepts involved, such as "flowers" and "plants". The dimensional values of these chunks were represented as separate nodes in the AMNs, and thus the chunk nodes were linked to the AMNs.

For simulating various experimental settings, the following manipulations were used: For simulating settings where SBR was dominant, RBR was de-emphasized. For simulating settings where RBR was dominant, RBR was emphasized. The relative emphasis of the two methods was accomplished through the *balancing* parameters. We set $c_{14} = 0.5$ and $c_{15} = 1.0$ for experiments 1 and 2, because of the heavy reliance on SBR as opposed to RBR as suggested by the analysis of the human data (see the earlier discussion of the human data). For simulating experiment 4, they were set at $c_{14} = 1.0, c_{15} = 1.0$, because this setting prompted more reliance on RBR as indicated by the human data. For simulating experiment 5, they were set at $c_{14} = 0.88, c_{15} = 1.0$, because the experiment involved an intermediate level of reliance on RBR as suggested by the human data. In all, these values were set in accordance with our interpretations of what happened under these different experimental conditions respectively.

At the bottom level of the NACS (the AMNs), although the associative memories were present, they were not very relevant for the performance of this task, because there was no sufficient prior training of the network with any data directly relevant to this task. [3]

Training of the model, before the simulation of the experimental test, consisted of presenting categorical features (dimension-value pairs) along with the category labels, to both levels of the NACS. The features (dimension-value pairs) captured similarities between entities. That is, if A was more similar to C than B was, then A would have more features in common with C than B would. And so on. Note that repeated presentations were not required. The one-pass presentation enabled the formation of chunks and associative rules in the GKS, but not much implicit knowledge in the AMNs. With a proper process of chunk encoding and associative rule encoding as in CLARION, one-pass presentation was sufficient for the GKS.

During test, when a category name was given, the category name was matched with a corresponding chunk label. The matching chunk was activated to the full extent (i.e., 1). Then, through associative rules as well as through similarity-based processes, conclusion chunks were also activated (to varying extents). Conclusion chunks were retrieved along with their strengths, combining SBR and RBR according to the balancing parameters.

For simulating ratings of conclusions (as in experiments 2, 4, and 5), the strengths of chunks derived from a proper combination of the results of SBR and RBR (as determined by the balancing parameters) were directly used. However, for simulating forced choices (as in experiment 1), a stochastic decision process based on the Boltzmann distribution was used to select between two possible outcomes.

Simulation Results

We simulated the data from experiments 1, 2, 4, and 5 of Sloman (1998) as described earlier. For each experiment, a set of simulation runs (i.e., simulated "subjects") equal to the number of the human subjects involved were used. The results and the statistical analysis of the results were as follows.

As described before, in experiment 1, subjects were to pick the stronger of the two arguments from each pair. The simulation of experiment 1 showed, the same as the human data, that the more similar argument from each

[3] For the associative memory network, the number of input units was 1800 (for representing all chunks specifiable with 60 dimensions of 30 possible values each), the number of hidden units was 500, and the number of output units was 1800. The learning rate was 0.2 and the momentum was 0.1.

pair of arguments was chosen more often: 82% of times (for inclusion similarity) and 83% of times (for premise specificity). t tests showed that these percentages were significantly above chance, either by subjects ($p < 0.001$) or by argument pairs ($p < 0.001$), the same as in the human data. In our simulation setup, there was a significant involvement of SBR (with $c_{14} = 0.5, c_{15} = 1.0$). If only RBR had been used, then similarity could not have made a difference, and thus both arguments in a pair should have been equally strong. This simulation demonstrated that the conjecture of the involvement of SBR in producing the human data in this experiment was a reasonable interpretation (see the earlier exposition of the human experiments), given the close match with the human data.

In experiment 2, subjects were instead asked to rate the likelihood of each argument. In this simulation, the mean rating was 0.86 for inclusion similarity and 0.87 for premise specificity. Both were significantly below 1, different from what would have been predicted if only RBR had been used, both by subjects ($p < 0.001$) and by arguments ($p < 0.001$), the same as in the human data. ANOVA also showed that across subjects and across argument pairs, there was a significant main effect of similarity (low vs. high; $p < 0.001$). With the same setup as the previous simulation, this simulation again demonstrated the same pattern of significant involvement of SBR in the human performance.

In experiment 4, subjects were asked to rate the likelihood of each argument, right after being presented relevant category inclusion relations. The simulation produced the mean judgment 0.99, exactly the same as the human data. Compared with experiment 2, explicit RBR based on category inclusion was much more prominent in this case, as specified in our simulation setup ($c_{14} = 1.0, c_{15} = 1.0$), which captured the human data accurately.

In experiment 5, ratings were obtained after subjects were asked to make category inclusion decisions. In this case, subjects were reminded of RBR involving category inclusion relations and therefore they were more likely to use RBR (compared with experiment 2), although not exclusively (unlike experiment 4). In the simulation, the mean judgment for experiment 5 was 0.91 for both inclusion similarity and premise specificity, as opposed to 0.86 and 0.87 for the two cases in experiment 2. ANOVA also showed a significant main effect of similarity (low vs. high), across subjects ($p < 0.001$), and across argument pairs ($p < 0.001$). This simulation replicated the human data well, which showed that our interpretation as embodied in the simulation setup ($c_{14} = 0.88, c_{15} = 1.0$), that is, less involvement of RBR compared with experiment 4 but more compared with experiment 2, was a reasonable one.

In all, simulation of this task successfully validated the interpretation and the analysis of human performance in this task and, to some extent, our framework in general.

Concluding Remarks

Overall, the simulation accurately captured the human reasoning data from Sloman (1998). The simulation was conducted based on our framework of mixed rule-based reasoning and similarity-based reasoning, which, along with other simulations published elsewhere (e.g., Sun 1995, 2002, Sun et al 2001, Sun and Zhang 2004), showed the cognitive plausibility of the CLARION architecture to some extent.

This simulation demonstrates the importance of similarity-based reasoning in human everyday reasoning. This similarity-based process is quite distinct from probabilistic reasoning as implemented in other existing cognitive architectures, such as ACT-R (see Anderson 1993 or Anderson and Lebiere 1998). Let us compare the two different approaches. ACT-R as described in Anderson and Lebiere (1998) tries to capture all inferences in a probabilistic framework. In so doing, it lumps together all forms of weak inferential connections in a unified way. Although this approach leads to uniformity, it has shortcomings as well. All similarity relations between any pair of any two objects must be explicitly represented with all the associated parameters, which specify probabilistic computation used to capture similarity-based reasoning (along with other inexact inferences). The problem is the complexity of representing all similarity pairings. This complexity is very high in ACT-R but in contrast is avoided in CLARION.

The limitations of probabilistic reasoning (Pearl 1988) in general include its neglect of many heuristics, simplifications, and rules of thumb (Tversky and Kahneman 1983, Sun 1995, Yang and Johnson-Laird 2001) useful in reducing the computational complexity of formal mathematical models. As a result, it suffers from higher computational complexity (Sun 1995).

We should also look into the framework of Collins and Michalski (1989), which apparently incorporated "similarity-based" reasoning through explicitly representing similarity in a complex logical formalism. Similarity was explicitly represented as a logical operator: That is, for almost any pair of any two objects, there would be a logical relation explicitly represented, denoting their similarity. Inferences could be performed on the basis of similarity operators, using a search process. The complexity of this representational framework was extremely high.

In general, logic-based models suffer from a number of well known shortcomings, including their restrictiveness concerning pre-conditions, consistency, and correctness, and their inability in dealing with inexactness (see, e.g., Israel 1987, Sun 1995). Their restrictiveness renders such models costly, difficult to specify, and difficult to use.

In a different vein, psychological work on reasoning is relevant also. Such work mostly centers around either mental logic (Rips 1994, Braine and O'Brien 1998) or mental models (Yang and Johnson-Laird 2001). Neither approach deals with similarity-based reasoning as captured in CLARION. Their focuses are elsewhere.

In sum, this line of work, combining similarity-based reasoning and rule-based reasoning (Sun 1995, Sloman

1998, Hahn and Chater 1998), offers a new approach for capturing some essential patterns of human everyday reasoning (albeit not all patterns of human reasoning). It complements logic-based "commonsense" reasoning models prevalent in AI, which is very much centered on logic and thus limited by logic. This work also points to new avenues of cognitive modeling, beyond the current psychology of reasoning (which largely focuses on various logics and mental models) and beyond existing cognitive architectures (Anderson and Lebiere 1998). In addition, this approach may well be extended to case-based and/or analogical reasoning (e.g., Sun 1995a).

Abstract

Perceptual processing of emotional facial expressions occurs very quickly, even without awareness. To determine whether the fast processing of facial expressions is categorical, we studied temporal characteristics of categorical perception (CP) of facial expressions. We investigated the effect of shortening stimulus duration on participant performance with respect to identifying and discriminating morphed facial expressions. The results of two experiments showed that CP was attenuated or even disappeared when facial stimuli were presented for as briefly as 50-75 milliseconds. These findings indicate that CP is irrelevant to the fast perceptual processing of facial expressions.

Facial expressions of emotion are processed very quickly, even without awareness (Morris, Ohman, & Dolan, 1998; Whalen et al., 1998). It has been proposed that this fast emotional processing provides a 'dirty' image of the external world, enabling organisms to detect salient stimuli immediately (Adolphs, 2002; LeDoux, 1996). What is still not understood, however, is how this fast and dirty processing of facial expressions works.

A hallmark of facial expression recognition is its categorical nature, that is, facial expressions are recognized as belonging to discrete categories of emotion, so-called *basic emotions* (e.g., Ekman, 1992; Izard, 1992). Reports on categorical perception (CP) of facial expressions are thought to provide strong evidence that people process facial expressions categorically (Calder et al., 1996; DeGelder, Teunisse, & Benson, 1997; Etcoff & Magee, 1992; Young et al., 1997). Previous studies have confirmed that recognizing facial expressions fulfills the following features of CP: (a) in identifying a stimulus within a continuum extending from one category to another, the rate of categorizing the stimulus changes abruptly at a boundary (category boundary); and (b) in discriminating a pair of stimuli that differ by a constant physical amount, discrimination is superior for pairs straddling the category boundary (between-category pairs), as compared to pairs falling within one category (within-category pairs). It has been argued that the perceptual system transforms the information continuously received from a given facial expression into categorical information corresponding to the most likely emotion (Etcoff & Magee, 1992).

In previous research, however, facial stimuli were presented for a relatively long period ($\geqq$750 ms), so it remains unclear whether the fast perceptual processing of facial expressions is categorical in nature. Our goal was to investigate the effects of shortening stimulus duration on CP of facial expressions and to examine whether the fast perceptual processing is categorical.

Experiment 1

In Experiment 1, participants identified facial expressions from three continua extending from anger to happiness, from happiness to fear, and from fear to anger. We investigated how shortening stimulus exposure duration (750 ms, 150 ms, 50 ms) affected the abrupt change in the rate of identification at the category boundary.

Method

Participants Twelve undergraduates and postgraduates participated (8 men, 4 women; 20-24 years old).

Facial Stimuli Three sets of eight gray-scale images of facial expressions were used. Each set consisted of a continuum extending either from anger to happiness, from happiness to fear, or from fear to anger. The original (endpoint) facial expressions were posed photographs of a Japanese woman, and interpolated (morphed) expressions between the two continuum endpoints were created with software for facial expression processing (Information-technology Promotion Agency, Japan (IPA), 1998).

The morph transformation started with the delineation of two endpoint expressions; landmarks were placed manually on critical positions of each image. There were 759 landmarks in total, 88 points of which were placed manually on corresponding positions of each image: for the head, 4 points; for the outline, 28 points; for the eyes, 5 x 2 points; for the eyebrows, 4 x 2 points; for the nose, 4 points; for the

mouth, 6 points; for the neck, 13 points; and finally for the hairline, 15 points. An intermediate face was then created with linear interpolation between point-to-point pixel intensity values, yielding a weighted blend of both facial configuration and texture of the two endpoint faces. Six intermediate faces were generated for each continuum, so that eight images from one endpoint to the other were spaced with a 14.3% gap.

Procedure and Design Participants performed the identification task (three sessions) by viewing stimuli presented on a 17-inch CRT monitor. Each trial began with an 800-ms presentation of a fixation point, followed by a blank interval of 300 ms, and then a facial stimulus from one continuum for 750 ms, 150 ms, or 50 ms. After a 300-ms blank interval, participants were asked to decide which endpoint category the face expressed. The continuum was manipulated across sessions: from anger to happiness (AH session), from happiness to fear (HF session), and from fear to anger (FA session). The order of the three sessions was counterbalanced across participants. Each session began with 24 training trials, followed by five blocks of 48 experimental trials, corresponding to two repetitions of the 24 combinations of faces (8) and stimulus durations (3). The order of the face-duration sets was fully randomized in each repetition.

Results & Discussion

Figure 1 displays the overall percentage with which a given endpoint expression was identified at each stimulus duration, for each continuum. As an estimate of the category boundary, the point at which two endpoints were identified with equal probability was computed by applying a logit model to each identification rate curve (Table 1). In general, the category boundary lay near the 50% morph. More importantly, Table 1 also indicates the slope of the logistic curve at the category boundary as a measure of the identification rate change at the boundary. Multiple comparisons (z tests) with Bonferroni's method (α=0.017) revealed that the slope at 50 ms was significantly, or marginally significantly, smaller than at 150 ms and at 750 ms for the anger-happiness and happiness-fear continua (AH session, 50 ms vs. 150 ms, z=2.37, p=0.018, 50 ms vs. 750 ms, z=3.67, p<0.001, 150 ms vs. 750 ms, z=1.48, p=0.139; HF session, 50 ms vs. 150 ms, z=2.69, p=0.007, 50 ms vs. 750 ms, z=4.07, p<0.001, 150 ms vs. 750 ms, z=1.74, p=0.082). No slope change was observed for the fear-anger continuum (all ps>0.35).

The decreased slopes of the identification rate curves for the anger-happiness and happiness-fear continua at 50 ms indicate that the CP of facial expressions is attenuated with the briefest stimulus exposure duration. The lack of slope change for the fear-anger continuum may be due to the originally weak categorical perception between fear and anger, which reflects their remarkable similarity with respect to the dimensional information of pleasure and arousal (Russell, 1997). Indeed, the slope for the fear-anger continuum was the smallest of the three continua at 750 ms. Likewise, there are previous reports that have failed to detect clear CP for the fear-anger continuum (Calder et al., 1996; DeGelder et al., 1997).

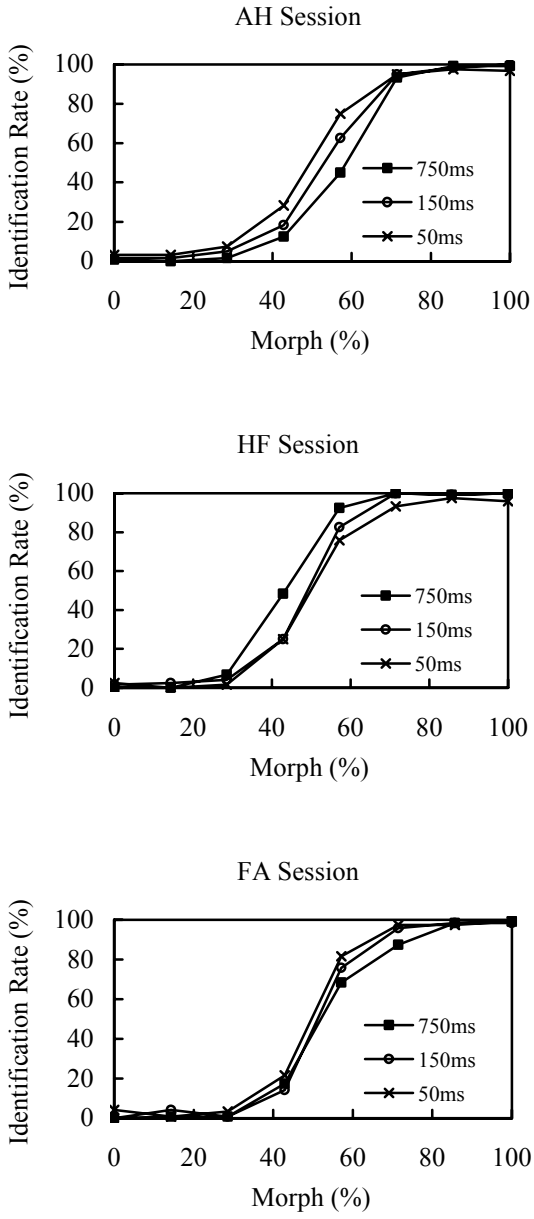

Figure 1: Overall percentage with which a given endpoint expression (top: happiness, middle: fear, bottom: anger) was identified at each stimulus duration, for each session. *Morph* represents a percentage of happiness (top), fear (middle), or anger (bottom) for a given face.

Table 1: Estimates of the position of the category boundary and the slope at the boundary.

Session	Duration	Boundary (%)	Slope
AH	750 ms	56.9	14.5
	150 ms	52.5	12.5
	50 ms	49.0	10.0
HF	750 ms	43.3	18.1
	150 ms	47.9	14.9
	50 ms	51.2	11.3
FA	750 ms	53.9	13.3
	150 ms	51.8	13.8
	50 ms	49.2	12.6

Note *Boundary* represents a percentage of happiness (AH Session), fear (HF Session), or anger (FA Session) for a morphed face.

Experiment 2

Experiment 1 revealed that the abrupt change in identification rate at the category boundary was attenuated at the briefest stimulus exposure duration, indicating that CP of facial expressions did not reflect fast perceptual processing. To further examine temporal characteristics of CP, Experiment 2 investigated whether superior discrimination for between-category pairs could be observed with the brief stimulus exposure duration when compared to discrimination for within-category pairs. Because a more accurate discrimination performance for between-category pairs is regarded as the key indicator of CP (Harnad, 1987), its disappearance at the brief stimulus duration provides crucial evidence that categorical perception does not occur rapidly. In Experiment 2, participants engaged in both discrimination and identification tasks of facial expressions from the happiness-fear continuum. We selected the happiness-fear continuum from the three continua used in Experiment 1 because it did not incorporate any gross changes in physical features (e.g., from open to closed mouth), which might obscure CP (Calder et al., 1996).

Method

Participants Twenty-three undergraduates participated (12 men, 11 women; 18-24 years old).

Facial Stimuli One set of 11 gray-scale images of facial expressions was used. The set consisted of a continuum extending from happiness to fear. The endpoint expressions and the morphing procedure to create interpolated faces were the same as in Experiment 1. Nine intermediate faces were generated so that the 11 images from happiness to fear were spaced with a 10% gap.

Procedure and Design Participants performed two successive tasks (two sessions each) by viewing stimuli presented on a 17-inch CRT monitor.

XAB discrimination task The sequence of the stimuli presented in each trial was as follows: (1) a fixation point for 450 ms; (2) a blank interval for 300 ms; (3) a facial stimulus 'X' for 150 ms or 75 ms (target); (4) a black-and-white checker-pattern for 150 ms (backward mask); (5) a blank interval for 750 ms; (6) and finally, two facial stimuli 'A' and 'B', positioned horizontally to the right and left of center, displayed until the participants responded (reference). Participants were asked to decide which reference was identical to the target.

The backward mask was used to restrict visual access to the target over the controlled stimulus exposure duration (Enns & DiLollo, 2000). Because the backward mask might degrade target perception, we used 75 ms as the brief exposure duration, which is somewhat longer than the 50 ms tested in Experiment 1. We also used 150 ms as the sole longer exposure duration interval, because we speculated that task difficulty might differ too much between 75 ms and 750 ms. Reference stimuli were spaced with a 20% gap, resulting in nine possible pairs. For each pair, there were four presentation orders; (X,A,B) = (A,A,B), (A,B,A), (B,A,B), (B,B,A). Target duration was manipulated across sessions, and the order of the two durations was counterbalanced across participants. Each session contained 10 training trials and two blocks of 36 experimental trials representing all combinations of pairs (9) and presentations (4). The order of the pair-presentation sets was fully randomized in each block.

Identification task Stimulus sequence in each trial was the same as in the XAB discrimination task, with the exception that reference stimuli were removed. Participants were asked to decide whether the target stimulus expressed fear or happiness. The order of the two sessions across which the target duration was manipulated was the same as in the XAB discrimination task. Each session contained 10 training trials and two blocks of 44 experimental trials corresponding to four repetitions of the 11 faces. The order of the faces was fully randomized in each repetition.

Results & Discussion

Identification Task Figure 2 presents the overall percentage of trials in which "fear" was identified at each stimulus exposure duration in the identification task. Application of a logit model to each identification rate curve revealed that the category boundary lay at 52.4% (150 ms) and 55.2% (75 ms). Contrary to the results of Experiment 1, logit models also showed that the slope at 150 ms (17.9) was somewhat smaller than at 75 ms (19.4), though this difference did not reach significance (z=1.03, p=0.303). As the slope was attenuated in proportion to the decreased duration in Experiment 1, these data suggest that the duration difference between 150 ms and 75 ms was insufficient to cause a significant slope change.

XAB Discrimination Task Figure 3 presents the overall correct response rate for each stimulus exposure duration in

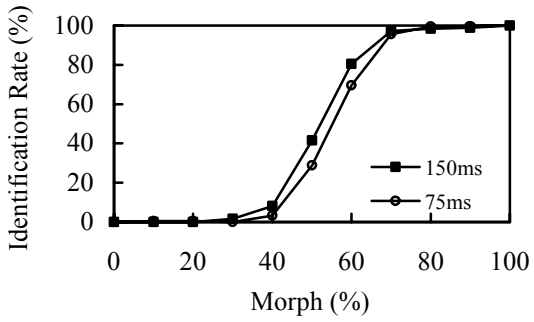

Figure 2: Overall percentage with which "fear" was identified at each stimulus duration. *Morph* represents a percentage of "fear" for a given face.

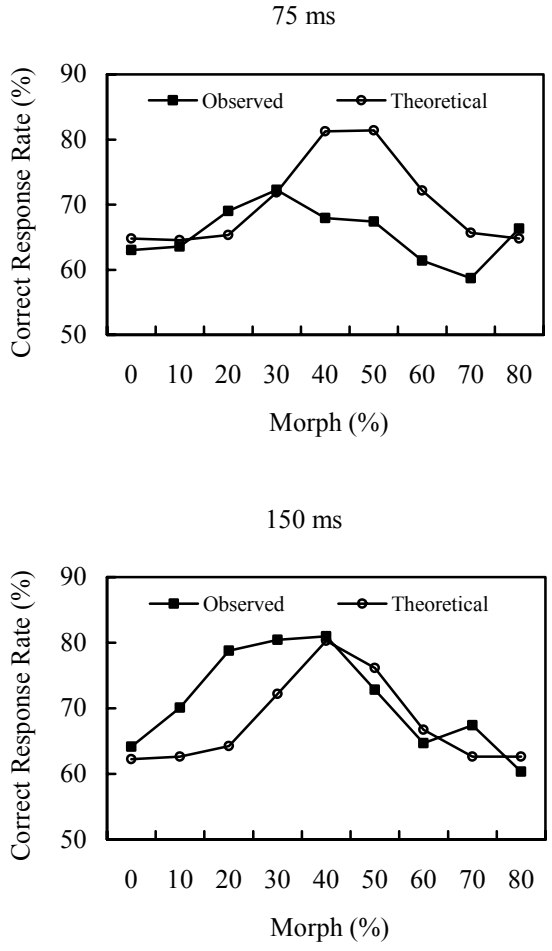

Figure 3: Overall correct response rate in the XAB discrimination task for each duration. *Observed*=observed rate. *Theoretical*=theoretical rate predicted from CP. *Morph* represents a percentage of "fear" for the less fearful face of a given pair.

the XAB discrimination task. The data from the identification task revealed that identifying between-category pairs was 40%-60% and 50%-70% at both durations. The peak in discrimination performance at the category boundary was found only at the 150-ms stimulus exposure duration.

We calculated the mean correct rate for between-category pairs (40%-60%, 50%-70%) and within-category pairs (the remaining seven pairs) for each duration, and conducted a 2 x 2 ANOVA of the mean correct rate with the two factors of pair (between-category or within-category) and stimulus duration (150 ms or 75 ms). A significant main effect of pair was found ($F(1,22)=7.79$, $p=0.011$, $MSE=0.008$), indicating better discrimination for between-category pairs (72%) than for within-category pairs (67%). The main effect of duration was also significant ($F(1,22)=9.74$, $p=0.005$, $MSE=0.011$), indicating worse performance at 75 ms (66%) than at 150 ms (73%). There was no significant interaction between the two factors ($p>0.25$), suggesting that discrimination of between-category pairs was more accurate than that for within-category pairs, at both durations. However, post-hoc paired *t* tests revealed that superior discrimination for between-category pairs was significant only at the 150-ms exposure duration (150 ms, $M=8\%$, $t(22)=2.42$, $p=0.024$; 75 ms, $M=3\%$, $t(22)=1.18$, $p=0.252$). Post-hoc comparisons also revealed that poorer discrimination at 75 ms was significant for both between-category and within-category pairs (between-category, $M=9\%$, $t(22)=2.36$, $p=0.027$; within-category, $M=4\%$, $t(22)=2.66$, $p=0.014$).

To indicate CP in the discrimination task, previous studies (Calder et al., 1996; Young et al., 1997) have reported correlations between observed and theoretical performances, predicted from CP. Calder and colleagues (Calder et al., 1996) assumed that discrimination between two facial expression stimuli depends on two cues: first, the physical difference between the stimuli, which is constant for any pair, regardless of their expressions; and second, the expression categories of the stimuli. To estimate the contribution of the first non-categorical cue, they computed the mean observed discrimination for the two pairs, placed at both ends of the continuum. To estimate the contribution of the second categorical cue, they calculated the difference in identification rates for the two relevant stimuli observed in the identification task, and multiplied the obtained difference by 0.25 (a constant). Calder et al. (1996) argued that summing the two estimates measures theoretical performance in the discrimination task.

Figure 3 also presents theoretical performance, based on the same formula as Calder et al. (1996), along with observed performance. The fit between observed and theoretical performance looks better at 150 ms than at 75 ms; indeed, their correlation was significant only at the 150-ms exposure duration (150 ms, $r=0.667$, $t(7)=2.37$, $p=0.050$; 75 ms, $r=0.362$, $t(7)=1.03$, $p=0.338$).

Analyses revealed that the superior discrimination performance for between-category pairs disappeared at 75 ms but was present at 150 ms, providing decisive evidence of null CP at the brief stimulus duration. In response to objections claiming that observing only one continuum is insufficient, studies using neuroimaging (Morris et al.,

1996; Morris, Friston, et al., 1998; Whalen et al., 1998; Wright et al., 2001) and developmental data (Kotsoni, DeHaan, & Johnson, 2001) have indicated that happiness and fear are the most distinct categories, and that the lack of CP between the two expressions is important. Critics might also insist that the disappearance of CP at 75 ms is a floor effect; however, discrimination for any stimulus pair at 75 ms was above chance (all $ps<0.01$), indicating that residual perception of differences in some visual properties was present. Moreover, the 75-ms duration was sufficient for accurate identification of near-endpoint facial expressions (see Figure 2). Thus, categorical perception did not occur, even with such well-preserved visual processing.

General Discussion

The present experiments revealed that categorical perception of facial expressions was attenuated and even disappeared with brief stimulus exposure durations. The abrupt change in identifying facial expressions at the category boundary was weakened at the 50-ms stimulus duration (Experiment 1), and the more accurate discrimination observed for between-category pairs than for within-category pairs was eliminated at the 75-ms stimulus duration (Experiment 2). Our findings indicate that the fast perceptual processing of emotional facial expressions is not categorical.

It has been postulated that the fast processing of facial expressions involves subcortical structures, specialized in the detection of *salient* stimuli (Adolphs, 2002). However, categorical perception refers to the processing of *ambiguous* stimuli or the transformation of an indistinctive facial configuration into a distinctive emotion category. Such fine analysis of emotional information may involve cortical structures, implying slower processing (LeDoux, 1996).

Etcoff and Magee (1992) have claimed that their observation of CP in facial expression recognition rejects the possibility that categorical processing of facial expressions is performed by higher conceptual and linguistic systems. There are data, however, demonstrating that verbal interference eliminated CP of colors and facial expressions, suggesting the essential role of verbal coding over visual coding (Roberson & Davidoff, 2000). Medin and Barsalou (1987) have argued that it is important to distinguish between *sensory perception categories* (SP categories), categories related to low-level perceptual experiences, and *generic knowledge categories* (GK categories), categories related to high-level knowledge representation. Shibui and colleagues (Shibui, Yamada, Sato, & Shigemasu, 2001) found that discrimination accuracy for within-category pairs of facial expressions was proportional to their semantic distance, and they inferred that facial expressions belong to cognitive GK categories. Our findings are consistent with the view that categorical processing of facial expressions is performed by higher cognitive systems.

Some researchers have postulated that CP of facial expressions supports the notion of basic emotions (DeGelder et al., 1996; Ekman, 1994), such that each emotion possesses an innate and specialized neuro-cognitive system. However, categorical perception is also known to occur for non-emotional visual categories such as identity (Beale & Keil, 1995; Levin & Beale, 2000), race (Levin & Angelone, 2002), and even familiar objects (Newell & Bulthoff, 2002). Categorical perception of facial expressions may thus reflect visual information processing that is common to general object recognition rather than specific to emotional content.

Abstract

Although an increasing number of cognitive scientists are convinced that cognition is *embodied*, there still is relatively little agreement on what exactly that means. Notions of what it actually means for a cognizer to be embodied range from simplistic ones such as 'being physical' or 'interacting with an environment' to more demanding ones that consider a particular morphology or a living body prerequisites for embodied cognition. Based on experimental evidence from a range of disciplines, we argue that one of the keys to understanding the embodiment of cognition is the sharing of neural mechanisms between sensorimotor processes and higher-level cognitive processes. The latter are argued to be embodied in the sense that they make use of (partial) simulations or emulations of sensorimotor processes through the re-activation of neural circuitry also active in bodily perception and action.

Introduction

Although an increasing number of cognitive scientists are convinced that cognition is *embodied* (e.g. Varela et al., 1991; Clancey, 1997; Clark, 1997; Lakoff & Johnson, 1999; Ziemke, 2002), there still is relatively little agreement on what exactly that means. Notions of what it actually means for a cognizer to be embodied range from simplistic ones such as 'being physical' or 'interacting with an environment' to more demanding ones that consider a particular morphology or a living body prerequisites for embodied cognition (cf., e.g., Chrisley & Ziemke, 2002; Wilson, 2002; Anderson, 2003; Ziemke, 2003).

This lack of agreement or coherence, after more than a decade of research on embodied cognition, has unfortunate consequences. Firstly, critics commonly argue that the only thing that embodied cognitive theories have in common is in fact the rejection of traditional, computationalist and supposedly disembodied cognitive science. Secondly, there is a certain trivialization of embodiment, not least among many AI researchers who consider as embodied any physical system, or in fact any agent that interacts with some environment, such that the distinction between computationalist and embodied cognitive theories disappears since, in some sense, all systems are embodied, and thus cognitive science has always been about embodied cognition (Chrisley & Ziemke, 2002). Thirdly, there is the 'misunderstanding' that perhaps embodiment is only relevant to sensorimotor processes directly involving the body in perception and action, while higher-level cognition might very well be computational in the traditional sense and only dependent on the body in the sense that mental representations ultimately need to be grounded in sensorimotor interaction with the physical environment.

This paper, on the other hand, argues that one of the keys to understanding the embodiment of cognition, in an important, non-trivial sense, is to understand the sharing of neural mechanisms between sensorimotor processes and higher-level cognitive processes. Based on experimental evidence from a range of disciplines, we argue that many, if not all, higher-level cognitive processes are body-based in the sense that they make use of (partial) *simulations* or *emulations* of sensorimotor processes through the re-activation of neural circuitry that is also active in bodily perception and action (cf. Clark & Grush, 1999; Grush, in press; Hesslow, 2002). As Barsalou et al. (2003) put it, the main point is that "simulations of bodily states in modality specific brain areas may often be the extent to which embodiment is realized".

The next section elaborates the key idea of this paper, i.e., cognition as body- and simulation-based in the above sense, in more detail. In the following sections then supporting empirical evidence from a range of disciplines is presented. The final section then presents a brief summary as well as some open questions and directions for future work.

Cognition as body-based simulation

The idea that even higher-level cognitive processes are in a strong sense grounded in bodily activity and experience is, of course, hardly new, but was developed already in the 1980s, most influentially by Maturana and Varela (1980, 1987) from a neurobiological perspective, and by Lakoff and Johnson (1980, 1999) from a linguistic perspective. Lakoff (1988) summarized the basic idea as follows:

> Meaningful conceptual structures arise from two sources: (1) from the structured nature of bodily and social experience and (2) from our innate capacity to imaginatively project from certain well-structured aspects of bodily and interactional experience to abstract conceptual structures.

Back in the 1980s, however, relatively little was known about exactly how such an *imaginative projection* from bodily experience to abstract concepts might work. In recent years more detailed accounts of how the sensorimotor structures of the brain are involved in cognition have been developed in several disciplines, often taking into account data from neurophysiological and neuroimaging studies. These accounts show that the traditional strong division between perception and action, as well as between sensorimotor and cognitive processes, needs to be revised.

A particular kind of "embodiment" theory that has emerged in different contexts are so-called *emulation* or *simulation theories*[1] (e.g., Barsalou et al., 2003: Decety, 1996; Frith & Dolan, 1996; Grush, in press; Hesslow, 2002; Jeannerod, 1994, 2001). The basic idea is that neural structures that are responsible for action and/or perception are also used in the performance of various cognitive tasks. As Hesslow (2002) pointed out, this idea is not entirely new; e.g. Alexander Bain suggested in 1896 that thinking is basically a covert form of behavior that does not activate the body and thus remains invisible to external observers. Today simulation theories, based partly on data from neuroscience, can further clarify the possible role of simulation in cognition, thus explaining in a more concrete way than before the embodiment of cognition.

One of the more comprehensive descriptions of the idea has been presented by Grush (in press; see also Clark & Grush, 1999). Based on the control theoretic concept of forward models (emulators), previously used to account for motor control (e.g., Wolpert & Kawato, 1998), Grush developed an emulation theory for several types of cognitive processes, including perception, imagery, reasoning and language. In a nutshell, he argued that emulation circuits are able to calculate a forward mapping from control signals to the (anticipated) consequences of executing the control command. For example, in goal-directed hand movements the brain has to plan parts of the movement before it starts. To achieve a smooth and accurate movement proprioceptive/kinesthetic (and sometimes visual) feedback is necessary, but sensory feedback per se is too slow to affect control appropriately (Desmurget & Grafton, 2000). The 'solution' is an emulator/forward model that can predict the sensory feedback resulting from executing a particular motor command.[2]

The following section summarizes a number of the many empirical studies that support the idea that cognition is body-based, especially as predicted by simulation theories.

Empirical Evidence

Several sources of evidence support the basic tenet of the simulation account, viz., that perceptual and motor areas of the brain can be covertly activated either separately or in sequence for use in cognitive processes. In particular, several studies have indicated that there are extensive similarities between the neural structures activated during preparation (and execution) of an action and mentally simulating an action (i.e., motor imagery), as well as between visual perception and visual imagery. The similarities are so striking that some have argued that internally activated actions and perceptions are the same as overt ones, except that the overt execution or sensory input is missing (e.g., Hesslow, 2002; Jeannerod, 2001).

The following subsections review some of the empirical evidence that suggest that sensorimotor structures of the brain are deeply involved in the generation of cognitive phenomena, such as imagery and problem solving.

Motor imagery

There is an extensive literature on the neural and behavioral similarities between actions and motor imagery (e.g., Decety, Jeannerod, & Prablanc, 1989; Jeannerod & Decety, 1995; Jeannerod & Frak, 1999; for reviews see Decety, 1996, 2002; Jeannerod, 1994, 2001).[3]

Motor imagery is the recreation of an experience of actually performing an action, e.g., the person should feel as if he/she was actually walking (Decety, 1996; Jeannerod, 1994). The evidence cited in support for the equivalence of performing an action and simulating an action comes mainly from three different sources: *mental chronometry*, *autonomic responses*, and *measurements of brain activity*.[4]

In *mental chronometry* experiments, it has been found that the time to mentally execute actions closely corresponds to the time it takes to actually perform them (Jeannerod & Frak, 1999). For example, Decety and Jeannerod (1996) found that Fitt's law (i.e., the finding that execution times increase with task difficulty) also holds for motor imagery. Decety et al. (1989) compared the durations of walking towards targets (with blindfolds) placed at different distances and mental simulation of walking to the same targets. In both conditions times were found to increase with the distance covered.

Autonomic responses, such as the adaptation of heart and respiratory rates, which are beyond voluntary control have been shown to be activated by motor imagery to an extent proportional to that of actually performing the action, and as a function of mental and actual effort (Decety, 1996; Jeannerod, 1994; Jeannerod & Decety, 1995).

[1] The terms simulation and emulation are used somewhat interchangeably in this paper, as in much of the literature, but it should be noted that they are sometimes used differently (e.g., Grush, in press).

[2] According to Blakemore, Frith and Wolpert (1999), this is also why it is not so easy to tickle oneself: the forward model produces predicted sensory feedback that 'prepares' the agent.

[3] There are also similarities between actions and other cognitive tasks, such as observing an action and prospective action judgments, which differ from motor imagery in that they do not produce a conscious motor image of performing an action and the brain activation is not as similar to overt actions as in motor imagery (cf., Jeannerod, 2001).

[4] Further evidence comes from effects on action performance after mental training using motor imagery and also from lesion studies.

Since the first study that investigated motor imagery using regional cerebral blood flow (rCBF) to indicate active brain areas (Ingvar & Philipson, 1977) there have been many neuroimaging experiments that confirm the first study's indication that similar brain areas are activated during action and motor imagery. The general conclusion is that there is a functional equivalence between performing an action and mentally simulating it (Decety, 2002; Jeannerod, 2001).

Together, these three types of evidence point to an explanation of motor imagery that implicates sensorimotor structures.[5] Although the focus above has been on actions, it should not be forgotten that the motor system also integrates sensory information when planning and executing an action (e.g., Grush, in press; cf. Desmurget & Grafton, 2000; Jeannerod, 1997). Thus, simulating an action might also involve an emulator mechanism that predicts the sensory feedback that would have resulted from the executed action (Decety, 2002; Grush, in press; Jeannerod, 1997, 2001).

Mental visual imagery

The discussion of motor imagery can be extended to the visual modality in that the same type of studies report that perceptual structures can and are internally reactivated when, e.g., visually recreating a previous perception. Many studies in cognitive psychology have found similarities between visual perception and visual imagery (Farah, 1988; Finke, 1989). For example, Shepard and Metzler (1971) performed a number of mental chronometry type experiments, where they compared the concrete manipulation of physical objects and corresponding manipulations performed mentally. In their experiments, the time between the two conditions was closely correlated, which suggests that mental imagery uses the same mechanisms as the visual system. Although alternative explanations are difficult to rule out, neuropsychological and neuroimaging studies offer more conclusive evidence of the involvement of sensorimotor areas of the brain in mental visual imagery (Farah, 1988; Hesslow, 2002).

Note that these findings do not necessarily influence debates on representational format, since both perception and imagery may be said to use the same format (Block, 1983). On the other hand, explaining cognition as reactivation of sensorimotor structures does not (at least in some cases) rely on the computer metaphor of symbol manipulation, and thus may offer a novel view that does not see the vehicle and the content of representations as separate entities but as constitutive of each other (Gallese, 2003; cf. Dreyfus, 2002; Thomas, 1999). Gallese argued that canonical neurons in the monkey brain illustrate how the interaction between an agent and its environment provides an example of such representations.

Canonical neurons

In the macaque monkey, neurons located in the rostral part of the inferior premotor cortex (area F5) of the monkey brain discharge during goal directed movements, such as grasping, holding, or tearing. However, they do not respond to similar movements, but only actions that have the same "meaning" (di Pellegrino et al. 1992; Rizollatti et al., 1996; Rizzolatti et al., 2002), which is why they are often interpreted as internal representations of actions, rather than motor or movement commands (Jeannerod, 1994; Rizollatti et al. 1996; Rizzolatti et al., 2002). Gallese (2003) emphasized seeing them as coding not physical parameters of movement, but a relationship between agent and object.

Some of the neurons in area F5, so-called *canonical neurons*, also have sensory properties and discharge both during the action they code and when an object that *affords* that action in the Gibsonian sense is perceived. Canonical neurons have a strict congruence between the type of grasping action and the size or shape of the object they respond to (Gallese, 2003). This implies that they implement affordances, e.g. code things that are graspable-in-a-certain-way, specifying not only perceptual and action aspects but a particular relationship between agent and environment (cf. Gallese, 2003, cf. also Dreyfus, 2002).

Problem solving using covert perception and action

Instead of adverting to symbol manipulation, a flexible inner world, in which an agent might try out possible action sequences, can be explained by internal activation of perceptions and actions (Clark & Grush, 1999, Grush, in press; Hesslow, 2002). That means, an agent can sustain such an inner world by letting an internally activated action elicit through an anticipatory mechanism internally generated perceptions that would be the likely result of executing that action in the particular external situation. As discussed above, the internal activation of sensorimotor structures is well supported, but the neural underpinnings of the anticipation mechanism are still an open issue. Some suggest the involvement of the cerebellum (e.g., Hesslow, 2002).

Some support for the involvement of this type of simulation of behavioral chains comes from the problem solving and planning involved in the Tower of London (ToL) problem (Shallice, 1982). Dagher et al. (1999) found that planning and problem solving activated higher motor areas (premotor cortex, prefrontal cortex) and the basal ganglia, and that they seemed to interact with visual and posterior parietal areas (cf. Schall et al., 2003). This gives some support to the idea that the subjects solved the problem by simulating the action of moving one ball to another location through the use of reactivated perceptions and actions (Hesslow, 2002).

[5] There are a number of unanswered questions concerning motor imagery worth mentioning here, which, however, do not affect the paper's main point concerning the embodiment of cognition. To what degree do actions and mental simulations of actions engage executive motor structures (such as, the primary motor cortex) (cf., e.g., Decety, 2002; Jeannerod & Frak, 1999), and how is the overt movement hindered (Jeannerod, 2001; Hesslow, 2002)? Although there may not be a complete overlap between the neural structures involved in real and mentally simulated action, the evidence suggests that they are not different in nature, but only in degree.

Social cognition and language

The use of internally reactivated sensorimotor structures has also been suggested to play a crucial role in social cognition, especially emotive states (cf. Barsalou et al., 2003; Nielsen, 2002). The evidence that is reported in this subsection emphasizes that perceptual and motor processes are not different in nature at the neural and behavioral level, but seem to be intimately linked in social cognition possibly through simulation mechanisms.

Embodiment effects Barsalou et al. (2003) argued that there are at least four types of well known phenomena in social cognition which can be explained by simulation of bodily states. The types of effects they mention are: a) perceived social stimuli produce bodily states, b) perceiving bodily states produce bodily mimicry, c) bodily states can produce and affect emotion states, and d) compatibility between bodily states and emotional states increases performance (see also Nielsen, 2002). These effects seem to arise automatically without any conscious mediating knowledge structures (Barsalou et al., 2003; Nielsen, 2002).

Firstly, social stimuli do not only produce cognitive responses, but at the same time automatically and unconsciously cause bodily responses (e.g., movement patterns, facial expressions). For example, subjects induced with an elderly stereotype (e.g., by watching elderly people) perform in a manner more similar to the elderly stereotype than control subjects (Barsalou et al., 2003).

Secondly, bodily responses sometimes are the same or similar to the eliciting social stimuli as in the many cases of facial mimicry. For example, watching somebody yawning often causes oneself to yawn too (cf. Barsalou et al., 2003).

Thirdly, bodily states can directly induce effects on affective states (Barsalou et al., 2003). One such effect is the facial feedback hypothesis, which states that a person's own facial expressions can (either directly from the brain areas responsible for the facial expression or through processing of proprioceptive feedback) produce or modify his/her experience of the emotional state (Nielsen, 2002).

Finally, when there is a mismatch between bodily state and affective state cognitive performance is degraded. Barsalou et al. (2003) argued that this is perhaps the most important effect because it indicates that embodied states are directly involved in higher cognition. That is, the affective states are thought to involve sensorimotor states and when there is an incompatible bodily state co-present it produces a competing sensorimotor state, which reduces performance. For example, Wells and Petty (1980) showed that head movements were faster when compatible with the message (e.g., nodding vertically to an agreeable message) than when incompatible (cf. Barsalou et al., 2003).

The findings discussed in this section suggest that bodily states are involved in social cognition and that they might constitute the very foundations of the particular social cognitive phenomena in question. An example of how perception, action, and social cognition come together at the level of single neurons is so-called *mirror neurons* in macaque monkeys (Decety & Sommerville, 2003).

Observation execution matching system Besides canonical neurons, area F5 of the monkey brain contains so called *mirror neurons*, which are neurons with sensory properties that become activated both when performing a specific action and when observing the same goal-directed hand (and mouth) movements of an experimenter (di Pellegrino et al., 1992; Rizzolatti et al., 1996). Mirror neurons provide a key example of sensorimotor brain structures also involved in (social) cognitive processes.

Although different hypotheses exist, many of the theories of the function of mirror neurons emphasize their role in social cognition (e.g., Decety & Chaminade, 2003; Gallese & Goldman, 1998; Rizzolatti & Arbib, 1998; Rizzolatti et al. 2002). These researchers acknowledge that area F5 and mirror neurons can be interpreted as a kind of observation-execution mechanism or resonance mechanism, which links the observed actions to actual actions of the subject's own behavioral repertoire. That is, it enables the monkey to understand the meaning of the observed action. Thus, mirror neurons can be interpreted as representations of actions, used both for performing and understanding actions (e.g., Rizzolatti et al., 1996; Rizzolatti & Arbib, 1998). [6]

Gallese and Goldman (1998) hypothesized that mirror neurons might be a basic mechanism necessary for "mind-reading", i.e., attributing mental states in others. They further argued that such mechanisms can explain how an agent determines what mental states of another agent have already occurred. When mirror neurons are externally activated by observing a target agent executing an action (allowing the subject to evaluate the meaning of the other's action), the subject knows (visually) that the observed target is currently performing this very action and thereby "tags" the "experienced" action as belonging to the target. However, how the subject can distinguish its own actions from those performed by others is relatively unknown (cf. Blakemore, Wolpert & Frith, 2002).

Language Some researchers have argued that conceptualization and language understanding cannot be achieved through the manipulation of amodal, arbitrary symbols alone, but has to be grounded in bodily interaction with the environment. In particular, Glenberg and Kaschak (2003) have outlined an explanation of language in line with the idea of cognition as body-based simulation as expressed in this paper, suggesting that language is partly achieved through the same neural structures used to plan and guide action.

[6] For practical and ethical reasons it is so far not possible to investigate the existence of mirror neurons (and canonical neurons) at the single neuron level in humans. However, many researchers have presented strong arguments for the existence of a similar system in humans (e.g., Fadiga et al., 1995; Grafton et al., 1996; Rizzolatti, & Arbib, 1998; Rizzolatti et al., 1996).

Under the heading of the *indexical hypothesis* they developed an account of language comprehension partly based on simulation of action. They argued that the meaning of a sentence is achieved by a process that indexes words to perceptual symbols which in turn retrieves the available affordances in the situation and determines their relevance through the particular sentence construction. Thus, the understanding of a sentence is essentially achieved through a simulation of action using the same neural systems active in overt behavior.

An empirical result that supports the close coupling between language and action is the "action-sentence compatibility effect" (Glenberg & Kaschak, 2002). It was found that the sensibility of a sentence is modified by physical actions. Reaction times increased when subjects read "toward sentences" that implied action toward the reader, such as "Open the drawer" *and* had to give the answer through an incongruent action, i.e., moving the hand away from the body. Conversely, when subjects answered through an action congruent with the sentence, reaction times decreased. Glenberg and Kaschak interpreted the result as indicating that understanding a sentence is dependent on structures usually used for action. Readers interested in more comprehensive reviews of the coupling between language and action/perception are referred to Glenberg and Kaschak (2003) or Zwaan (2004).

Summary and conclusions

This paper has presented an emerging framework of simulation based on terminology and ideas from control theory and data from neurophysiological and neuroimaging studies that explain higher-level cognitive processes as at least partly based on reactivations of sensorimotor structures of the brain. By reactivating mechanisms used in perception and action together with a predictive mechanism a flexible inner world emerges that can be used for many different higher-level cognitive tasks (cf. Grush, in press; Hesslow, 2002). Crucial to the embodiment of cognition, according to this account, is perhaps not so much the physical nature of a cognizer's body, or its interaction with the environment as such, but the relation between sensorimotor and higher-level cognitive processes, more specifically, the way that the latter are fundamentally based on and rooted in the former.

Although corroborating evidence comes from several disciplines, the simulation account is not yet a well established or coherent theory of cognition in general, and there are many questions still to be answered. For example, in current accounts it is unclear exactly what constitutes the difference between an executed, overt action and a simulated/imagined, covert one. Can this be accounted for in terms of simulation theories or are other, presumably higher-level, mechanisms required after all to selectively trigger one or the other?

Moreover, there is a *level of granularity* problem (cf. Meltzoff & Prinz, 2002) that seems to apply to many simulation accounts. That is, at what level of abstraction does the simulation occur? During imagery it seems that the simulation occurs on a low-level including very many of the aspects of actually perceiving or acting, as indicated by neuroimaging studies (e.g., Jeannerod, 2001), whereas in problem solving, as in the ToL task, more abstract aspects of actions may be employed, which might be supported by the finding that problem solving activity in the ToL seem to activate only higher motor centers, such as prefrontal and premotor cortex (Dagher et al., 1999). However, this is a speculative interpretation of the neuroimaging results.

The level of granularity is also an important issue in robotic models of simulation theories (e.g. Ziemke, Jirenhed & Hesslow, in press). Previous work in our lab has dealt with internal simulations at the lowest level, but current work also addresses simulation at more abstract levels of granularity. We believe that robotic models offer a fruitful approach to further investigating this and other open questions that need to be answered in the future development of simulation theories.

Computationally Recognizing Wordplay in Jokes

Julia M. Taylor (tayloj8@email.uc.edu)
Lawrence J. Mazlack (mazlack@uc.edu)
Electrical & Computer Engineering and Computer Science Department
University of Cincinnati

Abstract

In artificial intelligence, researchers have begun to look at approaches for computational humor. Although there appears to be no complete computational model for recognizing verbally expressed humor, it may be possible to recognize jokes based on statistical language recognition techniques. This is an investigation into computational humor recognition. It considers a restricted set of all possible jokes that have wordplay as a component and examines the limited domain of "Knock Knock" jokes. The method uses Raskin's theory of humor for its theoretical foundation. The original phrase and the complimentary wordplay have two different scripts that overlap in the setup of the joke. The algorithm deployed learns statistical patterns of text in N-grams and provides a heuristic focus for a location of where wordplay may or may not occur. It uses a wordplay generator to produce an utterance that is similar in pronunciation to a given word, and the wordplay recognizer determines if the utterance is valid. Once a possible wordplay is discovered, a joke recognizer determines if a found wordplay transforms the text into a joke.

Introduction

Thinkers from the ancient time of Aristotle and Plato to the present day have strived to discover and define the origins of humor. Most commonly, early definitions of humor relied on laughter: what makes people laugh is humorous. Recent works on humor separate laughter and make it its own distinct category of response. Today there are almost as many definitions of humor as theories of humor; as in many cases, definitions are derived from theories (Latta, 1999). Some researchers say that not only is there no definition that covers all aspects of humor, but also humor is impossible to define (Attardo, 1994).

Humor is an interesting subject to study not only because it is difficult to define, but also because sense of humor varies from person to person. The same person may find something funny one day, but not the next, depending on the person's mood, or what has happened to him or her recently. These factors, among many others, make humor recognition challenging.

Although most people are unaware of the complex steps involved in humor recognition, a computational humor recognizer has to consider all these steps in order to approach the same ability as a human being.

A common form of humor is verbal, or "verbally expressed, humor" (Ritchie 2000). Verbally expressed humor involves reading and understanding texts. While understating the meaning of a text may be difficult for a computer, reading it is not.

One of the subclasses of verbally expressed humor is the joke. Hetzron (1991) defines a joke as "a short humorous piece of literature in which the funniness culminates in the final sentence." Most researchers agree that jokes can be broken into two parts, a setup and a punchline. The setup is the first part of the joke, usually consisting of most of the text, which establishes certain expectations. The punchline is a much shorter portion of the joke, and it causes some form of conflict. It can force another interpretation on the text, violate an expectation, or both (Ritchie, 1998). As most jokes are relatively short, it may be possible to recognize them computationally.

Computational recognition of jokes may be possible, but it is not easy. An "intelligent" joke recognizer requires world knowledge to "understand" most jokes.

Theories of Humor

Raskin's (1985) *Semantic Theory of Verbal Humor* has strongly influenced the study of verbally expressed humor. The theory is based on assumption that every joke is compatible with two scripts, and those two scripts oppose each other in some part of the text, usually in the punch line, therefore generating humorous effect.

Another approach is Suls' (1972) two-stage model, which is based on false expectation. The following algorithm is used to process a joke using two-stage model (Ritchie, 1999):

- As a text is read, make predictions
- While no conflict with prediction, keep going
- If input conflicts with prediction:
  - If not ending – PUZZLEMENT
  - If is ending, try to resolve:
    - No rules found – PUZZLEMENT
    - Cognitive rules found –HUMOR

There have been attempts at joke generation (Attardo, 1996; Binsted, 1996; Lessard and Levison, 1992; McDonough, 2001; McKay, 2002; Stock and Strapparava, 2002) and pun recognizers (Takizawa, et al. 1996; Yokogawa, 2002) for Japanese. However, there do not appear to be any theory based computational humor efforts. This may be partly due to the absence of a theory that can be expressed as an unambiguous computational algorithm. In the cases of Raskin and Suls, the first does not offer any formal algorithm, and the second does not specify what a cognitive rule is, leaving one of the major steps open to interpretation.

Wordplay Jokes

Wordplay jokes, or jokes involving verbal play, are a class of jokes depending on words that are similar in sound, but are used in two different meanings. The difference between the two meanings creates a conflict or breaks expectation,

and is humorous. The wordplay can be created between two words with the same pronunciation and spelling, with two words with different spelling but the same pronunciation, and with two words with different spelling and similar pronunciation. For example, in $Joke_1$ the conflict is created because the word has two meanings, while the pronunciation and the spelling stay the same. In $Joke_2$ the wordplay is between words that sound nearly alike.

$Joke_1$: "Cliford: The Postmaster General will be making the TOAST.
Woody: Wow, imagine a person like that helping out in the kitchen!"
$Joke_2$: "Diane: I want to go to Tibet on our honeymoon.
Sam: Of course, we will go to bed."[1]

Sometimes it takes world knowledge to recognize which word is subject to wordplay. For example, in $Joke_2$, there is a wordplay between "Tibet" and "to bed." However, to understand the joke, the wordplay by itself is not enough, a world knowledge is required to "link" honeymoon with "Tibet" and "to bed."

A focused form of wordplay jokes is the Knock Knock joke. In Knock Knock jokes, wordplay is what leads to the humor. The structure of the Knock Knock joke provides pointers to the wordplay.

A typical Knock Knock (KK) joke is a dialog that uses wordplay in the punchline. Recognizing humor in a KK joke arises from recognizing the wordplay. A KK joke can be summarized using the following structure:

$Line_1$: "Knock, Knock"
$Line_2$: "Who's there?"
$Line_3$: any phrase
$Line_4$: $Line_3$ followed by "who?"
$Line_5$: One or several sentences containing one of the following:
$Type_1$: $Line_3$
$Type_2$: a wordplay on $Line_3$
$Type_3$: a meaningful response to $Line_3$.

$Joke_3$ is an example of $Type_1$, $Joke_4$ is an example of $Type_2$, and $Joke_5$ is an example of $Type_3$.

$Joke_3$: Knock, Knock
Who's there?
Water
Water who?
Water you doing tonight?
$Joke_4$: Knock, Knock
Who's there?
Ashley
Ashley who?
Actually, I don't know.
$Joke_5$: Knock, Knock
Who's there?
Tank
Tank who?
You are welcome.[2]

From theoretical points of view, both Raskin's (1985) and Suls' (1972) approaches can explain why $Joke_3$ is a joke. Following Raskin's approach, the two belong to different scripts that overlap in the phonetic representation of "water," but also oppose each other. Following Suls' approach, "what are" conflicts with the prediction. In this approach, a cognitive rule can be described as a function that finds a phrase that is similar in sound to the word "water," and that fits correctly in beginning of the final sentence's structure. This phrase is "what are" for $Joke_3$.

N-grams

A joke generator has to have an ability to construct meaningful sentences, while a joke recognizer has to recognize them. While joke generation involves limited world knowledge, joke recognition requires a much more extensive world knowledge.

To be able to recognize or generate jokes, a computer should be able to "process" sequences of words. A tool for this activity is the N-gram, "one of the oldest and most broadly useful practical tools in language processing" (Jurafsky and Martin, 2000). An N-gram is a model that uses conditional probability to predict N^{th} word based on N-1 previous words. N-grams can be used to store sequences of words for a joke generator or a recognizer.

N-grams are typically constructed from statistics obtained from a large corpus of text using the co-occurrences of words in the corpus to determine word sequence probabilities (Brown, 2001). As a text is processed, the probability of the next word N is calculated, taking into account end of sentences, if it occurs before the word N.

"The probabilities in a statistical model like an N-gram come from the corpus it is trained on. This training corpus needs to be carefully designed. If the training corpus is too specific to the task or domain, the probabilities may be too narrow and not generalize well to new sentences. If the training corpus is too general, the probabilities may not do a sufficient job of reflecting the task or domain" (Jurafsky and Martin, 2000).

A bigram is an N-gram with N=2, a trigram is an N-gram with N=3, etc. A bigram model will use one previous word to predict the next word, and a trigram will use two previous words to predict the word.

Experimental Design

A further tightening of the focus was to attempt to recognize only $Type_1$ of KK jokes. The original phrase, in this case $Line_3$, is referred to as the *keyword*.

There are many ways of determining "sound alike" short utterances. The only feasible method for this project was computationally building up "sounds like" utterances as needed.

The joke recognition process has four steps:

$Step_1$: joke format validation
$Step_2$: generation of wordplay sequences
$Step_3$: wordplay sequence validation
$Step_4$: last sentence validation

Once $Step_1$ is completed, the wordplay generator generates utterances, similar in pronunciation to $Line_3$. $Step_3$ only checks if the wordplay makes sense without touching the rest of the punchline. It uses a bigram table for validation. Only meaningful wordplays are passed to $Step_4$ from $Step_3$.

[1] $Joke_1$, $Joke_2$ are taken from TV show "Cheers"
[2] http://www.azkidsnet.com/JSknockjoke.htm

If the wordplay is not in the end of the punchline, $Step_4$ takes the last two words of the wordplay, and checks if they make sense with the first two words of text following the wordplay in the punchline, using two trigram sequences. If the wordplay occurs in the end of the sentence, the last two words before the wordplay and the first two words of the wordplay are used for joke validation. If $Step_4$ fails, go back to $Step_3$ or $Step_2$, and continue the search for another meaningful wordplay.

It is possible that the first three steps return valid results, but $Step_4$ fails; in which case a text is not considered a joke by the Joke Recognizer.

The punchline recognizer is designed so that it does not have to validate the grammatical structure of the punchline. Moreover, it is assumed that the $Line_5$ is meaningful when the expected wordplay is found, if it is a joke; and, that $Line_5$ is meaningful as is, if the text is not a joke. In other words, a human expert should be able to either find a wordplay so that the last sentence makes sense, or conclude that the last sentence is meaningful without any wordplay. It is assumed that the last sentence is not a combination of words without any meaning.

The joke recognizer is to be trained on a number of jokes; and, tested on jokes, twice the number of training jokes. The jokes in the test set are previously "unseen" by the computer. This means that any joke, identical to the joke in the set of training jokes, is not included in the test set.

Generation of Wordplay Sequences

Given a spoken utterance A, it is possible to find an utterance B that is similar in pronunciation by changing letters from A to form B. Sometimes, the corresponding utterances have different meanings. Sometimes, in some contexts, the differing meanings might be humorous if the words were interchanged.

A repetitive replacement process is used for generation of wordplay sequences. Suppose, a letter a_1 from A is replaced with b_1 to form B. For example, in $Joke_3$ if a letter 'w' in a word 'water' is replaced with 'wh', 'e' is replaced with 'a', and 'r' is replaced with 're', the new utterance, 'what are' sounds similar to 'water'.

A table, containing combinations of letters that sound similar in some words, and their similarity value was used. The purpose of the Similarity Table is to help computationally develop "sound alike" utterances that have different spellings. In this paper, this table will be referred to as the Similarity Table. Table 1 is an example of the Similarity Table. The Similarity Table was derived from a table developed by Frisch (1996). Frisch's table contained cross-referenced English consonant pairs along with a similarity of the pairs based on the natural classes model. Frisch's table was heuristically modified and extended to the Similarity Table by "translating" phonemes to letters, and adding pairs of vowels that are close in sound. Other phonemes, translated to combinations of letters, were added to the table as needed to recognize wordplay from a set of training jokes.

The resulting Similarity Table approximately shows the similarity of sounds between different letters or between letters and combination of letters. A heuristic metric indicating how closely they sound to each other was either taken from Frisch's table or assigned a value close to the average of Frisch's similarity values. The Similarity Table should be taken as a collection of heuristic satisficing values that might be refined through additional iteration.

Table 1: Subset of entries of the Similarity Table, showing similarity of sounds in words between different letters

a	e	0.23
e	a	0.23
e	o	0.23
en	e	0.23
k	sh	0.11
l	r	0.56
r	m	0.44
r	re	0.23
t	d	0.39
t	z	0.17
w	m	0.44
w	r	0.42
w	wh	0.23

When an utterance A is "read" by the wordplay generator, each letter in A is replaced with the corresponding replacement letter from the Similarity Table. Each new string is assigned its similarity with the original word A.

All new words are inserted into a heap, ordered according to their similarity value, greatest on top. When only one letter in a word is replaced, its similarity value is being taken from the Similarity Table. The similarity value of the strings is calculated using the following heuristic formula:

similarity of string = number of unchanged letters +
sum of similarities of each replaced entry from the table

Note, that the similarity values of letters are taken from the Similarity table. These values differ from the similarity values of strings.

Once all possible one-letter replacement strings are found, and inserted into the heap, according to the string similarity, the first step is complete.

The next step is to remove the top element of the heap. This element has the highest similarity with the original word. If this element can be decomposed into an utterance that makes sense, this step is complete. If the element cannot be decomposed, each letter of the string, except for the letter that was replaced originally, is being replaced again. All newly constructed strings are inserted into the heap according to their similarity. Continue with the process until the top element can be decomposed into a meaningful phrase, or all elements are removed from the heap.

Consider $Joke_3$ as example. The joke fits a typical KK joke pattern. The next step is to generate utterances similar in pronunciation to 'water.'

Table 2 shows some of the strings received after one-letter replacements of 'water' in $Joke_3$. The second column shows the similarity of the string in the first table with the original word.

Suppose, the top element of the heap is 'watel,' with the similarity value of 4.56. Watel cannot be decomposed into a meaningful utterance. This means that each letter of 'watel' except for 'l' will be replace again. The newly formed strings will be inserted into the heap, in the order of

their similarity value. The letter 'l' will not be replaced as it not the 'original' letter from 'water.' The string similarity of newly constructed strings will be most likely less than 4. (The only way a similarity of a newly constructed string is greater than 4 is if the similarity of the replaced letter is above 0.44, which is unlikely.) This means that they will be placed below 'wazer.' The next top string, 'mater,' is removed. 'Mater' is a word. However, it does not work in the sentence 'Mater you doing.' (See Sections on *Wordplay Recognition* and *Joke Recognition* for further discussion.) The process continues until 'whater' is the top string. The replacement of 'e' in 'whater' with 'a' will result in 'whatar'. Eventually, 'whatar' will become the top string, at which point 'r' will be replaced with 're' to produce 'whatare'. 'Whatare' can be decomposed into 'what are' by inserting a space between 't' and 'a'. The next step will be to check if 'what are' is a valid word sequence.

Table 2: Examples of strings received after replacing one letter from the word 'water' and their similarity value to 'water'

New String	String Similarity to 'Water'
watel	4.56
mater	4.44
watem	4.44
rater	4.42
wader	4.39
wather	4.32
watar	4.23
wator	4.23
whater	4.23
wazer	4.17

Generated wordplays that were successfully recognized by the wordplay recognizer, and their corresponding keywords are stored for the future use of the program. When the wordplay generator receives a new request, it first checks if wordplays have been previously found for the requested keyword. The new wordplays will be generated only if there is no wordplay match for the requested keyword, or the already found wordplays do not make sense in the new joke.

Wordplay Recognition

A wordplay sequence is generated by replacing letters in the keyword. The keyword is examined because: if there is a joke, based on wordplay, a phrase that the wordplay is based on will be found in $Line_3$. $Line_3$ is the keyword. A wordplay generator generates a string that is similar in pronunciation to the keyword. This string, however, may contain real words that do not make sense together. A wordplay recognizer determines if the output of the wordplay generator is meaningful.

A database with the bigram table was used to contain every discovered two-word sequence along with the number of their occurrences, also referred to as *count*. Any sequence of two words will be referred to as *word-pair*. Another table in the database, the trigram table, contains each three-word sequence, and the count.

The wordplay recognizer queries the bigram table. The joke recognizer, discussed in section on *Joke Recognition*, queries the trigram table.

To construct the database several focused large texts were used. The focus was at the core of the training process. Each selected text contained a wordplay on the keyword ($Line_3$) and two words from the punchline that follow the keyword from at least one joke from the set of training jokes. If more than one text containing a given wordplay was found, the text with the closest overall meaning to the punchline was selected. Arbitrary texts were not used, as they did not contain a desired combination of wordplay and part of punchline.

To construct the bigram table, every pair of words occurring in the selected text was entered into the table.

The concept of this wordplay recognizer is similar to an N-gram. For a wordplay recognizer, the bigram model is used.

The output from the wordplay generator was used as input for the wordplay recognizer. An utterance produced by the wordplay generator is decomposed into a string of words. Each word, together with the following word, is checked against the database.

An N-gram determines for each string the probability of that string in relation to all other strings of the same length. As a text is examined, the probability of the next word is calculated. The wordplay recognizer keeps the number of occurrences of word sequence, which can be used to calculate the probability. A sequence of words is considered valid if there is at least one occurrence of the sequence anywhere in the text. The count and the probability are used if there is more than possible wordplay. In this case, the wordplay with the highest probability will be considered first.

For example, in $Joke_3$ 'what are' is a valid combination if 'are' occurs immediately after 'what' somewhere in the text.

Joke Recognition

A text with valid wordplay is not a joke if the rest of the punchline does not make sense. For example, if the punchline of $Joke_3$ is replaced with "Water a text with valid wordplay," the resulting text is not a joke, even though the wordplay is still valid. Therefore, there has to be a mechanism that can validate that the found wordplay is "compatible" with the rest of the punchline and makes it a meaningful sentence.

A concept similar to a trigram was used to validate the last sentence. All three-word sequences are stored in the trigram table.

The same training set was used for both the wordplay and joke recognizers. The difference between the wordplay recognizer and joke recognizer was that the wordplay recognizer used pairs of words for its validation while the joke recognizer used three words at a time. As the training text was read, the newly read word and the two following words were inserted into the trigram table. If the newly read combination was in the table already, the count was incremented.

As the wordplay recognizer had already determined that the wordplay sequences existed, there was no reason to re-validate the wordplay.

To check if wordplay makes sense in the punchline, the last two words of the wordplay, $\mathbf{w_{wp1}}$ and $\mathbf{w_{wp2}}$, are used, for the wordplay that is at least two words long. If the punchline is valid, the sequence of $\mathbf{w_{wp1}}$, $\mathbf{w_{wp2}}$, and the first word of the remainder of the sentence, $\mathbf{w_s}$, should be found in the training text. If the sequence $<\mathbf{w_{wp1}}\ \mathbf{w_{wp2}}\ \mathbf{w_s}>$ occurs in the trigram table, this combination is found in the training set, and the three words together make sense. If the sequence is not in the table, either the training set is not accurate, or the wordplay does not make sense in the punchline. In either case, the computer does not recognize the joke. If the previous check was successful, or if the wordplay has only one word, the last check can be performed. The last step involves the last word of the word play, $\mathbf{w_{wp}}$, and the first two words of the remainder of the sentence, $\mathbf{w_{s1}}$ and $\mathbf{w_{s2}}$. If the sequence $<\mathbf{w_{wp}}\ \mathbf{w_{s1}}\ \mathbf{w_{s2}}>$ occurs in the trigram table, the punchline is valid, and the wordplay fits with the rest of the final sentences.

If the wordplay recognizer found several wordplays that "produced" a joke, the wordplay resulting in the highest trigram sequence probability was used.

Results and Analysis

A set of 65 jokes from the "111 Knock Knock Jokes" website[3] and one joke taken from "The Original 365 Jokes, Puns & Riddles Calendar" (Kostick, et al., 1998) was used as a training set. The Similarity Table, discussed in the Section on *Generation of Wordplay Sequences*, was modified with new entries until correct wordplay sequences could be generated for all 66 jokes. The training texts inserted into the bigram and trigram tables were chosen based on the punchlines of jokes from the set of training jokes.

The program was run against a test set of 130 KK jokes, and a set of 65 non-jokes that have a similar structure to the KK jokes.

The test jokes were taken from "3650 Jokes, Puns & Riddles" (Kostick, et al. 1998). These jokes had the punchlines corresponding to any of the three KK joke structures discussed earlier.

To test if the program finds the expected wordplay, each joke had an additional line, Line_6, added after Line_5. Line_6 is not a part of any joke. It only existed so that the wordplay found by the joke recognizer could be compared against the expected wordplay. Line_6 consists of the punchline with the expected wordplay instead of the punchline with Line_3.

The jokes in the test set were previously "unseen" by the computer. This means that if the book contained a joke, identical to the joke in the set of training jokes, this joke was not included in the test set.

Some jokes, however, were very similar to the jokes in the training set, but not identical. These jokes were included in the test set, as they were not the same. As it turned out, some jokes to a human may look very similar to jokes in the training set, but treated as completely different jokes by the computer.

Out of 130 previously unseen jokes the program was not expected to recognize eight jokes. These jokes were not expected to be recognized because the program is not expected to recognize their structure.

The program was able to find wordplay in 85 jokes, but recognized only seventeen jokes as such out of 122 that it could potentially recognize. Twelve of these jokes have the punchlines that matched the expected punchlines. Two jokes have meaningful punchlines that were not expected. Three jokes were identified as jokes by the computer, but their punchlines do not make sense to the investigator.

Some of the jokes with found wordplay were not recognized as jokes because the database did not contain the needed sequences. When a wordplay was found, but the needed sequences were not in the database, the program did not recognize the jokes as jokes.

In many cases, the found wordplay matched the intended wordplay. This suggests that the rate of successful joke recognition would be much higher if the database contained all the needed word sequences.

The program was also run with 65 non-jokes. The only difference between jokes and non-jokes was the punchline. The punchlines of non-jokes were intended to make sense with Line_3, but not with the wordplay of Line_3. The non-jokes were generated from the training joke set. The punchline in each joke was substituted with a meaningful sentence that starts with Line_3. If the keyword was a name, the rest of the sentence was taken from the texts in the training set. For example, Joke_6 became Text_1 by replacing "time for dinner" with "awoke in the middle of the night."

Joke_6: Knock, Knock
Who's there?
Justin
Justin who?
Justin time for dinner.

Text_1: Knock, Knock
Who's there?
Justin
Justin who?
Justin awoke in the middle if the night.

A segment "awoke in the middle of the night" was taken from one of the training texts that was inserted into the bigram and trigram tables.

The program successfully recognized 62 non-jokes.

Possible Extensions

The results suggest that most jokes were not recognized either because the texts entered did not contain the necessary information for the jokes to work; or because N-grams are not suitable for true "understanding" of text. One of the simpler experiments may be to test to see if more jokes are recognized if the databases contain more sequences. This would require inserting a much larger text into the trigram table. A larger text may contain more word sequences, which would mean more data for N-grams to recognize some jokes.

It is possible that no matter how large the inserted texts are, the simple N-grams will not be able to "understand" jokes. The simple N-grams were used to understand or to analyze the punchline. Most jokes were not recognized due to failures in sentence understanding. A more sophisticated tool for analyzing a sentence may be needed to improve the

[3] http://www.azkidsnet.com/JSknockjoke.htm

joke recognizer. Some of the options for the sentence analyzer are an N-gram with stemming or a sentence parser.

A simple parser that can recognize, for example, nouns and verbs; and analyze the sentence based on parts of speech, rather than exact spelling, may significantly improve the results. On the other hand, giving N-grams the stemming ability would make them treat, for example, "color" and "colors" as one entity, which may significantly help too.

The wordplay generator produced the desired wordplay in most jokes, but not all. After the steps are taken to improve the sentence understander, the next improvement should be a more sophisticated wordplay generator. The existing wordplay generator is unable to find wordplay that is based word longer than six characters, and requires more that three substitutions. A better answer to letter substitution is phoneme comparison and substitution. Using phonemes, the wordplay generator will be able to find matches that are more accurate.

The joke recognizer may be able to recognize jokes other than KK jokes, if the new jokes are based on wordplay, and their structure can be defined. However, it is unclear if recognizing jokes with other structures will be successful with N-grams.

Summary and Conclusion

Computational work in natural language has a long history. Areas of interest have included: translation, understanding, database queries, summarization, indexing, and retrieval. There has been very limited success in achieving true computational understanding.

A focused area within natural language is verbally expressed humor. Some work has been achieved in computational generation of humor. Little has been accomplished in understanding. There are many linguistic descriptive tools such as formal grammars. But, so far, there are not robust understanding tools and methodologies.

The KK joke recognizer is the first step towards computational recognition of jokes. It is intended to recognize KK jokes that are based on wordplay. The recognizer's theoretical foundation is based on Raskin's Script-based Semantic Theory of Verbal Humor that states that each joke is compatible with two scripts that oppose each other. The $Line_3$ and the wordplay of $Line_3$ are the two scripts. The scripts overlap in pronunciation, but differ in meaning.

The joke recognition process can be summarized as:

$Step_1$: joke format validation
$Step_2$: generation of wordplay sequences
$Step_3$: wordplay sequence validation
$Step_4$: last sentence validation

The result of KK joke recognizer heavily depends on the choice of appropriate letter-pairs for the Similarity Table and on the selection of training texts.

The KK joke recognizer "learns" from the previously recognized wordplays when it considers the next joke. Unfortunately, unless the needed (keyword, wordplay) pair is an exact match with one of the found (keyword, wordplay) pairs, the previously found wordplays will not be used for the joke. Moreover, if one of the previously recognized jokes contains (keyword, wordplay) pair that is needed for the new joke, but the two words that follow or precede the keyword in the punchline differ, the new joke may not be recognized regardless of how close the new joke and the previously recognized jokes are.

The joke recognizer was trained on 66 KK jokes; and tested on 130 KK jokes and 66 non-jokes with a structure similar to KK jokes.

The program successfully found and recognized wordplay in most of the jokes. It also successfully recognized texts that are not jokes, but have the format of a KK joke. It was not successful in recognizing most punchlines in jokes. The failure to recognize punchline is due to the limited size of texts used to build the trigram table of the N-gram database.

While the program checks the format of the first four lines of a joke, it assumes that all jokes that are entered have a grammatically correct punchline, or at least that the punchline is meaningful. It is unable to discard jokes with a poorly formed punchline. It may recognize a joke with a poorly formed punchline as a meaningful joke because it only checks two words in the punchline that follow $Line_3$.

In conclusion, the method was reasonably successful in recognizing wordplay. However, it was less successful in recognizing when an utterance might be valid.

On the Usefulness and Limitations of Diagrams in Statistical Training

Atsushi Terao (atsushi@edu.hokudai.ac.jp)
Graduate School of Education, Hokkaido University
Kita 11 Nishi 7, Sapporo 060-0811 Japan

Abstract

The purpose of this study was to examine the usefulness and limitations of vector diagrams, consisting of lines with arrows representing variables, in statistical training. Nineteen undergraduates learned advanced level statistics either with vector diagrams or in the conventional way and solved three problems. Vector diagrams sometimes helped the students understand descriptions in the text which were difficult in conventional explanations, but caused other difficulties. Vector diagrams were useful for solving one of the three problems, but not the other two. It is concluded that a property of diagrams or formulae can be a double-edged sword.

Students who are majoring in psychology or other relevant disciplines have to study statistics. Despite substantial effort by teachers, understanding statistics is often difficult for many students. This paper reports the results of a practical experiment in which the students learned to employ either "vector diagrams" or a conventional formula-based approach to the basics of regression analysis. The students were then asked to solve three problems using the given technique they learned.

Unlike many previous studies on using diagrams in educational settings, which focus only on the usefulness of diagrams, this study also investigates limitations of diagrams. Research on diagrammatic reasoning has found many "good" properties of diagrams (e.g., Barwise & Etchmendy, 1996; Cheng & Simon, 1995; Larkin & Simon, 1987). The researchers seem to consider these properties as if they are always support (at least do not impair) understanding and problem solving. The results of this study suggest that the same property, which definitely makes the solution of a problem easy, sometimes makes another problem difficult. Similarly, the results suggest that formulae do not necessarily have "bad" properties.

The vector diagrams used in this study consist of several vectors drawn as lines with arrows, each of which corresponds to a variable. For example, the correlation coefficient is defined as $\cos\theta$ where θ is the angle between two vectors, $\vec{x} = \{x_1 - \bar{x}, \cdots, x_n - \bar{x}\}$ and $\vec{y} = \{y_1 - \bar{y}, \cdots, y_n - \bar{y}\}$. The regression analysis is described as the projection of the dependent variable (actually the vector of the dependent variable like $\vec{y}$ in Figure 1) on the linear space of independent variables ($\vec{x_1}$ and $\vec{x_2}$ in Figure 1).

Tasks and Prediction

These are two basic assumptions in this study about the nature of diagrammatic and algebraic representations and operators.

One assumption is that the diagrammatic representation of a problem affords a far smaller number of operators than the algebraic representations of that problem. This assumption is two-fold. First, the problem space (the set of all possible problem states) is smaller when a problem is represented by a diagram. In the chapters on vectors in mathematics textbooks, the only diagrammatic operators one can commonly find are: extension (or reduction), rotation, projection, and (de)composition. Algebraic representations, by contrast, allow many kinds of manipulations such as the four basic operations of arithmetic, expansion or factorization, fraction operations, root operations (e.g., $\sqrt{a} * \sqrt{b} = \sqrt{ab}$), summation operations (e.g., $\sum(a + b) = \sum a + \sum b$), substitution, and so on. Second, I assume that the search space (the set of problem states a student actually considers), is also smaller when a problem is represented by a diagram. Whether a problem is represented by a diagram or a formula, students do not consider all possible operators because in each case some operators are difficult to use.

The other assumption is that a formula and its transformation become more concrete when they are connected to a diagram. This assumption seems to have no room for doubt because connecting a formula to a diagram increases the number of attributes the formula has. This assumption is related to the first assumption. Because of the limited number of diagrammatic operators, "diagrammatic inference" often requires using algebraic representations, although the diagrams play a crucial role in the inference. This means that students often have to do "heterogeneous inference," inference that use multiple forms of representation (Barwise & Etchemendy, 1996).

This study claims that any property of diagrams or formulae can be either a help or a hindrance in problem solving. For example, considering only a

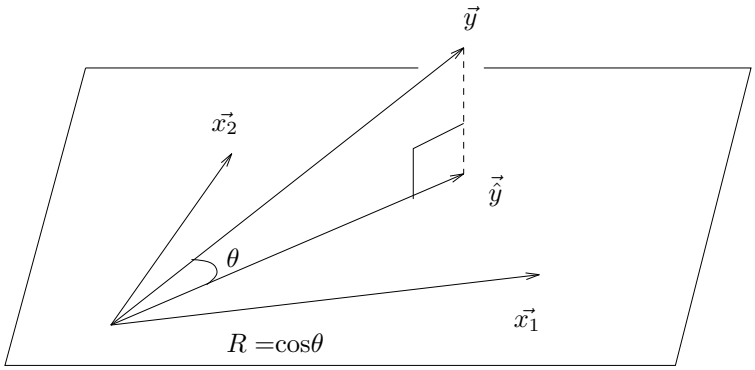

Figure 1: The definition of the multiple correlation coefficient R using a vector diagram

Table 1: Three Problems used in This Study.

Problem 1: The multiple correlation coefficient R indicates the goodness of fit of the model in multiple regression analysis. Consider the multiple correlation coefficient "R" in the case of simple regression. Please explain the relationship between this R and r, the simple correlation coefficient for the two variables x and y.
Problem 2: In the case of simple regression, if the number of paired values (x_i, y_i) is two, we can describe the values of one variable by using the other variable without any error, indicating $r = +1$ or -1. Give an explanation for the reason of this perfect description.
Problem 3: Explain the relationship between the regression coefficient $\hat{a_1}$ ($= S_{xy}/S_{xx}$) and the correlation coefficient r in the case of simple regression by using only the two variances S_{xx} and S_{yy}. S_{xy} means the covariance for the two variables x and y.

small number of diagrammatic operators can serve either as a constraint on the search (This is expected to be the case in Problem 1 in Table 1, as described below), or as a limitation if the correct solution path is outside of the search space (This is expected to be the case in Problem 2). The abstractness of formulae also can be an advantage or a disadvantage (This contrast is expected to be shown between Problem 1 and Problem 3).

Problem 1 If students learn regression analysis in a conventional way, R is defined by the formula

$$R = \frac{\frac{1}{n}\sum(y_i - \bar{y})(\hat{y}_i - \bar{\hat{y}})}{\sqrt{\frac{1}{n}\sum(y_i - \bar{y})^2}\sqrt{\frac{1}{n}\sum(\hat{y}_i - \bar{\hat{y}})^2}}.$$

This formula means that R is defined as the correlation coefficient between the expected value $\hat{y}$ and the observed value y. In the case of simple regression, we can say $\hat{y}_i = a_0 + a_1 x_{i1}$ and $\bar{\hat{y}} = a_0 + a_1 \bar{x}_1$. If these relations are used in the formula for R then the conclusion $R = |r|$ is obtained after a long series of algebraic manipulations.

Using a vector diagram, R is defined as $\cos\theta$ for two vectors $\vec{\hat{y}} = \{\hat{y}_1 - \bar{\hat{y}}, \cdots, \hat{y}_n - \bar{\hat{y}}\}$ and $\vec{y} = \{y_1 - \bar{y}, \cdots, y_n - \bar{y}\}$ as shown in Figure 1. Vector $\vec{\hat{y}}$ is the orthogonal projection of $\vec{y}$ on the plane spanned by $\vec{x}_1$ and $\vec{x}_2$. If we delete $\vec{x}_2$ from Figure 1 and redraw the orthogonal projection, we will obtain the answer as shown in Figure 2.

According to the basic assumption mentioned above, the problem/search space of the diagrammatic version of this problem is assumed to be smaller than the problem/search space of the formula version. The solution with vector diagram, consequently, should require less computation than the conventional solution. Note that in both solutions we started with the definition of R. In general, diagrammatic approaches often require less computation than conventional approaches (Cheng, 1992).

Other than the small problem/search space of the diagrammatic solution, the concreteness of diagrammatic operators also can contribute to finding the answer to this problem. In contrast, the formula version of the definition of R and its transformation are more abstract with no diagrammatic meaning, and the solution is a pure algebraic solution. Cheng and Simon (1995) pointed out that conventional mathematical approaches are often more complex than diagrammatic approaches because the bulk of the reasoning must center around abstract equations.

We therefore predict that a group of students which uses a vector diagram to solve this problem will show better performance than another group of students which tries to solve it in a conventional way.

In this study, after trying to solve the problems, the students read the correct solution and evaluated

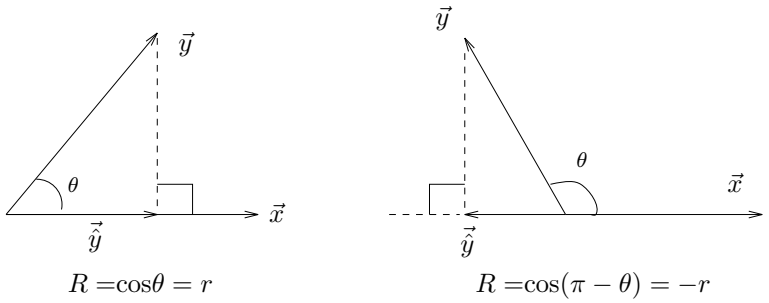

Figure 2: The answer to Problem 1 with vector diagrams

the degree of their understanding (to what degree they could understand the solution) and the degree of their conviction (to what degree they could accept it) on a 5-point scale. In Problem 1, we can expect some differences in these scores in accordance with the difference in difficulty of problem solving. However, there may be no difference in these evaluations between the two groups of the students. Even if it is difficult to make a long sequence of appropriate operators by their own efforts, just following the correct sequence may not be a tough task as long as the students are familiar with these operators.

Problem 2 This problem was chosen in this study to show that the limited number of diagrammatic operators, which is the property of vector diagrams considered to make Problem 1 easy, can also be a hindrance in problem solving. Among diagrammatic operators one can find in mathematics textbooks, I assume that the decomposition of a vector is relatively difficult to use for students because the pair of vectors that would be generated does not exist in the current problem state. If a diagrammatic solution of a problem requires students to use the decomposition operator, the correct solution path is likely to be outside of the search space, although this path is in the problem space. A crucial difference between the vector solutions of Problem 1 and 2 is in whether the correct solution path is within the search space or not, although some other differences remain uncontrolled. This experiment puts the external validity above the internal validity, and it is difficult in this kind of practical study to strictly control all factors.

In many conventional textbooks, the correlation coefficient is explained with a scatter diagram. In the case of Problem 2, two points will be plotted on the scatter diagram. The regression straight line is uniquely specified because two points define a unique line. For this problem, the comparison is not diagram vs. algebra but vector diagram vs. conventional way.

A vector diagram which can be used to solve this problem is shown in Figure 3. The vector $\vec{x}$ lies at right angles to the vector $(\bar{x}, \bar{x})$; the vector $\vec{y}$ lies at right angles to the vector $(\bar{y}, \bar{y})$. Students could find these spatial relations by drawing a diagram of concrete data chosen arbitrarily or by calculating the inner product. The fact that the vector $\vec{x}$ is parallel to the vector $\vec{y}$ means that the vector $\vec{y}$ is described as $\alpha\vec{x}$ where α is a scalar. Note that this solution needs only one kind of diagrammatic operator: Participants need to decompose each of (x_1, x_2) and (y_1, y_2) into two vectors as shown in Figure 3.

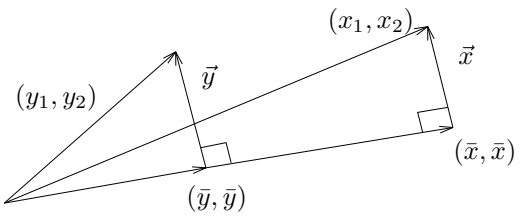

Figure 3: A vector diagram used to solve Problem 2

Our prediction is that the difficulty of using the decomposition operator will impair performance of the students. It is also expected that these students will have trouble in understanding and accepting the correct solution because the decomposition would be outside of the search space. This is contrary to the case of algebraic solution of Problem 1 because all problem states in this solution are expected to be included in the search space.

Problem 3 This problem was chosen to use in this experiment to show that the abstractness of algebraic solutions can sometimes help problem solving. Recall that it is thought that this property of formulae would make difficult the algebraic solution of Problem 1.

A conventional solution to this problem consists of a sequence of simple transformations of the equation defining the regression coefficient:

$$\hat{a}_1 = \frac{S_{xy}}{S_{xx}} = \frac{S_{xy}}{\sqrt{S_{xx}}\sqrt{S_{yy}}} \times \frac{\sqrt{S_{yy}}}{\sqrt{S_{xx}}} = r_{xy} \times \frac{\sqrt{S_{yy}}}{\sqrt{S_{xx}}}.$$

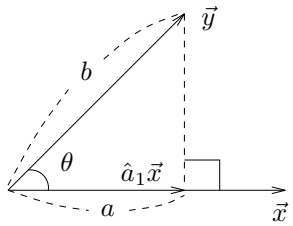

Figure 4: A vector diagram used to solve Problem 3

The transformations used in this solution look very formal and it is difficult to find any concrete meaning in them. For example, $\sqrt{S_{yy}}$ is forced to be put into the formula but this looks like a manipulation without any concrete meaning.

This problem represents a class of problems which could not be solved by purely diagrammatic thinking; rather, it requires heterogeneous inference, recruiting both diagrammatic and algebraic representations. Figure 4 shows a vector diagram which can be used to solve this problem. If two relations $a = \hat{a}_1\sqrt{\sum(x_i - \overline{x})^2}$ and $b = \sqrt{\sum(y_i - \overline{y})^2}$ are put into the equation $r = \cos\theta = \frac{a}{b}$, we will obtain the correct answer. The diagram gives some concrete meaning to this solution (the second basic assumption in this study mentioned above).

The prediction is that the students who use a purely algebraic approach will show better performance than the students who try to use a vector diagram. As mentioned in Problem 1, conventional algebraic approaches are often more complex than diagrammatic approaches because the bulk of the reasoning must center around abstract equations (Cheng & Simon, 1995). This study, however, claims that the abstractness of algebraic manipulation is not a "bad" property of formulae by nature. Heterogeneous inference requires students to use multiple representations simultaneously and it can burden students with a cognitive load. A pure diagrammatic solution, if any, is thought to be easier if this solution is as simple as the algebraic part of the heterogeneous inference.

We can expect some differences in the score of understanding and acceptance in accordance with the difference in difficulty of problem solving. However, similar to the case of Problem 1, there may be no difference in these evaluations between the two groups of students because just following the solution steps might not be very difficult.

Method

Participants

Participants were 19 undergraduate students majoring in psychology at Wakayama University, Japan. They had all taken or were taking a first introductory statistics course for psychology students, but did not know about the regression analysis taught in this experiment. In Japan, most of the undergraduate students learn algebra and vectors in high schools. This means they are ready for learning statistics either by conventional method or by an alternative, diagrammatic method.

Design

There were two experimental groups. In *formula* group, participants studied the basics of regression analysis in the conventional way in which formulae were mainly used. In *vector* group, the basics of regression analysis were taught with vector diagrams. The participants were assigned to one of these groups.

Before this experiment, participants received a simple pretest, the purpose of which was to evaluate their basic knowledge of statistics. This pretest consisted of five items, which required students to write formulae of mean, variance, SD, covariance, and correlation coefficient. Students got one point for each correct answer giving a maximum score of 5 points.

I tried to make sure that the two groups were of roughly comparable ability. Based on the results of the pretest, students were divided into nine pairs with one left over. Paired students' scores differed by a maximum of one point. Within a pair, the students were randomly assigned to one of the two groups. One remaining participant was assigned to the vector group. Thus, the vector group had 10 and the formula group had 9 participants. The two groups had roughly comparable spread of ability.

Materials

The text material was written by the author because no appropriate material was found. Two types of textual material was used corresponding to the two groups. To make these two textual materials have the same difficulty as much as possible, I first wrote the material to be used in the formula group and then "translated" it into the text used in the vector group.

Three problems shown in Table 1 were used in this experiment. All of the statistical concepts that were needed to solve these problems were explained in the textual material for both groups. Because of space limitation, I omit the detailed description of the content of these textual materials.

Procedure

There were two sessions in this experiment: understanding the text material, and problem solving. The experiment was conducted in groups of 3 to 8 participants.

In the first session, participants tried to understand the text material. If they found a description that was difficult to understand, they were required to underline that part in the textbook and to note the reason for the difficulty in the margin. The participants took about one hour to finish this session although there was no time limit.

After reading the text material, each participant reported to the experimenter (i.e. me) their difficulties in understanding the text. The experimenter gave each participant additional explanations about the difficult points in the text. All of the questions were resolved before the participants proceeded to the second session.

In the second session, the three problems shown in Table 1 were presented one by one. Fifteen minutes were allocated to solving each problem. Participants were allowed to look at the text material at any time. All participants were given a paper-and-pencil version of the test.

The participants received the correct answer after they had finished trying to solve each problem. They were required to evaluate to what degree they could understand

each solution and to what degree they could accept it on a 5-point scale ranging from 1: "very difficult to understand (or accept)" to 5: "very easy to understand (or accept)."

Results

Understanding text

It turned out that the two textual materials were similar in the sense that they had almost the same difficulty. Column 4 in Table 2 presents the number of descriptions reported as being difficult to understand in the text for each participant. There was very little difference in the number of reported difficulties during the learning session between the two groups in this experiment. The number was 8 in the formula group and 9 in the vector group.

A closer look at the reported difficulties revealed that vector diagrams often helped the students in understanding several points in which the students in the formula group had a difficulty, while other obstacles arose with vector diagrams. In the formula group, 5 of 9 participants (N, P, Q, R and S) said that it was difficult to understand the proof which showed that the range of correlation coefficient is from -1 to $+1$. Two participants (O and S) found difficulty in understanding the reason why dividing covariance by two standard deviations was the most proper way to capture the relation between two variables. One participant (R) said that she had trouble in understanding where a_0 and a_1 in the formula $\hat{y}_i = a_0 + a_1 x_i$ came from. In the vector group, all these points were not problematic for the students. No students in this group reported any difficulties in understanding the corresponding points in their textual material. Instead, they had trouble in understanding other points. Four of the 10 participants (D, G, H, and J) said that they did not know the concept of orthogonal projection (see Figure 1). Two participants (G and H) said understanding inner product—which was used in this group to define correlation coefficient—was difficult. Two participants (H and I) had difficulty in imagining n-dimensional vectors. One participant said the equation which describes the relation between the variance and a vector was difficult.

Problem solving

Columns 5, 8 and 11 in Table 2 present the performance of each participant and success S (%) in problem solving for each group; F means failure in problem solving. For each problem, the two columns to the right of the column indicating success or fail in problem solving show participants' self-evaluation of the degree of understanding and acceptance of the correct solution presented after their attempt at problem solving.

All in all, the results supported our prediction.

Problem 1 Vector representations facilitated solution of Problem 1. In the vector group, one participant (Participant F in Table 2) reached the conclusion $R = |r|$ and 5 participants found the answer $R = r$ in the case of $r \geq 0$. All of these students used vector diagrams. In the formula group, no participant got the answer $R = |r|$ or $R = r$ to this problem. The difference in success S (%) between the two groups was significant (Fisher's exact test, $p = .011$).

No significant difference was found in the self-evaluation scores for understanding and acceptance of the given correct solution.

Problem 2 and 3 In contrast to the good performance on Problem 1, no participant in the vector group succeeded in solving Problem 2 and Problem 3. The participants in the formula group showed relatively good performance. The difference in success S (%) between the two groups was significant in Fisher's exact test, $p = .003$ for Problem 2 and $p = .011$ for Problem 3.

The scores for understanding and acceptance of the correct solution to Problem 2 in the vector group were lower than the scores in the formula group. The differences in means between the two groups were significant, $t(9.0) = 5.28, p = .001$, for understanding; $t(17) = 3.15, p = .006$, for acceptance.

There was no significant difference in the scores of the two groups for understanding and acceptance in Problem 3.

Discussion

The limited number of diagrammatic operators can make the problem space smaller, and raise the probability of reaching the correct answer. We predicted that this property would improve performance on Problem 1 and the results supported this prediction. Formulae allow students to do many kinds of manipulation. For example, in Problem 1, participant R tried to get $R \times \frac{1}{r}$ and participant M considered $\frac{\{1/n \sum (x_i - \bar{x})(y_i - \bar{y})\}^2}{R}$. Note that it is next to impossible to do these manipulations on a vector diagram. If a diagram rules out these messy manipulations, it must be a big help for students.

Interestingly, the same property, namely, affording a small number of operators, could prevent students from finding the solution and understanding an explanation. This is the case in Problem 2. No participant in the vector group succeeded in solving this problem. The participants also had trouble in understanding and accepting the correct answer to this problem. After the experiment, participant A told me that understanding the decomposition of vectors was difficult, especially, $(\bar{x}, \bar{x})$ and $(\bar{y}, \bar{y})$ looked strange. This feedback suggests that the students were likely to rule out the decomposition operator necessary

Table 2: Summary of the Data from Experiment 2.

Ac: the score of evaluating the degree of acceptance of the correct solution (1–5)

to solve this problem. The low ratings for understanding and acceptance of the correct answer refute the possibility that the inability to solve this problem means that the participants carelessly failed to apply a familiar operator.

Similar to the case of properties of diagrams, a property of formulae can be either an advantage or a disadvantage. Abstractness is an example of such properties. This property was predicted to work against solving Problem 1 but to be an aid in solving Problem 3 in the formula group. The results of the experiment were consistent with this prediction. A formula and its transformation become more concrete when they are connected to a diagram. This is the case in heterogeneous inference, inference that use both diagrammatic and algebraic representations. A pure diagrammatic solution is easier if this solution is as simple as the algebraic part of the heterogeneous inference.

Conclusion

Previous research on diagrammatic reasoning has pointed out many "good" properties of diagrams and has claimed advantage for diagrammatic approaches over conventional (usually algebraic) approaches. From the results presented here, it seems that the story is not so simple. The results of this experiment indicate that the vector diagram is not a panacea for students struggling with statistics. The same property of certain diagrams or formulae can be either an advantage or a disadvantage. Teachers should keep this in mind and ponder how properties of diagrams or formulae can work in a particular situation.

Abstract

The purpose of this fMRI study was to provide evidence for the mathematician's belief that mathematical thinking emerges from the interplay between symbolic and visuo-spatial systems. Twelve participants were given algebra word problems and depicted the quantitative relations on a mental number line or made parts of an equation. The regions activated in depicting the picture were also recruited to make an equation.

Mathematics is a language. Many scientists say that mathematics is a language to describe the nature of phenomena they are looking at. It is well known that Nicolas Burubaki, a group of mathematicians, stressed the crucial role of formal symbol systems in mathematics.

On the other hand, many mathematicians and physicists emphasize the role of visuo-spatial reasoning in mathematics, which recruits qualitative, language-independent representations. For example, Albert Einstein stated "Words and language, whether written or spoken, do not seem to play any part in my thought process."

As Dehaene, Spelke, Pinel, Stanescu, and Tsivkn (1999) suggested, mathematical thinking may emerge from the interplay between symbolic and visuo-spatial systems. In this fMRI study, we approach this problem and provide evidence for this kind of mathematical thinking.

Psychological studies have revealed that if a problem apparently looks like a pure symbolic task, it can require students to have some visuo-spatial representations. For example, Griffin, Case and Siegler (1994) showed that the mental "number line", a qualitative representation of the number system, is crucial readiness for early arithmetic. Lewis used a number-line-like diagram to train undergraduate students having difficulty to solve "compare" word problems (problems containing more-than or less-than relations), and succeeded in improving their performance. Paige and Simon (1966) proposed that solving word problems is not a simple translation of problem sentences into equations, as Bobrow's (1966) STUDENT did, but needs "physical cues," a visuo-spatial representation. The 6th grade students who used our "Picture Algebra" strategy (Koedinger & Terao, 2002) to solve the compare word problem showed relatively high performance. We expect that using this strategy may better prepare students to learn formal algebra.

Functional magnetic resonance imaging (fMRI) gives us a new source of information about the mental representations used in mathematics. Dehaene et al. (1999) showed two different mental representations are used for different tasks. Exact calculation (e.g., 4+5=9) elicited left-lateralized activation in the left inferior frontal lobe, together with left angular gyrus and left anterior cingulate. This pattern was interpreted as suggesting that the participants recruited their symbolic systems and did language dependent encoding. Approximation (e.g., 4+5 is closer to 8 than 6), on the contrary, elicited bilateral parietal lobes activation. This pattern was interpreted as suggesting that the participants recruited visuo-spatial systems and did language independent encoding. Dehaene, Piazza, Pinel and Cohen (2003) reviewed neuro-imaging and neuropsychological evidence concerning various numerical tasks and proposed a hypothesis that three parietal circuits are related to number processing. The horizontal segment of the intraparietal sulcus (HIPS) appears to be a core quantity system, analogous to a mental number line. This area seems to be supplemented by two other circuits. One is the bilateral posterior superior parietal lobule (PSPL), which is considered to be involved in attention orientation on the mental number line. The other is the left angular gyrus, which is likely to support manipulations of numbers in a symbolic form (e.g., exact calculation).

Dehaene et al. (1999, 2003) suspected that mathematical thinking may emerge from the interplay between symbolic and visuo-spatial systems but did not provide direct evidence for this idea. For example, exact calculation and approximation mainly depend on the symbolic system and the visuo-spatial system, respectively, not necessarily a collaboration between these two systems.

In this study, we try to provide direct evidence for such a collaboration. We decided to use algebra word problems for three reasons. First, previous psychological research suggests that visuo-spatial reasoning plays a crucial role in solving these problems while they explicitly require students to use symbols (i.e., equations). This kind of problem is expected to show the interplay between symbolic and visuo-spatial systems. Second, algebra word problems are widely used in school mathematics curriculum, so that we can say the observed interplay is a prevailing form of reasoning, not a special form isolated to a very specific task. Third, there are plenty of studies using algebra word problem, the accumulated findings help us in valid reasoning from our results.

If algebra word problems recruit the visuo-spatial system as well as the symbolic system, we should see activation of some visuo-spatial areas when students try to make a correct equation for a problem. To find visuo-spatial areas, we asked our participants to make a pictorial representation of the problem in one condition. This task should activate visuo-spatial areas and most of these areas should also be activated when we ask the participants to make an equation of the same problem in another condition. We especially expect that the two hypothesized parietal visuo-spatial systems, HIPS and PSPL, show activation in both conditions.

Method

Participants

Participants were 12 right-handed, native English speakers. They were recruited by advertisement posted on an electric bulletin board in Carnegie Mellon University. Participants were provided written informed consent in accordance with the Institutional Review Boards at the University of Pittsburgh and at Carnegie Mellon University.

Tasks and Design

There was one *representation* factor and four *problem* factors. They were all manipulated within subjects. The representation factor was the mental representation the participants made from the problems. In the *picture* condition, the participants draw a mental image describing the critical relations in the problem; in the *equation* condition, the participants were required to construct an equation to the problem.

Table 1 shows two example problems. Each problem consisted of three problem sentences and used three letters as unknown quantities. The first sentence was an assignment sentence. In the equation condition, the participants memorize what letter the "x" is assigned to. In the picture condition, the participants imagined a number line and picked locations for the letters. The second and the third sentences described a qualitative relation between two letters. Hereafter we call them R1 (meaning "Relation 1") and R2, respectively. Participants could not find a numerical solution to these problems because they did not have a sentence referring to the total amount of the three unknown quantities. For example, if the first problem in Table 1 has the sentence "The total of the three quantities is 44," we can make an equation to find the three quantities like x+(x+6)+(x+8)=44. In the equation condition, the participants were told that the total sentence would be omitted and were required to make the left side of the correct equation like x+(x+6)+(x+8). For the first problem in Table 1, the participant can make the parts (x+6) and (x+8) from R1 and R2, respectively. In the picture condition, the participants imagine a picture describing the critical relations in the problem as shown in Figure 1. For the first problem in Table 1, the participants can imagine B to the right of the location A on the mental number line and add the distance, 6, to this picture. When they read and represent R2, the whole picture can be obtained.

Table 1: Sample of Problems.

Consistent/more-than/intransitive problem	
Assignment	x=A
R1	B is 6 more than A.
R2	C is 8 more than A.
Inconsistent/less-than/transitive_n problem	
Assignment	x=A
R1	A is 6 less than B.
R2	B is 2 less than C.

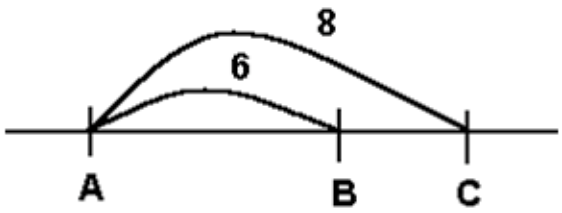

Figure 1: An example of pictures made from problems.

A first problem factor was the relation, whether R1 and R2 use *more-than* or *less-than* relations.

A second problem factor was the consistency, whether the relations used in R1 and R2 were consistent with the correct equation. A more-than problem was labeled either as a *consistent* problem if the correct equation uses "+"or labeled as an *inconsistent* problem if the correct equation uses "-". We use a similar labeling for the less-than problems.

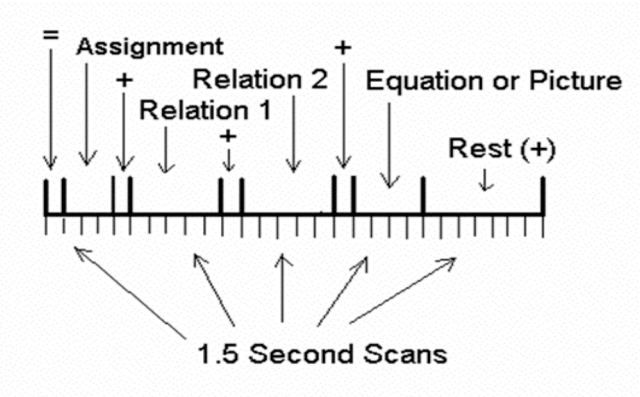

Figure 2: The 42-second structure of an fMRI trial.

A third condition was defined in accordance with the target stimuli presented at the end of each problem (trial). The problem was labeled either as a *correct* problem if the target is the correct target or as an *incorrect* problem if the target is incorrect.

A forth factor was transitivity. This factor was defined by the two relational sentences, R1 and R2. Considering the picture the participants were required to make seems to be an easy way to explain this factor. For the *intransitive* problem, an arc will be drawn over another arc as shown in Figure 1. This will be the case if either the former letter or the latter letter is common in R1 and R2. For example, R1 and R2 of the first problem in Table 1 use the same latter letter (A), and this is an intransitive problem. For the *transitive_n* problem (n stands for Normal), one arc should be drawn at the next position to another arc in the correct picture. A third level of this factor is represented by another problem. This type of problem, called the *transitive_d* problem hereafter (d stands for Delay), was made by changing the R1 and R2 of the transitive_n problem. In the transitive_d problem, participants in the equation condition are not able to make a part of the equation until they read R2. They need to remember R1 and make the two parts of the equation when R2 is presented. The purpose of making this unusual problem was to find brain regions which play a role in making equations going beyond simple encoding of problem sentences. Comparing the transitive_n problem with the transitive_d problem in the time period of presenting R1 might reveal differences between memory and processing areas but we will not say much about this comparison in this paper. There may be no difference between the transitive_n and transitive_d problems in the picture condition because the participants can describe the relation when they see R1. For example, for the transitive_d problem made from the second problem in Table 1 (R1: "B is 2 less than C."), the participants can imagine the spatial relation between B and C by just ignoring A used in the assignment sentence.

Combinations of the four problem factors (2x2x2x3) yielded 24 types of problems. The participants went through all of these 24 types in both the picture condition and the equation condition in the MRI scanner, so that each participant encountered 48 problems. The 48 problems were divided into four blocks: two blocks in the picture condition and the other two blocks in the equation condition.

Procedure

Pre-scan Practice Participants took about 20 minutes of pre-scan practice just before the scan. They went through one block of 12 trials (problems) in the picture condition and another block of 12 trials in the equation condition. Half of the participants started with the picture condition and the other half of the participants started with the equation condition. The time course in each trial was the same as the one in the scanner.

Event-related fMRI scan Event-related fMRI data were collected by using a singe-shot EPI acquisition on a Siemens 3T scanner, 1500 TR, 30 ms TE, 60^0 flip angle, 210 mm FOV, 26 axial slices/scan with 3.2 mm thick, 64x64 matrix, and with AC-PC on the 6^{th} slice from the bottom. There were 28 scans (42 seconds) for each trial, 12 trials for a block and 4 blocks for each participant. Two of these 4 blocks were for the picture condition and the other two blocks were for the equation condition. Half of the participants started with the first block in the picture condition and proceeded to the second block in the equation condition, the third block in the picture condition, and the last block in the equation condition. The other half of the participants started with the first block in the equation condition, then went through picture, equation, and picture conditions in this order.

The protocol of each trial of scan is illustrated in Figure 2. The three problem sentences appeared on the screen one by one. The assignment sentence was on the screen for 3500 ms; R1 and R2 were on the screen for 7500 ms. A target equation or picture was presented after the disappearance of R2. Participants responded to this target by pressing the button. If they thought the target was correct they pressed a button with the index finger of the right hand; if they thought the target is incorrect, they pressed the other button with the middle finger of the right hand.

fMRI data analysis Data processing was conducted using SPM99 software (http://www.fil.ion.ucl.ac.uk/spm/). Slice timing was corrected first and images were realigned. Realigned images were normalized to Talairac coordinates. Normalized images were smoothed with an 8 mm FWHM isotropic Gaussian Kernel. Analysis was carried out using the general linear model with a box-car waveform convolved with a hemodynamic response function. Only correct trials were used for analysis.

To find brain regions of interest (ROI), a random effects model was used. At the first level, mean images for each participant were created, depicting the subtraction of BOLD response during assignment sentence from BOLD response during R1 in each condition (picture and equation). Data from transitive_d problems were excluded to do this subtraction because of the unique nature of these problems. At the second level, these mean images were combined in one-sample *t*-test. We used a height threshold of $P < 0.0005$

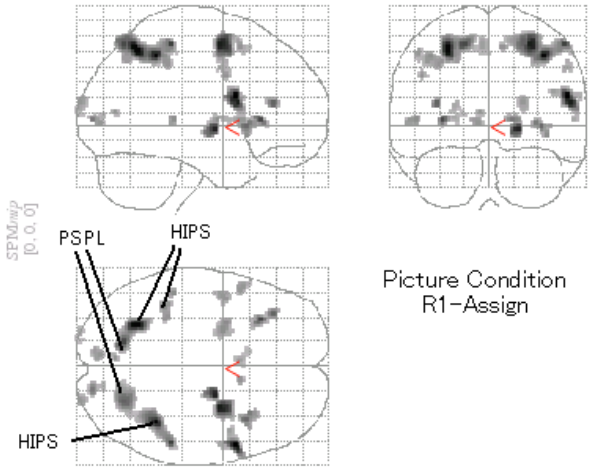

Figure 3: Regions of the brain that show activation in depicting a relation between two quantities in the picture condition as compared to the encoding of the assignment.

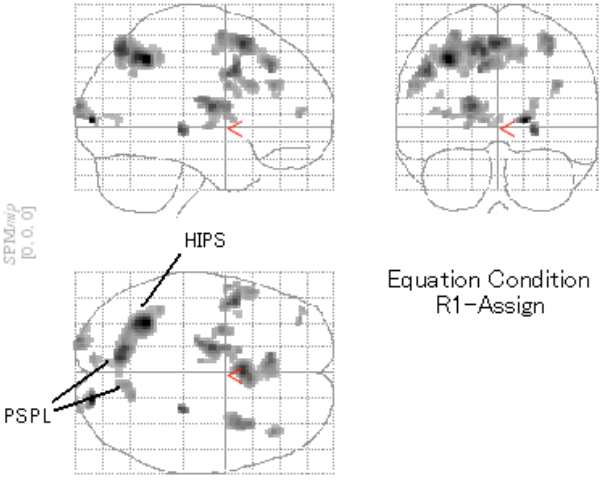

Figure 4: Regions of the brain that show activation in constructing parts of an equation in the equation condition as compared to the encoding of the assignment.

uncorrected (t > 4.44), with an extent threshold of eight contiguous voxels in an ROI. This analysis should show us the regions activated when constructing a number line to describe a quantitative relation or constructing parts of an equation from this relation. The subtraction between picture and equation conditions might be interesting but we did not conduct it, because this subtraction might hide visuo-spatial areas that are recruited not only in picture condition but also in equation condition.

Results

Figure 3 shows the brain regions which show activation during the period of R1 as compared to the assignment sentence in picture condition. We can infer that these regions may be related to using a mental number line to depict a relation between two quantities.

Figure 4 shows the brain regions in the equation condition obtained by the same subtraction (R1 - assignment). These regions should be related to constructing parts of an equation from sentences.

Comparing these two figures, we can see an overlap of activation especially in the parietal lobe (HIPS and PSPL). This means that constructing an equation, which apparently is a symbolic task, recruits the visuo-spatial system.

Areas for constructing a mental number line

A pattern of bilateral activation was obtained for drawing a mental number line to represent a quantitative relation. As we had expected, the active areas in parietal lobes occupied HIPS and PSPL (Tarairach coordinates of main peaks: -40, -40, 48, Z=3.75; -28, -60, 54, Z=4.63; 38, -46, 48, Z=4.62; 24, -68, 56, Z=4.12). Activation was also found during constructing a number line from R1 in the bilateral premotor cortices (-30, 2, 52, Z=3.79; -46, 2, 34, Z=3.72; -48, 0, 50, Z=3.68; 28, -2, 56, Z=4.52; 54, -2, 40, Z=3.51), bilateral supplementary motor areas (-4, 12, 56, Z=3.59; 10, 12, 54, Z=3.73), left Broca area (-52, 12, 4, Z=3.69), right inferior frontal sulcus (54, 8, 20, Z=4.75), left and right insula (-32, 26, 4, Z=4.27; 36, 16, 0, Z=4.05), left and right corpus striatum (20, -6, -2, Z=4.49; -24, -2, 6, Z=3.51), and right DLPFC, dorsolateral prefrontal cortex (-36, 34, 16, Z=4.07). Activation found in left and right visual cortex should reflect longer exposure to the visual stimulus: The period of R1 was longer than the period of assignment sentence.

Areas for constructing an equation

A pattern of left-lateralized activation was obtained for constructing parts of an equation from a sentence referring to a relation between two quantities. The bilateral PSPL and left HIPS activation were also found as in the picture condition (-34, -54, 46, Z=4.93; 16, -62, 50, Z=3.85). This means that the hypothesized parietal visuo-spatial system (Dehaene et al., 2003) was recruited when constructing parts of an equation from a problem sentence. Activation was also found during construction of parts of the equation from R1 in the left premotor cortex (-58, 2, 28, Z=3.87), bilateral supplementary motor areas and right Brodmann area 8 (-28, -2, 62, Z=4.00; -14, 8, 58, Z=3.79; 0, 12, 56, Z=4.53; 34, 8, 58, Z=4.06), bilateral inferior frontal sulci (-38, 8, 22, Z=3.44; -48, 6, 38, Z=4.43), left basal ganglia including thalamus and globus pallidus (-16 -10 14, Z=4.43), right parahippocampal gyrus (24, -30, -2, Z=4.38), and left and right DLPFC (40, 32 28, Z=3.95; -36, 50, 8, Z=3.77).

To confirm that several brain areas activated in picture condition also showed activation in equation condition, we plotted percent signal change along the time course. The base line for calculating the signal change was set by the average of first two scans. Remember that these areas were found in picture condition and no data from equation condition were used. Data from intransitive problems and transitive_n problems were combined in each condition.

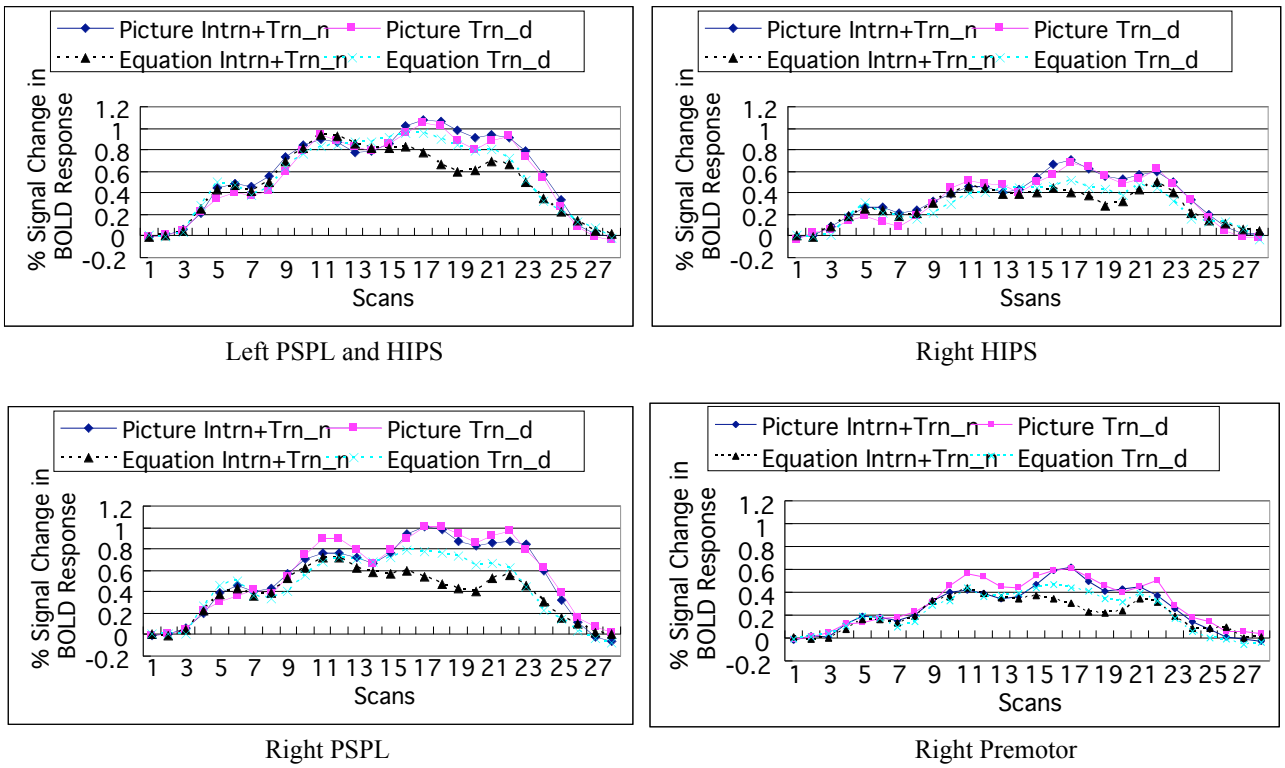

Figure 5: Percent signal change in BOLD response in four ROIs found in picture condition.

After finding ROIs, the signal change was calculated for each of the four problem types (picture--transitive_d, picture--others, equation--transitive_d, and equation--others) and for each participant, and then averaging across the 12 participants. Among many ROIs found in picture condition, because of the limited space of this paper, we only show the percent signal change at left PSPL and HIPS (-28, -60, 54; The number of voxels is 333), right HIPS (38, -46, 48; The number of voxels is 303), right PSPL (24, -68 56; The number of voxels is 241), and right premotor cortex (28, -2, 56; The number of voxels is 220.). These are the four biggest clusters of active voxels.

Figure 5 shows the percent signal change in each of these four ROIs. We can see that these areas found in picture condition also played a role, more or less, in equation condition. Other areas found in picture condition also showed a similar pattern of activation.

Discussion

The results of this experiment indicate that mathematical thinking emerges from the interplay between symbolic and visuo-spatial systems. The hypothesized two parietal visuo-spatial regions (Dehaene et al., 2003) showed activation not only when participants imagined a picture from a problem sentence but also when participants constructed parts of an equation from the sentence. We cannot deny a possibility that these parietal regions are involved in non-visuospatial mathematical reasoning. But it is reasonable we consider them as picture regions until some evidence is fond for this possibility in brain imaging research.

We might expect language areas to show greater activation on these symbolic tasks than in the more visuo-spatial picture task. However, while we found activation in language areas, particularly Broca's and the inferior frontal sulcus, we did not find clear differences in those areas between the two conditions. Perhaps the language areas are doing different kinds of computations in the two conditions, but we found no evidence to support this claim.

Our results seem to be consistent with the recent version of the ACT-R theory (Anderson et al., submitted). The ACT-R theory hypothesizes several buffers and their locations in the brain. For example, the goal buffer is supposed to be in DLPFC and the imaginal buffer in the parietal lobe. The theory also hypothesizes that production rules are stored in the corpus striatum. We found activation in these regions in this experiment. The recent version of ACT-R theory can predict the percent signal change in BOLD response based on the task analysis. We did a task analysis before conducting this experiment. Constructing an ACT-R model could provide us an explanation about the signal change in this experiment.

Readers might suspect that the parietal activation in PSPL and HIPS only reflects longer exposure to the relational sentence R1 (7500 ms) than the assignment sentence (4500 ms). This effect might be the case but it cannot explain the different pattern of activation between the picture and

equation conditions (see Figures 3 and 4) because it should have the same effect in both conditions.

Readers might also suspect that activation of visuo-spatial areas in the equation condition was an effect of use of the mental number line in the picture blocks spilling over to the equation blocks. Because we used a within-subject design, we cannot deny this possibility. Even if it is true, however, it is the effect that we expect in educational settings. Those participants who used visuo-spatial systems on equations may have enhanced their performance. Using a framework of production systems, we can write production rules that represent a purely symbolic processing of a problem sentence. For example, we can think of the following production rule to process R1:

IF x is bind to $A
  and R1 says "$B is $N more than $A
THEN represent $B as x+$N,

where the letter with $ means a variable. Visuo-spatial systems are not necessary if using this kind of production rule but it appears participants still used visuo-spatial reasoning to construct an equation. The following alternative set of production rules illustrates how use of the visuo-spatial systems may make this task easy:

IFR1 says "$B is $N more than $A
THEN
  $B is to the right of $A on the number line

IF x is bind to $A
  and $B is to the right of $A on the number line
THEN represent $B using a plus sign, as x+$N,

If the first production is already exists prior to algebra instruction, the second rule is easier to learn, perhaps, then the one above.

It has been shown that using a pictorial representation helps students solve algebra word problems (e.g., Koedinger & Terao, 2002; Lewis, 1989). These results can be interpreted that the students who learned to use visuo-spatial systems improved their ability to solve algebra word problems. Even if the results of this study only show that students can use visuo-spatial systems to solve algebra word problems only after trained with a pictorial representation, this encourages the educational practice of using a pictorial representation as a scaffold of learning.

There is an interesting episode in the pre-scan, practice session. A few participants showed bad performance in the equation condition. We asked them what they did to make equations. They revealed that they used a "direct translation" strategy which was similar to the strategy Bobrow's (1966) STUDENT used. For example, if R1 says "B is 6 more than A," they translated this sentence into the form of "B=6+A" before substituting "x" for a quantity. This strategy does not seem to need any visuo-spatial reasoning. The fact that the poor performer first used this kind of strategy suggests that students having difficulty with word problems may not learn to make use of visuo-spatial systems.

This study is still in progress and we only have scratched the surface in dada analysis. Further data analysis (e.g., statistical comparisons of the two conditions) should be done and it will provide insight into mathematical thinking.

Conclusion

Mathematical thinking emerges from the interplay between symbolic and visuo-spatial systems. Algebra word problems, which are widely used in current school curriculum, are not a pure language processing task. They appear to depend on the use of visuo-spatial systems.

Conclusion

Mathematical thinking emerges from the interplay between symbolic and visuo-spatial systems. Algebra word problems, which are widely used in current school curriculum, are not a pure language processing task. They appear to depend on the use of visuo-spatial systems.

Abstract

Whenever heterogeneous experts work together, shared knowledge comes into play. In recent years, two important research questions have emerged that we will address in the present paper. First, we analyzed if collaborative problem solving leads to the construction of shared knowledge. The second goal of this study was to demonstrate the assumed positive effect of shared knowledge on collaborative problem solving. Following Newell and Simon's (1972) classic view of problem solving, we distinguish shared knowledge about the initial situation, the goals, and the operators. The kind and amount of prior shared knowledge was varied as an independent variable in four experimental conditions. We showed that participants acquired shared knowledge during the cooperation and that most of this information was correct. Further results indicate that if collaborating partners have knowledge in common, their overall problem solutions are better than if they lack any kind of shared information. However, this effect seems to be mostly due to shared knowledge about initial situation and goals, as this leads to better solutions than shared knowledge about operators.

Introduction

Complex tasks often require the collaboration of experts with heterogeneous background knowledge. If we refer to this kind of collaborative problem solving, the construct of shared knowledge plays a very important role. Two lines of research dealing with the role of shared knowledge can be distinguished. On the one hand, there are studies that address the *acquisition* of shared knowledge in collaborative activities, especially in collaborative learning. On the other hand, many researchers focus on the *effects* of shared knowledge as a prerequisite for effective collaborative problem solving. In the present paper, we will address both issues in a net-based scenario.

Concerning the *acquisition*, it is mostly assumed that collaborative learning leads to the construction of shared knowledge (e.g. Pfister, Wessner, Holmer & Steinmetz, 1999; Roschelle & Teasley, 1995) through interaction and communication (Clark & Brennan, 1991). Although there is evidence for this assumption, this issue is seldom addressed quantitatively. In addition, the possibility of the emergence of false shared knowledge is often neglected. Only a few studies try to quantify the amount of shared knowledge (e.g. Fischer & Mandl, 2000; Jeong & Chi, 2000) and to analyze the way of its emergence (either through individual but similar experience with the learning material or by co-construction). There are several possibilities of co-constructing shared knowledge. One is that two interacting partners mutually build a piece of shared knowledge that contains novel information, which none of them possessed in full before (e.g. Roschelle & Teasly, 1995). Another possibility, analyzed here, is that one person communicates some of his specific information to his partner, so that the latter learns and understands it, which constitutes shared knowledge between the two. One goal of this article is to analyze and quantify if collaborative problem solving leads to the acquisition of shared knowledge and to determine if it is correct or not. As collaborative problem solving also requires participants to communicate and interact in order to find a solution and, furthermore, in this experiment, to represent it in a common whiteboard, we hypothesize that participants will acquire some sort of shared knowledge.

Concerning its' *effects*, shared knowledge is supposed to be an important variable determining the functioning of groups consisting of members with heterogeneous background knowledge (e.g., expert groups; Hinsz, Tindale & Vollrath, 1997, Smith, 1994). Shared knowledge about the distribution of information within the group is regarded as a major constituent of the group's transactive memory system, which guides information encoding and retrieval on the group level (Wegner, 1987). This shared meta-knowledge augments the group's memory capacity and enables effective retrieval of information held by the group members when needed for problem solving (Moreland, Argote & Krishnan, 1996). Shared mental models comprising shared knowledge about task, team, equipment and situation have been found crucial for effective expert team decision making, problem solving and co-ordination in complex dynamic environments (Cannon-Bowers, Salas & Converse, 1993; Rouse, Cannon-Bowers & Salas, 1992). Furthermore, effective communication requires common ground and shared vocabulary (Clark & Brennan, 1991; Waern, 1992). As shown by this brief summary, the importance of shared knowledge for collaborative activities is widely acknowledged throughout the literature, although the term 'shared knowledge' refers to rather different things. Empirical studies on problem solving that demonstrate the effectiveness of shared knowledge are still rare. In the present paper, we therefore want to develop a taxonomy of shared knowledge that is applicable to problem solving activities in general. Furthermore, we will analyze it's facilitating effects in collaborative problem solving and find out whether some components of shared knowledge are more effective than others.

A Taxonomy of Shared Knowledge for Collaborative Problem Solving

In line with Stasser and Titus (1985, 1987) we define *shared* knowledge as the kind of information two or more persons have in common, i.e., possess and understand in essentially the same way. Information available to only one person is called *individual* or *distributed* knowledge. Based on this definition our taxonomy of shared knowledge follows Newell and Simon's (1972) classic view of problem solving. According to Newell and Simon, knowledge about the initial situation, goals and operators is needed to solve a problem. Expanding this view to collaborative problem solving, shared knowledge can be conceptualized as *shared knowledge about the initial situation, the goals and the operators*. This taxonomy provides a more detailed description of shared knowledge and allows for the testing of differential effects of its components. Moreover, it is applicable to any problem without undue commitments concerning specific initial situations, goals and operators.

Analyzing the Effectiveness of Shared Knowledge

Design tasks are a widely used but scarcely investigated example of problem solving (Smith & Browne, 1993; Strube, Garg & Wittstruck, 2002). For our study, we chose the domain of web design with its heavy use of net-based communication between multiple experts as our experimental task: Dyads of subjects adopting the role of an information technology advisor (IT expert) and a representative of a fictitious company (company expert) have to design an online-shop that meets the company's needs. From the perspective of problem solving, the company expert's knowledge is characterized by information about the company's initial situation and goals. The expertise of the IT expert comprises knowledge about operators, i.e., rules to transform the company's goals and constraints into technical solutions.

As hypothesized above, shared knowledge is needed and facilitates collaborative problem solving whenever heterogeneous experts work together. Following this hypothesis and taking into account that individual problem solving requires individual knowledge about initial situation, goals and operators (Newell & Simon, 1972), we assume that collaborative problem solving requires shared knowledge about the initial situation, goals and operators. Therefore, we state the following hypotheses:

1. Shared knowledge, in general, leads to better problem solving performance than a total lack of shared knowledge.
2. Sharing knowledge about all components, the initial situation, goals and operators, is more effective than just sharing knowledge about the initial situation and goals.
3. Shared knowledge about the initial situation, goals and operators is more effective than sharing knowledge about operators alone.
4. Finally, we are interested in the particular difference of shared knowledge about the initial situation and goals as compared to shared knowledge about operators. Information about the initial situation and goals frame the problem and help to decide when a solution is reached. In contrast operators are means to transform one state into another, so we expect that sharing knowledge about the initial situation and goals has different effects than sharing knowledge about operators.

Method

Tasks and Materials

Design Task. Information needed for the design task was provided in two introductory texts, one for the role of the company expert and one for the role of the IT advisor.

After having acquired their task-relevant information (see next section), two participants worked on the design problem, one as the company expert and the other as the IT advisor. They were instructed to discuss solution features of the online-shop in preparation, via chat. Features which were chosen as part of the final solution were to be noted on a common whiteboard.

The introductory text for the company expert comprised 36 knowledge elements, 27 about the company's initial situation (IS) and goals (G), and 9 containing either shared knowledge or irrelevant filler information (depending on the experimental condition). Knowledge about IS and G was considered as a whole because a) this resembles the natural expertise of a company expert, e.g. a manager and b) knowledge elements about IS and G were of the same form, with the only difference that the goals were formulated as a request, e.g. "The company wants their customers to find the desired products quickly and easily". The introductory text for the IT advisor consisted of 27 knowledge elements about operators (O) and 9 shared elements or fillers. The operators had the form of if-then clauses with the 'then' part specifying a technical feature of the solution, and the 'if' part describing constraints to be fulfilled by the company. If the company's initial situation and goals match the 'if' part, the solution feature provided in the 'then' part should be marked as a desirable feature (DF) of the online-shop. If not, the solution feature should be marked as not being part of the online-shop's functionality (No DF). By integrating the 27 knowledge elements about initial situation and goals with the 27 operators, a total of 24 solution features (15 to be part of the shop and 9 to be rejected) were unambiguously determined. The following example should illustrate the task and a filler item (FI) for the company expert:

IS: Products cost between 7 and 180 Euro.

O1: If medium payments (5-1000 Euro) are expected, then the online-shop should provide the opportunity to pay by check or credit card.

O2: If micro payments (0.1-5 Euro) are expected, the online-shop should use systems like e-Cash.

DF: The online-shop should provide the possibility to pay via check and credit card.
No DF: E-Cash should be used for payments.
FI: The well known designer Philippe Starck designed the layout of the stores.

As participants were not true experts in the domain assigned to them, materials had to be simplified as compared to reality. Despite this simplification, the knowledge elements and solution features provided should be correct. Therefore, three experts on matters of the internet rated the correctness of the knowledge elements and the resulting solutions. As a result, several items were changed or eliminated.

Memory Test. To make sure that information provided in the introductory texts was acquired sufficiently, participants performed a memory test, similar to a recognition test. (The difference was that test items were not identical verbatim, but instead in meaning, to items presented during the learning phase.) The following example shows target (T) and distractor (D) for a knowledge element concerning the company's initial situation (IS). Items were presented in random order and should be classified as correct or false.

IS: Online sales should be integrated into the current business practices of the company, as it would be too costly to add additional personnel to process the online shop's orders by hand.
T: Due to personnel and administrative considerations online sales should be integrated into the business practices.
D: Due to personnel and administrative considerations online sales should be separated from the current business practices.

If the criterion of 95 percent correct responses was not reached, text and the subsequent test were presented again. This procedure was repeated until both subjects reached the criterion, or a time limit of 80 minutes was exceeded.

Further Tasks. In addition to the design task, participants had to complete two additional tasks. Prior to the experiment, they answered a questionnaire about relevant aspects of the IT advisor's knowledge. In order to make the experimental manipulation effective, only naive participants were accepted. As a fictitious company was used, there was no need to control for prior knowledge concerning the company. The final task was an unexpected repetition of the memory test already applied after reading the introductory texts. As opposed to the first time, the test now comprised *all* information relevant to the task for both subjects so that the amount of acquired shared knowledge can be determined.

Experimental Design

The kind and amount of prior shared knowledge (SK) was manipulated as an independent variable in four experimental conditions. In the first condition, no shared knowledge is available prior to collaboration (No SK). The company expert's introductory text only contains the 27 knowledge elements about the initial situation and goals (IS+G), as well as 9 fillers. Accordingly, the IT-expert is provided with 27 operators (O) and 9 fillers. In the second condition, SK (IS+G), knowledge about IS+G is shared. Prior knowledge of the company expert remains unchanged, whereas the 9 fillers of the advisor's prior knowledge are replaced by 9 knowledge elements about initial situation and goals. These 9 elements form the dyad's shared knowledge. Similarly, condition 3 with shared operators is realized, SK (O): Fillers in the company expert's introductory text are replaced by 9 operators, whereas the advisor's prior knowledge stays the same as in the first condition. Condition 4, SK (IS+G+O), provides shared knowledge about both components, starting situation and goals, as well as operators. Like in conditions SK (IS+G) and SK (O), the company expert receives 9 knowledge elements about operators, and the advisor 9 elements about initial situation and goals, in addition to the 27 knowledge elements of their own expertise.

By sharing either 9 IS+G elements or 9 operators in conditions SK (IS+G) and SK (O), 9 solution features can be determined by the advisor (condition IS+G) or by the company expert (condition O) alone, since the shared knowledge elements provide all the information they need in addition to their own expertise. Although each participant is provided with some shared information in condition SK (IS+G+O), the number of solution features that do not require any collaboration remains 9 because the shared knowledge is distributed redundantly. Both partners are able to find the same 9 solution features on their own in condition SK (IS+G+O). In sum, the maximum possible correct solution features is 24 in all conditions.

The variation of shared knowledge as described above focuses on task-relevant shared information such as operators or goals. However, as many of the knowledge elements contained technical terms, providing some of the same knowledge elements to both participants might also have encouraged participants to develop a shared vocabulary around the terms both were exposed to. Furthermore, shared meta-knowledge is another aspect of what is meant by shared knowledge in the present experiment: In conditions SK (IS+G), SK (O) and SK (IS+G+O) participants were told that there is some information they both have in common.

Dependent Variables

Acquisition of Shared Knowledge. The amount of shared knowledge that was acquired during the collaboration was measured by the relative number of items that were recognized in the same way by both cooperation partners in the final recognition test. Initially shared items in the conditions with shared knowledge were excluded as well as all items that had not been discussed during the cooperation

task[1]. This measure also allowed to differentiate between correct (items that were recognized correctly by both partners like a 'hit') and false shared knowledge (items recognized in the same way by both partners, but falsely like a 'miss').

Effects of Shared Knowledge. As an indicator of the effectiveness of shared knowledge, we chose solution quality as our dependent variable. It was measured by the amount of correctly noted solution features, ranging from 0 to 24. All features in the whiteboard were analyzed, only features mentioned more then once were excluded. Solution features were scored as correct if they corresponded to the ideal solution, as determined through the integration of the company expert's and the IT advisor's knowledge. Conversely, solution features contradicting the ideal solution were scored as false. Features that were neither correct nor false, were coded as irrelevant, e.g., intrusions or underspecified features.

In order to detect eventual differences in the difficulty of learning the knowledge supplied about IS+G and O, we measured the time required to read the introductory texts and to acquire the information, until the learning criterion was reached.

Subjects and Procedure

64 participants (47 females, 17 males) were randomly assigned to the 4 experimental conditions, as well as to the role of company expert or IT advisor. None of them had task-relevant prior knowledge as controlled by the first questionnaire. After having acquired the information presented in the introductory text according to the learning criterion, participants performed the design task for 50 minutes. This limit seemed to be appropriate as subjects finished their task quite easily within this timeframe. Afterwards, they completed the net-based questionnaire. The only task not expected by the participants was the final memory test. The experiment took between 2.5 and 3 hours all together.

Results

Acquisition of Shared Knowledge

As expected the hypothesis stating that collaborative problem solving leads to the acquisition of shared knowledge could be accepted for correct ($t_{(31)} = 23.25$, $p < .05$) as well as for false shared knowledge elements ($t_{(31)} = 4.71$, $p < .05$).

As table 1 shows, about one third of the discussed knowledge elements enter the pool of subject's shared knowledge. The amount of shared knowledge did not differ significantly between experimental conditions ($F_{(3,56)} < 1$), but participants acquired significantly more correct than false shared items ($F_{(1,56)} = 447.86$, $p < .05$).

[1] Note that information in the partner's domain can only be acquired by communication within the dyad.

Table 1: Mean relative number and standard deviations of correct and false shared knowledge (SK).

Condition	Correct SK	False SK
No SK	.37	.01
	(.07)	(.02)
SK (IS+G)	.36	.02
	(.06)	(.06)
SK (O)	.38	.09
	(.12)	(1.0)
SK (IS+G+O)	.33	.03
	(.09)	(.04)

Effects of Shared Knowledge

As the 24 solution features were unambiguously determined by combining the company expert's and the IT advisor's knowledge, solution features noted on the whiteboards had to be compared to this ideal solution. Because the features that subjects noted were often incorrectly formulated and thus ambiguous, criteria were defined to determine what variations could be accepted as correct. For example, if a solution feature was called 'eMoney' instead of 'eCash' this was counted in the same way. To control for objectivity, a second rater, blind to the hypotheses of the experiment, assessed all solution features again. 94 percent of all features were rated identically.

Table 2: Mean number and standard deviations of correct, false and irrelevant features.

Condition	Correct features	False features	Irrelevant features
No SK	9.00	1.50	4.50
	(3.46)	(1.41)	(3.46)
SK (IS+G)	14.50	.88	6.38
	(3.16)	(.35)	(3.85)
SK (O)	11.25	2.00	4.88
	(2.71)	(1.20)	(2.85)
SK (IS+G+O)	14.50	1.88	3.75
	(2.39)	(1.25)	(3.24)

ANOVA was carried out to compare the quality of the solution in the four experimental conditions. Table 2 shows the means in the 4 experimental conditions (main effect of shared knowledge: $F_{(3,28)} = 6.59$, $p < .05$). Linear contrasts were carried out to assess overall effectivity of shared knowledge (hypothesis 1), as well as the difference between shared knowledge about initial situation and goals, compared to shared knowledge about operators (hypotheses 4). Hypotheses 2 and 3 were tested by post hoc tests (Scheffé).

The first hypothesis was tested via a linear contrast of condition (No SK), in contrast to the average of conditions SK (IS+G), SK (O) and SK (IS+G+O). As expected, solution quality was poorer when shared knowledge was missing, compared to conditions SK (IS+G), SK (O) and SK (IS+G+O), which had different components of shared

knowledge ($t_{(28)} = 3.65$, $p < .05$). Concerning the relative effectiveness of shared knowledge about IS+G (hypotheses 4), compared to shared knowledge about O, the former lead to significantly better solutions than the latter ($t_{(28)} = 2.20$, $p < .05$). Hypothesis 2, stating better results with shared knowledge about IS+G+O, compared to shared knowledge about IS+G alone, was refuted. The same is true for hypothesis 3, stating better results with shared knowledge about IS+G+O, compared to shared knowledge about O alone, although means pointed towards the expected direction. All these analyses were computed for the correct answers.

Only a few false solution features were noted on the whiteboards, without significant differences between experimental conditions ($F_{(3,28)} = 1.60$, $p > .05$). The number of irrelevant features was also unaffected by the amount of prior shared knowledge ($F_{(3,28)} < 1$).

Subjects needed significantly more time to read and learn information about operators ($M = 2420$ m/sec, $SD = 618$), than those about the initial situation and goals ($M = 2025$ m/sec, $SD = 632$; $F_{(1,56)} = 6.61$, $p < .05$). There were no differences between the experimental conditions ($F_{(3,56)} < 1$).

Discussion

Concerning knowledge acquisition we assumed that the interaction during the design task would lead to the construction of shared knowledge. As results showed, participants in fact acquired shared knowledge even if the amount was smaller than it could have been. This result can be conceived as a first indicator for the importance of shared knowledge as it was acquired even though participants were not instructed to do so and testing was unexpected. Furthermore, most of this shared knowledge elements were correct, so that they can really help participants to construct a common representation of the task and the solution. In contrast to other studies (Fischer & Mandl, 2000; Jeong & Chi, 2000) we did not have problems in determining how this shared knowledge came about, as participants had no common learning or working material, so that the only way this could have happened is through co-construction. We also could be sure, that this shared knowledge did not exist prior to collaboration as the company expert's information was fictitious and knowledge in the domain of online-shops was controlled for.

Concerning the effectiveness, shared knowledge prior to collaboration leads to better solutions in net-based collaboration than working together without shared knowledge. Overall, solution quality was higher if there was shared knowledge (as in conditions IS+G, O and IS+G+O) than if shared knowledge was lacking, as in condition No SK. Although this general benefit of shared knowledge could be demonstrated, certain kinds of shared knowledge were more helpful in our task than others. Shared knowledge about initial situation and goals seemed to be more effective than shared operators, since the solution quality did not improve when shared operators were added in condition SK (IS+G+O). This result contradicted the hypothesis that sharing information about both components of shared knowledge, initial situation and goals on the one hand, and operators on the other, is most effective. In the present study, sharing initial situation and goals alone, was as effective as additionally sharing operators. Apparently, sharing operators did not seem to have a facilitating effect on collaborative problem solving. Although the comparison between conditions SK (IS+G+O) and SK (O) lacked statistical significance, means were in line with the assumption that sharing operators is not very effective in a task like our experimental one. This interpretation is strengthened by the results of directly comparing the effectiveness of shared knowledge about the initial situation and goals, with that about the operators. Shared knowledge about IS+G clearly led to better performance than sharing operators.

But how can this effect be explained? First, the structure of the operators is more complex than that of the initial situation and goal elements. While the latter are simple sentences, the operators always combine an 'if' part with a 'then' part. This means that the operators contain technical solution features (in the 'then' part), in addition to information about possible situations and goals of the company (in the 'if' part). Besides their more complex structure, operators contained more information, framed in technical terms, that was new to the participants. Finally, information about the company provides company experts with a more coherent view of the company, whereas operators, in comparison, form a rather loose collection of rules for possible situations. We may assume, therefore, that operators are more difficult to process than knowledge elements about IS+G. This assumption is supported by the higher reading and learning time for operators than for IS+G. As a consequence, understanding and applying operators should be more difficult for the company expert than understanding information about IS+G is for the IT-advisor. From this, it follows quite naturally that sharing knowledge about IS+G should be more effective than sharing knowledge about operators.

Secondly, the structure of the operators has an impact on the ease of integrating information about IS+G into the 'if' part of the operators. As an operator's 'if' part already contains information about possible states of the company's initial situation and goals, it should be easy for the advisor to integrate the shared IS+G information into his or her operators, since it is just an instantiation of what is already provided in the operators' 'if' part. Thus IS+G information, either shared, or newly received during collaboration, does not provide information completely new to the IT advisor. In contrast, if the company expert receives operators, the solution provided in their 'then' part is completely novel information to him, and not just a specification of what he already knows. To deduce the resulting solution feature might therefore be more difficult. In addition, the advisor is able to realize (when he or she receives the shared knowledge elements) that the task-relevant information from the company expert is just a specification of the knowledge already provided by his or her operators. Asking

the right question to gather the information needed should therefore be easier for the advisor than for the company expert. Having shared knowledge about operators does not allow the company expert to infer other possible solution features, since knowledge about the initial situation and goals does not contain underspecified information about possible solution features. So in contrast to the IT advisor, it should be more difficult for the company expert to develop a coherent view of the partner's expertise and thus ask for the appropriate information.

In conclusion, shared knowledge is an effective variable facilitating collaborative problem solving. In the present paper, we show that sharing knowledge about operators is less effective than sharing the initial situation and goals, as the latter is easier to understand and integrate, and additionally, allows making assumptions about the partners' expertise. But shared knowledge is not only a facilitator for collaborative problem solving that can be provided externally or already exists but is also co-constructed during the problem solving process. Of course, it should also be noted that on the basis of the single experiment reported here, it is an open question whether the results hold for other problems and materials as well. Furthermore, the problem reported here is a well-defined one with a clear solution. Concerning ill-defined problems it can be assumed that the positive effect of shared knowledge about IS+G is reduced. In fact, operators will always be more complex, because per definition they consist of an 'if' and a 'then' part. What is said about the ease of integrating the IS+G information compared to integrating operators and inferring the partner's knowledge will also hold true for ill-defined problems. But it is questionable whether these factors will be as helpful *in finding a solution* because in ill-defined problems several solutions are possible. So, having all information to integrate operators and IS+G information does not unambiguously allow to deduce all solution features. Therefore, we assume that sharing knowledge about IS+G is still effective, given the structural differences explained above, but that this effect is less strong.

Abstract

The effect of prior experience on bias in time predictions on two different types of laboratory task was examined in two studies. Experiment 1 revealed that prior experience of performing a substantial part of the same task led to greater time prediction accuracy. However, contrary to the weight of previous research, there was little evidence of the temporal underestimation indicative of the planning fallacy. In fact, temporal underestimation only occurred on a longer duration task when it was preceded by a much shorter task, which was either related (Experiments 1 and 2) or unrelated to it (Experiment 2). In contrast, temporal overestimation prevailed on tasks ranging from about 30 seconds' to four minutes' duration. Contrary to the theory of the planning fallacy, these studies indicate that people do take account of their performance on previous tasks and use such distributional information when predicting task duration. The potential role of the anchoring and adjustment cognitive heuristics in determining temporal misestimation is discussed.

Introduction

The process of predicting task duration has been the subject of considerable research (e.g., Buehler, Griffin & MacDonald, 1997; Koole & Van't Spijker, 2000). In general, such research has produced evidence of temporal underestimation on various laboratory (e.g., Josephs & Hahn, 1995) and real world tasks (e.g., Buehler, Griffin & Ross, 1994). Such research supports the cognitive judgment phenomenon known as the planning fallacy, which is the tendency to underestimate task duration despite being aware that previous similar activities took longer than anticipated (Buehler, Griffin & Ross, 2002).

The planning fallacy was identified by Kahneman and Tversky (1979), who suggest that distinct two types of data are available to people when predicting task duration. Namely, singular information, which is data about the task at hand; and distributional information, which concerns data about previous tasks. An aspect of singular information is the amount of work involved in completing a current task, whereas personal performance on previous similar tasks is an aspect of distributional information.

Kahneman and Tversky (1979) propose that the planning fallacy is a consequence of heuristic information processing whereby singular information becomes the focus of attention at the expense of distributional information, which is overlooked. Hence, temporal underestimation occurs because the current task is treated as a unique event, which is dissociated from previous similar activities.

Given that the neglect of distributional information has been suggested as a possible cause of the planning fallacy (Kahneman & Tversky, 1979), it is notable that the issue of prior task experience has received little empirical treatment in relation to time estimation. One exception is the work of Thomas, Newstead and Handley (2003; see also Thomas, Handley & Newstead, 2004), which revealed that prior experience of performing (or mentally planning how to complete) certain laboratory tasks led to a reduction in temporal misestimation. However, Thomas et al. (2003) found little evidence of the temporal underestimation indicative of the planning fallacy on short duration (i.e., up to four minutes' duration) laboratory tasks such as the Tower of Hanoi.

In fact, there was evidence of general temporal overestimation on such tasks, with underestimation only occurring on longer tasks when they were preceded by a shorter version of the same task. For example, temporal underestimation prevailed on the five-disk Tower of Hanoi task only when the three-disk version of this task was performed beforehand. The findings of Thomas et al. (2003) indicate that there are certain tasks on which the temporal underestimation indicative of the planning fallacy does not occur and is reversed.

Thomas et al. (2003) suggest that the temporal underestimation they observed may have been a consequence of participants using the anchoring and adjustment cognitive judgmental heuristics (Tversky & Kahneman, 1982). That is, information such as the perceived duration of the first task served as an anchor for time predictions on the second task, which were insufficiently adjusted according to the greater demands of the upcoming task. Such a judgment strategy would be expected to result in temporal underestimation if the perceived duration of a just-completed shorter task served as a basis for time predictions on a current task.

A principal aim of the present research was to further address the issue of prior experience by employing laboratory tasks that are not only less artificial than those employed by Thomas et al. (2003), but are more akin to the ones used in previous research supporting the planning fallacy (e.g., Byram, 1997). That is, tasks that have well-

defined components and must be completed sequentially by following a set of instructions.

The present studies also sought to determine the direction in which time predictions were biased (i.e., under or overestimation) on a laboratory task that takes longer to complete than those used in our earlier work, but is of similar duration to some of the laboratory tasks employed in previous research (e.g., Buehler et al., 1997). Given that the tasks employed by Thomas et al. (2003; 2004) were of shorter duration than the laboratory tasks used in research supporting the planning fallacy (e.g., Josephs & Hahn, 1995), it could be that temporal underestimation is only evident on tasks that take longer than four or five minutes to complete. Consistent with this suggestion, temporal underestimation has been observed on laboratory tasks ranging in duration from about 10 minutes (e.g., Francis-Smythe & Robertson, 1999) to over one hour (Byram, 1997). The issue of task duration was addressed in the present studies by employing tasks that were of similar duration to those used in our previous research alongside one that took longer to complete.

Experiment 1

The issue of task duration was addressed in this study by using three different versions of the same miniature construction kit (i.e., toy castle) manufactured by Playmobil®. One of these tasks (long duration task) took about 11 minutes to complete whilst the others took either four minutes (medium duration task) or 30 seconds to finish (short duration task). The medium and short tasks were sub-component versions of the long duration task, and involved constructing different parts of the same miniature castle. The issue of prior task experience was addressed by varying the order in which the long duration task was performed. That is, whether time prediction bias differed when the long task was performed after, or was preceded by, one of the two shorter tasks.

Method

Participants. Eighty (64 female and 16 male) students at the University of Plymouth participated voluntarily in partial fulfillment of a psychology course requirement. No biographical data other than gender was recorded.

Design, Materials and Procedure. A 2 (time: predicted vs. actual duration) x 4 (task experience: long then short task vs. short then long task vs. medium then long task vs. long then medium task) mixed factorial design was used. The time factor was a repeated measure, with participants producing a predicted and actual task completion time. Task experience was manipulated between groups, with participants being randomly assigned to one of the four equal-sized conditions.

Prior to judging task duration, the amount of time that participants were given to view the task components and instruction booklet differed according to the type of task that was about to be performed. Pilot testing revealed that 80 seconds were needed to preview the instruction booklet and the plastic components of the long task. Pilot testing revealed that the instruction booklet and the plastic components of the short and medium tasks could be previewed in 20 and 40 seconds, respectively.

The long duration task involved building a multi-turreted castle with surrounding jetty and battlements by assembling a series of molded plastic components in a pre-specified order. The medium duration sub-component task involved building the castle without the surrounding jetty and battlements. The short duration sub-component task involved building one wall of the castle. A digital stopwatch was used to measure task duration.

Results

Means (and standard deviations) of predicted and actual completion time on the second task are presented in Table 1.

Table 1: Predicted and Actual Duration of the Second Task Per Task Experience Condition (In Seconds).

Time	Task Experience Condition			
	Short-Long Task (n = 20)	Long-Short Task (n = 20)	Medium-Long Task (n = 20)	Long-Medium Task (n = 20)
Predicted	435.00 (181.70)	28.15 (20.12)	550.50 (129.59)	254.25 (109.20)
Actual	556.25 (147.18)	18.55 (18.00)	497.85 (124.14)	178.95 (35.68)

There was considerable variability within the predicted and actual task completion time data, and frequency distributions of these data from each task experience condition were positively skewed. Hence, these data were subjected to a logarithmic transformation before being statistically analyzed.

A 2 (time) x 4 (experience) split-plot analysis of variance (ANOVA) produced a main effect of task experience, $F(3,76) = 637.66$, $MSE = .14$, $p < .001$, with overall time being longest in the medium then long task condition. Pairwise comparisons (Scheffé) revealed significant differences between the means of all conditions ($ps < .05$) except those of the medium then long task and the short then long task conditions ($p > .10$). The main effect on the time factor was not significant ($F < 3$, $p > .10$).

The ANOVA also produced an interaction, $F(3,76) = 6.12$, $MSE = .11$, $p < .01$ (see Figure 1 below). This revealed that temporal overestimation was evident on the medium and short duration tasks, whereas the direction in which time predictions were biased on the long task differed according to the relative duration of the previous task. Specifically, temporal overestimation was evident when the medium task had just been completed, whereas underestimation occurred when the short task was performed initially. Tests for simple effects revealed that predicted and actual time differed significantly on the

medium and short duration tasks (ps < .05). On the long duration task, the difference between predicted and actual time was significant when the short task (p < . 05), but not the medium task was performed beforehand (p > .10).

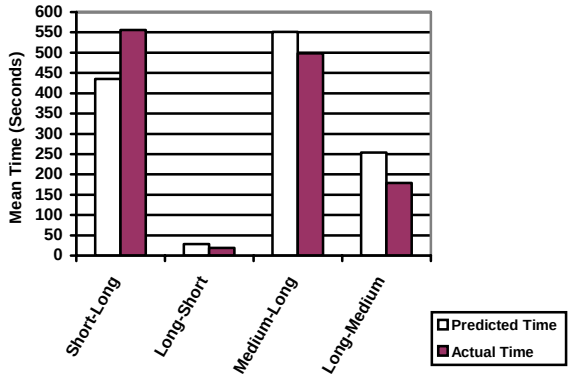

Figure 1: Predicted and actual completion time on the second task per task experience condition

Discussion

Temporal overestimation was evident on the medium and short duration sub-component tasks when they were performed after the long task. Consistent with the work of Thomas et al. (2003; 2004), this finding indicates that the temporal underestimation indicative of the planning fallacy (Kahneman & Tversky, 1979) is not evident (and is reversed) on another type of laboratory task with a duration of less than five minutes.

There was some evidence of temporal underestimation on the long duration task, but only when the short sub-component task had just been completed. The latter finding concurs with the notion that individuals might use the anchoring and adjustment cognitive heuristics when judging the duration of the second of two consecutive tasks (Thomas et al., 2003). That is, information about the previous task serves as an anchor for time predictions, which are insufficiently adjusted according to the relative demands of the current task.

In contrast, temporal overestimation (rather than underestimation) prevailed on the long task when the shorter duration medium sub-component task was performed beforehand. Thus, it seems that an anchoring and adjustment strategy was not used when judging the duration of the second task when a sizeable portion of this task had just been completed.

A possible explanation for these findings is that, due to differences in the extent of prior experience, different kinds of task-related information were used when predicting the duration of the long task. As completion of the medium task involved assembling half of the long task, participants in this experimental condition possessed considerable information about the nature of the long task when predicting its duration.

Given the extent of these individuals' prior task experience, they might have engaged in more thorough information processing when making a second time prediction. For example, they may have calculated the number of large plastic components required to complete the medium task, and appropriately scaled up this figure as a function of the greater number of major components involved in finishing the long duration task.

Using such a judgment strategy could result in temporal overestimation if it involved thinking about factors that delayed the completion of the previous task (e.g., fitting some plastic components together incorrectly). Thus, these participants may have erred on the side of caution because they took account of their previous task performance. In fact, time predictions were more accurate when the long task was preceded by the medium rather than the short task, suggesting that greater prior task experience was used to good effect.

As participants who performed the short task initially constructed only one wall of the Playmobil® castle (i.e., one part of the long task), they possessed little information about how to complete the long task when predicting its duration. In the absence of substantial prior task experience, these individuals may have used heuristic information processing when making a second time prediction. For example, time predictions may have been anchored on the perceived duration of the first task with insufficient upward adjustment for the longer duration of the second task. Thus, due to insufficient prior task experience, these participants may have relied on the anchoring and adjustment cognitive heuristics when judging the duration of the long task.

Whilst this study suggests that time predictions on the longer of two successive tasks might be based on information about the first task, the nature of this task-related information is not known. Given that the present tasks differed in duration, it could be that an anchoring and adjustment judgment strategy involving the perceived duration of the previous task is responsible for temporal underestimation when a longer task follows a shorter one.

In contrast, as the present tasks share the same structure (i.e., they are different versions of the same task), it could be that information about the nature of the first task formed the basis of time predictions on the second task. For example, the number of major plastic components involved in completing the previous task could serve as an anchor for time predictions on the current task. Temporal misestimation would be expected to occur as a consequence of using this kind of judgment strategy if the number of major plastic components differed between the first and second tasks. That is, if time predictions were not sufficiently adjusted from an anchor value to take account of the number of major plastic components needed to complete the second task.

Having found evidence of temporal underestimation on the long duration task when a much shorter version of it had just been completed, Experiment 2 sought to determine the type of information about a just-completed shorter task that

formed the basis of time predictions on the long duration task.

Experiment 2

The issue of the relevance of prior task experience was addressed in this study, where a related or an unrelated shorter duration task was performed before the long Playmobil® task. The related task was the short duration task from Experiment 1, whereas the unrelated task was the three-disk version of the Tower of Hanoi task. Pilot testing revealed that the three-disk task and the short sub-component task were of similar duration (Ms = 28.59 and 25.37 seconds, respectively).

Performing the short Playmobil® task initially would provide participants with some information about the nature of the long duration task, whereas no information about the long duration task would be acquired whilst completing the three-disk task.

If time predictions were based on information about the nature of the previous task, then they should be more accurate on the long duration task when the related task was performed beforehand. Conversely, if time predictions were based on information such as the perceived duration of the previous task, then the extent of judgment bias on the long task should not differ according to the relevance of prior experience.

Method

Participants. Fifty-six (42 female and 14 male) students at the University of Plymouth participated voluntarily. Forty-three individuals participated in partial fulfillment of psychology course requirement whilst the remainder were paid £2.50 each. No biographical information other than gender was recorded.

Design, Materials and Procedure. The long duration Playmobil® task, and a wooden Tower of Hanoi task apparatus containing three different-sized disks were used. A digital stopwatch was used to measure task duration.

There were two equal-sized groups of participants who performed either the three-disk task or the short sub-component task before the long duration Playmobil® task. The amount of time that participants were given to preview the plastic Playmobil® task components and instruction booklet differed according to the type of task that was about to be completed.

On the three-disk and short duration sub-component tasks, participants were given 20 seconds to preview the instructions and task apparatus or plastic components. Participants previewed the plastic components and instruction booklet of the long duration task for 80 seconds.

Results

Means (and standard deviations) of predicted and actual completion time on the long task are presented in Table 2.

Table 2: Predicted and Actual Duration of the Long Task Per Prior Experience Condition (In Seconds).

Time	Prior Experience Condition	
	3-disk Task First (n = 28)	Short Task First (n = 28)
Predicted	412.50 (137.99)	432.86 (177.66)
Actual	614.04 (125.32)	599.07 (140.91)

For the same reasons that were specified in Experiment 1, the predicted and actual completion time data were subjected to a logarithmic transformation before being statistically analyzed. A 2 (time) x 2 (task experience) split-plot ANOVA produced a main effect of time, $F(1,54) = 61.81$, $MSE = .07$, $p < .001$, with completion times exceeding predictions (Ms = 606.56 and 422.68 seconds, respectively). This finding indicates that temporal underestimation was evident on the long duration task. The main effect of prior experience and the interaction were not significant ($Fs < 1$, $ps > .10$). The absence of a significant interaction suggests that the extent of temporal underestimation on the long duration task did not differ according to the type of shorter task that was performed beforehand.

Discussion

Consistent with the results of Experiment 1, temporal underestimation was evident on the long duration Playmobil® task when the short sub-component task was performed beforehand. Temporal underestimation also prevailed on the long task when it was preceded by an unrelated task that was of much shorter duration (i.e., the three-disk Tower of Hanoi task).

The presence of temporal underestimation on the long task is consistent with Thomas et al.'s (2003) suggestion that the anchoring and adjustment cognitive heuristics are used when judging the duration of the second of two successive tasks. However, as the extent of underestimation did not differ significantly according to the relevance of prior experience, it seems that information about the nature of the previous task was not used as a basis for time predictions on the long duration task. Instead, some other kind of task-related information presumably served as a basis for time predictions on this task.

A possible candidate source of such information is the perceived duration of the previous task. That is, individuals judged how long the first task took to complete, and used this figure as a basis for their second time prediction. Indeed, at the end of the first experimental trial, several participants commented that the just-completed task had taken them less time to finish than they predicted. Whilst

such evidence is purely anecdotal, it indicates an awareness of temporal misestimation on both of the short tasks, and suggests that several individuals estimated the duration of the first task retrospectively.

An anchoring and adjustment judgment strategy involving the perceived duration of the previous task should result in time prediction bias when successive tasks differ in duration. That is, temporal misestimation is a consequence of failing to increase or decrease the current prediction according to the longer or shorter duration of the upcoming task (Thomas et al., 2003). Such insufficient adjustment from an anchor value (i.e., the perceived duration of the previous task) would lead to temporal underestimation if the current task took longer to complete than the previous one.

General Discussion

The present studies provide further insight into the role of prior experience in the process of predicting task duration. In Experiment 1, we found that, relative to building just one wall of the Playmobil® castle initially, constructing half of the castle on the first trial resulted in greater time prediction accuracy on the long duration task. This finding is consistent with previous research, which has found that prior experience attenuates bias in temporal (e.g., Josephs & Hahn, 1995) and non-temporal judgments (e.g., Smith & Kida, 1991) of task performance.

More importantly, this finding suggests that performance on previous similar activities is not only considered when judging task duration, but can also be used to good effect (i.e., to improve time prediction accuracy). Given that distributional information seems to be a key component of the planning fallacy, the role of prior task experience in mediating temporal misestimation is in need of further study. That is, further insight into how such distributional information can be used effectively will enhance our understanding of the planning fallacy phenomenon.

Whilst it has been shown that possessing considerable prior task experience reduces temporal misestimation (Experiment 1), the present research also indicates that the use of such distributional information does not always improve judgment accuracy. In both studies, there was evidence of temporal underestimation on the long Playmobil® task when it was preceded by a much shorter duration sub-component task. However, the extent of this temporal underestimation was similar when either the short sub-component task or an unrelated short duration task was performed initially (Experiment 2).

Consistent with our previous work (Thomas et al., 2003; 2004), this finding indicates that information about a just-completed similar task is considered when predicting task duration, but can lead to judgment bias. If, as we propose, an anchoring and adjustment strategy involving the perceived duration of a previous shorter task forms the basis of time predictions on a longer task, then an alternative interpretation of the planning fallacy suggests itself. That is, temporal underestimation is a consequence of time predictions being based on the shorter duration of a previous task, but being insufficiently scaled up according to the greater demands of the current task.

Whilst it is for future research to determine whether the present findings generalize to more everyday kinds of task, the use of the anchoring and adjustment cognitive heuristics could explain the prevalence of the planning fallacy on many large scale projects. That is, individuals who undertake such projects will typically have experience of performing similar but less complex tasks (Kidd, 1970). Moreover, as large scale (e.g., construction) projects tend to be performed infrequently, judgments of their duration can only really be based on the shorter duration of previous less complex tasks. If time predictions are anchored on the duration of previous smaller scale tasks, then temporal underestimation would be expected to occur.

In both studies, there was some evidence of the temporal underestimation indicative of the planning fallacy on the long duration Playmobil® task. This finding suggests that temporal underestimation might only be evident on laboratory tasks that are of longer duration than those employed in our earlier research. However, temporal underestimation was not evident on the long duration task when the medium sub-component task was performed initially (Experiment 1).

It was suggested that temporal overestimation on the long duration task was due to participants taking account of factors that delayed the completion of the medium task (e.g., incorrectly fitting some plastic components together) and incorporating such information into their second time prediction. Although further research is required to test the validity of this claim, it has been shown that thinking about such information can reduce bias in non-temporal judgments of task performance (e.g., Koriat, Lichtenstein & Fischhoff, 1980).

Given the present findings, it could be that, when prior experience is substantial, people incorporate potential impediments to optimal task completion into their temporal judgments on subsequent tasks. This kind of judgment strategy might lead to temporal overestimation, and also to greater time prediction accuracy. Support for the latter suggestion comes from Experiment 2, where time predictions on the long duration task were less biased when participants possessed more extensive prior task experience. That is, when the medium rather than short duration sub-component task was performed beforehand.

The existence of temporal overestimation on the short and medium duration sub-component tasks (Experiment 1) highlights the directional nature of time prediction bias. A possible explanation for the presence of temporal overestimation on tasks with a duration of up to four minutes is that people tend to judge task duration in whole minutes rather than seconds, or by using longer temporal units such as 5 or 10 minutes (Fraisse, 1984).

Given the duration of the two shorter tasks used in Experiment 1, temporal overestimation should prevail if participants used temporal units such as five minutes when judging their completion times on the medium sub-

component task. Likewise, giving a time prediction of two or three minutes would be expected to result in temporal overestimation on the short sub-component task. Thus, the reversal of the temporal underestimation indicative of the planning fallacy on the two shorter Playmobil® tasks could be a consequence of the type of time unit used to judge task duration.

Abstract

Previous studies using fMRI have found that the Fusiform Face Area (FFA) responds selectively to face stimuli. More recently however, studies have shown that FFA activation is not face-specific, but can also occur for other objects if the level of experience with the objects is controlled. Our neurocomputational models of visual expertise suggest that the FFA may perform fine-level discrimination by amplifying small differences in visually homogeneous categories. This is reflected in a large spread of the stimuli in the high-dimensional representational space. This view of the FFA as a general, fine-level discriminator has been disputed on a number of counts. It has been argued that the objects used in human and network expertise studies (e.g. cars, birds, Greebles) are too "face-like" to conclude that the FFA is a general-purpose processor. Further, in our previous models, novice networks had fewer output possibilities than expert networks, leaving open the possibility that learning more discriminations, rather than learning fine-level discriminations, may be responsible for the results. To challenge these criticisms, we trained networks to perform fine-level discrimination on fonts, an obviously non-face category, and showed that these font networks learn a new task faster than networks trained to identify letters. In addition, all networks had the same number of output options, illustrating that visual expertise does not rely on number of discriminations, but rather on how the representational space is partitioned.

Introduction

The Fusiform Face Area (FFA) in the ventral temporal lobe has recently received much attention. Initial work appeared to show that this area was selective for processing faces. Several fMRI studies showed high activation in the FFA only to face stimuli and not other objects (Kanwisher et al., 1997; Kanwisher, 2000). Further, studies involving patients with *associative prosopagnosia*, the inability to identify individual faces (Farah et al., 1995), and *visual object agnosia*, the inability to recognize non-face objects (Moscovitch et al., 1997), seemed to indicate a clear double dissociation between face and object processing. Prosopagnosic patients had lesions that encompassed either right hemisphere or bilateral FFA, while object agnosic patients' lesions did not (De Renzi et al., 1994).

Gauthier and colleagues have challenged the notion of the face specificity of the FFA by pointing out that the earlier studies failed to equate the level of experience subjects had with non-face objects, to the level of experience they had with faces (Gauthier et al., 1997; Gauthier et al., 1999a; Gauthier et al., 1999b). She showed that the FFA was activated when bird and dog experts were shown pictures of the animals in their area of expertise. Further, she illustrated that, if properly trained, individuals can develop expertise on novel, non-face objects (e.g. Greebles), and subsequently show increased FFA activation to them (Gauthier et al., 1999a). Expertise in these studies was operationally defined as the point in training when a subject's default response level (i.e. entry level) "shifts" from basic to the individual level. This is indexed by the subject's reaction time for verifying individual names becoming as fast as the time to verify category membership.

Neurocomputational models done first by Sugimoto and Cottrell (2001) and later extended by Joyce and Cottrell (2004) began to address the question of how and why the FFA gets recruited for these other tasks (Sugimoto & Cottrell, 2001, Joyce & Cottrell, 2004). Using four different types of stimulus classes (books, cans, cups and faces), Sugimoto and Cottrell found that the amount of expert-level experience on a previous task correlates with faster subordinate level learning relative to a system that processes the same stimuli, but not to a subordinate level. Thus, an area that is used for one expertise task will learn a second expertise task faster than an area used only for basic level discriminations. Joyce and Cottrell (2004) further found that an expert network's ability to separate individuals is reflected in highly variable responses at the representational layer (the hidden layer). This response variability extended to novel categories, permitting faster learning of these

categories. This suggests that the FFA is primed to win the competition for a new expertise task because of its ability to fine-tune its feature representations when given a novel fine-level discrimination task (Joyce & Cottrell, 2004).

While the human and computational studies of expertise are compelling, they are not undisputed. For example, proponents of the view that the FFA is face-specific claim that the objects used in human expertise studies, such as cars, dogs, birds, or Greebles, are "face-like", meaning they possess properties similar to faces. Thus any response of FFA to these stimuli is due to their featural similarity with faces, not because the FFA is a general-purpose, fine-level discriminator. While the network simulations, which illustrate expertise across a wide variety of non-face objects, may seem to argue against this criticism, a methodological issue makes these results less compelling. In previous simulations, non-expert networks were trained on a lesser number of discriminations (4 category labels) than expert networks (10 individual labels plus the 4 category labels). It has been argued (Mike Tarr, personal communication) that if an object recognition network simply had to make as many discriminations as the expert one, then it would also be able to learn Greebles faster.

The current simulations were designed to address the criticisms cited above. First, we train the networks to perform fine-level discrimination on an obviously non-face category: fonts. In this case, the basic level networks learn to identify letters presented in a variety of different fonts (a task any human can do with ease) while the subordinate level networks learn to distinguish the particular font in which a letter is written (a task few humans can do). To address the second criticism, we present both basic and subordinate level networks with the same stimulus set and have them perform an equal number of discriminations (e.g. 6 letter vs. 6 font discriminations). Thus, any advantage to learning to distinguish Greebles by the font network over the letter network cannot be due to the number of discriminations learned.

Experiments

We ran two sets of experiments. In the first, we investigated the ability of our basic visual object processing architecture (Dailey & Cottrell, 1999; Dailey et al. 2002; Joyce & Cottrell, 2004) to recognize letters and fonts. This allowed us to discover which fonts were difficult and which letters gave good generalization once their font had been learned (by training on other letters). We then used these results in the second set of experiments to perform a very controlled version of our previous "basic versus expertise network" experiments, and investigate generalization to Greeble expertise.

Experiment 1: Stimuli and Methods

The images used were 300x300 pixel images of letters. For this experiment, 15 different fonts were used, and for each of those 15 fonts, we had images of all 26 letters. The fonts were chosen to be somewhat difficult. Image preprocessing

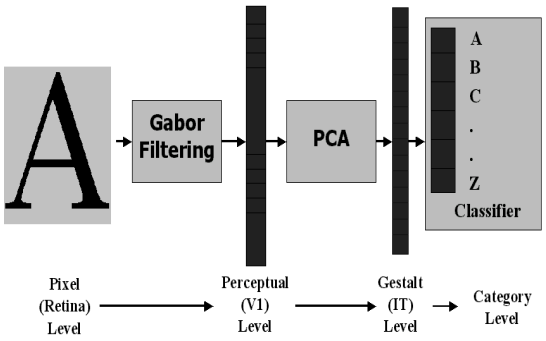

Figure 1: The expertise model.

of the different letters and fonts followed the procedures outlined in Dailey and Cottrell (1999). Each image was first processed using 2-D Gabor wavelet filters (5 spatial frequencies at 8 orientations each), a simple model of complex cell responses in visual cortex. The filters were applied at 64 points in an 8x8 grid, resulting in a vector of 2560 elements (Buhmann, Lades & von der Malsburg, 1990; Dailey & Cottrell, 1999). The vectors were then normalized via z-scoring (scaled and shifted so that they had zero mean and unit standard deviation) on a per-filter basis, a local operation. A principal components analysis (PCA) was then applied to the normalized vectors. The top 40 components were saved and renormalized. Projections of the stimuli onto these 40 dimensional vectors constituted the input to the networks. Figure 1 shows the expertise model, which includes the image preprocessing procedure.

A standard backpropagation network architecture was used for learning classifications. The network had 40 input units, each representing a principal component vector, a 30-unit hidden layer using the logistic sigmoid function, and 15 linear output units for the font network, and 26 linear outputs for the letter network. The learning rate and momentum were 0.01 and 0.5, respectively.

Letter training Letter networks were trained to identify letters across a subset of the 15 different fonts. Each network was given the letters from 13 different fonts as the training set and another font as the holdout set. It was then

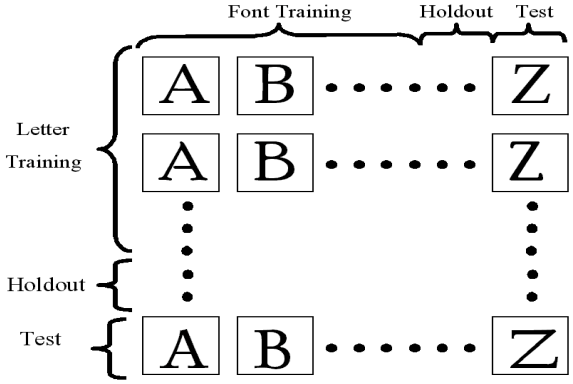

Figure 2: Training for Experiment 1. 26 letters and 15 fonts were used.

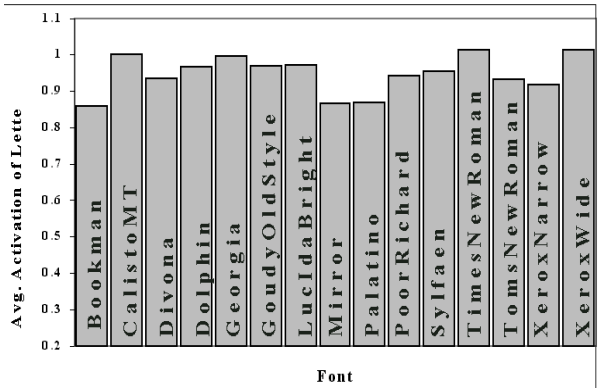

Figure 3: Average activation of letters for test fonts.

tested on the letters from the remaining font. Training was stopped at either an RMSE of 0.02 or when overtraining started to occur. The result was 15 letter networks, all trained and tested on different fonts. Figure 2 illustrates the training and test sets for Experiment 1.

Letter networks learned their task quickly. Figure 3 illustrates the average activation of letters for each font when that font was used as the test set. The amount of activation of an output unit can be thought of as the level of confidence that the letter unit activated corresponds to the correct letter. Although the letters in some fonts were harder to generalize to than others, the average activations were quite high across all fonts. Accuracy of the networks was also computed: if the activation of the unit corresponding to the correct letter is the highest among all other units, then the network was correct in naming the letter. As expected, all letter networks were able to name the correct letter with 100% accuracy.

Font training Training networks to be font experts (i.e. identify the font a letter is written in) for 15 different fonts proved to be quite difficult. Our networks never satisfactorily learned the problem. In order to determine which fonts were easy enough to learn, we performed multidimensional scaling on the distances between the fonts. Distances between fonts were defined as one minus the

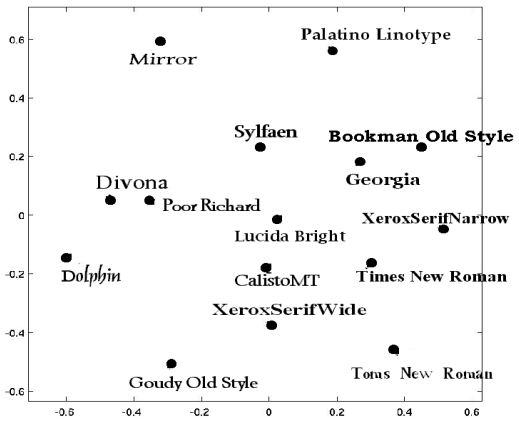

Figure 4: MDS of fonts.

	Avg. RMSE	Avg.Accuracy(%)
Easy Font Network	0.3419	86.19
Hard Font Network	0.4382	76.62

Table 1. Average RMSE and accuracy for font networks

average correlations between their corresponding letters, using their PCA representations. We then formed a 15 by 15 matrix of inter-font distances, and submitted this to a standard non-metric multidimensional scaling routine. The results for a two dimensional solution are shown in Figure 4. The plot shown had a stress of 1.9694.

We used this graph to find the three most separated and the three most correlated fonts. One group of networks was trained on the easier fonts (3 least correlated) and another group of networks was trained on the harder fonts (3 most correlated). Here, 24 letters from each font were used as the training set, 1 letter as the holdout set, and 1 letter as the test set. This was repeated so that each letter had a chance to be the test letter once. Training was stopped when overtraining started to occur. The result is 52 different networks, 26 from the easy font training and 26 from the hard font training.

With these reduced training sets, networks were successfully able to learn to discriminate fonts. Verifying our analysis, the hard font networks had a slightly harder time learning the task than the easy font networks (Table 1). Although the RMSE for both networks were high, they were still accurately able to name the correct font. In fact many of the networks had an accuracy of 100%.

We again computed average activations of output units, except this time for fonts across a test letter (Figure 5). The importance of this plot comes in the activation for particular letters. A high activation means that the network had an easier time generalizing to the font in that letter. This assisted us in choosing the highly generalizable letters as stimuli for Experiment 2.

Experiment 2: Stimuli and Methods

As discussed in the Introduction, Experiment 2 was carried out in order to provide a novel control for our computational model of the visual expertise hypothesis. We used the six

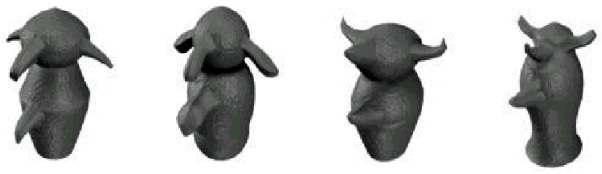

Figure 6: Examples of Greeble images.

most discriminable fonts, and the six letters that were the easiest to generalize to between fonts. Two sorts of networks, both with exactly the same training set, preprocessing, architecture, and number of outputs, were then trained to be either letter classifiers or font experts. While one might consider a letter network an "expert," for our purposes, we consider it a basic level classifier. The main characteristic of basic level categorization is that similar things are classified into the same category. The font expert, on the other hand, must take similar things (the same letter in different fonts) and differentiate between them. Our hypothesis is that such a network will learn the Greeble task faster than a letter network. Thus, training in Experiment 2 was divided into two separate phases. Phase 1 involved training the letter and font networks in a manner similar to that of Experiment 1. In Phase 2, the letter and font networks trained in Phase 1 were then trained to classify Greebles. Examples of Greebles are shown in Figure 6.

Using the results from Experiment 1, the 6 most generalizable letters and the 6 most discriminable fonts were chosen as the stimuli. In addition to these 36 stimuli, 5 different images of 10 unique Greebles were introduced in phase 2. The five different images were produced by jittering the image of a specific Greeble a few pixels on the x, y or x and y axes. Preprocessing of the images was as described in Experiment 1. Greeble images were also preprocessed using Gabor filters and PCA, however they were not included in the generation of the PCA eigenvectors. Rather, the eigenvectors produced via the PCA on the letter/font stimuli were applied to the Greebles. Thus, the PCA representations given to the networks contained no *a priori* information about how Greebles fit into the representational space.

As in Experiment 1, the networks consisted of 40 input units. The hidden unit layer was increased to 40 units due to the increased difficulty of having to solve two tasks. Finally, there were 16 output units, where 6 represented the category (fonts or letters), and 10 the Greebles. Learning rate and momentum remained the same.

Training procedures in Phase 1 were similar to that of Experiment 1, except that only 6 letters and 6 fonts were used. Here, 10 letter networks were trained such that for each network, the letters for a randomly selected font were used as the test set, the letters from another font were the holdout set, and the remaining 4 were used for training. For font networks, each of the 10 networks was tested on the fonts for a randomly selected letter, another randomly selected letter was used as holdout, and the rest were for training. All networks were trained to 2560 epochs. At each log base 2 epoch of training in Phase 1, the weights of the

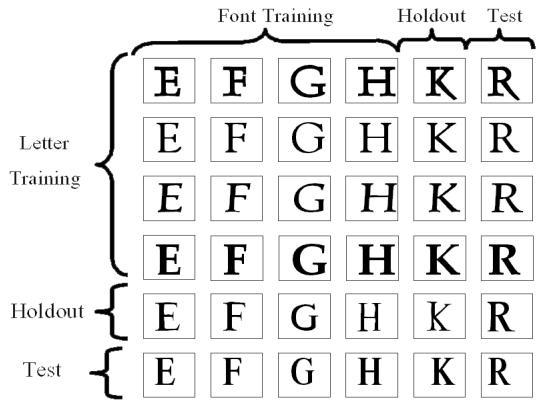

Figure 7: Phase 1 training for Experiment 2. 6 letters and 6 fonts were used.

letter and font network were saved. These weights were used as the starting points for networks in Phase 2 in order to show how varying levels of experience with a preliminary task affected learning of a secondary subordinate level task. For this phase, both font and letter networks ignored the 10 Greeble output units. This training procedure is shown in Figure 7.

In Phase 2 training, the networks trained in Phase 1 were trained to perform subordinate level classification on 10 Greebles. Training for this phase stopped when an RMSE of 0.05 was reached.

Experiment 2: Results

Phase 1 Training Based on the results from Experiment 1, we trained letter and font networks on stimuli that seemed the easiest to generalize to. Both networks were able to learn the task with extremely low error. As expected, the letter networks initially had an easier time learning the letters than the font networks did learning fonts. More importantly, accuracy on the fine-level discrimination task (classifying fonts) became just as good as basic level discrimination (classifying letters).

Phase 2 Training In the second phase of Experiment 2, the letter and font networks were trained to perform fine-level discrimination on Greebles. Again the results were as

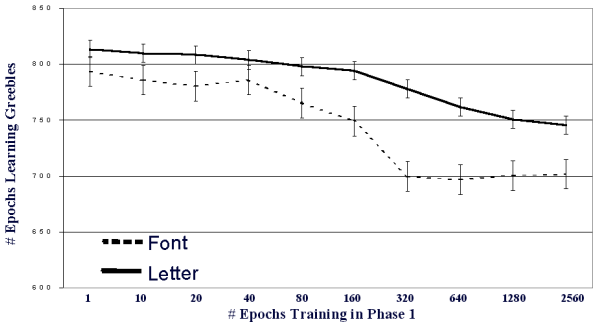

Figure 8: Number of epochs to learn the new task. Error bars denote standard error.

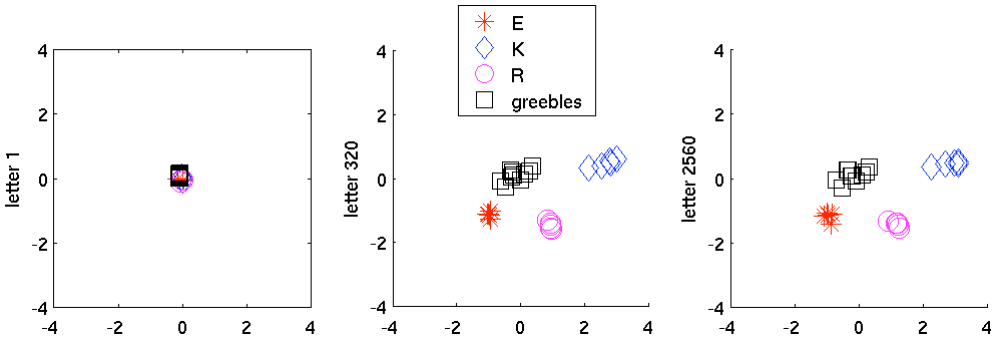

Figure 9: PCA of hidden units of letter network. Grouped by letter.

expected. Figure 8 shows the time in epochs needed for both the letter and font networks to learn the Greeble task as training on the initial task (either classifying letters or fonts) increased. All font networks, regardless of amount of training, learned the Greeble task faster than the letter networks. In addition, more experience with the font task resulted in improvement on learning the Greeble task while more experience with the letter task yielded little improvement (although there is some indication that the letter networks may catch up eventually). Further work will be necessary to evaluate this trend. However, the point remains that expertise in fonts is better than expertise in letters for Greeble training.

To further understand the behavior of the networks, PCA was done on the hidden unit representations prior to Greeble training. Figures 9 and 10 illustrate the spread of the stimuli in representational space based on the 2nd and 3rd principal components (the first PC just codes the overall magnitude change in the weights). In Figure 9 the six points in each symbol represent a given letter in 6 different fonts for a letter network, with one additional symbol representing how Greebles are represented prior to any training on Greebles. In Figure 10, each symbol represents a given font for a font network, and each individual point in that symbol a different letter.

Notice that for the letter network (Figure 9), the letters are grouped together by letter identity regardless of font. Similar inputs (the letters) are made *more similar* by this mapping. In the font network (Figure 10), over training, the fonts spread farther apart over time. Hence, in order to classify the font of each letter, the network must *amplify* small differences between similar items -- all the stimuli representing the same letter must be classified differently. This generalizes to the Greebles; in the font network, the Greebles are more spread out, making it easier for the font network to learn the distinctions between them. Figure 10 also shows that the fonts appear less spread out than the Greebles. This is because the network has learned to see all of the letters in the same font as "the same," whereas it has not learned anything about Greebles yet. It should be noted that each Greeble point is a different Greeble, so the network is already individuating them to some extent. These results are similar to those gathered in our previous network simulations using faces, cups, cans, books, and Greebles (Sugimoto & Cottrell, 2001; Joyce & Cottrell, 2004) illustrating that expertise in the font networks is due to the same mechanism as expertise in face and non-face object networks.

Conclusion

The current studies illustrate that: 1) expertise can be obtained with decidedly non-face-like stimuli and that font expertise exhibits similar properties to that of face and non-face objects seen in previous simulations, and 2) the expertise in previous simulations cannot be explained by a

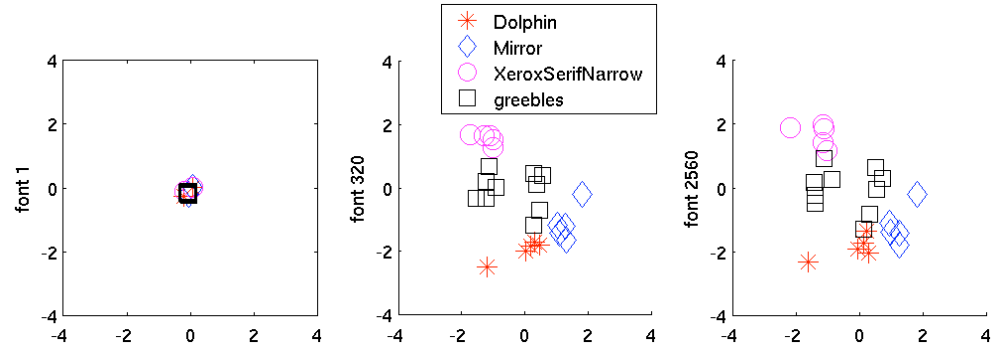

Figure 10: PCA of hidden units on font network. Points grouped by font.

greater number of subordinate level discriminations than basic level discriminations: in the current work these were equated and the results were qualitatively similar to those we have obtained previously.

Our first experiment gave us useful preliminary data for training font experts; it showed that the task of classifying fonts was possible, and revealed which letters and fonts were the easiest to generalize to and train on. The behavior of the networks in the second experiment was similar to previous studies, although our stimuli were different fonts, not "face-like" objects. When training the networks on a new task, the font expert networks learned Greeble classification faster than the letter networks, suggesting that previous visual expertise, whether it be on object or non-object, leads to relatively faster learning in a novel discrimination task. In addition, an equal number of discriminations were required of both letter and font networks. Thus, the expertise advantage could not be due to the sheer *number* of partitions the representational space was divided into, but instead is due to *how* the space was divided. We conclude that visual expertise does not depend on the type of stimuli, nor on the number of stimuli used for training, but on how you slice the space.

Future Work

We plan to train face networks to become font experts, thus generalizing the Greeble expertise work. We expect face expert networks will learn font expertise faster than basic level categorizers. We then plan to train human subjects to become font experts, using fMRI to image both prior to and after training to ascertain if font expertise training engages the FFA. We expect that the letter areas found in the left hemisphere will not become more highly activated by font training. Although it should be obvious from the way that letters are grouped together by the letter network, a future simulation should show that letter networks are difficult to train in font expertise.

Abstract

Based on Guo and Holyoak's (2002a, 2002b) work, we propose a stochastic comparison-grouping theory of multialternative decision making to explain three context-induced violations of rational choice. The attraction effect and the similarity effect are explained by stochastic comparison grouping, according to which similar alternatives are compared more frequently than dissimilar alternatives are. The compromise effect is explained by the assumption that attribute values are perceived according to a basic psychophysical function, in addition to the comparison grouping mechanism. Furthermore, this model explains individual differences in choice by assuming interpersonal differences in pre-existing attitude toward products.

Introduction

Rational theories of decision making suggest that choice is intrinsically determined by the utilities of individual alternatives, thereby unaffected by relationship among alternatives, which is a part of choice context. However, violations of this tenet have been found in many studies (e. g., Huber, Payne, & Puto, 1982; Simonson, 1989). Three much-studied findings of the so-called context-dependent choice warrants specific attention, as they constitute violations of axioms that are believed to be fundamental to rational choice. They are addressed together in this paper as they share important commonalities and can be explained by a unified framework. These findings include the attraction effect, the similarity effect, and the compromise effect (Huber, Payne, & Puto, 1982; Tversky, 1972; Simonson, 1989; Simonson & Tversky, 1992).

These effects all occur with the addition of a third alternative, called the decoy, to a two-alternative choice set and are all called *decoy effects*. Like in most research of the same line (e. g., Guo & Holyoak, 2002b; Roe, Busemeyer, & Townsend, 2001), they are examined in the present paper in a two-attribute form, which is schematized in Figure 1. The alternatives that constitute the core set are commonly referred to as the target and the competitor (also called the core alternatives in this paper), and the addition the decoy. The target and the competitor form a trade-off, that is, one is better than the other on one attribute but worse than the other on the other attribute. Depending on the position of the decoy relative to that of the target, three phenomena could occur. Two of them happen when the decoy is more similar to the target than to the competitor. If it is inferior to the target on all attributes, the choice probability of the target would increase relative to that of the competitor. This is called the attraction effect (Huber, Payne, & Puto, 1982). On the other hand, if a trade-off exists between the decoy and the target, the choice probability of the target would decrease relative to that of the competitor. This is called the similarity effect (Tversky, 1972). The third phenomenon occurs when the decoy sits between the target and the competitor, in which case the decoy, now constituting a compromise of the core alternatives, would be chosen most often. This is called the compromise effect. All three phenomena would potentially lead to violations of axioms of rational choice (will explain in detail later).

A number of explanations have been advanced for each of the three findings (e. g., Simonson & Tversky, 1992; Tversky, 1972; Tversky & Simonson, 1993), however, Roe et al. (2001) were the first to explain all three (in addition to other findings) with a single framework, implemented in a connectionist model derived from a previous stochastic mathematical theory (Busemeyer & Townsend, 1993). Their model accounts for these findings by variable lateral inhibition determined by similarity relations among alternatives and momentary shifting of attention from attribute to attribute. Subsequently, Guo and Holyoak (2002b) proposed a connectionist model accounting for the attraction effect and the similarity effect that is also based on inter-alternative similarity. They conceived the decision process as divided into two stages: the two more similar alternatives (i. e., the target and the decoy) are compared first, and joined by the competitor later. The first stage has an impact on the second stage and finally leads to these phenomena (will explain in detail later). The two-stage model derives its idea from perceptual grouping, according to which similar shapes are visually perceived as forming a unit. Analogously, similar alternatives are processed together at the early stage of decision process. In analogy to perceptual grouping, this mechanism is called *comparison grouping* in the present paper. Compared to Roe et al.'s model, the two-stage assumption is more consistent with some empirical studies that investigate decision processes of multialternative choice (Russo & Rosen, 1975; Satomura, Nakamura, & Sato, 1997). To explain the compromise

effect, Guo and Holyoak (2002a) used another feature of the same model in addition to the two-stage assumption.

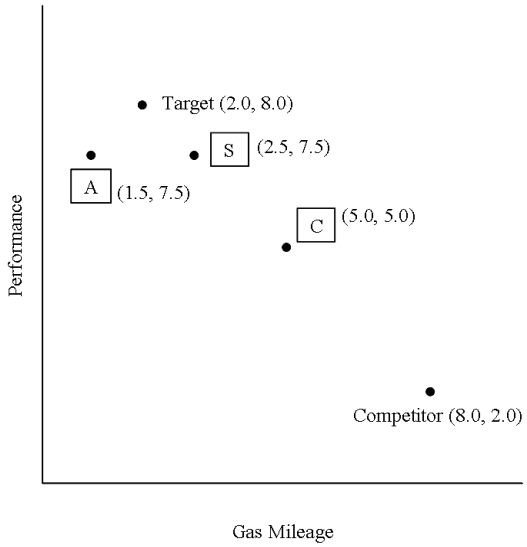

Figure 1: A summary of the phenomena simulated. The letters S, A, and C stand for the decoys for the similarity effect, the attraction effect, and the compromise effect respectively. The numbers in parentheses are attribute ratings.

Despite its explanatory simplicity and consistency with certain experimental data, the two-stage model seems oversimplified for describing human behavior – it is unlikely that people completely limit evaluation to just one pair of alternatives for a long period of time. Studies have shown that in multialternative choice tasks that resemble those giving rise to the three effects, people 1) momentarily shift attention across pairwise comparisons, and 2) similar pairs were compared *more frequently* than dissimilar pairs were (Russo & Rosen, 1975; Satomura et al., 1997). In addition, the second stage in that model was proposed to consist of triple-wise comparisons, whereas these studies suggested that choice predominantly consists of pairwise comparisons. Based on data from these studies, we propose a stochastic comparison-grouping model, in which all possible types of comparisons are performed momentarily with differential frequencies (Russo & Rosen, 1975; Satomura, Nakamura, & Sato, 1997). In addition, whereas Guo and Holyoak's model estimates choice probabilities from results of just one simulation by a mathematical conversion (Luce, 1959), the present model runs a large number of simulations to reflect decisions across individuals, thereby directly estimating choice probabilities. The psychophysical assumption (Guo & Holyoak, 2002a), proposed in conjunction with comparison grouping to explain the compromise effect, remains unchanged in the current model.

The Model

Decision Scenario and Model Architecture

The decision scenario used for simulation is adapted from that used by Roe et al. (2001). The decision maker has to choose one car from a set of two or three alternatives by evaluating two attributes; gas mileage and performance, which are measured on a 1 – 10 scale (see Figure 1). Accordingly, a connectionist model is constructed (see Figure 2). Each attribute or alternative is represented by one node (circle) in the network, with their relations represented by connections (lines with arrowheads). Each node has a certain degree of activation. For an alternative node, the activation stands for the valuation of the corresponding alternative; for an attribute node, it stands for the evaluative importance of that attribute. Node activations are within the range of 0.0 - 1.0.

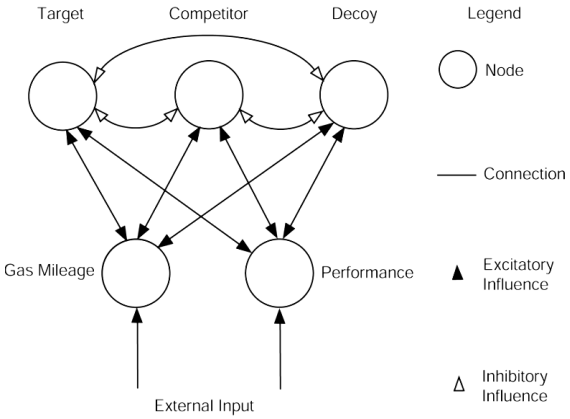

Figure 2: The architecture of the model. External Input represents the motivational and attentional sources that drive the decision process.

The connection between an attribute node and an alternative node, called the *attribute-alternative connection*, has an excitatory weight (i. e., when one node is more active, the other would be more active as well). The connection between each pair of alternative nodes has an inhibitory weight (i. e., when one node is more active, the other would be less active), also known as *lateral inhibition* in the literature. The lateral inhibition reflects the competitive relationship among alternatives. Via this mechanism, which would commonly result in one node achieving higher activation than the rest, the model "chooses" the winning alternative. All connections are bi-directional, reflecting the idea that influences can go either way between factors involved in decisions. The external inputs to the attribute nodes represent the motivational and attentional sources that drive the decision making.

This network representation was similar to Guo & Holyoak's (2002a, 2002b) model, and is consistent with common connectionist architecture used in decision modeling (e. g., Holyoak & Simon, 1999; Tsuzuki, Kawahara, & Kusumi, 2002).

Connection Weights and Initial Activations

The attribute-alternative weights reflect the perceived goodness of alternatives according to their attribute ratings, and were initially set to the corresponding attribute-alternative ratings. For example, the performance-target and gas mileage-target weights were first set to 8.0 and 2.0 respectively.

Recall that in Guo and Holyoak's model (2002a, 2002b) the perception of goodness follows a basic psychophysical function. In particular, this function reflects the idea that perceived goodness increases with negative acceleration with actual attribute value. Consistent with this idea, each attribute-alternative weight was further transformed by a logarithmic function:

$$w_{ij} = (\log_e (w_{ij} + \alpha) + \beta) / \gamma . \qquad (1)$$

Here, w_{ij} is the weight of the connection from node j to node i. α, β, and γ are set to 31.00, –3.35, and 0.905 respectively. Equation 1 reflects a weakly convex function. In addition, it serves as a normalization function that compresses these weights to values within a small range, which is comparable in magnitude to node activations (whereas the attribute values range from 0.0 to 10.0, the w_{ij}s range from 0.090 to 0.400.)

The lateral inhibitions are all set to -0.60. The initial activations of all nodes are conveniently set to 0.5, the middle point of the activation range, with the following qualification.

In reality, people usually have different pre-existing preferences regarding products. Accordingly, randomness was introduced to the initial activations of the alternative nodes, which were in the range of 0.5±0.25. The values follow a uniform distribution. As will be seen later, this randomness provides an explanation for individual differences in choice.

Running the Model

Connectionist models commonly run in an iterative fashion. In each iteration the activation of each node is updated according to the total influence it receives from the rest of the model – the activation increases if the influence is positive and decreases if otherwise. This influence can be understood as the overall reason for liking or disliking an alternative or attribute. A common activation function is used to specify this process (c. f., McClelland & Rumelhart, 1988).

$$a_i(t+1) = a_i(t) + \Delta a_i(t), \text{ where} \qquad (2)$$
$$\text{if } netinput_i > 0,$$
$$\Delta a_i = netinput_i (MAX - a_i) - decay . a_i$$
$$\text{otherwise}$$
$$\Delta a_i = netinput_i (a_i - MIN) - decay . a_i$$

$a_i(t+1)$ is the activation of node i at iteration (or time) $t + 1$; it is a function of $a_i(t)$, the activation of the same node at the previous iteration (or moment). $\Delta a_i(t)$ is the amount of activation change. The decay parameter reflects how much a neural signal decays over time (connectionist models draw analogies to neural processing), and is set to 0.04. The decay, however, does not play an important role in explaining the effects. *MAX* and *MIN* are the upper (1.0) and lower (0.0) limits of node activations. This equation specifies that node activation asymptotically approaches the upper or lower activation limit as a consequence of the total influence it receives from other components of the network. The total influence, $netinput_i$, is determined by the following equation.

$$netinput_i = istr . intinput_i + estr . extinput_i, \text{ where} \qquad (3)$$
$$intinput_i = \Sigma_j w_{ij} a_j(t)$$
$$extinput_i = 1$$

Intinput is the internal input that comes from all the attribute and alternative nodes, and depends on both the activation of the node feeding input to i and the connection strength that links the two nodes. *Extinput*, standing for the external input, should be a stable source of attention and motivation and is set to a constant. *Istr* and *estr*, set to 0.12 and 0.05 respectively, are constants that scale down activation changes so that the changes are not abrupt. Since the internal input is the source of these effects, *istr* is set to be larger than *estr*.

The model runs iteratively – in each iteration, the activation of each node in the model is updated according to Equation 2 and 3. The process reflects the evolution of valuation over time. This iterative process continues until an externally determined period of deliberation time, arbitrarily set to 100 iterations, is met.[1] The final winning choice is the alternative with the highest activation.

Stochastic Comparison Grouping

In a series of eye fixation studies, Russo & Rosen (1975) found that pairwise comparisons between similar options happen earlier and more frequently than other types of comparisons in multialternative choice. Consistent with that, Satomura et al. (1997) found that in decision tasks leading to the attraction effect, for the participants who chose the target (i. e., exhibited the attraction effect), 74% retrospectively reported that they compared the target to the decoy, while only 19% of them reported that they compared the target to the competitor. These studies give rise to the following modeling assumptions – All four kinds of possible comparisons (target-decoy, competitor-decoy, target-competitor, and target-decoy-competitor) are performed momentarily with different frequencies. To instantiate this in the model, for each iteration, a specific type of comparison is randomly chosen according to specified probabilities, and only the involved alternative nodes are updated.

[1] Other stopping criteria might be used. For example, the model can stop when the amount of activation difference across nodes is very large, or the amount of activation change becomes very small. However, according to our analysis, the type of criterion does not affect the qualitative pattern of the simulation results.

In simulating the attraction effect, the frequencies of these types of comparisons, in the order mentioned above, were set to the percentages of 74.0%, 10.4%, 10.4%, and 5.2% respectively. For example, for a random 74.0% of the iterations, only the activations of the target and the decoy were updated. These percentages were arbitrarily determined to roughly reflect previous experimental data (Russo & Rosen, 1975; Satomura et al, 1997), which suggested pairwise comparisons constitute the majority of the deliberation process, and the two similar alternatives were compared most often. To be consistent, the same decision process was employed for the similarity effect.

Simulations and Results

A total of 10,000 independent simulations, each standing for the deliberation of one individual, have been performed. For each simulation, the alternative with the highest final activation is the one chosen. Choice probability was obtained across all the simulations. The simulation results are presented both as choice probability (Table 1) and average node activation (Table 2). Note that choice probability is the criterion by which the modeling is judged.

Modeling Individual Differences

Note that node activation evolves as a continuous function of time. This means a node with high initial value tends to stay strong. For instance, if the initial value of the target is higher than that of the competitor, the target would tend to maintain relative advantage over the competitor in deliberation. Recall that initial activation values randomly vary across simulations. This randomness therefore leads to choice differences across simulations, and explains why sometimes the unlikely alternative was chosen. For example, the decoy was chosen with a slim chance in the attraction effect scenario – when the initial value of the decoy was very high relative to the target and the competitor, such initial advantage was too strong to be offset by the comparison-grouping mechanism. The modeling is consistent with the intuition that people have different pre-existing beliefs that randomly favor one alternative over another and tend to bias later decisions.

Binary Choice

The target and the competitor are set to equal additive attribute ratings: the target is rated 2.0 on gas mileage and 8.0 on performance, whereas the competitor is rated 8.0 on gas mileage and 2.0 on performance. The two attributes are assumed to be equally important. Consistent with the trivial prediction that their choice probabilities should be the same, the simulations yielded probabilities of 0.504 and 0.496 for them respectively. The slight inequality was due to the randomness in initial activations of the alternative nodes.

Attraction Effect

When the attraction effect occurs, the target benefits from the addition of the decoy more than does the competitor. Under some circumstances, this tendency leads to a higher choice probability for the target in the trinary set than in the core set. This constitutes a violation of the regularity principle of rational choice, according to which adding alternatives to a given choice set should not increase the probability of any alternative (Huber et al., 1982). In the simulation, the decoy was chosen to have attribute values of 1.5 and 7.5 for gas mileage and performance, respectively.

Comparison grouping, in conjunction with the competitive relationship among the alternatives, is able to explain this effect. Any time when the target is compared with the obviously inferior decoy (in modeling terms, this means the target node receives more input via the attribute-alternative connections than does the competitor), the activation of the target node increases whereas the activation the decoy node decreases. This differentiation is an intrinsic property of this type of connectionist model (c. f., McClelland & Rumelhart, 1988). Given that the deliberation process primarily consists of target-decoy comparisons, the target node would finally acquire higher activation than does the competitor.

The above analysis suggests that if the initial node activations were identical across the alternatives, the target would have been chosen for all simulations. However, with some randomness, it is possible that the competitor has a higher initial activation than does the target. If this initial difference, which has an impact on later comparisons, is large enough, the competitor would be chosen. This also suggests that with extreme initial values even the rather inferior decoy might be chosen. This seems consistent with the intuition that pre-existing beliefs regarding products carry a weight on later decisions.

The simulated choice probabilities of the target, the competitor, and the decoy were 58.7%, 36.6%, 4.8%. The probability of the target exceeds that in the binary choice scenario, thereby leading to a violation of the regularity principle.

Similarity Effect

In the decision situation that leads to the similarity effect, the target looks less attractive relative to the competitor once the decoy is introduced. Under certain situations, this would lead to a change of rank order of the target and the competitor. For example, in the simulated scenario, the core alternatives rank the same in the binary set, but the competitor would rank higher than the target if the similarity effect occurs. This constitutes a violation of the independence of irrelevant alternatives principle of rational choice, which states that adding a decoy to an original choice set should not alter the rank order of the alternatives (c. f., Tversky, 1972). Decoy was set to have attribute ratings of 2.5 and 7.5 for gas mileage and performance respectively. Note that its additive attribute rating is identical to that of the target.

Like in the case of the attraction effect, comparison grouping and inter-alternative competition are able to explain the similarity effect. Any time when the target is compared with the similarly attractive decoy, the activation

of both the target and the decoy nodes decrease due to their mutual inhibition of equal strength. This again is an intrinsic property of this type of connectionist model (c. f., McClelland & Rumelhart, 1988). Because the target-decoy comparison is the predominant type of comparison, compared to the competitor node, the target node hurts more from the comparison with the decoy, and would finally acquire lower activation than does the competitor.

The simulated choice probabilities of the target, the competitor, and the decoy were 27.8%, 39.7%, and 32.6%. Note that the tie between the target and the competitor was broken, indicating a violation of the independence of irrelevant alternatives principle.

In summary, the similarity effect and the attraction effect can be explained by frequency difference between the target-decoy and competitor-decoy comparisons. This also suggests that simulations of these effects should not depend on a particular specification of frequency ratio for the four types of comparisons – so long as this frequency difference is substantial, the two effects should be observed. In fact, other frequency ratios were used in our simulations and the same pattern was obtained (not reported here due to space limit).

Table 1: Simulation results as choice probability (estimated from 10,000 simulations).

Choice scenarios	Choice probability		
	Target	Competitor	Decoy
Binary choice	0.504	0.496	-----
Attraction effect	0.587	0.366	0.048
Similarity effect	0.278	0.397	0.326
Compromise effect	0.213	0.219	0.568

Table 2: Simulation results as average node activation and *SD*.

Choice scenarios	Average Node Activation (*SD*)		
	Target	Competitor	Decoy
Binary choice	0.293 (0.060)	0.294 (0.060)	-----
Attraction effect	0.320 (0.034)	0.305 (0.046)	0.233 (0.038)
Similarity effect	0.286 (0.033)	0.300 (0.046)	0.291 (0.033)
Compromise effect	0.275 (0.021)	0.276 (0.021)	0.291 (0.022)

Note. The results are computed from the simulations summarized in Table 1.

Compromise Effect

When the decoy for the similarity effect moves toward the competitor and finally reaches the middle point between the target and the competitor, the similarity effect turns into the compromise effect – The decoy changes from the least popular to the most popular alternative. In a decision scenario slightly different from the present one, this effect can also lead to a violation of the regularity principle (see Simonson, 1989 for more detail).

The comparison grouping assumption suggests that frequency of pairwise comparison increases with inter-alternative similarity. Accordingly, the percentages of the target-decoy, competitor-decoy, and target-competitor comparisons have the ratio of 2 : 2 : 1, inversely proportional to psychological distance[1]. The triple-wise comparison, being the least frequent, was arbitrarily set to one half as frequent as the least frequent pairwise comparison. Hence, the percentages of the four types of comparisons were set to 36.36%, 36.36%, 18.18%, and 9.10%.

The psychophysical assumption implemented in Equation 1 gives rise to this phenomenon. (This mechanism was still at work in the simulations of other two phenomena, but it did not play a causal role in producing them.) Take the target-decoy comparison for an example. The advantage of the decoy over the target (ratings of 5 versus 2 on gas mileage) looms larger than the advantage of the target over the decoy (ratings 8 versus 5 on performance) after the attribute ratings have been transformed into connection weights. (Calculated by Equation 1, the sum of the two attribute-alternative weights is 0.512 for the decoy, higher than the 0.505 for the core alternatives.) Hence the total input the decoy node receives via the attribute-alternative connections is the largest among the alternative nodes, making the decoy the winner.

The simulated choice probabilities of the target, the competitor, and the decoy were 21.3%, 21.9%, and 56.8%. Note that the specification of comparison percentages is not unique – so long as there is no frequency difference between the target-decoy and the competitor-decoy comparisons, neither the target nor the competitor would be bolstered relative to the other. The psychophysical mechanism would then guarantee choosing the decoy.

Comparison grouping provides a unified framework toward understanding the three phenomena. In particular, it explains why difference between the core alternatives exists in the similarity effect but disappears in the compromise effect, as comparison grouping can be modified by changing the similarity between the decoy and the core alternatives.

[1] This is just one way of specifying the inverse relationship between frequency ratio and similarity, which should be viewed as qualitative rather than quantitative. Note that in simulations of the other two effects, frequency ratios are not determined by the same function and just roughly reflect the inverse relationship.

Conclusion

We propose a stochastic comparison-grouping theory cast in a connectionist model to explain three important violations of rational choice. In addition, this model lends us understanding of the decision processes involved in these tasks.

A comparison is made between this model and previous accounts of the same findings. It extends Guo & Holyoak's (2002a, 2002b) model by incorporating insights from experimental data (Russo & Rosen, 1975; Satomura et al., 1997). In addition, it better accounts for individual differences in choice by introducing randomness in intial beliefs to the model. In comparison with Roe et al.'s (2001) model, both models use similarity relationship, but in different manners. Their model uses variable lateral inhibition that increases with inter-alternative similarity, whereas the current model proposes a similarity-based grouping mechanism. In addition, both models suggest momentarily shifted attention, again in different manners. In their model attention shifts from attribute to attribute, whereas in the present model attention shifts across different types of pairwise comparisons. The assumptions of this model seem more consistent with the aforementioned experimental data. Future studies are in order to further test the relative merits of the two models.

One apparent problem of the present model is that the modeling seems to depend on manually specified parameter values rather than psychological principles. Our justification is that these parameters specify linear transformations that do not alter the essence of the modeling assumptions. In addition, the same set of parameter values applies to all three phenomena.

Finally, this model is consistent with theoretical frameworks that relate cognition to perceptual processes (c. f., Medin, Goldstone, & Markman, 1995, Goldstone & Barsalou, 1998), and its proposed perceptual mechanisms might help us understand decision behavior at large.

Abstract

The paper clarified how actual expert dealers made profits and reduced the risk of loss in a virtual foreign exchange market, by comparing the way novice or general investors showed. As a result, we could find that the experts were risk-averse for losses and risk-seeking for profits while the novices showed the opposite behavioral tendency. This result was analyzed in terms of the prospect theory: It was found that the expert could be (partially) free from deposition effect and sunk-cost effect while the novices were not. It was also suggested that the experts' strategy of dumping losing currencies could be socially transmitted by the dealers' managers.

Introduction

How people make decision and learn in dispersed complex social systems has recently been considered important to be investigated. Here a dispersed complex social system is defined as a system without a centralized information resource and mechanism for deciding its behavior and, at the same time, with rapidly changing environments which provide their decision makers with information that continually changes. In this paper, we will focus on the (spot) foreign exchange market as a typical example of the complex social systems. This is because (1) the foreign exchange market have, as their constituents, a lot of market players (such as banks, investors, governments, and so on) who are different from one another in investment motivation, speculation, and stake etc., (2) it is not a centralized market, as the stock market, so that its market players have to fathom out market consensus based on limited information, and (3) it has rapidly changing environments which provide its decision makers with information on the order of seconds – the rate of change is typically faster than the decision makers can respond. So it is considered a good target of cognitive research to clarify how expert or skilled dealers make decisions, especially make profits and reduce the risk of loss, in the exchange market.

How can we investigate the process of expert dealers' decision making? For this purpose, experimental market (or economics) approach (for instance, Friedman & Sunder, 1994) seems useful: Experimental market is the field that attempts to understand the behaviors of the markets and their players by conducting experiments using real human subjects. From a cognitive perspective, the experimental market approach can be used to clarify the way of human biased decision making, by analyzing how market players actually make decisions in their conducting transactions on a virtual financial market that simulates the corresponding real market (Smith, 1996; Ueda, Taniguchi & Nakajima 2003). Namely, from the result of such a cognitive experiment on the markets, it is considered to understand how people or market players make decisions, in the real markets, under some biases such as representativeness (Kahneman & Tversky, 1972). This paper also adopts this **cognitive experimental market approach,** as its research methodology, in order to clarify what kind of biases influence expert dealers' decision making (profit making and risk hedge) in a virtual exchange market. We will pursue this research target, specifically by comparing the performance of expert or skilled dealers with that of novice or general investors.

There are some previous studies using the cognitive experimental market approach. For example, the U-Mart project aims to analyze the behaviors of the market, especially the conditions under which bumpy ride occurs, using a virtual future stock market (Kita, Sato, Mori & Ono 2003; Ueda, Taniguchi & Nakajima 2003). Because human players, as well as computer agents, participated in a series of experiments, it is possible to analyze the relation between the macroscopic behaviors, such as price fluctuation, of the market and the microscopic features of human players, which has not been realized yet.

Smith (1996 & 1997) analyzed, using three trained dealers as his subjects, how they reduced risks in dealing on a virtual spot currency market and proposed a feedback-control model of their risk management. Because he did not

compare the performance of his skilled subjects with that of novice or general investors, he did not clarify what kind of biases the skilled dealers had or were free from. In addition, it is a question that his subjects were actually expert dealers. In the experimental environment used in (Smith 1996; Smith 1997), each skilled subject was asked to make deals with a pre-installed computer dealer while, in that used in (Izumi, Nakamura & Ueda 2002), subjects were asked, in pairs, to make deals with one another through computer network, which virtually realized human-human dealing. In this sense, the latter environment can be said to be closer to the real dealing situation than the former. However, it is also a question that all of their subjects were actually expert dealers.

So, in this paper, we will ask real expert dealers to participate in our experiments and compare their performance with novice or general investors' one. Here, "expert" dealers mean those who had engaged in currency dealing or stock trading for more than five years, since this business field is a competitive jungle so that "engaging for five years" can be an index of being expert or skilled. On the other hand, we will ask graduate students majoring in economics to participate, as novice or general investors, in our experiments. Under this circumstance, we made two experiments in order to clarify how and under what kind of biases the expert dealers make profits and reduce the risk of loss in a virtual foreign exchange market. In this virtual market, only dollars and yen will be dealt.

This paper will be constructed as follows: In the second section, necessary terminology will be introduced. In the third and fourth section, the method of two experiments, which were made to clarify dealers' decision making, and their results will be explained. In the fifth section, the results obtained will be discussed from the perspective of the prospect theory (Kahneman & Tversky, 1979). In the final section, this paper will be concluded.

Terminology

Before we will explain our experiments, technical terms necessary for understanding dealers' trading behavior should be introduced.

Position: We will use this term from the point of the amount of dollars that each dealer has. "Long" means owning or holding dollars (i.e., the amount of dollars bought exceeds that of dollars sold). "Short" is the opposite of a long position. "Square" means the situation that the amount of dollars bought is equal to that of dollars sold. In our experiments, all the subjects were asked to start from the square position and to go back to the square at the end of the experiments.

Unrealized profits and losses (UPL): An increase/decrease in the value of dollars that is not "real" or "unrealized" because the dollars have not been sold. Once dollars are sold by a dealer, the profits/losses are "realized" by the dealer. If a dealer started from the square and bought one dollar at the rate of $1=Y100 and, after that, the rate has changed to $1=Y110, the dealer has Y10 as UPL, which will be realized when he/she sells the dollar to get back to the square. In our experiments, the performance of each dealer will be estimated in terms of UPL.

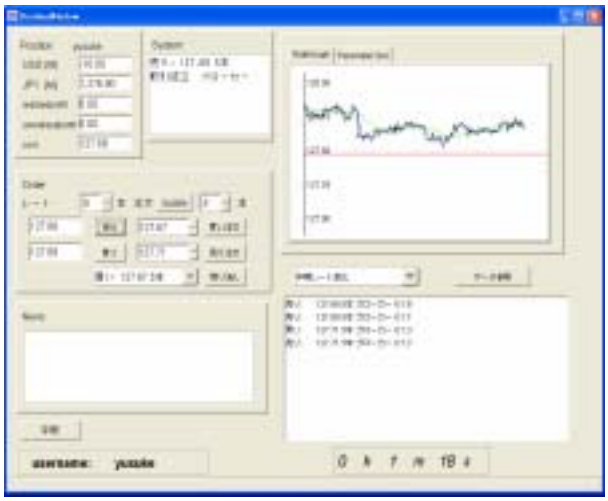

Figure 1: The user display of VDS (stand-alone type).

Lengthening vs. liquidation, profit-taking vs. loss cut: In this paper, such a dealing that the absolute amount of position increases is called "lengthening" while such a dealing that the absolute amount of position decreases is called "liquidation". Because it is related to dealers' risk management, the latter will be analyzed in detail. Moreover, liquidation can be divided into two sub-categories: profit-taking and loss cut.

Experimental Environment

The virtual dealing system (for abbrev., VDS; see Figure 1)[1], which we originally developed using Java language, was used in our experiments. The VDS was constructed so that users (subjects) could make dealings with one another through computer network; it simulates the functions and display of the actual dealing systems, such as Reuter 2000, so that users can get various fundamental information, such as interest rates and balance of trade, news and trends to buy and sell dollar/yen with other users or a broker[2].

The VDS is available both as a server-client system, in which multiple users make dealing with one another, all at once, through computer network, as is actual dealings, and as a stand-alone system, in which only one user makes dealing with the system's broker, as was in the experiment by Smith (1996 & 1997). In Experiment 1, it was used as the server-client system while, in Experiment 2, it was as the stand-alone system.

The VDS is designed so that we can get various users' dealing logs: For example, logs about what type and amount of dealing a user made at which time, and those about what type of information, news or trends a user referred to in his/her dealing. Therefore, by using the VDS, we can

[1] Because it was so built that the Japanese dealers would use, this VDS has Japanese signage, as denoted in Figure 1.

[2] Only one broker is assumed to exist in this VDS.

analyze what type of decision a user made referring to what kind of information.

Experiment 1

Purpose

The purpose was to make a hypothesis about how expert dealers made profits and reduced the risk of loss in a virtual foreign exchange market, by comparing the performance of the expert dealers with that of novice or general investors. The target was a dollar-yen exchange market, as already explained. Because this experiment aimed to explore a hypothesis about the way experts made decision, the server-client system was used so that it could provide the subjects with a dealing environment similar to the actual one.

Subjects

Eleven dealers, who had engaged in actual dealing or trading for more than five years, participated as "expert" dealers (we call this group of subjects **expert group**) while ten graduate students, who majored in economics, participated as "novice" or "general" investors (we call this group of subjects **novice group**).

Procedure

All the subjects of each group were gathered together, at a time, into one meeting room; the experiment of the expert group and that of the novice one were made independently.

The news and fundamental information given to the two groups were the same actual data during August, 1997; in the first half of this period, the rate was gradually moving up while, in the latter half, it rapidly and sharply declined, which was caused both by a decline in U.S. stock prices and by Japan's current account surplus. The rate change during the experiment was not calculated endogenously, i.e. as a result of dealings in the VDS, but given exogenously, i.e. the same as the actual change during this period: This was because the rate would have fluctuated quickly if the rate change had been endogenously calculated in such a dealing environment only with small number of market players. All the subjects were, in fact, given such an instruction that exchange rates were calculated by the orders of participating players, since the dealing environment of the experiment needed to be as close to the actual one as possible.

The subjects of each group were first explained about how they could use the VDS interface and make dealings through the VDS for 30 minutes. They were then given the information about the economic situation and fundamentals just before August, 1997[3]. After that, they were asked to make dealings through the VDS for 20 minutes[4].

[3] Because all the names of the currencies dealt, the target nations, and the proper names that came on were renamed, all the subjects did not notice that the rate and data given were the actual ones in the past. Of course, during the experiment, news was, from time to time, given to the subjects while the data of economic fundamentals and the trends of rate were always available.

[4] The events occurred in August, 1997 was compressed in the time frame of 20 minutes.

The data collected were the logs of each subject's positions, orders, referred economic information and messages of chatting, through the VDS, with other subjects.

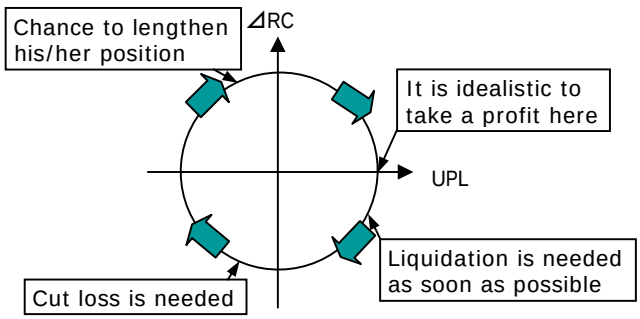

Figure 2: The risk space.

Method of analysis

The main purpose of the experiment was to make a hypothesis about how the respective groups made profits and reduced the risk of loss. So, for each subject, we plotted every log of dealing on the risk space (Smith, 1996): The risk space[5], which has an x-axis that denotes the value of UPL[6] for each dealing and has a y-axis that denotes the rate-of-change (RC) of exchange rates whose sign shows the increase in the absolute value of UPL[7], visualizes how each subject managed the risks caused by taking his/her positions (see Figure 2). By comparing the risk spaces of the expert group with those of the novice one, we can analyze how the expert dealers made decisions, especially reduced the risk of loss.

Result

Typical examples of the risk spaces plotted for the expert and the novice group are shown respectively in Figure 3 and 4; in these figures, a circle denotes buying dollars, a upside-down triangle does selling dollars, blue color does lengthening and red color does liquidation. From the nature of the figures, the lines of the graphs will extend towards high positive values of the x-axis if a subject waits to lock in profits after enough profits are made; in the same way, the lines will extend towards high negative value of the x-axis if he/she is so slow in cutting losses. Therefore, the higher the average profit is, the slower a subject tends to be in taking profits; the higher the average loss is, the slower he/she tends to be in cutting losses.

From these figures, we can find a tendency that the novices cut losses later than the experts. So, to statistically confirm the above, we calculated the average loss and profit respectively for the two groups in order to compare the average loss (or profit) of the expert group with that of the novice one. As a result, as for the average loss, we could

[5] The risk space used in this study was a little different from that used in (Smith 1996).

[6] The value of UPL was normalized, being divided by the amount of the maximum position of the subject.

[7] When a subject's position is long, $\Delta RC>0$ if dollar appreciation occurs while $\Delta RC<0$ if yen appreciation does.

find significant difference between the two groups (expert = -0.02854 (SD = 0.00035), novice = - 0.12315 (SD = 0.01124); p = 0.041<0.05, one-sided) while, as for the average profit, we could find no significant difference between the two groups (expert = 0.46511 (SD = 0.03293), novice = 0.37609 (SD = 0.02344); p = 0.190, one-sided).

From the above result, it is possible that experts can cut losses so fast that they may prevent the losses from increasing and, at the same time, can take profits at the right time while novices cannot: This is, however, considered to be little better than a hypothesis. It is because, as for the average profit, the number of dealings was so scarce that we could find no significant difference and because this result may be specific to a set of the exchange rate and news given to the subjects (hereafter, we call this set "scenario"). We therefore need to make an additional experiment to confirm the hypothesis obtained, with augmenting the number of dealings: The reason the number was small is considered to be attributed to the experimental environment of face-to-face dealing because almost all the expert subjects were acquainted with each other so that they, for a while, hesitated to make dealings. So we will make an experiment, as Experiment 2, by using a stand-alone type of VDS.

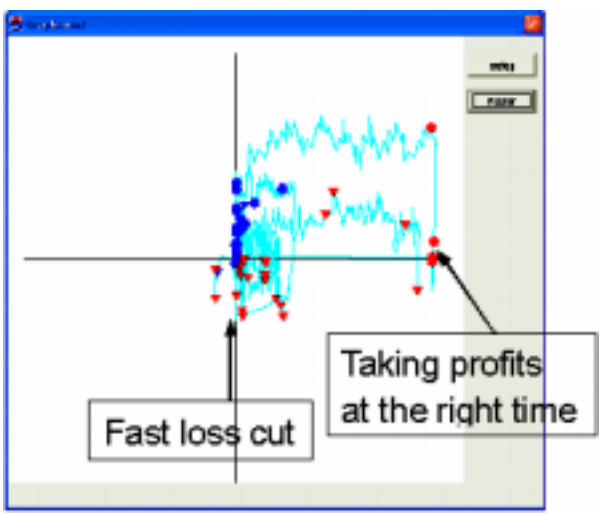

Figure 3: An example of the risk space of expert.

Figure 4: An example of the risk space of novice.

Experiment 2

Purpose

The purpose was to confirm the hypothesis derived from the result of Experiment 1: The hypothesis was that expert dealers could cut losses so fast that they might prevent the losses from increasing and, at the same time, could take profits at the right time while novices could not. Because of the reasons explained above, a stand-alone type of VDS was used in this experiment.

Subjects

Ten dealers, who had experienced more than five years' dealing, participated as "expert" dealers (**expert group**) while ten graduate students, who majored in economics, participated as "novice" investors (**novice group**).

Procedure

In this experiment, a stand-alone type of VDS was used so that all the subjects needed not to be gathered together at a time; each subject participated in this experiment independently. They were asked to make dealings with a computer dealer (computer-driven trading program) of the VDS.

The scenario (news and fundamental information) given to the two groups were the same actual data during September, 2000; through this period, the exchange rate showed a box or range rate, i.e. the rate fluctuated within the expected range. The rate change during the experiment was given exogenously, as was the same in Experiment 1[8].

All the subjects were first explained about how they could use the VDS interface and make dealings through the VDS for 40 minutes. They were then given the information about the economic situation and fundamentals just before September, 2000. After that, they were asked to make dealings through the VDS for 50 minutes.

The procedures other than the above were the same as those in Experiment 1.

Method of analysis

The same as that in Experiment 1.

Result

We calculated the average loss and profit respectively for the two groups in order to compare the average loss (or profit) of the expert group with that of the novice one. As a result, we could find significant difference between the two groups, both as for the average loss (expert = -0.01849 (SD = 0.00010), novice = - 0.031 (SD = 0.00005); p = 0.029 < 0.05, one-sided) and as for the average profit (expert = 0.09915 (SD = 0.00086), novice = 0.03619 (SD = 0.00013); p = 0.003 < 0.01, one-sided).

So our hypothesis was confirmed: We can say that the experts could cut losses so fast that they might prevent the losses from increasing and, at the same time, could take

[8] All the subjects were, in advance, informed of it.

profits (or lock in profits) after enough profits were made, whereas the novices could not.

Discussions

Analysis in terms of the prospect theory

From the results of the two experiments, we can say as follows: Expert dealers can cut losses so fast that they may prevent the losses from increasing and, at the same time, can take profits (or lock in profits) after enough profits are made. On the other hand, novices seem to be reluctant to sell currencies that lose value while they are inclined to lock in profits no sooner than the currencies they hold are profitable. Why is there a sharp contrast between the way experts make decision and that the novice do?

To answer this research question, we will introduce the prospect theory by Kahneman & Tversky (1979): The theory shows, based on the results of a laboratory experiment, that people's attitudes toward risks concerning profits may be quite different from their attitudes toward risks concerning losses. Namely the theory claims that people are, in general, risk-averse for profits and risk-seeking for losses.

By using the theory, the tendency that people are reluctant to lock in profits even when the losses increase while they are willing to do no sooner than their holdings become profitable can be explained by "deposition effect" (Shefrin & Statman 1985; Weber & Camerer 1998) and "sunk-cost effect" (Kahneman & Tversky 1979): The former means that people prefer certainty to uncertainty over a reference point while they show the opposite preference under a reference point. And the latter means that people tend to overestimate the cost needed for making a position; decision-makers are unduly influenced by resources that have already been spent and are therefore more likely to continue pursuing a previously chosen course of action.

This theoretical explanation seems to be true of the dealing behaviors of our novice subjects, because they sold promising currencies or winners too early and rode unpromising currencies or losers too long. That is, our novice subjects were considered not to be free from the biases of deposition effect and sunk-cost effect. On the other hand, our expert dealers seemed to avoid being distorted by these biases, because they could cut losses early and wait to lock in profits after enough profits were made.

Then the next question arises about whether expert dealers can be completely free from the biases. To clarify this point, we analyzed the dealing data in more detail. As a result, we could find that some expert dealers sometimes showed stepwise profit taking (see Figure 5). This stepwise way of profit-taking can be interpreted in two ways: One is that this indicates partial irrationality, which is subject to the biases, of their dealing behaviors and the other is that they were forced to take profits stepwise and to hedge risks caused by rapid price fluctuation because they could not fully predict the future exchange rate. Anyway, it can be said that even the expert dealers were not wholly free from the biases.

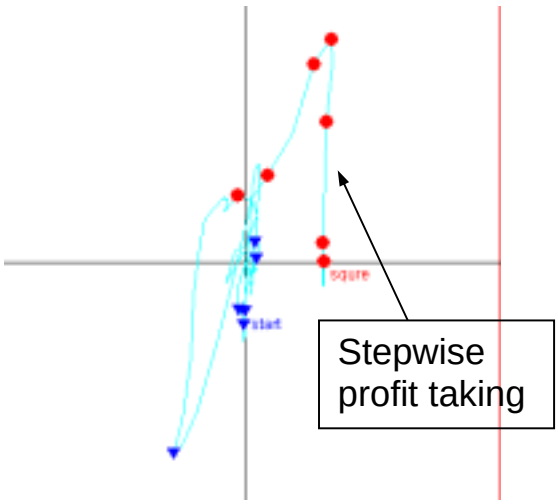

Figure 5: An example of the stepwise profit taking that some of the experts showed.

We also asked two investment managers why expert dealers can be free from the biases. Both of the managers said that dealers were taught, by their managers, to sell losers as early as possible because riding losers too long would only compound their losses, which might develop into a major management issue. On the other hand, the managers did not explicitly teach how to make profits. If this holds of dealers in general, it is possible that expert dealers have socially learned to be free from the biases. The investment managers added that a lot of dealers in the making had to drop out because it was quite difficult to learn to be free from the biases, which seemed easy on the surface.

To sum up, expert dealers can be (partially) free from the biases, in their decision making, that a lot of people are considered to have (Kahneman & Tversky 1979). This clarification, by using actual expert dealers as subjects, is the main contribution of this paper.

Conclusion

How people make decision and learn in dispersed complex social systems has recently been one of the important research issues. Especially the way of decision making needs to be investigated in real situations or settings. So, in this paper, we focused on the (spot) foreign exchange market as a typical example of the complex social systems and clarified how and under what kind of biases the expert dealers make profits and reduce the risk of loss in a virtual foreign exchange market. For this purpose, we asked real expert dealers to participate in our experiments and compared their performance with novice or general investors' one.

Our two experiments showed that the expert dealers could cut losses so fast that they might prevent the losses from increasing and, at the same time, could take profits (or lock

in profits) after enough profits were made. On the other hand, novices were reluctant to sell currencies that lost value while they were inclined to lock in profits no sooner than the currencies they held were profitable.

We analyzed this result in terms of the prospect theory (Kahneman & Tversky 1979). The prospect theory claims that people tend to sell promising currencies or winners too early and ride unpromising currencies or losers too long, under the influence of deposition effect and sunk-cost effect. This theoretical explanation was clarified to be true of the dealing behaviors of our novice subjects. On the other hand, it was also clarified that our expert dealers could avoid being distorted by the biases. In addition, it was possible that even the expert dealers were not wholly free from the biases because some of them showed stepwise way of profit-taking, which was considered not fully rational.

"Artificial market" research (Arthur, 1991) attracts attention of many researchers in recent years. In the artificial market research, computer programs as virtual market participants are built and simulated, where these computer programs mutually trade, for understanding the phenomena and features of real markets. The key is to build an artificial market with the appropriate features of the actual markets and their participants. The result of this paper is considered to be applicable to this artificial market research, especially to the construction of agents with the way of risk management in the artificial market model by Izumi & Ueda (2001). In this way, the result of this research is also of practical use.

Acknowledgments

We thank to all the subjects for kindly participating in our experiments. This research is partially supported by grant (Grants-in-Aid for Scientific Research, Scientific Research in Priority Areas 2003, No.A06-14) from Japan Society for the Promotion of Science.

Abstract

Cross-modal interaction in graphical communication is observed in collaborative problem-solving settings. Graphical communications, such as dialogues using maps, drawings, or pictures, provide people with two independent modalities: speech and drawing. Although the amount of drawing/self-speech overlap is strongly affected by activity-dependent constraints imposed by the task, the amount of drawing/partner's speech overlap is affected only weakly by these constraints. However, they do affect the function of the utterances in the case of drawing/partner's speech overlap. These results show that activity-level constraints affect the way speech coordinates drawing activities in cross-modal interaction. Furthermore, it suggests that turn-taking in multimodal communication requires general analyses integrating the functions of different modalities.

Introduction

Every joint activity requires coordination among its participants. When a band plays a piece, each member has to work on the same key, keep the same rhythm, and start and end at the same time (Clark (1996)). Some of these coordinating acts can be done across different modalities. In the case of music, a soloist can signal the end of her inprovisation not only with a phrase suggesting the solo's end, but also with eye-contact.

Communication is also a joint activity, and participants must coordinate with each other. One outstanding coordination principle in conversation is sequential turn-taking in speech channels. Several studies have been carried out on speech turn coordination, and some of them analyze cross-modal interaction between speech and nonverbal behaviors such as gaze and posture (Argyle et al. (1976), Kendon (1967)). In this paper, we investigate the interaction between speech and drawing, another powerful communication medium.

Turn-taking in speech involves a wide variety of factors such as sociological principles, the limitations of human cognitive capacity, and so on. One potentially strong factor for sequential turns in speech is the resource characteristics of media: speech media affords only one person's speech sounds at a time. Sacks et al. (1974) regard verbal turns as an economic resource, distributed to conversation participants according to turn organization rules. According to them, one of the main effects of these turn organization rules is the sequentiality of utterances. They observe that one party talks at a time in most cases.

Drawing, on the contrary, has quite different characteristics from speech. First, drawing is persistent whereas speech is not. Drawing remains unless erased, whereas speech dissipates right after it occurs. A drawing can be understood much later than when it is actually drawn, whereas speech must occur in real time. Second, drawing has a much wider bandwidth than speech. Two or more drawing operations can occur at the same time without interfering with each other, whereas simultaneous utterances are hard to understand. These resource characteristics allow for simultaneous drawing. There have been several studies on drawing interaction in the Human Computer Interaction field in the context of computer-supported collaborative work. Some researchers are optimimistic about the possibilities of simultaneous drawing (Stefik et al. (1987), Whittaker et al. (1991)), though others are not (Tatar et al. (1991)).

To approach this problem, Umata et al. (2003) have introduced yet another view based on the activity-dependent constraints imposed by the task performed in the interaction. The analyses show that sequential structure is mandatory in drawing either when the drawing reflects the dependency among the information to be expressed or when the drawing process itself reflects the proceedings of a target event. Further analyses show that speech interaction, which is already restricted by the resource characteristics of media, is not affected by activity-dependent constraints (Umata et al. (2004)).

The relation between drawing and speech modalities is, however, still not quite clear. Takeoka et al. (2003) analyzed face-to-face graphical communication and found that both utterances without drawings and utterances followed by the speaker's drawings behave similary in turn-holding function. They also show that longer silences are allowed while drawing is taking place. These results suggest that turns in communication can be maintained across speech and drawing modalities. This is also supported by the finding that drawing/self-speech overlap is much more frequent than drawing/partner's speech overlap (Umata et al. (2004)). The assumption of continuous turns across modalities is appealing from the viewpoint of modal integration: speech and graphic modalities decribe their target not just independently but also jointly, with linguistic phrases describing the target via graphics (Umata et al. (2000)).

In the following part of this paper, we analyze interac-

tion across these two modalities, focusing on drawing-speech overlap. The results show that the activity-dependent constraints strongly affect the amount of drawing/self-speech overlap, whereas they only weakly affect the amount of drawing/partner's speech overlap. These constraints, however, do affect how their drawing activities are coordinated verbally. We argue that activity-level constraints affect not only drawing-drawing interaction organization but also cross-modal interaction organization.

Drawing Turns and Speech Turns

As we have seen in the previous section, the sequentiality of speech turns has been attributed to the resource characteristics of speech, namely non-persistence and restricted bandwidth. The assumption is that we cannot comprehend two spoken utterances at the same time because of the bandwidth limitation, while we cannot delay comprehending one utterance until later because of the non-persistent characteristic. Drawing, on the contrary, functions quite differently in regard to these assumptions, and it may have potential for parallel turn organization. There have been seemingly contradictory observations of drawing turn organization; one is that drawing turns can be parallel, and the other is that they cannot be parallel. Umata et al. (2003) suggested that there is yet another kind of constraint based on the activities people are engaged in. According to this view, sequential structure is mandatory in drawing in some cases but not in others.

Sequentiality Constraints

1. Drawing interaction occurs in sequential turns under either of the following conditions:

(a) Information Dependency Condition: When there is a dependency among the information to be expressed by drawing;

(b) Event Alignment Condition: When drawing operations themselves are used as expressions of the proceedings of target events.

2. Sequential turns are not mandatory in drawing activities when neither condition holds (and when persistence and certain bandwidths of drawing are provided).

The rationale for the information dependency condition is the intuition that when one piece of information depends on another, the grounding of the former piece of information is more efficient *after* the grounding of the latter has been completed. This should be the case whether a particular speaker is explaining the logical dependency in question to her partners or all participants are following the logical steps together.

Event alignment is a strategy for expressing the unfolding of an event dynamically, using the process of drawing itself as a representation. For example, when you are reporting on how you spent a day in a town by using a map, you might draw a line that shows the route you actually took on the map. In doing so, you are aligning the drawing event with the walking event to express the latter dynamically. Our hypothesis is that simultaneous drawing is unlikely while this strategy of event alignment is employed. Under this condition, the movement or process of drawing is the main carrier of information. The trace of drawing has only a subsidiary informational role. Thus, in this particular use of drawing, its persistency is largely irrelevant. The message must be comprehended and grounded in real time, and the bandwidth afforded by the drawing surface becomes irrelevant. This requirement effectively prohibits the occurrence of any other simultaneous drawing.

An analysis on the corpus gathered from collaborative problem-solving tasks demonstrates that these two activity-dependent constraints can override the resource characteristics of the drawing media, thereby enforcing a sequential turn organization similar to those observed in verbal interactions (Umata et al. (2003)).

These activity-dependent constraints, however, do not affect the speech turn organization that is already affected by resource characteristics. The amount of simultaneous speech shows no difference among different task conditions (Umata et al. (2004)).

In the following part of this paper, we will look into the details of cross-modal overlap, based on the analysis of collaborative problem-solving task data gathered by Umata et al. (2003). We will compare the speech turn organization patterns in different task settings to see whether activity-dependent constraints affect the amount of drawing-speech overlap.

Method

An experiment in which subjects were asked to communicate graphically was conducted to examine the effect of the two factors presented above on their interaction organization. In these experiments, 24 pairs of subjects were asked to work collaboratively on four problem-solving tasks using virtual whiteboards.

Experimental Setting

In the experiments reported here, two subjects collaboratively worked on four different problem-solving tasks. All of the subjects were recruited from local universities and paid a small honorarium for their participation. The subjects were seated in separate, soundproof rooms and worked together in pairs using a shared virtual whiteboard (50 inches) and a full duplex audio connection. The subjects were video-taped during the experiment. They also wore cap-like eye-tracking devices that provided data indicating their eye-gaze positions. The order in which the tasks were presented was balanced between the 24 pairs so that the presentation order would not have an affect on the results. The time limit for each task was six minutes.

At the start of each task, an initial diagram was shown on the subjects' shared whiteboard and the subjects were then free to speak to one another and to draw and erase on the whiteboard. The only limitation to this drawing ac-

tivity was that they could not erase or occlude the initial diagram. All drawing activity on the whiteboard was performed with a hand-held stylus directly onto the screen, and any writing or erasing by one participant appeared simultaneously on the whiteboard in the partner's room. The stylus controlled the position of the mouse pointer and, when not drawing, the positions of both subjects' mouse pointers were displayed on the shared whiteboard.

Tasks

Deduction Task with an Event Answer (1e) A logical reasoning problem with a correct answer. The problem asks the subjects to describe the arrangement of people around a table and the order in which the people sit down. This seating arrangement and order must satisfy some restrictions (e.g., "The fifth person to sit is located on the left-hand side of person B."). A circle representing a round table was shown on the whiteboard at the start of the task. This task has strong informational dependency and strong event alignment.

Deduction Task with a State Answer (1s) A logical reasoning problem with a correct answer asking that the subjects design a seating arrangement satisfying some restrictions (e.g., "S cannot sit next to M."). A circle representing a round table was shown on the whiteboard at the start of the task. This task has strong informational dependency and loose event alignment.

Design Task with an Event Answer (2e) A task with an open-ended answer, asking subjects to make an excursion itinerary based on a given town map. A complete town map was shown on the whiteboard at the start of the task. This task has weak informational dependency and strong event alignment[1].

Design Task with a State Answer (2s) A task with an open-ended answer, asking the subjects to design a town layout to their own liking. An incomplete town map was shown on the whiteboard at the start of the task. This task has weak informational dependency and loose event alignment.

Data

During each task, all drawing, erasing, and mouse movements by each subject were recorded in a data file. Using this data, the amount of simultaneous drawing was calculated as the total time spent drawing simultaneously as a percentage of the total time either subject spent drawing (i.e., the sum of the time intervals in which both subjects drew simultaneously divided by the sum of the time intervals in which at least one of the pair drew on the whiteboard). Speech was recorded with video-data and labeled by hand. As with the drawing data, the amount of simultaneous speech was calculated as the total time spent talking simultaneously as a percentage of the total time either subject talked.

[1]Note that these categories are relative rather than absolute. For example, (2e) also has informational dependency to a certain extent in that each path has to start from the icon of the previous place they decided to visit. However, they can choose the next destination freely. Thus informational dependency is much weaker than in the cases of the seat arrangement tasks where one decision significantly narrows down the subsequent alternatives; e.g., seating a person *M* in a certain position means only *S* or *O* can sit right next to *P*, and so on.

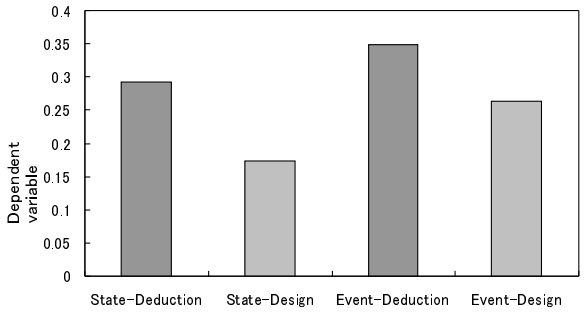

Figure 1: Proportion of drawing/self-speech overlaps

Analysis 1

Drawing/Self-Speech Overlap

As shown in Figure 1, the proportion of drawing/self-speech overlap time to total drawing time was the smallest in the design state (2s) condition. This data was entered into a 2 x 2 Analysis of Variance (ANOVA). Both problem type (deduction and design) and solution type (state and event) were treated as within-subject factors. Analysis revealed a main effect of problem type $F(1,47)=24.968$, $p<.001$ and solution type $F(1,47)=21.783$, $p<.001$ and showed no interaction $Fs < 1$.

Thus, it was shown that the proportion of drawing/self-speech overlap is smaller when the task has either weaker informational dependency or weaker event alignment, or both.

Drawing/Partner's Speech Overlap

As shown in Figure 2, the proportion of drawing/partner's speech overlap time to total drawing time demonstrated a significant, but smaller, difference in each condition compared to the case of self overlap. This data was entered into a 2 x 2 ANOVA. Both problem type (deduction and design) and solution type (state and event) were treated as within-subject factors. Analysis showed a simple main effect of solution type $F(1,47)=4.484$, $p=.04$. No effect was found for the problem type, and analysis showed no interaction $Fs < 1$.

The analysis showed that the proportion of drawing/partner's speech overlap is only weakly affected by the event alignment condition.

Discussion for Analysis 1

The amount of drawing/self-speech overlap is smaller when the task has either weaker informational dependency or weaker event alignment, or both. The activity-dependent constraints work on self-cross-modal overlap

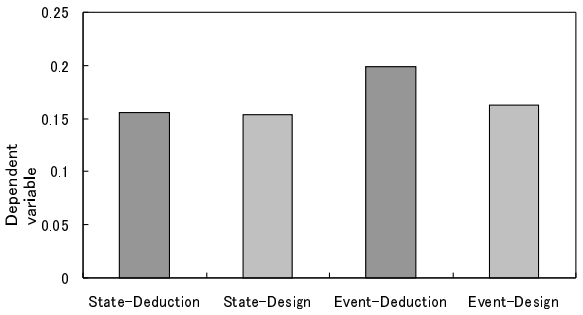

Figure 2: Proportion of drawing/partner's speech overlaps

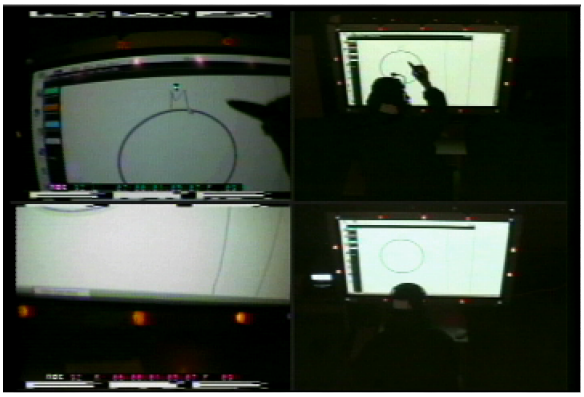

Figure 3: Sequential drawing interaction coordinated verbally (1)

in the opposite way of simultaneous drawing: the amount of simultaneous drawing is smaller when the task has stronger information dependency or weaker event alignment, or both.

This result seems quite reasonable if we consider the way people coordinate their drawing activities verbally. Whittaker et al. (1991) observed verbal coordination of drawing activities through the examination of shared whiteboard communication *with* and *without* the addition of a speech channel. They found that permanent media such as a whiteboard provides users with space for constructing shared data structures around which they can organize their activity. With the addition of a speech channel, people used the whiteboards to construct shared data structures that made up the CONTENT of the communication, while speech was used for coordinating the PROCESS of communication.

As observed in Umata et al. (2004), utterances coordinating drawing activities are also commonly found in our tasks. Figure 3 is a snapshot from the deductive state task (1s). Subjects *A* and *B* have just agreed to fix *M*'s seat first, and *A* suggests "*M*'s seat should be ... here, right?" while drawing the sign M. Then, *B* gives verbal acknowledgement, "Yes." Here, *A*'s utterance serves as a signal for his drawing activity.

Such signal utterances typically preceed drawings, and drawings follow, overlapping them. Signal utterances are expected to occur more often when people feel a stronger need to coordinate their drawing activities; i.e., in cases where activity-level constraints require sequential drawing turns. As expected, drawing/self-speech overlap is most frequent when the task has strong informational dependency or tight event alignment, or both.

There are two other possible explanations for the result. The first is that drawers have to give more verbal explainations of what they are doing as the task increases in difficulty. This does not seem to be the case, though. First, those signal utterances are usually quite simple and short: e.g., "*M* is here," "Station," etc. Second, their drawings are generally simple and easy to understand even in the tasks with stronger constraints. In the seat arrangement tasks ((1e), (1s)), each icon is an alphabetic letter standing for a person. Its position on the table icon simply shows where the person has to be seated, and the sequence of letters beside the table icon means the order of the seating. In the case of the excursion itinerary task (2e), the drawings were mainly route icons and labels showing time of arrival/departure and so on. The meaning of each drawing is also clear to the partner in this case. On the other hand, some icons can be unintelligible to the partners in the case of the town layout task (2s): a box can mean a building icon, a station icon, or anything else. Actually, people sometimes had to ask their partners for more clarification in (2s). Thus, the utterances about what they are drawing are likely to be just signals rather than detailed explanation of their drawing.

The second possible explanation is that simultaneous drawing and cross-modal overlap are affected not by the activity-level constraint but by the symbolic status of the drawing. That is, the drawing requires sequential drawing turn organization in (1s), (1e) and (2e) because they are not just a set of icons but rather a language-like symbolic system. This is also unlikely, since the drawings are almost equally simple throughout the tasks, as described above. It is possible, though, that more complicated symbolic systems require sequential turns and that it is difficult to separate the effect of the activity-level constraint and that of symbolic constraction. More work is required to illuminate the detailed mechanism underlining sequential drawing turn organization.

The activity-level constraints have a much weaker effect on the amount of drawing/partner's speech overlap. Because people cannot precisely predict when and where their partner will start drawing, verbal coordination of drawing activities typically takes the form of signal utterances. This may be why these constraints did not impact strongly on the amount of drawing/partner's speech overlap.

Another possible explanation is that turns in graphical communication tend to be maintained across speech and drawing modalities. Drawing/self-speech overlap is much more common than partner's speech overlap

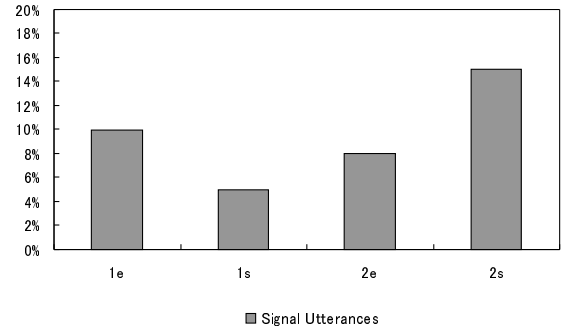

Figure 4: Frequencies of verbal signals for drawing

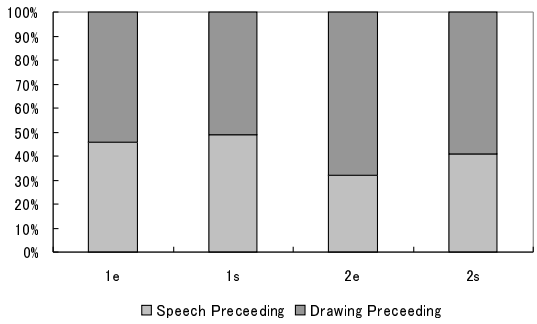

Figure 5: Frequencies of utterance preceeding overlap

(Umata et al. (2004)). The effect of activity-level constraints is much weaker, perhaps because the cross-modal turn organization already blocks speech overlap by partners.

Analysis 2

It was shown that the activity-dependent constraints affect the amount of drawing/partner's speech overlap only weakly, whereas they strongly affect the amount of drawing/self-speech overlap. In this section, we analyze drawing/partner's speech overlap in more detail to determine whether there are any differences among task conditions.

The drawing occurences analyzed above were all recorded as the time duration that the pen is touching the screen. Some drawing activities are divided into segments that are too small under this method. For example, some subjects drew many dots or lines to give colors to some icons. It is unreasonable to divide such an activity into many drawing occurences when we perform closer analysis on each overlapping case of drawing and speech modalities. The drawing occurences within 400 msec gaps are regarded as a *drawing unit* for the analysis below, in the same way as when we divide speech into utterance units. One member of each of the 24 dyads tested was randomly selected for the following analyses.

Verbal Signals for Drawings

The frequencies of verbal signals in all drawing/partner's speech overlap were compared among different task conditions. The analysis showed significantly different proportions among conditions ($\chi^2_{(3)} = 13.775, p < .003$). More concretely, verbal signals in drawing/partner's speech overlap are most frequent in the design state condition (2s), as shown in Figure 4 (adjusted residual: (1e) $= -1.2$, (1s) $= -8.7$, (2e) = -5.4, (2s) $= 15.3$). The design state condition has fewer verbal signals for drawing overall, so their high frequency in drawing/partner's speech overlap is rather outstanding.

Other Findings: Drawing Preceeded Overlaps

We also compared the frequencies of drawing preceeding overlap in drawing/partner's speech overlap among different task conditions. The analysis shows significantly different proportions between deduction conditions (1e, 1s) and design (2e, 2s) conditions ($\chi^2_{(3)} = 7.740, p < .005$). More concretely, the design conditions have fewer drawing preceeding overlap than the deduction conditions, as shown in Figure 5 (adjusted residual: (1e, 1s) $= -19.2$, (2e, 2s) $= 19.2$). People start drawing while their partners are speaking more often in the design condition than the deduction condition.

Discussions for Analysis 2

Drawing/partner's speech overlap includes more verbal signals for drawings in the design state condition (2s) than in any other condition. This reflects the parallel interaction style of drawing in (2s). While verbal signals serve to maintain sequential drawing interaction in the case with stronger activity-level constraints, these signals often serve to coordinate parallel drawing activities when they occur in (2s). Verbal signals also overlap the partner's drawings in some of these cases. Figure 6 shows one such case. Subjects *A* and *B* agreed to divide the design task into two sub-tasks, the design of a station plaza and that of a park. Then, *A* said "Station," and *B* said "I'll make the forest," before starting their respective drawing activities. Here, they verbally coordinated their simultaneous drawing activity, and their verbal signals overlap their partner's drawings.

Drawing preceeding overlap is more frequent in the design condition (1) than in the deduction condition (2). This means only the information dependency constraint affected the frequency of speech preceeding overlaps. Although we cannot give any clear explanation for this phenomenon, we assume this result reflects the different characteristics of these two activity-dependent constraints. The information dependency constraint has a more general nature across modalities: when one piece of information depends on another, the grounding of the former piece of information is more efficient after the grounding of the latter has been completed. On the contrary, event alignment is rather drawing-modality-specific: the drawing process reflects the process of the described event. In this sense, drawing activities are less dependent on the information given in speech modalities

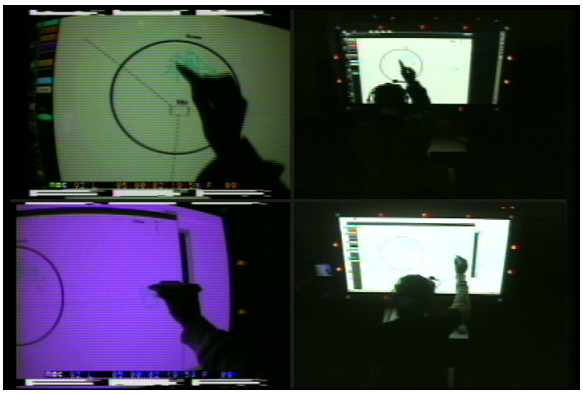

Figure 6: Parallel drawing interaction coordinated verbally

than in cases with strong information dependency. However, the mechanism causing this phenomenon remains unclear. More work is required to demonstrate how the two modalities interact.

Conclusions

Based on the data of collaborative task solving settings, we have analyzed cross-modal interaction in graphical communication. We found that the amount of drawing/self-speech overlap is strongly affected by the activity-dependent constraints, while the amount of drawing/partner's speech overlap is affected only weakly by these constraints.

There are, however, significant differences in the function of the utterances in the case of drawing/partner's speech overlap. Drawing/partner's speech overlap includes more signal utterances for drawing when the activity-level constraints are weaker. This result reflects the parallel interaction style of drawing under weak activity-level constraints.

The precedence of drawing/partner's speech overlap is also affected by the information dependency constraint. Although it is likely that the modality-general nature of this constraint plays a significant role, the mechanism of this phenomenon is still not clear.

These findings indicate that the activity-level constraints affect the way speech coordinates drawing activities in cross-modal interaction and suggest that interaction organization in multimodal communication is a complex phenomenon that requires general analyses integrating the functions of different modalities.

Stylistic and Contextual Effects in Irony Processing

Akira Utsumi (utsumi@se.uec.ac.jp)

1-5-1 Chofugaoka, Chofushi, Tokyo 182-8585, Japan

Abstract

Irony is perceived through a complex interaction between an utterance and its context and serves many social functions such as to be sarcastic and to be humorous. The purpose of this paper is to explore what role linguistic style and contextual information play in the recognition of irony (i.e., assessing the degree of irony) and in the appreciation of ironic functions (i.e., assessing the degree of sarcasm and humor). Two experiments demonstrated that the degree of irony and sarcasm was affected primarily by linguistic style (i.e., sentence type and politeness), while the degree of humor was affected by both linguistic style and contextual information (i.e., context negativity and ordinariness of negative situation). These results are almost consistent with the predictions by the implicit display theory, a cognitive theory of verbal irony. Discussion of the findings also suggests that the implicit display theory can account for an indirect effect of context on the degree of irony.

Introduction

Irony is an interesting pragmatic phenomenon whose processing involves complex interaction between linguistic style and contextual information. There are also good reasons for probing the mechanism of irony processing in cognitive science. First, irony offers an effective way of accomplishing various communication goals for maintaining and modifying social and interpersonal relationships that are difficult to do literally. Second, irony processing requires higher-order mindreading ability (Happé, 1993), which has been argued to play an important role in the interpretation of ordinary utterances (Wilson and Sperber, 2004). Third, as Gibbs (1994) argues, an ironic way of talking about experiences reflects our figurative foundation for everyday thought.

Recently, many studies have paid much attention to irony processing (e.g., Gibbs, 1994; Sperber and Wilson, 1995; Attardo, 2000; Colston, 2002; Giora, 2003). However, most of these studies focus only on the difference of processing between ironic utterances and literal ones, in spite of the fact that irony is communicated by various kinds of expression (Kumon-Nakamura, Glucksberg, and Brown, 1995; Utsumi, 2000). For example, to your partner who stepped on your feet many times during a dance, you can say ironically in various ways: not only an opposition statement like "You're really a good dancer", but also a true assertion "I love good dancers", a rhetorical question "Could you step on your own two feet?", a circumlocutory utterance "I guess you have a broken leg", and so on. The purpose of this study is to empirically examine how irony processing differs among different kinds of ironic utterances and what role style and context play in causing such differences.

The issue of controversy in irony research is according to what features of irony people distinguish irony from nonirony. Beyond the fallacious view that irony is a meaning opposition or a mere violation, a number of studies have proposed a variety of views of irony: Irony is an echoic interpretation of an attributed thought (Sperber and Wilson, 1995), joint pretense (Clark, 1996), relevant inappropriateness (Attardo, 2000), or indirect negation (Giora, 2003). However, these theories suffer from the same problem that they have attempted to provide necessary and/or sufficient properties for distinguishing irony from nonirony; there appear to be no such properties shared by all ironic utterances. To overcome this difficulty, I have proposed a more comprehensive view of irony, *implicit display theory of verbal irony* (Utsumi, 2000). The implicit display theory takes a comparative view that irony is a prototype-based category, which is the idea underlying cognitive linguistic research. Another point in which the implicit display theory radically differs from the previous views is that it claims a differential role of style and context, whereas the previous theories do not address such a difference or they confuse the different roles. According to the implicit display theory, style of an ironic expression is used to assess to what degree a specific ironic utterance is similar to the prototype of irony, while context motivates the addressee to interpret an expression ironically. The study I present in this paper empirically examined to what degree people perceive an utterance as ironic depending on style of the utterance and its context, and tested whether the claims of the implicit display theory can explain the observed result.

Another heated topic in irony research is the social function of irony, which provides a plausible answer to why people use irony. The functions are divided into negative ones such as to be sarcastic and to criticize, and positive ones such as to be humorous. Previous studies (e.g., Dews and Winner, 1995; Colston, 2002) have compared the degrees of negative effect between ironic utterances and literal equivalent utterances. However, these studies have not addressed how various kinds of ironic utterances differ in negative and positive functions. My study thus examined both negative and positive effects of various ironic utterances by asking people to rate the degree of sarcasm and humor, and tested whether the obtained finding can be explained by the implicit display theory.

Implicit Display Theory

The main claim of the implicit display theory is threefold (Utsumi, 2000). First, irony presupposes *ironic environment*,

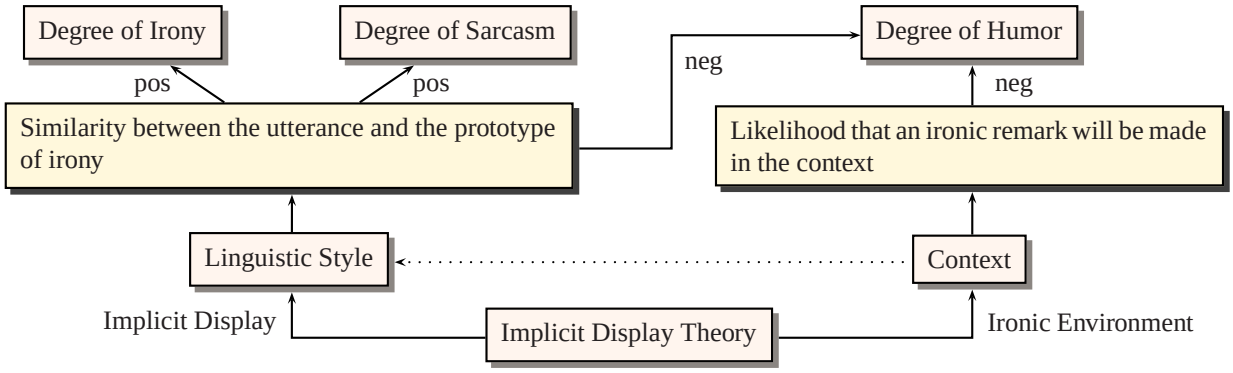

Figure 1: General hypothesis for irony processing elicited from the implicit display theory.

a proper situational setting in the discourse context. Ironic environment consists of (a) speaker's expectation, (b) incongruity between the expectation and the reality, and (c) speaker's negative attitude toward the incongruity. In order for an utterance to be interpreted ironically, the implicit display theory argues, the discourse situation must be identified as ironic environment through the process of checking or inferring these constituents. In the 'dance' example presented above, you have expected that your partner dances well with you but your expectation is not fulfilled, and you gets disappointed or angry at the result. That situation is thus identified as ironic environment.

Second, irony is an utterance that *implicitly displays* ironic environment. Implicit display of ironic environment is achieved by an utterance which (d) alludes to the speaker's expectation, (e) includes pragmatic insincerity by violating one of pragmatic principles, and (f) expresses indirectly the speaker's negative attitude by being accompanied by ironic cues. For example, your utterance "You're really a good dancer" in the above situation satisfies the three conditions of implicit display. First, it mentions, and thus alludes to, your expectation of the partner dancing well. Second, it is a literally false statement that violates the maxim of quality. Third, the hyperbolic word "really" is used to exaggerate the ironic attitude.

Third, as I mentioned in the introduction, irony is a prototype-based category characterized by the notion of implicit display. The prototype of irony is an abstract exemplar which completely meets all the three conditions for implicit display. The degree of irony can be assessed by the similarity between the prototype and a given utterance with respect to the three conditions. Let us consider again the 'dance' example. A circumlocutory statement "I guess you have a broken leg" can be interpreted ironically, but its degree of ironicalness may be much smaller than the typical type of irony "You're really a good dancer". This difference can be explained in terms of to what degree an utterance achieves the implicit display. The circumlocutory statement is only weakly related to the speaker's expectation by a number of coherence relations, whereas the opposition statement directly refers to the expectation. Furthermore, the circumlocutory statement is pragmatically insincere to a much lesser degree than the opposition statement including an apparent violation.

General Hypothesis

The implicit display theory posits the hypothesis for irony processing, which is summarized in Figure 1. On the one hand, style of an ironic sentence, which corresponds to properties of implicit display, governs how similar it is to the irony prototype, i.e., the degree of irony. On the other hand, context determines how likely one is to make an ironic remark, i.e., likelihood of irony, based on to what degree each of the three constituents for ironic environment holds in that context.

This differential role of style and context allows us to draw a general hypothesis about the degree of irony: *The degree of irony is affected by linguistic choice, not by contextual setting, and it is high to the extent that the properties of implicit display are satisfied*. Furthermore, it is reasonably assumed that the degree of sarcasm of ironic utterances proportionally depends on the degree of irony because sarcasm is often conveyed in the form of irony. It is therefore hypothesized that *the degree of sarcasm of an ironic utterance is affected only by linguistic style and it is high to the extent that the properties of implicit display are satisfied*. Note that the hypothesis on the degree of sarcasm does not hold true for victimless irony, which are often perceived as nonsarcastic (Kreuz and Glucksberg, 1989). Because this study attempts to explore the negative function toward a victim of irony, I did not use victimless ironies in the experiments.

Unlike irony and sarcasm, how the degree of humor is determined cannot be directly explained by the implicit display theory. I thereby adopt an incongruity-resolution model of humor (Attardo, 1997), a cognitive model widely accepted in humor research. The incongruity-resolution model argues that humor involves an incongruity between what was expected based on our conceptual pattern and what occurred in the humorous event, which is often expressed by a punch line in humorous texts. When such incongruity is resolved immediately by generating a reinterpretation of a humorous expression, humorous effect takes place. Since we are concerned with interpretable ironic utterances (i.e., they are assumed to be equally resolvable), it is hypothesized that the degree of humor proportionally depends on the degree of incongruity involved in ironic utterances. According to the implicit display theory, ironic utterances involve two kinds of incongruity: (a) incongruity between an expected type of utterance (e.g., ironic or literal) and the actual type of a given utterance (i.e., irony in this paper), degree of which is inversely related

to the likelihood of irony; and (b) incongruity (i.e., dissimilarity) between the irony prototype and a given ironic utterance. If the incongruity-resolution model and the implicit display theory are plausible, a general hypothesis about the degree of humor is as follows: *The degree of humor of an ironic utterance is affected by both linguistic style and context, and it is high to the extent that a discourse context is incongruous to the ironic environment or that the utterance is dissimilar to the irony prototype.*

Experiment 1

The purpose of Experiment 1 is to test the implicit display theory by examining how linguistic style affects the degree of irony, sarcasm and humor. Linguistic style of irony was manipulated by two factors: sentence type and politeness level.

Three sentence types were used in Experiment 1: opposition, rhetorical question and circumlocution. An opposition is a statement whose positive literal meaning is the opposite of the negative situation and thus includes the speaker's expected event or state. A rhetorical question is an interrogative statement by which the speaker rhetorically asks for the obvious fact to the addressee. A circumlocution is a kind of understatement which is weakly related to the speaker's expectation by a number of coherence relations. It is reasonably assumed that an opposition is more related to, and thus more alludes to, the speaker's expectation than a rhetorical question and a circumlocution, and that an opposition and a rhetorical question are pragmatically more insincere than a circumlocution. It follows that an opposition would be the most similar to the prototype of irony and that a rhetorical question would be more similar than a circumlocution.

Politeness is also an important linguistic property which can signal irony. Some experimental studies (Kumon-Nakamura et al., 1995; Okamoto, 2002) found that overpolite utterances are perceived as more ironic. In Experiment 1, politeness level was manipulated by the combination of the use or nonuse of Japanese honorifics (i.e., a system of politeness expressions incorporated into the grammar) and the relationship between the speaker and the addressee (good or bad). The reason for considering speaker-addressee relationship is that whether the use of honorifics shows overpoliteness is determined according to the speaker-addressee relationship (Okamoto, 2002). Generally speaking, when the speaker and the addressee are intimate or on good terms, an utterance with honorifics would be overpolite and unnatural. On the other hand, when they are not intimate or on bad terms, honorifics are usually used for an utterance to be appropriately polite; an utterance without honorifics would be impolite or rude. According to the implicit display theory, overpolite utterances are pragmatically insincere because they can be seen as violating the convention in linguistic politeness. Therefore, other things being equal, overpolite utterances are more similar to the prototype of irony than appropriately polite or impolite utterances.

Prediction

The general hypothesis by the implicit display theory makes the following predictions on the stylistic effect.

(1) Oppositions are the most ironic and the most sarcastic, and rhetorical questions are more ironic and more sarcastic than circumlocutions. On the other hand, circumlocutions are the most humorous, and rhetorical questions are more humorous than oppositions.

(2) Overpolite utterances, i.e., utterances with honorifics by the speaker who is on good terms with the addressee, are more ironic, more sarcastic and less humorous than appropriately polite or impolite utterances.

Method

Participants One hundred and twenty undergraduate students participated for this experiment. All were native Japanese speakers.

Materials and Design Twelve stories were constructed in which the addressee was responsible for the negative situation (and thus a victim) and in which the speaker gave a remark toward the addressee. Each of the stories had two versions: Speaker-addressee relationship is good or bad. Each story was followed by one of the six versions of the final utterance (three sentence types × with/without honorifics). An example of the stories and the final remarks is as follows[1]:

> In the restaurant, the customer was not served the ordered dishes for a while. He said to the master of the restaurant, who is on {good / bad} terms with him:
>
> Opposition: "This restaurant serves the dishes quickly."
> (*Kokoha ryouri wo dasunoga hayai* {*ne* / *desu ne*}.)
>
> Question: "Do you know the recipe for the dishes?"
> (*Ryouri no tsukurikata wo shitteiru* {*no? / no desuka?*}.)
>
> Circumlocution: "I think you are just going to buy recipe ingredients."
> (*Ima zairyou wo kai ni itteiru kato* {*omotta / omoimashita*} *yo*.)

Procedure Each participant was assigned to 12 different stories involving 12 combinations of conditions. The participants read each story and rated the final utterance at the end of the story on the following two 7-point scales: "How sarcastic is the speaker's remark?" (1 = not at all sarcastic; 7 = extremely sarcastic) and "How humorous is the speaker's remark?" (1 = not at all humorous; 7 = extremely humorous). After reading and rating all stories, they read the stories again and rated the degree of irony ("Do you feel the speaker's remark is ironic?") of all the final utterances on a 7-point scale (1 = not at all ironic; 7 = extremely ironic).

Results and Discussion

Type (opposition, rhetorical question, circumlocution) × Honorifics (with honorifics, without honorifics) × Relationship (good, bad) repeated-measures ANOVAs were conducted. In all analyses, the data were analyzed by subjects (F_1) and by items (F_2).

Irony and Sarcasm Ratings The main effect of sentence type was significant both for the degree of irony (only by subject analysis), $F_1(2, 238) = 5.30$, $p < .01$, and for the degree of sarcasm, $F_1(2, 238) = 16.18$, $p < .001$, $F_2(2, 22) = 5.39$, $p < .05$. Post-hoc pairwise comparisons ($p < .05$) revealed that oppositions were significantly more ironic and more sarcastic than circumlocutions, and more sarcastic than rhetorical questions, as shown in Figure 2. Moreover, rhetorical

[1]The original Japanese remarks used in the experiment are indicated by italics and honorific words are indicated by underlines.

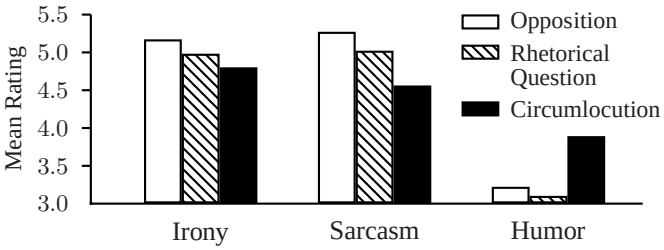

Figure 2: Mean ratings of irony, sarcasm and humor by sentence type.

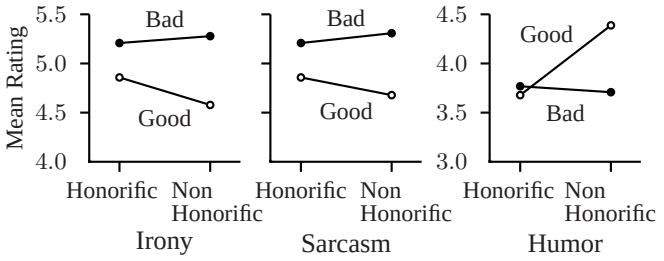

Figure 3: Mean irony and sarcasm ratings for honorific and nonhonorific utterances and mean humor ratings for honorific and nonhonorific circumlocutions in different speaker-addressee relationships.

questions were found to be significantly more sarcastic than circumlocutions. These findings are almost consistent with Prediction (1).

There was also a significant Honorifics $\times$ Relationship interaction only by subject analysis for the degree of irony, $F_1(1,119) = 5.44$, $p < .05$; and for the degree of sarcasm, $F_1(1,119) = 7.85$, $p < .01$. As shown in Figure 3, when the speaker was on good terms with the addressee, honorific utterances were rated as significantly more ironic and sarcastic than nonhonorific ones, but such difference disappeared when the speaker was on bad terms with the addressee. This result is consistent with Prediction (2) in that overpolite utterances are more ironic and sarcastic than appropriately polite utterances. However, the observed higher degrees of irony and sarcasm for the utterances by the speaker who is on bad terms with the addressee are not compatible with the prediction.

This finding against Prediction (2) was due to the significant main effect of speaker-addressee relationship. The final utterances were rated as more ironic and sarcastic when the relationship was bad than when the relationship was good, $F_1(1,119) = 21.73$, $p < .001$, $F_2(1,11) = 17.26$, $p < .01$ for the degree of irony; $F_1(1,119) = 60.55$, $p < .001$, $F_2(1,11) = 41.60$, $p < .001$ for the degree of sarcasm. This finding can be explained as an effect of contextual information (in this case, speaker-addressee relationship) on judgment whether an utterance indirectly expresses the negative attitude, i.e., condition (f) for implicit display. Information about the speaker-addressee relationship may provide an indirect cue to the speaker's negative attitude; the speaker is more likely to have a negative attitude, and thus his/her utterance is perceived as including more indirect cues and as more typical of irony when they have a bad relationship than when they have a good relationship. A number of empirical findings suggest that this explanation is plausible. Especially, in order to explain the finding that the speaker's occupations affected sarcasm ratings, Pexman and Olineck (2002) stated a similar view based on the implicit display theory: " The occupation stereotype influences interpretation because it contributes to the ironic environment. It contributes to that environment by indicating that the speaker is likely to have a negative attitude (tendency to be critical) and that such an attitude is likely to be indirectly expressed" (*ibid.*, 268).

Humor Ratings There was a significant interaction of Type$\times$Honorifics$\times$Relationship, $F_1(2,238) = 4.11$, $p < .05$, $F_2(2,22) = 4.42$, $p < .05$. The nature of this interaction was that the simple interaction of Honorifics $\times$ Relationship was observed for circumlocutions, $F_1(1,357) = 7.64$, $p < .01$, $F_2(1,33) = 7.51$, $p < .01$, but such interaction was not observed for oppositions and rhetorical questions. When the speaker and the addressee had a good relationship, circumlocutions without honorifics were rated as more humorous than those with honorifics but this difference was not observed when the relationship was bad, as shown in Figure 3. This result is consistent with Prediction (2).

There was a significant main effect of sentence type, $F_1(2,238) = 28.55$, $p < .001$, $F_2(2,22) = 19.14$, $p < .001$. Pairwise comparisons ($p < .05$) indicated that circumlocutions were significantly more humorous than oppositions and rhetorical questions, as shown in Figure 2. This result is compatible with Prediction (1).

The main effect of speaker-addressee relationship was also significant, $F_1(1,119) = 22.93$, $p < .001$, $F_2(1,11) = 37.14$, $p < .001$, showing that the utterances were rated as more humorous when the relationship was good than when the relationship was bad. We can consider two possible explanations for why good interpersonal relationship increases the degree of humor. One possible explanation may be that speaker-addressee relationship affects judgment for implicit display and thus the degree of humor, as I described above. Another explanation can be elicited from the motivational condition in which humor is experienced. Wyer and Collins (1992) stated that when the objective of the reader is to understand and enjoy humorous expressions, humor is more likely to be elicited. Therefore, a good relationship may motivate the addressee to enjoy ironic remarks, while a bad relationship may interfere with the addressee's enjoyable attitude toward them.

Experiment 2

The purpose of Experiment 2 is to test the implicit display theory with respect to contextual effect on the degree of irony, sarcasm and humor. In Experiment 2 two independent variables were considered: situational negativity (the situation is weakly or strongly negative) and ordinariness of negative situation (the negative situation is usual or unusual).

Situational negativity manipulates the degree of incongruity between the expectation and the reality, i.e., condition (b) of ironic environment, in such a way that the incongruity is perceived more easily, and thus irony may be more likely to be made, in the strongly negative context than in the weakly negative context. Ordinariness manipulates the manifestness of speaker's expectation, i.e., condition (a) of ironic environment. The expectation is more manifest in the context where an unexpected negative event occurs than in the

context where the same negative event repeatedly happens. Therefore, irony is more likely to be elicited from an unusual context than from an usual context.

Prediction

The general hypothesis by the implicit display theory makes the following predictions on the effect of context.

(3) Neither negativity nor ordinariness has an effect on the degree of irony and sarcasm.

(4) Ironic utterances in a weakly negative context are more humorous than those in a strongly negative context. In the same way, ironic utterances in an usual context are more humorous than those in an unusual context.

Method

Participants Forty-eight undergraduate students participated for this experiment. All were native Japanese speakers. None of them participated Experiment 1.

Materials and Design Eight out of 12 stories used in Experiment 1 were selected, because natural manipulation of negativity and ordinariness was not possible in the other four stories. Each story had four versions: a situation where a weakly negative event is usual or not, and a situation where a strongly negative event is usual or not. The stories of the weakly negative and unusual version were identical to the stories used in Experiment 1 except that the descriptions of the speaker-addressee relationship were deleted. Each story was followed by the final remark identical to the opposition utterance without honorifics used in Experiment 1. An example of the stories is as follows:

> {*In the restaurant* / *In the restaurant where it usually takes a while to serve dishes*}, the customer was not served the ordered dishes {*for a while* / *at all even after a very long time*}. He said to the master of the restaurant,

Procedure Each participant was assigned to eight different stories involving the four versions equally. The procedure was identical to that of Experiment 1.

Results and Discussion

The data was subjected to Negativity (weakly negative, strongly negative) $\times$ Ordinariness (usual, unusual) repeated-measures ANOVAs.

Irony and Sarcasm Ratings There were no significant main effects and no interactions for both ratings, which favors Prediction (3).

However, as I discussed in the result section of Experiment 1, there is a possibility that context (i.e., negativity and ordinariness) has an indirect influence on the degree of irony and sarcasm through its effect on judgment for implicit display. Especially, judgment on allusion to the speaker's expectation highly depends on manifestness of the expectation, because when the addressee does not know the speaker's expectation before interpreting an utterance the expectation must be inferred from the literal meaning of the utterance and contextual information (Utsumi, 2000). It is thus predicted that, other degrees of implicit display being equal, the degree of irony would be affected by context, primarily by ordinariness, when the speaker's expectation is implicit, but that it would not be affected by context when the expectation is explicit.

This prediction was tested by reanalysis of the data of Experiment 2. The stories used in Experiment 2 include two kinds of speaker's expectation: an expectation about a desirable event/state and an expectation about the addressee's belief. Because the speaker's expectation about the addressee's belief presupposes that the addressee does not notice it beforehand, it is assumed to be less manifest to the addressee than other types of expectation. Hence, the eight stories could be divided into two groups — explicit expectation version (n=4) and implicit expectation version (n=4) — according to whether the speaker's expectation is about the addressee's belief or not. An example of the texts including an implicit expectation is as follows:

> To a friend who eats sweets though she is on a diet:
>
> "You eat nothing at all today, are you?."
> (*Kyou ha zenzen tabenai nee*.)

In this case, the speaker's expectation is something like that the addressee (the speaker's friend) should know that her behavior is undesirable for a diet. Then the data of irony and sarcasm was subjected to Negativity $\times$ Ordinariness $\times$ Expectation (explicit, implicit) ANOVAs with repeated measures on the first two factors.

Concerning the degree of irony, there was a significant interaction of all the three factors, $F_2(1,6)=8.94$, $p<.05$. The nature of this interaction was that the simple interaction of Negativity $\times$ Ordinariness was significant for the implicit expectation context where the speaker's expectation was about the addressee's belief, $F_2(1,6)=6.44$, $p<.05$, but such interaction was not observed in the explicit expectation context. This finding is consistent with the prediction that context has an indirect effect on the degree of irony when the speaker's expectation is implicit.

The observed simple interaction of Negativity $\times$ Ordinariness for the implicit expectation was that in the weakly negative contexts the final utterances were rated as more ironic when the negative behavior was unusual ($M = 5.11$) than when it was usual ($M = 4.54$), but that in the strongly negative contexts the final utterances were rated as more ironic when the negative behavior was usual ($M=5.21$) than when it was unusual ($M=4.58$). This result can be interpreted as follows: The addressee is less likely to notice the speaker's expectation about his/her own belief, and thereby perceives an utterance as less ironic when his/her own negative behavior is usual than when it is not usual because of habituation effect. However, once the addressee's usual negative behavior becomes worse, he/she is more likely to be aware of the speaker's expectation because of dishabituation effect.

For the degree of sarcasm, however, there were no significant effects and interactions in the reanalysis. This result suggests that the speaker's expectation may be an important property which distinguishes irony from sarcasm; sarcasm may not need the speaker's expectation.

Humor Ratings Only the main effect of ordinariness was significant by item analysis, $F_2(1,7)=7.81$, $p<.05$. Ironic utterances in the expected contexts in which the addressee's negative behavior was usual ($M=3.23$) were rated as more humorous than the same sentences in the unexpected context

in which the negative behavior was unusual ($M = 3.06$). This result is consistent with Prediction (4). However, the result that the main effect of negativity was not significant suggests that context negativity may have little influence on the likelihood of irony.

General Discussion

As I mentioned in the introduction, the prototype-based view permits the implicit display theory to explain the obtained finding that the degree of irony differs among various utterances and contexts. For example, allusion-based theories such as Sperber and Wilson's (1995) echoic interpretation theory cannot explain why overpolite utterances were rated as more ironic than appropriately polite utterances. On the other hand, insincerity-oriented theories such as Attardo's (2000) relevant inappropriateness view cannot account for the finding that the speaker's expectation affects the degree of irony. (For details of the superiority of the implicit display theory over other theories, see Utsumi, 2000).

Furthermore, the echoic interpretation theory also fails to explain the finding that the degree of irony was affected by contextual information only when the speaker's expectation about the addressee's belief triggered irony. The reason for the difficulty in explaining such effect lies in their view that irony interpretively echoes not only the speaker's expectation but also other sources such as someone's utterances, opinions or even general norms, whereas the implicit display theory assumes that only the speaker's expectation is alluded to by irony. Therefore the echoic interpretation theory need not, and indeed does not, assume the speaker's expectation about the addressee's belief to explain irony like the 'diet' example; it assumes that irony echoes the general norm that teenagers want to be slim by a diet.

Concerning the functions of irony, the implicit display theory is more consistent with the obtained findings than the contrast-assimilation theory recently proposed by Colston (2002). He has claimed that the degree of negative effect of irony can be explained in terms of "contrast and assimilation" effects, which are often observed in perceptual judgment. If the discrepancy between the positive surface meaning of an ironic utterance and its referent negative situation is large, the ironic utterance is perceived as more negative than the literal one because of a contrast effect. On the other hand, if the discrepancy is relatively small, then an assimilation effect is more likely to occur, resulting in that ironic utterances are perceived as less negative. Although the contrast-assimilation theory seems to be compatible with the finding of Experiment 1 that the degree of sarcasm was graded according to the similarity to the irony prototype, the finding of Experiment 2 that situational negativity did not have an influence on the degree of sarcasm may provide evidence against the contrast-assimilation theory. If Colston's theory is right, an utterance should be more sarcastic in the strongly negative context and less sarcastic in the weakly negative context than the literal equivalent utterances, because negativity changes the degree of discrepancy between the utterance and the situation.

To sum up, it can be concluded that the implicit display theory provides a more consistent explanation of the obtained findings on both irony recognition and ironic function than other theories.

Abstract

We present a connectionist model of false memories called the Associative Self-Organizing Network (ASON) model. Four mechanisms underlying the Constructive Memory Framework (CMF) guide the design of the ASON model, a connectionist operationalisation of the CMF. Simulation studies of experiments in the DRM paradigm reveal the ASON model to exhibit false memories. In addition, the effects of Mean Backward Associative Strength and output order on the probability of false recall are simulated. We conclude that the ASON model is capable of simulating and explaining the main findings on false memories.

Introduction

Memory is fallible. Every day people are confronted with the shortcomings of their memory, when forgetting things such as -for example- the phone number of a good friend, the title of a book, or the location of their car keys. Memory can also fail in another way; instead of forgetting things that did happen, people may remember events that never took place. These memories can be just as realistic as memories of real events. Such memories of never-happened episodes are called *commission errors* or *false memories*. False memories may occur in different situations and their severity can range from attributing a memory to the wrong source to confabulating a complete event (Parkin, 1997).

Various studies suggest that false memories are not simply random errors (Gallo & Roediger, 2002; Schwartz et al., 1998). Instead, they appear to be an inevitable consequence of the dynamics of human memory (Schacter et al., 1998). False memories are considered to arise from the very same mechanisms that underlie veridical recall and recognition of true memories. More specifically, we hypothesize that false memories result from the way in which memory representations are stored, processed, and retrieved.

Our approach is to investigate the occurrence of false memories in a connectionist model called the Associative Self-Organizing Network (ASON) model. The ASON model is made up of two associatively connected self-organizing maps, for storing and representing stimuli and the contexts in which they occur. Although the scientific literature on false memories is abundant (e.g. Gallo & Roediger, 2002; Johnson et al., 1993; Schacter et al., 1998), to our knowledge, no connectionist model of false memories has yet been proposed.

The outline of the remainder of this paper is as follows. In the next section we discuss the theoretical background. Then, we present the Associative Self-Organizing Network as a model of false memories. In addition, three simulations are described. Finally, we discuss the results and conclude upon the approach.

Theoretical Background

The common view of memory is that of a (re)constructive process (Roediger & McDermott, 1995; Schacter et al., 1998). This means that memories, rather than being literal reproductions of past events, are considered to be reconstructions that are susceptible to a variety of distorting factors. In this view, memories are distorted by schemes, attribution processes, prior knowledge, assumptions, and so forth. This makes it almost impossible to draw a clear boundary between true and false memories in real life situations. For this reason, our study focuses solely on false memories occurring in the experimental setting of the Deese-Roediger-McDermott (DRM) paradigm. A false memory is formalized as a recollection of a stimulus that is ascribed to the experimental context, whereas it was *not* presented during the experiment. Below, we describe the DRM paradigm in more detail.

The DRM Paradigm

In order to investigate false memories experimentally, Roediger and McDermott (1995) developed the DRM paradigm, which was a variation of a design originally used by Deese (1959). The experimental set up is as follows. Subjects are presented with lists of twelve or fifteen words that are the strongest associates of a "critical lure"; a target word which is not presented. Immediately following the presentation of a list, subjects are instructed to recall as many of the list items as possible and to mention only those words of which they are certain that they appeared on the list. Despite this instruction, subjects are about equally likely to recall the critical lure as the other items on the list (Roediger & McDermott, 1995). After completion of the experiment, which usually involves the presentation of multiple lists, recognition performance of items on all the lists is tested. It is found that subjects identify the critical lure as being a list item as often as or more often than words that were actually presented (Roediger & McDermott,

1995). These results have been widely replicated, using various lists and different variations on the basic paradigm.

The propensity to elicit false recall and false recognition of the critical item varies widely with the type of list used. Roediger et al. (2001) investigated the causes of this variability and found that the strongest predictor of false recall of the critical lure was a variable called Mean Backward Associative Strength (MBAS). MBAS is defined as the average probability that a list item elicits the critical item as its associate. Roediger et al. found that MBAS correlates positively with both false recall (r = + .70) and false recognition (r = +. 43) of the critical lure.

The ASON model is inspired by the Constructive Memory Framework of Schacter et al. (1998). In the following section this framework is discussed in detail.

The Constructive Memory Framework

Many different theories exist that address the topics of memory formation, source monitoring or reality monitoring and false memories (e.g. Gallo & Roediger, 2002; Johnson et al., 1993; Reyna & Brainerd, 1995). The general assumption underlying these different theories is that memory is constructive. This is also the central assumption of the Constructive Memory Framework (CMF) (Schacter et al., 1998). CMF proposes four mechanisms that are involved in a constructive memory system.

First, according to CMF, episodic memories can be viewed as patterns of features, with different features representing different aspects of the episode. The constituent features of a memory representation are distributed widely across different parts of the brain. Forming an episodic memory involves binding together an arbitrary configuration of information from different sources (visual, auditory, affective, semantic etcetera) about a specific episode into a unitary whole (O'Reilly & Rudy, 2001; Rolls & Treves, 1998; Schacter et al., 1998). This process is called *feature binding*.

Second, each episode activates a unique representation that can easily be discriminated from memories of similar events. Even if different memories overlap extensively, the memory system is able to retrieve the unique characteristics of each particular episode, rather than retaining only the general similarities or gist (Reyna & Brainerd, 1995). This requires a process called *pattern separation* (Schacter et al., 1998).

Third, retrieval of memories involves a process of *pattern completion*. At retrieval, a small part of the original memory is used as a retrieval cue. The subset of features representing this part of the memory is activated. Activation spreads from the activated features to the rest of the constituent features that represent that experience, and the complete memory is reconstructed.

Fourth, once a memory is reconstructed, it must be decided whether the retrieved information constitutes a real memory or is derived from internally generated information, such as thoughts or fantasies. This process is called reality monitoring. Source monitoring is a broader concept and refers to determining the source of a retrieved memory. According to Source Monitoring Theory (Johnson et al., 1993), memories from different sources have different qualitative characteristics. Source monitoring decisions capitalize on these differences. When the source monitoring mechanism fails, source amnesia occurs. One is then able to remember specific information, but unable to recall the source of this memory.

The four mechanisms of the Constructive Memory Framework lead to the notion that false memories result from a combination of two factors: (1) memories from different sources (e.g. internal and external) may form overlapping representations, and (2) the source monitoring mechanism fails to distinguish between those representations.

The activation/monitoring framework, (Gallo & Roediger, 2002; Roediger et al., 2001) explains variations in the probability of false remembering in the DRM paradigm in terms of the two factors. According to this framework, two processes, activation and monitoring, take place during the encoding and retrieval of memories. Although activation occurs mostly at the encoding stage and monitoring mostly at the retrieval stage, both processes are at work during both encoding and retrieval. The activation/monitoring framework assumes that the presentation of some items can activate entire knowledge structures or schemata. As a consequence, non-presented items can be activated because they are strongly associated with the presented items (i.e., they are part of the same knowledge structure). The activation may be the result of conscious, deliberate association, or of automatic and unconscious spreading activation. In the case of the DRM paradigm, activation spreads from the list items to related or associated concepts. The critical lure receives much activation because this item is strongly associated to each of the presented list items. This assumption is supported by the high correlation between MBAS and false remembering of the critical lure. The stronger the association between the list items and the critical word, the stronger the activation of this critical word due to automatic or deliberate spreading of activation.

Summarizing, false remembering of the critical lure occurs when the monitoring process fails to correctly attribute its activation to an internal source and the critical lure is falsely ascribed to the learning context. This monitoring process is analogous to the source monitoring or reality monitoring mechanism proposed by Johnson et al. (1993).

Implementing CMF in a Connectionist Network

The CMF acted as a guideline for the design of the ASON model. The four mechanisms of the CMF translate into the following four desired abilities of the ASON model.

(1) Ability to form episodic memories, whereby each episode leaves a unique, distinctive trace that is easily distinguishable from memories of similar episodes (i.e., demonstrate feature binding and pattern separation).

(2) Ability to retrieve or reconstruct a complete representation when cued with only a small part of the original memory (i.e., exhibit pattern completion).
(3) Ability to spread activation among related or associated concepts.
(4) Ability to monitor memory using a mechanism that decides upon the trueness of each retrieved representation.

We incorporate the four abilities in the ASON model as follows.

(1/2) Feature binding and pattern completion. Feature binding is accomplished by using an associative network, or more specifically, an auto-associator. An auto-associator typically consists of one fully-connected layer. The network's task usually is to produce an output that is similar to its input. When an input pattern is presented, the network's connection weights are changed according to a Hebbian learning algorithm. Connections between simultaneously active neurons are strengthened, whereas connections between non co-active neurons are weakened. In this way, the network is able to associate co-occurring input elements. In addition, the auto-associator is able to completely reconstruct a stored pattern, when provided with only a small part of that pattern. In other words, it can also perform pattern completion (McLeod et al., 1998).

(1/3) Pattern separation and spreading activation. In an auto-associative network, pattern separation is obtained by using sparsely distributed representations. A competitive network can be used to transform densely distributed input patterns into more sparse, separated patterns which can be processed by an auto-associator without suffering from interference. A specific kind of competitive network is the Kohonen network or self-organizing network (Haykin, 1999). For our purposes, the self-organizing network has two important advantages over a standard competitive network. First, the self-organizing network creates a topological map of the input space (Haykin, 1999). A distributed, multidimensional input is transformed into a localist representation. The self-organizing principle ensures that the information regarding relations or similarities among input patterns is not lost in this transformation. By creating a topological map of the input space, the similarity between two input patterns is reflected in the lateral distance between the two neurons representing them. This is a biologically plausible way of representing information. There is evidence that at least lower level sensory representations are organized topologically (Haykin, 1999). However, it is still uncertain whether semantic information in higher association areas is represented in a topological way as well. A second important characteristic of a self-organizing network is that there is spreading of activation among neighboring neurons. When a specific neuron in the network is excited, activation spreads to its neighbors. The degree of spreading activation is a function of the distance between the excited neuron and its neighbor. The nearest neighbors receive the most activation, and activation decreases with increasing distance. Since the neighbors of the winning neuron represent concepts resembling the input pattern, there is spreading activation between related concepts. In this way the network resembles a semantic, or conceptual map. It is generally assumed that much of our knowledge is indeed stored in the form of semantic maps or knowledge structures.

(4) Memory monitoring. A memory monitor mechanism may be implemented in the form of a module that modulates the response thresholds or connection weights of neurons in the associative layer.

In the next section the incorporation of the ASON model is described in detail.

The Associative Self-Organizing Network

The ASON model, shown in figure 1, receives two different types of input; *context* input and *stimulus* input. Input is first processed by the input/output layer of the model. This layer is made up of two unconnected parts. One part processes contextual information, the other part deals with stimulus information. Both parts of the input/output layer have I neurons. The input of the model is formed by multidimensional binary patterns. In those patterns, each bit represents the presence or absence of a specific feature by which the stimulus (item) or context is characterized. The input patterns therefore reflect conceptual representations of different stimuli and contexts.

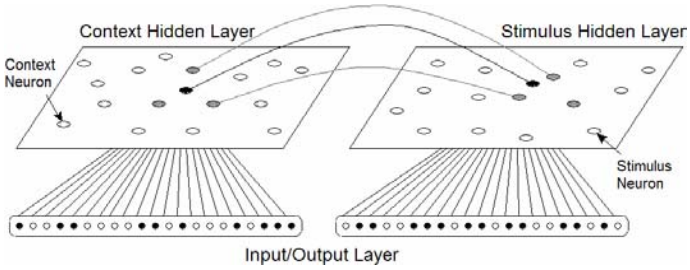

Figure 1: Schematic drawing of the Associative Self-Organizing Network. Each input pattern corresponds to one winning neuron in the hidden layer. Simultaneous presentation of a stimulus input and a context input causes an increase in the connection strength between the hidden neurons representing that stimulus and context, respectively.

Information is propagated from the input/output layer to the hidden layer. The hidden layer consists of two self-organizing maps. These maps are organized as two-dimensional lattices, each having $N \times N$ neurons. The part of the hidden layer that represents stimuli is henceforth called the *stimulus hidden layer*. The neurons making up this layer are called *stimulus neurons*. The other part of the hidden layer is called the *context hidden layer* and the constituent neurons are called *context neurons*. Both hidden layers are fully connected to each other via two-directional modifiable associative connections.

The Four Processing Stages

The processing of information in the ASON model proceeds in four stages: (i) the initialization stage, (ii) the topological-mapping stage, (iii) the learning stage, and (iv) the performance stage. Below, we discuss each of these stages in detail.

In the initialization stage, the connection weights between the input/output layer and the hidden layers, and those between both hidden layers are set to small random values.

In the topological-mapping stage, contexts and stimuli are presented to the input layer of the network and, using the Kohonen learning algorithm or SOM algorithm (Haykin, 1999), a topological organization in the hidden layers is created: semantically related concepts (overlapping input patterns) are represented by neurons that lie close to one another in the two-dimensional grid that makes up the hidden layer. In addition, associations are formed between stimuli and contexts. Whenever a particular stimulus co-occurs with a particular context, there is simultaneous activation of the winning context neuron and the winning stimulus neuron. Following an associative learning algorithm, the (associative) connection between these two hidden neurons is strengthened. Simply said, the stimulus is coupled to the context.

The learning stage simulates the learning phase of the DRM task. It refers to the presentation of the list items. During this stage, a number of stimuli are presented in one specific context -the learning context- and associations between the presented stimuli (the list items) and this context are formed. Due to spreading of activation, not only the connections between the winning context neuron and the winning stimulus neurons are strengthened, but also those between the context neuron and the neighbors of the winning stimulus neuron. The connections between the context neuron and even further neighbors of the winning stimulus neuron are actually decreased.

During the performance stage, the network can either perform a recall task or a recognition task. When performing a recall task, a context input is presented to the network as a recall cue. The winning context neuron in the hidden layer is determined and activation is propagated forwards through the associative connections towards the stimulus hidden layer. The stimulus neuron that is most strongly associated to the winning context neuron is activated and propagates its activation to the stimulus input/output layer. The weights of the connections between the winning stimulus neuron and the input/output layer have changed during the topological-mapping stage so that they have come to resemble the input pattern to which this neuron responds most strongly. Therefore, propagating activation through these connections will result in an output that resembles the original input pattern to a large degree. In other words, reconstruction of the stimulus that is most strongly associated with the presented context takes place. Subsequently, the connection between the winning context neuron and the activated stimulus neuron is 'blocked', the stimulus neuron with the second-strongest association to the context is determined and the next stimulus is recalled.

Most of the time, the stimulus recalled is one that was actually presented during the learning stage (a list item). Occasionally, however, the network recalls a stimulus that has not been presented. In other words, it has false memories. Clearly, false memories occur whenever there exists a strong association between the non-presented stimulus and the context, caused by spreading activation.

When performing a recognition task, the network is presented with a number of stimuli, both list items and a number of non-presented distractors (including the critical item). Based on the stimulus input, the winning stimulus neuron in the hidden layer is determined. The strength of the association between this winning stimulus neuron and the learning context is determined. If the strength exceeds a certain threshold, the stimulus is marked as a target and as a distractor otherwise. The decision whether to accept or reject a retrieved item is based on the strength of its association to the learning context. Raising the threshold reduces the probability of falsely recognizing the critical item, but it also decreases the hit rate. On the other hand, lowering the threshold leads to more hits, but also to more false alarms. This process is a formalization of the memory monitoring or source monitoring mechanism in various theories of memory (Gallo & Roediger, 2002; Johnson et al., 1993; Schacter et al., 1998).

To evaluate the ability of the ASON model to exhibit the false-memory performance as observed in the DRM paradigm, we performed a number of simulations that are described in the following section.

Simulations

Our simulations focus on three aspects of false memories in the DRM paradigm: the DRM effect, the role of association strength and the output order effect. All simulations were performed with the following parameter values: $I = 30$ and $N = 10$. The results reported do not depend critically on these choices.

The DRM effect The simulation of the DRM effect has two conditions; the DRM condition and a control condition. In the DRM condition, the network learns six list items that are semantically related to the critical lure. Their input patterns closely resemble the input pattern of the critical lure. In the control condition, the six list items are randomly chosen from the input set. After learning the six list items, the network performs a recall task. The results of the simulation are shown in figure 2. As is evident from the graph, the probability of recalling the critical lure is much higher in the DRM condition ($P = 0.65$) than in the control condition ($P = 0.05$), but it is lower than the average recall rate of the list items ($P = 0.78$). Hence, the ASON model simulates the DRM effect faithfully.

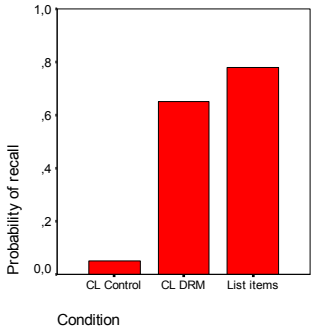

Figure 2: Probability of recalling the list items and the critical lure in the DRM (CL DRM) and control (CL Control) conditions.

The effect of association False recall and recognition of the critical lure is affected by a number of factors. As stated in the introduction, the most important factor is the Mean Backward Associative Strength (MBAS). A stronger association between the list items and the critical lure is correlated with stronger false recognition and false recall effects (Roediger et al., 2001). In the Associative Self-Organizing Network, spreading activation from the list items to the critical lure causes false recall and recognition of the latter. It is important to realize that in the ASON model concepts are related semantically instead of associatively. In contrast to what is proposed by the activation/monitoring framework, activation spreads along semantic relations rather than along associative connections. However, if we disregard this difference, we can define the Backward Associative Strength between two concepts as the lateral distance between the winning neurons that represent these concepts. The smaller the distance, the more related the two concepts are. In the network, the degree of spreading activation is a function of the distance between the excited neuron and its neighbor. Consequently, the smaller the average lateral distance between the list items and the critical lure, the stronger the activation of this critical item due to spreading activation from the list items will be. This stronger activation leads to a stronger association of the critical lure to the context, and therefore to an increasing likelihood of falsely recalling the critical lure. Figure 3a shows the results of a simulation in which the average lateral distance from the list items to the critical lure is varied. As can be seen, the probability of recalling the critical lure decreases sharply with increasing distance. The correlation between lateral distance and probability of recalling the critical lure is -.76. We compare our results with the results from a multiple regression analysis done by Roediger et al. (2001) where MBAS was found to be the strongest predictor of false recall of the critical lure (with the correlation between MBAS and probability of recalling the critical lure being +.73). Figure 3b shows the probability of recalling the critical lure as a function of MBAS, as found in the study of Roediger et al. (2001). Clearly, the results of the ASON model agree very well with those of Roediger et al.

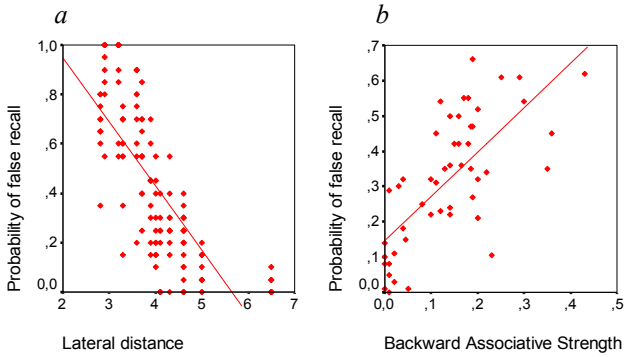

Figure 3: The probability of recalling the critical lure as a function of (a) average lateral distance between list items and the critical lure: r = -.76, and (b) MBAS: r = +.73.

The effect of output order In the third simulation we investigated the effect of output order on the probability of false recall. The *output order effect* (Schwartz et al., 1998) refers to the finding that the probability of a false memory increases with the position of items in the recall sequence.

The output order effect can be explained by the variation in association strength of presented and non-presented stimuli. False memories occur when non-presented stimuli , become strongly connected to the learning context through the processes of spreading activation and association. The association strength of those stimuli to the context is usually smaller than that of the most strongly associated targets, but larger than that of the most weakly associated targets. Since memories are generated in the order of their association strength, the probability that a false memory is generated increases with the position in the recall sequence. In our third simulation, the network performed a simple recall task, rather than a DRM task. The network learned twenty stimuli in a single context. Afterwards it performed a recall task. As can be seen in figure 4a, the probability of a false memory is largest in the last quartile of the output. Figure 4b shows the results of Schwartz et al. (1998), in which subjects performed a similar task. Evidently, our results have a striking similarity to the experimental results of Schwartz et al.

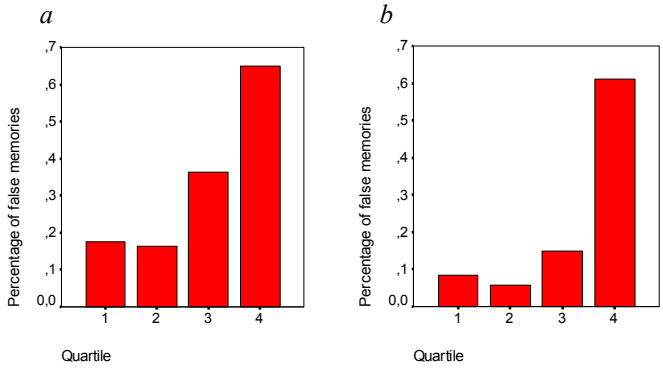

Figure 4: Number of false positives as a function of output order. Results of (a) our simulations, and (b) Schwartz et al. (1998).

Discussion and Conclusion

The ASON model demonstrates how the essential features of a constructive memory system, as put forward by CMF, can be translated into a connectionist model. Specifically, the ASON model incorporates the encoding processes of feature binding and pattern separation, as well as the retrieval processes of pattern completion and memory monitoring. In addition, it explains how spreading activation leads to high false memory scores for the critical lure in the DRM paradigm. The remaining question is to what degree the model's architecture resembles that of brain structures that are involved in the processes of storing, retrieving and monitoring of memory.

The brain structure that is considered to be responsible for the storage of episodic memories is the hippocampus (Rolls & Treves, 1998). The hippocampus is not thought to be the site of storage itself. Rather it is regarded as the mechanism that binds together the sensory features of a situation or episode to create a unitary representation of the experience. In other words, it is the structure that performs feature binding. The hippocampus receives, via the adjacent parahippocampal gyrus and entorhinal cortex, inputs from virtually all association areas in the neocortex. In addition, it gets input from the amygdala and from cholinergic and other regulatory systems (Rolls & Treves, 1998). It thus receives highly elaborated, multimodal information from various sensory pathways. Within the hippocampus, information is processed along a mainly unidirectional path, consisting of three major stages; the Dentate Gyrus (DG), the Cornu Ammonis 3 (CA3) and the Cornu Ammonis 1 (CA1). From CA1, backprojecting pathways lead via the subiculum and the entorhinal cortex back to the neocortex.

The hippocampus shares two essential characteristics with our model. First, there is a large degree of interconnectivity among neurons in the CA3 area of the hippocampus. This interconnectivity makes this area perfectly suited to perform auto-association. In fact, the idea that the CA3 area serves as an auto-associator that binds together the various elements of an episode is a core assumption in a number of computational models (O'Reilly & Rudy, 2001; Rolls & Treves, 1998). Second, the hippocampus receives a load of multimodal information from various cortical areas. The forward pathways to the hippocampus are thus characterized by strong convergence. It is hypothesized that these pathways, and the DG in particular, serve as a competitive network, transforming the widely distributed information in the cortex into more sparse, orthogonal and separated patterns that can be processed by the auto-associator without much interference (O'Reilly & Rudy, 2001).

Instead of a standard competitive network, the ASON model features a self-organizing map. The specific characteristics of this type of network, its ability to form a topological map of the input and spreading activation among neighboring neurons, can provide an explanation of false memories. Specifically, according to our model, false memories arise when activation spreads from the list items to the critical lure, causing a faulty association between this non-presented item and the learning context. This explains how false memories occur in the DRM paradigm, and gives an account of the effect of MBAS on false recall of the critical lure.

By incorporating the four mechanisms of the CMF, the ASON model is able to simulate the occurrence of false memories in the DRM paradigm and the effects of MBAS and output order on the probability of false recall of the critical item. Furthermore, its architecture is compatible with that of the hippocampus, the brain area that is widely acknowledged as being involved in the storage and retrieval of episodic memories. We conclude that this connectionist operationalisation of the CMF is able to simulate and explain the main findings on false memories.

Abstract

Past studies examining the effects of action on memory for route distance have overlooked the problem of the control of visual information. A new methodology was developed to investigate the involvement of action on the representation of route distance information in two experiments which eliminated the possible confounding effects of visual cues. In both experiments the number of turns was manipulated. Blindfolded participants learned new environments through verbal descriptions by imagining themselves walking in synchronization with metronome beats preset to match their natural walking speed. During turns, they were carefully moved. Following instructions, they performed an action at mid-route. Upon reaching the destination, their memories for the newly learned environments were tested through recall and measured again (with metronome beats representing footsteps). In Experiment 1 participants were exposed to the environment only once, and in Experiment 2 they were exposed to the environment twice. The results were consistent across the experiments and showed the influence of number of turns on remembered distances. Our data support the segmentation hypothesis with regard to the perception of the segment length and the influence of the number of turns on path distance estimates. However, our data point to a more parsimonious explanation in terms of body movement that triggers attentional processes which signal memory for events.

Introduction

When asked how far it is from one place to another there is much evidence that people do not give very accurate distance estimations. Investigations into the relationship between physical distance and cognitive distance have shown that the two differ. Furthermore, the differences between actual and cognitive distance are not random; cognitive distance is systematically distorted from the physical distance (Golledge, 1987).

The disparity in distance estimations has been explained as a function of the hierarchical organization of memory (e.g., Hirtle & Jonides, 1985; McNamara, 1986; Steven & Coupe, 1978), the organization of reference points (e.g., Sadalla, Burroughs, & Staplin, 1980), the modes of acquisition at learning (e.g., Thorndyke & Hayes-Roth, 1982), the contexts of learning (e.g., Gauvain & Rogoff, 1986; Taylor & Naylor, 2002), or the environment complexity (e.g., Sadalla & Magel, 1980; Thorndyke, 1981). Hence there is a disparate range of explanations for biases in distance estimation.

One possible explanation for bias in distance estimation, which has not been explored in detail, is that it may be a function of the actions we perform in the environment, and how those actions are cued on retrieval. This may provide a means of incorporating these multiple accounts of distance bias within a single unified framework. The view that cognition is grounded in the individual bodily interaction with the environment (e.g., Barsalou, 1999; Glenberg, 1997) is widely supported. Empirical evidence supporting the embodiment framework can be found across a range of domains. There is a tight coupling between visual perception and action. It has been shown that the representation of a visual stimulus generated from pictures or from purely linguistic descriptions can activate motor affordance, i.e., merely viewing an object, an image of an object, or hearing a description of an object results in the activation of the motor patterns necessary to interact with it (e.g., Richardson, Spivey, & Cheung, 2001; Tucker & Ellis, 1998). In language comprehension, understanding a sentence may call upon the same cognitive mechanisms as those used in planning and executing actions (Glenberg & Kaschak, 2002). It has also been shown that the representation of action or motor representation shares the same neural mechanisms as those that are responsible for the preparation and programming of actual movements (Decety, Jeannerod, & Prablanc, 1989). This evidence indicates that motor activation can occur as part of a cognitive process.

A number of studies have examined the effects of turning during route navigation. Sadalla and Magel (1980) found that paths containing several turns were perceived as being longer than paths of equivalent objective length with fewer turns, and the segmentation hypothesis has been used to explain this effect. The segmentation hypothesis claims that a right angle turn divides a pathway into segments and that the perceived lengths of the segments are combined to produce an estimate of total pathway length. Given two pathways of the same length but differing in the number of turns contained in each, the pathway with fewer turns will necessary have longer segments. These segments will be psychologically compressed to a greater extent than shorter segments (longer segments are underestimated relative to shorter segments). Therefore, the combination of a number

of compressed segments will yield an underestimation of total pathway length. This underestimation will be greater for the pathway with fewer turns. However, this study does not separate out a range of possible explanations for these effects, such as visual cues, or the rate of motion (stepping up or down, or turning) that influence the perception of traversed distance (Hermann, Norton, & Klein, 1986; Rieser, Pick, Ashmead, & Garing, 1995). For example, Hermann et al. (1986) found that the size of the effect of turns on memory for distance is affected by the number and complexity of visual cues in the environment. Therefore, to examine whether action is implicitly part of cognitive processes, it is important to have strict control over the visual information that participants could perceive and extract from the environment during navigation, and the performance of action (walking and turning). A new methodology was developed that considered all these factors in order to allow us to adequately measure whether action exerts an effect on distance estimation during navigation. In the present study, we manipulated the influence of turns on traversed distances to assess more precisely the mental mechanisms that mediate why complex routes (with many turns) were estimated differently from less complex ones (with fewer turns).

Experiment 1

The methodology was designed to control for the confounding factors present in previous studies, while maintaining realism for participants. In order to do this, a blindfold methodology was developed where participants heard linguistic descriptions describing environments over headphones, and had to imagine themselves walking around the environment in time with a series of metronome clicks preset to control for speed of walk and size of step (number of clicks heard). The aim was for participants to listen and visualize the landmarks' descriptions (thus minimizing the risk of participants gauging distances by counting steps). The environmental descriptions were formulated as guided tours, and were read by a female colleague and tape recorded for use in the experiments.

The linguistic descriptions used were controlled for number of words and detail presented. Typically the environments included five landmarks (e.g., a school, a museum, a post-office, a bank, a library, etc.). Each landmark was described by specifying its physical or historical features. Following is an excerpt of a typical description of an environment, used in the study (landmarks are in bold): "*You are in a place called Charlestown, a typical New England town. Your starting place is Victoria Park. I am going to take you on a walk from Victoria Park to St John's Basilica. It is quite a nice walk with lots of things to look at on the way. You are now standing at the gate of a place called* ***Victoria Park****. Victoria Park is renowned for its formal and shrub gardens. They are of interest and beauty in all seasons. During summer, Victoria Park hosts a Folk Music Festival. … You are now at the entrance of a place called the* ***Central Library****. Built of silvery-grey stone, the front of the building has columns and triple arches with elaborated decoration at the tops. Inside the Library, there is an intricately carved oak staircase. You are standing directly in front of the book return box. Now I will let you post the book in the return box. You can actually feel the return box in front of you. So feel the box and post the book. …*".

To encourage participants to visualize only the described scenes, a blindfold was used in order to eliminate visual information that they could have gathered from the test laboratory. Furthermore, to examine the influence of action the actual walking was replaced by mental walking. A metronome pre-set to each participant's natural walking speed (stride length and frequency of stepping) emitted beats to simulate their walking rhythm. So instead of actually walking, participants heard a certain number of metronome beats, which corresponded to the exact measure of the distance to be traversed. When the distance was mentally traversed the metronome beats ceased. However, during the simulated navigation through the environment, participants performed an action (e.g., put an object into a box) which occurred at mid-route. This manipulation allowed us to determine whether there was any difference in the perception of distance before versus after performing the action on the representation of distance. Participants also experienced the change in angular displacement when he/she arrived at 90-degree turn in the mental walk. In this instance, they were rotated to face in the appropriate direction. Once participants reached the destination landmark, their memories for the newly learned environments were measured through recall. Participants were told that they were now at the starting landmark again and had to "walk" on their own towards the destination (still wearing the blindfold). They had to describe what they "saw" on the way, and to instruct the experimenter to engage/disengage the metronome to signal the start of the mental walk or to stop walking. The dependent variables were the remembered traversed distances, which were again measured by metronome clicks. The experimental arrangement is shown in Figure 1.

Figure 1: Arrangement during tests. The participant is on the right, with the experimenter behind her.

Environment Characteristics. Participants learned two routes (Route A and Route B). They were not aware that Route B was the mirror image of Route A.

As each route contained 5 landmarks, there were 4 paths in each (denoted P1 to P4). Each path measured 64 meters which meant the total route length measured (64 m x 4) 256 m. Ninety-degree turns divide a path into segments. Each route contained 11 segments. The segment lengths were fixed at 8, 12, 16, 24, 32, and 40 m. These distances were combined to make up the length of 64 m for each path. Figure 2 shows a schematic representation of one of the environments used in the experiment. Note that in Route A, P1, P2, and P3 contained 1 turn each followed by P4 with 4 turns; in Route B, P1 contained 4 turns followed by P2, P3, and P4 with 1 turn each. The performance of action occurred at mid-route (at the middle landmark); P1 and P4 were located at the outer positions of each route, while P2 and P3 were located at the inner positions of each route.

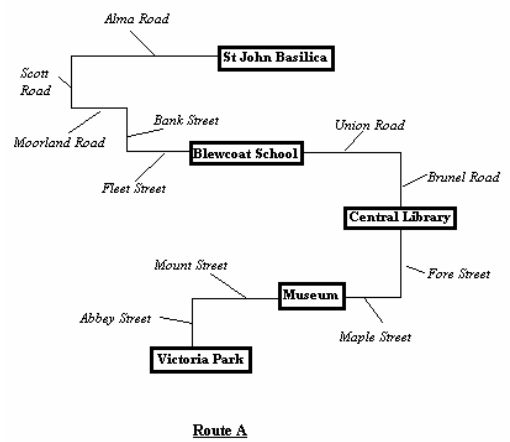

Figure 2: Configuration of Route A, in Experiment 1

Pilot Study. Before we ran the study, we tested the methodology on two pilot subjects in order to check whether they felt any discomfort during the test given that they had to wear a blindfold, and had to be physically turned during the testing procedure. However, the subjects commented that they were perfectly comfortable and relaxed during the test. We then proceeded to the first experiment using the new methodology.

Presentation. The study was presented to the participants as an investigation into people's memory for described places. They were told that they were going to listen to descriptions of imaginary walks through new environments, and were told that during the simulated walks they had to visualize the described landmarks. Additionally, they were asked to return a book or a parcel at some point en-route. The participants were not aware that their memory for distances was being tested.

Experimental Design. To examine the influence of action and the effect of number of turns on traversed distances, the experimental design used was a 2 route (Route A vs. Route B) x 2 position (inner vs. outer) x 2 action (before action vs. after action) within-subjects design.

Participants. Twenty-nine undergraduate students agreed to participate in the experiment in exchange for course credit. They were between 18 and 35 years old (mean age = 20.50, SD = 4.80). By agreeing to participant in the experiment, they were aware that they would wear a blindfold during the test.

Procedure. Participants were tested individually in a session lasting about 45 minutes. Initially, participants were instructed to walk round the room (following a pre-designated path) at their own natural walking speed so that step length and speed of walk could be established. Next, they were asked to put on the blindfold and headphones, and to stand comfortably at the centre of a circle marked on the floor. The experimenter familiarized the participants with the turning procedure: she spun the participant around on the spot, finishing by positioning him/her facing a box that was sitting on a table. At this time, the experimenter gave the participant the book or the parcel to carry with him/her. Then the participants were instructed to visualize the landmarks when they heard the descriptions, and to imagine walking in synchronization with the metronome clicks, and to stop imagining walking when the metronome ceased clicking. The experimenter then started the tape player and both listened to route descriptions through headphones. At the appropriate times, the experimenter stopped the player and engaged the metronome to implement the mental walking. During turns, the experimenter intervened by physically rotating the participants on the spot. Note that all turns were 90 degrees turns. At mid-route, participants performed the dispatch task as instructed, i.e., he/she extended his/her arm to reach the box, touched it to find the slot, and then dropped the objects into the box. Once the destination was reached, the experimenter spun the participant around again and positioned him/her in front of the box. Still blindfold, the participant's route memory was tested through recall. After the recall of the first route, the second route was immediately presented which was followed straight away by the recall.

For the recall, participants were told that they were taken back to the starting place from which they had to re-walk the routes. They were asked to describe back as accurately as possible what they "saw" en-route. They had to tell when they wanted to walk away from the landmarks and when they wanted to stop walking, so that the experimenter could engage and disengage the metronome. At turns, they had to rotate themselves on the spot and to indicate verbally the direction of turns. Once it was established that participants understood the recall instructions, the experimenter switched on the recorder that participants carried with them.

Data Treatment. The participants' recalls were transcribed. Then we proceeded to check the order of landmarks recalled

by the participants. In order to ensure that participants had a good understanding of the environments they learned, only responses with the correct sequence of landmarks were used in the analyses.

Data were obtained by first translating the number of metronome clicks (= steps) into traversed distances expressed in meters. The accuracy of turns with regard to amplitude and direction was not recorded in the present experiment.

Results

Responses from 13 participants (45%) were excluded. Twelve of these produced incorrect sequences of landmarks for one or both routes, and the remaining participant was eliminated because of poor English. Responses from 16 participants were used in the analysis (55%).

To check whether participants were not gauging distance by counting the number of steps a correlation between the total number of steps to walk Route A and Route B and the re-walked distances of both routes across participants was performed. The results showed no significant correlation, indicating that participants were not counting clicks and remembering the number of clicks on recall. As both Route A and Route B contained 11 segments each, in total there were 22 segments. For each segment, we averaged the remembered distances across participants in order to examine the correlation with the corresponding actual distances. We found an overall significant correlation between actual and remembered distances, $r_{(22)} = 0.68$, $p < 0.001$ (1-tailed), which indicates that longer segments were associated with remembering walking longer distances on recall. To examine the influence of action and the effect of number of turns on traversed distances, a 2 route (Route A vs. Route B) x 2 position (inner vs. outer) x 2 action (before action vs. after action) within-subjects ANOVA was performed on path distances. The results of the 3-way ANOVA are displayed in Table 1.

Table 1: Results of the 3-Way ANOVA on Path Distance Estimation in Experiment 1.

Source	df and F value	MS (error)	Significance
Route (R)	$F_{(1, 15)} = 1.89$	442.53	ns
Position (P)	$F_{(1, 15)} = 8.88$	1922.00	**
Action (A)	$F_{(1, 15)} = 0.93$	94.53	ns
R x P	$F_{(1, 15)} = 0.90$	105.12	ns
R x A	$F_{(1, 15)} = 0.85$	195.03	ns
P x A	$F_{(1, 15)} = 0.30$	128.00	ns
R x P x A	$F_{(1, 15)} = 8.44$	430.13	*

Note. ns: $p > .05$; *: $p < .05$; **: $p < .01$

No main effects of route, or action were found. However, there was a main effect of position on remembered path distances. Overall, participants remembered walking significantly longer distances on the outer paths (one of which contained 4 turns) than on the inner paths (which contained one turn). There was also a significant 3-way interaction between route, position, and action on remembered path distances. Follow up analyses indicated that in Route A, after the performance of action the outer path (i.e., P4 contained 4 turns) was remembered as being significantly longer than the inner path (P3 contained 1 turn), $F_{(15)} = 6.16$, $p < 0.05$. In Route B, the reverse was the case; before the performance of action the outer path (P1 contained 4 turns) was remembered as being significantly longer than the inner path (P2 contained 1 turn), $F_{(15)} = 6.64$, $p < 0.05$. This result confirmed that the influence of number of turns was a robust effect on remembered distances.

Discussion

We developed a new procedure in order to allow us to adequately measure whether action exerts an effect on distance estimation. During the experiment, none of the participants expressed any discomfort during or after the task, indicating that the methodology was appropriate.

That said, there was a large dropout rate (45%) due to participants not being able to reproduce the landmarks in the correct order (or to remember all the landmarks completely). This may have been because the task was too difficult, or because participants were exposed to the environment only once.

Despite the high dropout rate, we found that within the same routes, distance estimation was influenced by the number of turns contained in a path; paths containing four turns were remembered as being longer than paths with one turn. This result is in line with evidence from other studies (Sadalla & Magel, 1980), but with more control over visual information and action. Our procedure allowed us to observe the effect of number of turns on the same route through auditory simulated navigation, while Sadalla and Magel (1980)'s result was on separate paths, and involved actual walking. However, taking together both studies indicate that the influence of number of turns on memory for distance is a robust effect.

The absence of the effect of performing an action may be due to the salience of the action itself. The movement of dispatching (dropping) an object into a box may be perceived as a simple and routine activity therefore was not salient enough to exert an effect on spatial representation. A sequence of more pronounced movements to perform the dispatch task may make the action more memorable. For the moment, we were concerned by the high dropout rate. For that reason, in Experiment 2 we exposed participants to the same environments twice before their memories were tested using exactly the same methodology as in Experiment 1.

Experiment 2

Method

The method used was the same as in Experiment 1, except that this time participants were exposed to each environment twice before recalling routes.

As in Experiment 1, participants learned two different routes (Route A and Route B), and then they had to

reproduce each route trip in free recall. Route A and Route B were presented to participants in counterbalanced order.

Participants. Twenty-three undergraduate students agreed to participate in the experiment in exchange for course credit. Participants were between 18 and 46 years old (mean age = 24.17, SD = 7.84). They were tested individually.

Procedure. The procedure was exactly the same as in Experiment 1, however here participants were guided through each route twice before their memories for each route were tested through free recall. The tests lasted about one hour.

Results

As in Experiment 1, to be included in the analyses participants' responses must show the correct sequences of landmarks in both routes. Responses from 18 out of 23 participants (78%) were used in the analyses. Responses from 5 participants (22%) were eliminated (4 incorrect sequences of landmarks, 1 poor quality recording). The exposure to the environment twice seemed to work as the rate of data inclusion has much improved, although there is still quite a high rate of exclusion.

On average, we found that short distances were overestimated, whereas longer distances were underestimated. The overall correlation between actual and remembered distances was highly significant, $r_{(22)} = 0.68$, $p < 0.001$ (1-tailed). This result indicates that if the actual distances were longer, participants remembered walking longer distances as well.

To examine the influence of the number of turns, position, and action on path distance estimates, a 2 route (Route A vs. Route B) x 2 position (inner vs. outer) x 2 action (before action vs. after action) within-subjects analysis of variance was performed on path distance estimates. There were no significant effects of route, or action. However, there was a main effect of position on path distance estimates. Overall, participants walked significantly longer distances at the outer paths (one path contained 4 turns) than the inner paths (1-turn paths). There was a significant 2-way interaction between route and action; before action, remembered distances were shorter in Route A than in Route B; however after action, remembered distances were larger in Route A than in Route B. This effect was observed because of the influence of number of turns. There was also a significant 3-way interaction between route, position, and action. As in Experiment 1, the follow up analyses indicated that in Route A, after the performance of action the outer path (i.e., P4 contained 4 turns) was remembered as being significantly longer than the inner path (P3 contained 1 turn), $F_{(17)} = 4.09$, $p = 0.05$. In Route B, the reverse was the case; before the performance of action the outer path (P1 contained 4 turns) was remembered as being significantly longer than the inner path (P2 contained 1 turn), $F_{(17)} = 9.41$, $p < 0.01$. This result confirmed the robust effect of number of turns on remembered distances; the inner paths (P2 and P3) were not remembered significantly differently from one another.

Discussion

The fact that participants were exposed to the environments twice in order to acquire route knowledge substantially improved the data collection. Although the rate of exclusion was still high (22%) suggesting that some participants' memories for routes were imprecise, the majority of participants produced the landmarks in the correct order, and therefore distance estimates could be analyzed.

The results replicated those in Experiment 1. As expected, the effect of number of turns was also observed in this experiment; paths with more turns were remembered as being longer than paths with fewer turns. The absence of the influence of action may be due to the salience of the action itself. A more pronounced sequence of movements to perform the dispatch task may make the performance of action more memorable thereby the prediction of a difference between remembered distances before and after the performance of action would stand more of a chance of being found if present.

General Discussion

The new procedure was developed with the aim of controlling confounding factors, such as visual cues and the speed of walk in order to adequately investigate whether action exerts an effect on distance estimation during simulated navigation.

To begin with, in general during tests participants claimed they felt comfortable and relaxed with the task, which indicated that the methodology was an appropriate and sensitive procedure, especially given that participants had to wear a blindfold for the whole duration of the test that lasted about one hour. However, despite the relatively high dropout rate, the data we collected across both experiments indicated nevertheless that the methodology was successful. Future studies could present the environment a third time, which might improve the inclusion rate further.

Let us now consider how our data fit with current theories of environmental knowledge. Our results are in line with the segmentation hypothesis with regard to the perception of the segment lengths and the influence of the number of turns on path distance estimates. However, we found the same effect of number of turns on remembered distances without actually traversing any distance. Our data actually point to an interpretation in terms of attention processes that signal memory for events. Participants heard the metronome clicks representing their footsteps during mental walks. It was clear that they had internalized distance and direction as well as turns information for use during recall that had enabled them to get from the starting landmark towards the final destination. As they were not walking any distance, they seemed to have been encoding the action of turning. In the absence of direct visual information, the body movement triggers the retrieval process; i.e., the

participants' attention would focus on memory for events (actual turning). However, this form of representation is available for limited periods only; as time went on, memory faded and decayed (Thompson, 1983). The attention process then must be shifted in order to attend to the next event that came to mind. To proceed still further, the attention process had to be re-initialized. When walking naturally one average footstep measures about 70 cm, and there are two footsteps forward per second. Therefore, it will take 10 sec to walk 14 m. It is not surprising in terms of the attentional process that people remember only a certain distance (14 m) given that they can focus their attention only for the first 10 sec during retrieval. The fact that participants remembered walking longer distances in paths containing 3 turns than paths containing 1 turn corresponded to the fact that they were actually moving (turning) more often in paths with several turns as well. Consequently, the more turns in a path the more attention shifts were required and the longer the perceived distance. The cognitive mechanism uncovered in the present study is different from that of the segmentation hypothesis. We attributed the fact that paths with more turns were remembered as being longer than paths with fewer turns to the attention shifts during the retrieval process, and suggested that the function of body movement was to re-initialise the retrieval process.

Although the new procedure permits a more precise examination of processes involved in spatial judgment, work needs to be done regarding the large drop out rate. Maybe repeating the simulated walk three times would improve data collection. Additionally, the influence of action at the midpoint would stand more of a chance to be found if present by making the action more pronounced (through more extensive turning or walking on the spot).

More importantly, further work needs to be done in order to establish whether our results can be generalized. For example a comparison between the present study and a study where actual walking takes place is desirable.

Despite these limitations, the new procedure has allowed control over action and visual information during testing, and provides a means for future investigation of a range of possible action manipulations that have hitherto evaded controlled experimental procedures. It also provides important indication that basic processes underlying mental distance estimation seem to persist even in rather extreme sensory deprivation conditions.

Abstract

The Context Dependent Sentence Abstraction (CDSA) model and Latent Semantic Analysis (LSA) were compared in their ability to predict sentence similarity. Evidence supports the conclusion that the CDSA model better predicts human ratings for short phrases and sentences than does LSA. Alternative theoretical reasons are given for this finding.

Introduction

Researchers in many disciplines within cognitive science have proposed and tested theoretical claims about the meaning of natural language expressions. One of the contemporary models is Latent Semantic Analysis (LSA; Landauer & Dumais, 1997). LSA is a statistical, corpus based technique for representing world knowledge. It computes similarity comparisons between words or documents by capitalizing on the fact that words are similar when they are surrounded by similar words (i.e., the company a word keeps).

LSA takes quantitative information about co-occurrences of words in documents (paragraphs and sentences) and translates this into a K-dimensional space. The input of LSA is a large co-occurrence matrix that specifies the frequency of words in documents. LSA reduces each document and word into a lower dimensional space by using singular value decomposition. This way, the initially extremely large word-by-document co-occurrence matrix is typically reduced to about 300 dimensions. Each word ends up being a K-dimensional vector. The semantic relationship between words can be estimated by taking the cosine (normalized dot product) between two vectors. Although LSA performance has been shown to be impressive at the paragraph level (Foltz, Gilliam, & Kendall, 2000; Landauer, Laham, Rehder, & Schreiner, 1997), other research has found limitations of LSA at the sentence level (Kintsch, 2001). In this paper we will present the Context Dependent Sentence Abstraction (CDSA) model, a corpus-based model that builds sentence meanings based on combinations of pooled adjacent neighbors of individual words. We will first discuss a weakness with vector representational systems (e.g., LSA) in handling sentence comprehension and then turn to a description of the CDSA model, with evidence supporting it.

A weakness with LSA

One major strength of LSA is its versatility and simplicity in handling word meaning and sentence meaning by the use of vector representations. It could be argued, however, that there are potential theoretical problems with combining word vectors to form sentences. For example, the meaning created from a sentence in LSA is a linear combination of word vectors, without eliminating information for any word. Consider the sentence *the cow ate in the field.* In LSA all information about *cows* (e.g., animal, milk, burger), *ate* (e.g., food, grocery, digest), and *field* (e.g., grass, baseball, football) may be included in the sentence representation. It could be argued that this assumption is not theoretically plausible because much of this associated information is not relevant to the word in context. There must be constraints that narrow down the vast array of information that may be "primed" in the first stages of sentence comprehension. Indeed, Kintsch's construction-integration model (1998) has attempted to explain this convergence of activated

information by principles that guide the integration mechanisms.

Whereas the standard use of LSA is based on the assumption that a sentence's meaning is the sum of all the individual word meanings, there are extensions. Kintsch's predication algorithm (2001) tries to build meaning of a sentence by using syntactical information and LSA to create dependencies between subjects, predicates, and objects. For example, consider the sentences *the horse ran* and *the color ran*. The context established by *ran* has different meanings in these two sentences. Therefore, in the predication algorithm, constraints are made on what *ran* means in these sentences. The first step is to find the near neighbors of the word *ran* (i.e., words that give the highest cosine to *ran*). For the *horse* example, all the neighbors of *ran* are compared to the word *horse*. This provides words like *walk, gallop, crawl, rode,* etc. These neighbors of *ran* that are closest to *horse* (i.e., highest cosine) are then included into the vector for the sentence *the horse ran*. The same is done for the color example, resulting in different overall meanings. Including this additional information has been shown to more accurately capture the meaning of a sentence when we consider metaphor and causal inferences (Kintsch, 2001).

Kintsch's predication algorithm (2001) therefore imposes augmentations and constraints on the standard use of LSA. However, this algorithm still may not go the distance in solving the problem of information overload mentioned earlier. That is, predicating the verb *ate* to *cow* does give relevant information like *graze*, but all information about *cows* and *ate* are also included. To successfully implement context in the given example, we would want to include only information about "*cows eating"*, not about "*cows* and *ate* and *graze* and *field* and *pasture"*. While the predication algorithm solves some problems by adding information, it also may be limited by not taking any information away.

The need for contextual constraints

Computational representations like LSA go beyond general word meanings, but may not adequately handle contextual constraints. LSA may go some distance in handling proposition meanings that constrain words in context (Kintsch, 1998), but there still is a large landscape of representations and algorithms for combining information from words. We propose a new way of implementing contextual constraints. These contextual constraints are first built from simple individual word meanings that get established over time from their occurrences in the environment. But as sentences are constructed, similarities between the words in the constrained construction build a new meaning different from the sum of its parts.

The CDSA Model

Associationist frameworks (Landauer, 2002; Louwerse & Ventura, in press; Smith, Jones, & Landau, 1992) assume that it is critically important to measure and model the correlations between occurrences or events in the environment. We pursued a corpus-based model of word and sentence meaning, called the Context Dependent Sentence Abstraction (CDSA) model. In the CDSA model, semantic information within any word *w* is the pooled words that co-occur with word *w* in every context. One of the goals of this model is to try and capture the associations between words under a new level of specificity that considers the pool of their surrounding words.

In order to implement this model, it was necessary to make decisions about the learning rule and training set to be used. For this model, the deciding factor in each of these cases was psychological plausibility. That is, this model considers a corpus of prior experiences with words in context and the theoretical weights between words that change with experience, as opposed to a priori sets of features that are dictated by a brittle, symbolic model. The central question is how these weights change with experience. The proposed CDSA claims that they change by accumulating specific sentence exemplars.

Consider two words *chair* and *table*. The central question to be asked is what are all the possible relevant or useful relations that can exist between these two concepts? Each word has a neighborhood set that includes all words that co-occur with the target word. These words are the extensional meaning of the target word and serve as the basis for all associations. The neighborhood intersection is the relation that occurs when two words share similar co-occurrences with other words. Much like LSA, words become associated by their occurrence with many of the same words. For example, *food* and *eat* may become associated because they both occur with words such as *hungry* and *table*. Therefore the neighborhood set ***N*** for any word *w* is all the information we have in the exemplars for a word.

Neighbor weights

The neighborhood set for any word is intended to represent the meaning of a word from a corpus. But there were several theoretical challenges that arose when we developed the model. One dealt with how to differentially weight neighborhood words. We assigned *neighborhood weights* to each neighborhood word *n* of word *w* according to Equation (1).

$$\lambda_{n|w} = \frac{f(n \mid w)}{\sqrt{f(w)f(n)}} \quad (1)$$

The expression $f(n|w)$ designates the frequency of occurrence of the neighbor word *n* to target word *w*, whereas $f(n)$ is the total frequency of the neighbor word *n*, and $f(w)$ is the total frequency of the target word *w*. This formula essentially restricts the weights for the neighbor words as being between 0 and 1 in most cases. We adopted this simple assumption but we acknowledge that there are

other ways to guarantee the range of the weights being within 0 and 1.

Therefore, the weighting function was aimed at giving more importance to words that consistently co-occur and less importance to words that occur frequently in the corpus. Additionally, rare co-occurrences may be given low weights because they do not consistently co-occur with the target word.

Some important assumptions had to be made in order to build relevant associations to target words most effectively. The next section will explain the procedures of the algorithm written to perform these operations.

Neighborhood Intersection Algorithm

In order to construct the neighborhood set for any word, an algorithm was written that pooled all words ***N*** that co-occurred with the target word *w*. We used the Touchstone Applied Science Associates (TASA) corpus because of its size (750,000 sentences) and diversity of topics (reading a diversity of texts up to college level). Each sentence in the corpus served as the context for direct co-occurrence. So for entire set of sentence sentences ($s_1...s_C$) that target word *w* occurs in, every unique word in ($s_1...s_C$) is pooled into the neighborhood set ***N***. For example the neighborhood of *chair* may consist of: *table, sit, leg, baby, kitchen, talk*, etc. This represents the neighborhood ***N*** of each target word *w*. Each word in the set ($n_1...n_K$) of ***N*** is weighted by the function described in equation (1). To evaluate the relation between any two words w_1 and w_2, we follow the following algorithmic procedure:

1. Pool neighborhood sets for w_1 and w_2 ($\boldsymbol{N}_1$ and $\boldsymbol{N}_2$ respectively), computing the weights for all the neighbor words using Equation (1).
2. Calculate neighborhood intersection as follows:

$$\frac{\sum_{n \in N_1 \cap N_2} \left(\lambda_{n|w_1} + \lambda_{n|w_2} \right)}{\sum_{n \in N_1 \cup N_2} \left(\lambda_{n|w_1} + \lambda_{n|w_2} \right)} \qquad (2)$$

The numerator is the summation of weights over the intersection of the neighborhood sets ($\boldsymbol{N}_1$ and $\boldsymbol{N}_2$) whereas the denominator is the summation of weights over the union of the two neighborhood sets. This formula produces a value between 0 and 1.

In the next section we will discuss how the CDSA model was evaluated.

CDSA Model Evaluation

In four experiments we evaluated the CDSA model against LSA and human raters. The estimations of word and sentence meanings in the CDSA model and LSA were trained on the TASA corpus. Ratings in all four experiments were made by 10 undergraduate psychology students who were instructed to rate the similarity of various pairs of words (i.e., primarily from words from Spellman, Holyoak, & Morrison, 2001) on a 6-point scale that varied from 1 (very unrelated) to 6 (very related). A rating of 1 or 2 meant the rater could not easily find a functional or physical relationship between the word pairs (e.g. fish-office). The mean among the raters for each pair was taken as the basic data to test the models.

Experiment 1

Word Pairs A total of 64 word pairs was constructed that had a frequency over 10 in the TASA corpus. Some of the words were expected to be unrelated (e.g., chair-hear) and some related (e.g., chair-sit) in order to provide a sensitive range of values.

Results and Discussion

Human ratings (M = 3.57, SD = 2.20) were significantly correlated with the values produced by the CDSA model, $r = .71$, $p < .001$, and with LSA cosines, $r = .78$, $p < .001$. So both models fared quite well in accounting for the ratings of word pairs.

Neighborhood intersection estimation shared a relation to human ratings, so we might conclude that this type of association between words is used in human judgments. That is, by using all the co-occurrence information about a word, one can capture the meaning of a word. As can be seen, LSA was slightly more predictive of word relations than the CDSA model, although the difference was not statistically significant.

The lack of difference between models may be due to the construction of neighborhood sets for a single word in the CDSA model. Since there are many neighbors that exist for any particular word, there are many degrees of freedom that exist for determining the meaning for a single word. For instance, if one is asked to give an association to the word *cow*, there are many possible associations (e.g., *animal, milk, burger*, etc), which will lead to a very general non-specific representation of a single word.

The purpose of Experiment 2 is to try to use the model to represent the meaning of word-pairs. This involves imposing constraints on the neighbors for each pair in order to more accurately represent the contextual meaning of the pair. For instance, *cow-graze* should give a more specific representation of *cow* than *cow* without a context because constraints are built on the meaning of *cow*. These constraints initially involve measuring the neighborhood overlap between the neighbors of *cow* and the neighbors of *graze*, which then are used to compare to another set of information (e.g., word, sentence).

Experiment 2

A central theoretical assumption in Experiment 1 was the idea that neighborhood intersection plays a prominent role in the relation between words. But how can the current

model account for conceptual relationships beyond the word level? Figure 1 gives an illustration of how this could be done. If two pairs are being compared, the neighborhood overlap of each pair is pooled into F_1 and F_2. Then the intersection (Equation 2) is calculated to access the similarity between the two pairs. This constrains the degrees of freedom for the pair, which eliminates any information that is not mutually shared by both words in the pair (i.e., the problem found in Kintsch's predication algorithm). Therefore, each word is always dependent on the context in which it appears. As the context for a word becomes more specific (i.e., as reflected by the number of unique words it appears with), the less likely that the same context will be associated with any random word. For instance, *chair-sit* has a smaller neighborhood set than the sum of neighbors for *chair* and the neighbors for *sit*. This assumption therefore states that word pairs, or even sentences, are different than the sum of its parts, an assumption quite different from current models of associative learning like LSA.

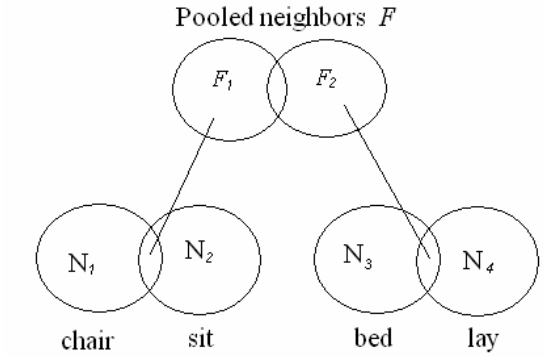

Figure 1: The recursive nature of neighborhood overlap. The neighborhood overlap (F_1) of *chair* (N_1) and *sit* (N_2) is intersected with to the neighborhood overlap (F_2) of *bed* (N_3) and *lay* (N_4).

Model modifications

Neighborhoods were first built on words within the pair as described in equation 1. As described in Figure 1, the neighborhood N_1 of *chair* is intersected with the neighborhood N_2 of *sit* to yield a new neighborhood F_1 that represents the "chair sit" neighborhood. Since any shared neighbor in N_1 and N_2 each have a separate weight, the average of the two weights (Equation (3)) is calculated to represent the new weight for each neighbor in F_1.

$$\lambda_{n|w_1 w_2} = \frac{1}{2}\left[\lambda_{n|w_1} + \lambda_{n|w_2}\right] \quad (3)$$

In the same manner, we obtain $\mathbf{F_2}$. Once F_1 and F_2 have been calculated for both word-pairs, the neighborhood intersection is calculated (as described in Equation (2)), to access the relationship between the 2-word pairs.

Additionally the union of the neighborhood weights (i.e., the entire neighbor weights of all words in each pair) was calculated for F to compare the effectiveness of intersecting the neighborhoods.

Word Pairs We constructed 53 word pairs that had a frequency over 10 in the TASA corpus. Separate sets of pairs were intended to be unrelated (e.g., bear/cave—pen/write), related by analogy (e.g., bear/cave—fish/pond), or related by both analogy and semantic relation (e.g., teeth/bite—leg/kick).

Results and Discussion

Human ratings (M = 3.46, SD = 1.62) were significantly correlated with CDSA intersection, r = .60, p < .001, and union, r = .51, p < .001. LSA cosines were also related to human similarity ratings, r = .64, p < .001.

It appears that imposing context reduced the correlation with rated similarity of 2-word pairs, compared with single-word pairs. As can be seen LSA performance also drops. Most notably, the union of neighbor sets does not perform as well as the intersection version of the CDSA model.

The purpose of Experiment 3 was to examine how performance would be affected by implementing more context through comparison of 3-word phrases.

Experiment 3

The process we used in building constraints on three-word combinations involves a multinomial neighborhood overlap (N-O) among all neighborhood pairs. Each neighbor that is shared by at least two neighborhoods is then pooled into F. Figure 2 gives an illustration of how this can be achieved..

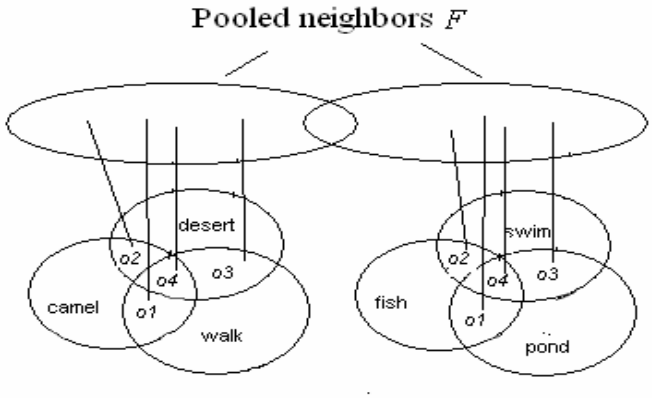

Figure 2: 3-word neighborhood overlap for two 3-word combinations. The neighbors of each combination are compared for neighborhood overlap, which are then pooled into a neighborhood F for each pair.

Model Modifications

Equation 3 is used to compute weights for the words that are in the intersection of any two neighborhoods (o_1, o_2, and o_3).

By making all possible intersections between each neighborhood N_1, N_2, and N_3, a select number of words may be counted three times. Therefore neighbors shared by all three sets (o_4; see figure 2) will be averaged (i.e., divided by 3) and eliminated from any other N-O to avoid multiple counts. The computation for the weights in the intersection of the three neighborhoods is simply an extension of equation 3, where the average is taken with three weights instead of two. Additionally each neighbor in o_4 is a special neighbor because it is shared by all neighbor sets. Therefore these neighbors are multiplied by a constant of 3 (i.e., since there are three sets) to give greater importance to these context bound neighbors. Once F_1 and F_2 have been pooled together by all the N-O for each pair, the neighborhood intersection is calculated (Equation 2), to access the relationship between the 3-word pairs.

Additionally the union of the neighborhood weights (i.e., the entire neighbor weights of all words in each pair) was calculated for F to compare the effectiveness of intersecting the neighborhoods.

Short phrases We constructed 58 three-word phrases that had a frequency over 10 in the TASA corpus. Some pairs were intended to be unrelated (e.g., bird/nest/fly—brush/paint/art), related by analogy-like relations (e.g., gun/shot/bullet — axe/chop/wood), and related by both analogy and semantic relation (e.g., dog/loud/bark—cat/quiet/meow).

Results and Discussion

Human ratings (M = 3.10, SD = 1.78) were significantly related to the CDSA intersection, $r = .63$, $p < .001$, and union, $r = .44$, $p < .001$. LSA cosines were related to human similarity ratings, $r = .47$, $p < .001$. The results give evidence that imposing context improves performance in calculating similarity. Furthermore, LSA performance continues to drop as more word context is introduced. This in part could be due to the lack of constraints that are put in the sentence representation in LSA.

Experiment 4

The purpose of the present experiment is to test the CDSA model to sentences of varying lengths (i.e., sentences ranging from 4 to 6 words). One challenge that arises in calculating sentence similarities is how to handle all the possible intersections between word neighbors within one sentence. Therefore three conditions were tested on how to calculate the final sentence neighbor set F. First, a multinomial approach entailing N-O among all neighborhood sets was pooled to get F. Weightings were computed between any N-O words as an extension of Equation 3, where the neighborhood intersections could entail 2-6 neighborhoods.

Second, a word-chunking maximum likelihood approach was used that calculated a set P for every three words in a sentence (Johansson, 2000). This chunking approach using a 3-word context to any target word was found to give equal performance to 5-word and 7-word contexts in syntactic tagging. So if a sentence had five words, a multinomial N-O calculation between the 1st 2nd and 3rd word neighborhoods would produce P_1 (i.e., as described in Experiment 3), then N-O would be calculated between the 4th and 5th neighborhood words to produce P_2 (as described in Experiment 2). Then the N-O between P_1 and P_2 would be calculated to produce the final neighborhood F for the sentence. The intersection between F_1 and F_2 (Equation 2) will give the final similarity between the two sentences. This word-chunking hypothesis is consistent with the intuition that adjacent words in a sentence constrain meaning more than nonadjacent words in a sentence.

Finally, the union of the neighborhood weights (i.e., the entire neighbor weights of all words in each pair) was calculated for F to compare the effectiveness of intersecting the neighborhoods.

Sentences We constructed 42 sentences whose words had a frequency over 10 in the TASA corpus. Sentences pairs were constructed of varying length (e.g., *blue bird fed babies nest tree -- bear protected cubs den*; articles, pronouns and prepositions were removed). Sentences were constructed so that about half were considered related and half unrelated.

Results and Discussion

Human ratings (M = 2.12, SD = 1.48) were significantly correlated to CDSA model 3 word chunking intersection, $r = .69$, $p < .001$, CDSA union, $r = .65$, $p < .001$, and the CDSA multinomial intersection, $r = .56$, $p < .001$. LSA cosines were also related to human similarity ratings, $r = .50$, $p < .001$.

The results give evidence that imposing context may be important when calculating sentence similarity. By applying an arbitrary rule set to sentences of varying lengths seems to yield better performance than just making all possible intersections among neighbors. Alternatively, the union of all the neighbors seems to perform just as well as a rule based intersection procedure. Possible reasons for this will be discussed next.

General Discussion

In sentence comprehension, comprehenders must understand the nature of word context and the constraints one word places on another (Kintsch, 1998). In other words, comprehenders will have to ask themselves: how does the meaning of one word affect the meaning of another word? The most straightforward relationship among words is an additive one, where the meaning of one word has no influence on the meaning of another word. In contrast, in the case of sentence comprehension, the levels of a one word can dramatically change the effects of another word. In this model, context refers to N-O among words in a sentence. That is, changing levels of one word can dramatically affect the meaning of another word. Thus, without structural constraints involving processes similar to

N-O, sentence meanings proceed in a radically different manner. Many relations shared between the pairs in the 4 experiments were abstract relations, ones that were only clearly established by filtering the individual word meanings and keeping shared information among words.

The word-chunking N-O approach appears to perform better than the multinomial N-O approach among all neighbors. Making all possible intersections among neighbors does not seem to be very psychologically plausible since it would involve making many comparisons between words that may not be relevant. For instance, comparing the first word to the last word in a sentence may not be important in evaluating the meaning of a sentence.

Possible improvements

As can be seen in experiment 4, N-O did not seem to help predict sentence similarity to a great extent over the union of all the neighborhoods in a sentence. This may be due to the arbitrariness of the rules used to calculate N-O for varying sentence lengths. For instance, if the sentence was 6 words long, N-O would be calculated for the three words and the last three words. With these two pools we would then calculate ***F***. This type of rule makes the assumption that all 6-word sentences follow the same syntactic structure. This obviously will not do for all 6-word sentences. Therefore, it seems likely that if the CDSA model was implemented with a syntactic parsing mechanism, it could give the correct word pairs to calculate N-O for any sentence.

Conclusion

The computational model presented here captures both word and sentence meaning. There are several reasons why using the CDSA model is advantageous. First, it uses simple mechanisms that are psychologically plausible. Second, it gives the freedom to add more information to the corpus at any time. Since the measures derived are computed on-line on the corpus, dynamically adding text to the corpus is not a problem. Essentially, many weights are changed between words as soon as text is added.

The proposed computational model captures word and sentence meaning by appealing to constraints reflected in a corpus analysis. Embodiment theorists (Glenberg & Robertson, 2000) may claim that there is no meaning derived from a corpus analysis because the words are not grounded in sensory-motor experience. In principle, one could have a more grounded corpus with units extensively embedded in sensory and motor experience. The TASA corpus was simply readily available. Whether the episodic experiences are reflected in TASA or in sensory-motor experience, the theoretical assumptions of the CDSA model are that, specific exemplars and associative processes are sufficient to account for the judgments of meaning similarity. The CDSA model uses simple mechanisms that rely on co-occurrences of words in exemplars.

One additional advantage of the CDSA model is that it allows more information to be added to the corpus at any time. Since the measures derived are computed on-line on the corpus, dynamically adding text to the corpus is not a problem. Essentially, weights are changed between words as soon as text is added.

Abstract

In this paper, a two by three approach to modeling categorization is presented. Similarity representations based upon a geometric, an additive tree and an additive cluster model are combined with an exemplar model and a prototype model in a single approach. The six models are applied to the categorization of pictorial known and unknown fruits and vegetables (Smits et al., 2002). For novel stimuli, the geometric exemplar model and the cluster models gave the best account, indicating a strategy where people compare stimuli with stored members on more general continua or a limited set of features. For well-known stimuli, the tree-based models gave the best account of the data, suggesting more elaborate taxonomic knowledge. More generally, the results show that different categorization models may perform better for different sets of stimuli, and that a systematic empirical comparison of such models is needed.

Introduction

A major contribution of categorization research over the last decades has been to establish the relation between similarity and categorization. Rosch and Mervis' (1975) seminal paper on the graded structure of categories showed that categories are ill-defined, and that the extent to which an instance of a category is seen as a typical member is positively related to similarity towards the category in question and inversely related to similarity towards relevant contrast categories (e.g., Verbeemen et al., 2001). Given the importance of similarity in categorization, a formal model should take a clear stance on two issues: The nature of similarity computation and the relevant objects of comparison in this calculation. First, the model must make assumptions about the nature of similarity, especially when the structure of the stimuli under investigation is not experimentally controllable. There are two main approaches to similarity, geometric and feature-based. The geometric approach (e.g., Carroll & Arabie, 1980; Shepard, 1964) represents stimuli in abstract space where similarity is inversely related to the distance between stimuli. In the feature-based approach (e.g. Shepard & Arabie, 1979; Tversky, 1977), similarity is considered a function of feature overlap, where commonalities increase and differences decrease overall similarity. Second, a model should specify the objects used in similarity calculation. In particular, information employed in making category decisions may be stored at the category level, or it may be stored at the level of individual instances of a category. The former approach is known as the prototype view (e.g., Hampton, 1979; Smith & Minda, 1998), and the latter as the exemplar view (e.g., Medin & Schaffer, 1978; Nosofsky, 1986). In this paper, we argue for a systematic evaluation of these formal models in a two by three approach that compares prototype and exemplar models on the one hand, and geometric and feature representations on the other hand.

The Generalized Context Model and a Geometric Prototype Model

In the generalized context model (GCM; Nosofsky, 1984, 1986, 1992), an exemplar model, categorization is assumed to be a function of similarity towards all relevant stored exemplars. In case (physical) dimensions are unavailable, the GCM fitting procedure starts with a multidimensional scaling procedure (MDS; Borg & Groenen, 1997) on proximity measures of all stimuli involved. The coordinates of these stimuli are then used as input for the model. In the case of two categories, A and B, the probability that stimulus x is classified in category A is given by:

$$\mathrm{P(A \mid X)} = \frac{\beta_A \eta_{XA}}{\beta_A \eta_{XA} + (1-\beta_A)\eta_{XB}} \qquad (1)$$

where β_A lies between 0 and 1 and serves as a response bias parameter towards category A. The parameters η_{XA} and η_{XB} denote the similarity measures of stimulus x toward all stored exemplars of category A and B, respectively:

$$\eta_{XA} = \sum_{j \in A} \exp\left[-c \left(\sum_{k=1}^{D} w_k \left| y_{xk} - y_{jk} \right|^r \right)^{1/r} \right] \qquad (2)$$

with y_{xk} and y_{jk} as the coordinates of stimulus x and the j-th stored exemplar of category A (or B for η_{XB}, respectively) on dimension k. The weight of the k-th dimension is denoted by w_k, with all weights restricted to sum to 1. The power

metric, determined by the value of r, is usually given a value of either 1 or 2, corresponding to city-block and Euclidean distance, respectively.

A prototype model can be constructed with the GCM as a start (Nosofsky, 1986, 1987, 1992; Smits et al., 2002). With the prototype defined as the central tendency of a category (Malt & Johnson, 1992; Malt & Smith, 1984; Rosch & Mervis, 1975), the object created by taking, on each dimension, the average coordinate over all members of the category, is a good way to define a prototype. The similarity function changes to:

$$\eta_{XA} = \exp-\left[c\left(\sum_{k=1}^{D} w_k \left| y_{xk} - \overline{y_{.k}} \right|^r \right)^{1/r} \right] \quad (3)$$

where $\overline{y_{.k}}$ denotes the mean value of all stored members of category A on dimension k. We will refer to (3) in combination with (1) as the Geometric Prototype Model (GPT).

A number of studies have already been conducted that compared prototype and exemplar models (e.g., Nosofsky, 1992; Nosofsky & Zaki, 2002; Smith & Minda, 1998, 2000; Smits et al., 2002). In many, the GCM performed better than prototype models. In the next section we elaborate on the major alternative to geometric similarity models, the contrast model (Tversky, 1977).

The Contrast Model and Categorization

In the contrast model, similarity between two stimuli is defined as a function of the features that these stimuli possess:

$$Sim(a,b) = \theta g(A \cap B) - \alpha f(A - B) - \beta f(B - A) \quad (4)$$

where $g(A \cap B)$ is a function of the features shared by objects a and b (the *common features*), and $f(A-B)$ and $f(B-A)$ are functions of the features that belong to one stimulus but not the other (the *distinctive features*). Different models have been proposed, mostly focused on either the common feature component or the distinctive feature components.

Pruzansky, Tversky and Carroll (1982) reanalyzed 20 data sets taken from various published studies, divided into two groups depending on the hypothesized structure of the stimuli used: conceptual (e.g., vegetables) and perceptual (e.g., polygons) stimuli. For 10 out of 11 studies of conceptual stimuli, analyses of proximity data proved better when performed by ADDTREE, a distinctive features approach to similarity. Seven out of nine studies of perceptual stimuli showed a clear advantage for low-dimensional MDS solutions.

A number of studies have been conducted that compared geometric and featural exemplar models. Lee and Navarro (2001) used additive clustering to extract common features from similarity data and provided excellent accounts of an artificial learning experiment with ALCOVE (Kruschke, 1992). Takane and Shibayama (1992) analyzed identification data of digits taken from Keren and Baggen (1981) and they too obtained excellent results for a featural version of the similarity-choice model (Luce, 1962) based on ADDTREE (Corter, 1982; Sattath & Tversky, 1977). Whereas clustering provides a very flexible way of representing similarity, allowing for overlapping clusters, additive trees are more restrictive in that they impose a hierarchy. There are, however, reasons to apply tree models, especially in the case of conceptual knowledge. A tree model produces, in general, a higher amount of features for the total set than additive clustering. But the amount of shared features is lower in general, and most weight is given to idiosyncratic features. This may be appropriate for well-known stimuli (McCrae & Cree, 2002), as people can be expected to have a fair amount of background knowledge about these stimuli, but it is unclear whether this is plausible in the case of novel stimuli.

The implementation of the feature structure in the GCM yields the *featural exemplar model* with similarities as:

$$\eta_{XA} = \sum_{j \in A} \exp-\left[c\left(\sum_{k=1}^{F} w_k \left(y_{xk}(1 - y_{jk}) + y_{jk}(1 - y_{xk}) \right) \right) \right] \quad (5)$$

where y_{jk} = 1 if stimulus j has feature k and y_{jk} = 0 otherwise. Therefore, the term y_{xk} (1-y_{jk}) is 1 if and only if the target stimulus x possesses the feature and the "reference" stimulus j does not, and vice versa for y_{jk} (1-y_{xk}). Each feature has a weight w_k that corresponds to the length of the segments in the tree. We will refer to this model as GCM-F (generalized context model – featural).

The *featural prototype model* will be illustrated using Figure 1, for an additive tree solution for birds and mammals. Distances between objects are defined by the sum of the horizontal segments on the shortest path between two stimuli (vertical segments are added for visual ease only). Each segment represents a feature that applies to all of its children with more general features closer to the left ("root") and more specific features located towards the right (endpoints) of the tree. The model is again formally similar to the featural GCM with the prototype treated as a pseudo-exemplar. The distance function equals:

$$\eta_{XA} = \exp-\left[c\left(\sum_{k=1}^{F} w_k \left(y_{xk}(1 - y_{pk}) + freq_{pk} y_{pk}(1 - y_{xk}) \right) \right) \right] \quad (6)$$

where y_{pk} is 1 if the prototype of A has the feature, and 0 otherwise. The frequency weighting term corresponds to the relative frequency or proportion with which the feature

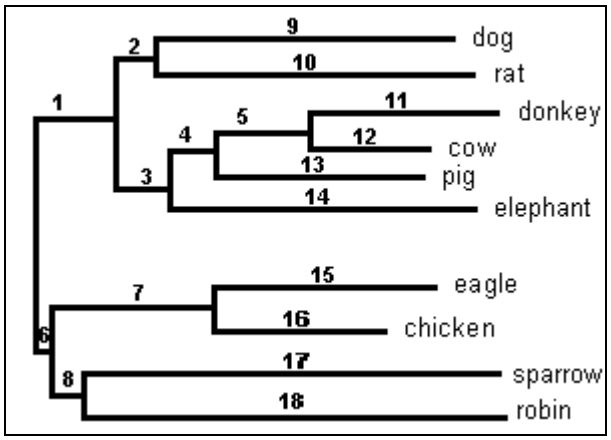

Figure 1: Example of a rooted additive tree.

occurs within *A*, i.e. the proportion of stored members of category *A* that possess that particular feature. This corresponds to the idea that the impact of the features in the prototype, which is seen as a pseudo-exemplar, depends on the prevalence of those features in the category[1]. We will refer to this model as FPT (featural prototype model).

The application of the featural models to an additive clustering solution, i.e. a common features model, is straightforward, as the feature structure is defined. This is not the case for additive trees as they produce distinctive features: a feature that adds to the difference between two stimuli may belong to one or the other. This is not a problem for exemplar models as distances between objects remain unchanged, but it will be required for a prototype model. To define a particular structure, one needs to define a root. If the root in Figure 1 is placed anywhere else it would imply that some members of one category possess some of the most general features of the other category but share none of the features belonging to members of their proper category. This is implausible as it would imply that some stimuli are seen as members of a category on a purely idiosyncratic basis and not because they share any features with that category, even though these stimuli would possess the most general features of a related contrast category. Therefore, in the remainder of this article, we will assume that the root is placed on the segment or path that best approximates this linearly separable structure (Medin & Schwanenflugel, 1981) for *stored* (well known) categories[2]. (This implies that one has to decide, *a priori*, which objects are considered to be stored members of a given category, as is the case for all other models. The choice of a root that best approximates separability serves to define the feature structure and not category membership for stored items, which is already determined.)

Analysis of Smits et al.'s data

Smits et al. (2002) analyzed a stimulus set consisting of pictures of 79 well-known items, retained after an exemplar *generation* task for the categories *fruit* and *vegetables*, and 30 fruits or vegetables, mostly exotic, that were completely unknown to participants. Ten participants completed a feature applicability task for all stimuli, for the 17 most frequently generated features for *fruit* and *vegetables,* generated by a different group of thirty participants. (Taking the most frequently generated features ensures that the analysis is not clouded by potentially unreliable features that are important to only a few subjects.) A similarity matrix was then obtained by correlating the feature applicability vectors for all 109 stimuli, after summing over participants. A different group of thirty participants classified the well-known stimuli as belonging to either *fruit* or *vegetables*. A group of twenty different participants did the same for the novel stimuli. Smits et al. then predicted category decisions based on the geometric versions of the GCM and the GPT and found a clear advantage of the GCM over the prototype model. Since their data from the categorization task had a fair amount of variance in the categorization proportions even for the well-known stimuli, it is possible to fit the respective models to old and novel stimuli separately. Therefore, we will analyze the data in a 2 × 3 × 2 framework, where the last factor is added to assess the fit of the models for old and novel stimuli separately.

Generating Similarity Representations

In order to obtain dimensions, similarities between 109 old and novel fruits and vegetables were reanalyzed with ALSCAL (Takane, Young & De Leeuw, 1977), using the BIC criterion (Schwarz, 1978)[3] to determine the optimal

[1] As the similarity structure was derived from the presented stimuli, we assume that a *presented* exemplar has all of its features to the full extent. Because a prototype is a construction after encountering exemplars, we assume that the activation and impact of its features is dependent on the frequency of those features in its own category (Kellogg, 1980). Because the prototype is treated as a pseudo-exemplar, we assume that its features can be no more than fully active (in the case of a feature that applies to all of its members), resulting in a factor of 1. We assumed that the features of *stored* exemplars in the *exemplar model* were not weighted dependant on the frequency of occurrence in *other* exemplars. This was confirmed post hoc: fit values were much worse when weighted for frequency.

[2] ADDTREE starts by grouping together the closest pair of objects, and then creates a dummy object with the average of the distance of the original objects to all other objects. This procedure is repeated until there are three objects left, and the root is placed so as to minimize the variance to the last three objects. Here we minimize the variance on the path that provides the best linear separation for *well-known* stimuli in a similar way.

[3] BIC = -2 ln(L) + k ln(n), where L is the likelihood value (the probability of the data given a certain model), k is the number of free parameters, and n is the number of data points. *Lower* means better, and only the difference in free parameters needs to be taken into account. The first term decreases with increasing model fit, the second is a penalty term that increases with the number of free parameters and data size. As such, the measure is a trade-off between model fit and model complexity. The statistic is most appropriate when the information provided by the data is relatively large as compared to any prior information, as is the case in all the

dimensionality (Lee, 2001b). A three-dimensional solution was chosen that explains 96 percent of the variance.

Following the same procedure for additive clustering, an analysis with ADCLUSGROW (Lee, 2001a) resulted in 32 clusters that explained 96 percent of the variance.

Finally, the same similarity matrix was reanalyzed using ADDTREE/P (Corter, 1982). The explained variance was 84 percent. The algorithm does not readily lend itself to the BIC-guided approach and usually fits to maximum complexity, in this case with 209 arcs (features). To the extent that this may cause the fitting of error, it may cause a drawback for the categorization models as the error would be "plugged" into the model, clouding the explanatory power of the underlying feature structure. At first sight this, and the lower fit value, would indicate that these models are less appropriate.

(It is important to note that these analyses were based on correlation patterns and not on the rough feature vectors, so the similarity algorithms, especially in the featural approach, are in no way restricted to have as much or less features than the original feature vectors.)

Fitting the Similarity Representations to the Categorization Models

The geometric models were fitted with the Euclidean distance metric ($r = 2$), as this resulted in clearly better fit values. The GCM and GPT were fitted as discussed previously with four free parameters: the bias parameter β, the sensitivity parameter c, and two dimension weights, as weights are restricted to add to 1. Feature weights for the tree- and cluster-based models were taken from the original solutions, however, to keep the number of parameters feasible for estimation, hence there are two free parameters, β and c. Stored members are the same in all models and are based on the earlier exemplar generation task. (Note that the tree-based models were based on the original ADDTREE solution after placing the root so as to provide the best linear separation, for known stimuli, between fruit and vegetables. Compared to the actual *generation* task for well-known stimuli, only one item, rhubarb, was generated as a fruit but closer to vegetables according to the ADDTREE solution.[4])

Results and Discussion All models were fitted by maximizing the binomial likelihood. Correlations between predicted and observed category decisions ranged from .85 to .93 with the best performing models ≥ .92, indicating a fair but not perfect amount of explained variance. The models were evaluated using BIC. Results are summarized in Table 1.

Analyses of the 30 novel stimuli separately are presented in the first panel of Table 1. The lowest (best) BIC value was obtained for the GCM, but the difference with the cluster-based exemplar and prototype models is small. All ADDTREE-based models performed clearly worse. The current results do not clearly favor exemplar or prototype models for novel stimuli, but it appears that the geometric approach to prototypes provides less explanatory power as compared to the clustering approach.

Table 1: -ln(L)[5] and BIC (only the difference in parameters taken into account) for the category *fruit* for all models.

	MDS		ADCLUSGROW		ADDTREE/P	
	GCM	GPT	GCM-F	FPT	GCM-F	FPT
1.*New*						
-ln(L)	73.95	83.27	81.38	82.12	90.83	93.01
BIC	160.69	179.33	162.76	164.24	181.66	186.02
2.*Well-known*						
-ln(L)	351.75	405.29	364.87	388.51	334.75	330.18
BIC	719.04	826.12	729.74	777.02	669.50	660.36

Analyses of the well-known stimuli resulted in a very different pattern. BIC values for the analyses of the 79 well-known stimuli separately are presented in the second panel of Table 1. The BIC values for the geometric and the cluster-based models were clearly higher (worse) than for the tree models. Clearly, the data from the well-known subset is best accounted for by the tree-based models that assume more elaborate taxonomic knowledge. The difference between the exemplar and prototype model is rather small and should be interpreted with caution. This result appears to contradict the earlier fit values where the MDS and additive clustering solutions provided a substantially better fit to the *similarity* data. In fact, a better fit to similarity data need not imply a better fit of the categorization model: those aspects of stimuli that are activated in a similarity task may very well be different from what is activated in a categorization task, especially after a concept has become well-elaborated. In other words, the less flexible and hierarchic structure of trees may not have captured all aspects of similarity, but the aspects it did capture may be more relevant for categorization of well-known concepts. Indeed, every aspect of similarity that is not used in categorization can be considered error in the model.

In fact, the most interesting pattern that emerges from these data is the fact that categorization of novel stimuli is best explained by those models that are based on the flexible representations that best explain similarity. These models have either a limited number of dimensions or a limited number of features, with little idiosyncratic features in the

analyses presented here. It is also fit to compare nonnested models. (For an extensive discussion, see Kass & Raftery, 1995.)

[4] In the actual classification task (not the *generation* task), the proportion of classifications for *rhubarb* as a fruit was only .33.

[5] This value is the most "democratic" measure as it only incorporates model fit, (incorrectly) disregarding the penalty term for free parameters. The measure is equal to the sum of minus the log likelihoods of the individual data points and is therefore sensitive to the size of the data set; hence differences in fit *between* the two datasets are *not* directly interpretable (the same is true for the BIC measure).

latter case. Categorization of well-known stimuli, on the other hand, is best explained by the models that use a representation that is less close to the similarity data but that impose a more elaborate taxonomy and more idiosyncratic features.

An interesting interpretative property of additive trees in this respect is the fact that, at each node of the tree, a feature that applies to all of its children is linked to a limited number of alternatives. Second, branches in the tree tend to have a higher weight as one goes down in the tree. This implies that the number and weight of commonalities decreases with the number of nodes between stimuli. It also means that those features that add most weight to the difference are less likely to be related as the number of nodes increases and vice versa. A similar argument was made by Markman & Gentner (1993) who presented stimuli with different ontological distances and found a similar pattern when subjects listed commonalities and alignable and nonalignable differences. A possible explanation for the good results of tree-based models could be that, as a concept becomes more elaborated, people tend to gravitate to an alignable structure that might dominate other, presumably less alignable, aspects of similarity.

Conclusion

The goal of the present paper was two-fold. First we presented a general framework, in which different models (i.e., exemplar and prototype models, embedded in either dimensional or featural similarity representations) could be systematically formulated, compared and tested. Given the framework, one can investigate precisely in what situations which model aspects perform best. Second, the framework was applied to categorization data of well-known and novel stimuli in the context of familiar natural language concepts. The results indicate that, depending on the amount of knowledge and mastery of the stimuli, different representational structures and different decision processes may operate.

One may wonder how these results relate to the findings from the category learning literature (e.g., Nosofsky, 1992; Smith & Minda, 2000; Stanton, Nosofsky & Zaki, 2002). In most of these studies, exemplar models embedded in multidimensional representations have been shown to account very well for the categorization data. However, in these studies, artificial categories are used almost invariably, with stimuli that vary along a limited number of salient dimensions. Formal models, such as the ones described in our paper, have seldom been applied to natural language concepts, which are far more complex than the stimuli used in the artificial category literature, and of which our participants arguably have a much richer and more elaborate knowledge than even the best trained participants have of artificial stimuli. (For other attempts to apply formal models to natural language concepts, see Bailey & Hahn, 2001; Smits et al., 2002; Storms, De Boeck, & Ruts, 2000, 2001; Verbeemen et al., 2001.) However, in spite of participants' extensive knowledge of such concepts, determining the relevant underlying dimensions or features for categorization with natural language concepts is perhaps the most crucial problem in modeling natural language categories (see, e.g., Murphy & Medin, 1985). The two by three framework that was presented here may serve as a valuable tool in this endeavor.

Abstract

There are two accounts explaining how background information can affect the conditional reasoning performance: the probabilistic account and the mental model account. According to the mental model theory reasoners retrieve and integrate counterexample information to attain a conclusion. According to the probabilistic account reasoners base their judgments on likelihood information. It is assumed that reasoning by use of a mental model process requires more working memory resources than solving the inference by use of likelihood information. We report a thinking-aloud experiment designed to compare the role of working memory for the two reasoning mechanisms. It is found that when working memory is preloaded participants use less counterexample information, instead they are more inclined to accept the inference or to use likelihood information. The present results add to the growing evidence showing that working memory is a crucial determinant of reasoning strategy and performance.

Introduction

There is evidence for a general link between working memory capacity and performance in a range of reasoning tasks (see e.g., Barrouillet, 1996; Gilhooly, Logie, & Wynn, 1999; Kyllonen & Christal, 1990). Previous studies showed that skilled reasoners generally give more normative answers and follow a high demand reasoning strategy (see e.g., Copeland & Radvansky, in press; Gilhooly, Logie, & Wynn, 1999). It is assumed that these normative answers are obtained by an analytic reasoning mechanism that hinges on working memory capacity (Klauer, Stegmaier, & Meiser, 1997; Meiser, Klauer, & Naumer, 2001). The present research continues this line of research and concerns causal conditional reasoning with everyday sentences.

Without labeling conclusions as (in)valid, we will investigate how people solve the following two conditional inferences with everyday causal sentences:

Modus Ponens (MP)
If cause, then effect
Cause occurs.
Does the effect follow?

Affirmation of the Consequent (AC)
If cause, then effect
Effect occurs.
Did the cause precede?

Examples of everyday 'if cause, then effect' sentences are: If you phone someone, then his telephone rings.
If you eat salty food, then you will get thirsty.
If someone has a high income, this person will be rich.
If a dog has fleas, then it will scratch constantly.

Abundant research established that when people reason on everyday conditionals, they spontaneously bring relevant background knowledge into account (for a review see Politzer & Bourmaud, 2002). This contextualization process is characteristic for common-sense reasoning and is responsible for our ability to adaptively cope with everyday situations. The current study focuses on how background knowledge is used for deriving conditional inferences.

There are two reasoning mechanisms describing how background information is used during reasoning. First, according to the probabilistic account reasoners derive the probability that the conclusion follows given the categorical premise and use this probability to draw a gradual conclusion (Lui, Lo, & Wu, 1996; Oaksford, Chater, & Larkin, 2002). For MP, reasoners will confine their knowledge base to the situations where the cause occurs. Based on this range of situations they then determine the likelihood that the effect follows. If they can induce that a particular effect always or mostly follows the cause, they conclude that the effect will (probably) follow. The endorsement of MP is thus directly proportional to L(effect|cause). AC is solved in analogy with MP. Reasoners activate all relevant situations where the effect occurs. Within this subset they infer the likelihood that the cause preceded the occurring effect. This likelihood L(cause|effect) directly reflects the AC acceptance rate.

According to the second reasoning mechanism the conclusion is attained by taking possible counterexamples into account. There is a strong and reliable effect of the number of available counterexamples on inference acceptance (see e.g., Cummins, Alksnis, Lubart, & Rist, 1991). The mental models theory describes how participants reason with counterexample information (Johnson-Laird & Byrne, 1991; Markovits & Barrouillet, 2002). When given a problem based on a causal rule, for instance, '*If you water a plant well, the plant stays green*', reasoners will start by representing the content of the conditional as a possibility: It is possible that a plant is well watered and green. Active consideration of the problem

content will then lead to an automatic activation of relevant background information. This information is used to complement the initial model. For MP and MT, the categorical premise triggers the retrieval of disablers. Some examples of disablers are: 'the plant caught a disease' or 'the plant was deprived of sunlight'. When reasoners retrieve at least one disabler, they do not conclude that the effect follows. For AC an automatic search for alternative causes starts, for example, 'the lack of water was compensated by adding fertilizer' or 'the plant is a succulent'. When reasoners retrieve an alternative cause, their mental models inform them that there are two conclusions possible (watered and not watered). As a result, they do not accept the default conclusion.

It is clear that the probabilistic and the mental model reasoning mechanisms both rely on available background information, but they focus on a different *type* of background knowledge: probabilities versus exemplars. Both information types have already been brought together by, e.g., Weidenfeld & Oberauer (2003); Verschueren, Schaeken and d'Ydewalle (2003; 2004a) integrated the two theories that explain how the information is taken into account in a dual process perspective. They label the probabilistic mechanism as heuristic and the mental model mechanism as analytic. Heuristic processes are generally considered as fast, automatic mechanisms that operate at a low cognitive cost and at the periphery of awareness. Analytic processes are generally slower, more demanding reasoning mechanisms that operate in a conscious and strategic manner (Stanovich & West, 2000). Verschueren et al. (2004a) manifest three reasons for linking the two reasoning processes to a heuristic-analytic polarity. (1) The heuristic reasoning process is mainly implicit - reasoners have no recollection of the range of situations that are taken into account to calculate a likelihood estimate whereas people reasoning by use of mental models are conscious of the counterexample(s) they retrieve. (2) The process based on likelihood information yields relatively fast results whereas using counterexamples requires a sequential thus slower reasoning process. (3) The heuristic conclusion is overwritten when a more analytical conclusion can be produced (see Verschueren, et al., 2004a for experimental evidence for 2 and 3). At present we will investigate whether both reasoning mechanisms differ in their working memory demands. If indeed the mental model account describes an analytical reasoning mechanism it should pose more demands on working memory capacity than the heuristic likelihood process.

Experiment

It is assumed that reasoning with counterexample information draws heavily on working memory resources, whereas the use of mere likelihood estimates imposes a far lesser demand on working memory. When participants reason based on counterexample information, the problem content as well as all models of relevant situations have to be represented. The larger the number of mental models that participants have to represent and maintain, the heavier the load on working memory during reasoning (Barrouillet & Lecas, 1999). Additionally, it has been found that counterexample retrieval efficiency suffers from dual task loads, which indicates that working memory is also involved in the retrieval of counterexample information (De Neys, 2003). In case the reasoners have a representation of both the conditional sentence and at least one counterexample, they subsequently have to integrate this information to see that there are two different conclusions for the same problem. This information manipulation and integration is considered as a crucial task of working memory.

For the reasoning process based on likelihood information, the demands on working memory are far less. The situations used for attaining a likelihood estimate are not actively represented in working memory, but rather briefly accessed. There is neither an active controlled search process nor a need for premise integration. The likelihood estimate is based on all relevant situations at a time and the final conclusion directly mirrors the obtained likelihood estimate.

When reasoners are asked to think aloud during reasoning, we can monitor which information they use for deriving conclusions. By concurrently checking the information that people use we get a direct indication of the underlying reasoning process. Only in case where people do not provide extra information but accept the conclusion without further argumentation, this procedural aspect is unclear. It can be that participants did use their background knowledge and found that the likelihood that the conclusion follows is sufficient to grant acceptance or that there are no counterexamples available. Or else it can be that they did not rely on background information and just satisfied the conclusion by restating the given information.

In a previous thinking-aloud study Verschueren, Schaeken and d'Ydewalle (2004b) showed that participants with low working memory capacity more often use likelihood estimates to solve an inference, whereas participants with a larger working memory capacity rather use counterexample information. These results can be considered as an indication for the difference in working memory demands of the heuristic and analytic process. This setup provides however only *correlational* evidence. Indeed, it is still possible that a third factor (e.g., general intelligence, motivation, etc.) explains both the performance on working memory tests as well as on reasoning tasks. The following experiment was designed to test whether there is a difference in the actual working demands of the two processes.

In this experiment we examined the effect of secondary task interference on the applied reasoning mechanisms. In the dual task methodology, a secondary task chosen to burden working memory capacity has to be carried out concurrently to the criterion task. The degree of disruption in the criterion task under dual

task conditions – as compared to single task conditions – is taken to reflect the dependence of the criterion task on working memory. The criterion task we used was a thinking-aloud conditional reasoning task. Concurrent verbalization allows us to monitor the information that reasoners consult for deriving conclusions. By checking the information that people refer to (likelihood or counterexample information) we get a direct indication of the underlying reasoning process.

Because the criterion task entails spontaneous verbalization, the choice of secondary tasks is limited. Pilot work revealed that concurrent motor, auditory or articulatory activity interfered with the participants verbalization. We therefore opted for a preload paradigm. Because a spatial load is less likely to interfere with verbalization than a verbal or numerical load, we worked with a spatial preload set-up. The evidence that spatial storage tasks tap a working memory feature crucial for reasoning is twofold: Klauer, et al.(1997) report that a concurrent spatial load led to a significant disruption of propositional (including conditional) reasoning. Second, in the visuospatial domain simple storage tasks have a similar correlation with executive functioning and reasoning as classic processing-and-storage tasks (Miyake, Friedman, Rettinger, Shah, & Hegarty, 2001; Suess, Oberauer, Wittman, Wilhelm, & Schultze, 2002). We can thus assume that the preload task taps working memory resources that are needed for reasoning, while at the same time minimizing a possible interference with the verbalization process. The dot memory task we used is a classic simple storage task (adapted from Miyake, et al., 2001; Oberauer, Suess, Wilhelm, & Wittman, 2003). We briefly presented a 3x3 matrix with 4 dots forming a complex pattern, afterwards participants were asked to reproduce this dot pattern.

In the preload-condition participants had to memorize the pattern of the dots while solving a reasoning problem. We will verify whether the use of counterexample information decreases when working memory is preloaded, compared to performance in the control condition. The decreement in the use of likelihood information should be significantly smaller than the decreement in counterexample use.

Method

Participants A total of 52 first year psychology students participated in the study.

Procedure and Design The participants were tested individually. The experiment was run on computer. Participants started by reading the instructions. They were told that they will be asked to think aloud while solving conditional inference problems. The reasoning instructions read that they should answer the question as in an everyday setting. Each participant then solved two test problems, e.g.,

> If someone catches a cold, then he will cough.
> Someone coughs.
> Did this person catch a cold or not?

The participants read the premises aloud and answered immediately. When they found that they had completed their answer, they pressed a key to go to the following problem. After the presentation of the reasoning instructions, the participants either reasoned with or without working memory preload. In the preload conditions participants started by practicing two dot patterns: A pattern was presented for 500ms and participants were immediately asked to reproduce this pattern. The overall performance on the test problems was nearly perfect. After these dot pattern practice trials, participants were given instructions for reasoning under preload. First, a dot pattern was presented for 500ms, next the reasoning problem occurred, participants read the premises aloud and answered immediately. The answers participants gave were recorded on tape. When they finished their answer, they pressed a key and a blue screen appeared where they were asked to reproduce the dot pattern. When they completed the dot pattern, they pressed a key to start the next trial. It was explicitly mentioned that they had to memorize the dot patterns correctly; they were told that an incorrect reproduction rendered the trial invalid. This was done to make sure that participants actively attended the dot pattern and tried their best in memorizing it. In the control condition, the dot patterns were presented for 500ms before the premise presentation. Participants were told that these dot patterns are presented as a control condition, they were asked to look at the dot patterns but not to memorize them. They read the premises and pressed a key when their answer was complete, the next trial started immediately. The time that participants needed to read and solve the reasoning problem was measured.

Materials and Design Based on previous research we selected 12 sentences with a maximally varying necessity and sufficiency of the cause (maximal variation in L(effect|cause), L(cause|effect), and in the number of available disablers and alternatives). We made sure that the reading time of all 12 sentences was comparable ($M_{\text{number of words}} = 9.5$, $SD = .314$). Twenty-six participants solved 12 AC inferences; the others solved 12 MP problems. The 12 sentences occurred always in the same order; the causes of the first six sentences and the last six sentences were equally necessary and sufficient. For both reasoning forms, half of the participants solved the first six problems under preload; the other six problems were solved without preload (control condition). For the other half of the participants the order of the preload/control conditions was reversed. Because we used 12 different sentences, transfer effects between the two conditions could be excluded.

Results

The obtained reasoning answers were literally transcribed. Next, the condition-codes were removed and the answer types were rated. It was indicated whether the answer reflected a simple acceptance of the

default conclusion or whether there was reference to a counterexample or to a likelihood estimate. There was no overall difference in the average response time for the preload (18.19s) and the control condition (18.53s). In the control condition, there was 26% inference acceptance, in 22% of the trials participants used likelihood information and in 64% they referred to counterexamples. These results are similar to those observed by Verschueren et al. (2004a; 18%, 18% and 66% respectively).

In the preload condition there were 6.4% combination trials (in a 'combination trial' participants refer to counterexample and likelihood information) whereas in the control condition there were 23.1% combination trials. The observation that combining the two types of information becomes less prevalent when working memory is preloaded, suggest that the information integration process that is characteristic for combination answers taps on working memory resources. For comparing the relative importance of both reasoning processes, we confined the analysis to trials where participants either referred to a likelihood or to counterexample information. Combination trials were excluded from the analysis (14.4%).

Task interference. Only 69% of the dot patterns were reproduced correctly. There was an effect of answer type on the correct reproduction of the dot patterns, $F(2, 21) = 6.696$, $p < .01$ (*Wilks' lambda* = .611). This interaction is displayed in Figure 1. When the dot patterns were correctly reproduced, there were fewer counterexamples mentioned than when the dot patterns were incorrectly reproduced, $F(1, 22) = 11.96$, $MSE = .458$, $p < .05$. On the correctly reproduced trials, there were more answers where participants referred to likelihood information, $F(1, 22) = 5.21$, $MSE = .037$, $p < .05$. There was no significant effect on the inference acceptance rates. These results reflect a *task interference*. When participants rely on a reasoning process that puts only a minor demand on working memory there are enough resources left to maintain and reproduce the dot pattern. In contrast, when participants rely on retrieval, manipulation and integration of counterexample information, working memory capacity is severely burdened. There are then not enough resources left to actively maintain the dot patterns, resulting in an incorrect reproduction. These results support the idea that using counterexample information draws heavily on working memory resources.

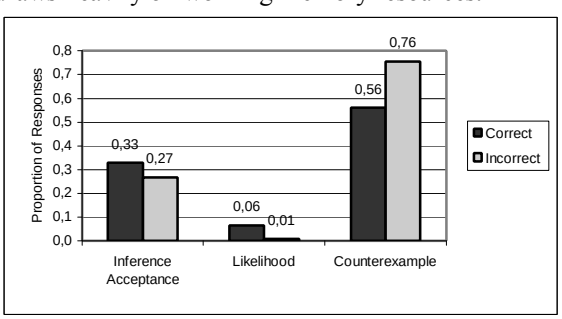

Figure 1: Difference in the proportion of the three types of answers for preload trials where the dot pattern was correctly versus incorrectly reproduced.

Effect of preload on the reasoning process. For examining the effect of preload on the types of answers, we only included the preload trials where the dot pattern was correctly reproduced. All analyses were run on proportions; the number of times each answer type occurred was divided by the total number of correctly reproduced trials. We ran an analysis of variance with sentences as the unit of analysis, and a 2 (inference type, between subjects) * 2 (preload, within subjects) * 3 (answer type, within subjects) design. We found a main effect of answer type. There were more answers referring to counterexample information (60.1%) than there was plain inference acceptance (27.7%) or likelihood information used (5.6%), F(2, 21) = 102, 72, p < .001 (*Wilks'lambda* = .08). The interaction between answer type and preload condition was marginally significant, $F(2, 21) = 3.120$ $p = .065$ (*Wilks'lambda* = .771). Figure 2 illustrates this interaction. There was a clear yet marginally significant decrease in the use of counterexample information when working memory was preloaded, $F(1, 22) = 3$ 304, $MSE = 0.078$, $p = .082$. There were significantly more inferences accepted in the preload condition, $F(1, 22) = 8.255$, $MSE = 0.131$, $p<.01$ while there was no significant increase in the use of likelihood information. No other interaction effects reached significance. The observation that there is more inference acceptance under preload corroborates previous effects of secondary task load on the conditional reasoning performance (De Neys, 2003).

The explanation provided by De Neys (2003) is that under preload, the resources available to participants are insufficient to retrieve counterexample information. The currently observed decrease in counterexample use is in line with this explanation. The increase in inference acceptance can also be - at least partially - related to an enhanced matching heuristic. We can assume that some reasoners do not engage in an active reasoning process based on counterexample retrieval, but simply restate the information from the conditional and blindly accept MP and AC. In this case the preloading should cause more participants to accept all conclusions, even on sentences where counterexamples can be automatically retrieved and likelihood estimations are high. In the preload condition, there were indeed more participants (13.5%) who accepted at least 75% of the inferences than in the control condition (7.7%). Even for sentences with many available counterexamples – for these sentences counterexamples can be retrieved automatically and likelihood estimations are very low - we found an increase in the inference acceptance rates (7.1% control vs. 19.8% preload). This shows that it is unlikely that participants consulted their background knowledge for deriving the conclusion and lends support for the hypothesis that the working memory preload led to an enhancement of the computationally low demanding matching heuristic.

In sum, as expected the resource dependent use of counterexample information decreased under preload, while the use of likelihood information was unaffected

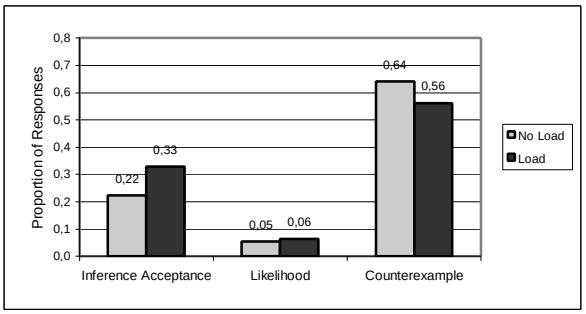

Figure 2: Proportion of answers of the three types for the preload versus control condition (only preloaded trials with correctly reproduced dot patterns).

by preload conditions. The decrease in use of the counterexample based reasoning process is at least partly compensated by shifting to inference acceptance.

Number of counterexamples used. Does the decrease in the use of counterexample information under preload reflect a decrease in a strategic validation tendency? If participants retrieve counterexample information to merely check whether the default conclusion can be falsified (see e.g., Schroyens, Schaeken, & Handley, 2003) they would need to retrieve only one counterexample to falsify the given conclusion. However, we did not find a difference in the number of trials where participants referred to only *one* counterexample (preload: 73% vs. control-condition: 82.4%). This raises doubt on the validation-hypothesis. In contrast, we observed a decrease in the proportion of trials where *more than one* counterexample was mentioned, $t(23) = 2.77$, $p < .05$ (preload: 17% vs. control-condition: 26%). This underscores the idea that in tasks without deductive instructions reasoners retrieve counterexample information to provide an adequate and informative conclusion rather than to merely falsify a default conclusion. When looking at the *total number* of specific counterexamples used, there were significantly more counterexamples used in the control condition (1.09) than when working memory was preloaded (0.86), $t(23) = 3.97$, $p < .01$.

If counterexample retrieval, representation and integration demand effort, we should observe an effect of counterexample retrieval on the secondary task performance. We tested whether there was a difference in the number of counterexample answers for the trials where the dot pattern was correctly versus incorrectly reproduced. We included the number of available counterexamples (few/many; measured by the generation task) because it is a strong predictor of counterexample use. There was a marginally significant interaction between the number of counterexamples used and the (in)correct reproduction of the dot pattern, $F(1.20) = 4.120$, $MSE = 2.866$, $p = .056$. Pairwise comparisons revealed that for sentences with many available counterexamples there were significantly more counterexamples produced when the dot patterns were not recalled correctly, $F(1, 20) = 6.946$, $MSE = 4.832$, $p<.05$ (not significant for few-sentences). This converges with the observed interference of counterexample use and correct dot pattern recall.

In general, these results sustain the idea that using counterexample information draws heavily on working memory resources whereas using likelihood information or matching is less resource demanding.

Discussion

Correlational studies revealed that differences in working memory capacity relate to differences in the conditional answer patterns. A possible explanation is that differences in reasoning performance do not simply relate to differences in a single reasoning predisposition, but are mediated by differences in the working memory demands of the active reasoning mechanisms. Highlighting the distinction between more heuristic strategies (such as matching and likelihood use) and more cognitively demanding analytical strategies (relying on counterexamples) may provide a more differentiated picture of the specific role of working memory in conditional reasoning. We found evidence for two conditional reasoning mechanisms with a differing working memory demand: a probabilistic account relying on likelihood information and a mental model account relying on counterexample information.

The results reveal that using counterexample information to attain a conclusion taps heavier on working memory resources than deriving the conclusion based on likelihood information. This provides additional support for considering the reasoning process based on likelihood information as heuristic and the reasoning process based on counterexample information as analytic. The differences in use of counterexamples/likelihood on participants with varying working memory capacity observed by Verschueren et al. (2004b) may thus be attributed to the working memory demands of the two reasoning mechanisms.

We found a large effect of working memory preload on the inference acceptance rates. When relating inference acceptance to the two reasoning strategies, it can reveal that either no counterexamples can be retrieved or that the likelihood estimation is sufficiently high. However, because we also observed an increase in inference acceptance on sentences for which pretests revealed many available counterexamples as well as likelihood estimates that are well below 1, it rather seems that the inference acceptance rates show that under preload some reasoners do not consult their background knowledge. When working memory capacity is burdened by preload, these participants are discouraged to engage in a demanding retrieval process. Instead they provide an answer that satisfies the inference question, simply by restating information from the premises. This strategically placed escape hatch can explain the increase in inference acceptance rates under preload.

Taken this together, we found evidence for the involvement of working memory in conditional reasoning. By analyzing the answers participants gave we were able to pinpoint which information participants used to attain their conclusion. We found

support for distinguishing two heuristic reasoning strategies -use of likelihood information and matching- and for an analytic strategy that takes counterexamples into account. Working memory preload yielded an increase in the use of heuristic strategies whereas the use of the analytical strategy decreased.

The present study is one of the first to combine a secondary task paradigm with a verbalization criterion task. Using a preload-paradigm is probably the best way to investigate the working memory demands of tasks involving verbalization. Although we cannot be entirely conclusive on a possible secondary task interference on verbalization processes (the answers were structurally similar to baseline results) this procedure enabled us to experimentally test the difference in working memory demands.

The effect of working memory capacity on inference making is at present only discussed on an intensive level: We investigated the *global* effect of a working memory dependent secondary task on the use of likelihood and counterexample information. Whether the working memory demands of the two processes coincide with the assumed differences in representation, retrieval and manipulation cost cannot be decided upon based on the present results. The data may also reflect the cost of determinacy: Giving a gradual uncertain answer may be overall less demanding than providing a determinate conclusion. There is also no information about the relative functional involvement of the different working memory components. Specific research with different types of well-chosen secondary tasks may reveal this crucial information.

In sum, distinguishing different reasoning mechanisms that can be used to solve conditional inferences can enhance our comprehension of how working memory mediates the reasoning performance. The specific working memory demands of different reasoning strategies co-determine the robust effect of working memory capacity on the conditional reasoning performance.

Abstract

Two experiments assessed whether grammatical gender of Italian nouns referring to animals and tools affects conceptual representations of the corresponding objects, comparing results from Italian and English. In the first experiment, we elicited semantic substitution errors (e.g., saying "hammer" when "axe" is intended), finding language-specific gender effects (more errors in Italian than English for words sharing gender) for words referring to animals but not for words referring to tools. In the second experiment, words sharing gender were judged as more similar in meaning by Italian speakers than English speakers, again only for animals and not for tools. Moreover, no such gender effect was observed for pictures of the same animals.

Introduction

As Roman Jakobson (1959) put it: "Languages differ essentially in what they must convey and not in what they may convey" (p.236). That is, languages differ in which conceptual or formal properties must be realized in sentential form. For example, in English the word "friend" does not indicate the sex of the friend, while in Italian the corresponding word is differentially inflected for a man ("amico") or a woman ("amica"). In English, adjectives used as predicates (e.g., "tall" in "The boy is tall" and "The girl is tall") do not agree in gender with the subject of the sentence, while they must in Italian (e.g., "Il ragazzo e' alto" or "La ragazza e' alta"). Such differences in obligatory expression may imply that speakers of different languages pay more or less attention to those dimensions of meaning. For example, Italian speakers may pay more attention to the sex of referents than English speakers. By extension, Italian speakers may tend to think of objects in the world as more male- or female-like on the basis of the words' grammatical gender (as suggested by the work of, e.g. Boroditsky, Schmidt & Phillips, 2003; Sera, Elieff, Forbes, Burch, Rodriguez, & Dubois, 2002). But how strong and pervasive can these effects be?

Here we present experiments investigating the conditions under which effects of a language-specific property (grammatical gender of Italian nouns) are present, contrasting performance by Italian and English speakers on translation-equivalent nouns. Grammatical gender allows a conservative test of language-specific effects on cognition because it is largely arbitrarily linked to meaning (although see Foundalis, 2002).

How could grammatical gender affect conceptual representations for objects? Effects of grammatical gender could arise as a consequence of general language-learning mechanisms based on similarity. According to this hypothesis (to which we will refer as "Similarity and Gender"), words that are similar to each other on any linguistic dimension (including but not limited to grammatical gender) may become more semantically similar as a consequence of the fact that words of the same syntactic class (e.g., same gender, same grammatical class, etc.) appear in the same syntactic contexts. For example, in languages with grammatical gender, nouns are used in sentences along with gender-marked determiners and adjectives, whether the nouns refer to sexuated entities or not. Sensitivity to shared sentence context could allow children to bootstrap properties of similarity in meaning from the syntactic contexts in which the words occur during language acquisition (Landauer & Dumais, 1997). This hypothesis does not require any explicit associations between grammatical gender and sex of human referents; instead it predicts that any effects of grammatical gender on semantic representations should be found in any gendered language (no matter how many gender classes are in the language), and that they should be found for all words (whether the referents are sexuated or not).

However, mechanisms mediating such effects may be more specific and limited. According to this other hypothesis (to which we will refer as "Sex and Gender"), effects of grammatical gender could arise because children would treat all grammatical categories as revealing specific semantic properties (Boroditsky, et al., 2003). In the case of grammatical gender, these effects would require linking the grammatical gender of nouns referring to humans to the sex of referents. Across languages there is a core correspondence between grammatical marking of gender and biological sex (Corbett, 1991), although the consistency of this mapping differs across languages. According to this view, children learning a gendered language would first notice the core correspondence between the gender of nouns and male/female semantic properties of human referents (and some animals). They would then generalize this correspondence to other nouns for which there is no clear conceptual foundation of gender,

assigning male or female features to referents in agreement with the grammatical gender of the corresponding words. Thus, words of the same gender would be more similar among themselves than words of different gender because they share male or female-like properties. Such a mechanism could be strongest for languages with the greatest degree of correspondence between the gender of nouns referring to humans and the sex of referents. This is the case in Romance languages which have only two genders and few exceptions to the consistent mapping between the gender of nouns referring to humans and sex of the referents. It could be weaker (if present at all) in languages with multiple genders and/or in which nouns referring to humans fall into more than two classes. Moreover, any effect of gender could be stronger for words referring to sexuated entities (e.g. animals) than for words referring to objects and abstract concepts, because semantic properties of sex are less relevant in these latter domains. Most of the studies investigating language-specific effects of grammatical gender (e.g. Boroditsky, et al., 2003; Sera, et al., 2002) have tested this hypothesis, either implicitly or explicitly.

In the experiments below we tested some predictions stemming from these views, considering grammatical gender of Italian nouns. As in other Romance languages, all nouns in Italian are marked for gender, either masculine or feminine. For nouns referring to humans and some animals, the gender depends on the sex of the referent (e.g., "ragazzo/ragazza" [boy/girl]; "leone/leonessa" [lion/lioness]), while for other animals gender does not depend upon the sex of the referent (e.g., "lupo" refers to both male and female wolves, although it is possible to mark the gender in some cases). For words referring to objects and abstract entities, instead, there are no such clear semantic correlates (with certain exceptions not addressed here). We investigate two semantic fields, animals and tools, to test the hypotheses outlined above. Both predict language-specific effects of grammatical gender on meaning, such that word pairs sharing Italian gender will show greater semantic similarity effects than the same word pairs in English translation. The two hypotheses make different predictions, however, suggesting that these effects may have different breadth. The Sex and Gender hypothesis predicts that greater language-specific gender effects should be observed for animals than for tools (as animals are sexuated entities), while the Similarity and Gender hypothesis predicts no category difference.

Experiment 1

Here we assessed whether grammatical gender affects online linguistic tasks such as picture naming. We begin with a linguistic task, as finding language-specific gender effects is not only evidence for a "thinking for speaking" view of language-specific effects on cognition (Slobin, 1996), but is also a pre-requisite to testing for broader language specificity in tasks less tightly tied to linguistic encoding. We focus upon *semantic substitution errors* (i.e., instead of producing a target word, speakers produce another word related in meaning, e.g., saying "hammer" when "saw" is intended) in picture naming. In previous work we have introduced a continuous picture-naming paradigm to elicit such errors (Vigliocco, Vinson, Lewis & Garrett, in press). Here we investigate whether semantic substitution errors in Italian tend to preserve the gender of the target word (i.e., masculine nouns are more likely to substitute for other masculine nouns, and feminine nouns for other feminine nouns). It is generally agreed upon in the language production literature that semantic substitutions arise during the process of retrieving the lexical entry corresponding to a concept, thus tapping into the interface between linguistic and conceptual knowledge (e.g., Garrett, 1984; Levelt, 1989). Moreover, these errors are sensitive to fine-grained semantic similarity: the likelihood of errors increases with greater semantic similarity (Vigliocco et al., in press). Thus, other factors being equal, if grammatical gender has a semantic effect, it should increase the likelihood that words of the same gender substitute for each other in a language such as Italian. However, other factors may not necessarily be equal, particularly non-language-specific factors such as semantic similarity not related to gender in a language-specific manner, or visual similarity among pictorial referents. In order to provide the tightest controls, we selected English as a baseline comparison language, using the same items (translation equivalent words) and the same tasks. This allows us to test for language-specific effects of Italian gender while avoiding concerns related to general semantic or visual similarity among the items used in our experiments. We investigate whether Italian errors tend to preserve gender above the English baseline level (based upon assigning Italian gender to English translations). It should also be noted that substitution errors are sensitive to phonological similarity between target and intruder (Dell & Reich, 1981), and Italian gender does have strong and reliable phonological correlates. To minimize the possibility that any observed language-specific effects of gender are due to phonological similarity, we also conducted analyses in which we excluded all errors with substantial phonological similarity to the target word.

Method

Participants

Participants were 27 native speakers of Italian from the London community and 20 English speakers from the UCL subject pool. The Italian participants had only rudimentary knowledge of English, and none of the English speakers reported moderate or better competence in any Romance language.

Materials

We selected 27 black and white line drawings of animals, avoiding those animals for which the gender of the noun strictly depends upon the sex of the referent. We further selected 50 black and white line drawings of tools. Most pictures came from Snodgrass and Vanderwart (1980), with additional ones prepared for the experiment. Name agreement was established for each of our participants during the experimental session (see also Vigliocco et al., in press); in general there was very strong name agreement in both languages, further ensuring that the words are suitable translation equivalents. Because in previous work we have established that substitution errors in this paradigm do not cross

semantic fields, we used a blocked presentation design, analyzing the data for the animals and the tools separately. We presented 77 blocks of 10 pictures each to every participant. Each block contained only animal or tool pictures (presented in random order within the block), and each picture appeared 10 times in the course of the experiment.

Procedure

The experiment began with a name agreement phase in which each picture was presented and participants were asked to name them. This phase allowed us to ensure name agreement across participants and also to identify specific naming preferences by individual participants (which might otherwise have been considered errors). Next, a practice series of blocks were presented in which the speed of presentation of each picture was adjusted for each participant (between 600ms and 1100ms) in order to render the task difficult but manageable for each speaker. After the training, the experiment started. Participants were told that their task was to name each picture as it appeared on a computer screen as quickly as possible.

Scoring Criteria

Participants' responses were transcribed and scored in the following categories: *Correct responses*: participants uttered the correct target word. *Different label*: participants used a different word than our intended target (e.g. "stag" for "deer"), but this different label was consistently used by that participant and did not refer to another item in the experiment. *Lexical errors*: participants produced a word that differed from the target and that did not qualify as a "different label". Lexical errors were further classified as "out of set" (intruding words that are not among the experimental items) and "within set" (those items from within the present response set). Because of the repeated presentation of a limited set of pictures to be named, most lexical errors tended to be other items from the response set. Because of this, and to minimize the possibility of linguistic variability beyond this particular set of item, analyses were performed only upon within-set lexical errors items. *Miscellanea*: other responses not included above, such as dysfluencies, incomplete utterances, inaudible responses, omissions and self-corrections. Table 1 reports a breakdown of the proportions of responses in the different scoring categories.

Table 1: Response Types
(IT: Italian, EN: English; A: Animals, T: Tools)

Response type	IT: A	EN: A	IT: T	EN: T
Correct & Different Label	.876	.935	.948	.910
Lexical errors				
Within-set	.021	.024	.013	.018
Out of set	.004	.001	.002	.002
Miscellanea	.100	.04	.133	.062

Results and Discussion

All analyses were carried out on within-set lexical errors. First, we eliminated all those items for which the average correct performance was not above 75% in both languages or for which the average correct performance differed more than 15% across the two languages in order to exclude additional cross-cultural differences. For each semantic field (animals and tools) we carried out two 2x2 ANOVAs. In all ANOVAs, proportion of errors was the dependent variable with target-error pair as a random factor. Independent variables were language (Italian, English) and Italian gender (shared between target and intruder or not shared). English words were assigned Italian gender for the purpose of the analysis. The first ANOVA was carried out on the within-set errors remaining after we excluded the cases discussed above (for *animals*: 103 errors in Italian and 73 errors in English; for *tools*: 90 in Italian, and 117 in English). For *animals*, this analysis showed a significant interaction between language and Italian gender, such that errors sharing gender with the target were more common in Italian (68%) than in English (41%); $F(1,63) = 8.03$, $p = .006$. Neither main effect was significant ($F < 1$). The results of the analysis for *tools* were similar; only the interaction between language and gender was significant: gender preservation was greater in Italian (61%) than in English (36%); $F(1,79) = 4.6$, $p = .04$; main effect $Fs < 1$).

In the second analysis we excluded all errors for which the target and the intruder shared phonological similarity. Phonological similarity between target and intruder was assessed as in Vigliocco et al. (in press). In this second analysis, only errors for which either of two measures of phonological overlap did not exceed the average + one standard deviation of that measure (in either language) were considered (for animals, leaving 64 errors in Italian and 42 in English; for tools, leaving 39 errors in Italian and 42 in English). This analysis for *animals* also showed a significant interaction between language and gender; such that even among target-intruder pairs with low phonological similarity, Italian target-intruder pairs tended to share gender (77%) more often than English pairs (43%) (interaction $F(1, 37) = 5.88$, $p = .020$; main effect $Fs < 1$). However, this interaction was not significant in the analysis for *tools* (all $Fs < 1$). Thus, for the tools, the language x gender effect observed in the complete set of errors may just be a consequence of greater phonological similarity in Italian for words sharing the same gender.

To summarize the results of this experiment, we found language-specific effects of grammatical gender; gender affects the likelihood of producing a lexical error for Italian speakers, compared to the errors produced by English speakers naming exactly the same pictures. This language-specific effect of grammatical gender, however, survives only for words referring to animals once phonological similarity is taken into account. This result suggests that language-specific effects are constrained even in a linguistic encoding task such as picture naming.

Experiment 2

The results of the error induction task in Experiment 1 show that language-specific effects of grammatical gender can be observed in an on-line task requiring lexical retrieval. In this

second experiment we sought to obtain converging evidence using a very different task. Moreover, we assessed the generalizability of these effects beyond linguistic materials by performing the same experiment using pictures as well as words as stimuli. As in Experiment 1, we contrast responses from Italian speakers for words and pictures referring to animals and tools with responses from English speakers. In this experiment we used the triadic similarity judgment task. Speakers of Italian and English were presented with triplets of words or pictures (translation equivalents in Italian and English) and their task was to judge which two of the three were more similar in meaning. This task has been successfully used in previous studies investigating semantic organization and its impairments (Fisher, 1994; Garrard, Carroll, Vinson & Vigliocco, in press). Particularly relevant here are the following facts. First, because all possible combinations of triads of a relatively small set of items are presented to the participants, this task allows us to consider semantic similarity at a very fine-grained level. Second, this task has been shown to be sensitive to linguistic variables at the interface between meaning and syntax. For example, Fisher (1994) showed that English speakers' judgments reflected differences in the subcategorization requirements of semantically related verbs; Garrard et al (in press) showed that English speakers' judgments reflected the distinction between "count" and "mass" nouns for words referring to food items (for which the semantic divide between entities and substances is less obvious). Thus, if grammatical gender of Italian nouns exerts influence upon semantic similarity, we should observe language-specific effects in this task. If this effect extends beyond the use of linguistic materials we should observe it also with pictures.

Because all possible triads within a category are to be presented to the participants, and in order to maximize the opportunity of observing grammatical gender effects, which could be masked by extreme semantic diversity in the item set, all participants were presented with words from only one of two categories (land animals in Experiment 2a, and tools in Experiment 2b), reported separately below.

Experiment 2a: Animals

Method

Participants

Participants were 24 native speakers of Italian from the London community, and 24 native English speakers from the University College London participant pool. The Italian participants had only rudimentary knowledge of English, and none of the English speakers reported moderate or better competence in any Romance language.

Materials

Words (and corresponding pictures) referring to 20 animals were selected for the experiment. Words were translation equivalents in Italian and English. The words and the pictures used were a subset of those used in Experiment 1.

Triads for the Italian and English conditions were created by first assembling all possible three-word combinations of the 20 items in the experimental set (for a total of 1,140 triads). The order of words in each triad was randomized; then the order of triads was randomized across participants. A separate set of picture triads were then created by replacing each word with its corresponding picture (this set was identical for Italian and English participants). Twelve participants from each language were assigned to the word condition and twelve to the picture condition. In each modality (word or picture) and language (Italian or English) condition, the 1,140 triads were divided into three lists, each containing 380 triads of words or pictures.

Procedure

All participants were told that the experiment concerned participants' judgments of meaning similarity among groups of words (or pictures), and that their task was to choose the two words (or pictures) out of the three which were more similar in meaning and to delete the odd one out. Instructions emphasized that the decision was to be made on the basis of meaning and not other types of similarity between the items (e.g., phonological similarity among the words or visual similarity among the pictures). After completing the task, participants were asked to describe the strategies they may have used to perform the task, to list the easiest and most difficult decisions, etc. For the purpose of the present study, the most important aspect of these questions was whether any Italian participants mentioned grammatical gender as an overt basis for making their decisions.

Design and Analysis

The dependent variable was similarity ratio: the number of times that a given pair of words/pictures was selected as "similar", divided by the number of triads in which those two items appeared in the experiment. Four participants completed each list of 380 items; thus each triad (either words or pictures) was judged by four different speakers of a language. Results were analyzed using a three-way mixed ANOVA with item pairs as a random factor. Independent variables were language (English or Italian, manipulated within item pairs), modality (words or pictures, manipulated within item pairs) and Italian gender (same Italian gender; different Italian gender, manipulated between item pairs). As in Experiment 1 this latter factor refers to the gender of the Italian translation or label.

Results and Discussion

No Italian participant indicated that they used grammatical gender in their similarity judgments in the post-experimental questionnaire. Table 2 reports the average similarity proportions for items of same vs. different Italian gender as a functions of language and modality.

Table 2: Average similarity ratios in Experiment 2a (Standard errors in brackets)

Language	Modality	Grammatical Gender Same	Different
Italian	Words	.336 [.022]	.331 [.021]
	Pictures	.315 [.026]	.351 [.025]
English	Words	.311 [.026]	.354 [.025]
	Pictures	.315 [.025]	.351 [.024]

Results were analyzed using a three-way mixed ANOVA investigating the effect of language, modality and Italian gender on similarity proportions. Only the three-way interaction (Language x Modality x Gender) reached significance ($F(1,188)=6.539$, $p=.013$); no other main effects and interactions were significant (all Fs < 1). Analysis of simple interaction effects within each modality revealed that the similarity proportion for same-gender items was relatively higher for Italian word judgments than for English word judgments (with the corresponding difference in the opposite direction for words differing in Italian gender), while there was no such language difference for picture judgments by speakers of either language.

Thus, in this experiment we found language-specific effects of grammatical gender for words referring to animals, but not for pictures referring to the same animals; Italian speakers' judgments of meaning similarity seem to be affected by shared grammatical gender. Experiment 2b assessed whether such a gender effect is present for tools.

Experiment 2b: Tools

Method

Participants

Participants were 48 native speakers of Italian from the London community, and 48 native English speakers from the University College London participant pool. The Italian participants had only rudimentary knowledge of English, none of the English speakers reported moderate or better competence in any Romance language. None of them had participated in Experiment 2a.

Materials

Words (and corresponding pictures) referring to 24 tools were selected for the experiment. Words were translation equivalents in Italian and English. The words and the pictures used were a subset of those used in Experiment 1. Word and picture triads for the Italian and English conditions were created as in Experiment 2a. In this experiment all possible three-word combinations of the 24 items in the experimental set yielded a total of 2,024 triads. These triads were divided into six lists each containing 337 or 338 words or pictures. This experiment was otherwise the same as in Experiment 2a.

Results and Discussion

No Italian participant indicated that they used grammatical gender in their similarity judgments in the post-experimental questionnaire. Table 3 reports the average similarity proportions for items of same vs. different (Italian gender as a functions of language and modality.

Table 3: Average similarity ratios in Experiment 2b (Standard errors in brackets).

Language	Modality	Grammatical Gender Same	Different
Italian	Words	.318 [.018]	.348 [.017]
	Pictures	.314 [.020]	.352 [.019]
English	Words	.316 [.017]	.348 [.017]
	Pictures	.308 [.019]	.357 [.018]

Results were analyzed using a three-way mixed ANOVA investigating the effect of language, modality and Italian gender on similarity proportions. No main effects or interactions were significant (Fs < 1), with the exception of the main effect of gender which was marginal ($F(1,274) = 2.49$, $p = .115$). This indicates an underlying tendency for tools sharing Italian gender to be more similar than items with different Italian gender. Because no interaction between language and Italian gender was observed, this main effect cannot reflect language-specificity. Thus, whereas grammatical gender affected Italian speakers' judgments of meaning similarity for words referring to land animals, no such effect was observed for either words or pictures referring to tools.

General Discussion

In the experiments reported above, we explored language-specific effects of Italian grammatical gender on semantic representations for the corresponding objects. These experiments combined on-line and off-line methodologies, assessing effects for two different semantic fields: one for which associations between grammatical gender and sex can be plausibly built (animals) and one for which they cannot (tools). Moreover, we further explored gender effects within the same task, using both words and pictures as stimuli, in order to establish the generalizability of any effect.

We found that language-specific effects of Italian grammatical gender are present, but highly limited. They are limited to a semantic field (animals) in which entities have biological gender, and in which the gender of some nouns can depend on the sex of the referent. However, this effect does not extend to a field for which distinctions in grammatical gender have no conceptual foundation (tools). These effects are further limited to tasks that recruit linguistic knowledge (picture naming or similarity judgments for words, but not similarity judgments for pictures).

Our results suggest a far more limited role of grammatical gender on semantic representations than it has been suggested in previous studies. For example, Sera et al (2002) showed that grammatical gender of Spanish and French nouns influenced speakers' assignment of a male or female voice to inanimate (and animate) objects, regardless whether the task was carried out using words or pictures as stimuli. However, speakers might have used gender in a strategic manner in this task. Boroditsky, et al. (2003) report studies suggesting that grammatical gender may have implicit effects. However, these studies are reported without enough methodological detail to address possible reasons for the different results.

Our results suggest that these gender effects are linked to assigning male- or female-like semantic properties to referents in agreement with the gender of the nouns. They provide evidence for a very constrained version of the Sex and Gender hypothesis described in the introduction. According to this view, language-specific grammatical gender effects should be stronger for semantic fields in which there is a conceptual motivation for establishing a link between gender of words and sex of the referent (such as animals), than for fields for which there is not such a clear conceptual motivation (such as tools). This hypothesis also predicts that language-specific effects of gender on meaning should be stronger for languages such as Italian that have strong transparent links between gender of nouns and sex of referents (male entities strongly tend to have masculine gender, and female entities strongly tend to have feminine gender). Although the present experiments do not directly address this second prediction, some other evidence is relevant here. Vigliocco, Vinson, Indefrey, Levelt and Hellwig (2004) investigated gender effects on semantic substitution errors in German, in a study similar to Experiment 1. Although German has grammatical gender, in contrast to Italian it has three genders (masculine, feminine and neuter) and a less transparent correspondence between the gender of nouns and sex of referents. No effect of grammatical gender was found on semantic substitution errors for animals (at least when speakers were asked to produce bare nouns). These different lines of investigation converge in suggesting that language-specific effects of gender do not arise as a consequence of a general mechanism sensitive to similarity.

Finally, the difference we observe in Experiment 2 between word and picture stimuli suggests that grammatical gender of Italian nouns (referring to animals) affects "thinking for speaking", but does not affect conceptual representations when language is not required (Slobin, 1996).

Structural Bayesian Models of Conditionals

Momme von Sydow (momme.von-sydow@bio.uni-goettingen.de)
Department of Psychology, Georg-August-Universität Göttingen, Abt. 1, Goßlerstr. 14

Abstract

In the past decade the traditional falsificationist view of hypothesis-testing tasks, such as Wason's selection task, has become criticized from a Bayesian perspective. In this report a normative extension of Oaksford's and Chater's (1994, 1998) influential Bayesian theory is proposed, that not only takes quantitative but also qualitative (structural) knowledge into account. In an experiment it is shown that humans appear to be sensitive to both the quantitative and the qualitative preconditions of the proposed normative models.

Introduction

According to falsificationism only tests of hypotheses that may lead to a falsification are normatively justified (Popper, 1934/2002). In the psychology of thinking Wason's (1966) selection task (WST) has become the most studied single task to investigate the testing of hypothesis, typically a indicative conditional in the form of "if *p* then (always) *q*." In this task, four cards are presented. The visible front sides of these cards represent the logical cases *p, non-p, q, non-q*. It is known that one side of each card shows either a *p*- or *non-p*-case and the other side either a *q* or *non-q*-case. In order to test whether the hypothesis is true or false, participants should turn over those cards that are needed to test the hypothesis. To falsificationists, who have been predominant in psychology of reasoning for long, only the selection of a *p*-card *and* a *non-q*-card is correct.

Since over three decades studies have shown that humans do not act in a falsificatory manner (e.g., Johnson-Laird & Wason, 1970): most participants selected the *p*-card and the *q*-card and only 4% selected the 'correct' combination of a *p*- and a *non-q*-card. Since 96% gave wrong answers in this very basic logical task, this finding casts doubt on the rationality of the so-called *animal rationale/zoon echon logon* (Aristotle).

In psychology, theories have been developed which kept a falsificatory core, but which explained the selections by additional mechanisms (e. g. mental model theory). Also other theories flourished, which completely broke with the concept of normative rationality altogether (Cheng & Holyoak, 1985; Cosmides, 1989; Gigerenzer & Hug, 1992). In the last decade, however, probabilistic and Bayesian approaches to the WST have been also proposed (early proposals were e. g. Kirby, 1994; Oaksford & Chater, 1994; Evans & Over, 1996). The optimal data selection model of Oaksford and Chater (1994, 1996, 1998; Oaksford, Chater & Grainger, 1999) represents the most refined approach and has received most attention (e. g.: Evans & Over, 1996; Laming, 1996; Klauer, 1999; Oberauer, 2000; Osman et al., 2001). Hence, I am here going to focus on this approach.

Models

The model of hypothesis testing by Oaksford and Chater (1994, 1998), shown in Table 1, distinguishes a dependence sub-model M_D and an independence sub-model M_I, which represent the truth or falsity of the conditional. As in logics $P(p \wedge \neg q | M_D)$ is set as zero. Different to logics the other cells in this model are quantified. By comparing of M_D and M_I it can be seen (without the further modeling steps) that in such a model not only the falsificatory selections *p-/non-q*-card selections, but also *q*-card-selections may provide a certain *information gain*. However the *non-p*-card never becomes informative, since Oaksford & Chater (1994) set $P(p)$ and $P(non\text{-}p|q)$ to be equal in both sub-models, which in turn cause a flexible q-marginal probability.[1]

This setting of parameters has been criticized by Laming (1996) as post hoc data model fitting, designed to preclude the prediction of (actually infrequent) *non-p*-selections. Laming argued that these assumptions could not be justified, since one may equally construct a model with different parameters that appears completely weird (Table 3). Oaksford & Chater (1996, p. 386) defended their setting of parameters: "Psychologically it reflects the finding that participants regard false antecedent instances (i.e., the not-p cases) as irrelevant to the truth or falsity of a conditional rule." (Cf. recently similar ideas by Over, in press, and by Evans, Headley and Over, 2003)

von Sydow (2002) argued at length against this view and in favor of a different approach. Oaksford's and Chater's above argument, for example, is against the spirit of their own approach, since by this argument also *non-q*-card selections could have been excluded a priori. Inspired by Laming's criticism, I discussed and empirically examined a model in which the resulting marginal probabilities $w(p_{res})$ and $w(q_{res})$ are set to be constant in both sub-models (Table 2). This model is actually long known from the philosophical literature on the raven paradox, but von Sydow has combined it with the further calculations of the refined model of Oaksford and Chater (1998), stressing that this model has necessary preconditions to be fulfilled by the empirical situation. At about the same time similar proposals were made (Hattori, 2002) and even Oaksford &

[1] Oaksford and Chater (1994, 1998) modified the probabilities used in Table 1 according to the following formula: $q:=[P(q)-P(p)\ P(M_D)]/[1-P(p)\ P(M_D)]$. Both models were analyzed, the pure model without the modification of $P(q)$ (Model 1) and the model with the modification. The predictions of both models are similar and in this paper I focus on the pure model (cf. table 4).

Table 1: Model of Oaksford and Chater (1994, 1998).
P(p) and P*(q|1-p)* are set to be the same in both sub-models (cf. footnote 1).
Notes for Table 1 to 3: The cells show probabilities for the Dependence Model M_D and the Independence Model M_I. Resulting marginal probabilities, $P(p_{res})$ and $P(q_{res})$, can differ from *P(p)* and *P(q)*. '*p*', '*q*' in italics abbreviates *P(p)*, P*(q)*.

M_D	q	non-q	
p	*p*	*0*	*p*
non-p	*(1-p)q*	*(1-p)(1-q)*	*1-p*
	q+p-pq	*(1-p)(1-q)*	*1*

M_I	q	non-q	
p	*pq*	*p(1-q)*	*p*
non-p	*(1-p)q*	*(1-p)(1-q)*	*1-p*
	q	*1-q*	*1*

Table 2: Model of von Sydow (2002), Oaksford and Wakefield (2003). *P(p)* and P*(q)* are set to be constant. (Cf. Table 1)

M_D	q	non-q	
p	*p*	*0*	*p*
non-p	*q-p*	*1-q*	*1-p*
	q	*1-q*	*1*

M_I	q	non-q	
p	*pq*	*p(1-q)*	*p*
non-p	*(1-p)q*	*(1-p)(1-q)*	*1-p*
	q	*1-q*	*1*

Table 3: Model of Laming (1996). *P(q)* and P*(p|q)* are set to be constant. (Cf. Table 1)

M_D	q	non-q	
p	*pq*	*0*	*pq*
non-p	*(1-p)q*	*1-q*	*1-pq*
	q	*1-q*	*1*

M_I	q	non-q	
p	*pq*	*p(1-q)*	*p*
non-p	*(1-p)q*	*(1-p)(1-q)*	*1-p*
	q	*1-q*	*1*

Wakefield (2003) in a revision turned to this model.[2] However, in these other proposals it was never stressed that in principle *all* models could be normatively justified (also the original one of Oaksford & Chater, 1994). In contrast, von Sydow argued that all could be justified, provided that their (implicit) preconditions hold in the experimental situation. In three experiments von Sydow (2002) ensured that the preconditions of the model from Table 2 were fulfilled, by ensuring fixed marginal probabilities. The results showed the predicted increase of *non-p*- and *non-q*-selections in high base rate conditions.

The aim of this present paper is to directly investigate whether humans are actually sensitive to these *different* structural preconditions. Therefore the original model of Oaksford and Chater (1994, 1998)[1], the model of von Sydow (2002) and also the model of Laming (1996) were modeled along the same lines. In regard to further steps of modeling (Bayes' Theorem, Wiener-Shannon-Information and the resulting *expected information gain* measure) I completely followed Oaksford and Chater (1998).[3]

Here only an extract of the modeling results can be presented (see Table 4). *Expected information gain* (*EIg*) values are shown for the different models for the parameter values used in the experiment (low base rate: *P(p)=.10, P(q)=.20, P(H$_D$)=.50*, high base rate *P(p)=.80, P(q)=.90, P(H$_D$)=.50*). Additionally also the normative predictions for the estimates of the marginal probabilities are shown. (The predictions are also mentioned in the results section.)

Table 4: Expected information gain and standardized expected information gain (with an error parameter) for card selections in different structural models (for low, *.10→.20,* and high base rates, *.80→90).* Resulting marginal probabilities $P(p_{res}|M_D)$, $P(q_{res}|M_D)$, $P(p_{res}|M_I)$, $P(q_{res}|M_I)$.[1]

[2] Oaksford, Chater & Larkin (2000) had distinguished a similar model of reasoning from their model of hypothesis testing. The revision has been announced – without any reasons and without own data – in an overview article (Oaksford & Chater 2001, p. 353), which can not count as a full revision of their model.

[3] For alternative proposals cf. Laming (1996), Klauer (1999), and Chater & Oaksford (1999).

Method

Design and Participants The experiment had a 2 (low versus high base rate condition) × 3 (the three structural models) between-subjects design.

Seventy-two participants from the University of Göttingen took part in the experiment. The participants were randomly assigned to the six experimental conditions.

Materials and Procedure. Each participant was presented with what I call a 'Many Cards Selection Task' (MST) with many depicted cards (instead of four cards in a WST) in a paper and pencil version.

In all conditions the same cover story was used. Participants were asked to suppose that they were physicians at a university hospital. Their task was to find out whether the following hypothesis was true or false: "If a patient is infected by the Virus Adenophage (A), then he always shows the symptom Thoraxpneu (●)" This hypothesis was set in bold print. In order to set the parameter $P(M_D)$ in all models *to 0.5* the participants were told that it is equally likely, that the hypothesis is true or that there is no correlation between the virus and the symptom at all. The participants were told, that the head nurse is in charge of all the patient files, in the form of 100 patient cards. Each patient card on the front side provides information about tested viruses and on the backside information about symptoms.

The cards were then shown to the participants. First the head nurse laid out the front sides of the cards, showing whether a patient had the specific virus (A) or not (-). Then she quickly takes up the cards. Thereby the cards are completely mixed (bold print). Secondly she then laid out the backsides of the cards, showing whether a patient has shown the specific symptom (●) or not (O).

Depending on the experimental condition it varies which cards are shown. The proportion of cards *p*- versus *non-p*-cards and *q*- versus *non-q*-cards resulted from how the parameters were set (low base rate: $P(p)=0.1$, $P(q)=0.2$, high base rate condition $P(p)=0.8$, $P(q)=0.9$).

In the structural condition with constant marginal probabilities (von Sydow; 2002) $P(p|H_D)=P(p|H_I)$ and $P(q|H_D)=P(q|H_I)$ were induced by showing *all* fronts and backs of the cards (after mixing them in between). For the Oaksford and Chater (1994)-model, with $P(p|H_D)=P(p|H_I)$ and $P(q|non\text{-}p \mid H_D)=P(q|non\text{-}p|\ H_I)$, also all cards were first shown with the virus-side facing upwards ($P(p|H_x)$). But after mixing, the symptom-sides only of those patients were shown who had no virus ($P(q|non\text{-}p \mid H_x)$). Thereby I directly provided information on $P(\neg p \wedge q)$ and $P(\neg p \wedge \neg q)$, which should remain constant in this model. No direct information was provided of the *q-/non-p*-marginal probabilities, which are not constant in this model. Similarly, in the Laming (1996)-condition, with $P(q|H_D)=P(q|H_I)$ and $P(p|q \mid H_D)=P(p|q \mid H_I)$, all cards were first shown now with the symptom-side visible. After mixing, the virus-sides of the cards only of those patients were shown, who have had the specific symptom. Thereby I directly provided information on $P(p \wedge q)$ and $P(\neg p \wedge q)$, which are constant in that model and no direct information on the *p*- and *non-p*-marginal probabilities.

All participants were then instructed that the head nurse was not willing to turn over many cards separately. She would only allow *one* card to be turned over on its own. Participants were asked, what card they would select to test their hypothesis. Firstly the participants should suppose the head nurse had put two patient cards in front of them, one of a patient with the virus (A) and one card of a patient without the virus (-) (*p*-card, *non-p*-card).[4] Secondly they should instead suppose a situation in which two patient cards were placed before them, one of a patient with the symptom (●), one of a patient without the symptom (O) (*q*-card, *non-q*-card). In both cases they had to choose which card they would turn over.

Finally, four questions were used (in a frequency format), to survey the participant's estimation of the marginal probabilities resulting in each model, that is: $P(p_{res}|H_D)$, $P(q_{res}|H_D)$, $P(p_{res}|H_I)$, $P(q_{res}|H_I)$. The participants were asked how many of all 100 patients would have the Virus A and how many of all 100 patients would have Symptom T, assuming that the hypothesis is true or false.

Results and Discussion

First the card selections are described, then the estimations of the marginal probabilities.

Card selections

Table 5: Percentages and number of selections of the *p*- and *non-p*-cards and *q*- and *non-q*-cards. (N=72)

	Structural Models					
	Sydow		Oaksford		Laming	
	low	high	low	high	low	high
p	92%, 11	25% 3	83% 10	83% 10	83% 10	58% 7
non-p	8% 1	75% 9	17% 2	17% 2	17% 2	42% 5
q	75% 9	25% 3	58% 7	17% 2	42% 5	45% 5
non-q	25% 3	75% 9	42% 5	83% 10	58% 7	55% 6

[4] The original WST with its four cards may be interpreted as a sequential task, in which the first selection may influence the second, or in which even a planned second selection may influence the first. This would not be modeled by the general approach of Oaksford & Chater (1994). Such effects are minimized by this forced choice design. (Cf. also Klauer 1999.)

Moreover, this design is a severe test of the predicted increase of *non-q*- and *non-p*-card selections: not only the relevance of these cards, but their relative predominance is tested against the normally common *p*-card and *q*-card selections.

von Sydow (2002)-Model For this model a rise in the proportion of *non-q*-selections and *non-p*-selection was predicted for the high base rate condition. The descriptive results are shown in Table 5 and visualized in Figure 1.

Both differences were statistically significant, the *q-/non-q*-effect (Pearson: χ^2 *(1, n=24)=6.0*, one-tailed, *df=1; p<.01*) as well as the *p-/non-p*-effect (Pearson: χ^2*(1, n=24) =10.9*, one-tailed, *p<.001*). The parameters in this experiment were chosen that for this model *EIg(non-q|high)= EIg(q|low)* and *EIg(non-p|high)= EIg(p| low)*. The results of the *q-/non-q*-effect are indeed perfectly symmetrical, the *p-/non-p*-effect descriptively only shows a small *p*-bias. *Within* the high base rate condition more *non-p* than *p* and more *non-q* than *q*-selections were predicted. These cards even became predominant in a statistically significant way (both: χ^2 *(1, n=12)=3.0*, one-tailed, *p<.05*).

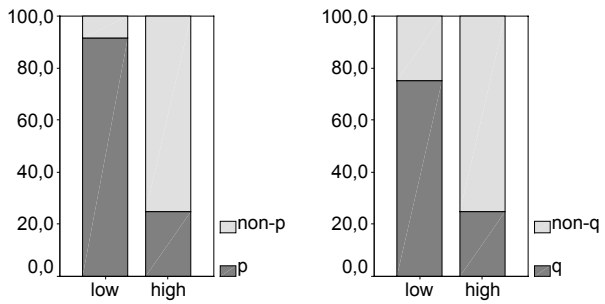

Figure 1: von Sydow-Model: (a) Proportion of *p-/non-p*-card selections and (b) proportion of *q-/non-q*-card selections in high and low base rate conditions.

Oaksford and Chater (1994)-Model This model similarly predicts an increase of *non-q-card* selections in the high base rate condition, but it does not predict an increase of *non-p*-card selections. The results are visualized in Figure 2.

For the *p-/non-p*-cards there was indeed no difference between the low and high base rate condition (Fisher-Yates test (*1, n=24*, one-tailed): *p=0.70*). As also hypothesized, the frequency of *non-q*-card selections was significantly higher in the high base rate condition than in the low base rate condition (Fisher-Yates test (*1, n=24,* one-tailed): *p<.05*). Even the perhaps surprising high rate of *non-q*-card selections in the low base rate condition appears reasonable with regard to the *EIG* and *SEIg* values (cf. Table 4).

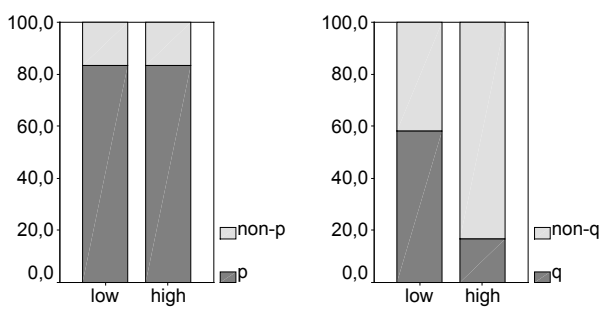

Figure 2: Oaksford-Chater-Model: Proportion of selections.

Laming (1996)-Model Although Laming's proposal was originally only thought as an absurd example, it was modeled and the prediction of a constantly high *non-q*-card selection and a *p-/non-p*-effect was derived.

As expected, no *q-/non-q*-effect was found (Fisher-Yates test (*1, n=23,* one-tailed): *p=.58*). But in difference to the predictions the *p-/non-p*-effect was not significant (Fisher-Yates test (*1, n=24,* one-tailed): *p=.18*). However, even here the results descriptively point in the predicted direction and in the high base rate condition over 40% preferred a *non-p*-card (figure 4).

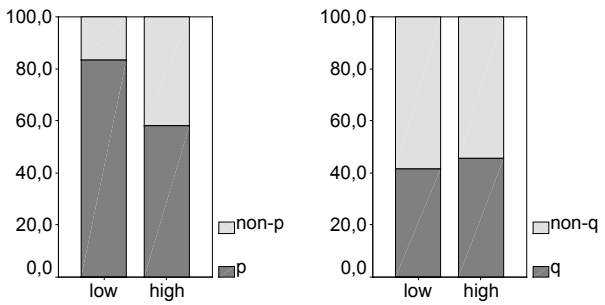

Figure 3: Laming-Model: Proportion of selections.

In summary, the card selections were clearly confirmative for both the von Sydow-model and the Oaksford-Chater-model, and they at least pointed in the predicted direction for the Laming-model.

Estimates of marginal probabilities Participants' estimates of the resulting marginal probabilities was a second depended variable to assess whether the participants fully understood the implications of the induced models.

Only an abridged analysis of these data can be given here. In Table 5 the means and modes of the subjective estimates of the marginal probabilities $P(p_{res})$ and $P(q_{res})$ are shown, if the participants had to assume the rule to be true or false.

An analysis of the data shows that the means are not the appropriate measures to assess the differences between the conditions, since in some cases *two* types of answers clearly predominated. Hence Table 5 also shows the modes (two modes are shown when both have the same frequency or when their frequency differed only by one). It was tested whether the number of cases represented by each mode of the estimations (or by the two modes) is predominant relatively to all other cases not matching that mode(s). This was tested for significance with a Chi^2-test *(df=1, one-tailed, 12≥N≥9).* (For Results cf. Table 5.)

In the von Sydow-Model the modes were all normative. Each mode had a frequency of over 70%. The χ^2-tests showed, that the number of estimations matching the modes was in all but one case significantly higher than all other estimations taken together (Table 5).

In the Oaksford-Chater-Model and in the Laming-Model a relevant number, but not all, of estimations confirmed the predictions. But it will be shown that the deviations also showed an interesting inner consistence.

Table 5: Estimates of the resulting marginal probabilities given the truth (M_D) or falsity (M_I) of the hypothesis. For each model the following values are shown: normative answers for $P(p_{res})$, then for $P(q_{res})$, means of these answers, modes. A mode (or two taken together) got an asterisk (*), if their predominance was also statistically significant. (They also always united over 75% of the answers.)

$P(p_{res})$ $P(q_{res})$		Sydow			Oaksford			Laming		
		Normative	Mean	Mode	Normative	Mean	Mode	Normative	Mean	Mode
Low base rate	M_D	10 20	10 18	10* 20*	10 28	10 19	10* 28;10*	2 20	13 17	2; 20* 20*
	M_I	10 20	10 19	10* 20*	10 20	10 18	10* 18*	10 20	5 19	2* 20*
High base rate	M_D	80 90	73 79	80* 90*	80 98	77 81	80* 98,80*	72 90	76 84	72;90* 90*
	M_I	80 90	76 85	80[5] 90*	80 90	73 58	80* 90; 50	80 90	67 77	72 90*

In both models the results clearly and significantly confirmed the predictions in regard to the constant marginal probabilities, that is in regard to $P(p_{res})$ in the Oaksford-Chater-Model and in regard to $P(q_{res})$ in the Laming-Model). In each of these four cases there was only one mode, which in number outweighed all other predictions significantly. Also as predicted, a change of modes (between M_D and M_I) was found in the Oaksford-Chater-Model in regard to $P(q_{res})$, and conversely in the Laming-Model in regard to $P(p_{res})$. But opposed to the predictions in both models two modes were found, given the hypothesis is assumed to be true. The two modes taken together significantly outweighed all other predictions in all four cases. In all these cases – independent of a high or a low base rate – one of the two modes exactly was the predicted one. The other mode in all cases was consistent with an equivalence interpretation of the hypothesis. In the Oaksford-Chater-Model this second mode of $P(q_{res}|M_D)$ matched the correct estimations of $P(p_{res}|M_D)$. Conversely in the Laming-Model the second mode of $P(p_{res}|M_D)$ exactly matched $P(q_{res}|M_D)$. Hence in both models one set of answers exactly shows the expected changes between M_D and M_I. Another set of answers is consistent with an interpretation of the hypothesis not as implication, but as equivalence. (Based on the low *N* no further analysis of this additional effect was possible.)

In summary, also the results for the estimations show that participants distinguished the tested models. The results for the von Sydow-model were unambiguously positive. In the Oaksford-Chater-Model and the Laming-model a substantial number of answers fully confirmed the predictions. In these models a second group, however, was consistent with an interpretation of the rule as equivalence. Interestingly, the ambiguity of the interpretation of the hypothesis appears to be a function of the induced model.

[5] Also here 70 % (of 11 answers) matched the mode.

General Discussion and Conclusion

The empirical results provide evidence that humans are sensitive both to the structural as well as to the quantitative aspects of the tested Bayesian models.

The card selections largely confirmed the predicted differential effects of structural models and of the card frequencies. Estimates of the resulting marginal probability provide evidence that at least a substantial part of the participants also understood these implications of the models.

Implications for Non-Bayesian Approaches

Approaches that are normatively based on basic formal logics (excluding e. g. fuzzy logics) and its falsificationist interpretation have clear normative predictions in all conditions of the experiment. In each and every case one equally ought to select the *p*- and the *non-q*-card, since these are the only cards by which a (conclusive) falsification could be achieved. The main traditional psychological theories of conditionals, the mental logics theory and the mental model theory (cf. Johnson-Laird & Byrne, 2002) are normatively still tightly linked to the falsificationist research program. But also with their additional psychological assumptions these theories cannot explain the particular pattern of probabilistic results found in this experiment.

Likewise the psychological theories which even break with any concept of normativity, such as the original pragmatic reasoning theory (Cheng & Holyoak, 1985) or the evolutionary social contract theory (Cosmides, 1989; Gigerenzer & Hug, 1992) cannot explain the fit of data to these normative models of reasoning.

The normative models as well as the empirical results of the experiment at least show the incompleteness of all these theories. This has to be said in such a cautious manner, since one has to concede that Bayesian models have not yet explained all the effects predicted by all these quite different theories either.

Implications for Bayesian Approaches

On the one hand the results of the present work show that the discussed Bayesian approaches of hypothesis testing (of single conditionals) need to be extended by a structural component, which determines what parameters are constant in that models.[6] On the other hand this extension (norma-

[6] The structural component proposed in this paper may be regarded as the *microstructure* of a conditional, which perhaps complements the effects of *macrostructure* already discussed in the context of causal Bayes-nets (cf. Waldmann & Hagmayer, 2001)

tively as well as empirically) strongly confirms the general approach of exactly these extended Bayesian models.

Working with a MST and by clearly fixing the preconditions, the results, not only of the model von Sydow (2002), Hattori (2002) and Oaksford & Wakefield (2003) *but also* the original model of Oaksford & Chater (1994, 1998, similarly now Over, in press, Evans et al., 2003) could be supported. (The evaluation of the model of Laming remained ambivalent.) Moreover the objection of Laming (1996) that the assumptions of the discussed basic models are licentious, which in principle affects all models, has been ruled out by introducing experimentally exactly the preconditions of these models.

But these largely confirmative results also show the necessity to extend Bayesian models discussed by the structural aspect examined. From this it results that it is false, both normatively and empirically, to assume that only *one* universal Bayesian model could and should fit all data. Also those authors who have adopted a probabilistic or Bayesian account, mostly still seek a universal model for hypothesis testing or reasoning with conditionals (e. g. Oaksford & Chater, 1994, 1998; also Oaksford & Wakefield, 2003; and even Evans et al., 2003 and Over, in press). Instead the results of my experiment show that additional hidden preconditions need to be taken into account. In this regard I do follow early writings of Evans & Over (1996), which stressed that there is no universal technical measure of uncertainty reduction. On the other hand, in my opinion, only the more sophisticated models in the tradition of Oaksford & Chater do allow a detailed investigation of the phenomena in question. This paper could be seen as contribution towards a synthesis of these positions.

On the larger scale such a synthesis would sustain normative necessity, as the logicistic research program also has done. Nevertheless it allows for a plurality of preconditions, which has been stressed by domain specific accounts. Whether *domain-specific normative Bayesian models* may serve as a more general research program can only be found out by further theoretical analysis and empirical investigation.

Acknowledgments

I am grateful to York Hagmayer, Michael Waldmann and Björn Meder for useful comments on the experiment and on earlier versions of this paper. I also would like to thank Nick Chater and two anonymous reviewers for their helpful comments.

Abstract

Interruptions are often seen as distracting or sometimes devastating elements that need to be minimized or eliminated. However, interruptions are also used to increase efficiency, productivity, prevent errors, and even influence behavior. Existing theories and taxonomies of interruptions fail to account for the helpful aspects of interruptions. Therefore we propose a theoretical framework to help explain the positive aspects of interruptions. Warnings & alerts, reminders, suggestions and notifications are examples of interruptions that have beneficial outcomes by changing and influencing behavior. We propose a cognitive theory of interruptions based on the properties of the users, their tasks, and best presentations depending on the desired effectiveness of the interruption. Norman's 7-stage action model serves to explain how and why an interruption is accepted, and potential mismatches between the goal of the interruption and the user. Potential applications of this model include better understanding the effects of interruptions, and guidance to design effective and persuasive warnings and alerts, reminders, suggestions and notifications.

Introduction

Interruption has been an active area in human-computer interaction research for some time. A comprehensive review was provided by McFarlane and Latorella (2002). Interruptions are typically defined as a change or disturbance in a process or in people's activities.(Cooper & Franks, 1993; McFarlane & Latorella, 2002) Interruptions are categorized along different dimensions by different researchers, such as source, effect, content, applicability, and duration by Cooper & Franks (1993) and individual properties, methods, meaning, source, channel, change, and effect by McFarlane and Latorella (2002).

Significant research has been expelled in determining how to classify, prevent, minimize, and provide tools to help users deal with interruptions. However, there is little understanding how interruptions can be exploited for positive outcomes, while at the same time minimizing some of their most disruptive properties. After all, interruptions are constantly used to help manage and complete important everyday tasks. Such interruptions also have the ability to influence and change behavior. In order to better understand and explain how interruptions can be engineered to be positive and persuasive we propose a theoretical framework and conceptualization. The theoretical framework may also guide designers on discovering factors to help develop appropriate interruptions.

Effects of Interruptions

Detrimental Effects of Interruptions

The effects of interruptions are generally described as negative Users perceive an interrupted task as being more difficult to complete than an uninterrupted task (Bailey, Konstan, & Carlis, 2000). An interruption is also thought to take longer to process and return back to task when it is unrelated to the task at hand (Cutrell, Czerwinski, & Horvitz, 2001). The added memory load seems to make it difficult for a task to be resumed. It also becomes difficult to remember what task was being processed before the interruption. (Burmistrov & Leonova, 1996; Dix, Ramduny, & Wilkinson, 1995). Further, the complexity of the task being interrupted effects the disruptiveness of an interruption. Interrupting complex tasks inhibits performance, and has no effect on simpler tasks (Burmistrov & Leonova, 1996). Interestingly, people can recall details about interrupted tasks better than uninterrupted tasks.(McFarlane & Latorella, 2002)

People also have individual differences in their ability to respond and manage interruptions (McFarlane & Latorella, 2002). Interruptions also affect performance. Users are thought in general to perform slower on interrupted tasks (Bailey et al., 2000), although some evidence exist that an interruption may actually speed up task completion (Zijlstra,

Roe, Leonara, & Krediet, 1999). However, the actual effect of an interruption will likely depend on the actual tasks being performed, and the interruption itself. There is conflicting evidence if similarity between the interrupted and interrupting tasks has any effect on performance (Bailey et al., 2000; Gillie & Broadbent, 1989).

Timing of interruptions may also have an effect. Interruptions coming early during a search task are described as likely to result in the user forgetting the primary task goal than an interruption arriving later on (Cutrell et al., 2001). The presentation of the interruption are also important. For example aurally presented interruptions are thought to be acknowledged more quickly than visual stimuli. Auditory ongoing tasks are more resistant to interruptions than visual ones (Latorella, 1996) Thermal interruptions have larger detrimental effect than light on disruptiveness and performance (Arroyo, Selker, & Stouffs, 2002). Motion as a notification system is effective compared with static items (Bartram, Ware, & Calvert, 2001). Traveling motions as a visual stimuli are more disruptive than anchored motions (Bartram et al., 2001)

Therefore much effort has been expended to determine the negative effects of various interruptions and their modalities. However there are also different perspectives from which the effects of interruptions may be viewed. Indeed an interruption may be devastating to the task in progress. But when looking at the individual performing various tasks, the interruption may not have a detrimental impact on the whole. Most research has focused on the task level, which may be an inappropriate level of analysis in some cases.

Beneficial Effects of Interruptions

Types of interruptions that may serve beneficial purposes include warnings and alerts, reminders, notifications and suggestions. Of course warnings and alerts etc., may not always be interruptions. We define a warning and alert etc. as an interruption when it causes a change or disturbance in a person's activity or behavior. Table 1 summarizes the characteristics of these interruptions. We provide examples in a healthcare context, although these types of interruptions would also exist in other domains. Our examples are also technologically focused and include persuasive interruptions embedded into computer systems, mobile devices, and medical equipment which are increasingly being used in healthcare.

Warnings & Alerts are usually a sign or signal of something negative occurring, or a notice to be careful. They are intended to make people aware of an impending danger or difficulty. For example, drug interaction warnings embedded into drug prescribing systems warn doctors and pharmacists about dangerous drug-drug interactions when prescribing or filling a prescription. These warnings are designed to interrupt the current task, and alert the clinician to a potential adverse event. Although such warnings may be critical in preventing errors, it is found that in practice such warnings are often ignored or overridden (Wilson, 2003), suggesting the need for better designed warnings. Hospitals are increasingly 'buzzing' with auditory alerts from a variety of medical equipment (Meredith & Edworthy, 1995). The purpose of such devices are to monitor patients and alert physicians or nurses when they need to take action. However, there is rarely any synchronization or awareness between the large number of standalone medical equipment emanating various alerts and tones; resulting in many ignored warnings.

Warnings and alerts are often urgent and need to be handled quickly. Warnings and alerts may either have an explicit or implicit action associated with them. For example a drug interaction warning may indicate explicitly that there is a potential interaction with a drug and provide a list of medications that may be suitable replacements. An audible alert may be more implicit, simply indicating an off nominal state, without providing any explicit instructions or actions.

Reminders are a form of interruption that cause an individual to remember or recall an event. Clinical decision support systems often remind physicians of standard tests or procedures that conform to clinical practice guidelines. (Bates et al., 2003) Such reminders are deemed important as they provide a mechanism to foster uniformity in treatment and to assist in managing the burgeoning costs of healthcare. These reminders often occur while the physicians is documenting or ordering the tests and procedures. Medication reminders may also assist patients in adhering and complying with their medication regimens (Bennett & Glasziou, 2003). Although the urgency or importance of reminders may vary, many will include an explicit associated action. For example a medication reminder may announce the time, dose and route for the drug.

Suggestions are ideas or proposals that are propagated to individuals. Patients often receive suggestions and recommendations from their care-givers. For example diabetics are urged to exercise more and eat healthier. Physicians may be informed that their patient may be eligible for a particular clinical trial. Pharmaceutical companies also engage in suggestive practices to prescribers when they promote their particular brand of medication. Such suggestive interruptions can be from face-to-face encounters with a pharmaceutical sales representative or through the use of sponsored drug reference databases. Suggestions are unlikely to be of high urgency or importance. But effective suggestions may explicitly state associated actions that are recommended.

Notifications are usually described as the process of informing. Notifications are defined as the most generic type of interruption, with the least degree of importance or urgency. A notification may purely be informational in purpose with no explicit instruction for action. For example

a notice stating the availability of a patient's lab results informs a physician that their requested order is ready. However, notifications may lead to actions implicitly without specific instructions. For example the lab test may indicate that a particular patient needs an immediate surgical procedure. Therefore notifications may lead to implicit actions.

Table 1: Beneficial Interruptions and their Characteristics

Interruption Type	Importance / Urgency	Action
Warnings & Alerts	High	Implicit or Explicit
Reminders	High-Low	Explicit
Suggestions	Medium – Low	Explicit
Notifications	Low	Implicit

Persuasive Interruptions

Fogg (1998) suggests computers and technology can be persuasive (change attitudes or behavior) as tools, social actors and/or media. We suggest that technology-based interruptions can be designed so they too can influence behavior and attitudes in order to achieve positive outcomes. In fact beneficial interruptions described earlier as warnings and alerts, reminders and suggestions disrupt a person's current task, and may cause them to change their behavior. Of course not all positive interruptions need to change or influence behavior. The persuasiveness of interruptions may be directly linked to the interruption type and their corresponding importance to deliver a particular message. For example warnings may be high in importance, and need to influence a change in behavior immediately and therefore very persuasive. While a notification, which is just informational in content, may not influence behavior and therefore may not be particularly persuasive.

Theoretical Framework

We propose a theoretical framework for interruptions (figure 1) to help explain the different dimensions that are involved in making an interruption persuasive and beneficial. Table 2 shows the details of the framework in a form of taxonomy.

User Properties

Individuals or users that are affected by interruptions are likely to have unique characteristics and properties. Therefore it is important to identify key features that may impact the effectiveness of interruptions and how they respond and deal with them. For example a physician has different characteristics than a nurse. A challenge in producing effective interruption are to deliver them when most opportune and least detrimental. Therefore a users location, environment, time of day (or week or year), or schedule (in Outlook for example) may be exploited to establish if they can be interrupted. Horvitz et al have explored the use of subtle clues in design of attentive user interfaces to discover the attention of users combined with user preferences in design of notification platform to intelligently route messages (Horvitz, 1999).

Task Properties

In addition to determining user characteristics, it is also important to determine properties of the interrupted and interrupting tasks. Certain tasks may be particularly susceptible to the detrimental effects of interruptions. However, determining a user's current task is challenging. Computer based tasks may be more amenable to discovering current task or workload. But in more complex, dynamic or distributed domains, it is likely that the users will interact with a multitude of (unlinked) devices including phones, pagers, PDA's, among others.

Various methods to determine user interrupt-ability have been explored. Instant messaging applications allow users to indicate their current availability. Alternatively, task complexity may be automatically measured. The number and type of applications the user has open, or number of key strokes, or mouse clicks within a certain time period may indicate the user's workload. The user's contextual information may also be exploited, such as time of day or week. A user may conduct certain tasks at certain times of a week. However, many users do not follow a rigid schedule and may elect to make changes. Another approach has been to discover "activity awareness" between groups which take into account situational, group, task and tool factors and subsequently provide a notification system to indicate availability. (Carroll, Neale, Isenhour, Rosson, & McCrickard, 2003) However, further work is needed to discover how best to determine current task properties in order to present an interruption at the most optimal time.

Presentation

In addition to user and task properties, the presentation of an interruption may be critical. The presentation of an interruption involves two stages. First, the interruption must alert the user of its presence. Heat, light, sound, vibration, and motion may capture attention differently with different efficiencies. Second, a message representation must be delivered. Analysis of the user, task and priority of the interruption context will help determine the appropriate mode of interruption. The presentation may also differ depending on type of interruption and on the device used to interrupt. A visual pop-up may effectively capture a users attention while using a computer, but may be ineffective on a cell phone stowed in coat pocket.

In addition to being effective and minimally disruptive, the message of the interruption can also be engineered to be persuasive. In a multi-tasked environment, users are presented with a multitude of interruptions and are constantly deciding whether to act upon the interruption. If

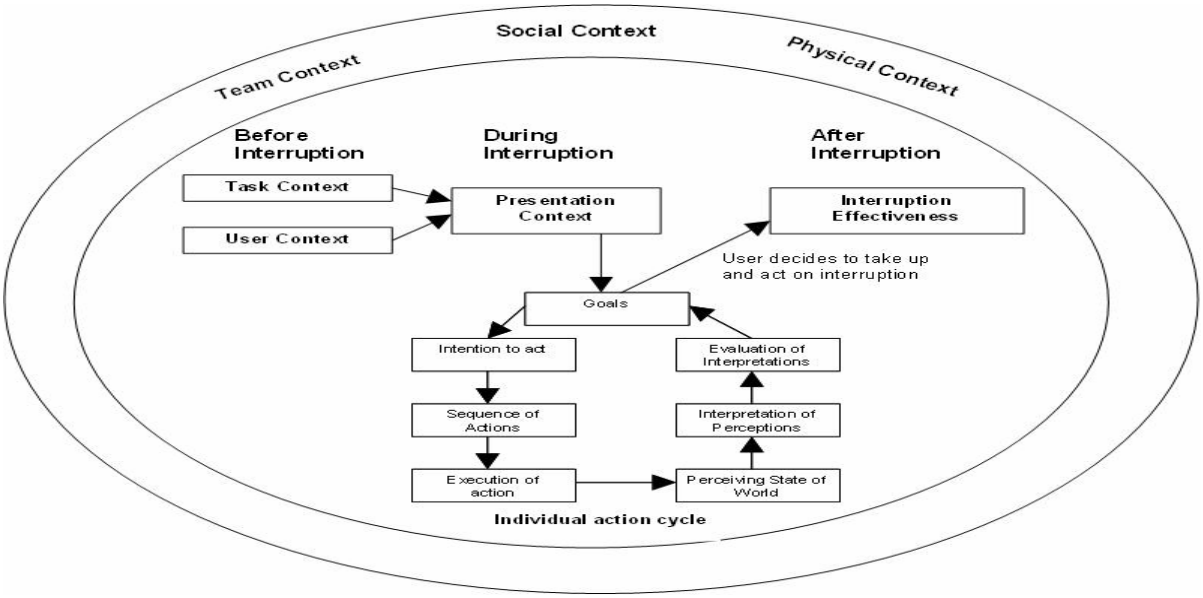

Figure 1: Cognitive theory of persuasive interruptions

different interruptions (such as a warning or notification) are presented with the same degree of persuasiveness they may be handled in the same manner. However, persuasive elements such as positive reinforcement, personalization, and social cues amongst others can also be used to enhance the persuasiveness of an interruption when appropriate. Currently there is little research on how modifying the persuasiveness of a message of an interruption effects its acceptance.

Individual Action Cycle

Norman's 7-stage action model has been incorporated into the cognitive theory in order to help explain at the individual action level why an interruption is accepted and acted upon (Norman, 1988). The seven stages are divided into three categories, one for goals, 3 for stages of executions and 3 for evaluation. The goal stage may be particularly important because an individual's perceptions or intentions may need to be related to intention of the interruption itself as personified by its presentation. The stages of execution are also useful in determining if the suggested interruption can be acted upon. The evaluation stage where the individual perceives the state of the world after executing an action may also assist in determining the success of an interruption. Therefore the 7-stage action model provides a useful perspective in helping to explain how modifying the presentation of an interruption impacts discrete stages of individual action.

Interruption Effectiveness

The effectiveness of an interruption will largely depend upon the original goal and perspective used. A drug interaction warning that interrupts a physician while inputting order entry may be effective if it results in a change of medication; as it may avoid a hospitalization for the patient. However, it may also cause the physician to lose focus and forget the original task. Therefore it is important to clarify the perspective from which effectiveness is judged. In our model we propose cognitive, perceived value and performance based measures to evaluate and engineer interruptions once the perspective has been defined. Cognitive factors may include loss of memory or disruptiveness of interruptions. Perceived value factors such as annoyance and anxiety are often associated with interruptions. Interruptions affect performance, by changing time to complete tasks, providing opportunities for errors, and forgetting to resume previous tasks.

Similarly they may effect financial performance or result in a more favorable outcome (such as prevention of hospitalization) In our model, information from the context of the user, tasks and presentation can be exploited in order to find an optimal balance between cognitive, perceived value and performance measures depending on the perspective and desired outcomes.

Assessing Context

The surrounding conditions or circumstances that make up the environment around an individual may provide important information in order to successfully deliver an interruption. The dynamics of interruptions in team environments are different than those of single individuals. In team environments, a team member can intercept an interrupting activity for another team member who is already engaged in a previous task. An audible interruption targeted to one team member may interrupt the work of colleagues nearby. Or an interruption for one individual may result in a cascade of interruptions for others.

Table 2: Taxonomy of Persuasive Interruptions

		Examples
User Properties	Individual characteristics of users, their contextual situations and preferences	
Context	Where is the individual? Where can an individual be interrupted? Is an interruption more appropriate at a certain location or time	Hospital, Emergency Room (ER), Attending to critical patient, etc.
Characteristics	What are the individual characteristics of users? What are their strengths and limitations?	Expertise, skills, knowledgebase, age, education, cognitive capacities and limitation
Task Properties	The properties of the interruption itself and the task it will interrupt	
Interruption Type	What is the intent of the interruption?	Warning, alert, reminder, suggestion or notification
Interrupted Task Type	What task will be interrupted?	Work related (computer based, meeting etc.), Social (lunch, sleep etc.)
Task Interrupt Scale	How important is the task to be interrupted?	Low, Medium, High
Stage of Interruption	What is the stage of the current task?	Goals, Intention to Act, Sequence of actions, Execution of action sequence, Perceiving state of the world, Interpreting the perception, Evaluation of interpretations
Broadcast or Single Interruption	Is the interruption in the context of team or collaborative environment, or individual environment?	Individual, small team, large team, etc.
Presentation	Factors addressing how the interruption can be presented to the user	
Customization	To what degree is the presentation customized?	Generic, Personalized, Targeted or Tailored
Mode of Interruption	How will the user be alerted of the presence of the interruption?	Heat, lights, sound, vibration, and motion
Display type	How will the message be communicated?	Prompt, pop-up, voice alert
Device	What device will be used to convey the message of the interruption	Personal Computer (PC), Personal Digital Assistant (PDA), Telephone, Cell phone, Pager
Persuasive elements	What types of persuasive techniques are incorporated into the interruption?	Media, Tool, Social Actor, Positive reinforcement, personalization, credibility etc.
Interruption frequency	How often will the interruption be presented?	Once only, more than once, every hour etc.
Resumption method	How will the individual be assisted to resume their original task?	Log of previous tasks, reminder of previous task, screenshot of previous state etc.
Interruption Effectiveness	Assessing the effectiveness of the interruption	
Perspective	Who is the intended beneficiary of the interruption? What is the net benefit?	Physician being interrupted, Patient, Healthcare system
Cognitive	What is the cognitive impact of the interruption on the individual?	Loss of memory, disruptiveness, number of errors
Perceived value	What are the individual perceptions of the interruption?	Annoyance, anxiety, interest, boredom, curiosity
Performance	How does the interruption effect the performance of the interrupted task? To what degree is the task associated with the interruption completed?	Completion of tasks, time to complete task, number of errors, dollars saved

Benefits of Persuasive Interruption Model

Other models of interruptions have been developed in an attempt to eliminate, minimize or manage the detrimental effects of interruptions. However, these models fail to describe the positive effects of interruptions. Latorella's (1996) Stage Model of interruption management is a detailed description of how people may manage an interruption and how it effects a current task in terms of detection, distraction, disturbance and disruption. The model of persuasive interruptions is more concerned with dimensions of the user, task and presentation properties and how that influences the effectiveness of the interruption. We suggest Norman's 7-stage action model can explain how and why an individual receives an interruption. McFarlane

(2002) has also proposed a taxonomy of human interruptions that includes elements such as source, individual characteristics, method of coordination etc. Our model incorporates features of McFarlane's taxonomy but is more operationalized and detailed. For example McFarlane suggests looking at the individual characteristics of users, while we expand this view to also consider other relevant contextual features, such as time, location and environment.

Conclusion

In this work we identify and discuss four types of beneficial interruptions: warnings and alerts, reminders, suggestions and notifications. We then propose a theoretical framework and taxonomy in order lay the foundation to develop guidelines for persuasive interruption design.

Future work will improve the framework by experimentally testing and validating the model of persuasive interruptions. We are particular interested in discovering the effects of various persuasive techniques when applied to the message of an interruption. Potential applications of this model include better understanding the effects of interruptions, and guidance to better design effective and persuasive interruptions.

Revising Causal Beliefs

Abstract

The aim of our studies is to examine how contradictions affect causal beliefs. For example, the discovery that your colleague Mark who has been following diet A suffers from iron deficiency may lead you to revise your belief that diet A provides a sufficient supply of iron. Would you also revise your belief that it causes you to lose weight? Experiment 1 shows that our belief that Mark will lose weight is reduced after encountering the contradiction. Experiment 2 shows that people are also less likely to believe that others will lose weight. The results suggest that people resolve contradictions by generating explanations that revise their causal model.

Belief Revision

As we go through life, we are constantly changing our beliefs. We give up old attitudes and we add new ones. When we discover credible information that contradicts our existing beliefs, then rationally we must revise our beliefs in order to restore consistency. Our aim is to examine how this is done.

For example, imagine you believe the following:

If the drink contains sugar, then it tastes sweet

and you believe that in fact:

The drink on the table contains sugar.

But when you taste the drink you discover that it is not sweet leading you to withdraw your earlier inference. Much of our everyday reasoning is non-monotonic. People frequently overturn old conclusions in the light of new evidence. They readily suppress valid deductive inferences when they are presented with new information (Byrne, 1989; Byrne, Espino & Santamaria, 1999).

The discovery that the drink does not taste sweet may also lead us to revise our initial beliefs. Perhaps the drink does not contain sugar. Or it may be that a drink containing sugar doesn't necessarily cause it to taste sweet. For example, perhaps it contains a lot of lemon which suppresses the sweetness. Both possibilities are sufficient to resolve the inconsistency so one question is how to choose from among these possibilities. Logic provides no guidance (Revlin, Cate, & Rouss, 2001). The problem has been studied in philosophy (e.g., Harman, 1986) and in artificial intelligence (e.g. Gärdenfors, 1988). The focus there has been to develop formal principles to guide rational belief change (e.g., Alchourrón, Gärdenfors, & Makinson, 1985). The major principle underlying all existing theories of belief revision is that we should minimize the amount of information that is lost when we revise our beliefs (e.g., Gärdenfors, 1988; Harman, 1986; James, 1907).

Despite the extensive research in developing formal models of belief revision, evidence on how people revise their beliefs is sparse. The way they do so may be very different from the formal systems developed in artificial intelligence (Legrenzi, Girotto, & Johnson-Laird, 2003). Work on attitude change does suggest that, in the face of new evidence, people will treat all contextually relevant beliefs as modifiable in order to increase consistency (Festinger, 1957; Simon & Holyoak, 2002; Thagard, 1989).

What should we do when we discover information that contradicts a causal belief? To the extent that causal relations describe law-like generalizations, the minimal change may be to retain the causal belief and to give up some of the factual information that led to the contradiction. Alternatively, when causal beliefs describe a theory, then evidence to the contrary is reason to dispense with the theory (Popper, 1959).

Studies show that people frequently focus on conditionals more than categorical facts when they revise their beliefs (e.g., Elio & Pelletier, 1997) although less so when they describe familiar causal than unfamiliar relations (Byrne & Walsh, in press, Walsh & Byrne, 2004) and the tendency to do so will depend on the initial degree of belief in the conditional (Diuessaert, Schaeken, De Neys & d'Ydewalle, 2000). Furthermore, when people revise a causal statement, they rarely reject it outright (Byrne & Walsh, 2002). Instead, they may revise their interpretation of the relation (Johnson-Laird & Byrne, 2002). They frequently modify their causal belief by stating that the contradictory example is an exception to the rule or by imagining that possible disabling conditions are present (i.e., factors that prevent a cause from producing its usual effect; Byrne & Walsh, 2002). And people retain a higher degree of belief in a causal conditional when there are few available disabling conditions (Elio, 1997).

We address three questions which examine how a contradiction to a causal belief impacts on our belief system. The questions provide clues to the processes underlying belief change. In Experiment 1, we examine whether resolving a contradiction to a causal belief leads people to revise their judgment about that single belief or whether it has implications for other causal judgments. In attempting

to minimize the changes they make, people may alter a causal belief in a way that leaves other causal beliefs unchanged. Alternatively, if people introduce disabling conditions to modify a causal belief, this may lead to changes which resonate through the belief system. Support for this latter view comes from the finding that when people discover that a cause does not produce an expected effect, they may doubt whether other expected effects will follow (Walsh & Johnson-Laird, 2004).

People may mentally construct a causal model to represent the causal relations between events (e.g., Sloman & Lagnado, 2004). In Experiment 2, we examine whether people use their existing causal model to generate explanations about the situation in which the contradiction occurred or whether their explanations involve a change to the causal model itself. In addition, we examine whether people generate just one or several alternative hypotheses to explain the contradiction.

Experiment 1

We propose that when people encounter a contradiction to a causal belief they generate an explanation for why the cause occurred without the effect (Walsh & Johnson-Laird, 2004). Rather than giving up their belief in the causal relation, they tend to modify it (Byrne & Walsh, 2002) and they may do so by specifying certain conditions that will disable the relation. For example, imagine that despite your belief that exercise causes weight loss, you discover that Anne has exercised but didn't lose weight. Rather than inferring that exercise is not effective you may decide that it is only effective if it is cardiovascular or if you do not at the same time consume more calories. If our hypothesis is correct, then the explanation may influence other causal judgments, for example, whether the exercise increased Anne's fitness level. Our experiment was designed to test this hypothesis.

Method

We constructed six experimental problems. Each problem began by stating a pair of causal statements with a common antecedent, for example:

Jogging regularly causes a person to increase their fitness level.

Jogging regularly causes a person to lose weight.

To measure initial belief in the first statement, we asked the following question:

Tim jogged regularly. What is the probability that his fitness level increased?

We then introduced a contradiction to the second causal statement and we examined whether this influenced their belief in the first statement:

Sam jogged regularly but he did not lose weight. What is the probability that his fitness level increased?

The six problems were of the same form but with different causal materials.

We also constructed two control problems, which did not involve any contradiction and again we measured whether there was any belief change. For example:

Sam jogged regularly and he did lose weight. What is the probability that his fitness level increased?

Participants responded to the questions by giving a number between 0 and 100 (where 0 = definitely not and 100 = definitely).

The participants were 23 undergraduates of Brown University who took part in return for payment or course credit.

Results

Table 1 shows the mean probability ratings before and after the contradiction. The probability of the second consequent was rated as significantly lower after reading the contradiction (mean = 59%) than before reading the contradiction (mean = 77%; t (df = 22) = 6.07, $p < .001$). The pattern occurred for 21 out of 23 participants and the remaining two were tied. The pattern also occurred for each of the six types of semantic content and there was no significant difference in the amount of belief change between the different contents. In the control problems, there was no significant change in the probability of the second consequent when no contradiction was presented ($p > .5$).

Table 1: Mean probability ratings for experimental and control problems in Experiment 1

Problem format:	If A then B If A then C
Experimental Problems	
Given:	Probability of B (0-100)
A	77
A and not C	59
Control Problems	
A	81
A and C	82

The results show that when people receive information that contradicts one causal statement, they will be less confident that other expected consequents will follow from the same cause. One explanation for our finding is that people resolve the contradiction by introducing conditions which would disable the relation. These disabling conditions may also reduce the probability that other consequents will follow from the same cause. An alternative explanation is that people are generally less confident about what they've been told, perhaps because they consider the source less credible, so they reduce their judgments. In our second experiment, we compare these hypotheses.

Experiment 2

The aim of our second experiment was twofold. First, we wanted to know whether people's causal judgments depend on the explanation that was generated for the contradiction

and on that explanation alone. If their probability judgments depend on their explanations, then their judgments should be predictable from their explanation regardless of the contradicted fact. In contrast, if a contradiction just reduces confidence, then their probability judgments should vary with contradiction, and not with the explanation. We tested this by explicitly asking participants to generate an explanation for the contradiction before making a causal judgment, e.g.,

(1) Anne jogged regularly but she didn't lose weight.
Why?
What is the probability that her fitness level increased?

We then asked participants to use this explanation to make another causal judgment. For example, if a participant gave the explanation that Anne's appetite increased, then we asked them the following question:

(2) John jogged regularly and his appetite increased.
What is the probability that his fitness level increased?

If people use their stated explanation (and not the contradicted fact) to make the causal judgment in (1) and they don't consider any other hypotheses, then we expect the probability judgments in (1) and (2) to be equal. Previous research has shown that people frequently neglect to consider alternative hypotheses (e.g., Klayman & Ha, 1987). However, if reasoners do consider other explanations or if their causal judgments are reduced merely because they have less confidence in what they have been told, then we expect these judgments to differ.

The second question that we address in this study is whether people draw on information that already exists in their causal model to generate an explanation for a contradiction or whether resolving a contradiction leads people to revise the causal model itself. We did this by asking participants two further questions. Before reading the contradiction we asked them the following:

(3) Tom jogged regularly.
What is the probability that his fitness level increased?

And after reading the contradiction and generating the explanation, we asked them the following:

(4) Mary jogged regularly and you don't know if her appetite increased.
What is the probability that her fitness level increased?

If a reasoner's causal model already contains information about the relation between appetite and fitness level and they use this information in answering (3), then we expect their responses to questions (3) and (4) to be equal. But if they change their causal model when resolving the contradiction, we expect their answer to these two questions to be different. This study examines these two questions.

Method

We used the same six pairs of causal beliefs as used in the experimental problems in Experiment 1. Each pair was followed by five questions as presented in Table 2. The questions were presented orally to the participants and the experimenter recorded their responses. The first question again measured participants' initial belief in the probability of the first conditional. Question 2 introduced a contradiction to the second conditional. This time we explicitly asked participants to generate an explanation for why the contradiction might have occurred before asking them to rate the probability that the consequent of the first conditional occurred.

The following three questions measured the probability of the consequent of the first conditional under different conditions, namely, when the explanation given in question 2 was either, unknown, absent, or present. For example, take the problem described in Table 2. If participants answered question 2a by saying that Kevin was taking sleeping pills, then in question 3 we told participants that Frank was worried but it is not known if he is taking sleeping pills and we asked for the probability that he had difficulty concentrating. In question 4, we asked for the same probability judgment given that Helen was not taking sleeping pills. And finally, in question 5, we asked for the probability given that Evelyn was taking sleeping pills.

Table 2: The format of the problems used in Experiment 2

Worrying causes difficulty in concentrating. Worrying causes insomnia.
1. Mark was worried. What is the probability that he had difficulty concentrating?
2. a. Kevin was worried but he didn't have insomnia. Why? b. What is the probability that he had difficulty concentrating?
3. Frank was worried but *you don't know if the explanation holds.* What is the probability that he had difficulty concentrating?
4. Helen was worried and *you know that the explanation does not hold.* What is the probability that she had difficulty concentrating?
5. Evelyn was worried and *you know that the explanation does hold.* What is the probability that she had difficulty concentrating?

The experiment allows us to examine whether the probability ratings depend on the single explanation that was generated for the contradiction. The experiment also allows us to test whether participants change their causal model before and after the contradiction.

The participants were 20 undergraduates of Brown University who took part in return for payment.

Results

The mean responses for each question are presented in Table 3. The results replicate the finding of Experiment 1. The probability of the second consequent was rated as significantly higher in question 1 before reading the contradiction (mean = 85%) than in question 2 after reading the contradiction (mean = 63%; $t = 5.03$, $p < .001$).

Table 3: Mean probability ratings for each of the five questions in Experiment 2

Problem format:	If A then B If A then C
Given:	Probability of B (0-100)
1. A	85
2. A and not C	63
3. A and explanation unknown	71
4. A and explanation absent	85
5. A and explanation present	62

Our second finding was that responses to question 2 and question 5 did not differ significantly ($t = 0.60$, $p > .5$) and this pattern occurred for all six types of problem content. For problems in which the contradiction reduced the judged probability of B (response to question 2 was lower than to question 1), participants gave the same answer to question 2 and 5 for 53% of problems. We would expect greater variety if participants were considering multiple hypotheses. Hence the results are consistent with the view that in many cases, people consider just the one hypothesis given in their explanation and they fail to consider other possibilities. They allow this hypothesis to mediate their later causal judgments without considering the possibility that they are wrong (see also Shaklee & Fischhoff, 1982).

Finally, our results suggest that people resolve contradictions by making a change to their causal model. Ratings for question 1 were significantly higher than for question 3 when the explanation was unknown (mean = 71; $t = 5.37$, $p < .001$). People do not merely change their causal judgments about the specific case in which the contradiction occurred. They extend these changes to new situations. Responses to question 1 did not differ significantly from responses to question 4 (mean = 85; $t = 0.1$, $p > .8$). People do not generally resolve contradictions by drawing on events that they have already represented in their causal model.

We also examined the nature of explanations given for the inconsistency. The most common explanation was to introduce a disabling condition which would prevent the cause from producing its usual effect. 74% of responses were of this type. In many cases, the conditions disabled the cause from both consequences. For example, the fact that worry did not lead to insomnia may be explained by the fact that the person did relaxation exercises. This in turn may reduce the probability that worry will lead to a difficulty in concentrating. The next most common type of response was to suggest that the level or amount of the cause was not sufficient to produce the effect, for example, there was not enough sugar in the drink or the person was not very worried. 18% of responses were of this type. In both cases, the pattern of responses and significance ratings for the probability of B were the same as for the overall ratings.

Discussion

The results of our experiments confirm previous findings that people prefer to modify than to give up a causal belief when they encounter a contradiction. The results also give us insight into how those modifications alter other causal judgments. In Experiment 1 we showed that when we discover a situation where a cause does not produce an expected consequence, we become less certain whether the cause will lead to other expected consequences in this instance. The results of Experiment 2 show that we also become uncertain about whether other expected consequences will follow in a situation involving a different agent.

The findings suggest that discovering a contradiction can lead us to change the information that we use to make causal judgments. The contradiction makes salient or forces us to imagine conditions that may impact on these judgments. Hence the basis for making our judgments has changed.

The results reaffirm the view that monotonic logic systems are inadequate for understanding how people reason. In most cases, when people reason from cause to effect the conclusion is indeterminate. It is rarely possible to state all of the conditions in which the cause will necessarily produce an effect (e.g., Johnson-Laird & Byrne, 2002). One approach used by artificial intelligence researchers is to make the default assumption that all of the necessary conditions are present unless there is information to the contrary (Minsky, 1975). Similarly, people may mentally construct models that do not represent all of the information explicitly (Johnson-Laird & Byrne, 1991) although they may consider additional factors if they come to mind easily (Cummins, Lubart, Alksnis & Rist, 1991).

An alternative way to approach these problems is to assume that judgments are probabilistic. Probabilistic judgment does not require specification of all of the conditions that prevent a cause from having its usual effect; the judgment merely reflects the likelihood that this occurs.

Our results suggest that when people encounter a contradiction they generate explanations. The most common type of explanation is to describe a condition that disables the cause from its effect. These disabling conditions may often be ones that people haven't previously considered and as a result they introduce these new conditions into their causal model. These new conditions may have the effect of disabling the cause from other possible consequences.

Introducing a new disabling condition into a causal model could have two possible results. One is that it could explain

why the effect does not always follow from the cause but the probability judgment may remain unchanged. A second possibility is to decide that this new condition should lower the probability that the effect will follow from the cause. Our results suggest that people tend to use the second approach. When our participants considered new conditions, they used these to reduce their probability judgment further.

Abstract

Attention is a complex multilevel system subserved by at least three interacting attentional networks in the brain. This paper describes a multilevel computational model of attentional networks, developed in both the symbolic architecture of ACT-R and the connectionist framework of leabra. We evaluated the model using the Attentional Networks Test and the simulation results fitted the empirical data well. We argue that developing multilevel computational models helps to link findings at different levels.

Introduction

Suppose a student S was asked to solve the equation "2x + 3 = 9" (Figure 1A), and he used 2 seconds to produce the answer "x = 3". Both cognitive scientists X and Y were interested in understanding how S did it. Scientist X recorded S's detailed verbal protocol (Figure 1B), based on which, and other relevant behavioral measures, X hypothesized the possible knowledge structures underlying S's problem solving and developed a symbolic computational model that simulated the process (Figure 1C). On the other hand, scientist Y adopted sophisticated brain imaging techniques such as electroencephalograph (EEG) and functional Magnetic Resonance Imaging (fMRI) and acquired a high-resolution recording of S's brain dynamics during problem solving (Figure 1D). Based on some well-established neural computing principles, Y then developed a biologically realistic connectionist model to simulate the brain activities underlying S's performance (Figure 1E). Though both models fitted the data well, the two models are clearly different. While the symbolic model offers a description of the process with psychological plausibility and high behavioral relevance, the connectionist model emphasizes the process' biological realism and brain foundations. One question is, do we, cognitive scientists who endeavor to discover unified theories of cognition, have justifiable reasons to prefer one to another?

This question and similar others have led to a long debate in the rather brief history of cognitive science (e.g., Churchland & Sejnowski, 1992; Newell, 1990; Rumelhart & McClelland, 1986). Recently a BBS (Behavioral and Brain Sciences) target article was dedicated to this issue (Anderson & Lebiere, 2003). The authors adopted a set of 12 criteria, which they called "The Newell Test", to systematically compared and contrasted ACT-R, a rule-based cognitive architecture (Anderson & Lebiere, 1998), and the connectionist modeling framework. Their conclusion was that both frameworks had great strengths as well as serious limitations as candidates of the unified theory of cognition.

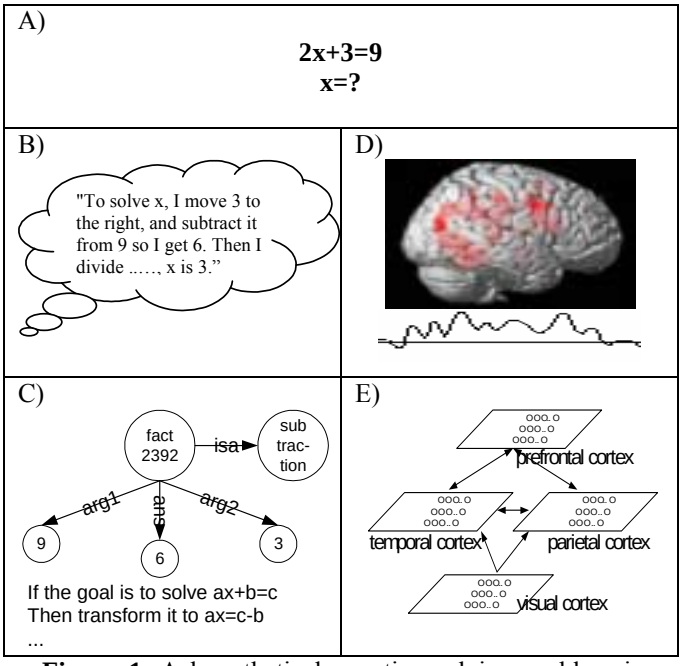

Figure 1. A hypothetical equation-solving problem is presented in A. Verbal protocol and brain imaging data are presented in B and D. Sketches of a symbolic model and a connectionist model of task are presented in C and E.

This is hardly surprising given the inherent complexity of the human mind itself. It has long been recognized that the mind is a multilevel construct and can be analyzed at different levels. Marr, for example, distinguished and separated among computational theory, representation and algorithm, and hardware implementation (Marr, 1982). Similar distinctions were made by Newell among different bands of cognitive functions (Newell, 1990). Newell argued that different bands utilize different basic operators, which have different time scales. More importantly, different bands form a hierarchy. Multiple lower lever basic operators can be combined to form higher level basic operators. In other words, lower level operators can be summarized up at higher level though this summarization may not be linear.

Single level analyses have been the dominant methodology in cognitive science. Experimental psychology and symbolic modeling, for example, largely depend on controlled experiments and behavioral observation. Recent advances in cognitive neuroscience allow us to directly observe, with high temporal-spatial resolutions, how an active brain functions during cognitive performance (Posner & Raichle, 1994). As a result, biologically realistic neural networks modeling has flourished (O'Reilly & Munakata, 2000). Efforts have also been made to probe the function of mind at lower molecular levels (e.g., Bellugi & George, 2001; Squire & Kandel, 2000). While all these levels of analyses tell us important aspects of the mind, neither of them alone is adequate to describe the whole picture. The human mind is a complex entity and may leave shadows at different levels when it works (Penrose, 1996). However, in order to achieve a unified theory all of the pieces have to be somehow linked together.

One approach would be to develop so called "hybrid systems", which typically combine symbolic and subsymbolic components together (e.g., Sun & Alexandre, 1997). We, for example, have developed a hybrid model of human abductive reasoning by combining a Soar component (a symbolic architecture) for hypothesis generation and a connectionist component for hypothesis evaluation (Johnson, Zhang, & Wang, 1997). Although hybrid systems take advantage of both types of components and can become quite powerful, they often bear little true psychological and neurophysiological significance due to the fact they are artificially assembled systems. While it is well agreed that human cognition involves mechanisms and operations at, among others, both psychological and neuronal networks levels, simply piecing them together is *ad hoc* and trivializes the problem (see also Wang, Johnson, & Zhang, 2003)

In this paper we argue that we need a multilevel modeling approach. That is, we need to develop well-fitted computational models at multiple levels for any given cognitive phenomenon. Because the mind manifests itself at multiple levels, each level is real and tells a unique story of the mind on its own. When we develop models for a specific phenomenon at multiple levels, we would be able to compare them, contrast them, and more importantly, mutually justify them. By doing so, we expect that a more complete picture of the mind might emerge.

This paper is organized as follows. We first briefly review findings on human attentional networks and introduce the Attentional Network Test (ANT) (Fan, MaCandliss, Sommer, Raz, & Posner, 2002). We then demonstrate the multilevel modeling approach by reporting and cross-validating two computational models for the same ANT task, one developed in ACT-R, and the other in leabra, a biologically realistic connectionist modeling framework (O'Reilly & Munakata, 2000). While both models fitted data well they emphasized different levels of explanations. Finally the implications of this practice are discussed.

Human Attentional Networks

Although "everyone knows what attention is" (James, 1890), how attention works remains one of the most challenging questions in science (Parasuraman, 2000; Pashler, 1998). Recent advances in cognitive psychology and cognitive neuroscience have suggested that there exist multiple attentional networks in the brain, each of which subserves different types of attention (Fan et al., 2002; Posner & Dehaene, 2000; Posner & Petersen, 1990). At least three attentional networks, for alerting, orienting, and executive control, have been distinguished at both cognitive and neuroanatomical levels (see Figure 2A). Specifically, alerting involves a change in the internal state to become ready for any incoming task-related events. Neuroimaging evidence has revealed that the alerting network consists of some frontal and parietal areas particularly of the right hemisphere. Orienting, closely related to the conventional selective visuo-spatial attention, involves selectively focusing on one or a few items out of many candidate inputs. Evidence has shown that the orienting network includes parts of the superior and inferior parietal lobe, frontal eye fields and such subcortical areas as the superior colliculus of the midbrain and the pulvinar and reticular nucleus of the thalamus. Finally, executive control of attention is related to monitoring and resolving conflicts. Executive control is often needed in higher level mental operations including planning, decision making, error detection, novel or not well-learned responses, and overcoming habitual actions. Converging evidence from neuroimaging and neuropathology studies has suggested that the executive control network consists of the midline frontal areas (anterior cingulate cortex), lateral prefrontal cortex, and the basal ganglia.

The ANT paradigm was recently developed to simultaneously measure the performance of the three attentional networks and evaluate their interrelationships (Fan et al., 2002). It is essentially a combination of a spatial cueing task (Posner, 1980) and a flanker task (Eriksen & Eriksen, 1974), as illustrated in Figure 2B. The stimulus consists of a row of 5 horizontal arrows and the participants' task is to report the pointing direction (left or right) of the center arrow (the target) by pressing a key. The four arrows surrounding the target, with two on each side, are called the flankers. These flanker arrows point either in the same direction as that of the target (the congruent condition), or in the opposite direction (the incongruent condition). An additional condition (the neutral condition) is also included in which the flankers are four straight lines with no arrowheads. To introduce an orienting component, the row can be presented at two locations, either above a fixation point (top) or below it (bottom). To introduce an alerting component, the row may be preceded by a cue (the cued condition) or may not (the no-cue condition). In addition, when there is a cue, this cue may be presented at the center fixation location (the center-cue condition), at the top or bottom location where the stimulus row is to appear (the

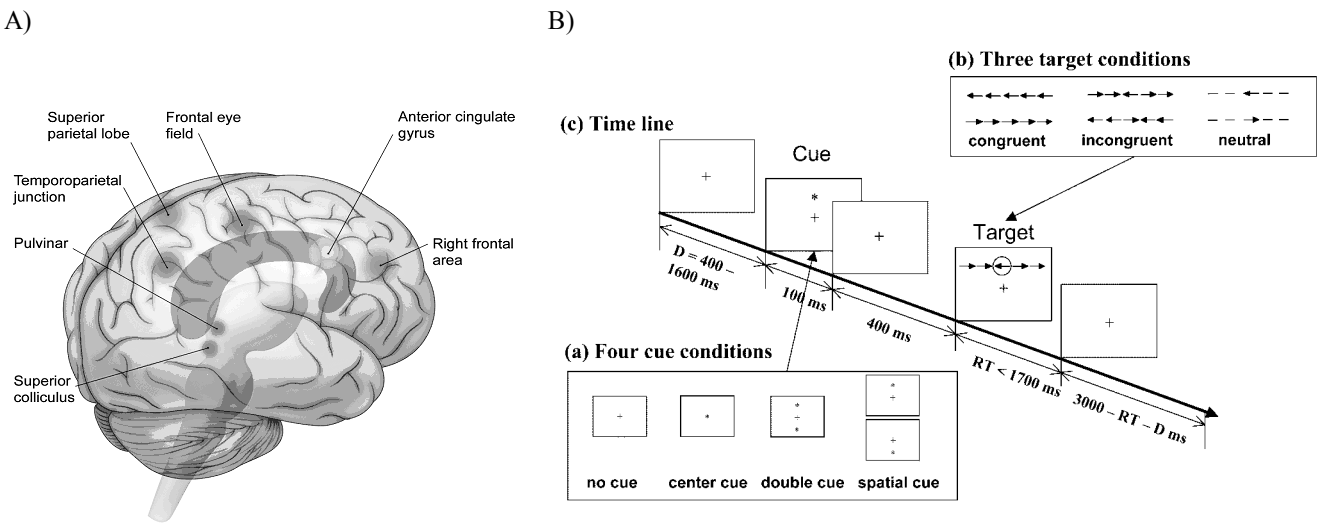

Figure 2. Human attentional networks (A) and the ANT task (B)

spatial-cue condition), or at both top and bottom locations (the double-cue condition). Note that while a spatial-cue precisely predicts where the stimulus is to appear, in both the center-cue condition and the double-cue condition the participant cannot infer that information from the cue.

Fan et al. (2002) tested 40 normal adult participants using the ANT paradigm. Their reaction time (RT) results are shown in Figure 3A. They then proposed the following formula as a measure of the efficiency of each of the three attentional networks:

· Alerting efficiency = RT(no-cue) – RT(double-cue),
· Orienting efficiency = RT(center-cue) – RT(spatial-cue),
· Conflict efficiency = RT(incongruent) – RT(congruent),

which resulted in the efficiency measures of 47 ± 18 ms, 51 ± 21 ms, 84 ± 25 ms, for alerting, orienting, and executive control, respectively.

Fan et al. (2001) also reported an fMRI study using the ANT paradigm. Their results were consistent with the general findings shown in Figure 2A.

Multilevel Computational Modeling of Human Attentional Networks

While both the behavioral and neuroimaging studies using the ANT paradigm revealed important psychological and neurophysiological characteristics of human attentional networks, there exists a gap between these two levels of analyses. In particular, how do these different attentional neural networks work together to generate psychologically meaningful behavior? It has been well agreed that the link between neural activities and psychological performance is nontrivial and must be taken into account seriously to avoid "neo-phrenology". Developing well-principled and constrained computational models help in the regard (Cohen & Tong, 2001).

Traditional computational modeling approaches to human attention have typically adopted various connectionist modeling techniques (e.g., Cohen, Dunbar, & McClelland, 1990). While it has been fruitful, this practice fails to account for the manifestations of attention at symbolic/cognitive levels. As we illustrated earlier, attention, as an essential aspect of human cognition, is a complex multilevel construct. In order to understand the computational mechanisms of attention at different levels and the links among them, we need multilevel models.

We have developed a multilevel model for the ANT task. One sub-model was developed in the symbolic modeling framework of ACT-R and focused on the psychological aspects of the task. The other was developed in the connectionist modeling framework of leabra and emphasized the neurophysiological aspects of the task. A preliminary cross-validation of two models is discussed.

ANT on ACT-R

ACT-R is a production rule based cognitive modeling architecture developed by John Anderson and colleagues over a period of nearly two decades (see Anderson & Lebiere, 1998). In essence, ACT-R explains human cognition by proposing a model of the knowledge structures and knowledge deployment that underlie cognition. Although ACT-R consists of a nontrivial subsymbolic component for computations involving activation and association, it is fundamentally a symbolic modeling framework in that it relies extensively on various symbolic structures for knowledge representation. For example, ACT-R makes a fundamental distinction between declarative and procedural knowledge. Declarative knowledge corresponds to things people are aware of and can usually describe to others and is represented in ACT-R by chunks. Procedural knowledge is knowledge that people display in behavior but are not conscious of and is represented by production rules (condition-actions pairs). Both chunks and production rules are fundamental symbolic structures in ACT-R and are regarded as the atomic components of thought in the sense

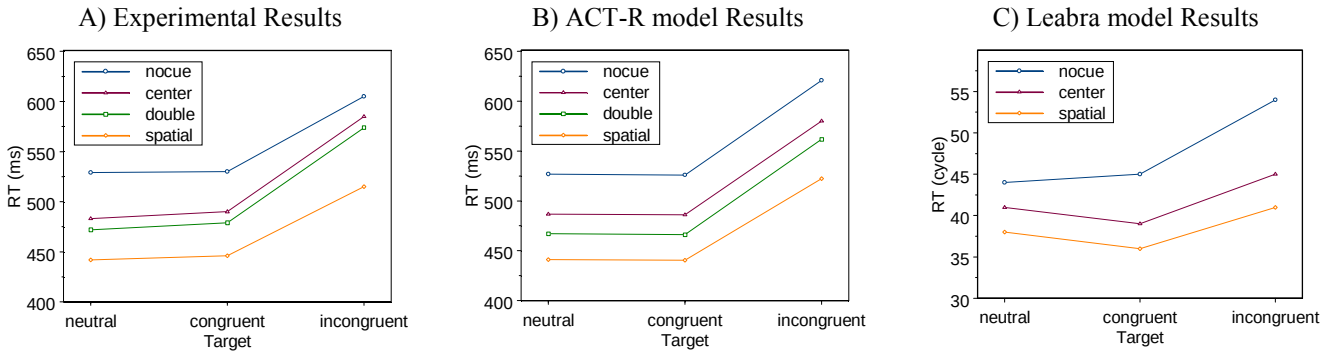

Figure 3. Experimental (A, based on Fan et al. (2002)) and modeling results (B and C).

that they are as far down as one can go in the symbolic decomposition of cognition. In ACT-R, on average every fifty (50) milliseconds, one production rule is chosen to fire, a few declarative chunks are processed, and cognition advances one step. Therefore, it is claimed that ACT-R captures the symbolic grain size of cognition.

We developed a computational model for the ANT task in the framework of ACT-R (Wang, Fan, & Johnson, 2004). Our purpose is two-fold. First, we want to explore how different types of attention work together in a single framework to produce the cognitive performance. Second, such a model offers a solid testbed for us to cross-validate those models based on various connectionist modeling results and neuroimaging data.

We started by analyzing the major functional components in the ANT task. We distinguished six major stages in a typical ANT trial: fixation and cue expectation; cue or stimulus judgment; cue processing; stimulus expectation; stimulus processing; and response. We then mapped these functional components onto 36 ACT-R production rules. With these rules our model could perform the ANT task and interact with the same experimental environment that human participants interact.

We evaluated the performance of the model by using the model as a "simulated subject" to perform the ANT experiment. The RT results of 100 "simulated subjects" are presented in Figure 3B. A correlation analysis shows very high correlations (0.99 for RTs and 0.97 for error rates) between the simulation and experimental results. We then followed the same procedure discussed early to estimate the effects of the three attentional networks based on the simulated RT data, resulting in the efficiency measures of 55 ± 7.4 ms, 45 ± 7.0 ms, 86 ± 7.4 ms, for alerting, orienting, and executive control, respectively. A close match between the two sets of data is apparent, with a notable exception that the simulated standard deviations are consistently smaller than the empirical ones. The reason is that we did not add any between-subject variance in our model. As a result, these simulated variances actually reflected those within-subject variations in performing the ANT task. Overall these results suggest that the model captured well the various attentional effects that the ANT task was designed to measure.

The concept of production rule is fundamental to our model of attention. One of the key features of the model is that it mapped the effects of attentional networks to production rules. Rules fire in sequence and operate at a rate of about 40-50 ms per production rule. As argued by ACT-R, production rules define the atomic components of thought at the symbolic level. When we examined the efficiency measures of attentional networks reported in Fan et al (2002) it seemed that they (51 ms, 47 ms, and 84 ms, for alerting, orienting, and executive control, respectively) fell well into the range of a few rule firings time period. Perhaps all we need is about one (for alerting and orienting) or two (for executive control) additional production rules to explain symbolically the work of attentional networks. This is indeed what our model demonstrated.

ANT on Leabra

Leabra (*l*ocal, *e*rror-driven and *a*ssociative, *b*iologically *r*ealistic *a*lgorithm) is a connectionist modeling framework proposed recently by O'Reilly and Munakata (2000). There are at least three features that distinguish it from other connectionist modeling frameworks. First, it has sound neurological foundations. It is biologically realistic in multiple aspects. Its neurons compute based on membrane potentials and ion channels. Its neuronal connections are often bi-directional and cannot change signs (i.e., changing from an excitatory link to an inhibitory link, and vice versa). It uses biologically inspired learning rules such as Hebbian learning for unsupervised learning and the generalized recirculation algorithm (but not the biologically unrealistic backpropagation) for error-driven learning. Second, leabra is a coherently integrated framework. Many distinctions in traditional neural network modeling, including supervised vs unsurprised learning, feedforward vs recurrent networks, and pattern recognition vs self-organization maps, are all unified in a single coherent framework, based on well-supported biological principles. Third, partly due to its biological realism, it is now possible, for example, to designate a specific neural network to simulate a specific area of brain, and flexibly connect the multiple such networks, each of which can have its own properties such as the average activation level and the connection density, to simulate various brain pathways. As a result, it offers great

flexibility to build a hierarchy of neural networks and link network activities to higher-level symbols.

A connection model of the ANT task was developed in the framework of leabra. The structure of the model is shown in Figure 4. This model contains modules for all the three attentional networks. In addition, it contains modules for perception (visual input and primary visual cortex), object recognition (object pathway), and response (output). The networks are connected in such a way that they conform to the known functional an anatomical constraints as much as possible (Farah, 2000; O'Reilly & Munakata, 2000).

The model works as follows. When a cue comes on, the primary visual cortex module is activated, which in turn triggers the alerting network. This cue-induced alerting affects later stimulus processing because the alerting network will remain excited for a while which will activate the orienting network in general causing it to become ready for the incoming stimulus. In addition, when the cue is a spatial one (i.e., a cue that indicates where the target stimulus is to appear), it will further make the corresponding sub-region of the orienting network even more excited. This occurs because the orienting network adopts a retinotopy-based spatial representation of the environment. This extra excitation in the sub-region of the orienting network will facilitate the corresponding stimulus processing in the object pathway network, due to the connections between them. This accounts for the orienting effect. Finally, note that it is the object pathway network that is responsible for the arrow direction detection. When the incongruent stimulus (e.g., a left arrow flanked by four right arrows) is presented, the object pathway network may propose different responses, which compete for the final expression in the output network. The executive control network then activates making the center arrow defeating the flankers. This is where the executive control attention plays a role.

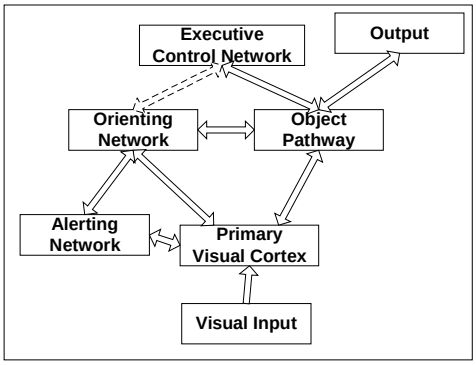

Figure 4. A leabra model of ANT.

The performance of the model was evaluated by using it to perform the ANT task. Stimuli are presented to the model in a similar way as to a human. Depending on the conditions, a cue, which can be either a center cue or a spatial cue, may be presented for a fixed time period before the stimulus presentation (note that the double cue condition was not simulated here since the current version of model were not equipped with enough neurons). The number of cycles the output module takes to produce a stable response after the stimulus presentation serves as a measure of the reaction time. The simulation results are shown in Figure 3C. A regression analysis showed that

RT(ms) = 12 * RT(cycle)

with a R-square of 0.99. It is clear that the model fits the behavioral data reasonably well.

Discussion

Human attention is a multi-component multilevel construct. Both behavioral and neuroimging studies using the ANT paradigm revealed important aspects of the function of human attentional networks. Multilevel computational modeling helps to probe how these multiple components work together and manifest themselves at multiple levels.

The multilevel model we reported in this paper consisted of a sub-model developed in the framework of ACT-R and the other in the framework of leabra. While the former sub-model focused on the symbolic knowledge structure of cognitive performance and psychological plausibility, the latter focused on the subsymbolic neural information processing and biological realism. However, since both models simulated the same ANT task and fitted the empirical data well, the combined multilevel model offered a real possibility to cross-validate the models and probe the computational link among different levels.

First of all, the model illustrated interesting relationships between production rules and underlying neural computation. As demonstrated in the ACT-R model, rules are fundamental units of psychological reality and typically proceed serially. However, the underlying neural networks process information in parallel. The parallelism of neural computation and the serial nature of rule firing can be mapped against each other along the time line. Since both types of models decompose the cognitive performance into sub-units that occur at tens of millisecond scales, the mapping may be able to tell how rules are implemented in neural level computation. Based on the models, for example, we can map one ACT-R rule (40 ms in the current model) to about three leabra cycles (about 12 ms per cycle). Though such a simple and linear mapping should not be taken literally, it does provide a vivid footnote about how parallel neural computing is summarized psychologically by serial rule firings. It illustrates that we may not be able to find a "rule center" in the brain. Instead, rules can be implemented anywhere in the brain – they are simply pattern matching. For example, there is a symbolic rule that summarizes the conflict monitoring and detection operation typically subserved by the anterior cingulate cortex. The general neural priming underlying alerting in the alerting networks is summarized by another task switch rule.

Our model also demonstrates how functionally identical operations can be implemented by different mechanisms at different levels. One interesting finding from Fan et al. (2002) is the small but reliable difference in RT (about 11 ms) between the center-cue and the double-cue conditions.

A convenient explanation is that in the double-cue condition due to *diffused attention* both stimulus locations had been primed a little, which saved a little time when the stimulus appeared later. While it is easy to model priming and diffused attention in a connectionist model (e.g., our leabra model), how it is implemented at a symbolic rule level raises a challenge. Our ACT-R model adopted a mechanism in which several symbolic and psychologically meaningful move-attention operations were carried out sequentially. The simulated RT difference was 19 ± 8 ms.

The multilevel model for human attentional networks we reported in this paper has allowed us to compare/contrast the computational mechanisms at different levels and to probe the important computational links between psychologically meaningful mental operations and neural activities. It also enjoys potentially significant prediction power in that the model at one level can lead to nontrivial predictions about the operations at another level. However, we recognize that for this approach to work models at each level have to be independently and/or mutually validated. Further analyses and more detailed alignments of our current model remain to be done.

Abstract

Previous research has shown that interlocutors in a dialogue align their utterances at several levels of representation. This paper reports two experiments that use a confederate-priming paradigm to examine whether interlocutors also align their spatial representations during dialogue. Experiment 1 showed a significant reference frame priming effect: Speakers tended to use the same reference frame to locate an object in a scene as the frame that they had just heard their interlocutor use. Experiment 2 demonstrated the same pattern even when the speaker's description and their partner's previous description involved different prepositions. Hence the effect cannot be explained in terms of lexical priming of a particular preposition. Our results are strong evidence that interlocutors in a dialogue align non-linguistic as well as linguistic representations.

Research on dialogue has suggested that the traditional methods employed in psycholinguistics may not give a true, or at least complete, account of human language. The traditional approach focuses largely on monologue and involves investigating single word utterances in isolated controlled circumstances, e.g. the picture naming paradigm, or the lexical decision task. However, Clark (1996) pointed out that the natural setting for language is dialogue, and that language does not normally occur in these isolated circumstances, thus questioning the ecological validity of traditional methods. The realization of this has led to a research program into how language is used in dialogue (e.g., Clark & Wilkes-Gibbs, 1986; Horton & Keysar, 1996; Garrod & Anderson, 1987). Research in this framework has shown that interlocutors in a dialogue tend to align their utterances: Over the course of a conversation participants will come to communicate in a similar fashion to each other. This occurs at several levels of communication, including the conceptual (Garrod & Anderson, 1987), lexical (Clarke & Wilkes-Gibbs, 1986) and syntactic (Branigan, Pickering, & Cleland, 2000) levels. In these experiments, participants usually achieved alignment without resorting to overt negotiation. In the case of syntactic alignment at least, many subjects were not aware that they were aligning.

Pickering and Garrod (in press) proposed a mechanism for how alignment is achieved between interlocutors. According to this theory, alignment is the basis for successful dialogue; misunderstanding occurs when alignment is not achieved. Alignment occurs when the two interlocutors employ equivalent representations at different levels, and arises from an automatic priming mechanism. This allows alignment to be achieved quickly and efficiently without reliance upon time-consuming strategies of open negotiation. Indeed, such strategies are only employed when the primitive mechanisms fail. To prevent unnecessary negotiation Pickering and Garrod suggest a second primitive mechanism that allows repair of representations when misalignment occurs; see Garrod and Pickering (2004) for a summary.

Dialogue research has shown alignment of linguistic representations, but alignment is hypothesized also to occur for conceptual representations, such as those associated with object location. A speaker's conceptual representation of where objects are located is reliant upon an overall spatial representation, which underpins the use of spatial language. In order to describe object locations effectively it is important that both interlocutors take the same perspective (Levelt, 1989) concerning the objects they are locating. For example, an addressee must understand whose left a speaker is talking about. In the same way that interlocutors align on which lexical terms should be used to describe a scene, it would be advantageous for interlocutors to align on which perspective a scene should be described from.

The perspective that is taken depends upon the reference frame that is applied to a spatial representation of a scene. A reference frame is an axial co-ordinate system that defines regions extending from the origin, whose axes are labelled with directional terms. The object to be located (figure object) can then be located in relation to another object (reference object) based upon the directional axes of the reference frame. However, there are three different types of reference frame (at least in English; other languages use

only two or even one; Levinson 2003) that a speaker can employ in order to locate an object: absolute, relative, and intrinsic. It is important that the addressee knows which of these the speaker is using in order to successfully understand an utterance.

The absolute reference frame locates an object based upon salient, stable features of the environment, for example, the cardinal directions. The dot in Figure 1 can be described as *west of the chair* if the page is held horizontally with the top of the page facing north.

The intrinsic reference frame locates an object based upon the directional features of the reference object. The dot in Figure 1 can be described as *above the chair* because it is in alignment with the top of the chair.

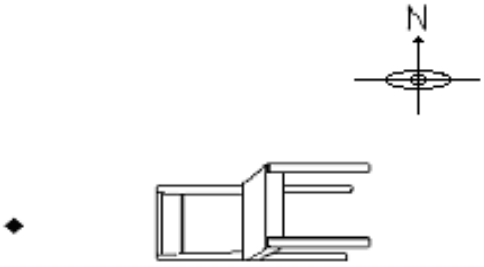

Figure 1. The dot can be described as west using an absolute reference frame, above using an intrinsic reference frame or left using a relative reference frame.

The relative reference frame locates an object in relation to the viewpoint of an observer. The axes of the reference frame are labelled based upon the features of the person upon whose viewpoint the location is based. In Figure 1 the dot would be described as *left of the chair* using a relative reference frame. (In many cases the relative reference frame is used from the viewpoint of a speaker or an addressee, but it can also be from a third person perspective.)

The above tripartite classification of reference frames follows that proposed by Levinson (1996, 2003), and is distinct from the classification traditionally employed in the psycholinguistic literature, which identified absolute, deictic, and intrinsic reference frames, all defined on the basis of their origin. (Deictic reference frames are all reference frames with an egocentric origin.) Levinson pointed out that this traditional system is not an appropriate way to categorize reference systems because it is possible to have a non-deictic relative reference frame, such as *The ball is to the right of the tree as you look at it*, and a deictic intrinsic reference frame such as *The ball is in front of me*.

When describing an object's location, an individual has to select one of these reference frames to use in preference to either of the other two reference frames. Carlson-Radvansky and Jiang (1998) showed that reference-frame selection is achieved via inhibition of non-selected reference frames. When participants used a relative reference frame to identify an object's location, they were slower to describe an object's location using an intrinsic reference frame immediately afterwards. Inhibition operates not only on the endpoint of an axis, but on at least the entire axis, e.g. if *left* (intrinsic) is inhibited then using *right* or *left* (intrinsic) in the subsequent description will take longer than using a relative reference frame.

The findings of Carlson-Radvansky and Jiang (1998) suggest that reference frames are influenced by low-level priming. However, the results do not establish whether or not this occurs during dialogue: Reaction time was used as a measure of cognitive effort in trials whereas in dialogue any effect of priming must manifest itself by a change in the person's linguistic behaviour. Furthermore, Carlson-Radvansky and Jiang's (1998) experiment only investigated inhibition of the endpoint of an axis and the inhibition of the axis itself. If interlocutors align reference frames, we would expect them to align the entire reference frame rather than just part of it. Therefore it is unclear whether this kind of priming is enough to cause the alignment of reference frames between interlocutors in the manner described by Pickering and Garrod (in press).

In two series of experiments Schober (1993, 1995) showed that the reference frame which an individual selects is affected by their partner in a conversation. Individuals who described the location of an object to a partner who viewed the scene from a different perspective were more likely to describe the location from their partner's perspective. When the partner queried such descriptions, they used their own perspective to describe object location. Schober concluded that interlocutors use conscious strategies to collaborate in ways of describing object location.

Schober's results suggest that interlocutors may align reference frames. However, it is not clear that this is necessarily the case. In his experiments, two participants interacted freely, allowing little control over what was said by each pair. This means that pairs of participants may be reverting to default reference frames. Furthermore, in a large proportion of trials participants located objects using terms that required no reference frames (e.g. *next to*, *between* and so on).

The present work is an experimental investigation to discover whether or not interlocutors align reference frames. The investigation uses a confederate-priming paradigm (e.g. Branigan et al., 2000) where a naïve participant and a participant who is - unknown to the naïve participant - a confederate of the experimenter and who is following a script, communicate during the experiment. If interlocutors do align reference frames then they will use a reference frame significantly more when they have just heard an utterance using that reference frame than when they have just heard an utterance using an alternative reference frame. Alternatively interlocutors may select a reference frame based solely upon the perceptual properties of the spatial

array, in which case they should be unaffected by the reference frame just used by their partner. Our experiments also set out to separate priming for reference frames from lexical priming. If priming of reference frames exists separately from lexical priming, we can expect subjects to use a reference frame significantly more if they have just heard an utterance using that reference frame even if the same spatial term is not applicable to both utterances.

Experiment 1

Method

Participants 12 students of the University of Edinburgh were paid volunteers in the experiment, which lasted 20 minutes. All were native English speakers.

Materials The experiment was run on two computers positioned back to back, using E-prime software. One program was created for the confederate and consisted of sentences positioned in the centre of the screen of the form "The dot above the chair". This formed the script for the experiment. The second program was for the participant and displayed pictures for the match and describe phases of the experiment.

12 monochrome objects were used as reference objects, all fitting into a rectangle 93 pixels high and 121 pixels wide. Two versions of each object were used, one rotated 90° clockwise and one rotated 90°anti-clockwise.

The figure object was an 11x11 pixel square rotated so that its vertices were the top, bottom, leftmost, and rightmost points. The figure object was located above, below, left, or right (in a relative reference frame) of the reference object. The centre of the figure object was positioned between 125 and 130 pixels from the centre of the reference object.

Design There were 3 within-participants and within-items factors: Prime Reference Frame (Relative vs. Intrinsic); Preposition (Same Preposition vs. Different Preposition); and Target Plane (Vertical vs. Horizontal). These are exemplified in Figure 2. The prime scene in Figure 2 can either be described as *The dot above the camera* (relative reference frame) or *The dot right of the camera* (intrinsic reference frame). In the top diagram of Figure 2, alignment requires using the same preposition (either *above* or *right of*); in the bottom diagram, alignment require using a different preposition (either *left* or *below*). Finally, the top target scene is aligned vertically whilst the bottom target scene is aligned horizontally.

Two lists of 96 trials were constructed, with each trial consisting of a match phase and a describe phase. The reference objects in each list were rotated clockwise and anti-clockwise on half of the trials each. Reference frame was counterbalanced across list and rotation. Preposition overlap was counterbalanced across rotation in each list. Participants saw 12 trials in each of the 8 conditions formed by crossing the three factors. The trials were presented in a fully randomized order, which was different for each participant.

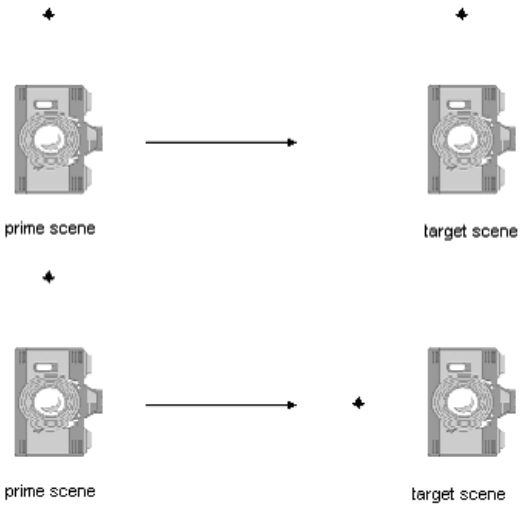

Figure 2: The top diagram shows the 'same preposition' condition. The bottom diagram shows the different preposition condition.

Procedure The two participants were introduced to each other (throughout the experiment, the experimenter treated the confederate as if she was a naïve participant).

The participant and confederate each sat at a computer each. The computers were situated back to back so that neither could see each other, or the other's screen. After hearing instructions, participants pressed the space bar to begin a practice session of 8 trials, one trial corresponding to each of the 8 conditions. Instructions then appeared on the screen signalling the end of the practice session and the start of the experiment. Each trial proceeded as follows: After participants pressed <space> to begin, the match screen appeared. The match screen contained two examples of a reference object (both the same, with one on the left and one on the right) and a dot located above, below, left or right of each one. The confederate gave a description of the location of the dot in relation to the object. The participant then chose which of the two examples on the screen matched the confederate's description of the dot location accurately, pressing the M key if it was the right-hand example and the Z key if it was the left-hand example. Participants were told that if they were not sure which picture matched their partner's description to pick the one they thought matched most closely.

After selection the match scenes disappeared (no feedback was given) and a fixation cross appeared in the centre of the screen. This remained on screen for 1000ms. The fixation cross was then replaced by a reference object in the centre of the screen with a dot above, below, left, or right of it. Participants then described the location of the dot in relation to the object. After describing this they pressed space and the scene disappeared. It was replaced by a fixation cross in

the centre of the screen for 500ms. This then disappeared and the next trial began with a match task.

Results

For the analysis participants' first responses were used. The percentage of intrinsic responses were then analyzed using two 2x2x2 repeated measures ANOVAs (by participants (F1) and by items (F2)), with Prime reference frame (intrinsic or relative), preposition (same or different), and Target plane (horizontal or vertical) as factors.

Table 1 shows the mean number of intrinsic responses used by subjects in each of the 8 conditions. There was a significant main effect of Prime reference frame (62.9% vs. 53.3%; $F1(1,11) = 26.86$, $p < .01$; $F2(1,11) = 9.35$, $p < .05$). That is, participants were significantly more likely to use an intrinsic reference frame after the confederate had used an intrinsic reference frame, compared to when the confederate had used a relative reference frame.

Table 1:
Mean percentage of intrinsic responses in Experiment 1.

	Relative Prime		Intrinsic Prime	
	Same	Diff	Same	Diff
Vertical	32.3	52.8	54.9	52.3
Horizontal	63.6	64.4	73.3	70.9

When the figure and reference objects were aligned vertically, participants used an intrinsic reference frame 48% of the time compared to 68% when the alignment was horizontal. This difference was significant ($F1(1,11) = 8.07$; $p < .05$; $F2(1,11) = 101.17$; $p < .01$), showing that participants were significantly more likely to use an intrinsic reference frame when the objects were aligned horizontally than when they were aligned vertically.

As expected there was no effect of preposition ($p > .05$): Participants used an intrinsic reference frame as much when the prepositions were the same as when they were different. This is regardless of which reference frame the confederate used.

There was a significant two-way interaction between Prime Reference Frame and Preposition ($F1(1,11) = 13.07$; $p < .01$; $F2(1,11) = 6.19$; $p < .05$). All other two-way interactions were non-significant ($p > .05$). Post-hoc analyses showed that these interactions occurred because of a difference between two of the eight conditions, relative, same, vertical and relative, different, vertical: The former yielded 32.3% intrinsic responses whereas the latter yielded 52.8% intrinsic responses ($t(23) = -2.91$; $p = .01$).This means that participants were more likely to use a relative reference frame when the reference and figure object were aligned vertically (i.e. they would use *above* and *below* to describe the dots' location) following the confederate using a relative reference frame when there was preposition overlap (i.e. the confederate used above or below) than when there was no preposition overlap (i.e. the confederate used left or right).

Discussion

The results of Experiment 1 show an effect of alignment of reference frames. Participants were more likely to use an intrinsic reference frame after the confederate had used an intrinsic reference frame.

The significant effect of Target Plane indicates that participants preferred to use the lexical terms *above* or *below* to *left* or *right,* regardless of reference frame. This was expected because the top/bottom axis is easier to identify (than the left/right axis) due to asymmetries of the reference objects along this axis (Bryant & Wright, 1999).

One of the important goals of the experiment was to distinguish lexical priming effects from reference-frame priming effects. A sole effect of reference frame priming would have meant that participants aligned reference frames as much when the prime and target scenes were the same (represented in the upper portion of Figure 2) as when the prime and target scenes were different (represented in the lower portion of Figure 2). However, the presence of a significant interaction between Prime reference frame and preposition condition meant that this was not the case. This interaction was caused by two of the conditions; the other three pairs of same/different conditions yielded no significant differences between them. This indicates that the apparent lexical priming effect was evident only when the relative reference frame was used and the figure and reference objects were aligned vertically. Such a situation would seem unusual, because it should be the case that lexical priming is evident for all same/different pairs of conditions.

However, there is an alternative explanation for this pattern of data that does not rely upon lexical priming. We noted that participants used intrinsic left and right differently (in fact, inversely) to the confederate. Thus, participants would describe the prime scenes in Figure 2 as *the dot left of the camera*, whereas the confederate described them as *the dot right of the camera.* Therefore for half of the match tasks in the relative, vertical, different condition, the non-matching scene also provided a match to the confederate's description if an intrinsic reference frame was applied (according to the participant's interpretation). This would be the only condition in which potential confusion could arise. Therefore, for this condition, if participants chose the non-matching scene in the match task they would effectively be primed to use the intrinsic reference frame rather than the intended relative reference frame.

In Experiment 2, we therefore made the confederate describe intrinsic left and right in the way that participants had done in Experiment 1, in order to see whether the observed interaction was due to lexical priming, or was instead an artefact of the participants' misinterpretation of what the confederate was describing as intrinsically left and right.

Experiment 2

Experiment 2 was a replication of Experiment 1, with the exception that what was described as left and right intrinsic was reversed in accordance with participants' interpretations from Experiment 1. 16 further students from the University of Edinburgh were paid volunteers in the experiment, which lasted 20 minutes.

Results

The analyses were conducted in the same fashion as Experiment 1. Table 2 shows the mean number of intrinsic responses used by subjects in each of the 8 conditions. As in Experiment 1, there was a significant main effect of Prime Reference Frame ($F1(1,15) = 6.79$; $p < .05$; $F2(1,11) = 24.36$; $p < .01$): Participants used an intrinsic reference frame more often following an intrinsic description by the confederate than following a relative description by the confederate.

Table 2:
Mean percentage intrinsic responses in Experiment 2.

	Relative Prime		Intrinsic Prime	
	Same	Diff	Same	Diff
Vertical	32.1	26.6	41.2	39.1
Horizontal	39.6	38.1	52.1	48.9

However, the interaction between Prime Reference Frame and Preposition did not reach significance, indicating that there was no effect of using the same lexical item for the prime and target ($F1(1,15) = .018$; $p > .05$; $F2(1,11) = 3.02$; $p > .05$). All other interactions were non-significant (all $p > .05$).

General Discussion

The results of this study show that interlocutors align reference frames when describing objects' locations. Importantly, the results indicate that alignment is not due to lexical priming caused by the experimental participant repeating the preposition just used by the confederate.

The apparent lexical priming effect shown in Experiment 1 was due to the participants interpreting left and right intrinsic differently to what was intended by the confederate. When the source of this difficulty was addressed in Experiment 2, this effect was not evident. The results showed no difference in the proportion of reference-frame alignment when the naïve participant used the same preposition as the confederate, as when a different preposition was used.

Our results support the hypothesis that interlocutors align at many levels of representation when conversing (Pickering & Garrod, in press). Furthermore, it extends this alignment beyond linguistic representations and into an aspect of conceptual representation, i.e., the spatial domain. These results, however, do not precisely determine the mechanism by which alignment is achieved. In particular it is not clear whether participants make some use of a deliberate strategy to make the task easier for their partner. For example, it is possible that participants may be partly aware of the importance of aligning without realizing exactly what they are aligning on.

What is surprising about these results is that there was no cumulative effect of lexical priming and reference frame priming. Other studies have shown a larger alignment effect when more factors are common between the prime and the target (e.g. Branigan et al., 2000; Cleland & Pickering, 2003). The lack of a cumulative effect may be due to the nature of the lexical items used in this experiment. The prepositions were used to refer to both their intrinsic relation and relative relation, and so held little meaning independent of the reference frame.

The results also support the work of Carlson-Radvansky and Jiang (1998) who showed that reference frames were subject to negative priming. Their investigation only focused upon inhibition along a single axis of a representation. The results of this study extend these findings and show that activation of one axis of a reference frame activates the whole reference frame (at least in 2 dimensions), indicating that reference frames are a holistic representation.

Previous work (Schober, 1993, 1995) has shown that interlocutors will co-ordinate the reference object and origin of a reference frame to the matcher in a match-and-describe task. However, this did not show that interlocutors were aligning reference frames; as Levinson (2003) has argued, it is possible to have a non-egocentric relative reference frame and an egocentric intrinsic reference frame. The results presented here provide strong evidence that interlocutors do align reference frames. Ongoing work is investigating the predictions made by Levinson's definitions of reference frames that an egocentric/intrinsic description (e.g. *the ball in front of me*) can prime the use of an allocentric/intrinsic description (e.g. *the ball in front of the car*).

Previous work (Branigan et al., 2000; Clark & Wilkes-Gibbs, 1986; Garrod & Anderson, 1987) has shown that interlocutors align representations during dialogue. The results of these experiments extend this body of evidence to show that independent of lexical priming, alignment extends beyond the language faculty and that interlocutors also align reference frames to describe objects' locations in a scene.

Abstract

Many evaluations of cognitive models rely on data that have been averaged or aggregated across all experimental subjects, and so fail to consider the possibility that there are important individual differences between subjects. Other evaluations are done at the single-subject level, and so fail to benefit from the reduction of noise that data averaging or aggregation potentially provides. To overcome these weaknesses, we develop a general approach to modeling individual differences using *families* of cognitive models, where different groups of subjects are identified as having different psychological behavior. Separate models with separate parameterizations are applied to each group of subjects, and Bayesian model selection is used to determine the appropriate number of groups. We demonstrate the general approach in a concrete and detailed way using the ALCOVE model of category learning and data from four previously analysed category learning experiments. Meaningful individual differences are found for three of the four experiments, and ALCOVE is able to account for this variation through psychologically interpretable differences in parameterization. The results highlight the potential of extending cognitive models to consider individual differences.

Introduction

Much of cognitive psychology, as with other empirical sciences, involves the development and evaluation of models. Models provide formal accounts of the explanations proposed by theories, and have been developed to address diverse cognitive phenomena ranging from stimulus representation (e.g., Shepard 1980), to memory retention (e.g., Anderson & Schooler 1991; Estes 1997), to category learning (e.g., Ashby & Perrin 1988; Berretty, Todd, & Martignon 1999; Kruschke 1992; Tenenbaum 1999). One recurrent shortcoming of these models, however, is that (whether intentionally, or as an unintended consequence of methodology) humans are usually modeled as 'invariants', and not as 'individuals'. This occurs because, most often, models are evaluated against data that have been averaged or aggregated across subjects, and so the modeling assumes that there are no individual differences between subjects.

The potential benefit of averaging data is that, if the performance of subjects really is the same except for 'noise' (i.e., variation the model is not attempting to explain), the averaging process will tend to remove the noise, and the resultant data will more accurately reflect the underlying psychological phenomenon. When the performance of subjects has genuine differences, however, it is well known (e.g., Estes 1956; Myung, Kim, & Pitt 2000) that averaging produces data that do not accurately represent the behavior of individuals, and provide a misleading basis for modeling.

Even more fundamentally, the practice of averaging data restricts the focus of cognitive modeling to issues of how people are the same. While modeling invariants is fundamental, it is also important to ask how people are different. Experimental data reveal individual differences in cognitive processes, and in the psychological variables that control those processes, that also need to be modeled.

Cognitive modeling that attempts to accommodate individual differences usually assumes that each subject behaves in accordance with a different parameterization of the same basic model, and so the model is evaluated against the data from each subject separately (e.g, Ashby, Maddox, & Lee 1994; Nosofsky 1986; Wixted & Ebbesen 1997). Although this avoids the problem of corrupting the underlying pattern of the data, it also foregoes the potential benefits of averaging, and guarantees that models are fit to all of the noise in the data.

Another problem with individual subject analysis, from a model theoretic perspective, is that fitting each additional subject requires an extra set of free parameters, and so leads to a progressively more complicated accounts of the data as a whole. As has been pointed out repeatedly in the psychological literature recently (e.g., Myung & Pitt 1997; Pitt, Myung, & Zhang 2002), it is important both to maximize goodness-of-fit and minimize model complexity to achieve the basic goals of modeling. Unnecessarily complicated models that "over-fit" data often do not provide any insight or explanation of the cognitive processes they address, and are less capable of making accurate predictions when generalizing to new or different situations.

A better approach, therefore, is to partition subjects according to their individual differences, and model the averaged or aggregated data from each group. Under this approach, data are addressed by a set of models, called a model *family*, where a different parameterization is applied to each group of subjects. Where averaging is appropriate, within groups of subjects, it is applied. Where averaging is not appropriate, between groups of subjects, it is not applied.

In this paper, we apply these ideas to model individual differences in category learning, using Kruschke's (1992) well known, empirically successful, and widely used ALCOVE model. Our basic approach, however, is applicable to any model of category learning or, indeed, models of other cognitive phenomena.

Modeling Individual Differences in Category Learning

Formally, a model family $\mathcal{M}$ partitions the subjects S into G groups $S \rightarrow \{S_1, \ldots, S_G\}$, and so partitions the complete data D into G averaged data sets $D \rightarrow \{D_1, \ldots, D_G\}$. For the ith data set, a model family also specifies a model parameterization θ_i. Any possible partitioning of subjects can be considered, including the possibility that all subjects are in the same partition (corresponding to aggregating across subjects), or that each has their own partition (corresponding to a complete individual analysis). Differences in the category learning processes between groups are revealed by differences in the parameter values they use.

Because of the enormous flexibility allowed by model families, they can be made almost arbitrarily complicated, and could potentially fit any data set perfectly by adding new models, with extra parameters, to account for any remaining unexplained variation in data. It is necessary, therefore, for model fitting methods to use model selection criteria that balance goodness-of-fit and model complexity. The application of Bayesian model selection criteria (e.g., Pitt *et al.* 2002) is most easily pursued by specifying a probabilistic account, in the form of a likelihood function, of the relationship between a parameterized model family and empirical data.

To develop a likelihood function for category learning, suppose, under a proposed partitioning of subjects, the ith partition has k_i subjects, and that the n category learning trials are divided into blocks, with the jth block having b_j trials. Choosing one block with $b_1 = n$ corresponds to an analysis of the average response probabilities over all trials. Choosing n blocks with all $b_j = 1$ corresponds to a trial-by-trial analysis.

In a two category learning experiment, the data take the form of counts, d_{ij}, of the number of correct responses made by all of the subjects in the ith partition on the jth block of learning trials. Suppose also that a category learning model M, with its parameterization θ_i, predicts a correct response probability of γ_{ij} at the ith group of subjects on the jth block. Then the likelihood of the data arising under the model is given by the binomial distribution: $p(d_{ij} \mid M_i, \theta_i) = \binom{b_j k_i}{d_{ij}} \gamma_{ij}^{d_{ij}} (1-\gamma_{ij})^{b_j k_i - d_{ij}}$. The likelihood of a model family simply extends this result to consider every block of trials and every partition, so that

$$p(D \mid \mathcal{M}) = \prod_i \prod_j \binom{b_j k_i}{d_{ij}} \gamma_{ij}^{d_{ij}} (1-\gamma_{ij})^{b_j k_i - d_{ij}}. \quad (1)$$

The extension of this likelihood function to more general category learning experiments with more than two possible category responses, using a multinomial distribution, is straightforward.

Having defined the likelihood function, the Bayesian Information Criterion (BIC: Schwarz 1978) can be applied to balance goodness-of-fit with the complexity of a model family. The BIC is given by:

$$\text{BIC} = -2 \ln p(D \mid \theta^*) + P \ln N, \quad (2)$$

where P is the number of parameters in the model family (i.e., the sum of all the parameters used by the models for each group), N is the total number of data, and θ^* is the maximum likelihood parameterization over all the models. Different possible model families, corresponding to different groupings of subjects, can be compared in terms of their BIC values, with the minimum BIC corresponding to the most likely account of the data.

Demonstration Using ALCOVE

Kruschke's (1993) Study

ALCOVE is a model of category learning that uses an exemplar-based stimulus representation, similarity-based generalization that is mediated by selective attention, and error-based learning from external feedback. The standard ALCOVE model Kruschke (1992) uses four free parameters. These control the rate of learning for attention weights (λ_a), the rate of learning for the associations between stimulus representations and category responses (λ_w), the gradient of the generalization function that measures stimulus similarity (c), and the way in which different levels of evidence for category alternatives are mapped onto response probabilities (ϕ).

Kruschke (1993) considered the ability of ALCOVE to model human category learning for filtration and condensation Categorization tasks (Garner 1974). The results of four separate experiments were reported, covering two filtration tasks (called position-relevant and height-relevant, due to the nature of the stimuli) and two condensation tasks (called condensation A and

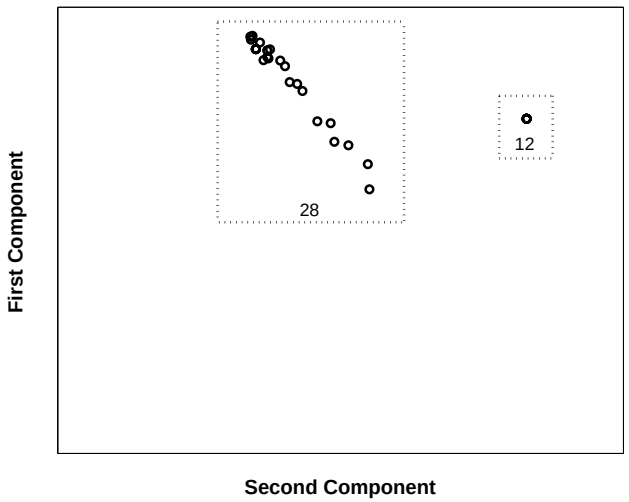

Figure 1: The application of the heuristic for partitioning subjects to find two groups for the position-relevant filtration data.

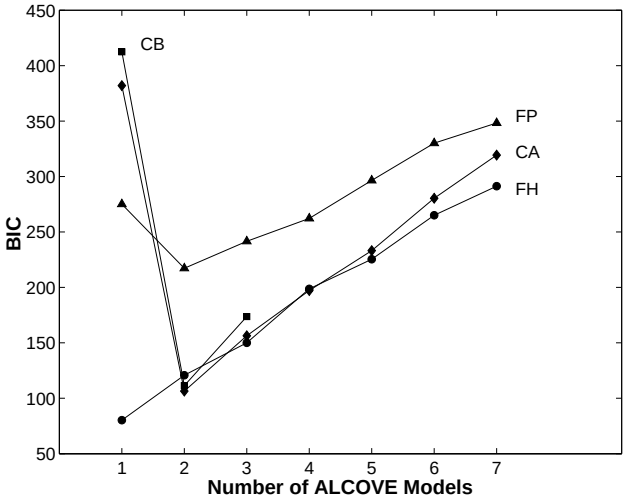

Figure 2: The pattern of change in BIC values for each clustering of the position-relevant filtration (FP), heigh-relevant filtration (FH), condensation A (CA) and condensation B (CB) category learning data.

condensation B). The data involved a total of 160 subjects, with 40 completing each task. Kruschke (1993) fit ALCOVE to all four sets of experimental results simultaneously, using trial-by-trial data formed by averaging across all 40 subjects. An examination of the individual learning curves in the raw data, however, reveals a large degree of variation between subjects within each experiment, and raises the possibility that there are psychologically meaningful individual differences in category learning.

Heuristic for Partitioning Subjects

In classification and clustering, an essential requirement for the determination of homogenous classes is a calculable similarity or distance measure between objects being compared (Gordon 1999). For category learning, the objects are the individual experimental observations for each subject, (i.e., each subject's learning curve). A candidate measure for describing the similarities between these curves is the correlation coefficient, which we used in a two-stage heuristic. In the first stage, singular value decomposition is applied to produce an ordered eigenvector-based representation of the similarities between the learning curves of subjects. In the second stage, a simple k-means clustering algorithm is applied to this representation to find clusters of subjects.

For each of Kruschke's (1993) four category learning tasks, this heuristic was applied to produce a range of partitions of the data, from a single group with all 40 subjects, to seven groups with differing numbers of subjects in each group. As a concrete example of this process, the clusters found when the subjects were divided into two groups for the position-relevant filtration task are shown in Figure 1. Each circle represents the learning curve of a subject, represented according to their values along the first two component eigenvectors. The two groups of subjects identified by k-mean clustering are superimposed using broken lines. One cluster on the left encompasses 28 of the subjects, while a much tighter cluster on the right encompasses the remaining 12 subjects.

Model Fitting and Evaluation

For each of the clusterings for each task, maximum likelihood fits of ALCOVE were found using a different parameterization for each group according to Eq. (1). BIC values were then calculated for each model family using Eq. (2), giving the results[1] shown in Figure 2. It is clear that the minimum BIC for three of the four tasks (position-relevant filtration, condensation A and condensation B) is achieved when two separate groups of subjects are considered, while the height-relevant filtration data are best modeled by considering all of the subjects as learning in the same way.

Figures 3 and 4 give more detailed results for, respectively, the position-relevant filtration and condensation

[1]The full range of BIC values for the CB task is not shown because, when four or more groups are considered, at least one of the groups contains only subjects who become less accurate as learning blocks progress. ALCOVE is qualitatively unable to accommodate the decrease in the averaged learning curve for this type of group, leading to very poor fit, and very large BIC values. We have omitted these values.

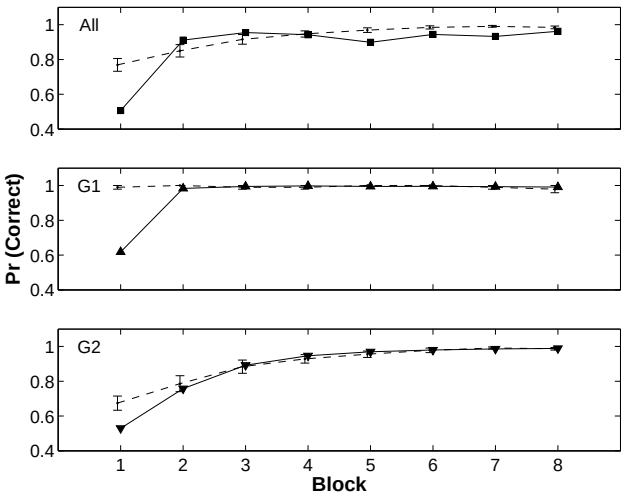

Figure 3: The change in accuracy across learning blocks for the subjects (broken lines) and ALCOVE (solid lines), for the one group ("All") and two group ("G1" and "G2") model families on the position-relevant filtration task.

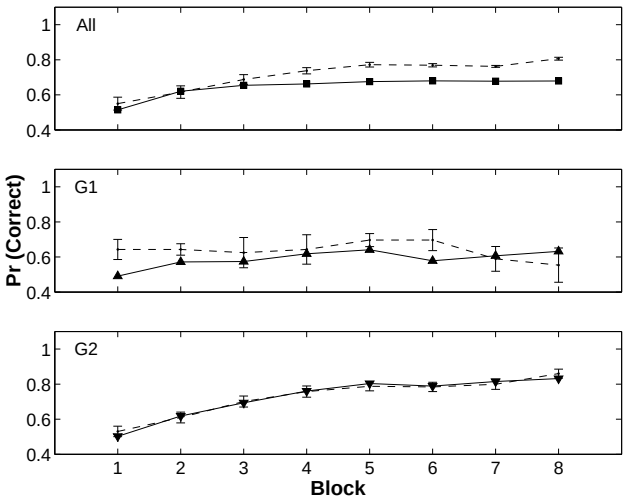

Figure 4: The change in accuracy across learning blocks for the subjects (broken lines) and ALCOVE (solid lines), for the one group ("All") and two group ("G1" and "G2") model families on the condensation A task.

A tasks. In both of these figures, the top panel, labeled "All", shows the average accuracy of all subjects across the eight learning blocks, and the maximum likelihood fit of ALCOVE to these data. The middle and bottom panels show the first (G1) and second (G2) groups of subjects proposed by the two-group model family that is prefered by the complexity analysis. These panels show the average accuracy for both groups of subjects separately, together with the maximum likelihood ALCOVE learning curve.

Figure 3 shows that the moderate learning evident when treating the subjects as having no individual differences is better modeled as coming from two distinct groups of subjects. Some subjects, in the first group, maintain near-perfect accuracy throughout the category learning task. Other subjects, in the second group, learn more gradually, only achieving near-perfect accuracy in the last few learning blocks. Figure 3 shows that, with the exception of the rapid achievement of accuracy in the first block for the first group of subjects, ALCOVE is able to model both of these patterns of learning[2].

In a similar way, Figure 4 shows that the gradual increase in accuracy, evident when treating the subjects as having no individual differences, is better modeled as coming from two distinct groups of subjects. The first group exhibits almost no learning, while the second learns at a moderate rate. Once again, ALCOVE is able to model both of these patterns of learning. In fact, ALCOVE has more difficulty accommodating the learning data resulting from averaging across all of the subjects. What the individual differences analysis developed here suggests is that this inability may not indicate a fundamental weakness in ALCOVE, but rather that the averaging process involved in summarizing human performance has masked important individual differences, and corrupted the underlying learning patterns in the original data.

Table 1 shows the maximum likelihood parameter values for each group of subjects in the model family with the lowest BIC value, for all four learning tasks. These parameter values are generally interpretable in terms of the different learning behavior revealed by the individual differences analysis. For example, for the position-relevant filtration task, the first group of subjects have a greater λ_w value than the second group, consistent with their more rapid learning. For this task, both groups have high ϕ values, consistent with their decisiveness (or 'confidence') in mapping evidence into response probabilities. Both groups of subjects in the condensation A task, however, have much lower ϕ values, consistent with their inferior learning performance, and the first group in this task, who basically fail to learn, have a very low ϕ value. Other comparisons of this type, both within and across tasks, generally have meaningful and useful interpretations,

[2]It is possible the application of one of ALCOVE's descendents, such as RASHNL (Kruschke & Johansen 1999) or the unified mixture of experts model (Kruschke 2001), which emphasize rule-oriented learning and incorporate a rapid attention shifting capability (Kruschke 1996), could overcome the deficiency.

Table 1: Maximum likelihood parameter values for each group of subjects in the model family with the lowest BIC value, for all four learning tasks. FP=position-relevant filtration, FH=height-relevant filtration, CA=condensation A, CB=condensation B.

Task	Group	λ_w	λ_a	c	ϕ
FP	G1	0.38	0.49	1.68	3.20
	G2	0.06	27.0	6.83	2.66
FH	All	0.23	0.58	1.56	1.00
CA	G1	0.47	1.14	2.53	0.27
	G2	0.24	0.38	7.52	0.93
CB	G1	0.41	0.32	0.79	0.31
	G2	0.17	0 .02	3.37	1.09

and highlight the ability of ALCOVE to represent psychologically important variations in category learning through its free parameters.

Discussion

There are at least two conclusions that can be drawn from modeling individual differences in Kruschke's (1993) category learning data using ALCOVE. The first is that there is strong evidence for large and meaningful differences in the learning behavior of groups of subjects for three out of the four tasks. Previous analyses, adopting the standard cognitive modeling practice of considering all of the subjects as a single group, are insensitive to these potentially important patterns of variation. The second conclusion is that, for these data, the basic ALCOVE model is generally able to capture the individual differences in learning, when asked to model appropriate groups of subjects. It does this by applying different psychologically meaningful parameterizations to accommodate variations in learning behavior. In this sense, what the results presented here demonstrate is that accounting for individual differences using model families has the potential to extend and increase the usefulness of existing cognitive models significantly.

From this promising start, there are a number of directions in which the basic approach described here can be refined and extended. Most generally, the extension to other cognitive phenomena provides a rich set of opportunities for future research. As with category learning, there is evidence of individual differences in the similarity data used to model stimulus representations (e.g., Ashby *et al.* 1994), and in the curves of forgetting used to model memory retention (e.g., Anderson & Tweney 1997; Heathcote, Brown, & Mewhort 2000; Myung, Kim, & Pitt 2000; Wixted & Ebbesen 1997), and in a range of other data from which cognitive models have been developed.

Considering a broader range of cognitive phenomena highlights the possibility of extending individual difference accounts to incorporate fundamentally different models to capture between-subject variation, rather than relying solely on parametric variation within the same basic model. In memory retention, for example, one group of subjects could be modeled using a power function while another group is modeled using an exponential decay function. For stimulus representation, some groups of subject could be modeled using a featural representation while others use a dimensional representation. In the category learning context considered here, it may make sense to model some subject groups using ALCOVE or its descendants, but apply a very different category learning model to others, such as the fast and frugal account provided by Categorization-By-Elimination (Berrety *et al.* 1999).

One of the weaknesses of the demonstration presented here is the reliance on the BIC to compare different competing individual differences models. While the BIC is conceptually and computationally straightforward, it is insensitive to the complexity effects arising from the functional form of parametric interaction within the individual models (Myung & Pitt 1997). This is a potentially important shortcoming, especially if fundamentally different models are used to explain performance for different subject groups. There are, for example, many competing models of retention that use two parameters (Rubin & Wenzel 1996), with different complexities that the BIC is unable to distinguish. The obvious remedy for this problem is to use more sophisticated model selection criteria that are sensitive to all of the components of model complexity. These include measures such as the Stochastic Complexity Criterion (SCC: Rissanen 1996) and Normalized Maximum Likelihood (NML: Rissanen 2001). For cognitive models that resist the formal analysis needed to derive these measures, an alternative is to use numerical methods, such Markov Chain Monte Carlo (e.g., Gilks, Richards, & Spiegelhalter 1996) to approximate the Bayesian posterior distributions that compare model families.

A final possibility for refining the approach demonstrated here is to use a more principled optimization approach to determine the groupings of subjects. The method used here, based on k-means clustering of correlations, is a sensible heuristic one. It is particularly well suited to a model like ALCOVE that requires considerable computation effort when finding maximum likelihood parameter values. The clustering heuristic is designed to identify good partitions of the subjects into groups, and only requires parameter fitting to be done once for each possible number of subject groups. For other models, however, such as analytic models of memory retention, finding maximum likelihood parameterizations is straightforward. In these cases, a more explicit optimization approach to finding partitions could be adopted, because repeated pa-

rameter fitting is possible. For example, a stochastic hill-climbing procedure could be used to find subject groups that minimize the BIC, SCC or NML of the model family.

Collectively, these possibilities describe a principled and general approach for building and evaluating cognitive models, using a variety of basic models and numbers of parameterizations, to accommodate individual differences. It is a more general approach to cognitive modeling than one that averages data, assuming there are no individual differences. It is a more powerful and succinct approach than one that uses subject-by-subject analysis. While much of the work to realize this potential remains to be done, the demonstration presented here, using multiple ALCOVE models to capture differences in category learning, provides a good concrete example of its potential. It shows how using model families, and relying on principled model selection criteria, can be used to develop detailed and interpretable accounts of both how people are cognitively the same, *and* how they are different.

The Origin of the Linguistic Gender Effect in Spoken-Word Recognition: Evidence from Non-Native Listening

Abstract

Two eye-tracking experiments examined linguistic gender effects in non-native spoken-word recognition. French participants, who knew German well, followed spoken instructions in German to click on pictures on a computer screen (e.g., *Wo befindet sich die Perle*, "where is the pearl") while their eye movements were monitored. The name of the target picture was preceded by a gender-marked article in the instructions. When a target and a competitor picture (with phonologically similar names) were of the same gender in both German and French, French participants fixated competitor pictures more than unrelated pictures. However, when target and competitor were of the same gender in German but of different gender in French, early fixations to the competitor picture were reduced. Competitor activation in the non-native language was seemingly constrained by native gender information. German listeners showed no such viewing time difference. The results speak against a form-based account of the linguistic gender effect. They rather support the notion that the effect originates from the grammatical level of language processing.

Introduction

Gender is a grammatical category that varies largely across the languages of the world. The range goes from elaborate gender systems in some languages to the absence of gender in others. Both German and French are languages with grammatical gender. The form of definite articles, for example, marks gender in both languages. German definite articles are $der_{(masc.)}$, $die_{(fem.)}$, and $das_{(neut.)}$; French definite articles are $le_{(masc.)}$ and $la_{(fem.)}$ respectively. Grammatical gender usually becomes most noticeable when we learn a second language with gender. Is it *der Berg* ("mountain") or *die Berg* in German? Do the French say *le citron* ("lemon") or *la citron*? The present study investigated how gender marking influences the recognition of spoken-words in a non-native language. Results help clarify the origin of the linguistic gender effect.

It is generally accepted in the psycholinguistic community that during the recognition of spoken words, multiple word candidates get simultaneously activated and compete against each other (e.g., Marslen-Wilson & Welsh, 1978; McQueen, Norris, & Cutler, 1994). When a native speaker hears, for example, the German word *Perle* ("pearl"), lexical representations of words with similar onsets, such as *Perücke* ("wig"), will initially be activated along with *Perle*. Activated word candidates compete for recognition until they no longer match incoming segmental information. Thus, *Perücke* will drop out of the competitor set as the /l/ in *Perle* is being heard. It has also been shown that non-native listeners consider candidate words in both the non-native and their native language simultaneously (e.g., Marian & Spivey, 2003; Weber & Cutler, 2004). Thus, for French listeners the beginning of German *Perle* may additionally activate French words like *perruque* and *persil*.

Eye-tracking is a methodology that has been found to be eminently suited for the investigation of competitor activation (e.g., Tanenhaus, Spivey-Knowlton, Eberhard, & Sedivy, 1995). It makes use of the fact that participants make saccadic eye movements to pictures of objects on a computer screen as the names of the objects are mentioned in spoken sentences. Locations and latencies of eye movements on pictures are recorded using a camera mounted on a headband and can be used to examine lexical competition in spoken-word recognition. While participants hear the name of a target picture, they look more often to pictures with names that are similar in onset with the target name than to pictures with phonologically unrelated names. It has been shown that such competition effects, defined as fixation proportions to pictures, closely map to activation levels of word candidates as simulated in computational models of spoken-word recognition such as TRACE (Allopenna, Magnuson, & Tanenhaus, 1998; Dahan, Magnuson, & Tanenhaus, 2001).

By now, numerous eye-tracking studies have successfully confirmed phonological competitor activation in spoken-word recognition. Dahan, Swingley, Tanenhaus, and Magnuson (2000) took the subject one step further by testing whether morphosyntactic context can affect competitor activation. In particular, they tested whether gender marking on definite articles influences the recognition of subsequent nouns. A number of studies had already looked at lexical gender effects in word recognition using experimental paradigms other than eye-tracking (e.g., Bates, Devescovi, Hernandez, & Pizzamiglio, 1996; Colé & Segui, 1994; Grosjean, Dommergues, Cornu, Guillelmon, & Besson, 1994). These studies found that the presence of gender-congruent articles or adjectives enhances the recognition of target nouns whereas gender-incongruent forms slow recognition down. Dahan et al. (2000), investigated the role of gender information on spoken-word recognition more directly: They tested the activation of competitors that matched the initial sounds of a target noun

but mismatched the gender marking on the article. They found that the presence of a gender-marked definite article could prevent early activation of competitors inconsistent with that gender: Upon hearing *cliquez sur le bouton* ("click on the$_{(masc.)}$ button"), French listeners did not fixate the picture of a *bouteille* ("bottle$_{(fem.)}$") more often than pictures with unrelated names.[1]

The study by Dahan et al. (2000), however, could not assess the origin of the lexical gender effect. Are listeners really sensitive to grammatical gender information in the preceding context or is it simply listeners' sensitivity to the co-occurrence of the form of the article with the form of the noun that restricts lexical access? In order to reduce the high co-occurrence of definite articles and nouns, Dahan and colleagues interposed a gender-marked adjective in a follow-up study. In their preliminary results, activation of gender-mismatching competitors was no longer reduced when low frequency gender-marked adjectives preceded target nouns. This was seen as evidence for a form-based origin of the gender effect. In a Russian eye-tracking study, however, Sekerina (2003) found that gender-marked color adjectives do restrict referential sets to gender-matching nouns. She interpreted the results as evidence for a grammar-based effect of gender in spoken-word recognition.

Spoken-word recognition in a non-native language offers the possibility to distinguish between a form-based and a grammar-based account of the linguistic gender effect. The gender of a noun can differ across languages: *Canon* is, for instance, feminine in German but masculine in French. The present study tested whether French listeners, who are highly proficient in German, use native French gender information during the recognition of spoken words in German. Since the form of the article differs in German and French, presentation of the German article should not give rise to co-occurrence information for the French form of the article and a given noun. Thus, if the gender of words in French exerts an effect on the recognition of spoken words in German (even though French is not presented), this would strongly suggest that the locus of the gender effect is not form-based.[2]

Recent eye-tracking studies have shown that listeners cannot deactivate the lexicon of the native language even in a monolingual non-native situation where the native vocabulary is irrelevant (Marian & Spivey, 2003; Spivey & Marian, 1999; Weber & Cutler, 2004). Native language competitors that were phonologically related to the non-native target were activated more than phonologically unrelated words: Upon hearing the English target *desk*, Dutch listeners, who knew English well, fixated the picture of a lid more than unrelated pictures because the Dutch name for lid (*deksel*) was phonologically related to *desk* (Weber & Cutler, 2004). Similarly, grammatical information from the native language might interfere with non-native listening. Imagine native French speakers listening to German in an eye-tracking study. Spoken instructions in German tell them to click on target pictures on a screen. The name of the target picture is preceded by the definite article in the instructions, and target and competitor names overlap in onset in both languages. In the non-native presentation language German, target and competitor names share gender, so the gender marking on the article cannot exclude the competitor as a lexical candidate. In the native language French, however, target and competitor differ in gender. If we find no competitor activation for French listeners, this would suggest that they use native French gender information to disambiguate between target and competitor.

Experiment 1

Method

Participants Eighteen native speakers of French, mostly students (mean age of 22), took part in the experiment for monetary compensation. They had normal or corrected-to-normal vision and normal hearing. On average, they had studied German as a foreign language for 10 years in secondary education, starting at a mean age of 12 (ranging from 10 to 16). To confirm their high proficiency in the non-native language, they underwent a vocabulary test in German after completing the eye-tracking experiment. For each target and competitor noun in the experiment plus a number of filler nouns with neuter gender, they had to name the correct gender. The average score was 78% correct.

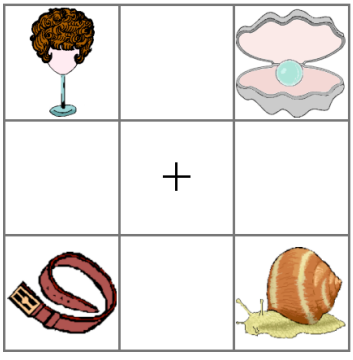

Figure 1: Example of visual display presented to participants.

[1] Dahan et al. (2000) also showed that when no phonological overlap between picture names was given, gender-marked articles were not sufficient to restrict participants' attention to pictures with gender matching names.

[2] Only very few studies have looked at gender marking effects in non-native spoken-word recognition. Guillelmon and Grosjean (2001), for example, found in an auditory naming study no effects of congruency for late English-French bilinguals. It is not established yet whether gender marking influences competitor activation in a second language.

Table 1: Examples of German (G) target-competitor pairs and their French (F) translations.

		target	competitor
same-gender pair	G	Perle$_{(fem.)}$	Perücke$_{(fem.)}$
	F	perle$_{(fem.)}$	perruque$_{(fem.)}$
		"pearl"	"wig"
different-gender pair	G	Kassette$_{(fem.)}$	Kanone$_{(fem.)}$
	F	cassette$_{(fem.)}$	canon$_{(masc.)}$
		"tape"	"canon"

Materials Thirty German nouns referring to picturable objects were chosen as targets.[3] Each target was paired with a competitor. The onset of the competitor overlapped phonemically with the onset of the target in both German and French (e.g., German target *Perle* /pɛrlə/ was *perle* /pɛrl/ in French; German competitor *Perücke* /pɛrykə/ was *perruque* /pɛryk/ in French). The target was always of the same gender in German and French, but the gender of the competitor divided the pairs into two groups (see Table 1). In 15 "same-gender" pairs, target and competitor shared gender in both languages. The target *Perle* ("pearl"), feminine in both German and French, was for example paired with the competitor *Perücke* ("wig"), also feminine in both languages. In these pairs, neither German nor French gender information could constrain initial competitor activation. In 15 "different-gender" pairs, target and competitor still shared gender in German, but were of different genders in French. The target *Kassette* ("tape"), feminine in both languages, was for instance paired with the competitor *Kanone* ("canon"), which is feminine in German but masculine in French. Whereas German gender information could not exclude the competitor as a potential lexical candidate in these pairs, French gender information could.

Two phonologically unrelated distractors, with random gender, were added for each target (e.g., *snail* and *belt*). Neither the German nor the French names of the unrelated distractors overlapped with the German target nouns. The target was heard in the experiment, whereas competitor and unrelated distractors were not heard. The overall lexical frequency of targets and competitors did not differ significantly in either of our target-competitor pairs.

Thirty filler trials were added. Great care was taken in the fillers to dispel expectations that pictures with phonologically similar names or matching gender were likely targets. Three more representative trials were constructed as practice trials.

All pictures were colored line drawings, taken from the IMSI MasterClips Image Collection (1990). In pre-tests, we asked participants to name and rate target and competitor pictures. The agreement between participants' responses and intended names was 88% correct, and the goodness of the pictures was rated with a mean of 5 on a scale from 0 to 6.

German target nouns, preceded by their definite article with nominative case marking, were embedded in a carrier sentence (e.g., *Wo befindet sich die Perle*, "Where is the pearl"). Spoken instructions were recorded. The duration of putative overlap between target and competitor (e.g., the duration of /pɛr/ in *Perle*) was on average 200 ms for same-gender pairs and 174 ms for different-gender pairs.

Procedure Participants were tested individually. At the beginning of a session, they received instructions in German, telling them to click on the object on the screen that was mentioned in a sentence. Sentences were presented auditorily over headphones and started 550 ms after the appearance of the pictures on the screen. The set of pictures was not shown to the participants before the experiment.

While they were listening, participants' eye movements were monitored using an SMI EyeLink head-mounted eye-tracker. A camera on the participants' dominant eye provided the input to the tracker. Onset and offset times and the spatial coordinates of the participants' fixations were recorded (250 Hz sampling rate). All pictures were presented in color on a 3 x 3 gray grid (see Figure 1). Each cell measured 7.5 x 7.5 cm, corresponding to a visual angle of approximately 7°, which is well within the resolution of the eye-tracker (better than 1°). The pictures of a target item, its competitor, and two unrelated distractors were displayed together in one trial. Positions of target and competitor objects were randomized across trials. Each experimental trial was preceded by at least one filler trial. Along with the eye movements, the position of the mouse click was recorded.

For the analysis, graphical software was used to display the locations of the participants' fixations as dots superimposed on the four pictures for each trial and each participant. Fixations were coded as pertaining to the cell of the target object, the competitor object, or one of the two unrelated distractors. Fixations that lay clearly outside the cell of an object were not used for the computation of the fixation probabilities. Saccade times were not added to fixation times.

Results and Discussion

Seventeen trials were removed from the analysis because participants clicked on an object other than the target or no fixation on the target object was found (3.2% of all trials). The low percentage of errors suggests that French participants had no difficulties performing the task in German. Fixation proportions, at successive 10 ms time frames, were averaged over participants and items for separate analyses.

[3] Since the French gender system is limited to feminine and masculine, selected German target nouns were either of feminine or masculine gender, but never neuter.

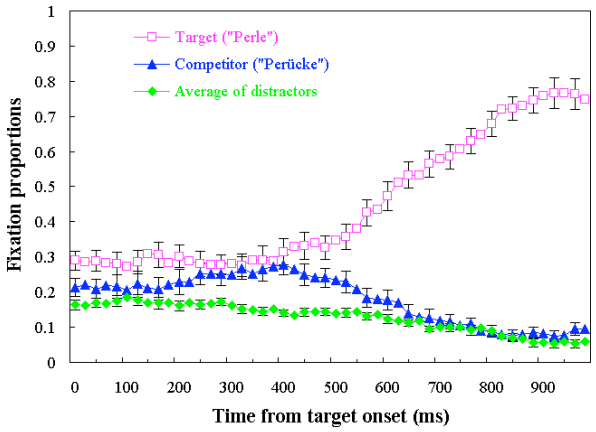

Figure 2: Same-gender pairs. Fixation proportions of French listeners over time for German targets, competitors, and averaged distractors.

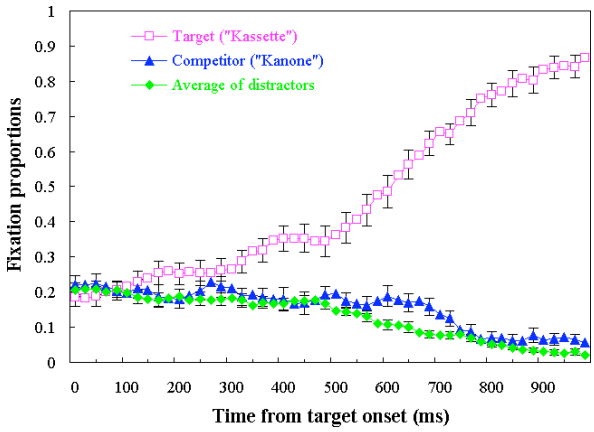

Figure 3: Different-gender pairs. Fixation proportions of French listeners over time for German targets, competitors, and averaged distractors.

Figure 2 presents the averaged proportions of fixations after target noun onset for trials with same-gender pairs. Fixation proportions for the two unrelated distractors were averaged. It takes typically about 150 to 200 ms before a programmed eye movement is launched (e.g., Matin, Shao, & Buff, 1993). Thus, fixations on the target object that are triggered by acoustic information are observable starting around 200 ms after target noun onset.

In same-gender pairs, French listeners fixated competitor objects more than distractor objects. Between 200 and 600 ms, the proportion of fixations was on average 23.9% for the competitor and 14.9% for the unrelated distractors. A one-factor ANOVA on the mean proportion of fixations between 200 and 600 ms, with picture (with the two levels 'competitor' and 'unrelated distractors') as the within-participants factor, showed that the competitor was fixated significantly more than the average of the unrelated distractors ($F_1[1, 17] = 11.41$, $p < .005$; $F_2[1, 14] = 13.92$, $p < .005$). Neither gender information from the non-native presentation language, nor gender information from their native language could narrow the lexical candidates down to the target. In consequence, the competitor was activated during the presentation of the target due to their phonological similarity.

Prior to the point that fixations could be driven by acoustic information from the target noun, no variation between fixation proportions was found. Analyses in the 0-200 ms time window showed no reliable difference in initial fixations between competitor and unrelated distractors ($F_1[1, 17] = 2.15$, $p > .1$; $F_2 < 1$). Thus, the difference between fixations to the competitor and the unrelated distractors in the 200-600 ms time window cannot be attributed to a general bias toward the picture of the competitor.

The pattern of results changed for different-gender pairs. French participants no longer fixated competitor objects more than distractor objects (see Figure 3). Over the 200-600 ms time window, 17.9% of the fixations were on average to the competitor and 15.6% to the distractors. A one-factor ANOVA confirmed the lack of a difference in viewing times (F_1 & $F_2 < 1$). As before, no reliable differences were found for different-gender pairs in initial fixation proportions between 0 and 200 ms after target noun onset (F_1 & $F_2 < 1$).

In different-gender pairs, gender information carried by the article in German could not constrain competitor activation, but French gender could. Despite its phonological similarity with the target noun, the competitor was not activated when the article of the target noun did not match in gender with the competitor in French. Evidently, French listeners used native French gender information to constrain competitor activation in German.[4] The experiment was conducted in German, and the linguistic form of the article did not exclude the competitor as a potential lexical candidate. In other words, the probability of the target noun being *Perle* or *Perücke* was equally high after hearing the phoneme sequence /di:pɐr/, *die Per*. Nevertheless, competitor activation was eliminated for French listeners. This suggests that the high form-based co-occurrence of article and target did not constrain lexical access in our experiments, but rather grammatical gender carried by the article did.

Experiment 2

As a control, we presented the same stimuli to listeners whose native language was German. If native gender information of the pictures had restricted eye movements in Experiment 1, both same-gender pairs and different-gender pairs should now offer competition for German listeners in Experiment 2, since in German target and competitor share gender in both pairs.

[4] The same analyses were run again after removing trials for which the French native speakers made a mistake in the vocabulary test. The results were comparable.

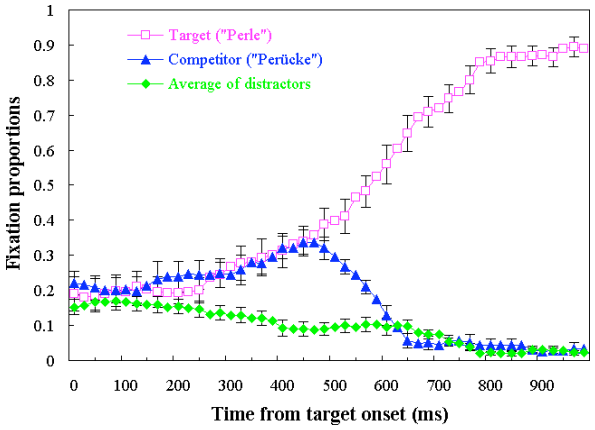

Figure 4: Same-gender pairs. Fixation proportions of German listeners over time for German targets, competitors, and averaged distractors.

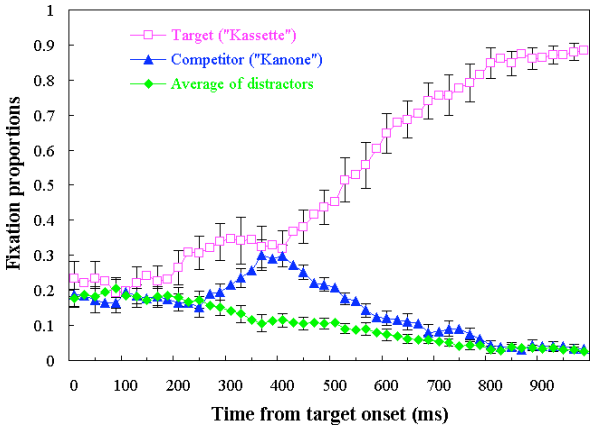

Figure 5: Different-gender pairs. Fixation proportions of German listeners over time for German targets, competitors, and averaged distractors.

Method

Participants Twelve native speakers of German participated, in return for a small payment. They were all students (mean age of 21), and had normal or corrected-to-normal vision and normal hearing. They had all learned French as a second language in school, but were not required to exercise their proficiency here.

Materials The materials were as in Experiment 1.

Procedure The procedure was as in Experiment 1. Participants were not made aware of potential cross-language competition in the experiment.

Results and Discussion

Participants never clicked on an object other than the target. Figure 4 shows the averaged proportions of fixations after target noun onset for trials with same-gender pairs. As is immediately apparent, higher fixation probabilities were observed for the competitor than for the unrelated distractors. Over the 200-600 ms time window, the proportion of fixations was on average 26.74% for the competitor and 11.16% for the unrelated distractors. This difference was significant in a one-way ANOVA ($F_1[1, 11] = 22.97$, $p < .002$; $F_2[1, 14] = 19.47$, $p < .01$). Just as the French listeners in Experiment 1, German listeners activated competitors when gender-marked articles could not exclude them as potential lexical candidates. No reliable difference in viewing times was observed in the first 200 ms after target noun onset ($F_1[1, 11] = 1.30$, $p > .2$; $F_2[1, 14] = 1.97$, $p > .1$).

In contrast to the French listeners, however, German listeners also looked more often at the competitor than at the unrelated distractors in different-gender pairs. Between 200-600 ms after target noun onset the proportion of fixations was on average 20.98% for the competitor and 11.84% for the unrelated distractors. An ANOVA showed a significant effect of type of picture ($F_1[1, 11] = 10.68$, $p < .01$; $F_2[1, 14] = 8.34$, $p < .02$). Again, viewing times for competitor and unrelated distractors did not differ in the first 200 ms after target noun onset (F_1 & $F_2 < 1$).

The results of Experiment 2 showed that during the presentation of the target noun, German listeners activated the competitor in both same-gender and different-gender pairs.

Summary

A recent eye-tracking study by Dahan et al. (2000) has shown that grammatical context can constrain lexical access. In their study, French participants followed spoken instructions in French to click on pictures on a screen while their eye movements were monitored. Eye movements to pictures were interpreted as evidence for the activation of the words corresponding to those pictures. We know from previous eye-tracking studies that competitor pictures with names that overlap in onset with the name of a target picture are fixated more than pictures with unrelated names (see e.g., Tanenhaus et al., 1995). In the spoken instructions in Dahan et al's study, the names of the target pictures were immediately preceded by articles. In the absence of gender marking on the article (i.e., French plural article *les*), competitor activation was found for phonologically related nouns. However, when competitors matched in initial sounds with a target noun but mismatched in gender marking on the preceding article, early competitor activation was eliminated.

The present eye-tracking studies investigated the role of linguistic gender for the process of listening to a non-native language. An interesting aspect of non-native listening is that the gender of words can vary between the native and the non-native language. Thus, gender information as conveyed

by the presentation language, i.e. the non-native language, can be opposed to gender information from the listeners' native language. In Experiment 1, French participants followed spoken instructions in German to click on pictures on a computer screen (e.g., *Wo befindet sich die Perle*, "Where is the pearl"). When target and competitor noun shared gender in both German and French, French participants fixated competitor pictures more than unrelated pictures. However, when target and competitor were of the same gender in German but of different gender in French, early fixations to the competitor picture were eliminated. This result was interpreted as evidence that competitor activation in the non-native language was constrained by native gender information. In Experiment 2, German listeners were presented with the same materials and showed no such difference in viewing time.

In general, our results support Dahan et al's (2000) findings that gender information influences lexical access, but also crucially offer new insights with respect to the origin of the gender effect. On one account, listeners compute distributional regularities between the co-occurrence of the form of the article and the form of the noun and use these form-based regularities to restrict lexical access. On another account, distributional regularities would be computed using grammatical categories. On the form-based account, probabilities would express the likelihood of the target being *Perle* upon hearing the segmental sequence /diːpɛr/; on the grammar-based account, probabilities would express the likelihood of the target being *Perle* upon hearing /pɛr/ plus having feminine gender information from the context. Within one language, these two accounts are difficult to tease apart. However, non-native listening offered the possibility to separate them, because linguistic gender effects of the non-presentation language are unlikely to be caused by form-based regularities of that language.

The fact that, for French listeners in Experiment 1, competitor activation in German was eliminated when French gender information mismatched the gender of the target speaks against an form-based account of the linguistic gender effect. Our results rather support the notion that the linguistic gender effect originates from the higher, grammatical level of language processing.

Acknowledgments

We thank Delphine Dahan for inspiring discussions on the topic. Further thanks go to Alissa Melinger for helpful comments on an earlier version of this paper. This research was funded by SFB 378 "ALPHA" to the first author, awarded by the German Research Council.

Structural Differences in Abstract and Concrete Item Categories

Abstract

We explored reasons why categories of abstract items, such as *cognitive processes* or *communication*, are weak determinants of abstract item similarity. Three experiments, using exemplar listing tasks and similarity ratings on the exemplars, compared the structure of taxonomic categories of abstract versus concrete entities. In comparison to concrete item categories, we found that there were consistently fewer typical items for abstract item categories, but that nonetheless item pairs within abstract item categories were rated about as similar to each other as items matched in typicality in concrete categories. Abstract item pairs from different categories were more similar than concrete item pairs from different categories, indicating lower semantic distance of the categories. Taken together, these data suggest that taxonomic categories are less informative for abstract than concrete items. We discuss alternative factors in abstract concept organization.

Taxonomies for Abstract Items

When asked to sort the items *apple*, *cabbage*, *squirrel* and *duck* into stacks, most people will presumably sort them into types of *produce* and *animals*. Concrete item categories have a strong, graded structure organized around prototypical items, and are relatively distinct from other categories. As a consequence, concrete item categories offer salient dimensions that are readily used in reasoning involving their members. Because of their family resemblance structure, in which items share groups of features with other category members, two typical items from the same category, such as squirrel and duck, are likely rated as similar. Categories are important organizational structures that enable us to use our knowledge in reasoning processes such as classification, similarity judgments, and to effectively acquire new knowledge through analogies and inferences. As such, categories touch upon and inform many areas of research that are central to cognitive science.

Categories for concrete things are only a subset of our knowledge. We also have representations of abstract and complex entities, such as processes, events, mental experiences, stories, and relations. Abstract concepts constitute a large and important part of our daily experiences and actions. Even so, very little is known about categories of abstract concepts. A complete understanding of the organization of our knowledge cannot be achieved unless we understand how other kinds of things are organized.

There are several reasons to expect that taxonomic categories for abstract items are not as distinct and salient as those for concrete items. First, some research has shown that abstract items (in this case, verbs) are not organized into distinct clusters, but that classes of such items overlap with others on many dimensions (Huttenlocher & Lui, 1979; Miller & Johnson-Laird, 1976). The features of concrete items are highly correlated; that is, given that two items share a feature, they typically share some other features as well, making them more similar to each other than to items in different categories. As a consequence, categories are more distinct from one another. In contrast, a verb may share features with verbs from many different categories to a similar extent. Hampton (1981) has made a similar proposal for abstract concepts in general. Thus, categories of relational concepts may overlap more and offer less constraint on their processing.

Second, taxonomic similarities appear to have little impact on similarity judgments of abstract concept pairs. When people rate the similarity of item pairs that are taxonomically similar and that also share a thematic relation, people tend to focus on the thematic relation for abstract items, but on the taxonomic relation for concrete items. For example, participants often rate *jealousy* and *anger* as similar because jealousy *may lead to* anger. Much less frequently, participants refer to the information that both are emotional states (Wiemer-Hastings & Xu, 2003). In contrast, given an item pair like *cat* and *mouse*, participants will more frequently refer to both being animals than to one *chasing* the other (Wiemer-Hastings & Xu, 2003; Wisniewski & Bassok, 1999). Participants use thematic relations as explanations for concrete item similarity judgments mostly when no taxonomic similarity is present; for abstract item pairs, thematic relations are used frequently also when items are taxonomically related.

One possible explanation for this striking effect is that taxonomic similarity of abstract items, e.g., the similarity of two emotions, or two cognitive processes, is not salient information. This raises the question how useful taxonomic abstract item categories are. Abstract categories may be useful for talking about groups of abstract items, such as events, but they may not reflect actual knowledge organization in memory. For example, the concepts joy, sadness, wedding and farewell could be organized into emotion terms and events, or into concepts of positive versus negative connotation, respectively. There is no salient dimension here along which to unambiguously split

the four words into two groups, and the relations between joy and wedding, or sadness and farewell, are quite salient. If taxonomic classes of abstract items turn out to be of little functional use, the next question would be whether abstract items are organized around some alternative information. The results discussed above suggest thematic relations as one possible source for abstract category organization. Recently, it has been found that when given a choice, individuals routinely sort even concrete items around thematic relations (Murphy, 2001; Lin & Murphy, 2001). For example, when presented with the four items squirrel, mouse, nut, and cheese, people may sort them into pairs of animal and type of food (squirrel – nut; mouse – cheese) instead of animals and foods. Since such thematic relations have already been shown to play a very prominent role in similarity judgments of abstract item pairs, chances are good that they will provide dominant information to their categorization as well.

The main concern of this paper is the question why people do not effectively use taxonomic abstract item categories, such as emotions, cognitive processes, actions, attitudes, attributes, and so on in category-related tasks such as similarity ratings. The main hypothesis was that abstract and concrete item categories differ in the amount of constraint that they place on membership. This was examined in two separate hypotheses. First, it was hypothesized that participants would generate fewer typical examples for abstract than for concrete item categories. That is, we expected that fewer abstract items would be listed by a large number of participants. Related to this issue, we also hypothesized that abstract item categories would be less distinct than concrete item categories. That is, we predicted that members of two abstract item categories would be almost as similar to each other as members of the same abstract item category. Abstract items from the same category may share comparatively fewer category-specific features, and may share relatively more features with members of other categories. Three experiments tested these hypotheses.

Experiment 1

Experiment 1 compared the numbers of types and tokens generated for abstract versus concrete item categories. In accordance with the first hypothesis, it was predicted that significantly more participants would list the same items for concrete categories than for abstract ones.

Method

Twenty participants generated exemplars for 24 commonly used categories, 12 for concrete, and 12 for abstract items. Example categories are *tools*, *pets*, *object attributes*, and *positive emotions*. Category lists were constructed from taxonomic trees and extended to include a variety of categories. Since there is no well-established taxonomic model for abstract items, abstract item categories were taken from ontologies and social categories. Each participant listed exemplars for all categories, to control for individual differences. Categories were listed in random order. There was no time limit. Participants were instructed to list as many exemplars for each category as they could think of.

Results & Discussion

For each category, types and tokens were calculated. Type scores count different exemplars, whereas tokens also count repeated mentions of exemplars. The ratio of both indicates the agreement among participants or the mean production frequency for each exemplar. A highly available exemplar should be mentioned by many participants, resulting in a higher production frequency or token / type ratio. Categories that place strong constraints on cognitive processing would be characterized by higher token / type ratios.

Abstract and concrete categories did not differ in the number of types that were generated. However, more idiosyncratic responses were generated for abstract item categories. Consistent with the prediction, more participants listed the same exemplars for concrete item categories (see Table 1), t (10)=7.93, p<0.001. For the vast majority of abstract item categories, individual exemplars were listed by fewer than 2 participants, whereas on average, at least 3 participants listed exemplars for concrete item categories.

Table 1: Types and Token / Type Ratios from Experiment 1

	Types	Tokens / Type
Concrete	37.75	3.41
Abstract	35.42	1.57

Token / type ratios for concrete item categories varied from 2.25 (*foods*) to 4.78 (*pets*), *SD*=0.79. In contrast, very few participants listed the same exemplars for abstract item categories. The token / type ratio varied only very little across the different abstract item categories (*SD*=0.43), with the token /type ratios ranging from 1.06 (*prosocial actions*) to 1.82 (*social offenses*). The only exception to this dichotomy was one abstract item category, *object attributes*, which is actually relatively concrete, and which had a ratio of 2.71. Without this category, the standard deviation of ratios for abstract categories was reduced to *SD*=0.26.

Overall, it seems that low agreement is a general characteristic of abstract item categories, which could indicate that these categories do not reflect actual organization in memory. Instead, participants may retrieve exemplars out of a different organization, leading to high response variation. A possible confound that may account for the observed differences was that abstract item categories tend to be broader categories than concrete item categories. Experiment 2 varied the broadness of the categories systematically to test this.

Experiment 2

Experiment 2 replicated the procedure used in Experiment 1 with categories of different specificity levels. One set of categories was at a broad, abstract level, another set was more specific. Generally, specific categories contain fewer members and should thus place stronger constraints on exemplar production. The expectation was, accordingly,

that agreement would be higher for specific categories. The categories used in this Experiment are shown in Table 2.

Table 2: Categories Used in Experiment 2

	Broad	Specific
Abstract	Actions	Reasoning
	Mental Processes	Mental Disorders
	Communication	Object attributes
	Events	Character Traits
	Attitudes	Offensive Actions
Concrete	Animals	Wild animals
	Plants	Pets
	Foods	Tools
	Liquids	Office Supplies
	Natural Substances	Beverages

We also selected abstract and concrete item categories that were based on situations. Three such categories were based on *scenes* or *settings*, and three were based on *events* or *scripts*. Both have been shown to be efficient schemata for organizing knowledge in a systematic way (Shank & Abelson, 1977; Tversky & Hemenway, 1983). It has been argued that abstract items are characterized by situational contexts, rather than by internal features (Barsalou & Wiemer-Hastings, in press; Wiemer-Hastings & Graesser, 2000). Abstract concepts typically involve agents, goals, relations, actions and events, and emotional or cognitive experiences. As such, they are akin to abstract situation schemata, and may be organized around situations. Thus, we predicted that abstract, but not concrete, items generated for a given situation, are perceived as similar to each other.

Method

Sixty undergraduate students at Northern Illinois University participated in this experiment. Twenty participants each generated exemplars for broad categories, more specific categories and for situation categories that were either a setting (e.g., *workplace*) or an event (e.g., *wedding*). For the situation-based categories, abstract item instructions asked for "actions, events, or mental processes that could occur in the situation"; concrete item instructions asked for "objects occurring in the situation". The settings and events were identical for both groups to allow for direct comparison. Altogether, there were ten broad and ten specific categories (five abstract, five concrete), and six situation-based categories.

Results & Discussion

As in the first experiment, we evaluated the results through token /type ratios. The data replicated the findings from Experiment 1. Table 3 shows the results. Interestingly, the use of more specific categories (e.g., *offensive action* instead of the broad *action*) did not improve agreement scores, even though it had an effect on the number of types listed.

The token / type ratio for broad category exemplars did not statistically differ between concrete and abstract items, suggesting that broad superordinate categories of concrete items structurally resemble abstract item categories. A significant difference was found for specific categories, where the token / type ratios were significantly higher for concrete than for abstract items ($t(8)=3.76$, $p<0.01$) and also higher than for concrete items listed for broad categories ($t(8)=3.10$, $p<0.05$). That is, switching to a more specific category level increased category constraint for concrete, but not for abstract items.

The data suggest that the abstractness level does not have much of an impact on how many typical exemplars are produced for abstract categories. It seems, then, that the differences observed for concrete versus abstract items reflect a more general difference: Abstract item categories do not have many typical exemplars, and the few typical exemplars have relatively low typicality scores, as measured by the number of participants naming each. These first results suggest that categories may not provide the strong basis for inferences and similarity judgments for abstract items that is usually seen for concrete items.

Table 3: Types and Token / Type Ratios from Experiment 2

		Types	Token / Type
Broad	Abstract	42.2	1.63
	Concrete	34.8	1.78
Specific	Abstract	30.6	1.49
	Concrete	28.6	3.25
Situation	Abstract	36.3	1.60
	Concrete	57.7	2.07

Surprisingly, the pattern did not change much for situation categories. Participants generated substantially more items for concrete situation categories than for other categories, suggesting that this category type places low constraint on concrete items. This is not the case for abstract items. Still, the token / type ratio was significantly higher for concrete than for abstract items, $t(10)=2.72$, $p<0.05$. That is, there seems to be more consensus on what concrete items occur in situations than what abstract processes, events or states may.

Experiment 3

Previous experiments suggested that taxonomic category membership plays a minor role in similarity judgments for abstract items (Wiemer-Hastings & Xu, 2003). We suspect that this is due to overlapping categories, such that members of the same category may be only slightly more similar than members of different categories. Accordingly we predicted that, overall, item pairs should be more similar for items from the same category, but that this effect should be more pronounced for concrete item pairs than for abstract ones. That is, we expected that the difference in similarity for same- vs. different-category abstract item pairs would be significantly smaller than for concrete item pairs.

Alternatively, item pairs used in previous experiments were very untypical exemplars of their respective categories, which could have lowered the salience of their category membership. In the present experiment, we

control for this by collecting similarity ratings only for the most typical items for abstract item categories. If membership in the same taxonomic category does not substantially increase similarity ratings, compared to ratings of members of different categories, then typicality is unlikely the reason for people's neglect of taxonomic similarity in similarity judgments.

With respect to the situation-based categories, we had no strong predictions. However, we suspected that concrete items may be less constrained by such categories than by taxonomic categories, thus that situation-based abstract item categories may actually be more distinct.

Method

We used high-frequent exemplars collected in Experiment 2 for different category types to make sure they would be typical items for the categories. There were two constraints: first, we omitted some items that had been generated for multiple categories (with the exception of *happiness* and *happy* for one set for lack of alternative choices). Second, the exemplars selected from concrete versus abstract item categories were matched in typicality, for fair comparison. This means that the concrete item pairs used in Experiment 3 were not the most typical of their categories, but instead were matched in typicality (as measured by generation frequency in Exp. 2) to the abstract item pairs. Accordingly, the actual differences between these categories are likely strongly underestimated in this Experiment.

Fifty-seven undergraduates from Northern Illinois University participated in this experiment for course credit. Four participant groups were formed at random to judge the similarity of items generated for broad, specific, abstract situational, or concrete situational categories, respectively. For the broad and specific categories, participants were presented with three items from each of five categories, resulting in 15 items presented in random order. Abstract and concrete items were rated by the same participants, but were blocked to avoid contrast effects on the ratings. For the situation-based categories, there were six categories for abstract and concrete items each. Since 18 items had to be rated in pair-wise combinations, concrete and abstract items were presented between-subjects to avoid fatigue effects.

Each item was rated against each other item in the context of the entire list, to allow for category information to affect the ratings. Thus, if category information was accessible from the items, we expected that items associated with the same categories would be rated as more similar to each other than to items not belonging to the category. The order of ratings was varied so that item pairs were presented in ascending vs. descending order, and so that each item was presented equally often in first vs. second position of the item pairs. Ratings were made on a 6-point scale.

Results & Discussion

We predicted that the difference in similarity for abstract item pairs within and between categories would be significantly smaller than for concrete item pairs. A mixed ANOVA tested the effects of within-subject variables abstractness (concrete vs. abstract) and category membership (same vs. different), and between-subjects variable category level (broad vs. specific) on similarity ratings. The mean similarity scores for these variables are shown in Tables 4 for broad and specific categories.

Table 4: Ratings from Experiment 3

	Broad		Specific	
Category	Abstract	Concrete	Abstract	Concrete
Same	3.63	3.88	2.94	3.84
Different	2.74	1.98	2.00	1.45
Difference	0.89*	1.90*	0.94*	2.39*

Category Distinctness of Abstract Items Similarity was rated significantly higher for items of the same categories than those of different categories across all item groups, $F(1, 25)=154.88$, $MSE=0.21$, $p<0.001$. This was a large effect, $\varepsilon^2=0.86$. Further, consistent with our prediction, an interaction of category membership with concreteness was revealed, $F(1, 25)=46.68$, $MSE=.21$, $p<0.01$. This effect was moderately high, $\varepsilon^2=0.65$. As can be gathered from the difference scores in Table 4, concrete item categories had a larger semantic distance overall (difference $M=2.14$) than abstract item categories ($M=0.92$). Similarity ratings among abstract items were significantly higher for same-category pairs than between-category pairs, but, consistent with our predictions, this difference was significantly smaller than for concrete item categories.

Category Type There was a small significant effect of category level, $F(1, 25)=4.77$, $MSE=1.35$, $p<0.05$; $\varepsilon^2=0.16$. Overall, as we expected, specific categories produced greater differences in same-versus different category pair similarity. Table 4 shows that this effect is almost absent for abstract item categories (the interaction of category membership and concreteness approached significance, $p=0.09$). So, specific categories of abstract items are not more distinct than broad categories – their members are quite similar to members of other specific categories. This suggests that low category distinctness is a general problem for abstract items categories that spans different category levels. This finding is consistent with the results from Experiment 2, which showed that category specificity had no impact on the production frequency of the exemplars.

Situations and Abstract Items Table 5 shows the mean similarity scores obtained for situation-based categories. The pattern of similarities is almost reverse from the one obtained for taxonomic categories: Abstract item pairs are more similar for same-category pairs than concrete ones, and abstract item categories are more distinct.

In comparison to taxonomic categories, the most striking difference is the low similarity of concrete items of the same situation-based category. Abstract items that are typical for a given situation seem to be as highly similar to each other as members of the same taxonomic abstract item category. This is an important finding because it suggests that situations put semantic constraints on abstract, but not on concrete items. Accordingly, situation knowledge may

affect abstract item processing (such as similarity ratings) relatively more than concrete items.

Table 5: Ratings for Situation–Based Categories

Category	Abstract	Concrete
Same	3.44	2.28
Different	2.50	1.78
Difference	0.94*	0.50

In an ANOVA, the interaction of concreteness and category membership approached significance, p=0.07. Specifically, only similarity ratings of *abstract* items differed significantly for pairs of the same versus pairs of different categories. The semantic distance was the same for taxonomic and situation categories for abstract items. In contrast, there was a drop in distinctness for concrete situation-centered categories (M=0.50) as opposed to the taxonomic categories.

Conclusions

We have shown that abstract and concrete item categories differ systematically. The observed differences may explain some of the processing differences for abstract and concrete items. In particular, abstract item categories were found to have exemplars with low production frequencies, i.e. very few exemplars are named by two or more individuals. Experiment 2 showed that the token / type ratio for abstract item categories is at the same level as that for general concrete item categories. Thus, asking for exemplars of *mental processes* may be somewhat akin to asking for exemplars of *objects*. However, they differ from broad concrete item categories in at least two important respects: First, more specific subcategories of abstract items do not evoke exemplars with higher production frequencies, as they do for concrete items. Experiment 2 showed that in fact, the token / type ratio dropped slightly from broad (1.63) to specific (1.49) abstract item categories. At the same time, the number of different exemplars mentioned was lowered, suggesting that the more specific categories were indeed smaller categories.

Second, Experiment 3 shows that broad concrete item categories are more distinct than either broad or specific abstract item categories. Thus, we do not think that the difference between abstract and concrete item categories can be reduced to a difference in the abstraction level with abstract item categories being "super-superordinate" categories. An alternative explanation may be that abstract item categories are not organized around typical exemplars which, having most resemblance to the other exemplars, are recollected most often. Instead, it may be that participants have to actively construct the category as an ad hoc category. Memory for abstract concepts does not seem to be organized around taxonomic categories that can be recalled easily using a category label.

Further, the data suggest that abstract categories, regardless of category level, are less distinct from each other than concrete categories. Rated similarity is significantly higher for members of the same category versus members of different categories. However, the difference is much smaller than for concrete item categories (with the notable exception of situation-based categories). At this point, it is important to remember that the concrete exemplars used in the third Experiment were actually not the most typical exemplars of their categories by far, that is, the differences we observed in category distinctness probably substantially underestimate actual differences.

Considering these differences, it does not come as a surprise that taxonomic categories are used less as a basis for similarity judgments of abstract than of concrete item pairs. We also predict based on these data that there would be little agreement in sorting tasks using abstract items since there does not seem to be a strongly organized categorical structure for abstract items.

The data raise the question how meaningful abstract item categories are. Are they merely nominal in function, to enable us to talk about them at an abstract level? Or do they have any impact on the representation and processing of abstract concepts? Our data do not give conclusive answers to these questions but suggest that categorization of abstract items follows different principles and perhaps functionalities from that of concrete items. Referring to related studies, in what follows we will outline a few hypotheses. First, it is informative to link the present findings to studies that explore the content of abstract concepts in comparison to concrete concepts. Second, research on similarity processes, which are presumably involved in categorization, suggests that thematic relations may be an important source for structuring abstract concepts. It is possible that this is linked to the first issue – that the content of abstract concepts is more compatible with thematic than with taxonomic processing.

Conceptual Content

Hampton (1981) found that not all abstract concepts fit a prototypical structure and suggested that this may be due to lower feature correlations. Most likely, this is related to the content of abstract concepts. Hampton suggested on the basis of feature lists that their content consists of social components of situations, e.g., agents, behaviors, and goals. More recent findings are consistent this view. Analyses of conceptual content through property generation tasks suggest that abstract concepts have few "properties" in the classical sense (i.e., perceptual or functional features, parts) but instead have a high percentage of features that are related to situations and to subjective experiences in a situation (Barsalou & Wiemer-Hastings, in press; Wiemer-Hastings, Krug & Xu, 2001; Wiemer-Hastings & Xu, under review). Knowledge of situations is also linked to concrete concepts (e.g., part of our knowledge of chairs is that a person can sit on them to eat or to write), but concrete concepts are further distinguished through a high proportion of entity properties (i.e, external and internal parts, surface features, etc.), of which abstract concepts have very few or none.

Abstract concepts have two specific characteristics that are likely related to the observed lack of distinctive categories for abstract items. One is the smaller set of

features that are used to describe them, which may reflect that the concepts themselves have a lot more overlap than concrete concepts do. This could be directly linked to the high similarity scores of exemplars listed for different categories (Experiment 3). This may be accentuated even more by the other characteristic, namely that features of abstract concepts are significantly less specific than those of concrete concepts (Wiemer-Hastings & Xu). For example, a concrete item may be linked to a specific action (e.g., eating) while an abstract item may simply be linked to *some action*. The differentiation of categories requires a relative large feature basis to arrive at categories that are characterized by somewhat distinct clusters of features. General features are not likely to offer such differentiation.

Hierarchical category structures have been linked to correlated features. Concrete item properties such as parts and functions may be systematically correlated, e.g. because of causal links between their features (e.g., a bee *can fly* and *has wings* – it can fly *because* it has wings). In contrast, situation properties can be more flexibly linked to form a seemingly unlimited variety of abstract concepts. An agent can be found in a large variety of situations and there are few constraints on their specific set-up. Thus, categories governed largely by situational features may all overlap since they would all involve the same kinds of features, to different extents. For example, emotions and cognitive processes would both involve a person, a situation that the emotion / cognition is related to, and an element of introspective experience. As a result, abstract item categories may have *more overlap* with *less distinction*.

Taxonomic versus Thematic Relations

One central purpose of categories is to allow for inferences about novel objects, based on their similarity to known objects. Likewise, categories in memory enable us to generate instances that could serve a particular function. Categories can be structured around taxonomic information, where several items are *a kind of X* (e.g., *gadgets, emotions*) or thematic information, where items fill complementary roles in a proposition. For example, they may be related via an instrument function (*knife, meat*), a causal relation (*cause, effect*) a temporal sequence (*question, answer*) or through a variety of other relations. Both taxonomic and thematic relations are part of our knowledge of abstract and concrete concepts, but there may be a functional advantage in the majority of situations to using one over the other when dealing with concrete or abstract concepts. In particular, as suggested by the findings discussed initially in this paper, taxonomic inferences may be more critical for novel concrete objects or reasoning involving objects, while thematic inferences may be more functional when processing abstract concepts. For example, to specific actions require objects with specific functional or perceptual features; identifying one is facilitated by categories organized around functional and perceptual features. In contrast, abstract item categories may have less practical relevance. For example, to understand an emotion, it may be more important to process events and traits leading up to it than to have quick access to other emotions.

Our data suggest that taxonomic relations of abstract items are comparatively weak. We suggest that abstract items may be organized quite differently from concrete items. For example, Experiments 2 and 3 show that situations provide as much structure for abstract items as taxonomic categories. While concrete items are used across different situations, abstract items that occur in a similar context are perceivably interrelated. We suspect that in the future, cognitive scientists may discover quite different structural principles for abstract item categories, and that they will centrally involve thematic relations.

Abstract

This paper aims to study the effect of structure in a graphical layout on object-location memory. In two experiments several structures have been examined in respect to the performance of object-location retrieval. The results show that beside simple object-to-object spatial relations also the spatial relation of three objects is encoded in human spatial memory as a noisy distance-angular pair. Further the results show that noise in spatial memory is not symmetric, but seems to be distorted towards a higher accuracy to the horizontal directions.

Introduction

One aspect of human spatial memory is the usage of allocentric frames of references to encode and retrieve the location of an object. This aspect of human spatial memory implicates that the structure of a graphical layout might affect the performance of object-location encoding and retrieval.

Basically the study presented in this paper is motivated by some experiments performed recently in the community of information visualization. One experiment of Travanti & Lind (2001) investigated object location memory in hierarchical information structures across different instances of 2D and 3D displays. The results of their tests show, that the 3D display improves performance in the spatial memory task they designed. They were aware that their result does not prove their hypothesis that the natural appearance of the 3D display used in the test actually affected the improved performance. They speculated that possibly other visual properties of an item in the 3D display were used as a reminder for the memory task. Cockburn (2004) showed that neither the natural appearance nor the different sizes of the items in the 3D display affected the performance of object-location retrieval. In both studies the memory task was to associate alphanumerical letters to the items. Therefore Cockburn suspected that the vertical orientation of Travanti & Lind's 2D display made the formation of effective letter mnemonics more difficult than the horizontal 3D layout, because words and word combinations normally run horizontally left to right. By analyzing these studies we came to the conclusion that one major factor had not been considered - the factor of the object-to-object spatial relations (the structure of the graphical layout respectively).

The effect of layout structure on object-location encoding and retrieval could best be investigated if a computational model of human spatial cognition is considered. Recently some compelling works toward this goal has been published (Wang et al 2002; Johnson et al 2002). This paper shows one application area for computational models of human spatial memory, but also sheds some new light on the requirements of such a model.

Design of the Experiments

The papers cited above inspired the design of the experiments in this study. There were two phases in the cited experiments. In the encoding phase the subjects had to learn associations of alphanumerical letters to one object in the structure. During the encoding phase a click on one of the objects in the display highlighted the object and revealed a letter at the top of the display, which had to be associated to the position of the object. In the retrieval phase the subjects had to find all of the letters, one at a time. A randomly selected letter had been shown at the top of the display area, and the subject had to click the object associated with it.

This design of the experiment has two drawbacks. First the subjects are free to choose the objects in the encoding phase and second that alphanumerical letters are used as retrieval cues. The first point gives subjects the opportunity to develop strategies for learning the object-letter associations. In combination with the usage of alphanumerical letters this increases the probability that subjects create mnemonics through possible abbreviations of words that can be read from a row.

In respect to a cognitive model these are task specific aspects. The study of this paper was interested in more general mechanisms of object-location encoding/retrieval. To meet this goal the design of the experiment had to prevent subjects from further processing object-locations in the encoding phase. This suggested the task of memorizing a randomly created sequence of highlighted objects from the structure. The number of correct repeated sequences is used as a measure of performance. Furthermore allows this kind of memory task an effective analysis of the errors subjects make.

Two experiments were performed. The first experiment investigated the factor horizontal vs. vertical orientated

layout structure and the factor of the existence vs. non-existence of symmetric features in the layout structure. The second experiment focused on the investigation of noise in the encoding of spatial object-to-object relations.

Subjects and Apparatus

30 volunteer subjects (only male, average age 35) were recruited from the staff of our institute to perform both experiments. All subjects had normal or corrected-to-normal vision. Three sets of different structures have been created. Each structure consisted of red spheres of equal size. The layout structures were presented against a black background on a 21'' VGA monitor with a resolution of 1280x1024 pixels. The monitor was in front of the subjects within 2 feet. Subjects were asked to respond by clicking with a mouse. Subjects wore a head-mounted eye-tracking device while they were conducting the experiments.

Experiment 1

The first experiment aimed at showing if the performance of recalling objects is still improved in the horizontal oriented structures, even if in the experimental design no semantic content is used. Further one horizontal structure was added that contains not the symmetric features of the horizontal structure used by Travanti & Lind and Cockburn. Another purpose of this experiment was to show if there is any learning progress in the performance of object-locations encoding/retrieval. It might be possible, that subjects become more familiar with a structure the longer they are exposed to them. In combination with the factor of symmetric features in the structure it might be speculated, that in the presence of symmetric features a subject needs less time to become familiar with the structure.

Materials

Figure 1 shows the three structures that were used in the first experiment. The first two structures are similar to the structures used by Travanti & Lind. Each structure consists of 25 spherical items. The first structure represents a 2D display of a tree-structure, like it is used in most common graphical user interfaces. The second structure represents the structure of the 3D display, where any perspective clues have been removed. The third structure is equivalent to the first one except that it is rotated by 90^0 counterclockwise.

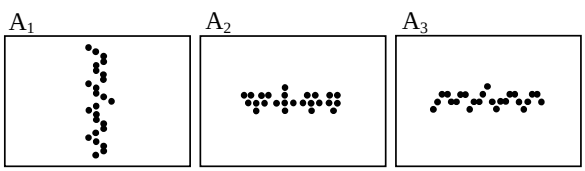

Figure 1: Set of structures used in experiment 1.

Design and Procedure

In each encoding retrieval trial, the subject was presented one structure. After an acoustical signal the computer started to highlight objects of one randomly created sequence. Only one object of the sequence was highlighted at once. The sequences were five items long. The highlighted object differed from the not highlighted objects by color (blue instead of red), increased size and a cross that appeared within its circle shape. The end of a sequence was indicated by an second acoustical signal. Subjects were instructed to repeat the highlighted objects in correct order, by clicking them with the mouse. After five objects had been clicked, another acoustical signal rang out and a short online questionnaire with a subjective rating occurred. Subjects had to rate how confidant they were about their answer and the degree of difficulty to memorize the sequence. The questionnaire was inserted between the tests of two sequences to reduce stress by diversion. Each subject was tested on all structures. The experiments consisted of three blocks. In each block the same structure was tested four times in succession. Between each block there was a break of one minute. Subjects were randomly divided into six groups with five persons, where in each group the order of the three blocks belongs to one of the six possible permutations.

Before the main experiment started, each subject passed through a training run, consisting of two blocks of four sequences. The structures presented in the training run consisted of 16 objects randomly located on the display. The length of the sequences subjects had to learn varied between four and six items.

All sequences for the training run and for the actual test were created randomly only with the property that not the same item occurred in the sequence one behind another. For each subject new random sequences were created. This was done to avoid that for one structure an easy sequence would have been created by chance (e.g. the items of a sequence are only in one row). In general for each structure there might be sequences that are easy to learn, but for some structures these are more likely than for others. And clearly this is a property of a structure that one likes to deduce from its spatial layout. To fix the sequence across subjects would mean that two different factors are controlled. Creating random sequences for each subject means to balance the factor of the sequence among subjects. To fix a sequence across subjects would be interesting to study one specific factor in detail. This was done in parts in the second experiment that is reported in the next section.

Results and Discussion

Accuracy data The number of correct and incorrect repeated sequences for each structure is shown in Table 1.

Table 1: Contingency table (2x3) of correct and erroneous sequences

Structure	A_1	A_2	A_3
Correct seqs.	46	61	63
Erroneous seqs.	74	59	57

The effect of structure approaches significance (2x3 contingency table $p = 0.056$, $\chi^2 = 5.77$). When comparing the numbers of correct repeated sequences between each pair of structures with a one-sided analysis of the corresponding 2×2 contingency tables, the exact Fisher test yields that performance in the horizontal oriented structures are significantly higher ($p<0.05$), whereas the symmetric features in the structure did not show any significant effect.

Learning progress Figure 2 shows the development of the performance by each trial in the same structure.

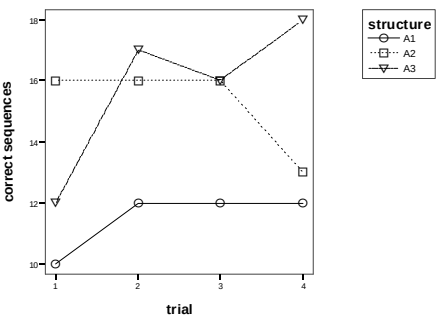

Figure 2: Development of performance in dependence of number of trials.

Structure A_1 with no symmetric features exhibits an increasing performance with each trial, whereas the horizontal oriented structure with symmetric features even shows a decrease in the last trial. The effect of trials on performance is not significant in any structure (2x4 contingency table $\chi 2$ statistical test). Hence, this effect may result from noise in the data.

The most important result of experiment 1 is that it shows that the horizontal oriented structures do improve performance, even if no alphanumerical letters are used as retrieval keys. However, this result may be culture dependent. For example people, who are used to read in columns instead of rows, might be more familiar with horizontal oriented structures.

One culture independent reason for this result might be that the human field of view is more extended into the horizontal direction. This increases noise of allocentric and egocentric memory chunks in vertical directions. If this hypothesis was right, people used to read in columns would profit from a horizontal oriented tree view in two ways: First the horizontal structure would increase performance of object-location retrieval and secondly, inscriptions could be written in columns instead of rows.

Experiment 2

The second experiment aimed at showing how the aspects of human spatial memory, like they are discussed in Wang et al (2001, 2002), affect the performance of object-location encoding/retrieval in dependence on different graphical layout structures. Another purpose of experiment 2 was to collect eye movement data for a more detailed analysis of how subjects encode object-locations.

Materials

The structures used in the second experiment are shown in Figure 3. They are divided into two subsets, because the limited pool of subjects didn't allow testing all permutations needed to prevent order effects.

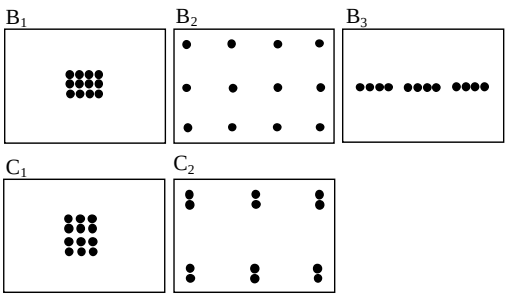

Figure 3: Set of structures used in experiment 2.

Justification The structures in set B and C were created to test some factors assumed to play an important role in the process of object-location encoding/retrieval in structures. The motivation to choose these structures is founded in the assumptions and expectations before the experiments were performed. Mainly the following factors were expected to contribute to the overall performance:

1. Hierarchical features.
2. Noise in the location of an allocentric memory chunk.
3. Noise in the location of an egocentric memory chunk
4. Higher activation of allocentric memory chunks if objects are in spatial vicinity.

The last factor seems plausible, because the effort to assess spatial object-to-object relations is smaller if objects are close together; possibly no eye movement is needed. This last factor would give the spatial narrow matrix B_1 an advantage over the spatial wide matrix B_2 in respect to performance of object-location encoding/retrieval. But also the other factors listed above may contribute. In the linear structure the noise in the memory chunks are more grievous than in the matrices, because there is only one dimension that contributes information, whereas in the case of the matrices also the direction contributes. The tables below show which structure profits by which factor compared to another structure in its set. A + sign in one cell means, that the structure of the row takes an advantage over the structure in the column in respect to the factor of the table, whereas a – sign indicates the opposite The factor of hierarchical features is balanced within each set, so this factor is not included in the tables. (For this purpose the linear structure has been separated into three groups with four objects).

Table 2: Which structure profits by which factor in set B.

Less noise in allocentric memory chunks

	B_1	B_2	B_3
B_1		0	++
B_2	0		++
B_3	--	--	

Less Noise in egocentric memory chunks

	B_1	B_2	B_3
B_1		--	-
B_2	++		+
B_3	+	-	

Higher activation of allocentric memory chunks

	B_1	B_2	B_3
B_1		++	+
B_2	--		-
B_3	-	+	

Table 3: Which structure profits by which factor in set C.

Less noise in allocentric memory chunks

	C_1	C_2
C_1		+
C_2	-	

Less noise in egocentric memory chunks

	C_1	C_2
C_1		-
C_2	+	

Higher activation caused by spatial vicinity

	C_1	C_2
C_1		+
C_2	-	

To estimate the overall performance, the tendencies shown in the tables have to be quantified. Furthermore, not any factor might contribute equally to the overall performance. Without any computational model it can only be speculated about these questions. However, in the setup used in the experiment, it can be assumed that the differences in the noise of the egocentric memory chunks are nearly negligible, because the changes in the average visual angles between the different objects in the scene are small compared to the human field of view. Whereas the directional angular of the allocentric memory chunks possibly covers the whole range. The effect of noise in the allocentric memory chunks in the structure B_1 and B_2 are expected to have an equal effect, because all relative distances are equal. It was expected, that the effect of decrease in performance in the linear structure would be very distinct.

Structure C_1 and C_2 differ only by the distances between the six pairs of objects; the distances between the two objects within a pair are equal. The hypothesis for this structure is that for sequence containing transitions between objects of two far distant pairs it will become more difficult for the subject to encode the location of the object within a pair. This results from a higher noise in the spatial object-to-object relation. To show this effect one predefined sequence was used. This allows analyzing behavior of subjects more efficient. Data from experiments can be used for the parameterization of stochastic models. The regularities found by the algorithms can be analyzed and interpreted (Winkelholz et al., 2003).

Design and Procedure

The experimental design was similar to experiment 1. This time the sequences were six items long. Furthermore, the experiment consisted of two blocks instead of three and in one block each structure from each set was presented once. The first three structures in each block were chosen from set B ordered by one of the possible six permutations. The last two structures in each block were C_1 and C_2, which order again was balanced within groups of subjects.

Except for one sequence in each block all sequences were created randomly for each subject. One sequence for the structures of set C was predefined. Like mentioned above, this was done to be able to analyze experimental tracing data effectively. The sequence was predefined for the structures C_1 and C_2 respectively. The predefined sequence is shown in Figure 4 on the left. It was used in the first block for structure C_1 and in the second block for C_2 or vice versa. By alternating, which structure in the first block starts with the predefined sequence, the effect of remembering the sequence in the second block had been balanced between the structures C_1 and C_2.

Results and Discussion

Accuracy data The numbers of correct repeated sequences are shown in the contingency tables 4 and 5.

Table 4: Contingency table (2x3) of correct and erroneous sequences in set B.

	B_1	B_2	B_3
Correct seqs.	38	34	16
Erroneous seqs.	22	26	44

Table 5: Contingency table (2x2) of correct and erroneous sequences in set C.

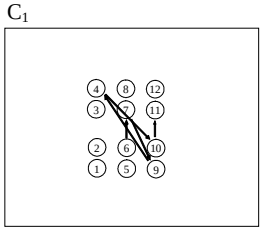
	C_1	C_2
Correct seqs.	35	25
Erroneous seqs.	25	35

The performance in the linear structure is significantly lower than in the structures of the matrices (exact Fisher-test $p<0.001$). Although the number of correct sequences in the narrow structure is a little bit higher than in the wide matrix, this difference is not significant. In table 5 the number of correct and incorrect sequences from the randomly created sequences and the predefined sequence are combined.

Analysis of errors A look at the errors subjects made in their answers gives more insight into the underlying cognitive processes. To analyze the answer sequences for the predefined sequence in set C we used a modified algorithm for variable length markov chains (VLMC) (Ron et al 1996, Bühlmann & Wyner 1998) to parameterize a stochastic model by the answer sequences. Roughly speaking this algorithm can be seen as a filter for subsequences (called contexts) from the data that contain predictive information. We modified this algorithm in a way that only contexts that contain significant predictive information in a statistical sense are included into the model (Winkelholz et al 2004). To apply this algorithm to the answer sequences the objects in the structure has to be assigned to symbols. The contexts of erroneous behavior found by this method in the answer sequences of the structures C_1 and C_2 are shown in Figure 4. In the first column of the table the contexts found by the algorithm are

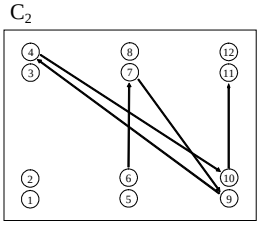
shown in parenthesis, followed by an arrow, and the most probable next symbols that occur in the answer sequences, if this context is given. E.g. "(7,10)->3", means: If subjects had clicked on object 7 followed by object 10, the most probable object they will click next is object 3. If on the right side of an arrow, more than one symbol/number is listed, they are ordered by their probabilities, with the most probable next symbol first. On the right of an arrow possible next symbols are listed, as far as their frequencies for the given context meet one of the two conditions: First, the frequency is significantly higher than for the symbols with lower frequencies. Second, the frequency does not differ significantly from the frequency of the symbol with the next higher probability.

C_1



Context -> Next Symbol	Interpretation
(4)->10, 11	Omission of object 10.
(6)->7,9	Omission of object 7.
(10) ->11, e	Surprised by the end.
(b)->6,7 (7,6) -> 9 (b, 7) -> 6	Changed order of the first two events in the sequence
(4,9)->11 (9)->4,11	The spatial vicinity, caused subject to mistake 9 for 10.

C_2



Context -> Next Symbol	Interpretation
(9)-> 4,3 (3)->10	The spatial vicinity, caused subject to mistake 3 for 4.
(7) -> 9,10	The spatial vicinity, caused subject to mistake 9 for 10.
(7,10) -> 3	If subject mistake 10 for 9 he also mistake 3 for 4.
(4)->10,11 (4,11)->e	Omission of object 10.

Figure 4: Contexts of erroneous behavior found by the parameterization of a stochastic model. Left: The structure with symbols assigned to the objects and the predefined test sequence. Right: Table with contexts and possible interpretation.

In structure C_2 with the more distant pairs there are more contexts concerning with the confusion of the objects within the pairs of the upper left, and down right corners, whereas for structure C_1 there are more contexts concerning the omission of an object. The most notable context for structure C_2 is "(7,10)->3". The angular between the line from 7 to 10 and the line from 10 to 3 is nearly similar to the angular between the lines 7 to 9 and 9 to 4. Therefore this context indicates that subjects used the relative change in angular direction of two transitions as a reminder.

Eye movement data Currently only the eye movement data of the structures C2 and B2 have been analyzed. Only these two structures exhibit spatial distinct features that allow a reliable assignment of fixations to attended features in the structure. In the structure C2 the fixations were only assigned to one pair. The resolution of the eye tracking device was not sufficient to distinguish between fixations within each pair. For the analysis of the eye movement data in the encoding phase of the predefined test sequence the same method as in the analysis of the errors in the answer sequences was used. The pictures obtained from this procedure are shown in Figure 5. Each picture shows the transitions in the eye movement between the pairs of objects, when the object shown as a filled circle is highlighted. The most probable pairs of objects that will be fixated next if one fixation and the highlighted object is given are presented as arrows starting at the currently fixated pair of objects.

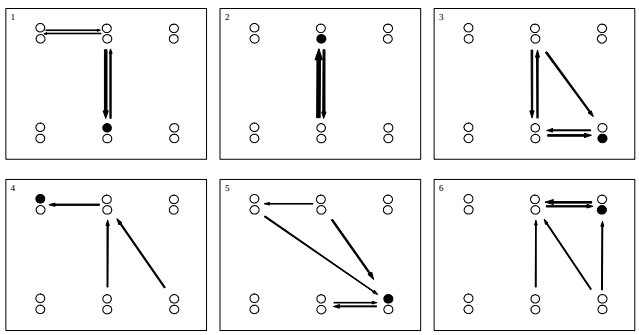


Figure 5: Eye movement data during the encoding phase for the predefined sequence (see figure 4).

The sizes of the arrows are scaled by the frequency of this transition. Although the predefined test sequence does contain two transitions that connect the objects from the upper left corner to the down right corner, there is only one transition in eye movement that connects these pairs directly. Even in the case of a transition from the down right to upper left corner in the test sequence subjects first fixated the group more near to the currently fixated pair of objects (picture 3-4). It was expected that after these transitions in the test sequence occurred, subjects would tend to repeat these transitions by eye movement to create memory chunks for this spatial relation. Instead subjects seem to create spatial relations to the pairs in the middle column. This result becomes more affirmed by taking a look at the eye movement data of the randomized sequences of the structures C_2 and B_2. An overlay of the transitions in the randomized test sequences and the corresponding transitions in the eye movement data are shown in Figure 6.

Although the transitions in the test sequences contain equally transitions between distant objects, these transitions are merely absent in the eye movement data. In both structures most transitions in eye movement are transitions between locations in the vicinity of the two objects in the middle of the screen. In the case of the matrix, movements of the fixation toward objects at the border are very sparse, whereas in the structure with the pairs of objects there are noticeable more fixation movements toward each pair of objects. This also explains the not expected result**,** that there is no significant difference in the performance of the wide and the narrow matrix structure. Possibly, it is sufficient to fixate a location in the middle of the screen to asses most of

the spatial object-to-object relations. Moving attention in the visual buffer to repeat transitions is possible without moving fixation. Therefore the effort to repeat transitions of the test sequences in structure B_1 and B_2 are similar. Different in structure C_2; here subjects needed to move fixation to resolve which object within a pair had been highlighted.

Conclusions and Future Work

The experiments reported in this paper showed how single aspects of human spatial memory affect the overall performance in memorizing tasks of object-locations in layout structures. A computational model that quantifies the interaction of the different aspects of object-location memory is needed to get reliable predictions about the overall performance. The development of such a model within a general architecture of cognition like ACT-R, (Anderson & Lebiere, 1998) enables the implementation of meaningful cognitive models for the application field of information visualization.

The results of the two experiments make the following suggestions with regard to a computational model within the ACT-R architecture:

First, like Wang et al (2002) suggested the model should encode spatial object-to-object relations between the previously and currently attended objects as memory chunks.

Second, also the relation between three objects should be encoded in a memory chunk. In the same fashion as object-to-object relations are encoded this can be done by the visual module whenever attention shifts between three different objects. This memory chunk should be of the form of a noisy angular. Thus the model would show the systematic failures found in the analysis of the answer sequences.

Third, the results from the comparison of the horizontal and vertical oriented structures in the first experiment suggest that noise in the memory chunks of spatial memory is distorted towards a higher accuracy in the horizontal direction. This is a plausible assumption, because the human vision field of view is more extended into the horizontal direction and this should be true for coordinates in all frames of references.

Fourth, eye movement data showed, that subjects need not to gaze at objects they are attending to assess their locations in different frames of references. Therefore it may be disputed, if developers of cognitive models within ACT-R need to control fixation and attention independently. The noise in the assessed object locations should depend on the distance to the current location of fixation.

Abstract

E-consulting services such as asynchronous helpdesks for hardware and software are a common and comfortable way to get expert advice. However, the constraints of asynchronous communication and the experts' inclination to forget about the exclusiveness of their specialist knowledge may impair the advisory success. Against this background, an assessment tool has been developed which aids helpdesk experts in evaluating an inquirer's background knowledge. In a previous study, it could be demonstrated that the assessment tool increased the effectiveness and efficiency of asynchronous communication. In order to test the mechanisms that make the assessment tool effective, another dialogue experiment was conducted that varied the validity of the information displayed in the assessment tool. The results showed that the information presented to the experts did not only sensitize them for the inquirers' needs but also allowed for specific adaptation to their individual knowledge state. Hence, the validity of the information provided by the assessment tool is crucial.

Introduction

Inasmuch as knowledge becomes ever more specialized and complex, individuals often lack the expertise necessary for making a decision or solving a problem on their own (Nückles & Bromme, 2002). Thus, in many situations, laypersons are reliant on expert advice. The proliferation of the Internet offers new possibilities for laypersons to enlist the assistance of experts. Not only can laypersons retrieve expert information publicly available from the World Wide Web but they can also obtain personal advice from experts in a one-to-one fashion. Helpdesks for hardware and software are a prominent example of e-consulting services that enjoy increasing popularity (Moncarz, 2001). Virtually every large computer company and university computer centre offers helpdesk support, often in a text-based, asynchronous way via electronic mail. The aim of computer consulting is to convey knowledge, which enables the inquirers to solve their problem by themselves, for example, when new and complex software has to be learned or an unexpected technical problem with the computer suddenly occurs. The advisory success heavily depends on the experts' ability to provide intelligible and informative explanations for inquirers with differing levels of experience, ranging from very inexpert to more advanced users (Chin, 2000; Kiesler, Zdaniuk, Lundmark, & Kraut, 2000). Thus, in order to give effective and satisfactory advice, experts should adapt their communication to the knowledge prerequisites of the client (Clark & Murphy, 1982). Both from an educational (e.g., Renkl, 2002) and psycholinguistic perspective (e.g., Clark, 1996), adaptation to a communication partner's prior knowledge is regarded as fundamental for comprehension and learning.

Research on expertise has shown that experts, as compared to novices, possess an extensive and highly differentiated knowledge base that facilitates a rapid categorization of problem situations and the activation of routine problem solving strategies (Chi, Glaser, & Farr, 1988). However, these very characteristics of expert knowledge might interfere with the task of taking into account the limited domain knowledge of a layperson. Hinds (1999) called this phenomenon the 'curse of expertise'. She reported two experimental studies in which experts systematically underestimated the difficulties laypersons faced when performing a complex task. Alty and Coombs (1981) analyzed face-to-face advisory dialogues between computer experts and clients. They found that the computer experts rarely attempted to ascertain the clients' prior knowledge and rarely monitored the clients' comprehension of their explanations. As a result, the clients often did not understand the advice given. From these studies it can be concluded that in order to assure effective advice, experts should be supported in taking into account the knowledge prerequisites and comprehension of the client.

In face-to-face communication, the communication partners can use a variety of situational and interactional cues to monitor their interlocutor's comprehension moment by moment and thereby refine and update their mental model of what the other person knows or does not know (Clark, 1996; Nickerson, 1999). In Internet-based counselling, however, the evaluation of an interlocutor's knowledge and the continuous construction of a mutual understanding are considerably more difficult when compared with face-to-face communication (Clark & Brennan, 1991). First, in asynchronous communication, nonverbal feedback is virtually impossible because the interlocutors cannot see nor hear one another. Second, the costs of message production are higher than in verbal communication because every message has to be typed on a keyboard. Third, there is no set sequentiality between a message and its reply, because the interlocutors' turn taking may be interrupted by messages from third parties, which can impair comprehension (Clark & Brennan, 1991). Given these constraints, the pos-

sibilities to establish a mutual understanding are clearly more restricted as compared with face-to-face communication. On the other hand, asynchronous communication also offers affordances that can facilitate adaptation to a communication partner. It allows for a careful planning and revision of a message before it is sent. There is time to reflect about a communication partner's background knowledge and communicational needs.

The Assessment Tool - A Measure to Support Asynchronous Communication

From the preceding discussion it can be concluded that it would be useful to provide helpdesk experts with a support procedure that compensates for the constraints of asynchronous communication on the one hand, and takes advantage of the affordances on the other hand. When computer experts communicate with clients via an Internet-based helpdesk, they are in an anonymous communication situation with only little information available about the client. Therefore, the procedure should enable the expert to achieve a relatively concise and veridical evaluation of a client's knowledge state right from the start, because the lack of nonverbal feedback, the raised production costs and the limited sequentiality impede the continuous construction of a mutual understanding considerably. With regard to experts' inclination to forget about the exclusiveness of their knowledge, the procedure should encourage them to carefully reflect about a client's knowledge prerequisites in order to facilitate adaptation to the client's communicational needs. The better the computer experts' model of the client's knowledge is, the better the experts can adapt their explanations to the client's knowledge (Clark & Murphy, 1982).

In this paper, an assessment tool will be empirically tested that supports computer experts in constructing a mental model of the client's knowledge state in asynchronous communication (see also Nückles, Wittwer, & Renkl, 2003). The tool consists of a small Internet-based questionnaire by which users who place a technical support inquiry are asked to provide the expert with several self-assessments of their computer expertise (cf. Figure 1). For example, the clients are asked to rate their general level of computer knowledge as well as their knowledge of concrete specialist terms semantically relevant to the topic addressed by their inquiry. The assessment tool can be especially useful to the expert if it enables them to form a picture of the client's knowledge level based on a small number of highly relevant information items. The assessment tool provides the expert with information about the client right from the start, which normally can only be collected during the course of the interaction process. Consequently, it should facilitate the collaborative effort of communication (Clark, 1996). However, the assessment tool can only be effective if the medium of communication allows for careful planning and the revision of one's communicational contributions. Therefore, the assessment tool seems to be especially suitable for asynchronous, written communication because there is time for reflection and revision before a message is sent.

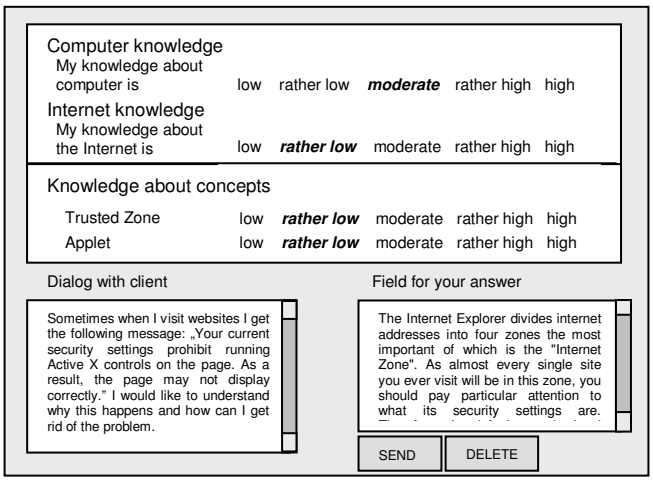

Figure 1: Screenshot of the assessment tool available to the computer expert.

The assessment tool has already been successfully tested in a web-based dialogue experiment between computer experts and clients (Nückles & Stürz, in press). With the assessment tool, the clients acquired significantly more knowledge than the control group without the assessment tool (increased communicative effectiveness). At the same time, they wrote back only half as often in response to the experts' explanations (increased communicative efficiency). Although the study demonstrated that the assessment tool approach was successful, it is unclear which mechanisms led to the increase in communicative effectiveness and efficiency. There are two main theoretical explanations that may account for these findings.

Theoretical Explanations of the Assessment Tool Effect

In Nickerson's theory (1999), the construction of a mental model of another person's knowledge is conceptualized as an anchoring and adjustment process (Tversky & Kahneman, 1974), where one's model of one's own knowledge serves as a default model of what a random other person knows. This default model is transformed, as individuating information is acquired, into models of specific other individuals. Accordingly, one could argue that the assessment tool presented individuating information about the client's knowledge level that provided the computer expert with a relatively specific anchor right from the start of the advisory dialogue. This enabled the expert to calibrate their mental model of the client's knowledge more quickly and accurately than would have been possible without the assessment tool, that is, only on the basis of the client's written questions and comments. According to this explanation, communicative effectiveness was raised because the assessment tool provided the expert with specific information that helped them to adapt to the client's individual knowledge level.

On the other hand, it may be argued that communicative effectiveness was raised *not* because of the *information* pre-

sented, but simply because the assessment tool increased the expert's awareness of the client and counteracted the tendency of de-individuation in Internet-based communication (Gunawardena, 1995). The experts were sensitized to reflect about the client's knowledge, for example which computer concepts are *typically* known by laypersons and which are not. This may have helped them to produce explanations that were more intelligible or informative for the *typical* layperson, irrespective of the *specific* knowledge level of an individual client. According to this explanation, the assessment tool had a more or less non-specific sensitizing effect on the expert. Against this background, the goal of the present experiment was to test whether the availability of *specific* information about the client's knowledge would make a difference at all, that is, support the experts' adaptation and thereby enhance communicative effectiveness and efficiency.

To this purpose, we modified the experimental design employed by Nückles and Stürz (in press). First, instead of using self-assessments, the assessment tool in this experiment provided the expert with objective information about the client's knowledge. Although self-assessments have proven to be good predictors of computer expertise (cf. Richter, Naumann, & Groeben, 2000; Vu, Hanley, Strybel, & Proctor, 2000), they still are not completely valid. Therefore, by using objective data about the client's computer knowledge, we increased the power for detecting a potential effect of specific adaptation. Secondly, a third experimental condition was included, in addition to a communication condition with the assessment tool and a condition without assessment tool. The information displayed in this additional condition was randomly drawn from the pool of knowledge data of clients who had previously participated in the experiment. The random data condition checked to see whether a distortion of the information about the client's knowledge level would impair the communication process. Consequently, the inclusion of this experimental condition would enable us to evaluate whether the *specific information* displayed by the assessment tool would influence the adaptivity of the experts' explanations.

Predictions

Sensitization hypothesis. If the assessment tool mainly had a sensitizing effect on the computer expert, that is, the information about the client was of little surplus value, it should make no difference whether the displayed information was valid or distorted. Accordingly, the mere presence of an assessment tool is supposed to increase the experts' awareness of the client and this alone should help them to improve their explanations. Consequently, in the conditions *with* the assessment tool the clients should acquire substantially more knowledge compared with clients in the condition *without* the assessment tool. Moreover, if the clients received explanations that were more intelligible and more informative compared with the condition without the assessment tool, they should experience less comprehension problems and should be more satisfied with the explanations. Hence, this should lessen their need of writing back in response to an expert's explanation. Consequently, the frequency of questions, and more specifically, the frequency of comprehension questions should be reduced in both conditions with the assessment tool.

Specific adaptation hypothesis. If the information provided by the assessment tool facilitates the adaptation to a specific client's knowledge, both the increase in communicative efficiency and effectiveness should be substantially larger in the condition presenting valid data about the client as compared with the other conditions. In contrast, communicative effectiveness and efficiency should be the lowest in the random data condition, because the distorted information should result in a biased mental model of the client's knowledge and this should impair the expert's adaptation to the client's actual knowledge state to some degree.

Method

The assessment tool. The assessment tool provided the computer experts both with ratings of the client's general computer knowledge and their Internet knowledge (see Figure 1). Apart from these global evaluations, it was also displayed to what extent the client already knew the meaning of two specialist concepts semantically relevant to the understanding of the problem addressed by an inquiry. Thus, the experts had the possibility to adapt their explanations both to the client's general knowledge background and, on a more concrete level, to their prior knowledge regarding a specific inquiry. The values displayed in the assessment tool were determined through an objective and standardized assessment procedure. To this purpose, an updated version of the computer and Internet knowledge test developed by Richter et al. (2000) was constructed and pre-tested on 40 humanities students. In the experiment, the number of items that a client had solved correctly in the general computer knowledge subtest (10 items) and in the Internet knowledge subtest (10 items) was translated into values on the corresponding five-point scales in the assessment tool (cf. Figure 1). For example, if a client had solved only one or two items out of the ten items of the Internet knowledge subtest, this was indicated as a *low* Internet knowledge level. In contrast, if the client had solved nine or ten items of a subtest, this would be represented in the assessment tool as a *high* knowledge level. To assess the client's knowledgeability regarding the specialist concepts they were asked to describe the meaning of each of the concepts. Two raters independently scored the written descriptions for correctness by using the five-point rating scale displayed in the assessment tool (see Figure 1). Inter-rater reliability was .92.

Participants. 60 computer experts and 60 clients participated in the experiment. Computer experts were recruited among advanced students of computer science. The laypersons serving as clients were recruited among students of psychology and the humanities. The results of the knowledge tests showed that the clients covered a wide range of

different knowledge levels. In the general computer knowledge test, a mean of 5.33 correctly solved items was obtained with a standard deviation of 2.50 and a range of 10 items. In the Internet knowledge test, the clients were able to solve 5.80 items on average with a standard deviation of 2.33 and a range of 8 items. Thus, there was ample opportunity for the experts to adapt their explanations to clients with different prior knowledge levels.

Design. Computer experts and clients were combined into dyads that were randomly assigned to the experimental conditions. A one-factorial between-subjects design was used comprising three different conditions: (a) communication with an assessment tool displaying valid information about the client's knowledge (in the following labeled 'valid AT'), (b) communication without assessment tool ('no AT'), and (c) communication with an assessment tool displaying random information about the client's knowledge ('random AT'). Dependent variables encompassed measures of communicative effectiveness (i.e., the client's increase in knowledge) and communicative efficiency (i.e., the number of questions asked by the client in response to an expert's explanation).

Materials. A pool of 20 inquiries was constructed that demanded explanations of relevant Internet topics and problems. Based on expert ratings regarding the familiarity and relevance of the inquiries, six of them were selected for the experiment. Three inquiries required the computer expert to explain a technical concept. The other three were more complex. They asked the expert to instruct the client how to solve a problem and, additionally, to provide an explanation why the problem occurred in order to help the client understand the nature of the problem (e.g., "I'm running Internet Explorer 6. Whenever I try to print a website consisting of several frames, my printer only prints out one frame. I would like to understand why this happens and what I can do so that the frames are printed out all at once?").

Procedure. In the beginning of the experiment, the students serving as clients were administered the general computer knowledge test, the Internet knowledge test, and the concept description task. In addition, their prior knowledge about the six inquiries to be discussed in the communication phase was determined. The students were encouraged to try to answer each of the inquiries if possible. They were informed that they were participating in a study on students' knowledge about computers and the Internet. Thus, it was made certain that the students had no reason to assume that their test results would later be relevant to the communication phase of the experiment. This was important because otherwise the students' self-perceptions of their test performance might have influenced their behavior during the advisory exchange with the computer expert. In the communication phase, the expert and client sat in different rooms and communicated through a text-based interface. The client's task was to sequentially direct each one of the prepared six inquiries verbatim to the expert by typing the prepared wording of the inquiry into the text form of the interface. The expert was asked to answer each inquiry as well as possible. The clients were encouraged to write back and ask as many questions as needed. In the experimental conditions with the assessment tool, the completed form was visible to the expert during the entire course of the exchange. When the client asked a new inquiry, the assessment tool was automatically updated with regard to the client's knowledge about the specialist concepts relevant to the current inquiry (see Figure 1). After the communication phase, the clients were again asked to write down their knowledge about each of the six inquiries. In this way, it was possible to calculate the individual increase in knowledge for each client (cf. Table 1).

Results

Before the client's individual increase in knowledge was computed, it was made sure that the clients had no substantial prior knowledge about the inquiries. The mean scores of the clients' answers collected *before* the communication phase clearly ranged below one (4-point rating scale, cf. Table 1) indicating that, on average, the clients did not know the correct answer to the inquiries prior to the exchange with the computer expert. There were no differences between the experimental conditions, $F < 1$.

Communicative effectiveness. In order to compute the clients' individual increase in knowledge, the mean scores of the clients' answers to the six inquiries prior to the communication phase were subtracted from the corresponding mean scores after the communication phase (cf. Table 1). The maximum score to be attained was three points. An ANOVA performed on the individual difference scores revealed an overall effect of experimental condition, $F(2, 57) = 5.37$, $p < .01$, $\eta^2 = .16$ (strong effect). Following the sensitization hypothesis, a substantial increase in knowledge should be observed in the conditions with an assessment tool but *not* in the condition without an assessment tool. The validity of the displayed information should make no difference. This prediction was represented by the following contrast: valid data: 1, random data: 1, no assessment tool: –2.

Following the specific adaptation hypothesis, the information displayed by the assessment tool should indeed make a difference: The client's increase in knowledge should be larger in the valid data condition compared with the condition without the assessment tool and the random data condition. The smallest knowledge increase would be expected in the random data condition, because the distorted information should impair the expert's adaptation to the client's knowledge level. This linear trend hypothesis was represented by the following contrast weights: valid data: 1, no assessment tool: 0, random data: –1.

The results of the contrast analysis clearly contradicted the sensitization hypothesis and supported the specific adaptation hypothesis. The planned contrast representing the sensitization hypothesis failed to reach statistical signifi-

cance, $F < 1$, whereas the contrast testing the specific adaptation hypothesis was highly significant, $F(1, 57) = 9.99$, $p < .01$, $\eta^2 = .15$ (strong effect). Table 1 shows that the mean values of the clients' increase in knowledge evidently displayed the predicted linear trend with the largest increase in knowledge occurring in the valid data condition and the smallest in the random data condition.

Table 1: Means and standard deviations (in parentheses) of the dependent variables of the experiment.

	Experimental Condition		
Dependent Variable	Valid AT	No AT	Random AT
Mean scores of the clients' answers *before* the communication phase*	0.46 (0.38)	0.68 (0.73)	0.58 (0.50)
Mean scores of the clients' answers *after* the communication phase*	1.97 (0.71)	1.66 (0.55)	1.37 (0.59)
Mean differences of the clients' increase in knowledge	1.52 (0.81)	0.99 (0.78)	0.80 (0.54)
Total number of questions per expert-client exchange	2.15 (1.73)	4.35 (2.98)	4.70 (2.54)
Number of comprehension questions per expert-client exchange	1.75 (1.74)	3.80 (2.44)	3.85 (2.13)

Note. *For each answer up to three points could be assigned (0 = no or wrong answer, 1 = predominantly wrong answer, 2 = roughly correct answer, 3 = completely correct answer).

Communicative efficiency. To obtain a measure of communicative efficiency, we counted the total number of questions the client produced in response to the expert's explanations during the whole exchange, that is, throughout the six inquiries. An ANOVA performed on the total number of questions revealed a significant overall effect of experimental condition, $F(2, 57) = 6.27$, $p < .01$, $\eta^2 = .18$ (strong effect). When the analysis was restricted to the frequency of comprehension questions, that is, to those questions by which the client explicitly articulated a comprehension problem, a similar result was obtained, $F(2, 57) = 6.36$, $p < .01$, $\eta^2 = .18$ (strong effect). To test the sensitization hypothesis and the specific adaptation hypothesis, planned contrasts were computed with the contrast weights reported above. As before, the data analyses yielded no support for the sensitization hypothesis, regardless of whether the total number of questions or the number of comprehension questions was used as the dependent variable, $F(2, 57) = 1.87$, *ns*, and $F(2, 57) = 2.95$, *ns*, respectively. On the other hand, the specific adaptation hypothesis was also confirmed with regard to communicative *efficiency*. The linear contrast was significant when the total number of questions was considered, $F(1, 57) = 10.67$, $p < .01$, $\eta^2 = .16$ (strong effect), and also when the analysis was restricted to the comprehension questions, $F(1, 57) = 9.76$, $p < .01$, $\eta^2 = .15$ (strong effect). With valid data in the assessment tool, the laypersons wrote back only about half as often in response to an expert's explanation as compared to the other experimental conditions (cf. Table 1, last two rows). Thus, only the provision of valid information reduced the frequency of questions by which the client explicitly articulated a comprehension problem or asked for further information. On the other hand, most of the questions occurred in the condition that presented distorted information about the client's knowledge.

Discussion

The dialogue experiment presented in this paper replicates the results found in a previous study (Nückles & Stürz, in press). The approach to support asynchronous communication between computer experts and laypersons by means of an assessment tool has indeed proven to be successful. More importantly, the present findings also allow for conclusions about the mechanisms that led to the increase in communicative effectiveness and efficiency. The clients acquired the most knowledge and asked the fewest questions when the computer expert was presented *valid* data about the client's knowledge. When the information was distorted, the client's knowledge acquisition was impaired. The clients in the random data condition profited the least from the experts' explanations and asked the most questions. These results clearly contradicted the sensitization hypothesis and supported the specific adaptation hypothesis. Thus, it can be concluded that it was in fact the *individuating information* about the client's knowledge that led to the increase in communicative efficiency and effectiveness. From the perspective of Nickerson's anchoring and adjustment model (Nickerson, 1999) the assessment tool improved the communication between expert and client because the information about the client's knowledge provided the computer expert with a *specific* anchor right from the start of the counselling process. This enabled the expert to calibrate their mental model about the client's knowledge more quickly and accurately than would have been possible without such individuating information or with distorted information.

The present findings show that the assessment tool fostered specific adaptation to the clients' knowledge. It is still unclear *how* the experts exactly used the information about the client to produce adaptive explanations. It is plausible to assume that the experts used a 'linear strategy'. For example, they might have reasoned that 'the lower the client's knowledge level, the more extensive my explanations should be' in order to provide the client sufficient context for comprehension (cf. Clark, 1996). Indeed, we found such a correlation between the extensiveness of the experts' explanations and the client's displayed knowledge level ($r = -.32$, $p < .05$). Still, the correlation was rather low. It cannot help to fully understand the cognitive heuristics the computer experts used to adjust their explanations to the client's knowledge. Thus, beyond the tendency to link explanatory

extensiveness to the client's knowledge level, the experts apparently used the information displayed by the assessment tool to adjust their explanations in more sophisticated and individualized ways. One possibility is that the experts referred to the information in the assessment tool to make decisions during the planning phase of an explanation, for example, whether a technical term they intended to use in their answer would already be known by the client, or would have to be introduced in case it was not known (so-called 'pruning', see Chin, 2000). To explore such possibilities, we are currently running a 'think-aloud' study in which we are investigating how the experts developed a qualitative representation of the client's knowledge from the quantitative information provided by the assessment tool and how this qualitative representation was used to generate instructional explanations for the client. In addition, 'thinking aloud' protocols of the client's comprehension processes could help to identify features of the expert's explanations that hinder or enhance the clients' understanding. The identification of features that make an expert's explanation well adapted to a specific knowledge level could be interesting both for the design of advice-giving systems (e.g., Chin, 2000) and intelligent tutoring systems (e.g., Dede, 1986).

The finding that information about a client's knowledge fostered the provision of adaptive instructional explanations might also be suggestive of ways in which Internet-based collaborative settings other than helpdesk communication could be supported. In the realm of distance learning, many universities offer online courses where students of diverse educational backgrounds and with a wide range of different knowledge participate. As the tutors in these courses have to provide instructional explanations for people they – at least initially – do not know, an assessment tool could provide valuable information that may help the tutors to adapt their explanations to the learners' knowledge level. Hence, an assessment tool might also be an appropriate method to support online tutoring (Siler & VanLehn, in press).

ACT-R is *almost* a Model of Primate Task Learning: Experiments in Modelling Transitive Inference

Abstract

We present a model of transitive inference (TI) using ACT-R which strengthens the hypothesis that TI is not dependent on underlying sequential ordering of stimuli, but rather on the learning of productions. We nevertheless find a weakness in the ACT-R sub-symbolic learning system and suggest improvements.

Introduction

The last decade has shown an increasing body of work indicating that ACT-R (Anderson and Lebiere, 1998) can be used to model human learning in an impressive variety of tasks. However, ACT-R has been slow to gain acceptance in mainstream experimental psychology as a useful model, possibly because it does not seem a very good correlate to the physical learning systems we find in the brain.

In previous and concurrent work, we have been exploring another model of task learning which also seems at first blush artificial and not particularly parsimonious, but has also shown an impressively tight fit to human and animal experimental data otherwise unaccounted for. This is the Harris (1988) production-rule-stack model of one of the main testbeds of task learning in the animal literature, the transitive inference task. We developed the two-tier model (Bryson, 2001; Bryson and Leong, 2004), which accounts for all of the Harris model's data, while extending the model to account for both learning and failing to learn this task (a common outcome in live subjects). We've also found potential neurological correlates for the two-tier model.

The two-tier model hypothesises two learning systems: one for connecting perceptual contexts to actions, and another for prioritising which of those perceptual contexts to attend to if more than one are present simultaneously. We realised that this model had similar aspects to ACT-R, which also has two learning systems, one symbolic and one statistical. We therefore decided to apply ACT-R to the transitive inference learning task. Our results show that ACT-R is far better than the standard TI models at accounting for the particular (and somewhat controversial) data set that prompted the Harris (1988) model, and for some individuals provides a better model than Harris (1988), though for others it cannot. Our results lead us to believe that the two-tier model is the best existing model of transitive inference, although ACT-R is close enough that it is probably fixable. ACT-R demonstrates one significant simplification over the two-tier hypothesis, and has one important difference from real mammalian task learning.

Transitive Inference

Transitive inference (TI) formally refers to the process of reasoning whereby one infers that if, for some quality, $A > B$ and $B > C$, then $A > C$. In some domains, such as integers or heights, this property will hold for any A, B or C, though for others it does not (see Wright, 2001, for a recent discussion). TI is classically described as an example of concrete operational thought (Piaget, 1954). That is, children become capable of doing TI when they become capable of mentally performing the physical manipulations they would use to determine the correct answer, a stage they reach at approximately the age of seven. In the case of TI, this manipulation involves ordering the objects into a sequence using the rules $A > B$ and $B > C$, and then observing the relative location of A and C.

Since the 1970's, however, apparent TI has been demonstrated in much younger children (Bryant and Trabasso, 1971) and a variety of animals, from monkeys (McGonigle and Chalmers, 1977) to pigeons (Fersen et al., 1991) — not normally ascribed with concrete operational abilities. The behaviour of choosing A from AC without training after having previously been trained to select A from AB and B from BC is consequently sometimes referred to as "transitive *performance*", and whether it implies sequential ordering at all is now an open issue.

The main motivation for *not* considering TI in animals to be based on a sequential structure is a dataset due to McGonigle and Chalmers (1977), which they have subsequently replicated both with monkeys and children. This data set concerns what happens if subjects demonstrating TI are asked to select between *three* items rather than two. Some individuals show significant, systematic degradation in performance, which cannot be explained by a sequential model. Some researchers have dismissed the triad data as resulting from confusion in the subjects due to the extra item. These criticisms were dealt with in a replication by McGonigle and Chalmers (1992) which provided the main data set used in this paper and by Harris and McGonigle (1994). The fact that the systematicity of the degradation has now been success-

fully accounted for further validates this data set. This data concerns monkeys trained on 4 adjacent pairs drawn from a 5 item sequence, AB, BC, CD, DE.

The Models

Due to space constraints we will not review the more traditional, sequence-based or simple-associative models of TI, but see further (Wynne, 1998; Bryson and Leong, 2004). These models cannot account for the triad data set.

Harris and McGonigle

Harris (1988) showed that both pair and triad TI performance could be accounted for if we assume that monkeys learn a production rule stack. A *production rule* is a basic AI representation which connects a stimulus to a response. A *stack* is a prioritised list. In the Harris model, each monkey learns one rule per possible stimulus, or up to 5 rules in total. One of two actions is associated with each rule, either *select* or *avoid*. If a subject applies the rule $A{\rightarrow}s(A)$ (see A implies select A), then it will simply pick up A, regardless of whether other items are present. However, if a subject applies the rule $A{\rightarrow}a(A)$ it will pick up anything *but* A. If more than one other item is present, the subject is at chance for which object it will pick up. If more than one rule could apply, then whichever rule is higher in the stack (has higher *priority*) will be applied.

Although Harris' hypothesis may seem obscure, it shows a remarkable match to the data. If one assumes that rules are limited to the case that the action refers to the object attended to, then only 16 of the 1920 ($10 \times 8 \times 6 \times 4$) possible stacks of four rules operate correctly on all training pairs (Harris and McGonigle, 1994). All 16 of these stacks also correctly perform TI on *all* pairs automatically, thus already accounting for one of the mysteries of transitive performance.

The degradation some subjects display on the triad tests is a consequence of the random aspect of the *avoid* rules. In fact, triads can be used to discriminate which rule stack an individual subject has learnt. For example, a stack that consists entirely of selects $(s(A), s(B), s(C) \ldots)$ will never make any errors. One that starts with $a(E)$ will be at chance between the other two options whenever E is present in a triad.

Table 1 shows all of the possible discriminable stacks as identified by Harris and McGonigle (1994). Because only the highest-priority applicable rule fires and there are always at least two applicable rules (since there are at least two stimuli), there is no way to discriminate the two lowest-priority rules using triad performance. These stacks therefore only reflect the top three rules of the stacks.

The Two-Tier Model

A successfully trained two-tier model creates a replication of the production-rule-stack model (Bryson, 2001). However, the two-tier model is dynamic, and as such gives us insight into why animals have trouble learning the initial pairs for the TI task, the sorts of mistakes they may make, and the impact of training régimes. The first tier of the two-tier model is a single-vector neural network (NN) which learns the prioritisation of the stimuli. The second tier is a set of small two-item vectors which each learn to associate an action with one of the stimuli. The learning rule for the NNs is a slight simplification of standard delta learning (Widrow and Hoff, Jr., 1960).

Simulations using the two-tier model show artificial subjects successfully learning the training data only about 25% of the time when training pairs are presented in a random order. However, switching to the training régime applied by McGonigle and Chalmers (1992) shown in Table 2, which is standard for primates, the success rate increases to about 75%, which is comparable to live subjects (Bryson and Leong, 2004).

Further, the sorts of errors made by artificial subjects failing to learn are consistent with those shown by live subjects — they tend to confuse the middle pairs. Analysis of the networks shows that this is nearly always a consequence of misprioritising the rules representing the end pairs. An agent can guarantee it always selects A in the pair AB (the only pair A appears in) by learning $a(B)$, and there is a great inclination to learn about middle rules because these are the ones that have the most data (and the most confusing data, since B is sometimes rewarded but sometimes penalised.) However, there are no successful stacks which do not have one end point or the other at the highest priority (see Table 1). The training régime greatly increases the probability of learning correct prioritisation. For further details see Bryson and Leong (2004).

Table 1: Enumeration of Harris and McGonigle Stacks

	Rule Depth				Rule Depth		
#	1	2	3	#	1	2	3
1	s(A)	s(B)	s(C)	5	a(E)	s(A)	s(B)
2	s(A)	s(B)	a(E)	6	a(E)	s(A)	a(D)
3	s(A)	a(E)	s(B)	7	a(E)	a(D)	s(A)
4	s(A)	a(E)	a(D)	8	a(E)	a(D)	a(C)

Table 2: Primate TI training régime (Chalmers and McGonigle, 1984; McGonigle and Chalmers, 1992)

P1	Each pair in order (DE, CD, BC, AB) repeated until 9 of 10 most recent trials are correct. Reject if requires over 200 trials total
P2a	4 of each pair in order. Criteria: 32 consecutive trials correct. Reject if requires over 200 trials total
P2b	2 of each pair in order. Criteria: 16 consecutive trials correct. Reject if requires over 200 trials total
P2c	1 of each pair in order. Criteria: 30 consecutive trials correct. No rejection criteria
P3	1 of each pair randomly ordered. Criteria: 24 consecutive trials correct. Reject if requires over 200 trials total
T	Pair and triad testing

ACT-R

As for the above models, ACT-R also learns production rules, but any number of these rules may have their preconditions for firing satisfied at any given time. In this case, ACT-R's conflict-resolution system selects the rule with highest *utility* value.

Rule utilities are changed by ACT-R's sub-symbolic processing system. It is possible to attach *success* or *failure* tags to productions and when such a rule is fired, ACT-R backtracks to discover which rules fired previously and increments or decrements their utilities respectively. More precisely, the utility of a rule is given by:

$$U = PG - C + \epsilon(s) \tag{1}$$

where G is the *goal value*, C is the *expected cost*, $\epsilon(s)$ is the *expected gain noise* and P is the *expected probability of success*:

$$P = \frac{\text{Successes}}{\text{Successes} + \text{Failures}} \tag{2}$$

In our experiments, rather than make arbitrary changes to ACT-R's many available parameters in an attempt to best fit the data, we have used mostly defaults. The most notable exception to this is that we set the initial Failure count to 1 which, along with ACT-R's default setting of 1 for Successes[1], gives an initial probability of success of 0.5. This change was also made by Belavkin and Ritter (2003) in their Dancing Mouse model. To maximise the number of successful agents, we also tried a range of values for s (which affects the variance of the noise function), finally deciding upon $s = 1$.

One trial consists of two or three items displayed on-screen which the agent encodes into its goal buffer. The goal state is then changed, enabling it to make decisions about which item to pick (see below). Once an item has been picked, either a reward or no reward is displayed appropriately, the agent notes its success or failure respectively and the next trial begins.

We have tested two different approaches to solving the TI problem in ACT-R. In the first, the *select* and *avoid* rules for each item are independent, concurrent candidates for execution. For three displayed items, this corresponds to six conflicting rules that have their preconditions satisfied. Henceforth we refer to this approach as *ACT-R-1*.

In the second, the agent must *focus* on a displayed item before either *select*ing or *avoid*ing it, as in the two-tier model. This results in an extra stage of conflict-resolution for the agent. With three options there are at first three candidate *focus* rules whose actions alter the agent's goal state. This, in turn, satisfies two further rules; *select* and *avoid* for the focus-item. We call this approach *ACT-R-2*.

Results

As with the two-tier model and live subjects, our ACT-R model produces both agents that successfully learn the task and agents that do not. 44 of the 100 agents tested with ACT-R-1 successfully passed the training régime. This compares to 35% of those using ACT-R-2, or 75% of those using the two-tier system. We examine these groups separately.

Successful Agents

The stack model proposed by Harris and McGonigle (1994) attempts to fit the McGonigle and Chalmers (1977) triad data to any of the eight discriminable correct stacks (Table 1). In contrast, the ACT-R agents learn only two possible solutions.

There are two rules which are always successful for all pairs: s(A) and a(E). This means that, provided these rules are discovered by the agent, their utilities will begin to converge to maximal, given by:

$$\begin{aligned} \lim_{t\to\infty} U &= \lim_{t\to\infty} (PG - C) \\ &= \lim_{t\to\infty} \left(\frac{\text{Successes}}{\text{Successes} + \text{Failures}} \right) G - C \\ &= \lim_{t\to\infty} \left(\frac{1}{1 + \frac{\text{Failures}}{\text{Successes}}} \right) G - C \\ &= G - C \end{aligned} \tag{3}$$

where t is the number of trials, and G and C remain constant at ACT-R default values throughout. Therefore any successful ACT-R agent will have these two rules at highest priority. This eliminates half of the Harris and McGonigle stacks, leaving 3, 4, 5 and 6 (Table 1).

In addition, because the top-two rule utilities are converging to the same value, it becomes essentially arbitrary (in fact, governed by the expected gain noise) whether s(A) or a(E) occupies the top stack position for any given choice. In other words, the ACT-R agents do not learn a totally ordered stack, but effectively a pair of stacks. The two possible pairs are:

Hybrid Stack 1 (HS1): s(A)a(E)s(B) & a(E)s(A)s(B)
Hybrid Stack 2 (HS2): s(A)a(E)a(D) & a(E)s(A)a(D)

Table 3 shows each triad with the expected percentage of trials in which each item in that triad is chosen. These probabilities are the same for both Hybrid Stacks, except for the triad BCD. In this case, the format is HS1 / HS2. A 75%/25% split occurs when both A and E are present in the triad. We assume that half the time s(A) has top priority and is thus selected. Otherwise, a(E) has top priority, giving an even chance of A or the other item being selected.

Taking into account the noise added to the system, this model well describes the behaviour of many of the ACT-R agents. In 45% of cases, one of the Hybrid Stacks fitted the agent's distribution better than any of the individual stacks, and a further 47% were best fitted by Stack 5; a contributor to HS1.

Failed Agents

Despite these encouraging results, a majority of the ACT-R agents failed the training régime (Table 2), which is not true of the monkeys (albeit there were only seven

[1]The default is Failures $= 0 \Rightarrow P_{initial} = 1$.

test subjects) or children (Chalmers and McGonigle, 1984). Virtually all of the agents which failed did so at stage P2a (Table 2), typically having seen less than 300 training pairs in total. There are two exceptions for both ACT-R models which failed at P3.

To best understand why agents fail, we examine each training pair and determine what causes agents to pick the wrong item:

AB Since s(A) almost always has a high utility, errors on this pair tend to be caused by interference from s(B), whose utility is driven up by its success on pair BC. Ironically, then, it is agents who are too successful too soon who fail because of this pair, training stage P2a having the most stringent pass criteria.

BC C is picked when s(C) is too high relative to s(B) or, less frequently, a(C). Occasionally a(B) adds to this interference but, due to the success of s(A), rarely attains a high enough utility.

CD The symmetric case of BC. Here a(C)/a(D) interference is the chief cause of error (see Figure 1).

DE As for AB, if a(D) is discovered early to be a good rule, it interferes with a(E) causing small but significant errors in P2a.

For some agents (around 25%), failure is a result of a combination of the above interferences. If many of the interfering rules are interdependent (eg. s(B), s(C), a(C), a(D)) then this can lead to a more even distribution of errors across all training pairs. Conversely, if two sets of independent rules (eg. s(A), a(B), a(D), a(E)) are interfering, often two training pairs are consistently incorrect, with little or no error on the other two.

As Tables 4 and 5 show, agents confuse the middle pairs far more often than the end pairs (see also **Analysis**). This, in turn, is most often the result of s(C) and a(C), both of which perform incorrectly for one of the middle pairs. We have restricted these data to the last 200 trials carried out by the failed agent. This focuses on the specific phase of training at which the agent failed and removes the noisiest choices, made during P1.

ACT-R-2	0	42	50	8

Analysis

For ease of statistical comparison, we applied the χ^2 test in the same way as Harris and McGonigle (1994): by excluding item E, which (usually) has an expected value of 0.

For three of the five individual test subjects for whom McGonigle and Chalmers (1977) triadic data is available, one of the hybrid stacks fits better than any of the eight others (Table 6). As explained in the **Successful Agents** section above, and in contrast with the Harris and McGonigle stacks, the hybrid stacks do not represent a total ordering. Thus it would seem that neither do some monkeys form a total ordering, and their choices cannot be perfectly modelled by a simple production-rule system. For Bump and Brown, however, our model is rejected ($p < 0.01$), suggesting that other monkeys do come up with a total ordering, which cannot be well modelled in ACT-R.

The two-tier model does support both models, although its admittedly simplistic learning rule tends to favour the total ordering. These results suggest that

an improved priority-learning rule for either the two-tier model or ACT-R could result in a highly accurate model of TI and possibly task learning in general.

There were just five monkeys who passed criteria and so were included in the triad phase of the 1977 experiment. These five only represented three of the eight stacks in Table 1. This may render the grouped data unrepresentative, but our ACT-R model still displays a better correlation than Harris and McGonigle (1994) of α-choices, as shown in Table 7, where α represents the *correct* choice in a given triad (see also Table 8).

Table 7: Correlation of α-choices to group data

Group	r	p
ACT-R-1	0.688	$p < 0.05$
ACT-R-2	0.692	$p < 0.05$
Hybrid Stack Model	0.616	$p < 0.1$
H & M Stack Model	0.634	$p < 0.05$

Upon closer examination of the choices made for each triad, we see ACT-R closely matching the monkey data for those triads which do not contain the item E (Table 8). For those that do, ACT-R makes more mistakes, suggesting that the monkeys do not have a(E) at as high a priority. This might reflect a primate bias against having identical priorities for rules.

There may be a good reason for favouring priorities over utilities for ordering rules. For example, there is no circumstance in which an ACT-R agent can reach a stable enough solution to reduce error to zero. Suppose such a situation was attained. Then every decision made would result in success and thus increase the utility of the executed rule. Eventually, these rules (of which there must be at least three to produce a correct stack) would converge upon the same value (see Equation 3 above). But since no three rules in a correct stack are independent for all triads, they will start to interfere with each other, causing error to be re-introduced.

This phenomenon is best demonstrated by examining the errors of agents who did not take part in structured training, but were presented with the training pairs in a random order. Here, as is usual, the s(A) and a(E) rules have high, convergent utilities (these rules *are* independent for all training pairs). Then the utility of one (or both) of the other successful rules, s(B) and a(D), will also start to converge. This results in errors made on the *end pairs* since s(B) interferes with s(A) for AB (Figure 2) and a(D) interferes with a(E) for DE. Neither s(C) nor a(C) can attain a high utility, because they will perform incorrectly on one of the middle pairs (BC and CD). The final result is that the middle pairs are chosen consistently correctly, whereas the end pairs have small errors (typically around 15%). This certainly seems somewhat biologically implausible, and contradicts the *End-Anchor Effect* (Bryant and Trabasso, 1971; Wynne, 1998).

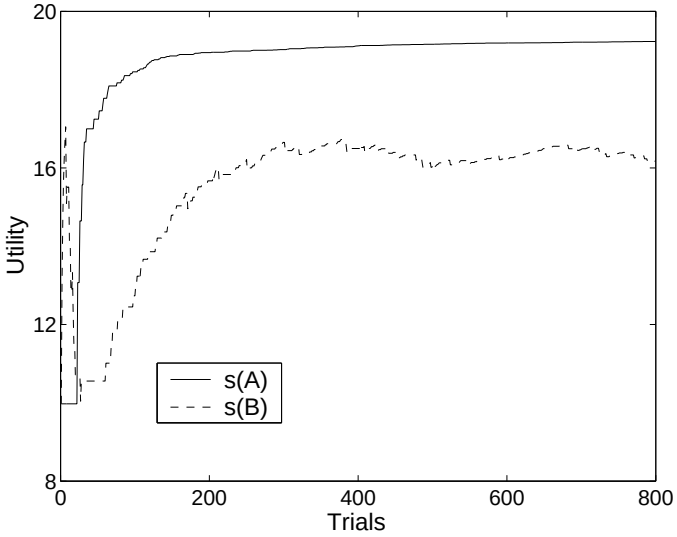

Figure 2: Interference with s(A) prevents the utility of s(B) reaching above a certain level

Conclusions and Further Work

The ACT-R models lack in their ability to represent stable, totally ordered stacks, which some real subjects appear to form. On the other hand, the Harris and McGonigle (1994) stacks lack the flexibility to represent more dynamic solutions to the TI problem. For this reason we conclude that the two-tier model is the best existing model of TI. On the other hand, the fact that there is no significant difference between ACT-R-1 (where no initial item focus is required) and ACT-R-2 (where this focus is required) implies that the two-tier model can be simplified to allow arbitrary numbers of stimulus action pairings, as is the default case in ACT-R.

Table 8: Percentage of items selected - triadic analysis

Means	78	22	1	70	28	2	71	27	2	75	25	0	75	25	0

There are several obvious next steps. First, as stated in the **Introduction**, the learning rules for priorities in both the two-tier model and ACT-R need improvement, though in different ways. We will be focusing on improving the two-tier model, but would be happy to see or support ACT-R being modified to reflect these results. Also, we suggest two possible improvements to the ACT-R model. Allowing ACT-R to compile its own system of rules from a minimal starting set (Anderson and Lebiere, 1998) may provide a more natural solution, although interpreting the underlying decision processes would be more difficult. Starting with a high initial noise would allow the agents to always discover and benefit from the most successful rules, while rapidly reducing this noise level (in conjunction with the *entropy of success* (Belavkin and Ritter, 2003)) would be necessary in order to obtain a stable enough solution to pass stage P2a of the training régime.

The other obvious next step would be to collect and analyse more triad testing results across a larger number of primates. For our purposes, it would be useful to have triad testing on subjects who fail TI training as well as those who succeed. We are investigating collaborations in this area.

The greatest significance of this work is that it gives further evidence for a non-sequence-based representation underlying the TI task and further supports the utility of the McGonigle and Chalmers (1977) triad data set.

Abstract

In daily life we often perform sequences of actions, which with practice are accomplished by overlapping mental operations for successive actions. Is it possible to derive performance predictions for such sequences from a characterization of the mental operations for a single stimulus-response pair? We explore this by examining the joint timing of eye movements and manual responses in a typing-like task following Pashler (1994). Participants made separate choice responses to a series of five stimuli spread over a wide viewing area. Replicating Pashler's results, responses to the first stimulus (RT1) were elevated, with inter-response intervals (IRI) for subsequent items rapid and flat across items. The eyes moved toward the next letter about 800 ms before the corresponding manual response (eye-hand span). Analyses of manual responses show multiple components to the RT1 elevation. Analyses of dwell times show that the eyes move to the next stimulus before the completion of all central processing.

Introduction

Current frameworks of human performance modeling often follow traditional theories of human cognition, treating human behavior as a succession of stages composed from a limited number of component mental operations, such as perceptual, cognitive and motor processes. The nature and duration of these mental operations are derived from studies of response time in discrete tasks, which often last less than one second. In the real world, however, tasks are rarely completed with a single discrete action. Rather, they often require the performance of a series of discrete actions integrated into a fluid behavior sequence in response to multiple stimuli during an extended period of time. In the transition from discrete to continuous new behaviors emerge, not previously observed, such as coordination and overlapping among component mental operations. It is an important question for human performance modeling whether models of single-task performance, described at the level of elementary mental operations, are sufficient to characterize behavior in extended, fluid sequences.

The successes of current human performance modeling suggest the answer is yes, at least for highly skilled behavior (e.g., Gray et al., 1991; Matessa et al., 2002). Coordination and overlapping among component operations are simulated by enforcing logical dependencies among operations distributed across different resources, interleaving upcoming operations in the slack time created by queued bottleneck processes, and allowing operations from different resources to proceed concurrently. The success of this approach depends on the underlying assumption that component mental operations inferred from discrete task performance do not function differently in extended task environments. This assumption has yet to be tested. Also, success has been achieved for tasks that are largely perceptual-motor, with good fits obtaining after about 100 contiguous trials (e.g., John et al., 2002).

The goal of the present research is to investigate the coordination of component mental operations in extended task sequences that require a sequence of simple choice responses. To better contrast the coordination among component operations that may arise in extended task performance with the simple progression through set stages thought to underlie discrete task performance, we choose an extended task that consists of a monotonic sequence of identical discrete tasks. This approach helps place the emphasis on the coordination among component operations of different instances of the same task rather than among different tasks. Of all possible cases of coordination, we are especially interested in how movements of the eyes are coordinated with other underlying mental operations. Eye movements are an integral part of most cognitive activities. Their effortless and seamless integration with other components of task performance provides possibly the best example of coordination and the most challenging task for human performance modelers. Yet in existing frameworks the implementation of eye movements (or gaze resources) tends to be greatly simplified. In addition, the way by which eye movements are used is usually based on empirical findings from task conditions where eye movements are specifically made to meet instructions rather than generated naturally in accord with task goals. Little has been known on how task-driven eye movements are coordinated with the succession of stages and processes thought to characterize the underlying mental operations.

In this paper, we present our recent work on how eye movements are integrated with underlying component mental operations in extended tasks. We begin by reviewing existing literature on extended task performance with eye movement measures. Then we present the results of two earlier extended task experiments, followed by a new

experiment designed to address specific issues raised by the previous work. In the end, we discuss the implications of our results with an emphasis on how they inform us on modeling human performance in extended tasks.

Eye movements in extended tasks

Although eye movements occur naturally in almost all daily activities, to characterize the patterns of eye movements researchers in the past have focused activities with a clear script. Examples of such activities range from golf putting (Vickers, 1992), driving (Land & Lee, 1994), to tea making (Land & Hayhoe, 2001), and block-copying (Pelz et al., 2001). A common finding in such observations is that the eyes move in anticipation of upcoming actions during activities that involve scripted behavior.

The existence of preview in extended task performance characterizes the proactive nature of eye movement control. In tasks that require mostly non-visually based decisions, it seems intuitive that the eyes could move away prior to the response as soon as information acquisition is completed. *But, when can the eyes move and what determines it?* Answers to these questions are critical to understanding the coordination between eye movements and other mental operations. As typical fixation durations generally range from 200 to 400 ms, exceeding the time needed for perceptual registration, which can be estimated at around 100 to 150 ms (Salthouse & Ellis, 1980), this suggests that certainly other variables are involved.

Previous Research

Previously, we (Wu & Remington, 2004) examined the coordination between ongoing mental processing and the generation of eye movements in a task requiring multiple manual responses to multiple stimuli on each trial. Specifically, we were interested in two empirical questions. First, in an extended task with multiple stimuli to be responded to, when do the eyes move away from a stimulus? Second, in such an extended task how is the processing sequence affected by difficulty manipulations at separate stages? By independently varying the difficulty of perceptual and central stages we can determine which is on the critical path for the sequence of responses.

We adopted a typing-like task introduced by Pashler (1994). Participants viewed a series of five letters sequentially and responded to each individually in different preview conditions. Pashler manipulated preview to test how the mental processing of two or more stimuli were overlapped in time. He measured the reaction time (RT) to the first stimulus (RT1) and computed the inter-response intervals (IRIs) for subsequent responses. With no preview, RT1 and subsequent IRIs were roughly equivalent and constant across the stimulus sequence. With preview, RT1 was elevated, compare to no preview, while IRIs were constantly low. The same effects were observed regardless of whether 1 or 4 preview items were presented. Pashler interpreted the constant IRIs as an indication of a bottleneck central processing stage of response selection, which would only allow the selection of one response at a time. The fact that IRIs reflected the duration of response selection is further supported by the findings that varying the duration of stimulus recognition and response production had little to modest effect on the durations of IRIs.

Pashler's (1994) task presents a simple example of the operations of three critical mental components (perception, response selection, and response production) and a clear theoretical account for the coordination among them. In this case, characterization of a single task was sufficient to account for the IRI results without further assumptions. The model, however, did not predict the elevated RT1. The experimental paradigm represents a good compromise between the simplicity of typical discrete trial experiments, and real-world behavior.

In our previous work, we adopted Pashler's complete preview condition and incorporated an eye movement component by reducing the size of stimulus letters and increasing the separation between them. Identification of stimulus letters thus required successive saccades and fixations. In two separate experiments, we examined response time, dwell time (fixation duration), and eye-hand span associated with manipulation of the duration of perception and response selection stages.

Our first experiment examined the effect of perceptual difficulty on dwell time. Perceptual difficulty was manipulated by having two luminance conditions for the stimuli, Dim and Bright (5.2 and 46.2 cd/m2, respectively). Participants made sequential fixations to each of the five stimulus characters randomly drawn from the set T, D, and Z, and made choice responses accordingly. Those three letters were mapped to three response keys (V, B, and N) on a PC keyboard and assigned to the first three digits of the right hand. We measured the manual RT to each of the five stimuli and the IRIs. In addition, we derived three eye movement related measures: 1) eye-hand spans, which represent the elapsed time between the initial fixation on a particular stimulus to the moment when the corresponding manual response is generated; 2) dwell time, which represents the duration for which fixation is maintain on a particular stimulus; and 3) release-hand spans, which represent the elapsed time between the end of fixation on a particular stimulus to the moment when the manual response is generated. In fact, dwell times and release-hand spans make up eye-hand spans.

Figure 1 shows mean manual RTs, eye-hand spans, and dwell times as a function of stimulus in our first experiment. The pattern of manual RT results resembled what Pashler (1994) found in conditions with preview; specifically, the elevation of RT1 and constantly short IRIs of subsequent responses. The effect of perceptual difficulty was minimal on RT1/IRIs and appeared to be restricted to S1. Dwell time was lengthened in the Dim condition, though the amount of increase did not reach statistical significance. Results of this experiment confirmed that dwell time encompasses perceptual processes.

Our second experiment examined the effect of response selection difficulty on dwell time. The difficulty of response selection was manipulated by using two sets of stimuli to create two mapping conditions. One set included four alphabets T, D, Z, and Q mapped in this arbitrary order onto keys V, B, N, and M, and assigned to the four digits of the right hand; another set included digits 1, 2, 3, and 4 mapped in this natural order to the same four keys and fingers.

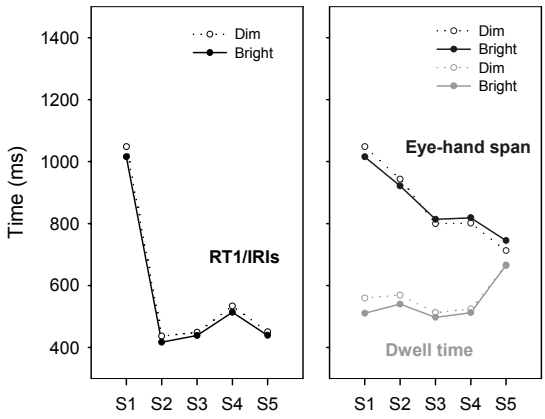

Figure 1. Results of Wu & Remington (2004), Experiment 1

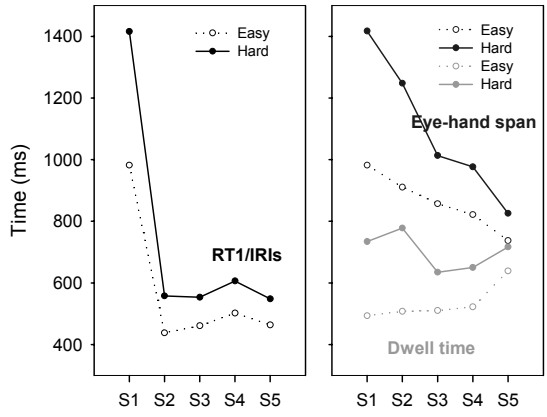
Figure 2 shows mean manual RTs, eye-hand spans, and dwell times as a function of stimulus in our second experiment. Again, the manual RT results replicated the general pattern observed in our first experiment and in Pashler's (1994) study; RT1 was elevated, and IRIs were constant and rapid. In addition, mapping difficulty had a strong effect on manual as well as oculomotor responses. Difficult response mapping resulted in increases in IRIs. It also significantly increased dwell times. Results from this experiment suggest that fixation durations appear to include response selection related processes as well.

Present Experiment

Results from our previous work (Wu & Remington, 2004) provided some answers to the questions posed earlier. In an extended task such as this, the eyes move away at some point during the response selection stage but definitely after completion of the perceptual stage. Results from our



previous work also featured some unexpected patterns of coordination between the eyes and the hand. One in particular is the interrelated temporal constraint among

Figure 2. Results of Wu & Remington (2004), Experiment 2

dwell times, IRIs and eye-hand spans. Except for the Hard mapping conditions in the second experiment, dwell times were mostly constant across stimuli, as were IRIs. In other words, the eyes dwell for a constant duration, and the hand releases responses also at a constant but faster rate. This leads to the observed decrease in eye-hand span across stimuli.

The response of RT1 to the Easy and Hard mapping conditions was also unexpected. Though we always see an elevated RT1, its increase of approximately 400 ms in the hard condition was about twice the increase in IRI and dwell time, which were both about 200 ms. This means that the dwell time did not fully accommodate the increase in RT1. Certainly, this is difficult to account for in a model that assumes that eye movements are triggered at a fixed point in processing. It is difficult to speculate about the reasons for the greater increase without more information about the source of the general elevation of RT1 seen in all our experiments. Thus, the present experiment was designed in part to investigate variables responsible for elevated RT1. In particular we examine the role of planning for a sequence of responses or fixations.

We also attempt to vary the central difficulty within a trial. One explanation for constant IRIs is that the earlier responses are delayed in order to be coordinated with stages in the processing of the subsequent response. It follows that, if no subsequent response is required, eye-hand spans should not be elevated. In the present experiment, we vary central difficulty using a Go/No-Go procedure. On each trial, only 2 or 3 positions contained target characters mapped with a key response. The rest were filled with dummy characters and participants were asked to skip them. We compare dwell time on Go and No-Go responses, and eye-hand spans on Go responses that are preceded and/or followed by No-Go responses to evaluate the impact of central difficulty.

Method

Participants Fourteen undergraduate students recruited from local colleges near NASA Ames Research Center participated in the experiment for course credits.

Apparatus The experiment was conducted using a PC with a 21-inch monitor. Participants were seated in a comfortable chair with their head secured on a head-and-chin rest placed 53.5 cm in front of the monitor. Eye movements were recorded with an infra-red video-based eye tracking system (ISCAN), which outputs data at a temporal resolution of 120 Hz and a spatial resolution of approximately 0.5˚ visual angle.

Stimuli and Display The primary stimulus display consisted of a row of five small characters (letters or symbols) spread over a wide viewing area. The characters were spaced equally (5.5˚ apart) and centered on the middle of the display. Each character subtended 0.34˚ in height and was presented at 11.7 cd/m2.

Design and Procedure Each trial began with the presentation of a white fixation cross (0.3˚) in the center of the display. After the participant had maintained fixation

within a 6˚ radius around the fixation for 500 ms, the fixation was erased and a small filled square (0.34˚) appeared at the leftmost stimulus position. Participants were instructed to move their eyes to fixate the small square when it appeared and maintain fixation at that location. The small square remained for 1 sec, followed by a blank interval of 500 ms. Then the five stimulus characters appeared simultaneously. Participants were asked to look at the characters one at a time, decide what they are, and make responses accordingly. Participants then pressed the spacebar to proceed to the next trial, which began following an inter-trial-interval of 250 ms.

There were six experimental conditions and two control conditions. Trials of different experimental conditions differed in the number of required successive responses in a sequence (one, two, and three), and in the stimulus position on which these sequences occurred (first and second). The six types of trials can be represented as the following: TXXTT, TTXXT, TTTXX, XTXXT, XTTXX, and XTTTX, with T denoting letter stimuli that required a key response (Go stimuli) and X denoting letter stimuli that required no response (No-Go stimuli). Go stimuli were randomly drawn from the letter set T, D, and Z, with the constraint that no letter was repeated in two adjacent positions. This constraint however does not prevent repetition of responses; the same letter could occur in two positions interposed by Xs. Five participants had 40 trials of each type administered in 2 blocks of 120 trials. Nine participants had 60 trials of each type administered in 3 blocks of 120 trials.

Trials in both of the two control conditions consisted of a single target (Go) stimulus in the first position (i.e., TXXXX), though different instructions were given for each. In the first condition, called Respond-Then-Scan (i.e., TXXXX), participants were asked to respond to the first letter stimulus, as before, and fixate each of the rest. In the second condition, called Respond-Only (i.e., T____), they were asked to respond as quickly as possible to the first stimulus only. There were 40 trials in each control condition. The two control conditions were administered after the experimental conditions and in the same order (Respond-Then-Scan first, Respond-Only second) to each participant.

No single aspect of task performance (e.g., manual or oculomotor, speed or accuracy, etc) was emphasized. The only specific instruction given to the participants was to treat each character independently and not group responses.

In all experiments eye movements were monitored and recorded. The recording of eye movements began at the moment when the small square appeared, and ended after the participant had responded to the rightmost stimulus. A calibration procedure was administered before each block of trials to maintain accuracy of recordings.

Results and Discussion

Figure 3 presents mean manual RTs and eye-hand spans as a function of stimulus. Cases where RT1 occurred to S1 (S1-RT1) are plotted separately from cases where RT1 occurred to S2 (S2-RT1). We discuss manual responses and eye fixations separately.

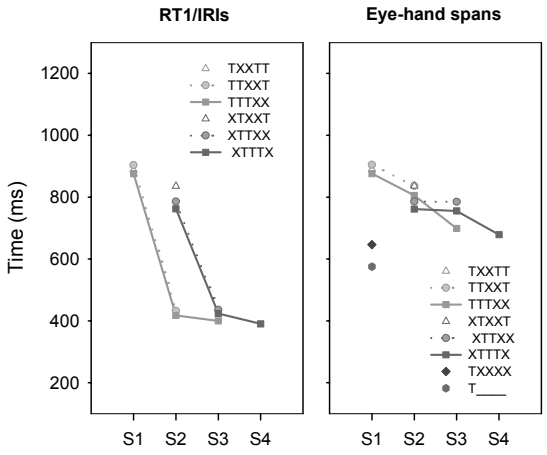


Figure 3. RT1/IRIs and eye-hand span results from the present experiment

Manual Responses The general pattern of elevated RT1 followed by rapid, flat IRIs is apparent in Figure 3. It is striking how closely aligned the curves for all stimulus conditions are. The only significant effect of the arrangement of stimulus was that RT1 was significantly slower when made to S1 (S1-RT1) than to S2 (S2-RT1). The general elevation of RT1 for both S1-RT1 and S2-RT1 suggests that cost is incurred for the first response in a sequence, not just to the first possible stimulus position. These similarities in patterns and magnitudes strongly suggest that the RT1/IRIs patterns are related closely to the production of sequences of responses. Indeed, the fact that RT1s for sequences such as "TTTXX" are equivalent to those for "TXXTT" is a strong indication that the difficulty of the next item has no effect on the current response. In other words, difficulty does not propagate backwards.

There are at least two possible explanations for the difference in RT1 between S1-RT1 and S2-RT1. It is consistent with at least some of the RT1 elevation being due to retrieval of stimulus-response mappings. If one assumes that the No-Go stimulus can elicit retrieval of response mapping for Go stimuli then that retrieval would have been done during S1 processing. This account is similar to accounts of first-trial cost in task switching studies (Logan & Bundesen, 2003). Alternatively, there is more uncertainty associated with S1 targets. If S1 is a non-target then S2 will always be a target. This reduction in uncertainty is a possible confound, though it is difficult to see how it would produce a speed up since the identity of S2 is not known until it is fixated.

Comparisons with the two control conditions provided evidence of sources contributing to the general RT1 elevation. RT1 was fastest (575 ms) in the Respond-Only condition, where participants were instructed to respond only to the first item and ignore the rest. RT1 was 72 ms slower (647 ms) in the Respond-Then-Scan condition, where participants were instructed to respond to the first item and fixate the others in turn. A plausible explanation for this overhead is that the elevated RT1 in the Respond-Then-Scan condition reflects a dual-task cost (cf. Pashler,

Carrie, & Hoffman, 1993), where the response task and the fixation task compete for a limited-capacity resource. There were no instructions as to how to perform manual and eye movement components; participants were free to do them concurrently or in sequence. We cannot say at present whether this overhead in combining the two behaviors, respond and fixate, arises from trying to do the two concurrently or would also be present with a strictly serial strategy. Some evidence suggests that trying to do the manual response concurrently with the fixation scan would cause interference. Pashler et al. observed interference between manual responses and voluntary eye movements in dual-task conditions, where participants were instructed to do both task as rapidly as they could. However, in their experiments substantial cost occurred only for anti-saccades, where subjects had to move away from a newly presented stimulus. A small cost obtained when moving to a specified color. Note that in both conditions the cost could reasonably be ascribed to a decision on the stimulus to determine where to move. In the present experiment the scan is fixed, making it difficult to see how stimulus decision processes could account for cost in the Respond-Then-Scan condition.

It is also hard to see why there should be a dual-task cost unless participants attempted to do the two tasks concurrently. Since there were no constraints or instructions on how to perform the task, any attempt to do them concurrently would have arisen naturally.

Another explanation might be that the Respond-Then-Scan condition forces participants to switch between tasks, resulting in a task-switching cost. However, task-switching costs are generally thought to arise from the retrieval of task-relevant knowledge, usually stimulus-response mappings. It is hard to explain how a switch cost would appear on S1 rather than on S2.

We prefer at present a more general explanation in terms of increased preparation time for the more complex behavior of Respond-Then-Scan. This account also helps explain why RT1 is further elevated in the full-response condition, with 2-3 targets. Here the preparation involves not only the sequencing of an initial response with a subsequent pattern of fixations, but of interleaving the responses.

There was one other significant RT1 effect whose meaning is not clear. S2-RT1 decreased significantly (from 837, 784, to 761 ms, *ps* < .05 based on pairwise *t* tests) as the number of required subsequent responses went up. This decrease was not observed for S1-RT1. It is hard to see how subsequent targets could facilitate a response to a current target. One argument is that the presence of a subsequent target could induce participants to rapidly complete the first item. The eyes fixated the next item prior to responding to the current one. If the next item is not a target they might decide to delay responding, and continue moving the eyes. If it is a target they know they must respond quickly and deal with the new item.

Dwell Time and Eye-Hand Span As in previous experiments, fixation durations remained relatively constant across stimuli. Not surprisingly, fixation durations on target (Go) stimuli were always longer than No-Go stimuli. More interesting comparisons arise when one regards fixation durations as a consequence of the previous stimulus (Figure 4). Here the dwell times suggest that the attempt to interleave the mental operations for successive stimuli pushes cost on to the subsequent stimulus. When the fixated stimulus is a target (a Go stimulus) dwell times were shorter by ~60 ms for targets that were preceded by dummy stimuli (i.e., XT) than by target stimuli (i.e., TT). When the fixated stimulus was a dummy stimulus this difference (TX compared to XX) was ~30 ms. This effect was found in several individual comparisons as well as in an analysis grouping all occurrences of each.

Condition	s1		s2		s3		s4	s5		T preceded by

Figure 4. Dwell times for S1-S5 in all conditions

Lengthened dwell times for stimuli preceded by targets suggest that the demand of making manual responses interfered with eye movement related processes. The eyes leave a stimulus prior to the completion of all the processing, such that the remaining processing for the previously fixated item delays one or more operations on the subsequent stimulus. A more detailed explanation rests on assumptions about the underlying resource architecture, which specifies the operations that can occur in parallel and those that must be done sequentially. The effect can be explained by adopting the common assumption that perceptual, cognitive, and motor operations execute in parallel, constrained only by logical or data dependencies. By this account, dwell times for the second stimulus are lengthened because cognitive resources required for stimulus-response mapping for the first stimulus postpone central processes on the second. Since central cognitive operations logically require data from perception, the inference is that this time is shorter by ~70 than that required for response selection. With continued explorations of similar factors it should be possible to obtain parameter estimates for processing operations that would permit a full model of extended task performance based on individual trial data.

Other aspects of the eye-hand span results resembled those found in previous experiments. As before, eye-hand spans decreased across the stimulus/response sequence. Figure 5 shows the results of the two constituents of eye-hand spans, dwell times and release-hand spans. There are several notable findings. First, it is evident that the difference among RT1s in cases where RT1 occurred to S2 was mainly due to the difference in release-hand spans. If one assumes that release-hand spans represent the time taken to complete remaining processes after fixation is terminated, it is foreseeable that release-hand spans may also include processes necessary for programming and coordinating response sequences. The fact that eye-hand spans decreased at a constant rate suggests that the coordination may not be restricted to each pair of responses. In the present set of experiments the maximal number of responses is set at five. It is possible that participants could

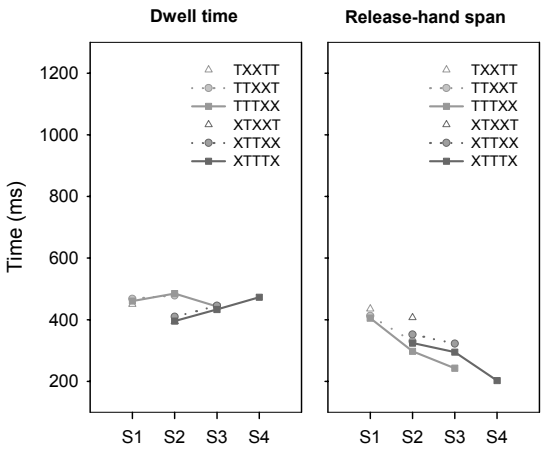

Figure5. Mean dwell time and release-hand span results

plan for five responses. Whether the trend will hold for longer sequences has yet to be tested.

General Discussion

The conditions of the experiment were designed to identify variables contributing to the elevation of RT1, and provide insight into the relationship of eye movements to manual responses by examining the effects of stimuli that required no manual response. Our previous experiments showed large eye-hand spans indicating that substantial processing remained on previous item after the eyes had moved. Analyses of dwell time responses to manipulations of stimulus-response compatibility suggested that dwell times encompassed central processes associated with response selection. Here dwell times for targets were elevated by ~70 ms when the preceding stimulus required a response. A straightforward account in terms of stage processing might estimate that the processing remaining after the eye movement is ~70 ms + the time for perceptual processing on the next task. Given a reasonable estimate of perceptual processing time of ~150 ms, it would seem that ~220 ms of central processing remain after the eyes move.

However, this explanation has difficulty accounting for the smaller increase (~30 ms) found on No-Go fixations in the same condition. That there is any effect of previous target at all is evidence that central processing is required to decide whether or not to respond to the No-Go stimulus. It might be assumed that the smaller effect for No-Go dwell times indicates more than postponement. That is, there may be interference between response-related processes on the two adjacent target stimuli. Since evidence for postponement is well known in dual-task studies, more evidence will be required to determine whether interference is acting here, rather than a more complicated postponement process.

Conclusions

We have evidence that RT1 elevation is due to a combination of factors including preparation for eye movement sequences, preparation for hand response sequences, and retrieval of stimulus-response mappings. Dwell times indicate that there is imperfect time sharing of the processing and response to successive stimuli. Mental operations on the previously fixated stimulus result in delays in processing the subsequent stimulus. These data can provide numeric estimates of internal processing times required to fully model these results.

Visual Analogy: Reexamining Analogy as a Constraint Satisfaction Problem

Abstract

Holyoak and Thagard proposed that the retrieval and mapping tasks of analogy can be viewed as constraint satisfaction problems, and described a connectionist implementation of their proposal. In this paper, we describe another constraint satisfaction method for the two tasks in the context of visual analogy: in our method, the source cases are organized in a discrimination tree, and all the source cases are searched *at once*. We also present an evaluation of the method for retrieval and mapping of 2-D line drawings from an external memory. The evaluation is based on structural constraints, and uses subgraph isomorphism as the similarity measure. One result is that a decomposition of the retrieval task into feature-based reminding and structure-based selection appears to provide little computational benefit over just selection.

Introduction

Holyoak and Thagard proposed that the retrieval (Thagard, Holyoak, Nelson, & Gochfeld, 1990) and mapping (Holyoak & Thagard, 1989) tasks of analogy can be productively viewed as constraint satisfaction problems. Their proposal incorporated structural, semantic and pragmatic constraints and used graph isomorphism as the primary similarity measure. Their mapping system, called ACME, and the complementary retrieval system, named ARCS, provided connectionist implementations of their proposal. In ACME, nodes are constructed for each map hypothesis (between a source element and a target element), with inhibitory and excitatory links between different nodes, and the network is run until it reaches quiescence. The work described here builds on Holyoak and Thagard's proposal but seeks a different solution to the retrieval and mapping tasks. While we also view the retrieval and mapping tasks as constraint satisfaction problems (CSPs), our method for addressing the tasks (i) organizes the source cases in a discrimination tree, (ii) uses (general-purpose) heuristics to guide the search, (iii) performs a backtracking search, and (iv) searches all the source cases *at once.*

The goal of our current work is to develop a computational theory of *visual* analogy. Analogies transfer relational knowledge from a source (or base) case to a target problem. Depending on the nature of the target and the source, the knowledge transferred in an analogy may pertain to different kinds of relations, for example, causal, functional or teleological relations. In visual analogy, the pertinent relations are spatial relations among visual elements. In a different part of the project, we have developed a technique for transfer of spatial knowledge, given a target problem and a source case and given a mapping between the two (Davies & Goel, 2001, 2003). In the part described in this paper, we focus on the retrieval and mapping tasks.

Our methodology is to start with simple problems and incrementally add complexity to them. This incremental nature of the methodology is manifested in three ways: firstly, visual knowledge can be of many forms, such as depictive bit-mapped representations, sketches, or animations, but our work deals specifically with diagrammatic knowledge represented symbolically as discrete geometric elements and the spatial relations between them; secondly, though visual analogies, like analogies more generally (as proposed by Holyoak and Thagard), can involve semantic and pragmatic constraints, we start with just the structural constraints imposed by requiring source and target to match structures; and thirdly, from a graph theoretic perspective, there may be more than one sort of graph isomorphism measure that may be the ideal measure, such as maximal common subgraph, but we begin with subgraph isomorphism as our metric.

The retrieval task, in this work, assumes a computer-based library of 2D line drawings, takes as input a query (target) in the form of a drawing (and no other information), and gives as output the source drawings that are most similar to the target. The mapping task takes as input a target problem and a source case, and gives as output correspondences between the basic elements of the source case and the target problem.

Retrieval

Following earlier work on analogical retrieval—e.g., MAC/FAC (Forbus, Gentner, & Law, 1995)—our retrieval architecture supports a two-stage process for diagram retrieval: reminding (or initial recall), and selection. The architecture consists of (up to) six basic components: an initial stage generating feature vectors, a process that generates a semantic network describing the contents (spatial structure in this case) of an drawing, a process that matches a target's description (semantic network) to source descriptions from memory, a working memory with potential sources to match with the target, and finally, an interface to the rest of the analogy system in which this retrieval would be taking place.

The reminding task takes as input a target example and returns as output references to stored drawings whose feature vectors match that of the target. The stored drawings are indexed by feature vectors describing their spatial elements; the feature vector for the target is constructed dynamically. References to those drawings with sufficiently similar feature vectors (according to some appropriate criteria, as explained below) are brought into the working memory. In the selec-

tion stage, the semantic networks of the drawings in working memory are matched with that of the target example. Drawings whose descriptions match the target description sufficiently well are collected and returned.

While the reminding stage of the retrieval process uses a vector of features—i.e. a vector of attribute-value pairs—as a heuristic to gauge the potential of a source drawing matching the target drawing, the selection task uses the spatial structure of line drawings—i.e. the qualitative arrangement of the various shapes in them—to actually match the target to the source drawings.

Visual cases are represented in three distinct ways: the the drawings themselves, the feature vectors, and the network of spatial relations. The representation of the drawings themselves is simply object-based: a list of each visual element, such as lines, triangles, etc., and their specific geometric properties (location, and so on). The feature vector is a multiset of the object and relation types contained in a semantic network. A multiset is a set that can contain more than one of each element (e.g. $\{2 \cdot A, 3 \cdot B, \ldots\}$). Given a semantic network describing an drawing, a feature vector in our system would look something like this: $\{3 \cdot \texttt{rectangle}, 2 \cdot \texttt{circle}, 3 \cdot \texttt{leftOf}, 1 \cdot \texttt{contains}, \ldots\}$.

A drawing is recalled, in the first stage, if the multiset of shape and relation types contained in it is a superset of that of the target. The method scans all stored drawings, calculating whether or not the multiset of objects and relations in the target is a subset of the multiset of objects in each source drawing, and returning those for which this is the case. That is, if Q is the feature vector for the target, and $S_1, S_2, \ldots, S_k$ are the feature vectors of the drawings currently in memory, then the method returns those drawings for which $Q \subseteq S_i$.

Figure 1 illustrates a simple 2D line drawing and its representation in terms of spatial relations in our system. The system at present recognizes four types of spatial elements: individual lines, triangles, rectangles, and ellipses (circles and squares are special cases of ellipses and rectangles, and are not treated as being of a separate type). Also, it presently recognizes five types of relations among the elements: `left-of`, `right-of`, `above`, `below`, and `contains`. The automatic generation of a semantic network for a target drawing works by taking the input drawing (in XFig format) and comparing every pair of shapes using the available predicates. If a particular predicate holds, a link is added between the associated nodes in the semantic network, with the appropriate label. As an example, the semantic network in Figure 1 would represent the drawing shown above it.

Memory Organization

When a source drawing is added to memory, several things happen. First, its description is generated, the network of relations describing the spatial layout of the drawing, as well as its feature vector. Second, once this network is generated, each "term" in the network, by which we mean a link (relation) together with its incident nodes (elements), is added to a discrimination tree. This allows the selection method to match individual terms in the target with all terms of the same form that appear across *all* source drawings in memory, thus allowing all of the descriptions of all of the drawings to be searched at once.

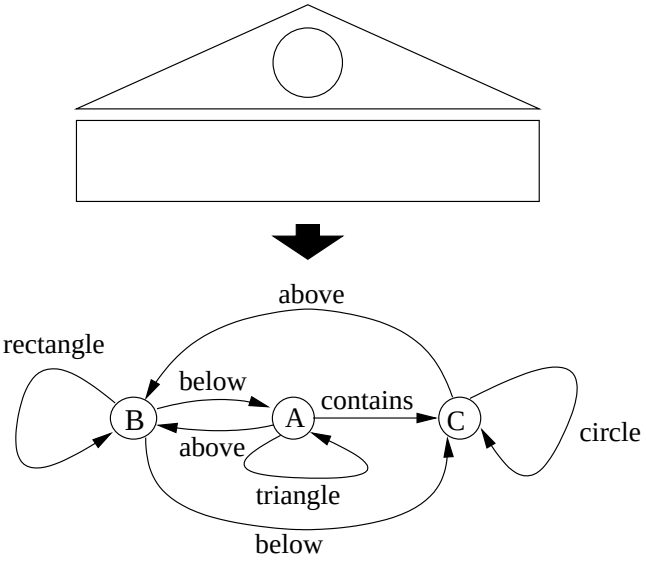

Figure 1: An example of a three-node semantic network in our language. Each pair of objects is tested, and links added for each relation that holds.

The selection method, described below, builds a set of potential assignments for each target element, and in evaluating these, it looks to see what terms each source element is involved in, and this involves the index into memory by individual terms. The overall scheme is to build a representation of all possible mappings, and reduce this list by screening out the ones that don't work. Ones that don't work are screened out because they do not satisfy the constraints imposed by the problem. This is constraint satisfaction, and this is what it means to solve the problem by constraint satisfaction.

Constraint Satisfaction

The core of the system is the selection process. The process finds a correspondence between the target drawing and the source drawings in working memory, eliminating drawings for which no correspondence can be found.

The selection problem is essentially one of matching objects (variables and constants) in the target and the source under the constraints imposed by the terms in which they appear. The target has a set of variables (its objects, the nodes in the semantic net) to be matched to some constants (i.e. values) from the sources and the relationships between these variables impose constraints on the values to which they can be matched. This is constraint satisfaction. This algorithm works by maintaining an index of all the terms across all of the source descriptions. It recalls individual terms from memory and puts them together to form the complete matching. When a source drawing is stored in memory, its description is generated and indexed in this way, by each term that appears in it. There is a separate table for each type of term, i.e. one for `left-of`, one for `above`, etc.

Treating the target elements as variables to be assigned values, the potential values are the nodes from the source descriptions in memory, all of which are considered at once. That is, the method is not performing a separate test on each

source in memory, but, rather, it is running a search procedure on the entire memory considered collectively. The constraints on the values assigned to the variables (the target nodes) are precisely those imposed by the subgraph isomorphism problem: if nodes A and B from the target are to be matched with nodes X and Y from memory, respectively, then, first, X and Y must be in the same description; second, all relations that hold between A and B must also hold between X and Y, respectively. If these constraints are met, then A can be matched with X and B can me matched with Y. Here the constraints are all either unary (say, A is a circle—a type constraint), or binary (say, A is left of B—a relational constraint). The only exception is the constraint that all values be from the same description, but this can be inferred from the binary constraints.

This matching process works in three phases: initialization of domains, reduction of domains, and finding the matching, where matching means subgraph isomorphism. The first phase initializes the target domains to sets of values that have the same incoming and outgoing edges. The second phase reduces these domains by eliminating values that are not all in the same drawing. These two phases reduce the selection of values for each variable. The third phase actually computes the isomorphism using constraint satisfaction and backtracking.

The first phase (initialize domains) works by finding nodes in memory that "look similar" to the target nodes: if a target node A is incident on, say, three links whose labels are R, S, and T, then the algorithm builds a list of all nodes in memory—across all the source descriptions—that have at least three incident links with labels R, S, and T. The second phase (reduce domains) works by ensuring that the set of source descriptions (document IDs) that are represented in the domain of (list of values for) each variable is the same. This serves to eliminate any value from the domain of any variable that does not come from a description represented in every other variable's domain.

These two stages are the "real" first stage of the algorithm, and our results, described in (Yaner & Goel, 2003), showed that the feature-vector-based first stage was really quite redundant, and offered little improvement. Viewed as such, this first stage applies two heuristics to the sources from memory: (i) prune any individual element (as opposed to entire drawings) that don't have the same "signature" (as just described) as the corresponding target element, and (ii) prune any terms whose associated drawings are not represented in every target element's domain. The latter one enforces subgraph isomorphism. It is important to note that these are both logically implied by the similarity metric that the last phase, described below, implements. It would be an interesting experiment to look at other heuristics that prune out mappings that might have otherwise been returned by the last phase.

The last phase (find matchings) is the one that actually does the work. The basic procedure is one that generates matchings, checking them for consistency as it goes, and backtracking when necessary. The test, here, is actual subgraph isomorphism: if A is related to B in the target, then the relations (links, edges) between $m(A)$ and $m(B)$ must include at least those that held between A and B, where $m(*)$ is a mapping from target to source. This algorithm returns all valid mappings. The idea is that the first two phases have restricted the set of possible mappings so that there aren't nearly as many, now, as there would have been if a pure depth-first search had been done.

In general, the time complexity of depth-first search, such as this is, is on the order of $O(k^d)$ in the worst case, where k is the branching factor of the state space and d is the maximum depth. In this case the depth is the number of elements in the query, and the branching factor is the number of elements across all sources in memory. However, the space complexity, as with depth-first search in general, is only $O(kd)$, i.e. it's linear in the size of the problem. Note that this is a backtracking search, however, so large portions of the state space are cut off at each step. With 42 test images in memory, the number of objects in a drawing ranging from 3 to over 50 (the average was about 12), the number of terms in the description ranged from a couple of dozen to over eight thousand. There were 21 queries with this test set, with two to five spatial elements in each, and up to several dozen terms. With this test data, the system was retrieving drawings in about 9.32 seconds on average (across all 21 drawings), doing an average of about 1.49 million memory accesses (to the index of terms across all the drawings) per retrieval.

Galatea

Since the system does retrieval essentially by producing all possible mappings that it is capable of finding, we adapted a version of the system to the mapping process for use in a system called *Proteus*, a visual analogical reasoning system. The transfer stage of *Proteus*—implemented in a system called *Galatea*—is described in Davies and Goel (2001, 2003).

Galatea solves problems represented in a high-level visual language called Covlan (Cognitive Visual Language). The system solves these problems by analogy to existing problems whose solutions are mapped out as a sequence of transformations on the knowledge states that are represented in this language. *Galatea* solves the problem by taking a mapping between the initial knowledge states of the source and target and mapping the transformations and generating the intermediate knowledge states (and mappings between them), and thereby constructing the rest of the transformations and knowledge states leading to the solution to the target problem. The mapping system, then, needs to connect the initial knowledge state of the source and the target drawing. From the perspective of retrieval and mapping, the relevant issues pertaining to *Galatea* are: (1) what is that knowledge representation, and (2) what are the nature is of the required mappings?

Covlan consists of knowledge states, primitive elements, primitive relations, primitive transformations, general visual concepts, and correspondence and transform representations. In Covlan, all knowledge is represented as propositions. In this paper we will only be concerned with the primitive elements and the primitive visual relations. The primitive elements are `polygon`, `rectangle`, `triangle`, `ellipse`, `circle`, `arrow`, `line`, `point`, `curve`, and `text`. There is also a `set` element type, with members that have `in-set` relations back to the set they are members of, though these do not correspond to visible entities—this is purely for grouping purposes. Each element is represented as a frame with attribute slots such as `location`, `size`, `orientation`, and

`thickness`, but these attributes will not concern us, since mappings between attribute values are not part of the required mappings, and thus representing them in the semantic network is not necessary.

Primitive visual relations represented are touching, `above-below`, `right-of-left-of`, `in-front-of-behind`, and `off-s-image`. A typical knowledge state is represented with a node corresponding to that knowledge state (e.g. `L14-simage1`), and elements (which may be sets) are represented with `contains-object` relations from the knowledge state element to the visual elements themselves.

We describe next some example problems originally designed for *Galatea*. The first example problem is a fairly simple one: dividing a pizza into some number of slices based on analogy to the problem of dividing up a cake into some number of pieces. In this case, there is a cake (or pizza), and a set of people in the initial problem state. Set members are not mapped, and the division is made in transformations in later problem states, so the only possible mappings are cake to pizza and set of people to set of people, or cake to set of people and set of people to pizza. The problem, as represented in *Galatea*, does not contain any visual relations between the set of people and the cake (or pizza), and thus there is nothing constraining the mapping to be the "correct" mapping. The latter mapping will probably lead to failure in the transfer stage, but both are returned by our system.

A more complex and interesting example is based on Gick and Holyoak's fortress/tumor problem (1980). In this problem, we have an army attacking a fortress over mined roads, and the general decides to split his army to avoid setting off the mines, and a target case in which there is a patient with a tumor and a doctor who wants to kill the tumor with radiation. The supposed analogy is to split the beam (somehow) to avoid killing the healthy tissue that is in the way. The visual representation of these problems has a fortress (and a tumor represented similarly) and four roads (sections of the body surrounding the tumor), and an army represented by an arrow (a ray of radiation represented similarly). The "correct" analogy maps the set of roads to the set of body parts, the fortress to the tumor, and the army to the ray. However, there being three of each thing to match, and the particular representation chosen not using the visual relations (though it could have), there was nothing constraining the mapping, and all six possible correspondences were returned. Had visual relations constrained it, the number of possible mappings would have been smaller.

Mapping

Galatea has set up the requirements for the mapping task such that only visual elements are to be mapped, not attribute values, and so attribute values (which can be represented as propositions, and hence can be represented in a semantic network) are not included in the input to the mapping system. In addition, members of sets are (generally) not to be mapped, and so any visual element on the left-hand side of an in-set relation can be pruned from the mapping system's input, as well. With these two constraints, the mapping system was run on several sample problems, two of which were described above. Four other problems of similar nature and size were also run on this system.

function GENERATEMAPPINGS

14: **return** $fMappings \bigcup rMappings$

Algorithm 1: Generate Mappings

The mapping algorithm (see Algorithm 1) works as follows: the outer procedure (generate mappings) first retrieves the named source and target representations from memory, then applies the above heuristics to it, and finally generates the mappings and returns them. Since it computes subgraph isomorphism, as above, we run it both ways—attempting to map source onto target, and also attempting to map target onto source and reversing the returned mappings. Thus it is possible to find the target within the source or vice versa, finding the source within the target. The algorithm for FINDPROJECTIONS is identical with that of the third phase, "find matchings", above.

It's important to note that this does not actually solve the mapping problem; it particular, it returns *all* mappings, so that an additional search or evaluation stage is necessary to find the relevent ones. This is where pragmatic and semantic constraints may start to enter back into the picture. Our work to date has begun with only structural constraints as an experiment, and we plan to reintroduce other constraints as the larger problem context is reintroduced.

At any rate, the cake/pizza example described above, when run through this system, came up with two mappings: one that maps the cake to the pizza and the set of people to the set of people, and one that maps the cake to the set of people and the other set of people to the pizza:

Cake *maps-to* Pizza
Set12 *maps-to* Set14

Cake *maps-to* Set14
Set12 *maps-to* Pizza

Set12 is the set of people in first cake problem knowledge state, and Set14 is the set of people in the first pizza problem knowledge state. *Proteus*, recall, does not map members of sets, and so the individual people are not mapped onto each other, only the sets. The first one, obviously, is the "correct" one, the one that would lead to a successful transfer and evaluation of the problem solution.

The fortress/tumor problem was more interesting. The heuristics pruned out the set of roads and body parts, as well as the shapes and sizes and positions of all the elements, and so the only details left to influence the mappings were the fact that the elements were part of the problem. There were three elements, thus, remaining, for each one: Fortress and Tumor, Soldier-Path and Ray, and Set1 (the set of roads) and Set2 (the set of body parts surrounding the tumor), and six mappings produced:

Fortress *maps-to* Tumor
Soldier-Path *maps-to* Ray
Set1 *maps-to* Set2

Fortress *maps-to* Tumor
Soldier-Path *maps-to* Set2
Set1 *maps-to* Ray

Fortress *maps-to* Ray
Soldier-Path *maps-to* Tumor
Set1 *maps-to* Set2

Fortress *maps-to* Ray
Soldier-Path *maps-to* Set2
Set1 *maps-to* Tumor

Fortress *maps-to* Set2
Soldier-Path *maps-to* Tumor
Set1 *maps-to* Ray

Fortress *maps-to* Set2
Soldier-Path *maps-to* Ray
Set1 *maps-to* Tumor

Now, this really represents all correspondences between three things and three things. The primary reason for this is that the representation chosen for this particular problem does not involve any reference-frame relations such as `left-of` or `right-of`. If it had, these relations would constrain the mappings.

Discussion

In the introduction, we mentioned Holyoak and Thagard's ACME system (1989) and noted the similarities and differences between our work and theirs. ANALOGY (Evans, 1968) was an even earlier AI program that performed the task of finding similarities and differences between visual cases. It performed simple geometric analogies of the kind that appear on many intelligence tests. Let us suppose that each of A, B, C, D, E and F is an arrangement of simple geometric objects, e.g., a small triangle inside a large triangle, a small circle inside a larger circle, etc. Given an analogy A:B, and given C and multiple choices D, E and F, ANALOGY found which of D, E, and F had a relationship with C analogous to that between A and B. It represented the objects and the spatial relationships between them in the form of semantic networks, which enabled it to compare the spatial structure of the various arrangements. However, since ANALOGY performed an exhaustive and linear search of the mappings, its method cannot scale up to any realistic problem.

While ANALOGY was an early program that matched symbolic descriptions of two drawings and found similarities and differences between the drawings, MAGI (Ferguson, 2000) and JUXTA (Ferguson & Forbus, 1998) are two recent systems that find mappings between symbolic representations of two drawings (or two portions of the same drawing). These systems use truth maintenance as the mechanism for keeping track of new constraints and retracting old conclusions.

Our decomposition of the retrieval task into feature-based reminding and structure-based selection is similar to that of MAC/FAC (Forbus et al., 1995). The similarity is specially striking because in its current stage ours deals only with structural constraints; as noted in the introduction, we plan to explore and exploit semantic and pragmatic constraints in the next stage. However, in contrast to MAC/FAC, the experiments described in (Yaner & Goel, 2003) indicate that the two-stage decomposition of the retrieval task provides little computational benefit over just one-stage retrieval based on structure-based selection.

In computer-aided design, FABEL (Gebhardt, Voß, Gräther, & Schmidt-Belz, 1997) was an early project to explore the automated reuse of diagrammatic cases. In particular, TOPO (Börner, Eberhard, Tammer, & Coulon, 1996), a subsystem of FABEL, used the maximum common subgraph (MCS) of the target drawing with the stored drawings for retrieve similar drawings. Gross and Do (1995) describe a method for retrieving designs that contain a given design pattern in the domain of architectural design. Gross and Do's heuristic method is very simple: given two drawings, it compares the type and number of spatial elements and the spatial relations by counting. Their method is roughly equivalent to the first stage in the two-stage retrieval process.

In computer vision, Grimson and Huttenlocher (1991) developed a similar method for object recognition. They begin with a model with a set of features, such as a set of potential edges in some arrangement, and sensor data with a set of sensor features (edges, vertices, etc.); a lot of sensor features might be noise. The task is to find a set of sensor features that comes from one (and the same) object. Their method matches model features to sensor features under some transformations within specific limit of tolerance. The model imposes constraints, for instance, by its arrangement of features. Although they do not describe it as constraint satisfaction, their method in fact is in assigning values to variables under unary and binary constraints imposed by the arrangement by using a backtracking depth-first search.

Constraint satisfaction methods have become common in AI: Prosser (1993) describes methods of constraint satisfaction with backtracking; and Bayardo and Schrag (1997) provide evidence of applicability of constraint satisfaction with backtracking for real-world intractable problems in planning and scheduling. Our method of constraint satisfaction with

backtracking, with the case memory organized into discrimination trees, builds on the work of Ounis and Paşca (1998). They view the general problem of associative image retrieval as one of computing projections over conceptual graphs representing their content. Although they do not describe it as a constraint satisfaction method, their algorithm, in fact, is doing constraint satisfaction to compute the projection. However, their method is limited to constraint satisfaction with generate and test with no backtracking.

Conclusions

We have described a constraint satisfacton method for the retrieval and mapping tasks of analogy. Our method (i) organizes the source cases in a discrimination tree, (ii) uses (general-purpose) heurstics to guide the search, (iii) backtracks (if and when needed), and (iv) searches all the source cases at once. We also presented an evaluation of the method for the retrieval and mapping of diagrams from an external memory.

Our laboratory-scale experiments, with drawings containing only up to fifty spatial elements and their representations containing only up to eight thousand terms, indicate that the method of constraint satisfaction is fast and appears quite promising for use in practice. On the one hand, we fully expect that the complexity of the task will significantly worsen for larger drawings and larger libraries of drawings, but, on the other, we also expect that it should be possible to develop significantly faster methods for the task. For example, we expect that use of spatial aggregations and abstractions to organize the representation of the spatial structure of a drawing in the form of a linked hierarchy of semantic networks would partition the search space performance especially for large, complex drawings (e.g. Papadias, Kalnis, & Mamoulis, 1999). In addition, more sophisticated constraint satisfaction techniques such as forward checking and intelligent variable ordering, to name just a couple of common ones, can be brought to bear on the problem as well, taking advantage of structure in the knowledge representation and the search space.

Abstract

How are art works created by artists? In this study, we focused on the drawing processes of a Chinese ink painter through a field study and a field experiment. In the field study, we observed processes of fusuma drawing in a temple, and in the field experiment, we asked the painter to draw sixteen pictures (eight drawings in BLANK condition and eight drawings LINES condition). We analyzed those drawing processes and found that: (1) this artist seems to gradually form a global image of the drawing as he draws each part one by one; (2) lines that the audience drew seem to create new constraints for his drawing and force him to create new patterns; and (3) moving his brush in the air before actually drawing lines on the paper seems to serve one of the following functions: Positioning (where to draw), rehearsal (how to draw), and image generation (what to draw).

Introduction

It is widely believed that only talented people can create great works of art. Despite this, the psychology of creativity has demonstrated that ordinary cognitive processes underlie the emergence of images or concepts (Weisberg, 1993). Although cognitive psychology ought to be interested in such creative cognitive processes, few empirical studies on the artistic creative process have been conducted (Getzels & Csikszentmihalyi, 1976). Among the few studies that have been conducted, some are relatively old and pre-date the information processing revolution that has occurred in the field (e.g., Eindhoven & Vinack, 1952). More recently, studies have used techniques such as interviewing in order to understand the creative process but have neglected on line methods (e.g., Mace & Ward, 2002; Cawelti, Rappaport & Wood, 1992). Despite these efforts, creative cognitive processes are not yet well understood. At this early stage of cognitive study on artistic creation, it seems that multi-method approaches are most appropriate. For example, Getzels & Csikszentmihalyi (1976) have approached creativity from several perspectives by using several test batteries, such as IQ tests, creativity tests, personality tests, and observations and interviews of art-making processes.

Viewing the state of creative study, in the present study, we try to answer the question, "How does a painter create his/her works?" We offer a case study based on observations, interviews, and a field experiment with detailed cognitive analyses of the drawing processes of a *Suibokuga* (Chinese ink painting) painter.

Method

Subject: Mr. K. is a *Suibokuga* painter in his early 60's with about 18 years of experience of painting in that style. He usually draws *Sansuiga*, which are traditional Chinese landscapes of mountains and valleys, on fusuma (Japanese sliding doors) or folding screens in temples and shrines. He has also exhibited his works at museums in the USA and France in addition to many places in Japan. He has a special style of drawing. He improvises his drawing in front of audiences by incorporating random lines that the audience drew onto blank paper.

Period of observation: This field study was conducted from 1998 to 2001, with a follow-up interview conducted in 2003. We observed his drawing processes and collected substantial on-line data about his drawing. Also, we investigated his drawing processes through conducting a field experiment.

Data described in this paper: In this paper, we focus on the following two data sets in this field study: (1) process data of a fusuma drawing in temple X; and (2) data from a field experiment.

In the temple, spending about one and a half-hour, the painter drew a picture of mountain and river across four fusuma sliding doors. We set up two video cameras from both sides of the fusuma doors to capture his drawing process. After he finished his drawing, we interviewed him about his drawing process. In this case, he did not ask the audience to draw random lines because the master of the temple asked him not to do so.

In the field experiment, we asked him to draw eight pictures created from fifteen random lines drawn by two experimenters (we call this the LINES condition) and eight pictures created on blank paper (we call this the BLANK condition). The themes of the paintings are the four seasons. We asked him to draw two pictures of each season in each condition: spring; summer; fall; and winter. The order of task presentation was counter-balanced by condition. The order of the season for each task was randomized. We recorded the processes of his drawing with two video cameras. He drew three or four pictures in his studio in a day. It took a total five days between June and December to complete the field experiment. Usually it took about 20 to 30 minutes for him to finish a picture. In the third day of the experiment, he reported that he

could not concentrate on drawing and drew just one picture. In the second day of the experiment he thought a picture in the BLANK condition was not good enough. Therefore he drew another picture with the same theme once more in the final day.

Goal of this study: This study describes the drawing process of a *Suibokuga* painter through a field study. Unlike laboratory experiments, field studies can be problematic with regarding to variable control. In addition, since this is a single case study, we also cannot generalize our findings to all artists. However, through field studies such as this, we can propose new hypotheses or offer useful insights with high levels of ecological validity. Especially, in domains where few previous studies exist, starting from field studies can be very useful in order to find important questions and hypotheses and to lead to further research projects that follow realistic and meaningful directions.

Results and Discussion

The following three main features were identified through our field study;

(1) The painter seems to form a global image of the drawing gradually as he draws each part one by one;
(2) The painter draws pictures in fairly patterned ways. Lines that the audience drew, however, seem to create new constraints for his drawing and force him to create new patterns;
(3) The painter often moves his brush in the air before actually drawing lines on the paper. Based on our data analyses, we describe three possible functions of these movements.

Processes of Drawing Images

Mr. K draws his paintings very smoothly and quickly. Although it might look as if he had already formed an image of the entire picture before starting to draw, our analyses of the drawing process and an interview with him revealed that he starts drawing with a local image of the picture. Then, he gradually forms a global image as he draws each part one by one.

When we interviewed him just after he finished drawing fusuma doors in the temple, he said, " Not the entire picture. Starting from here, the pine tree that I first drew, then there and this bridge and here, then the cedar trees above the stairway. Then the roof of the hat. I had an image of only those parts at the beginning"(See Figure 1). It seems that he does not form the entire image before he starts drawing. How can he draw so smoothly without forming the whole image or complete plans in his mind before starting to draw? We analyzed his drawing processes in detail to answer this question.

Figure 2 shows the process of his drawing on the fusuma doors of the temple. The circled numbers on the fusuma doors indicate where and in what order he drew. The circled numbers on the tatami mats indicate where and in what order he moved. We divided the process into five sections based on his movements. The first four sections were segmented when he moved backward to survey the entire picture for more than one minute. The rest of his drawing processes were combined into one section, because he moved backward and forward very often without long pauses. In the first section, he sat on a tatami mat and started drawing a tree on the left-most part of the fusuma door. After he drew the central part of the left fusuma doors for about 22 minutes, he stepped back in order to see the entire picture. Then he started drawing on the second door from the right and paused to observe what he drew many times. When this part of the picture became more formed, he moved backward and looked at the picture occasionally. At almost the end of his drawing in the last section, he moved back and forth frequently, adding a few lines here and there. This analysis of his drawing processes and his interview in the temple suggests that he gradually formed his plans for the painting while he was drawing. Although this is a single case analysis, we observed that he drew the fusuma doors in this way on many other occasions.

Mr. K cannot look at the entire picture without stepping backward when he draws on such big fusuma doors. Although he can take in the entire picture when he draws on a small-sized paper, he still has to spend a certain amount of time planning and monitoring when he draws, even though he can see the entire picture at a glance. Therefore, we measured the duration and timing of pauses in the data from the field experiment in order to infer his planning and monitoring process as while drawing. We divided drawing processes into small cycles. One cycle consisted of the period from his soaking the brush in the sumi ink plate, lifting up, drawing on the paper, and soaking it in the ink plate again. We counted the distribution of pauses by length and found that the frequency drastically dropped above nine seconds. This suggests that there might be some functional difference in pauses shorter than nine seconds and those longer than nine seconds. The frequent occurrence of the shorter pauses probably indicates that he moves the brush from one place to another or ink plate, etc. And, the less frequent occurrence of the pauses longer than nine

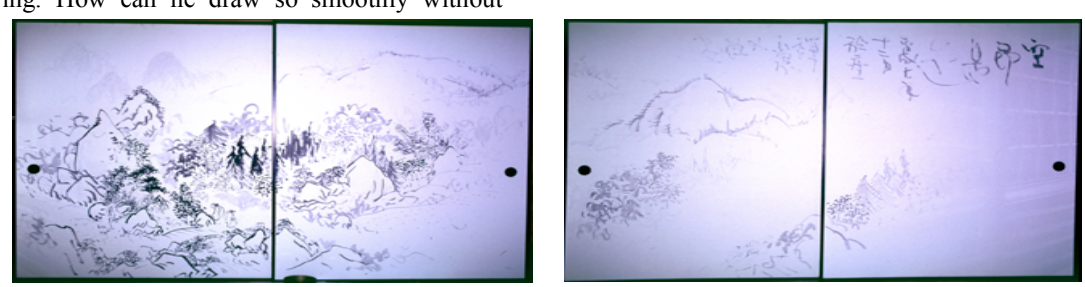

Figure 1: Picture on fusuma doors at temple X

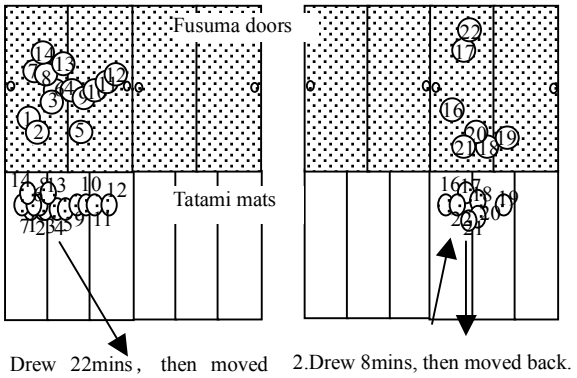
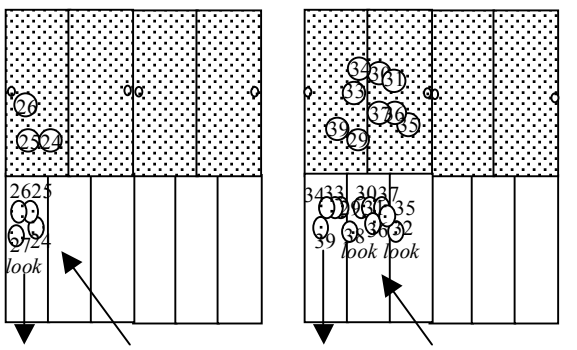
seconds would mean that he spent time thinking about the



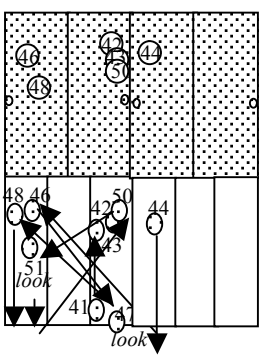
1. Drew 22mins, then moved back.

2.Drew 8mins, then moved back.



3.Drew 5mins, then moved back.

4. After intermission, drew 11mins, then moved back.



5.Moved back and forth (5mins.).

Figure2: Processes of drawing on the fusuma doors in temple X

pictures, planning and monitoring his drawing processes[1].

Table 1 shows the data from the field experiment. When counting pauses equal to or longer than nine seconds, we found that there was about the almost same number of pauses in the first and the second half of his drawing in each condition, t (7) = -2.37, p = .050, t (7) = -1.80, p = .862 (See Table 1).

Table 1: Mean number of pauses (nine or more seconds) during drawing

	Whole drawing	First half: Second half	Before drawin with lines
BLANK condition	5.0	1.4 : 2.4	
LINES condition	11.4	5.6 : 5.8	4.5

This suggests that he plans and monitors his drawing through the entire process of drawing. There were more pauses in the LINES condition than in the BLANK condition, F (1, 7) = 19.166, p = .003. When we focused on the frequency of pauses just before he drew from random lines, we saw about the same frequency of the pauses as a difference between each condition, F (1,7) = 3.163, p = .119. This probably means that he needs to think about local drawing plans in order to incorporate those random lines into his picture when he creates pictures from random lines.

In summary, it appears that the painter plans and monitors through the entire process of drawing. He first forms a mental image of a small area (creates a local drawing plan), and gradually forms the entire mental image of the picture as he draws each object.

Lines as Constraints

Analyses of the contents and patterns of Mr. K's drawing suggest that he drew pictures in a fairly patterned way. Through our observation, we found that he drew objects one by one. In the field experiment, he started to draw his paintings from a tree in fifteen out of the sixteen pictures. Then rocks, houses, people and mountains followed. We observed in many other occasions that he drew pictures in the same way. It suggests that he uses some strategies in order to draw certain objects in a relatively stable order in various situations. However, when we interviewed him, he said, "All of the pictures that I created from random lines are more unique and nicer than those created in a traditional way." What kind of difference is there between both conditions? We investigated the differences in time of drawing and the number of drawing cycles between pictures in the LINES condition and pictures in the BLANK condition (See Figure 3 and Table 2).

First, the mean time of drawing (except for the time of painting shadows or shading ink lines which always occurs at the end of his drawings) was calculated in each condition. In the BLANK condition, the mean time of drawing was about ten minutes (M = 640.13 sec, SD = 170.91 sec), and, in the LINES condition, it was about eighteen minutes (M = 1050.38 sec, SD = 199.40 sec). The time of drawing in the LINES condition was significantly longer than the time of drawing in the BLANK condition, t (14) = 3.87, p < .01. We also counted the number of drawing cycles in each condition and calculated the mean number. The mean number of drawing cycles in the LINES condition was significantly higher than that in the BLANK condition, t (14) = 3.91, p

[1] Our criterion gains plausibility from experiments in previous studies. For example, Chase & Simon (1973), with perception and memory tasks in chess, presumed the long time interval while glancing chess pieces placed on the board was needed to combine several chunks, and the short time interval to access to a single chunk. Thus, it is also reasonable to think that the difference of time interval reflects upon the processes of thinking during drawing.

Table2: Differences between the BLANK condition and the LINES condition

Measures	BLANK condition Means and (*SD*s)	LINES condition Means and (*SD*s)	*p* of *t* Tests
Time of drawing(sec)	640.13 (170.91)	1050.38 (199.40)	< .01
Number of drawing cycles	30.0 (8.80)	43.5 (4.92)	< .01
Time of one cycle(sec)	23.3 (7.50)	25.5 (6.85)	n.s.

< .01. These results indicate that it takes more time and more drawing cycles to create new pictures from random lines.

This result suggests that these lines somehow influenced drawing. Therefore, we investigated how these lines were used in his drawing. There were fifteen random lines drawn by the experimenters on each paper in the LINES condition. With an average of 9.3 out of fifteen lines, he would create new object starting from others lines. In the other 5.7 instances he incorporated the other's line into an existing object. Thus, the random lines triggered his drawing process and created new constraints on his drawing.

There seemed to be some differences in terms of quality between pictures in the LINES and BLANK conditions. To check this possibility, we asked twenty undergraduate students to rate their impressions of the paintings using a semantic differential method.

The procedure is as follows: Twenty undergraduates who did not major in art were presented pictures randomly with twelve word pairs of opposite meaning as a paper and pencil task. All words were adapted from adjectives used in the study of emotions when appreciating pictures (Ichihara, 1968) and interviews of the painter. Subjects were asked to rate the pictures based on a seven-point scale for each word pair.

Factor analysis with a principal factor solution was used to create scales across the word pair items. The three distinct factors with an eigenvalue above 1.0 were recovered and the ratio of variance contribution was 65%. These factors were rotated with Varimax and the factor loading was calculated (See Table3).

Four items are strongly correlated with the first factor, which we term *good composition*: modulated / non-modulated; well composed / poorly composed; focused / unfocused; and well-balanced / ill-balanced (*alpha* = .82). The second factor, which we term *liveliness*, is strongly correlated with the items: lively / dull; static / dynamic; energetic / non-energetic; and powerful / power less (*alpha* = .77). The final factor, which we term *simplicity*, strongly correlated with the items: clear cut / mixed up; simple / complex; relaxed / crowded; and light / heavy (*alpha* = .73).

We conducted a single-sample version of Hotelling's T^2 to compare their rating scores of paintings from the two conditions (See Figure4).

Figure 3: Picture in the BLANK condition (top) and picture in the LINES condition (bottom)

The mean scores of *good composition* and *simplicity* in the BLANK condition were significantly higher than those in the LINES condition, *F*s (1, 159) = 93.838 and 28.479, respectively, *p*s < .001. This result indicates that pictures in the BLANK condition are well composed. Also, because there is fair amount of white space in these pictures, it creates the impression of simple picture. The painter draws the BLANK pictures with the style of traditional *Sansuiga* paintings. On the other hand, the mean score of *liveliness* in the LINES condition was higher than that in the BLANK condition, *F* (1, 159) = 4.153, *p* < .05. This result indicates that pictures in the LINES condition were characterized by liveliness and were dynamic. Thus, the character of LINES pictures is different from traditional *Sansuiga* paintings.

Mr. K also thinks that this way of drawing is more exciting than the traditional way. When we interviewed him asking why he wanted to draw from random lines, he answered:

> "Creating from random lines, I have to incorporate the others' world into my world... I have to use them with my lines...Seriousness! I enjoy playing this game in earnest. There is not just myself. I get serious about drawing in this way. Yes. I am highly motivated with this way."

Thus, these lines seem to create new constraints for his drawing and force him to create new patterns.

Roles of Hand Movements in Drawing Processes

From our observations in the field studies, we noticed that the painter moved his brush in the air very often before he actually drew lines on paper. We wondered why he did so.

This kind of hand movement is not unique to this painter. For example, Henry Matisse moved his brush in a similar way in the video, "Matisse: Voyage". When we talked with researchers in architectural design and in art education, they agreed with us that painters or designers often draw in the air before they draw on paper. This kind of hand movement is not even unique to painters. Sasaki & Watanabe (1983) also found that when writing Kanji characters, Japanese people often moved their fingers in the air. They interpreted this phenomenon to mean that

Table3: Result of Factor Analysis
(Varimax rotated factor pattern)

	Score: 7 ------ 1	Ⅰ	Ⅱ	Ⅲ	SMC
Good composition	Modulated--Non-modulated	**.70**	.27	.05	.57
	Focused--Unfocused	**.80**	.11	.13	.67
	Well-balanced--Ill-balanced	**.80**	.11	.16	.67
	Well-composed--Poorly-composed	**.79**	.07	.15	.66
Liveliness	Lively--Dull	.13	**.86**	-.03	.75
	Static--Dynamic	.06	**-.65**	.28	.50
	Energetic--Non-energetic	.20	**.85**	.13	.77
	Powerful--Power less	.42	**.62**	-.31	.65
simplicity	Clear cut--Mixed up	.56	-.15	**.63**	.72
	Simple--Complex	.29	-.16	**.62**	.49
	Relaxed--Crowded	.37	.20	**.70**	.67
	Light--Heavy	-.15	-.18	**.75**	.62
	Contributions	.410	.319	.271	

people use their body to remember Kanji Characters. Thus, it would be reasonable to hypothesize that moving in the air would have some important function not only when writing Kanji characters but also when drawing pictures.

We identified the timing of when he moved his brush in the air to investigate the role of the movement in his drawing. The cycles of drawing that we mentioned above were divided into three sections in order to identify the timing of his brush movement in the air. The first section, *beginning* section, was from his soaking the brush in the sumi ink plate until just before putting it on paper. The second section, *middle* section, was from his starting to draw until finishing to draw. The final section, *end* section, was from his lifting up the brush from the paper until just before soaking it in the ink plate. Then, we counted the number of brush movements in the air for each section.

The following coding scheme was used to identify brush movements. If the painter moved his brush more than once in a circle in the air, except for changing the posture of holding his brush or moving the brush from one place to another, we identify the movement as drawing in the air. A main coder coded the drawing processes of all sixteen pictures. After being taught this scheme and practicing coding independently, another coder coded one picture. The consistency between two coders was 90%. The percentage of intra-coder consistency of the main coder was 96%. Thus, the scheme was considered reliable.

Table 4 shows the mean number of drawing in the air and the percentage in each section in each condition. Although the frequency of drawing in the air in the LINES condition is higher than in the BLANK condition,

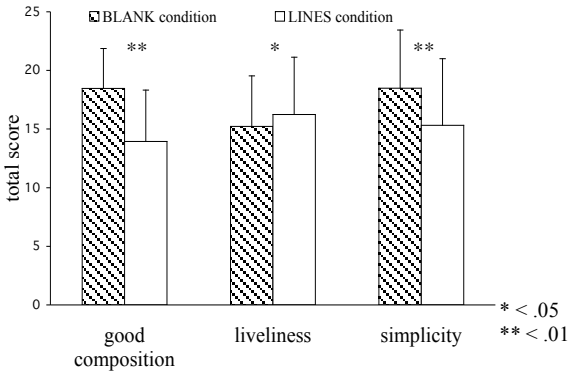


Figure4: Mean scores of three factors in each condition. Error bars represent 1*SD*.

the percentage of the drawing in each section is about the same between the two conditions. In the beginning section, the percentage of the drawing in the BLANK condition was 60% and that in the LINES condition was 56%. In the middle section, the percentage of drawing in the BLANK condition was 35% and that in the LINES was 36%. This indicated that Mr. K often draws in the air at the beginning and middle of drawing cycles. Thus, it would be reasonable for us to assume that drawing in the air has some important functions in drawing processes since they occur before the painter actually draws on paper.

Next, we focused on the relationship between pauses and drawing in the air. The percentage of pauses with drawing in the air in the BLANK condition was 59% and that in the LINES condition was 86%. This suggests that he often moves the brush in the air in order to think about drawing plans to incorporate lines into his picture. Furthermore, in the LINES condition, the percentage of pauses with drawing in the air, when he added on to others' lines, was 97% and when he drew without adding lines to others' lines was 59%. These results suggest that by moving the brush in the air, he generates a mental image to facilitate incorporating others' lines.

In order to further investigate the function of the drawing in the air, we interviewed him about his drawing process while showing a video record of his drawing a *Sansuiga* picture. While watching a part of the videotape in which he was drawing in the air, he said to us,

> "I might be checking how I feel when I touch the brush. Umm... Is this my habit? I always do this, don't I...I may move my hand in the air to rehearse my brush stroke...I always draw in the air before starting to draw on the paper. This seems to be my habit, doesn't it? Although I do not draw any actual objects on the paper, through drawing the form in the air, I can judge if the balance of the objects is OK. I have never realized my habit before you pointed it out. But, now I noticed it..."

This quote tells us that he probably moves his hands in order to plan how to use his brush and actually draw the image of objects in his mind. This is a quite reasonable candidate function of this hand movement. But, we need to be careful before making any conclusions on this issue based on the data from this field study. It would be, however, worth proposing some plausible hypotheses for future research. At this moment we propose the following

Table 4: Percentage of drawing in the air in three different sections

	Beginning section	Middle section	End section
BLANK condition	19.1 (60%)	11.0 (35%)	1.5 (5%)
LINES condition	29.0 (56%)	18.5 (36%)	4.0 (8%)

three functions as good candidates. First, by drawing in the air, the painter decides where to put the brush on the paper. We call this *positioning*. Second, the painter rehearses his brush movement so that he can draw smoothly. This is related to how to draw. We call this *rehearsal*. Third, by drawing an object in the air, the painter generates a mental image of what he plans to draw next. We call this *image generation*.

We could not confirm these hypotheses with this field study, because we could not control variables systematically. Further studies are needed to investigate the roles of drawing in the air.

General Discussion

This study focused on a traditional art, Chinese ink painting. Mr. K has an enormous amount of knowledge of the painting style and draws pictures using this knowledge. However, knowledge is not enough to create new pictures improvisationally and smoothly. When he drew the picture in temple X, he went backward to look at the entire picture. Also he occasionally covered this picture in progress with his hands to narrow down the space of focus. That is, he limited the drawing space to make planning or monitoring the picture easier. Thus, he could gradually form a mental image of a picture as the actual drawing on the paper progresses.

Knowledge and skills accumulated in years of expertise enable an artist to create artworks fairly quickly and smoothly. It seems that each brush of drawing evokes a local image of *Suibokuga* in Mr. K's memory. He creates his pictures combining those images based on certain rules that he learned from books or his experience. This process is highly effective when producing certain kinds of artwork.

On the other hand, artists often become bored while producing similar works too many times. When bored, artists want to try something new to stimulate their artistic motivation. In this *Suibokuga* painter's case, the method of asking the audience to draw random lines and incorporating them into his own picture is one such example. Creation of new patterns in artistic works seems to emerge through artists' intentional manipulation of constraints in a creation process. We found that even in a case of traditional art, artists sometimes conduct this kind of manipulation intentionally.

Artistic creation requires hands-on activities. Just having an image or a concept is not enough. In order to implement an image or a concept into an actual artwork, an artist needs to use his/her body. Sasaki et al. (1983) suggested that people would imagine the figure of Kanji characters by moving their hands. In the study of embodied representation, Barsalou (1999) has argued that sensorimotor processes, such as body movement, could affect the cognitive processes. Similarly, body movement in artistic creation, such as moving a brush in the air, also seems to play an important role in creative processes. In this way, artistic creation is a highly embodied process.

We could not make strong conclusions with this field study, since we could not control variables systematically. In addition, because this is a single case study, we also cannot generalize our findings to artists. However, we believe that our findings offer an essential first step towards future studies of the process of artistic creation from cognitive perspectives. We are currently conducting other studies regarding the creative process of Japanese contemporary artists in order to uncover potential similarities and differences between traditional and contemporary arts in an effort to generalize our hypotheses.

Abstract

Cross-linguistic research in the framework of the Competition Model (MacWhinney & Bates, 1989) has shown that case-marking is the major cue to sentence interpretation in Japanese, whereas other cues such as animacy and word order are much weaker. Japanese is a pro-drop language. Many Japanese sentences are grammatical without subjects and objects. When subjects are absent, case-markers are also unavailable to use. However, Japanese honorific and humble verbs may provide important information to determine the agent when the case-marking cue is absent. This study examined the usage of honorific and humble verbs as the agreement cue in Japanese sentence interpretation by native speakers in comparison to their usage by second language learners of Japanese.

Introduction

Japanese uses specific affixes on the verb to mark social relations of power and solidarity. These markings are called honorifics. This use of formal grammatical markings is a unique feature of Japanese that has often been used as evidence for the operation of links between language, culture and thought (Whorf, 1967). Apart from these fascinating links to culture, honorifics can also serve the more mundane function of helping to distinguish the actor of the transitive verb. This paper is aimed at discovering the role of the verbal agreement cue in processing by native speakers. We are also interested in tracking the acquisition of this cue by second language learners of Japanese. Our study is couched within the framework of the Competition Model (MacWhinney & Bates, 1989) which emphasizes the relation between statistical regularities in the language and the strength of these cues for both first (L1) and second (L2) language speakers.

In order to interpret a transitive sentence, we have to identify the actor or agent. In the English sentence, *the doctor met the patient*, native speakers interpret *the doctor* as an agent who was engaged in meeting someone. This is because nouns placed before verbs are considered to be the actor in English. On the other hand, Japanese uses a completely different set of cues to determine the actor or agent. Although it has a basic SOV word order as in *the doctor the patient met*, Japanese also allows other word orders such as *the doctor met the patient* (SVO), *the patient the doctor met* (OSV), and *the patient met the doctor* (OVS). Each of these sentences yields the same interpretation with *the doctor* as the agent. Instead of relying on a word order cue, Japanese has case markers, such as *ga* (subject marker), *wa* (topic marker), *o* (object marker), and *ni* (dative marker) to mark case roles. The exact grammatical characterization of these participles has been the subject of dispute for years among Japanese linguists (Kuno, 1973), but there is little disagreement regarding the general importance of case role markings in the language. In general, a noun followed by the subject marker *ga* is likely to have an agentive role in any word order in Japanese. For example, a sentence like *kanja* (patient) *ni* (dative marker) *atta* (met) *isha* (doctor) *ga* (subject marker), in the order of OVS provides a meaning *the doctor met the patient*, although OVS order is not canonical in Japanese.

Cue Competition

Some theories tend to emphasize the universality of syntactic types across languages and the importance of a single "basic" order within languages (Chomsky, 1981). However, from the viewpoint of processing models, online sentence interpretation must rely at least initially on surface cues to role marking, and these cues vary markedly across languages. As we have already seen, English sentence interpretation relies heavily on word order (Bates & MacWhinney, 1989). This reliance would seem to support the central role of a fixed word order, as conceived in generative linguistic theories. However, other languages do not follow this pattern. A series of previous studies in the framework of the Competition Model have shown that case marking is the dominant cue in Japanese, Hungarian, and German, whereas subject-verb agreement cue is important in Italian, French and Spanish, and animacy distinction is the crucial determiner of interpretation in Chinese sentences (MacWhinney & Bates, 1989). English is unique in this sense in that it is the only well-studied language that depends so heavily on a word order cue.

Cue usage also varies developmentally within a single language. Children first focus on conspicuous cues that they can pick up easily (Slobin & Bever, 1982). Gradually they shift their cue usage to those that have high availability and

reliability in the language (McDonald, 1989). For example, Japanese children first focus on animacy distinction, because they already possess fairly clear ideas about which nouns are animate and which are inanimate. In contrast, learning of the case-marking system is a lot more complex than animacy, although it emerges eventually as the dominant cue in Japanese. Thus Japanese children rely on the animacy cue to interpret sentences first and then they later shift their cue usage to the case-marking cue which has high availability and reliability, i.e., it is a cue which is often present and which usually provides a correct interpretation.

Typically, languages make use of several cues for marking case roles. In most sentences, these cues agree with each other to guide a correct interpretation, though cues sometimes compete against each other. Sentences with inanimate subjects, such as *The study looked at Japanese children*, are quite common in written English. Here, word order provides a cue indicating that *the study* is the agent, whereas the animacy cue suggests that *Japanese children* should be the agent, because an animate noun is generally preferred as agent because of its dynamicity. Despite this cue competition, word order wins over animacy because word order has the highest availability and reliability in English (McDonald, 1987). On the other hand, when word order and animacy compete in Japanese sentences, animacy wins over word order because animacy is stronger in Japanese. Thus, in the parallel Japanese sentence *Japanese children* would be the agent (Sasaki & MacWhinney, in press). Similarly, when all of case marking, word order and animacy compete, case marking wins over animacy, and animacy wins over word order (case > animacy > word order), because case is the strongest cue in Japanese (Sasaki & MacWhinney, in press). Because Japanese word order is so flexible, it is the weakest cue in Japanese.

Unlike children's speech or child first language acquisition, in adult Japanese language use, in addition to theses basic cues, new cue emerges to compete with the other basic cues. This new cue is the honorific cue which is used along with verbs as morphological markings. Honorific and humble verbs are not used in children's speech because children are not yet expected to fully understand hierarchical society in Japanese culture that is reflected in the language use. However, the appropriate use of honorific and humble verbs becomes crucial in order to survive in adult Japanese society.

Cultural and Linguistic Interactions

Like Spanish and Italian, Japanese allows frequent omission of subject and object nominals. In English, pro-drop sentences, such as *∅ saw the black cat*, are considered to be ungrammatical. However, *neko* (cat) *o* (object marker) *mita* (saw) in Japanese is completely grammatical. Some Japanese linguists even claim that it is inappropriate to use the word "pro-drop" to describe Japanese constructions because subjects are not dropped but absent from the beginning (Kaneya, 2002). In Japanese, sentences without subjects and objects are completely grammatical. For example, the following short dialogue is very common in Japanese conversation.

A: "kuroi neko mita?"
[black cat saw?]
B: "un, mita."
[yeah, saw]

The subject is absent in utterance A, and both the subject and object are absent in utterance B. Yet, they are both grammatical (see more of these examples in Kaneya, 2002). Linguistically, word order cannot be an important cue because subjects and sometimes objects are both dropped in Japanese.

Japanese also marks cultural preferences regarding the status of the grammatical third person through the morphology of verbs and adjectives. Some verbs and adjectives carry information identifying the agent. However, the shape of this information is limited in specific ways, because Japanese culture inhibits stepping into others' psychological or physiological territory (Kamio, 1995). Verbs and adjectives that describe a third person's mental state have a special conjugation. Adjectives are usually used with *–garu* for third person, and verbs for third person are used in the *–teiru* form. For example, adjectives like *hoshii* (want, desirable), *ureshii* (happy), *itai* (painful) are all used with the adjectival third person marker *–garu* as in *hoshi-garu*, *ureshi-garu*, *ita-garu*. Verbs like *omou* (think), and *komaru* (have trouble) are used in the *–teiru* form in *omo-tteiru*, and *koma-tteiru*. It is ungrammatical to say *kanja* (patient) *ga* (subject marker) *ureshi* (happy-1st person, dictionary form), because a first person adjective cannot describe a third person subject. Rather, *ureshii* here should be *ureshi-garu* (3rd person). Therefore, even if subjects are dropped, sometimes verbs and adjectives will provide sufficient information to determine the agent.

Similarly, honorific and humble verbs are very useful cues that can be used for a variety of both transitive and intransitive verbs in Japanese. Honorific verbs cannot be used for the first person, but only for the second or the third person particularly for superiors. Humble verbs can be used only for the first person or the speaker's in-group members. For example, *o-hanashi-ninari-mashita* (honor + talk + honor + past tense) may indicate that the agent is someone superior to the speaker, and cannot be either the speaker or someone inferior to the speaker. Similarly, *o-hanashi-itashi-masu* (honor + talk + humble + non-past) indicates the action of the (humble) speaker or the speaker's (humble) in-group members. Even without overt mention of the subjects, these honorific and humble verbs provide evidence that is sufficient to identify the agent.

Considering the fact that subjects are frequently absent in Japanese, these verbal markings of honorific status should be one of the more reliable cues in Japanese. Although these cues are not always available, they should always be reliable when they are available particularly in adult speech.

Previous studies (Sasaki & MacWhinney, in press) have shown that the case-marking cue is the dominant cue in Japanese. However, when subjects and objects are absent, case markers are also naturally absent. When the dominant cue is unavailable, other cues must be used instead. As we have seen already, other cues such as animacy and word order have been examined in relation to the case-marking cue. However, the use of Japanese verb marking for honorific status has not yet been examined.

This study has two goals. The first is to measure the use of the honorific agreement cue by native Japanese speakers in comparison to case-marking cue and word order. Honorific and humble expressions are used only when there are social and psychological distances between the speaker and the listener, or between the speaker and the target person addressed. The availability of the honorific and humble verb cue would be high, particularly in adult speech under a hierarchical pressure, although overall availability of the honorific verb agreement cue in general speech may not be higher than that of the case-marking cue. Therefore, we can hypothesize that honorific verb agreement cue may not be stronger than the case-marking cue, yet it should be an important cue when case is absent.

The second goal of the study is to examine how second language learners acquire this verb agreement cue. Unlike native speakers, second language learners have not yet developed an entrenched usage of the case-marking cue. Moreover, when they first begin to pay attention to honorific marking, they may at first tend to overestimate and overgeneralize its importance, because the instruction is focusing specifically on this structure which learners tend to master in a short period of time.

Methods

Participants

Twenty native Japanese speakers, 16 advanced level Japanese learners as a foreign language, and 29 intermediate level Japanese learners participated in the study. Native Japanese speakers were recruited in Pittsburgh with a mean age of 31.6, and with a mean of length of residence in the United States less than 3 years. L2 learners were recruited from advanced and intermediate levels of Japanese courses at Carnegie Mellon University. Both intermediate and advanced learners have learned honorific and humble verb systems in class, though advanced learners have been exposed to them approximately for a year longer than intermediate learners. Some of advanced learners had an experience of studying abroad in Japan. No learners have an experience of studying abroad more than three months.

Stimuli

Three factors controlled in the study were word order, case-marking, and honorific cues with three levels for each. Word orders consisted of NNV, NVN, and VNN (N=Noun, V=Verb). Thus there were always two nouns and one verb used in every condition. The three levels for case-marking factor were nominative, dative and zero. When the first noun is marked with a nominative case and the second noun with a dative case, it is described as Nom_Dat condition, and Dat_Nom is used for the reversed case marking condition. Zero indicates the zero case marking condition. Honorific agreement cues were manipulated using simple transitive verbs such as *call*, *meet*, and *talk* with three levels of agreement: agreement-yes, agreement-no, and agreement-missing. Agreement-yes and agreement-no indicate whether the verb used in each condition agreed grammatically with the first noun. The agreement-missing condition contains plain verbs without modification of honorific or humble styles. Half of agreement-yes and agreement-no conditions used honorific verbs and the other half used humble verbs along with noun features differing in positional superiority. In order to control animacy effects, all nouns were animate. Each condition consisted of a noun combination differing in occupational superiority such as teacher-student, general-soldier, and president-employee.

For example, in the condition of order-NNV, case-zero, agreement-yes, sentences like, *sensei* (teacher) *gakusei* (student) *ohanashi ninari masu* (talk-honorific), was used. In this condition, we can see whether participants used either the case-marking or the verb agreement cue to interpret the sentence. Case is zero, so it provides no clues to determine the agent, whereas the verb agreement cue suggests that the honorable person should be the agent. In another condition where case is available, e.g., *sensei* (teacher) *ga* (subject marker) *gakusei* (student) *ni* (dative marker) *o hanashi itashimasu* (talk-humble), we can see clear competition between case and verb agreement cue. Case suggests *sensei* (teacher) marked with *ga* (subject marker) to be the agent whereas verb agreement with humble verb suggests *gakusei* (student) to be the agent although it is marked with a dative marker.

In addition to these three factors, filler sentences were inserted to guarantee that subjects treated the task in a natural fashion. The filler sentences excluded honorific agreement factor and superiority features in nouns. They controlled only word order and case-marking factors. The fillers also served the function of breaking up any tendency to lock into processing for specific verb types.

All three factors were fully crossed with three levels for three participant groups: native Japanese speakers, advanced learners, and intermediate learners. The full-factorial design of 3x3x3 was manipulated with the total of 54 sentences in addition to 18 filler sentences.

To create each sentence, the total of forty eight words was used: six base nouns (three superior and three subordinate nouns) with three case-marking forms (nominative, dative, and zero), and five base verbs with three agreement forms (honorific, humble, and plain) for experimental sentences, and five nouns (no superiority difference) with three case-marking forms for filler sentences. A male native Japanese speaker recorded the sentence components with a normal reading speed with no accents, and digitized with 16-bit

monaural .wav format at a 22-kHz sampling rate using CoolEdit 2000. Each sound file of nouns and verbs was combined into the appropriate sentence pattern using E-Prime 1.1 with complete random orders. The intonation patterns of combined words for all statements were indistinguishable, which prevented listeners from using any prosodic cues.

Procedure

In this task, all participants sat in front of a computer, and heard from a headphone a series of sentences that were composed of two nouns and a simple transitive verb. As the sentence began, the computer screen displayed pictures describing two nouns in each sentence. The pictures remained displayed until participants pressed a key indicating their choice of one of the pictures as the agent. Pictures were accompanied by words describing the pictures. For example, "teacher" (in Japanese) was shown on top of a picture of "teacher". This is to decrease non-native speakers' processing load. The subject identification task by itself for non-native speakers may put heavy processing load on their memory particularly when the cue competition is high, so they were instructed not to worry about memorizing words they did not know.

Participants were asked to choose or identify the picture that performed the action described in each sentence. They were instructed to choose either of the two nouns as agent, and to push a button corresponding to either of two pictures shown on the computer screen. If they thought the person on the right side did an action, they pushed the right button. If they thought the person on the left side did an action, they pushed the left button. They were instructed to press the button as quickly as possible after they heard a sentence. The response as a choice of the first noun was measured after 5 practice sentences.

All participants were tested individually in a small quiet room and were asked to complete the same task, although native Japanese speakers and non-native speakers were given different instructions before the task. Native Japanese speakers were told that sometimes sentences were culturally inappropriate or grammatically incorrect, and they were asked to respond quickly using their intuitions in the case they found some sentences unnatural. As it was mentioned earlier, these sentences were set up to test the usage of cue competition. For non-native Japanese speakers, additional instructions were given. In order to refresh learners' memory and make them comfortable about the use of honorific and humble verbs, each non-native participant went through a brief review on verb conjugations. They were also briefly informed about social and hierarchical differences between roles such as general vs. soldier, and president vs. employee, which were used in the experiment.

Results

ANOVAs were performed using percentage of choice of the first noun as agent as the dependent variable. The main

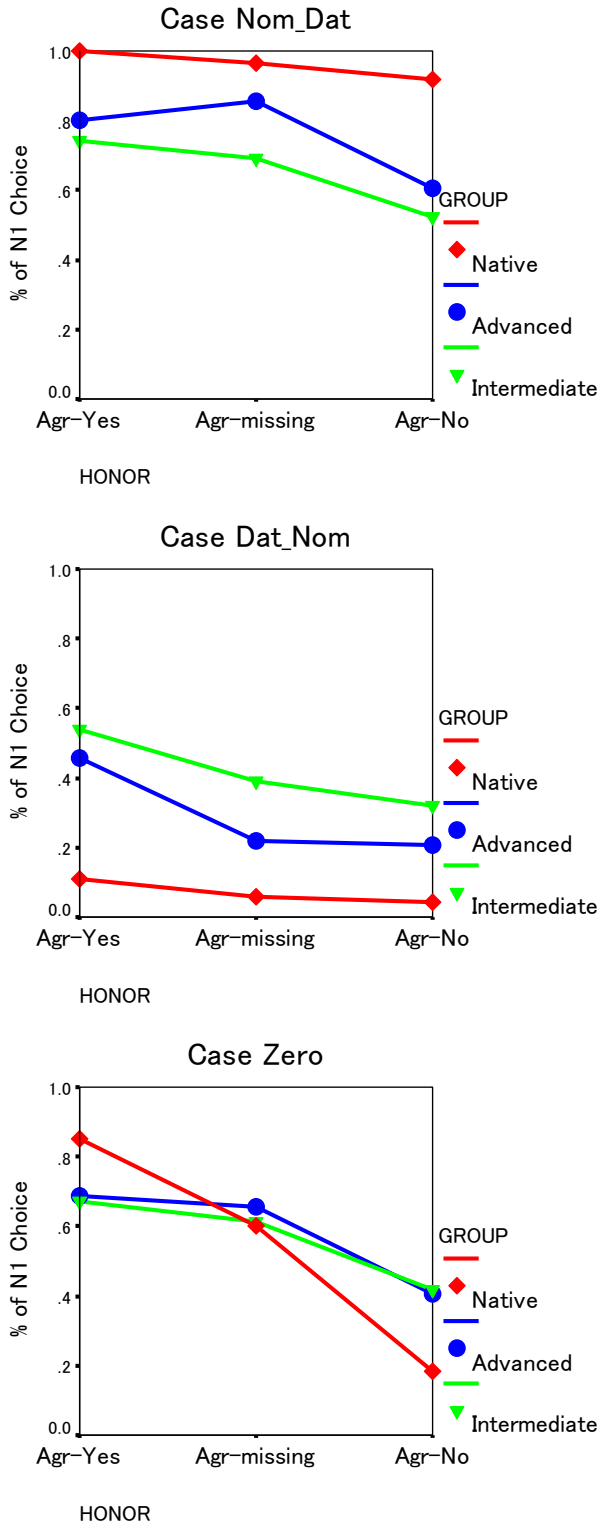

Figure 1: The percentage choice of the first noun as agent in the condition of (1) Nom_Dat case (the first noun is marked with the nominative case, and the second noun is marked with dative case) crossed with the agreement cue, (2) Dat_Nom case and (3) Zero case (neither nouns were marked with case).

effects of case and honorifics were significant (Case: $F(2, 61) = 164$, $p < 0.001$; Honor: $F(2, 61) = 17.7$, $p < 0.001$), but word order was not. The non-significance of the word order effect shows that none of the groups, including L2 learners, relied on the word order cue. The interaction between case and honorific agreement was also significant ($F(4, 59) = 20$, $p < 0.001$). The use of nominative case for the first noun and dative case for the second noun is shown in Figure 1. In the Nom_Dat condition, native speakers consistently used the case-marking cue, despite the presence of an agreement cue. L2 learners also made use of the case-marking cue, though they relied much less on case than did native speakers. Native speakers' first noun choice for Nom_Dat was over 95% in all three agreement conditions, whereas the first noun choice of advanced and intermediate learners dramatically decreased in the condition where verbs do not agree with the first noun feature (advanced: 60%; intermediate: 52%).

Similarly, in the Dat_Nom case condition, native speakers consistently showed the strong use of the case-marking cue to select the second noun as agent. The second noun is marked with a nominative case in this condition, so the lower percentage of the first noun choice indicates the heavier reliance on using the case-marking cue. The first noun choice by native speakers was less than 11% in all agreement conditions, whereas L2 learners' first noun choice was higher. When the verb agrees with the honorific status of the first noun, learners' first noun choice increased noticeably (advanced: 46%; intermediate: 54%). This shows that learners placed heavy reliance on the honorific agreement cue even when it contradicted the case-marking cue.

In the zero case-marking condition, the first noun choice by native speakers showed a clear decline from agreement-yes to agreement-no conditions (agreement-yes: 85%; agreement-missing: 60%; agreement-no: 18%). Because the case-marking cue was unavailable in this condition, native speakers relied on the honorific verb agreement cue to determine the agent. On the other hand, learners' usage of verb agreement cue was not as robust as native speakers'.

Discussion

The patterns of Japanese native speakers' performance in the experiments showed that the case-marking cue was still the dominant cue in Japanese. Despite the presence of the honorific verb agreement cue, native speakers consistently chose nouns marked with the nominative case as agent. However, when case was absent, the honorific verb agreement cue became an important and reliable cue to determine the agent. Even though Japanese has a canonical SOV word order, we did not find any effects of the word order cue in the absence of case. This confirms the results from the previous studies. Importantly, we demonstrated within a single experiment both inattention to word order and attention to honorific agreement. Thus, it appears that honorific agreement is the second major cue in Japanese sentence processing, after case-marking.

The second important finding of the study is that cue availability determined cue strength. Native speakers' first noun choices were not entirely controlled by the agreement cue. There was 85% first noun choice in the agreement-yes condition and 18% in the agreement-no condition. This suggests that even native speakers are sometimes unsure about the correct use of honorific and humble verbs. As we have already discussed earlier, honorific and humble verbs are not frequently present in younger people's daily linguistic input until they start working in businesses. Some of the participants of native speakers in the study were graduate students who have no experience working in businesses. Therefore, their cue usage of the honorific verb agreement cue might not have been as strong as we could find in speakers from the business environment. Further study of the use of this cue by speakers from the business community may help us understand the extent to which increased availability of the cue could lead to an increase in its relative strength when it is placed in conflict with case-marking.

The third finding of the study relates to the cue usage patterns by L2 learners. As we predicted, their usage of both the case-marking cue and the honorific agreement cue was more variable than that of native speakers. Interestingly, they overused the honorific agreement cue even when the case-marking cue was available to use. On the other hand, they did not use the honorific cue as much as they could, when case was absent. This suggests that learners' use of the case-marking cue has not yet stabilized at native speaker levels after about two years of learning Japanese. Moreover, the overuse of the honorific cue indicates that learners tend to focus on a single cue when this is at the focus of an instructional module or experiment. This tendency to focus on individual cues may prevent them from fixing the relative strength of each cue among all available cues in the target language. To counteract this tendency, instructors may need to present learners with input that illustrates competition between the relevant cues. In particular, learners need more experience with sets of sentences in which case marking is either present or absent and in which honorific agreement is either present or absent.

Angular Disinhibition Effect in a Modified Poggendorff Illusion

Abstract

Visual illusion can be strengthened or weakened with the addition of extra visual elements. For example, in Poggendorff illusion, with an additional bar added, the illusory skew in the perceived angle can be enlarged or reduced. In this paper, we show that a nontrivial interaction between lateral inhibitory processes in the early visual system (i.e., *disinhibition*) can explain such enhancement or degradation of the illusory percept. The computational model we derived successfully predicted the perceived angle in a modified Poggendorff illusion task with an extra thick bar. The concept of disinhibition employed in the model is general enough that we expect it can be further extended to account for other classes of geometric illusions.

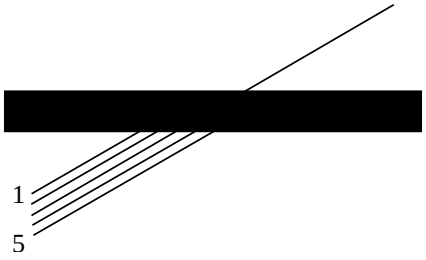

Figure 1: **The Poggendorff Illusion.** The original Poggendorff illusion is shown. The five lines below the horizontal bar are labeled 1 to 5 from top to bottom. Line 3 is physically collinear with the line on top. In this example, line 4 is perceived to be collinear.

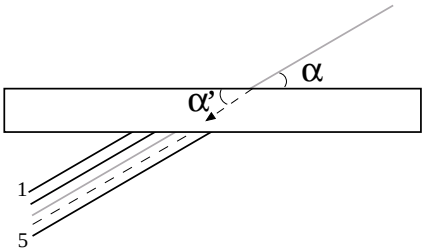

Figure 2: **The Angle Displacement in the Poggendorff Illusion.** The actual angle α ($= 30°$) and the perceived angle α' ($> 30°$) are shown. The gray line shows the straight line penetrating the bar. The dashed line below shows the perceived direction in which the line on top seemingly extends to.

Introduction

Visual illusions are important phenomena because of their potential to shed light on the underlying functional organization of the visual system. For simple illusions, a simplistic explanation can be sufficient, but when multiple effects exist in an illusion, the final percept can be quite complex. For example, when we perceive an angle, our perception of the angle is usually greater than the actual angle (*expansion* effect), but when there are multiple lines and thus multiple angles, the expansion effect can be either enhanced or reduced.

Such an interference effect can be demonstrated in a modified Poggendorff illusion. In the original Poggendorff illusion (see, e.g., Tolansky 1964; Morgan 1999), the top and the bottom portions of the penetrating thin line is perceived as misaligned (figure 1). Figure 2 shows how such a perception of misalignment can occur. The line on top forms an angle α with the horizontal bar, but the perceived angle α' is greater than α (i.e., exaggerated). As a result, the line on top is perceived to be collinear with line 4 on the bottom, instead of line 3 which is physically collinear. However, when an additional bar is added, the perceived illusory angular expansion effect is altered: the effect is either reduced (figure 3) or enhanced (figure 4) depending on the orientation of the newly added bar. Understanding the functional organization and the low-level neurophysiology underlying such a nontrivial interaction is the main aim of this paper.

Neurophysiologically speaking, in the original case where two orientations interact, lateral inhibition between orientation cells in the visual cortex can explain the enlargement in perceived angle. However, as we have seen in figures 3 and 4, when an additional orientation response is triggered, lateral inhibition alone cannot explain the complex effect. Our observation is that this complex response is due to disinhibition, i.e., inhibition of another inhibitory factor resulting in effective excitation (Hartline et al. 1956; Hartline and Ratliff 1957, 1958; Stevens 1964; Brodie et al. 1978). Unlike simple lateral inhibition between two cells, we explicitly accounted for disinhibition in our computational model to describe the complex interactions between multiple orientation cells. The resulting model based on the neurophysiology of the early visual system was able to accurately predict the perceptual performance for the modified Poggendorff illusion.

The rest of the paper is organized as follows. First, a neurophysiological motivation for our computational model is presented, followed by a detailed mathematical description of the model. Next, the results from the computational experiments with the model is presented and compared to psychophysical data, followed by discussion and conclusion.

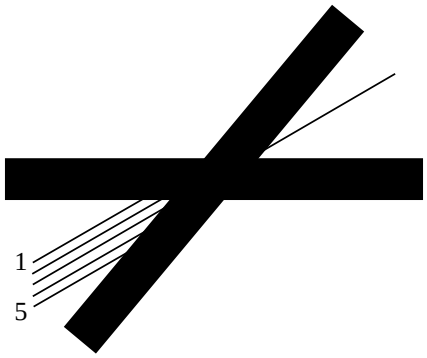

Figure 3: **The Poggendorff Illusion with an Additional Thick Bar of 50 °.** The Poggendorff figure with an additional bar at 50° is shown. In this case, line 2 is perceived to be collinear (i.e., $\alpha' < 30°$).

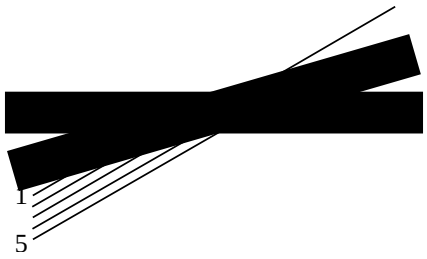

Figure 4: **The Poggendorff Illusion with An Additional Thick Bar of 20 °.** The Poggendorff figure with an additional bar at 20° is shown. For this case, unlike in figure 3, line 4 (or to some, line 5) is perceived to be collinear ($\alpha' > 30°$). (The α' in this case is slightly greater than in original Poggendorff figure.)

Computational Model of Disinhibition in the Visual Cortex

Let us first consider how orientation columns in the visual cortex interact in response to several intersecting lines. For each line at the intersection, there are corresponding orientation columns that respond maximally, with a Gaussian response distribution. As multiple simple cells are activated by the different lines at the intersection, the response levels will interact with each other through lateral connections. Thus, there are two issues we want to more precisely address: (1) what exactly is the activation profile (or the response distribution) of the orientation-tuned cells, and (2) how these cells interact with each other through the lateral connections.

The Activation Profile of Orientation Columns

Each simple cell in the primary visual cortex responds maximally to visual stimuli with a particular orientation. The response of these cells to different orientations can be modeled as a Gaussian function:

$$y = y_0 + \frac{A}{\sigma\sqrt{\pi/2}}\exp(-2\frac{(x-x_c)^2}{\sigma^2}), \qquad (1)$$

where y_0 is an offset; x_c is the center (or mean); σ is the standard deviation; and A is a scaling constant (Martinez et al. 2002).

It also comes to our attention that the cell tuned for a certain orientation, say α, should respond to the opposite orientation, which is $\alpha + 180°$. However, experiments have shown that the peak at the position $\alpha+180°$ is somewhat smaller than the peak at α (Alonso and Martinez 1998). To accurately model this, we need two Gaussian curves to fit the responses of a cell to a full range of orientations from $-180°$ to $180°$.

The fitting curve can be written as follows:

$$\begin{aligned} y &= y_0 \\ &+ \frac{A}{\sigma\sqrt{\pi/2}}\exp(-2\frac{(x-x_c)^2}{\sigma^2}) \\ &+ \frac{AK}{\sigma\sqrt{\pi/2}}\exp(-2\frac{(x-x_c+\pi)^2}{\sigma^2}), \end{aligned} \qquad (2)$$

where K is the rate of activation for the opposed direction ($K < 1$). Such an asymmetric response enables the the simple cells to be sensitive to the direction (as well as orientation).

Using the equation, we can now visualize the response profile of simple cells tuned to orientations ranging from 0 to 360°. Figure 5 shows the responses of orientation columns tuned to -90°to 270° (x-axis) to inputs of two different orientations, 0 and 30°. Figure 6 shows the responses of the same set of orientation columns to inputs of two orientations of 0 and 150°. From these two figures, we can observe that for each specific orientation input, the excitation is tuned at that value with a peak in the Gaussian curve, and at the same time, the opposite orientation tuned cell shows a lower peak response. The asymmetry in responses occur in both an acute angle (figure 5) and an obtuse angle (figure 6). Note that even though the difference in orientation between 0° vs. 30° and 0° vs. 150° is 30° in both cases, the response profile greatly differs in the 0° vs. 150°case.

This is an improvement over conventional excitation profile models such as Gabor filters (Daugman 1980), which make no distinction between these two angles in the two figures. Using the more accurate response profile, we will next investigate how these response profiles can interact.

Column Level Inhibition and Disinhibition

Our observation that the angular enlargement sometimes seems to be weakened when there are more than two bars or lines in the Poggendorff illusion (figure 3) led us to hypothesize about the potential role of a recurrent inhibition effect, i.e., disinhibition. Basically disinhibition is the inhibition on other inhibitory factors, resulting in a net excitatory effect at the target. Experiments on the Limulus (horseshoe crab) optical cells showed that the final response of each receptor resulting from a light stimulus can be enhanced or reduced due to the interactions through inhibition from its neighbors. Note that disinhibition has also been found in vertebrate retinas such as in tiger salamanders (Roska et al. 1998) and in mice (Frech et al. 2001). In the following, the Limulus neurophysiology giving rise to disinhibition is summarized, followed by the description of our computational model based on the Limulus model.

Hartline-Ratliff's model of disinhibition Experiments on Limulus optical cells have shown that lateral inhibition effect

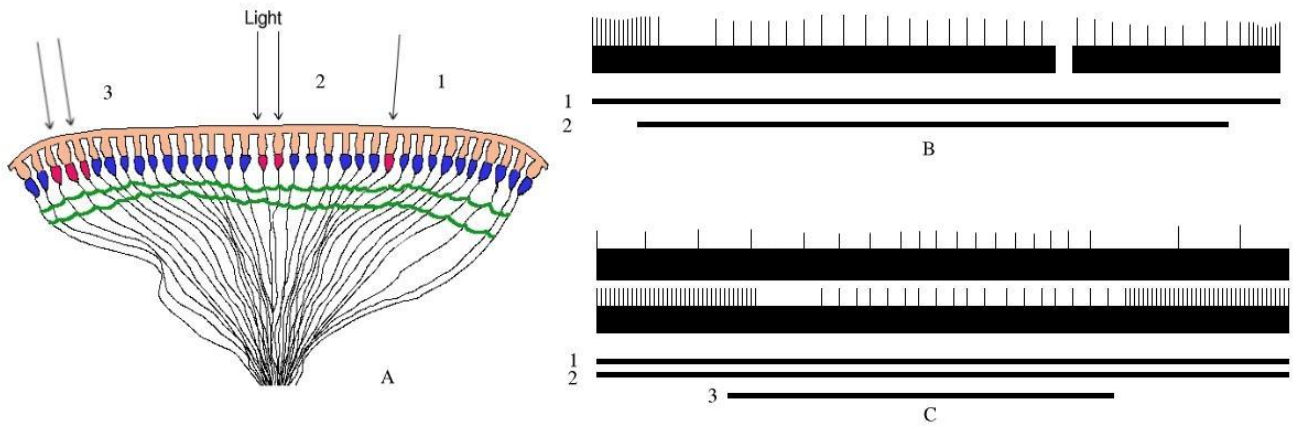

Figure 7: **Lateral inhibition in Limulus optical cells.** The figure shows the disinhibition effect in Limulus optical cells. (a) The retina of Limulus. Point light is presented to three locations (1, 2 and 3). (b) The result of lighting position 1 and 2. The top trace shows the spike train of the neuron at 1, and the two bars below show the duration of stimulation to cell 1 and 2. When position 2 is excited, the neuron response of position 1 gets inhibited. (c) Both 1 and 2 are illuminated, and after a short time, position 3 is lighted. The top two traces show the spike trains of cell 1 and cell 2. The three bars below are input duration to the three cells. As demonstrated in the figure, when position 3 is lighted, neurons at position 2 get inhibited by 3, so its ability to inhibit others get reduced. As a result, the firing rate of neuron at position 1 gets increased during the time neuron at position 3 is excited. This effect is called disinhibition. Redrawn from (Hartline and Ratliff 1957).

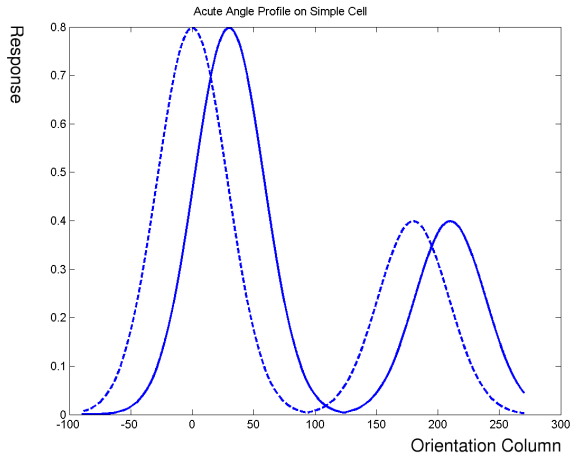

Figure 5: **The Activation on Simple Cell by an Acute Angle (**30°**).** The dotted curve is the responses of the orientation columns (x-axis) to a horizontal line of 0°, and the solid curve is the responses to 30° line.

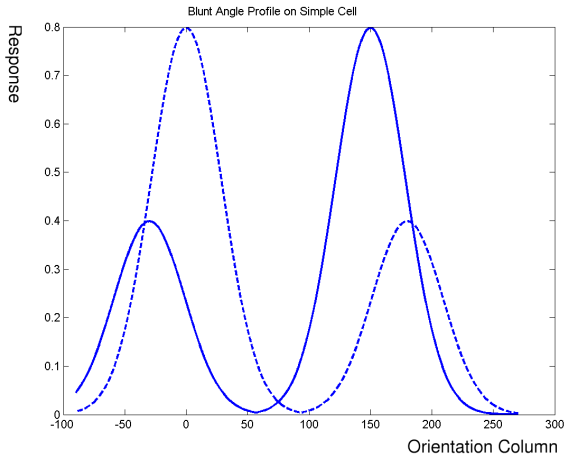

Figure 6: **The Activation on Simple Cell by Blunt Angle.** The dotted curve is the responses of the orientation columns (x-axis) to a horizontal line of 0°, while the solid curve is the responses to a 150° line.

is recurrent (figure 7; see Hartline and Ratliff 1957, 1958). The final response of a specific neuron can be considered as the overall effect of the response from itself and from all other neurons. Conventional convolution operation using lateral inhibition alone does not account for the effect of disinhibition which plays an important role in the final response. The final response of each receptor resulting from a light stimulus can be enhanced or reduced due to the interactions through inhibition from its neighbors, which may be important. (Such disinhibition effects have been found to play an important role in brightness-contrast illusions Yu et al. (2004).)

Hartline and his colleagues also did significant mathematical modeling of the Limulus optical cell response. The Hartline-Ratliff equation describing disinhibition in the Limulus can be written as follows (Hartline and Ratliff 1957, 1958; Stevens 1964):

$$r_m = \epsilon_m - K_s r_m - \sum w_{m \leftarrow n}(r_n - t_{m \leftarrow n}), \qquad (3)$$

where r_m is the response, K_s is the self-inhibition constant, ϵ_m is the excitation of the m-th ommatidium, $w_{m \leftarrow n}$ is the inhibitory weight from other ommatidia, and $t_{m \leftarrow n}$ the threshold.

Brodie et al. extended this equation to derive a spatiotemporal filter, where the input was assumed to be a sinusoidal grating (Brodie et al. 1978). This model is perfect in predicting Limulus retina experiments as only a single spatial frequency channel filter, which means that only a fixed spatial frequency input is allowed (Brodie et al. 1978). Because

of this reason, their model cannot be applied to a complex image, as various spatial frequencies could coexist in the input. In the following section, we will build upon the Hartline-Ratliff equation and derive a filter that can be used in modeling orientation columns.

A simplified model of disinhibition Based on the Hartline-Ratliff equation above, we derived a model for two-dimensional disinhibition as follows (Yu et al. 2004):

$$\mathbf{r} = W^{-1} \times \mathbf{x}. \tag{4}$$

where $\mathbf{r}$ is the output vector, $\mathbf{x}$ is the input vector and W is the weight matrix:

$$W_{ij} = \begin{cases} -w(|i,j|) & \text{when } i \neq j \\ 1 & \text{when } i = j \end{cases}, \tag{5}$$

where $w(i,j)$ is the kernel function (usually a difference-of-Gaussian) defining the inhibition rate from the j-th neuron to the i-th neuron. Based on this simplified model of disinhibition, we can now more easily derive the disinhibition effect at the orientation column level.

Applying disinhibition to orientation cells Cells occupying the same single orientation column in the cat visual cortex are known to inhibit each other (Blakemore and Tobin 1972). From this, we can postulate that a group of cells tuned to the same orientation representing different lines (e.g., intersecting lines) may compete with each other through inhibition.

Now let us consider the mathematical description for the inhibition at the column level. Suppose a group of orientation cells tuned to orientation α receives n lines as their inputs. The initial excitation $E_{\alpha i}$ for a cell inside this group α can be calculated as follows:

$$\begin{aligned} E_{\alpha i} &= y_0 \\ &+ \frac{A}{\sigma\sqrt{\pi/2}} \exp(-2\frac{(\alpha - x_c(i))^2}{\sigma^2}) \\ &+ \frac{AK}{\sigma\sqrt{\pi/2}} \exp(-2\frac{(\alpha - x_c(i) + \pi)^2}{\sigma^2}), \end{aligned} \tag{6}$$

where y_0 is an offset, A is a scaling constant for the Gaussians, σ is the standard deviation, K is the rate of activation of the opposite direction, and $x_c(i)$ is the orientation of the i-th input line. In this way, we can calculate the excitation E of the cell to the i-th line on a certain group of cells tuned to α. All those parameters in this equation are fairly standard parameters, which does not require a precise tuning.

Using the Hartline-Ratliff equation (Hartline and Ratliff 1957) for recurrent lateral inhibition and the simplified model of disinhibition (Yu et al. 2004), the final response R of cell i in orientation column α can be obtained as follows:

$$R_{\alpha i} = E_{\alpha i} - W \times R_{\alpha i}, \tag{7}$$

where W is a constant matrix of inhibition rate (or weight, controlled by a free parameter η: $w_{ij} = \eta$ if $i \neq j$, and 0 otherwise). From this, we can finally derive the response equation which accounts for the disinhibition effect:

$$R_{\alpha i} = (I - W)^{-1} \times E_{\alpha i}, \tag{8}$$

where I is the identity matrix.

By applying the orientation α to all the columns, the projection of each line to the columns should shift a little bit depending on the strength of the activation of each line. Thus, the final perceived line orientation γ can be obtained by finding the maximum response after the inhibition process:

$$\gamma_i = \text{argmax}_{\alpha \in C} R_{\alpha i} \tag{9}$$

where γ_i is the perceived orientation for the i-th line, R is the responses of i-th neuron tuned to orientation α and C is the set of all the orientation columns in layer 4 of the visual cortex.

Experiments and Results

Prediction of Angle Expansion without Additional Context

To test the model in the simplest stimulus configuration, we used stimuli consisting of one thick bar and one thin line. The thick bar was fixed at 0°, and the thin line was rotated to various orientations while the perceived angle was measured in the model. The enlargement effect of the angle varied depending on the orientation of the thin line. As shown in figure 8, we can observe that there are three major characteristics of this varying effect. First, for the acute angles, there is an increment in the angle of the perceived compared to actual, but for the obtuse angles, the perceived angle is less than the actual angle. Second, the peak is around 20° for the largest positive displacement, and around 160° for the largest negative displacement. Third, there is an obvious asymmetry in the displacements between the acute angles and the obtuse angles. Note that the peak at 20° is greater in magnitude than the dip at 160°. As compared in figure 8, these results are consistent with results obtained in psychophysical experiment by Blakemore et al. (1970).

Prediction for the Modified Poggendorff Illusion

Disinhibition effect is the key observation leading to our extension to the angular expansion model based on lateral inhibition alone. Because of disinhibition, when more than two lines or bars intersect, the perceived angle of the thin line will deviate from the case where only two lines or bars are present. Figure 9 shows the prediction of our model (solid line) when a second thick bar of varying orientations was added to the original Poggendorff illusion (see figure 3 and 4 for an example). If disinhibition effect did not exist, the solid line would have come out flat, however, there is an interesting peak and a valley in the predicted response. The effect demonstrated in figure 3 is accurately predicted by the peak near 20°, and the effect in figure 4 by the valley near 50°. So, at least for these two cases, we can say that our disinhibition-based explanation is accurate. However, does the explanation hold for an arbitrary orientation? To test this, we conducted a psychophysical experiment to measure human perceptual performance and compare the results to the model prediction (the results are shown as data points in figure 9).

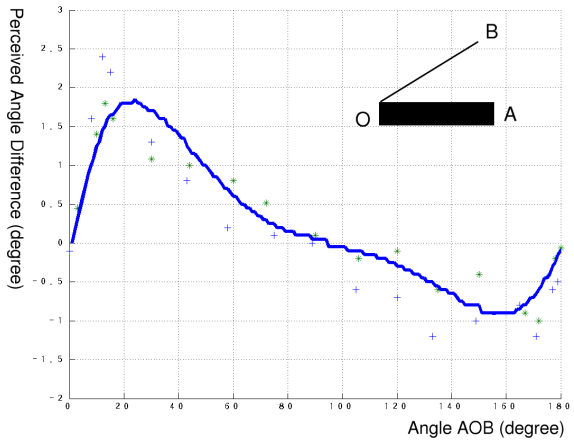

Figure 8: **The Variations of Perceived Angle Between Two Intersecting Lines.** The x-axis corresponds to the angle $\angle AOB$ (inset), from 0 to 180°. The y-axis is the difference between the perceived angle and the actual angle. The solid line is the result predicted by our model, and the data points * and + are data from human subjects in Blakemore et al. (1970). The curve was generated in two iterations, with the following parameters: $\eta = 0.009$ and $\sigma = 1.0$ for the first pass; $\eta = 0.005$ and $\sigma = 0.5$ for the second. The other parameters remained the same for both iterations: $y_0 = 0.0$ and $K = 0.5$.

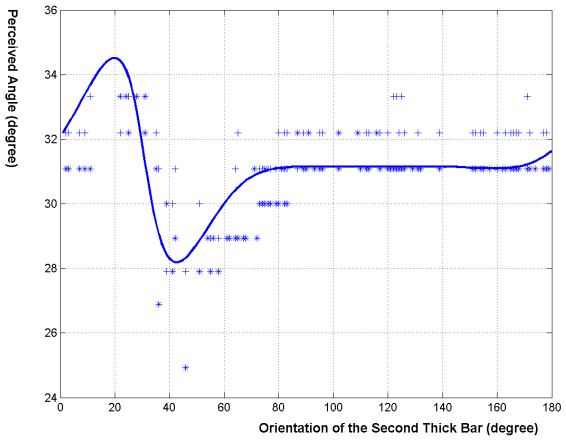

Figure 9: **Perceived Angle in a Modified Poggendorff Illusion.** The results from the computational model (solid line) and human experiments (data points marked * and +) on a modified Poggendorff illusion (figure 3) are plotted. The second thick bar was rotated while the perceived angle was measured. The x-axis indicates the angle of the second bar. The y-axis shows the perceived angle of the thin 30° line. The model prediction and the human data are in close agreement. The parameters used in this experiment were as follows: free parameter: $\eta = 0.02$; standard parameters: $y_0 = 0$, $\sigma = 0.5$, and $K = 0.5$.

Experimental methods Two subjects with normal vision participated in the experiment (the authors YC and YY). An LCD panel with a 1024×768 resolution, which is supposed to be high enough to avoid line aliasing aritfacts, was used to display the stimuli. The computer program displayed two thick bars and one thin line on the screen, similar to the stimulus in figure 3. The first thick bar was fixed in the center of the screen at 0°, and the width was 100 pixels. The thin line, 5 pixels in width, intersected the horizontal bar at a fixed angle of 30°. The second thick bar, 100 pixels in width, intersected at the same point as the the other two, where as the angle was varied from trial to trial. The program also displayed up to 10 thin lines (all 30°) below the horizontal bar, from which the subjects were asked to choose the one that is the most collinear to the thin line above the bar. The subject was allowed to click on the line of choice, and the perceived angle was recorded for each click, and a new stimulus was generated. A total of 101 trials were recorded for each subject.

Results Figure 9 shows the result of the psychophysical experiment (data points * and + for YC and YY, respectively), along with the prediction of the model (solid line). The peak (near 20°) and valley (near 50°) are apparent in the experimental data, and the overall shape of the curve closely agrees with the model prediction. The results show that our model of angular interaction based on disinhibition can accurately explain the modified Poggendorff illusion, and that low-level neurophysiology can provide us with insights into understanding the mechanisms underlying various visual illusions. Note that for this experiment, our disinhibition model is more comprehensive than the calculation method of simply summing up two Poggendorff effects by two separate bars. First it is because disinhibition is the summing up between all the pairs of bars at neuronal level, and second, simply summing up the effects of two bars omits the interactions between the lateral inhibition effects.

Discussion

We have presented a model based on angular inhibition by considering the disinhibition effect. The soundness of the theoretical extension lies in the fact that it is grounded in physiological and psychological facts. First, at the cellular level, lateral inhibition and disinhibition effects are found in the visual column of cat (Hubel and Wiesel 1962; Blakemore and Tobin 1972) and it is known that the opposite directions of the same orientation evoke an asymmetric response (Alonso and Martinez 1998). Our prediction of the angle variations for acute and obtuse angles shows asymmetric properties and matches these experiments. Second, our model can correctly predict the disinhibition caused by more than two lines intersected and the results match with our own experimental observation using the same kind of stimuli.

Besides the Poggendorff illusion, our model has the potential for explaining other geometric illusions, such as the café-wall illusion. Fermüller and Malm (2003) showed a variation of the café-wall illusion where adding some dots in strategic places significantly reduced the perceived distortion. Such a correctional effect can be explained by our model. Because the newly introduced dots give rise to a new orientation component (as the second thick bar did in our modified Poggendorff illusion), the disinhibitory effect caused by that new orientation can reduce the distortion formed by the existing orientation components.

Even though the disinhibition model presented in this paper is largely motivated by low-level neurophysiology, disinhibition can potentially serve a more general function. For ex-

ample, disinhibition can also be applied to higher brain functions such as categorization and memory (see Vogel (2001) for a model of associative memory based on disinhibition).

Conclusion

In this paper, we presented a neurophysiologically based model of disinhibition to account for a modified version of the Poggendorff illusion. The model was able to accurately predict a subtle orientation interaction effect, closely matching the psychophysical data we collected. We expect the model to be general enough to account for other kinds of geometrical illusions as well.

Abstract

Is configural information or featural information more important for facial identity recognition? How are the skills for processing these types of information developed? To investigate these issues, Mondloch et al. designed three sets of face images based on a single face, "Jane", to measure featural, configural, and contour processing. These stimuli were tested on human subjects of different ages in a same/different task. We test our model [Dailey et al., 2002] of face processing on these stimuli. We find that our model is overly holistic: It finds the configural differences the easiest to detect, while adult human subjects find featural changes the easiest to detect. We then introduce a representation of the important parts of the face (eyes and mouth) to our holistic model. We find that only a relatively small amount of holistic representation, compared to parts representations, is necessary to account for the data.

Introduction

We have developed a model of face processing that accounts for a number of important phenomena in facial expression processing, holistic processing and visual expertise [Dailey and Cottrell, 1999, Cottrell et al., 2002, Dailey et al., 2002, Joyce and Cottrell, 2004]. Here, we investigate the model's ability to account for human sensitivity to variations in faces that are considered theoretically important for face identification. Face processing is typically described as *holistic* or *configural*. Holistic processing is typically taken to mean that the context of the whole face has an important contribution to processing the parts: subjects have difficulty recognizing parts of the face in isolation, and subjects have difficulty ignoring parts of the face when making judgments about another part. Configural processing means that subjects are sensitive to the relationships between the parts, e.g., the spacing between the eyes. We will use the two terms *configural* and *spacing* interchangeably in this paper. Holistic processing can easily be captured by a model that uses whole-face template-like representations as ours does: interference from incongruent halves of a face occurs when making judgments about a different part (e.g, expression on top when a different expression is on bottom [Cottrell et al., 2002]). However, configural effects related to spacing information are attenuated by the alignment procedure that we typically use, which warps the image so the eyes and mouth are always in the same three positions.

Diamond and Carey [Diamond and Carey, 1986] were among the first to discriminate between the types of processing involved in face/object perception and recognition. Based on studies looking at the inversion effect to faces, landscapes and dogs in both dog novices and dog experts, they proposed that first-order relational information, which consists of the coarse spatial relationships between the parts of an object (i.e. eyes are above the nose), is sufficient to recognize most objects. By contrast, second-order relational information, which is needed for face recognition and recognition of individuals within categories of expertise, is reserved for visually homogeneous categories where slight differences in configuration must be used to distinguish between individuals (e.g. a slight change in the distance between the eyes and the nose). Diamond and Carey [Diamond and Carey, 1986] suggest that experience allows people to develop a fine-tuned prototype and to become sensitive to second-order differences between that prototype and new members of that category (e.g. new faces).

One implication of the Diamond and Carey study is that the inversion effect (a large reduction in same/different performance on inverted faces, compared to inverted objects) is based on a relative reliance on second-order relational information, and that perhaps this characteristic distinguishes face/expert-level processing from regular object recognition. Farah et al. [Farah et al., 1995] found that encouraging part-based processing eliminated the inversion effect, whereas allowing/encouraging non-part-based processing resulted in a robust inversion effect. Thus Farah et al. conclude that the inversion effect, in faces and other types of stimuli, is associated with holistic pattern perception.

However, subjects are also quite sensitive to changes in the features themselves – substitutions of different eyes or mouths can make the face look quite different. The Thatcher illusion [Thompson, 1980] suggests that parts are processed somewhat independently, and only loosely connected to the representation of the whole face. Recently, a study by Mondloch et al. that varied these different aspects of a face (configuration, feature changes, and changes to contour of the face) found differing levels of sensitivity to the type of manipulation in a same/different paradigm. While the manipulations were not performed parametrically (no equating of the diffi-

culty of discrimination was performed), but in a rather ad hoc manner, the results are consistent across subjects. Hence this is a crucial set of data to account for with our model.

In the following, we describe Mondloch et al.'s experiments and our attempts to account for their data. We find that our model must be augmented with a representation of the parts of the face in order to account for most of the data. Finally, we discuss plans for future work.

Mondloch's Stimuli and Experiments

Mondloch et al. began with a single face (called Jane) and modified it to create twelve new versions (called Jane's Sisters). These were divided to three sets of stimuli: a configural set, a featural set, and a contour set (Figure 1). The four faces in the configural set were created by moving the eyes and/or the mouth. The four faces in the featural set were created by replacing Jane's eyes, nose and mouth with those of four different females. The four faces in the contour set were created by pasting the internal portion of Jane's face within the outer contour of four different females. The control stimuli were called "cousins" and consisted of three different female faces (Figure 2).

Figure 1: Jane is shown as the left-most face in each panel, along with her "sisters" from the configural set (panel A), the featural set (panel B), and the external contour set (panel C). (from [Mondloch et al., 2002])

Figure 2: The control stimuli: the cousin set. (from [Mondloch et al., 2002])

These stimuli were presented to 6, 8 and 10-year-old children as well as adults in a series of same-different trials. One face appeared for 200ms. After a 300ms interval, the second one appeared until the participant responded. There were also trials in which upside down versions of these faces were presented.

In this work, we concentrate on modeling the adult data, and hence focus on the black bars in (Figure 3). The results (Figure 3) showed that when stimuli were presented upright, the relative accuracy for adults in each set of stimuli was $cousin > featural > configural > contour$. This is interesting because it suggests that, at least for this stimulus set, subjects were more sensitive to individual feature differences than to configural changes. When the face images were presented upside down, however, the order was $featural > contour > configural$, and there was an inversion effect, i.e. the accuracy rate decreased. Note that the configural set, for which inverted accuracy was the worst, showed a larger inversion effect (measured by the mean accuracy of upright trials minus that of inverted trials) than the featural set.

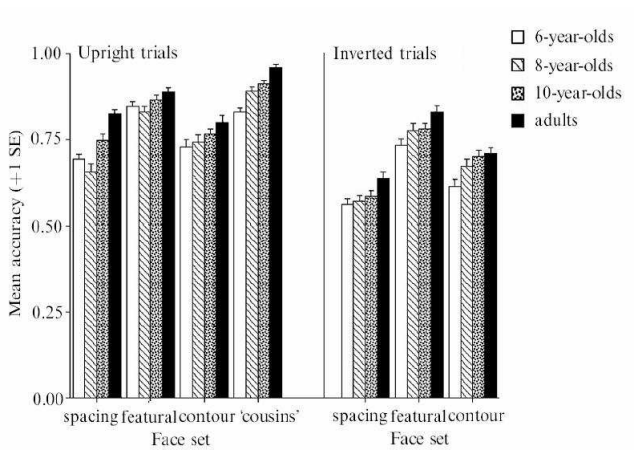

Figure 3: Mean accuracy for each face set and each age group when stimuli were presented upright (left panel) and inverted (right panel). (from [Mondloch et al., 2002])

A Computational Model of Face Recognition

Our model is a three level neural network that has been used in previous work (Figure 4). The model takes manually aligned face images as input. The images are first filtered by 2D Gabor wavelet filters, which are a good model of simple cell receptive fields in cat striate cortex [Jones and Palmer, 1987]. PCA (principal component analysis) is then used to extract a set of features from the high dimensional data. In the last stage, a simple back propagation network is used to assign a name to each face. We now describe each of the components of the model in more detail.

The Training Set

The FERET database is a large database of facial images, which is now standard for face recognition from still images[Phillips et al., 1998]. We used 662 face images (545 upright images of 117 individuals and 117 inverted images of 20 individuals (that were also included in the upright images)) in the training. The inverted faces were used in order to give a reasonable representation

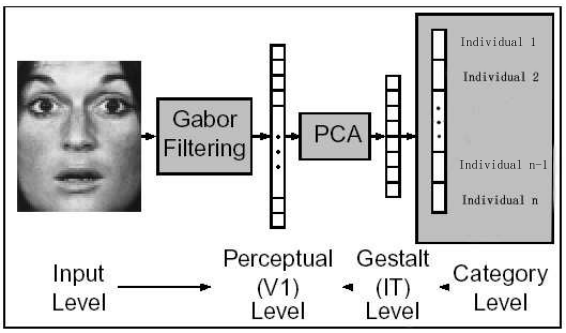

Figure 4: Object recognition model (from [Dailey et al., 2002])

of upside down faces in the PCA layer of the network. In [Dailey et al., 2002], where the task was to learn facial expressions, images were aligned so that eyes and mouth went to designated coordinates. This alignment removed the configural information which is crucial for our work because we are trying to understand how configural processing and featural processing interact with each other in the face recognition task. To avoid this negative effect, we required that the relative spacing between the parts of the face remain the same. The face images were rotated, scaled and translated so that the sum of square distance between the target coordinates and those of the transferred features (eyes and mouth locations) was minimized (Figure 5). Thus, a triangle represented by the eyes and mouth is scaled and moved to fit closely to a reference location, but the triangle is not warped. This way of alignment keeps configural information without affecting holistic processing. The aligned images were 192 pixels by 128 pixels.

Figure 5: Two examples of face image normalization. The faces were cropped with the eyes and the mouth as close as possible to the target position while keeping the shape of the triangle among these features the same.

Perceptual Layer

Research suggests that the receptive fields of the striate neurons are restricted to small regions of space, responding to narrow ranges of stimulus orientation and spatial frequency[Jones and Palmer, 1987]. DeValois et al[DeValois and DeValois, 1988] mapped the receptive fields of V1 cells and found evidence for multiple lobes of excitation and inhibition. Two-D Gabor filters [Daugman, 1985](Figure 6) have been found to fit the 2D spatial response profile of simple cells quite well[Jones and Palmer, 1987]. In this processing step the image was filtered with a rigid 23 by 15 grid of overlapping 2-D Gabor filters[Daugman, 1985] in quadrature pairs at five scales and eight orientations [Dailey et al., 2002](Figure 7). We thus obtained $23 \times 15 \times 5 \times 8 = 13,800$ filter responses in this layer, which is termed the *perceptual* layer [Dailey et al., 2002].

Figure 6: A Gabor function is constructed by multiplying a Gaussian function by sinusoidal function[Daugman, 1985]. We use five scales and eight orientations.

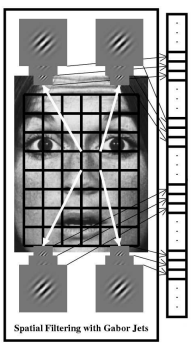

Figure 7: An image filtered with a rigid 23 by 15 grid of overlapping 2-D Gabor filters in quadrature pairs at five scales and eight orientations (from [Dailey et al., 2000])

Gestalt layer

In this stage we perform a PCA of the Gabor filter responses. This is a biologically plausible means of dimensionality reduction[Dailey et al., 2002], since it can be learned in a Hebbian manner. PCA extracts a small set of informative features from the high dimensional output of the last perceptual stage. The eigenvectors of the covariance matrix of the patterns are computed, and the patterns are then projected onto the eigenvectors associated with the largest eigenvalues. At this stage, we produce a 50-element PCA representation from the 13,800 Gabor vectors. Before being fed to the final classifier, the principal component projections are shifted and scaled so that they have 0 mean and unit standard deviation, known as z-scoring (or whitening).

Categorization layer

The classification portion of the model is a two-layer back-propagation neural network. 20 hidden units are used. A scaled tanh [LeCun et al., 1998] activation function is used at the hidden layer and the softmax activation function $y_i = e^{a_i} / \sum_k e^{a_k}$ was used at the output layer. The network is trained with the cross entropy error function [Bishop, 1995] to identify the faces using localist outputs. A learning rate of 0.05 and a momentum of 0.5 were used in the results reported here. 10 percent of the images are selected randomly as a test set and another 10 percent as a holdout set [Dailey et al., 2000]. The network achieves 85-90 percent accuracy within 50

epochs. This is remarkable given that for faces in the test set, there were only 2-3 images in the training set on average. This classification rate was decent enough to show that our model represented face images well.

Modeling Mondloch et al.

Training and Learning

For the following experiments, we simply trained the network on all 662 images, since we are only interested in obtaining a good face representation at the hidden layer. Training was stopped at the 50th epoch based on the above pilot experiment, as we assumed the network had achieved "adult" level identity recognition expertise at this point. After training, the preprocessed Jane stimuli images were presented to the network.

Modelling Discrimination

Hidden unit activations were recorded as the network's representation of images. In order to model discriminability between two images, we present an image to the network, and record the hidden unit response vector. We do the same with a second image. We model similarity as the correlation between the two representations, and discriminability as one minus similarity. Note that this measure may be computed at *any* layer of the network. We computed the average discriminability between images in each of the stimuli sets (featural, configural, etc., both upright and inverted). The average within each set was taken as the measure of the network's ability to discriminate each set. The average of the discriminabilities was computed over 50 networks which were all trained in the same way, but used different initial random weights.

The results (Figure 10 top graph) showed that our model was too holistic, i.e. the model showed high sensitivity to the configural set. As a first pass at adding featural information to the model, we took a cue from Padgett and Cottrell (1998), who developed a parts-based model for facial expression recognition. They simply had rectangular windows over the eyes and mouth and extracted features from those as input to a classifier. Similarly, Pentland et al. (1994) used "eigenfeatures", PCA of local patches, as input to a face identification classifier. From our grid of Gabor filters, we extracted three sets of Gabor responses that corresponded to the left eye, the right eye and the mouth respectively (Figure 8). A 10 dimensional PCA representation was extracted from each of them. Then we gave both the global and local PCA to the network as input.

We repeated this experiment multiple times, keeping the 30 local feature principal components (PC's) as input to the network, while varying the number of global PC's. The results (Figure 10) show how different combinations of global and local PC's affect the behavior of the network. The graph on the top is the result of the original model (50 global PC's with no local PC's). The graph second from the top is the result of 50 global PC's plus 30 local PC's. The remaining graphs show the effects of progressive reduction in the number of global PC's from 30 to 0 in steps of 10, while holding the number of local PC's constant at 30. When the number of

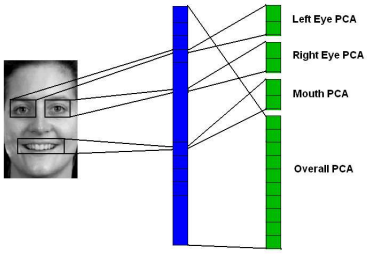

Figure 8: We extracted local PCA representations for the eyes and the mouth. The responses of Gabor filters from patches around the eyes and mouth were extracted and PCA was done on them separately.

global PC's is decreased below 20, the discriminability of the feature set began to exceed that of the configural set in the upright image trials.

Note that the local feature PC's did help the model pay more attention to features because the discriminability of the feature set has increased. Also, when the number of the global PC's was reduced, the discriminability of the feature, configural, and cousin sets increased. The discriminability of the cousin set started around 0.35 when 50 global components with 30 local components were used and ends up at around 0.45 when no global components were used. We can observe a gradual increase in discriminability over the sequence of the graphs from top to bottom. This gradual increase is also seen for the configural set and the feature set, which each grew from around 0.2 to 0.3. Further, the qualitative pattern for the inverted faces is reproduced in almost every variation.

Discriminability at processing stages

Where do these effects come from? Recall our definition of discriminability: one minus similarity, where similarity is equal to the correlation between representations. Hence, we can assess similarity and discriminability at each stage of processing, i.e., original images, aligned images, Gabor filter, PCA, z-score PCA. Note that for preprocessing stages, we are only comparing discriminability between a small number of images (Jane and her sisters), because these stages are identical for all 50 networks.

The order of discriminability for all combinations of local and global PC's and for both image orientations is the same for the first three stages. The order of the sets does not change until the PCA and z-score PCA stages. Figure 9 shows the discriminability of each set of different combinations of global PC's and local PC's at the PCA level and the z-score PCA level for upright images. When there are no local PC's (i.e., the original model), the configural set exceeds the feature set. When there are 30 local PC's and 50 global: the order is correct ($cousin > feature > configural > contour$) at the PCA stage, though the differences are very small. These differences are enlarged at the z-scored PCA stage. As reductions in the number of global PC's leave proportionally more local PC's, we observe the same correct

ordering and progressively larger differences between the sets at these last two stages. Also there is a trend towards increased discriminability for cousin, featural and contour sets.

A change in set order can also be observed at the PCA and z-score PCA stages for the inverted image results (not shown in figures here). The configural set shows a larger inversion effect than the feature set, which is consistent with human data. We also observe an increasing gap between the featural set and the configural set ($featural > configural$) when the local PC's are introduced and as their proportion is subsequently increased (as the number of global PC's is reduced). However, the contour set is always less discriminable or at most as discriminable as the spacing set, which is the wrong order – contour should be more discriminable than spacing in inverted images. The correct ordering shows up in the hidden layer for all networks except the ones with no global PCA or no local PCA (see Figure 10), suggesting that both are needed.

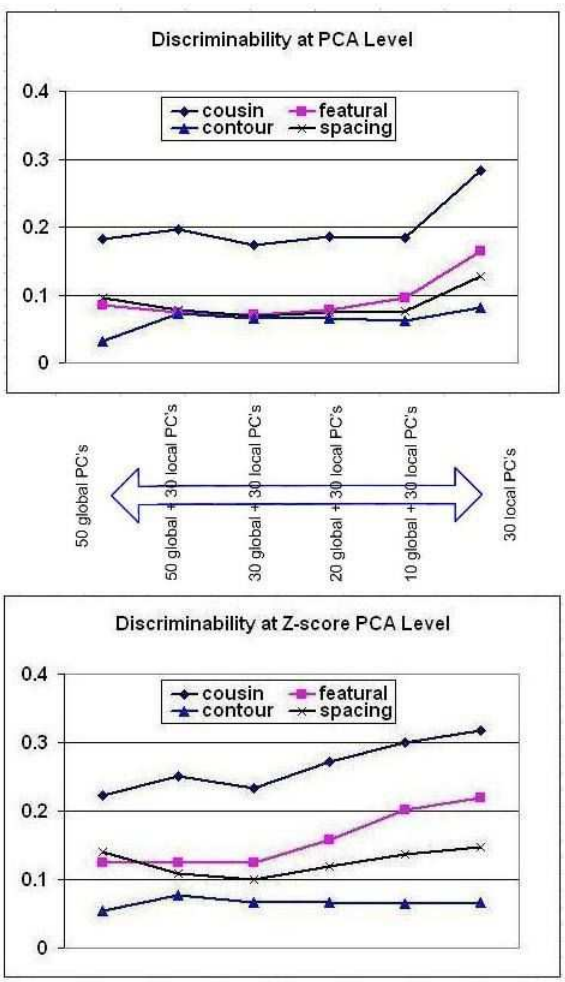

Figure 9: The discriminability of different combination of global PC's and local PC's at the PCA and the z-scored PCA level.

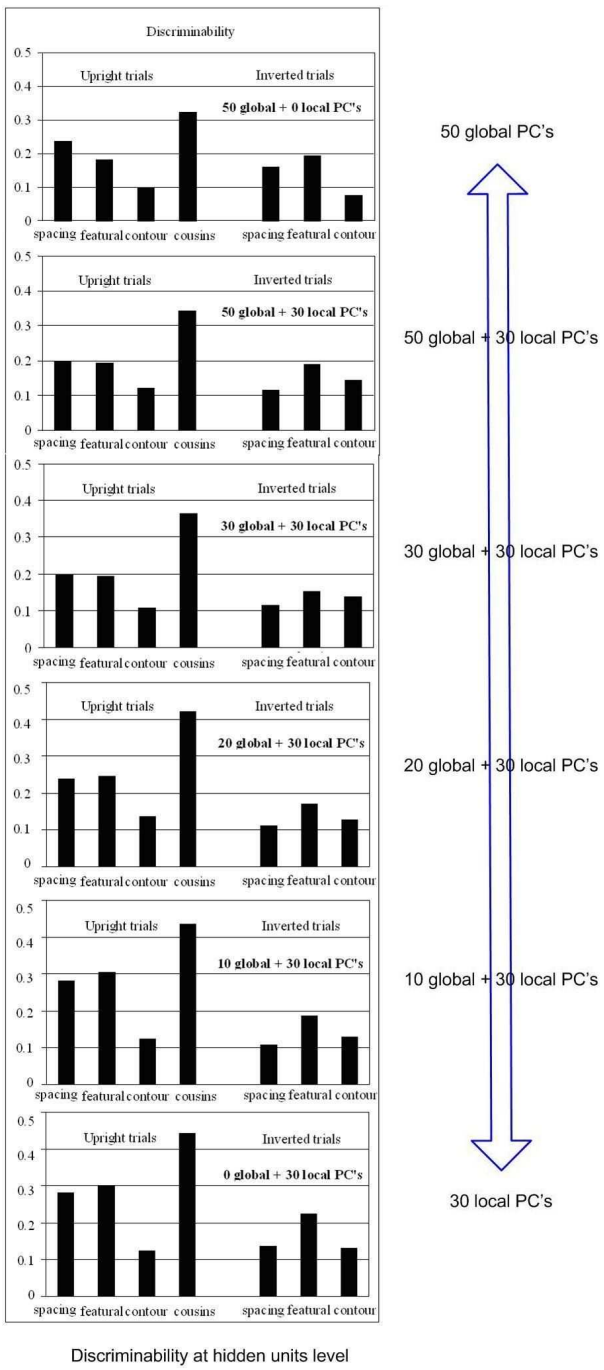

Figure 10: The discriminability of different combination of global PC's and local PC's at the hidden layer.

Discussion

While our standard model has accounted for a fair amount of data over the years, this particular set of data required substantial modifications. We found that our original model was too holistic, in that it was more sensitive to configural changes versus featural changes. This is not surprising given the way the model is constructed. Global PCA of the Gabor representation should act similarly to global PCA of grayscale images. This representation is known to develop ghostly-looking, whole face templates that we have called holons, and others have termed eigenfaces. These representations have proved to be very useful in modeling holistic processing effects. For example, when two halves of different faces are aligned, it is more difficult for the model to identify the top half of a face due to interference from the bottom half, even if the input from the bottom half is severely attenuated to simulate attention to the top [Cottrell et al., 2002]. This is due to the bottom half of the face matching giving a partial match to the templates corresponding to the other person's face.

Adding a parts-based representation, here implemented as a local feature PCA, turned out to be helpful in making the model more sensitive to features. This type of representation can be thought of as a schema for each part. It could be developed through attending to parts of the face, where the parts become well-represented via foveation. As proportionally more of this representation was used, the network's upright discriminability profile qualitatively matched the human subjects results.

Our model successfully showed inversion effects on the configural set and the featural set. This effect on the configural set was especially large, which is consistent with human behavior. The order for inverted trials qualitatively matched the human subjects results when both global and local components were used. While the model showed a strong inversion effect on the configural set, the model did not show any inversion effect on the contour set. This suggests that our model used the information mostly, if not entirely, from the inside of the face instead of the contour. Infants, on the other hand, are known to use the contour of the face before they are able to use the inside of the face for recognizing their mothers. In the future, we intend to add a developmental component to our model, in order to model this "outside-in" progression.

How can a system grasp linguistic variety?

Computer systems that interact with people using natural spoken dialogue offer many possibilities for effective and efficient interaction. But, a dialogue system for a new domain requires a great deal of expert attention to either collecting data for a new domain or designing a model of the language that people use when solving problems in that domain. Consider the extension of a checkers-playing dialogue system to other games such as Go: game-specific phrases and terms would need to be added – both "official" and colloquial versions. Prior work here includes identifying new lexical items, new word-sequence correlations (Galescu, Ringger, & Allen 1998), or new phrase patterns using existing words or word classes such as *color* or *animal* (Bulyko, Ostendorf, & Stolcke 2003). In this paper, we take a slightly different approach by focusing on semantics. Given a specification (as a sample dialogue), we want to identify alternate ways of talking about the same things. These alternates may not necessarily use any of the words that their counterparts in the script use. In fact, the more dissimilar such new phrases are in terms of surface features, the more helpful they would be if added to the vocabulary and syntax that the system can understand. Such a technique should prove useful when expanding the linguistic coverage of a dialogue system to cover what people say in practice. We describe these techniques in the context of an equipment purchasing system – part of the multisite CALO project, an intelligent personal assistant.

Start with a script

Any dialogue system typically starts with some data collection or user interviews or some other technique designed to give a basic idea of what the users of the system will eventually say. The requirements for the system can then be easily expressed in terms of a dialogue script. The initial script for our domain of computer purchasing began:

System: Hello, this is CALO. User: Hello CALO.
S: Hello. U: I would like you to buy a computer for me.
S: Ok; what kind of computer would you like?

Add human-human dialogues

As part of the dialogue system effort, Rochester collected a set of approximately 40 human-human dialogues carried out by ~20 people playing the role of "buyer" and ~4 people playing the role of "agent". In order to collect dialogue aimed at the computer purchasing domain, we provided a short scenario to role-play when buying the first computer - "You are a small business owner looking to buy a computer", etc. The second scenario was self-directed, that is, "Now get a computer for yourself." These dialogues were recorded and transcribed. Those utterances that closely matched lines from the script we used directly as additional training data. Those utterances about capabilities beyond the scope of the initial system – such as warranty purchases – we reserved for later use. That left a wide range of utterances concerning concepts that are present in the script, but using different words and syntax. We wanted those.

Mine them for semantic matches to script lines

We used Latent Semantic Analysis (http://lsa.colorado.edu) to extract utterances from the human-human dialogues that were similar to each line in the script. For each utterance in the dialogues, we calculated its similarity to each line in the script, and assigned it to the line with the highest similarity. We then hand-filtered the resulting data to yield new ways of saying lines in the script, such as:

On a similar topic, but system initiative rather than user:
Script/User: I would like you to buy a computer for me.
Dialogue/*System: Hello would you like to buy a computer*

With similar meaning, but very different words and syntax:
Script/*S: Ok, I'll start looking.*
Dialogue/S: I'll go ahead and uh save this.

Less similar in meaning, but still reasonable alternatives.
For example, after "*Ok; what kind of computer would you like?"*:
Script/U: A lightweight laptop computer with 500 mb of ram.
Dialogue/U: Pentium processor.

From the utterances paired with the 28 lines in the script, 41 were identified to be useful matches. CALO developers at Rochester and IHMC used these to extend the language understanding of the CALO dialogue system.

A COMPUTATIONAL FRAMEWORK FOR THE STUDY OF COLLABORATIVE LEARNING

Rick Alterman (alterman@cs.brandeis.edu)
Svetlena Taneva (svet@cs.brandeis.edu)
Computer Science Department, Volen Center for Complex Systems, Brandeis University
415 South Street., Waltham, MA, 02454 USA

There are a large number of research questions on collaborative learning that cannot easily be answered by simply collecting and comparing quantitative data on the performance of individual and collaborative learners. More often than not, critical information is available only if access to a detailed recording of the students' collaborative work is available. For certain research endeavors in the collaborative learning domain, we need to know how the students organized their task, what roles the students played, and how they participated. Videotaping is an example of a technology that has been used to investigate collaborations within the workplace. But there are some difficulties with using this approach for the studying of collaborative learning, not the least of which is the extensive time-cost of collecting and transcribing video data. We argue that groupware applications are an ideal platform for experimental investigations of collaborative learning.

At Brandeis we have been developing principles, tools, and methods for cognitively engineering groupware systems that support online collaboration. One part of this project is to develop a toolkit that enables the rapid development of groupware applications that can be used as experimental platforms. A key component of the groupware systems that are generated is that a complete transcript of all the online activity is automatically captured in a form that is replayable by an analyst using a replay device (that is created as the system is developed). Students at Brandeis have successfully used this toolkit in a HCI class to produce a working groupware system; each team of students had 28 days to write the code. Another part of our research project is to develop discourse analysis techniques for modeling the online collaborative work of users and the cognitive load it entails for each of the participants. These techniques have been taught in a class on Computational Cognitive Science.

In this poster, we will present some of the details of an experimental study of collaborative learning that we are currently conducting. Some of the questions about collaborative learning that we want to investigate are:

- How does the amount and type of participation affect individual learning?
- What do the participants talk about (i.e. which aspects of the activity do they spend the most effort on)?
- How do the participants organize their collaboration?
- How closely do the participants work together?

Corresponding to each one of these questions are significant hypotheses about the role of participation and/or explanation in collaborative learning tasks.

Our study compares the performance of individuals and pairs of students (with little or no prior programming experience) as they learn to draw figures using JScheme. As a part of this study, we constructed a platform (GrewpTool) for collaborative programming that has been used to support several kinds of classroom related activities. In our experimental study, GrewpTool collects, in a replayable transcript, the representational work of individual subjects and all of the communication between paired subjects. The participants in our experiment complete both a pre and a post test, whose score difference indicates how much they learn.

Our study has produced an enormous amount of data for analysis. The replay of an individual session of collaboration is one of the tools available for analyzing the interactional data. Given this tool, extracting specific and accurate answers to questions about participation is feasible, but the data is not easily codable and the task is labor intensive.

We have developed some automatic methods for analyzing the interaction that can be used to guide the ethnographic analysis of the subjects' online behavior. Each of these representations is relevant to answering questions of the sort listed above. We will show automatically generated representations that depict how close each pair worked together, how they organized their collaboration, the type and amount of each subject's participation, and the content of their conversation. Each of these representations can be created because all of the subjects' participation is mediated by the computer and therefore automatically recorded and transcribed. Given this analysis of the data, it is possible to more selectively engage in the labor-intensive task of analyzing the replay of each session. Given these kinds of representations of data it is easier to explore the effects of explanation, participation, and organization on learning.

Moral Cognition: A Dual-Process Model

Eric C. Anderson (ecanderson@hampshire.edu)
School of Cognitive Science, Hampshire College
893 West St., Amherst, MA 01002 USA

Introduction

For centuries philosophers have debated the roles that intuition and reasoning play in making moral judgments. Hume proposed that people possess a 'moral sense' that allows them to distinguish between right and wrong, while Kant argued that reason is, or should be, the basis for making moral judgments.

In the last 40 years psychologists have addressed this question using scientific methods. Kohlberg (1986) emphasized moral reasoning in his cognitive developmental stage model which posits that people progress through a series of six universal stages of moral reasoning. Haidt (2001) recently proposed a dual-process model of moral cognition that rejects reason as the primary cause of moral judgments and posits intuition as more influential. Intuition is characterized as fast, automatic processing that is not available to introspection. Reasoning, on the other hand, is characterized as slow, deliberate processing. While reasoning, people are aware of progressing through a series of steps to generate a judgment (Haidt, 2001; Kahneman, 2003).

We propose a modified version of the social intuitionist model. This dual-process 'interactionist' model proposes both intuition and reasoning processes are used, but their use depends on the situation being judged. Specifically, the model proposes that reasoning processes are used when people have no intuitions or when they have conflicting intuitions. However, when one dominant intuition is generated, reasoning processes are not engaged.

Methods

To asses the interactionist model, an experiment was conducted in which 60 participants read moral dilemmas used by Greene et al. (2001) and made judgments about them in two time conditions. In the fast time condition, participants made judgments immediately without reasoning about the dilemma, while in the slow time condition, participants had as much time as needed to make judgments. If reasoning processes are important, then disrupting that process should decrease people's ability to make judgments. Participants were tested on three different types of dilemmas: dilemmas that produced no intuitions; dilemmas that produced conflicting intuitions; and dilemmas that produced one intuition.

Findings

The findings support the interactionist position by suggesting that participants used intuition and reasoning differently depending on the dilemma being judged. In situations that were predicted to require reasoning (no-intuition dilemmas and strong-conflicting intuition dilemmas), participants did poorly in the fast time condition (Figure 1). However in the dilemmas when reasoning was hypothesized to be causally inert (no-conflicting intuition dilemmas), there was no difference in participants' performances between the time conditions. These findings call into question both strong intuitionist and strong rationalist positions but support the dual-process interactionist model.

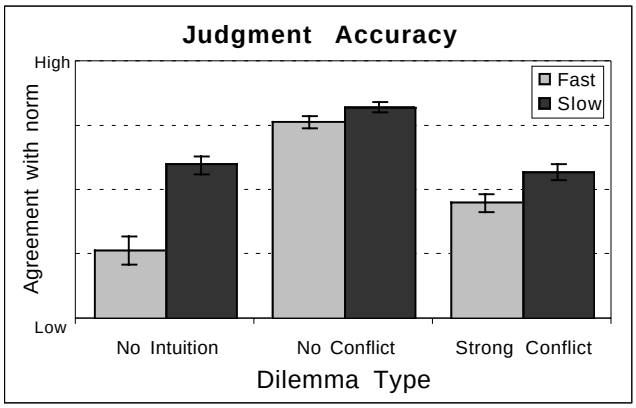

Figure 1: Judgment accuracy based on agreement with the empirically established moral norm.

Empirical Results for the Use of Meta-language in Dialog Management

Michael L. Anderson (anderson@cs.umd.edu)
Institute for Advanced Computer Studies, University of Maryland
College Park, MD 20472

Bryant Lee (blee3@wam.umd.edu)
University of Maryland
College Park, MD 20742

Introduction and Background

As is well known, dialog partners manage the uncertainty inherent in conversation by continually providing and eliciting feedback, monitoring their own comprehension and the apparent comprehension of their dialog partner, and initiating repairs as needed (see e.g., Cahn & Brennan, 1999; Clark & Brennan, 1991). Given the nature of such monitoring and repair, one might reasonably hypothesize that a good portion of the utterances involved in dialog management employ meta-language. But while there has been a great deal of work on the specific topic of dialog management, and it is widely (if often tacitly) accepted that meta-language is frequently involved, there has been no work specifically investigating and quantifying the role of meta-language in dialog management. Thus, this small study investigated the correlation between meta-language and dialog management utterances in three dialog files of the British National Corpus (BNC).

Approach and Methods

The three BNC files used in this study, KRF, KRG, and KRH, are transcripts of a series of *Ideas in Action* radio programs, some of which are interviews. Because interviews are more structured than informal conversation, they involve explicit dialog management, and are therefore a good place to start an investigation into the relation between meta-language and dialog management. Focusing exclusively on the interviews in these three files gives 5900 lines to study.

These three files had been previously annotated for meta-language, using the annotation scheme and methods reported in (Anderson, *et al*., 2004).

To identify and annotate the dialog management utterances, we were guided by an analogy with the TRAINS domain and dialogs (Gross, Allen & Traum, 1993). In the TRAINS domain, the base-level actions are moving trains between cities, and the assigned task is to plan and manage these moves through cooperative dialog. In our case, we defined the interview itself as the task domain, the base-level actions as utterances, and the task as planning and managing these base-level actions, i.e. planning and managing the interview itself. As in TRAINS, this management is accomplished through dialog. The utterances involved in planning and managing the interview were identified and annotated according to Dialog Act Markup in Several Layers (DAMSL) (Allen & Core, 1977).

We are still analyzing the results of this annotation for specific correlations between meta-language and the different DAMSL information levels and functions. However, we report some preliminary results, below, for the overall relation between dialog management and meta-language.

Results

Of the 5900 lines annotated, 581 were dialog management utterances, and 1020 included meta-language. 312 lines were both dialog management and meta-language.

Table 1: Meta-language and dialog management results

	Meta	-Meta	Totals
DM	312	269	581
-DM	708	4611	5319
Totals	1020	4880	5900
$X^2 = 597.56$ $p << 0.001$ $\Phi = 0.318247$			

Thus, 53.7% of dialog management utterances involved meta-language. To the best of our knowledge, this is the first quantitative confirmation of the tacitly held assumption that meta-language is frequently involved in dialog management. Detailed results can be found at http://www.cs.umd.edu/projects/metalanguage

Introduction

We report on a study that investigates the relationship between visual working memory and verbal working memory and a performance measure in endoscopic instrument navigation in GI Mentor II (a simulator for gastroscopic surgery). Baddeley's (1998) three-component model of the working memory contains a central executive and two subsidiary slave systems – the phonological loop and the visuo-spatial sketchpad. Both the visual working memory, rehearsal processed based, and the verbal working memory falls within the phonological loop category – when using digit span tasks. We hypothesize that the visual working memory test scores will correlate with the simulator performance measure. We also predict that tasks involving a higher degree of central executive functions will be more discriminate in correlation with the performance measure. We have added the verbal working memory task to distinguish and rule out verbal working memory as a major factor for predicting endoscopic simulator performance – and thus define and elucidate the visual working memory phonological loop function for predicting endoscopic simulator performance.

Method

22 medical students (novices, 11 women and 11 men), ranging in age between 22 and 40 years at Karolinska Institutet, Huddinge University Hospital in Sweden, participated in the study. All participants completed a one hour session in the MIST-VR simulator and the GI Mentor II simulator. We will only present findings from the GI Mentor II simulator. The selected GI Mentor performance score measures the efficiency of screening (ES). The working memory (WM) tasks were taken from the WAIS III test battery (Wechsler, 2003): Forward digit span task (FDS), backward digit span task (BDS) and an alphanumerical task (ANT) – with the forward digit span being the least demanding on the central executive function and with the alphanumerical task being the most demanding.

Results & Discussion

There were significant Pearson's r correlations found between the visual working memory test scores and the simulator performance score and between the verbal visual working memory test score ANT and the simulator performance score.

Table 1. Pearson's *r* correlations between performance score (ES) in the GI Mentor II simulator, Visual Working Memory scores and Verbal Working Memory Scores.

Visual WM task	Verbal WM task
Fds *r*=.607, p=.031	Fds *r*=.306, p=.166
Bds *r*=.570, p=.043	Bds *r*=.324, p=.152
Ant *r*=.617, p=.029	Ant *r*=.639, p=.013
ES	ES

Our findings suggest that visual working memory correlates with the simulation performance measure. The verbal working memory is dependent on more advanced central executive functions to discriminate significant differences for the performance tasks while the visual working memory tasks show a more uniform result regardless of central executive effort. An extension of this study is currently exploring these findings further

Learning to Categorize in the Context of Item Triples

Janet K. Andrews (andrewsj@vassar.edu) & Kenneth R. Livingston (livingst@vassar.edu)

Background

We evaluate the relative contributions of two mechanisms of category learning: 1) *abstraction* across examples of the same category and; 2) *differentiation* between examples of different categories. A novel "triples" paradigm is introduced in which each classification target is presented with two different context items. Learners are informed of the structure of the triples so they may take advantage of knowledge about the relative category status of the items. We use feature-based categories with perceptually subtle variation among examples. The study is designed to advance a naturalistic yet controlled basis for the study of category learning by using multiply-instantiated feature values (Markman & Maddox, 2003) and three-way rather than binary classification decisions.

In a control condition, items were presented one at a time. Learning was also tested under five experimental conditions based on the following triple structures: aAA (both context items match the category of the target 'a'), aAB (one matching and one mismatching context item), aBB (both context items mismatch the target, but the context items match one another), aBC (both context items mismatch the target and the context items also mismatch one another), and aXX (no systematic structure).

One possible learning strategy is to locate common features between items known to belong to the same category and perform abstraction -- in which case the aAA group should have an advantage. Another potential strategy is to identify contrasts between items known to belong to all three categories -- in which case the aBC structure should be most beneficial. The aAB structure is least informative under either strategy because the learner is unable to know for certain whether any pair within the triple are in the same or different categories. The aBB group benefits from weaker forms of both abstraction and differentiation on each trial.

Method

The stimuli consisted of organism-like patterns created in Adobe Photoshop that varied systematically along three dimensions: body-aspect ratio, flagella length, and stripe width. Each dimension had eight possible values. Three categories called Gex, Kij, and Zof were defined using the higher or lower four dimension values (e.g., Zofs had rounder bodies, longer flagella, and wider stripes) for a total of 192 possible items. Each category was distinct from the other two in terms of exactly one dimension.

Each of sixty-six college students was randomly assigned to one of the six conditions described above (single item control condition, aAA, aAB, aBB, aBC, or aXX) and tested in two phases, a training phase of 144 trials with feedback given on target classification responses, and a test phase without feedback and using all 192 stimuli. Except for the single target control condition, stimuli were always presented in the triples context, and the structure of the triple was carefully explained to participants at the outset.

Results

The manipulation significantly affected accuracy and speed of performance during the first (training) phase of the experiment ($F(5,60) = 3.423$, $p = .0087$), with the aBC condition yielding the best performance (83% correct overall, with chance performance of 33%). As expected the least learning took place in the aAB group (55%). To our surprise, the aAA group was also quite low (63%) and did not differ significantly from the aAB group. Performance was intermediate in the aBB (74%), single item control (73%), and aXX (69%) conditions, which did not differ significantly. Examining performance over the course of 12 blocks of 12 training trials, the aBC condition was most accurate for every single block. Overall accuracy in phase two ranged from 61% (aAB) to 78% (aBC), but there was no main effect of condition at that point.

These results indicate that, at least in the early stages of learning in this context, between-category differentiation is more important than within-category abstraction. Additional experiments are underway to explore whether removing the information given about the triples structure, or highlighting it more dramatically, will alter the outcome.

Semantic Complexity and Language Production: Simple vs. Complex Verbs

Introduction

Because language is a discrete combinatorial system in which smaller representations at one level combine to form larger representations at another level, verbs can differ with respect to the number of smaller representations that comprise them. The semantic and morphological levels are most closely related to a verb's meaning, and it has been shown that lemmas that share overlapping semantic features compete for production when encoded in the same local context (e.g., Breedin, Saffran, & Schwartz, 1998). This study investigated the competition between complex and simple verbs using a speech error elicitation task intended to induce contextual errors where one verb replaces another in a perseveration, anticipation, or complete exchange (e.g., Baars. 1992). Here, complex verbs contained all of the same semantic features as a simple verb in addition to additional features at the semantic and morphological levels. Two experiments tested the hypothesis that more complex verbs would replace their simpler counterparts more often than vice versa in contextual errors due to being associated with a greater number of activated semantic features at the point of lemma selection.

Experiment 1

Experiment 1 investigated the antonymic contrast between verbs where one is semantically and/or morphologically marked. For instance, in the semantic + morphological condition, the verb UNTIE has all of the features of TIE plus a negation feature at the semantic level and an additional morpheme at the morphological level. In the semantic only condition, the verb DECODE contains all of the semantic features of ENCODE, but does not consist of an extra morpheme at the morphological level. It was predicted that complex verbs in both conditions would replace their simpler counterparts (denoted *simple* → *complex*) in contextual errors more often than vice versa. An asymmetry was also predicted such that the additional morpheme and semantic features of the complex verb in the semantic + morphological condition would result in an even greater number of *simple* → *complex* speech errors than in the semantic only condition.

The results of Experiment 1 are listed in Table 1. As predicted, the effect of error type was significant, as was the interaction between error type and complexity condition. There is evidence that the additional morpheme in the semantic + morphological condition gave the complex verb lemmas an additional advantage over their simpler counterparts.

Experiment 2

This experiment examined the contrast between simple and complex verbs that differed with respect to an added feature of manner specification as well as morphological aspect features. The lemma representations of complex verbs like JOG contain all of the semantic features of the lemma representation of a simple verb like GO plus a specification of manner. In addition, the morphological features of progressive aspect were added to half of the complex verbs (i.e. "is jogging"). Again, more *simple* → *complex* errors were predicted than the reverse, and the added morphological features were expected to enhance this effect.

The results of Experiment 2 are listed in Table 1. The effect of error type was significant both conditions, as was the effect of complexity condition. The interaction was not significant, indicating that the additional morphological aspect features in the semantic + morphological condition did not contribute to the complex verb's lemma activation beyond that of the additional manner feature.

Table 1. Results for Experiments by Subject (p-values)

Effect	Experiment 1	Experiment 2
Error Type	<.001	<.001
Complexity Cond.	>.05	.04
Interaction	.02	>.05

Analogies in the Wild: Generated Analogies as Assertions of Categorization

Leslie J. Atkins (latkins@umd.edu)
Department of Physics & Department of Education and Curriculum, University of Maryland
2226 Benjamin Building, University of Maryland, College Park, MD 20742 USA

Analogies in the wild

The research described here is an attempt to understand analogies that are spontaneously generated by students in science classrooms and in science discussions. Most analogy research and associated models of involve the *interpretation* or *application* and not the *generation* of analogies. Analysis of student discourse presented in this poster shows that analogies generated "in the wild" have features that are neither elicited nor explained by research on analogy interpretation. It is the main thesis of this poster that generated analogies are best understood as assertions of categorization in which the base is a prototypical member of an (often) ad hoc category. Categorization research, perhaps because of its focus on the categories that participants and cultures generate, can account for the following phenomena present in generated analogies: multiple analogies, the choice of base, and the variable representation of the base. Furthermore, the ontology of mind implied by a categorization model is consistent with other findings from cognitive science, linguistics and education research.

Features of generated analogies

Far from what transfer studies would suggest, analogies are frequent in discussions about physical phenomena in science classrooms. In one fifth grade class, when discussing whether or not water will spill from a falling cup, students generate multiple analogies: it is like swinging a toy in a basket, throwing a bucket of water, an astronaut in a space shuttle, or tossing a container of dice. I argue that these analogies serve to assert and negotiate a category, and that this assertion is strengthened by multiple analogies.

The choice of the base in these analogies is consistent with categorization as well. While students may have experiences whose features and structure are similar to the topic at hand, the choice of base is often structurally similar and perceptually dissimilar. If one assumes that analogies are assertions of categorization, then these findings may be accounted for by arguing that the choice of base is the category prototype. In categories, prototypes are the first category members to be elicited; they are used to reason about the category as a whole, and are artifacts of cognitive models. Discourse analysis of analogies finds features of prototypes to be features of the base of generated analogies.

The representation of the base is generally taken for granted in models of analogy. However, there is evidence in generated analogies that the representation of the base is variable and can shift depending on the cognitive model a student applies. When reasoning about the relationship between light and heat, students draw an analogy between light and money. This base changes representation during the discussion from one of wealth (in which \$1.00 can unproblematically change to 4 × \$0.25) to one of currency (in which a dollar never "turns into" four quarters). Consistent with categorization research (Lakoff, 1987), this shift in representation is indicative of the change in cognitive model that is applied.

Ontology of mind

Concepts have long been treated as mental representations that are accessed and acted on by computational processes. This assumption of concepts as stable representations and its implications on the ontology of concepts in the mind has been called into question in several fields, including psycholinguistics, categorization, and education. Despite these concerns, the most widely accepted and used models of analogy ascribe representations to concepts and treat these as fixed— perhaps an artifact of the nature of the analogy studies. A categorization model of analogies, in particular the relationship between categories and cognitive models, addresses these concerns and accounts for analogies using a manifold ontology of mind.

Past research

The claim of analogies as assertions of categorization is not new to the conversation. However, past studies on analogy as categorization have been in vitro studies on the interpretation of analogies. Such scenarios limit the ability to observe variability in analogical reasoning, providing an incomplete picture of the nature of analogy. When viewing analogies that are created by students, the similarities between analogies and categorization become apparent.

Acknowledgments

A Bi-Polar Theory of Nominal and Clause Structure

Jerry T. Ball (Jerry.Ball@mesa.afmc.af.mil)
Human Effectiveness Directorate, Air Force Research Laboratory
6030 S. Kent Street, Mesa, AZ 85212 USA

It is argued that the basic structure of nominals and clauses is bi-polar—consisting of a *referential* pole and a *relational* pole. The locus of the referential pole is the *specifier*. The locus of the relational pole is the *head*. For nominals, a determiner functioning as an *object specifier* is the typical referential pole. The determiner functions to ground the nominal in a situation model (Kintsch, 1998). For clauses, an auxiliary verb functioning as a *predicate specifier* is the typical referential pole which grounds the clause in the situation model. For nominals, a noun functioning as the head is the typical relational pole (albeit a non-relation). However, some relations may also head nominals ("kick" in "the kick"). The reason a relation can head a nominal is because the object specifier determines the referential type of the expression, not the head. The object specifier coerces the relation, causing it to be viewed objectively. For clauses, a main verb functioning as the head (or *predicate*) is the typical relational pole. However, most adjectives ("he is *sad*"), prepositions ("he is *out*"), indefinite nominals ("he is *a man*") and some adverbs ("he is *there*") can also function as heads of clauses. Again, the predicate specifier determines the referential type of the clause, not the head. The referential and relational poles may be combined in a single lexical item. For nominals, pronouns, proper nouns, demonstratives and some quantifiers may combine the referential and relational poles. For clauses, tensed verbs combine the two poles. The words which occur between the specifier and the head are typically attracted to one pole or the other. *Modifiers* are usually attracted to the relational pole where they combine with the head. *Referential Modifiers* which encode referential meaning may also be attracted to the referential pole. For clauses, the negative particle tends to combine with the referential pole as is suggested by the clitic forms "isn't", "didn't", and "hasn't" and the requirement for do-insertion ("he does not run" vs. "he runs"). Adverbial modifiers tend to combine with the relational pole. For nominals, ordinal quantifiers tend to combine with the referential pole, whereas cardinal quantifiers tend to combine with the relational pole ("the←first ten→books"). Adverbs, which typically function to modify relations, usually combine with a relational modifier and not the head in nominals ("very" combines with "old" in "very old man").

The bi-polar structure of nominals and clauses does not consider *complements* which are an element of relational meaning. The combination of a relational head with its complements interacts with the encoding of referential meaning in interesting ways. In nominals, the complements of relational heads ("kick" in "the kick") are suppressed by the referential function of the object specifier. Expression of the complements requires introduction of relational modifiers ("of the ball" and "by the man" in "the kicking of the ball by the man"). In tensed clauses, the complements are expressed normally, but in non-finite clauses, expression of the subject *argument* (argument and complement are used synonymously) is suppressed, and in passive clauses, the subject argument is expressed, but corresponds to the object in the active construction, with the subject argument of the active construction being left unexpressed.

The bi-polar theory resolves problems that have plagued uni-polar theories like X-Bar Theory (Chomsky, 1970) and Dependency Grammar (Hudson, 2000). The shift to functional "heads" in X-Bar Theory leads McCawley to lament "…all sorts of things…get represented as heads of things they aren't heads of" (in Cheng and Sybesma, 1998). For example, in "the dog" treating "the" as the head of a DP taking the NP complement "dog"—when "dog" by itself isn't even an NP. Likewise, Hudson's strongly endocentric version of dependency grammar leads him to suggest that "the" is a pronoun that just happens to take a complement.

The bi-polar theory outlined above is called **Double R Theory** (Referential and Relational Theory). Double R Theory is focused on the grammatical encoding and integration of referential and relational meaning within the broader scope of Cognitive Linguistics (Langacker 1987, 1991; Talmy 2000; Lakoff, 1987). Adding a specifier as the locus of referential meaning is an extension of Langacker's (1991) conception of nominals and clauses with the specifier functioning as the locus of Langacker's *grounding predication*. Details of Double R Theory are available at www.DoubleRTheory.com.

102 Gilmer Hall, PO Box 400400, Charlottesville, VA 22904-4400

Introduction

A number of studies show age differences in *source memory* (see e.g., #1, 2, 5). However, few studies examine age differences in *monitoring accuracy* for such tasks. The current study uses a paradigm inspired by Koriat and Goldsmith (1996) and Kelley and Sahakyan (2003) to examine age differences in monitoring accuracy for a source memory task when overall accuracy is matched between younger and older adults. This study also examines how differences in monitoring accuracy bear on the ability to regulate overall accuracy when the option to withhold responses is given.

Method and Results

Older adults (OA), younger adults (YA), and older adults who were matched on source accuracy with younger adults (O-M) were presented sentences spoken by one of two speakers: one male and one female. At test, participants were asked to identify the source of each item as male, female, or as new. Following each response, participants were asked to give a confidence judgment and were given the choice of either submitting or withholding their answer. Source accuracy is shown in Table 1. OA were worse than YA in making source judgments, while no differences were found between O-M and YA. However, while YA were able to significantly improve their source accuracy by withholding responses, OA and O-M were not.

Table 1: Source accuracy in forced and free testing conditions

	OA	YA	O-M
FORCED	0.66	0.79	0.76
FREE	0.68	0.85	0.78

Table 2: Monitoring Accuracy

	OA	YA	O-M
Calibration	0.17	0.10	0.15
Gamma	0.03	0.58	0.45

Monitoring accuracy data are shown in Table 2. OA and O-M were significantly worse at monitoring the accuracy of their responses compared to YA. We hypothesized that older adults' diminished monitoring ability was due to *misrecollections*. We tested this hypothesis by completing an analysis in which old items for which high confidence source misattributions occurred were removed. The results are shown in Table 3. Removing misrecollections resulted in no monitoring differences between YA and O-M.

Table 3: Adjusted Monitoring Accuracy

	YA	O-M
Calibration	0.11	0.09
Gamma	0.66	0.67
# Misrecollected	2.61	6.44

Discussion

OA were found to be less accurate in making source memory judgments than YA. Furthermore, even when older participants were matched with YA on source accuracy, they showed an impaired ability to accurately monitor their responses. This impairment was due to a large number of misrecollections, and when these items were removed from the analysis, no differences were found in monitoring accuracy. OA and O-M were also unable to effectively withhold responses to improve their source accuracy scores, compared to YA. This was due to two factors: older participants' impaired monitoring ability and their use of a lax criterion in making submit-withhold decisions.

Background

School-age children acquire hundreds of new words each year, many of which are acquired incidentally, from uses in discourse contexts. Although children are adept word learners, lexical acquisition from oral language is not necessarily inevitable. Children have particular difficulties in the acquisition of terms that involve complex semantic representations, such as science terms (Braisby, Dockrell, & Best, 1999). Learning science terms poses particular challenges for acquisition because they are 'conceptually complex' and can be understood at various levels of abstraction (Meyerson et al, 1991). Our study investigated the kinds of knowledge children acquire about a science term during the process of lexical acquisition.

Understanding the process of lexical acquisition requires a thorough assessment of the nature of children's word-related knowledge (Beck & McKeown, 1991). While previous studies of word learning have focused on what drives children's acquisition of word meanings, less is known about the nature of children's lexical representations, particularly those relating to complex vocabulary. When children acquire a new word, they must identify the sound in the speech stream to encode a phonological representation and then establish a mapping between the word and concept. Ultimately a detailed semantic representation is developed for the new term.

Because of this multifaceted representation, ascertaining the nature of vocabulary knowledge requires multiple measures (Beck & McKeown, 1991). These measures should include both production and comprehension, moving beyond the conventional multiple-choice comprehension task. Indeed, recent research has indicated that tapping into children's knowledge of conceptually difficult concepts may necessitate creative methods, such as drawing-based assessments (Gross & Teubal, 2001).

Assessing knowledge across a range of tasks does not, on its own, provide information about the maturity of children's lexical representations. Although seldom used in lexical acquisition research, comparison with adults' performance allows us to identify knowledge gaps.

The Study

The present study examined children's representations of a science term following a fortuitous exposure to the term. Thirty children's (mean age = 6.7 years) knowledge of the term eclipse was examined before and after a partial solar eclipse that was visible throughout Europe in the summer of 1999. There was considerable media interest at the time, but no general formal educational instruction occurred because children were on summer break.

Our study assessed the nature of understandings that children acquired about the term eclipse and a control term, comet (which was not related to an eclipse) at three points in time (baseline test, two-week post-test, and five-month post-test), using a range of assessment tasks (multiple-choice comprehension, picture-naming, drawing, and eclipse 'making' task). Also, children's knowledge was compared to 15 adult controls during the baseline test and two-week post-test. According to the two-week post-test and five-month post-test, children acquired extensive knowledge about eclipses, but not comets. The majority of children successfully named and drew eclipses and 'made' an eclipse using models of the sun, moon, and earth. Also, children's eclipse knowledge more closely approximated adult-level understandings at the two-week post-test than at the baseline test. Overall, the study offered an important insight into the nature of children's lexical knowledge when words are acquired. The study also identified effective methods for tapping into children's lexical knowledge.

Cue Onset Asynchrony in Task Switching

Svetlana Evt. Bialkova (s.bialkova@nici.kun.nl)

Ab de Haan (a.dehaan@nici.kun.nl)

Herbert J. Schriefers (schriefers@nici.kun.nl)

Nijmnegen Institute for Cognition and Information

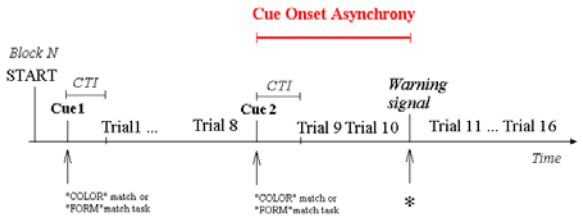
The Overlapping Cues Paradigm (OCP) and Cue Onset Asynchrony (COA) are introduced as an experimental tool to investigate the dynamics of control mechanisms involved in task switching in a situation with "competition" between two concurrent task goals. We report three experiments focusing on the questions (1) what are the consequences for task performance when two sequentially implemented and overlapping goals are in "conflict"? (2) In such overlapping goal situations, what are the consequences of differences in time pressure (externally paced Cue Target Interval)? (3) How are task switch costs affected by stimulus driven factors (Convergent vs. Divergent trials)?

Experimental paradigm

In the experiments there were two tasks, detection of a form-match or a color-match between a colored geometric figure functioning as a reference and an array of four figures. Which of the two tasks the participant had to perform was indicated by corresponding cues, either the word "Form" or the word "Color" (see figure). Two cues, separated by 8 trials, were presented within each block of 16 trials in two possible combinations: non-conflict (Cue1=Cue2) or conflict (Cue1≠Cue2). Two trials after Cue2, a star was presented as warning signal, which forced a task switch in the conflict condition, but not in the non-conflict condition. The Cue Onset Asynchrony refers to the distance between Cue2 and the Warning-signal.



Manipulated factors

Within the experiments we manipulated the following factors: 1. Task type with levels "Color" match and "Form" match; 2. Cue type with levels non-conflict (Cue1=Cue2) and conflict (Cue1≠Cue2); 3. Stimulus convergency with levels Convergent stimuli (the two different tasks require the same response) and Divergent stimuli (the two tasks require different responses); 4. Cue Target Interval duration (CTI): self-paced (Experiment1); 200ms (Experiment 2) and 900ms (Experiment 3).

Results and discussion

The results show (1) Slower performance for the conflict than for the non-conflict condition on trial 9 (after Cue2) and on trial 11(after warning signal) associated with **top-down control** during COA in order to suppress a conflict if Cue1≠Cue2; (2) For non-conflict condition and self-paced CTI, better performance on trial 9 than on trial 8, and on trial 11 than on trial 10: elimination of restart costs presumably based on **forward facilitation;** (3) On trial 9, faster and more accurate performance for convergent than for divergent condition, because of stimulus driven, **bottom-up control.** And a consequence: On trial 10 better performance if trial 9 was divergent rather than convergent, presumably associated with **backward inhibition;** (4) Different patterns of performance for self-paced and externally paced CTI, associated with different control strategies for the conflict and the non-conflict condition for different CTI.

Issues for further research

These findings reconcile some opposite previous views regarding control mechanisms in task switching and provide a perspective for new investigations on executive control. In the next step we intend to implement two main modifications: a spatiotemporal manipulation of COA, concerning the variation of the relative position at which Cue2 and Warning signal are presented, and second, a spatiotemporal manipulation of Convergency, concerning the variation of the relative position at which Convergent stimuli are presented.

Introduction

Klahr and Simon (1999) identified four approaches to scientific studies of science emerging in recent decades: (a) Historical accounts of scientific advances, (b) psychological experiments of non-scientists on structured and ill-structured problems, (c) observations of researchers' daily work in science, and (d) computational modeling of scientific discovery processes. Our study fits as (c) observations of daily work in organic synthesis laboratories as others have done in biomechanical engineering (Nersessian, et al, 2002) and molecular biology (Dunbar, 1995). We expect to develop a grounded theory (Glaser & Strauss, 1967) of scientific reasoning within a community of practice (COP).

Theoretical Framework & Methodology

Cognitive apprenticeship is situated learning within a proficient COP through each participant's immersion with frequent opportunities for practice, reflection and discussion while pursuing goals (Lave & Wenger, 1991). When Dunbar studied four different laboratories, all four COPs practicing molecular biology reasoned very similarly, i.e., similar experimental heuristics, mental representations, and problem solving heuristics, and differed only in their own combinations of these features. He noted that researchers interacted with the COP's domain knowledge and fellow researchers to reduce reasoning errors. Logic in scientific reasoning requires *substantial leaps* from the data to infer conclusions (Toulmin, 1977). Toulmin explains that each field (COP) has different things to reason about, different consequences to gauge, and thus, different criteria for justifying inferred conclusions. Thus, apprentices must learn COP-specific standards of justifiable reasoning.

Video data collected included 80 hours of researchers working in the lab, gathering and interpreting data, interacting with mentors, and attending group meetings. Semi-structured interviews, field notes, and laboratory notebook pages supplemented video data. All COP data were analyzed for norms, practices and reasoning.

Results & Conclusions

We asked how scientific reasoning, is instantiated when apprentice researchers pursue their daily work towards Ph.D. "certification" as scientists. This organic COP synthesizes compounds for potential in treatment of diseases, e.g., HIV. The research director determines norms of distributed work from success in funding proposals**;** each project proceeds from a different foundational molecule, however uses similar techniques, equipment, and instruments to perform chemical reactions. Long series of reactions and what makes them work (a mechanical system) lead to a molecule engineered to possess specific and valuable properties.

Problems punctuate researchers' progress. We define a problem as a *difficulty* when the issue shows a basic lack of understanding of the process or inability to get the mechanical system working whereas an *anomaly* is an unexpected and therefore, problematic, piece of evidence. Experience with COP problems inspires integration of explicit declarative knowledge of chemical properties and mechanisms with functional procedural knowledge, whose product is often tacit expertise.

Scientific reasoning is instantiated as "street smarts" developed in a specific research COP where reasoning: (a) Is guided by expectations of the organic synthesis COP's norms and standards (constraints) while researchers do valued COP work. (b) Leads to and develops further apprentices' learning in what to notice, understand, and take advantage of in terms of physical, human, and disciplinary COP resources (affordances). (c) Determines causal interactions of relevant variables in a mechanical system causing difficulties. (d) Is *learning how* to interpret the COP's typical kinds of evidentiary formats in feedback because evidence is often evident only to COP members. (e) Recognizes anomalies in feedback. (f) Deciphers and explains anomalies.

Quantity and quality: A model of how linguistic input drives lexical and cognitive development

Arielle Borovsky (aborovsk@cogsci.ucsd.edu)

In early childhood, words are acquired at a very fast pace. Yet there is also much variation in the overall number of words children learn. While these differences have often been attributed to learning abilities of the child, there is also considerable evidence that this variation can be attributed to the amount of language exposure (Huttenlocher et al, 1991). At the same time, there is some debate about whether grammatically simple or complex child-directed speech (CDS) aids in lexical development. On one hand, some results suggest the number of isolated words in CDS predicts words known (Siskind, 2001), but on the other, there are findings that longer CDS utterances are correlated with improved vocabulary scores (Hoff & Naigles, 2002).

Gopnik & Meltzoff (1997) offer one explanation of how differences in speed of lexical learning might result from cognitive changes that are influenced by linguistic input. Here, a child's ability to learn new words improves with the realization that objects can be classified through grouping new words into known categories. Evidence that the vocabulary spurt coincides with the ability to sort objects into multiple categories lends support to this hypothesis. However, these data are derived only from indirect measures of categorization abilities in children, and it remains unclear what variables might promote the emergence of category knowledge that could facilitate word learning.

In this study, we use simple recurrent networks (SRNs) to explore the relationship between language input (in amount of input, the frequency distribution across categories, and grammatical complexity) on category formation, and the relationship between category formation and rate of acquisition of new words.

Methods

Input: 6 corpora, ranging in size from 20-1000 sentences were developed. 52 nouns were assigned to one of four categories: *animals* (15), *humans* (15), *food* (12) and *objects*(10). 33 verbs were assigned to *eating*, *motion*, *perception*, *action*, *communication*, *change of state* categories. Sentences were either transitive (NVN) or intransitive (NV). One additional corpus of 1000 sentences was developed with additional constructions of NVNN, NVNV and NVNVN.

Simulations: Each of the 7 corpora were used to train 10 SRNs on a next-word prediction task.

Analysis*:* Every 20,000 sweeps, each network was probed to determine (a) rate of new noun learning and (b) internal category structure developed by each network. Category structure was measured by average precision (Keibel & Elman, in prep), which quantifies the similarity of hidden unit values of all nouns in a category. New word learning was tested by training each network on new words in sentences. Learning was measured by the activation value of the word's node when tested in five unseen sentence contexts.

Results and Discussion

Networks that had been exposed to larger vocabulary had a strong effect in facilitating rate of acquisition of new words. Additionally, networks trained with simpler grammatical constructions learned new words faster than ones with complex input. The measure of category formation, AP, correlated well with these results: we found that category coherence values were higher in networks that learned words faster. That is, networks that had been trained with more sentences and simpler syntax showed evidence of better category formation.

These results support the idea that category knowledge plays an important role in lexical acquisition; new words are learned more quickly with better developed category structures. These data also suggest that both the amount and nature of the input (e.g., grammatical complexity; frequency distribution across specific items) play a role in the induction of lexical categories.

Acknowledgements

We are grateful to Holger Keibel for his invaluable advice on measurement of category development.

Retention of Contextually Biased Interpretations of Conceptual Combinations

Novel expressions frequently emerge during everyday language use. For example, a demographic group of middle class mothers who spend time chauffeuring their children to soccer matches and other activities has come to be referred to as "soccer moms." Such terms are introduced to provide labels for meanings that may not have been previously characterized in an efficient manner. These are examples of what Gerrig (1989) has referred to as *sense creation.* The present study concerns the retention of such newly created meanings.

In the series of experiments reported here, participants were asked to read a series of vignettes. All of these vignettes were designed to bias a rare interpretation, as established through out-of-context pre-testing. In the first experiment, participants were randomly assigned to one of three groups. One group was allowed to define the target conceptual combination immediately after reading the vignette, another group read all of the vignettes, then defined the target combinations, and a third group read the vignettes, then completed a 30-minute filler task prior to defining the target combinations. The second experiment was similar to the first in that a series of time delays were introduced to examine the time course of contextual bias. In this experiment, however, type of instruction (explicit reference to a subsequent memory test versus no such mention) was manipulated, in addition to length of delay (in this case, immediate, within one hour, or after two days).

Results from both experiments indicate that, while not permanent, contextual bias has a powerful and relatively long-lasting influence on the way people interpret novel noun-noun combinations. The present study provides evidence that the interpretation of conceptual combinations cannot be completely understood by considering the relationship of the two nouns in the pair or by the relationship between the head and the modifier noun, but must also consider the powerful effects of disambiguating discourse contexts. In our study, it was shown the discourse contexts provided a more powerful influence on interpretations of noun-noun pairs than did the similarity of the nouns considered out of context. Meanings (or interpretations) that were rarely given to a pair of nouns seen out of context were strongly biased by accompanying discourse contexts. Furthermore, these contextualized interpretations persisted over time, with effects observed up to a two day retention interval even though they were only exposed a single time to the brief discourse contexts. Although discourse contexts had a strong effect on interpretations of noun-noun pairs, the number of out-of-context dominant interpretations increased following longer retention intervals. In sum, these findings indicate that interpretations of noun-noun combinations can be strongly affected both by discourse contexts as well as the relationship between the two nouns in each pair.

Finding the Change:
The Role of Working Memory and Spatial Ability in Change Blindness Detection

Gary L. Bradshaw (glb2@ra.msstate.edu),
Courtney Bell (cmb18@msstate.edu),
J. Martin Giesen (jmg1@ra.msstate.edu)

Introduction

Change blindness, an inability to spot changes in a visual scene, occurs when normal motion transients are masked by factors such as blank screens, "cuts" from one camera to another, and the like (Simons, 2000). Rensink, O'Regan, & Clark (1997) employed a "flicker" technique to induce change blindness: two versions of an image are presented in alternation, but a blank visual screen is shown between each image. Under these circumstances subjects may take many seconds to notice even large changes in the image, especially if the change occurs in a background element.

Change blindness reveals important limitations in our ability to process visual scene information. Several explanations have been advanced to explain why change blindness occurrs. To date, no single explanation has gained broad acceptance (Simons, 2000).

In the current report, we consider a complementary question: given that change blindness occurs, what factors enable people to overcome it? Our methodology is to exploit the natural individual differences that appear between individuals in their ability to detect changes.

Method

Our methodology was to administer a broad variety of individual differences tests to a large set of subjects then perform correlational and regression analyses to determine the ability factors that predict change blindness detection.

Following the administration of a demographic questionnaire (not discussed further), subjects completed a battery of tests: Integrating details (Alderton, 1989); shape memory (Ekstrom, French, Harman, & Dermen, 1976); identical pictures (Ekstrom et al., 1976); perceptual speed (Guilford & Zimmerman, 1947); a change blindness test; and a measure of operations span (Hambrick & Engle, 2002).

The change blindness task included 20 trials. On each trial two different versions of a photograph were shown repeatedly in sequence, with a blank gray screen appearing between each pairing of the images. Subjects knew a change appeared in each trial and were allowed to view the images until they detected the change. After detection one version of the image reappeared with a set of 5 regions identified, and subjects selected one region to indicate where the change took place.

85 subjects completed the battery of tests during a 1-hour session for class credit. Data from 8 subjects were discarded due to computer errors.

Results

The correlational analysis showed that several ability tests correlated significantly with the *accuracy* of change blindness detection (Table 1), while other factors correlated with the *latency* of change detection .

Table 1: Correlations with Change Blindness Accuracy

	Int. Details	Shape Mem..	Indent Pictures	Percept. Speed	Op. Span
Change Blind. Accuracy	.448**	.406**	.240*	.472**	.493**

* sig at $\alpha < .05$; ** sig at $\alpha < .01$

A stepwise regression analysis revealed that only three factors independently predicted accuracy on the change blindness task: operation span, perceptual speed, and shape memory. The heavy involvement of operation span indicates an important role of working memory in successfully detecting changes in an image. Curiously, measures that are designed to measure spatial ability, such as integrating details, did not show an independent effect. A different set of factors correlated with the latency of change blindness detection, suggesting different mechanisms are involved.

Building Mental Models of Multimedia Procedures: Implications for Memory Structure and Content

Tad T. Brunyé & Holly A. Taylor
Department of Psychology, Tufts University
490 Boston Ave., Boston, MA 02155

David N. Rapp
Department of Educational Psychology, University of Minnesota
206A Burton Hall, 178 Pillsbury Dr. SE, Minneapolis, MN 55455

The present experiments examined memory for procedural instructions following three presentation formats. In three experiments participants learned procedures for assembling toys either with instructions presented in text-only, picture-only, or multimedia formats. Testing examined recall, serial order knowledge, and source knowledge. In Experiment 1A, multimedia learning produced faster and more accurate serial order determinations and greater recall, but more source monitoring errors, compared to the other formats. Experiment 1B demonstrated that additional multimedia exposure following initial learning can further influence memory. Experiment 2 examined working memory processes during multimedia learning by attempting to selectively interfere with visuo-spatial and articulatory resources. Contrary to Baddeley's (1992) working memory model, verbally- and spatially-based divided attention tasks failed to selectively interfere with individual slave-system processing, suggesting central executive involvement in the sequential 2-back concurrent tasks. These results provide empirical support for the underlying nature and potential benefits of mental representations following multimedia experiences.

Experiment 1

Participants were presented with a total of 18 5-step Kinder Egg™ toy assembly sequences in picture-only (6), text-only (6), or multimedia (6) format. Half of the participants performed a verbal concurrent task. Subsequent testing included order verification (O.V.), instructions recall (I.R.), and source monitoring tasks. Order of testing for the O.V. and I.R. was reversed in Experiment 1B to test the effects of subsequent multimedia exposure on recall performance.

Results

Congruent with past research (e.g., Mayer & Anderson, 1991), multimedia produced the highest accuracy rates on both the order verification and recall tasks. Interestingly, multimedia also produced the highest source monitoring error rates, with a tendency for participants to inaccurately recall multimedia presentations as picture-only. No evidence for selective verbal interference was found. Additionally, later exposure to pictures following text-only presentations increased recall accuracy.

Experiment 2

Experiment 2 replicated Experiment 1B with the addition of a spatially-based divided attention task.

Results

In line with Experiment 1, dependent measures revealed significant multimedia effects. Verbal and spatial concurrent tasks did not selectively interfere with articulatory or visuo-spatial working memory, respectively.

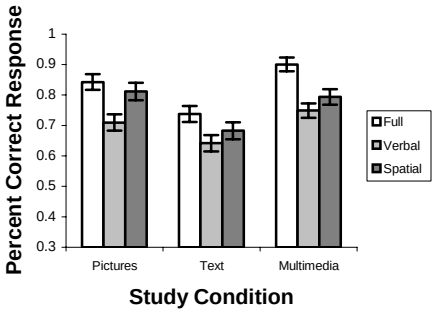

Figure 1: Percent correct response as a function of presentation condition and attention group.

Conclusions

The combination of pictures and text consistently produced higher accuracy rates on tests examining memory structure and content in comparison to pictures or text alone. However, learners are more prone to source monitoring errors after learning with multimedia in comparison to the other two presentation formats. Further research should examine selective working memory interference, with a particular emphasis on multimedia processing.

Behavioral and Electrophysiological Evidence for Configural Processing in Fingerprint Experts

Thomas A. Busey
Indiana University, Bloomington

John R. Vanderkolk
Indiana State Police Laboratory, Fort Wayne, Indiana

Holistic processing has been studied in faces, and may represent one process underlying the development of expertise. In this work we examine how fingerprint examiners show evidence of configural processing when viewing fingerprint fragments. We find evidence for configural processing when fingerprints are presented in noise. Converging evidence was demonstrated in electrophysiological recordings. A particular component of the EEG/ERP known as the N170 is reliably delayed for inverted faces. This component was also delayed for inverted fingerprints, but only for fingerprint experts. The results constrain models of perceptual expertise and provide converging evidence that the delayed N170 component reflects the absence of configural processing.

Iconic Gesture Production in Controlled Referential Domains

Ellen Campana (ecampana@bcs.rochester.edu)
Department of Brain and Cognitive Science, University of Rochester
Meliora Hall, University of Rochester, Rochester, NY 14627 USA

Laura Silverman (lauras@psych.rochester.edu)
Department of Clinical and Social Sciences in Psychology, University of Rochester
Meliora Hall, University of Rochester, Rochester, NY 14627 USA

Introduction

Research on naturally occurring gestures during face-to-face communication has often taken second-seat to the study of spoken communication. This might be due, in part, to widespread beliefs that gesture is too unconstrained to study in a controlled way. Studies in the past have often confounded message selection and gesture/speech form. For example, in one often-used paradigm, participants describe a video they've recently watched to a partner. In these studies the participants 1) select which episodes they describe, 2) decide how to describe the episodes (including word choice and the choice to use gesture), and 3) decide how much information is "enough" to say in order to get the point across to the listener. This confounding of parameters increases noise and adds to the perception that gesture is too unconstrained to study in a controlled way. This study demonstrates that gestures can be predicted precisely when the referential domains are controlled, and it offers a tool for future studies of gesture production.

Method

Participants were 11 individuals from the University of Rochester community. They received either course credit or $7.50 in compensation for their time. Participants were seated at a table, across from a partner with a laptop. The participant was shown a card (figure 1) and instructed to "get their partner to click on the target quadrant by doing anything [they wanted], short of getting out of [their] seat and pointing directly to the target". There were no further restrictions on communication. The partner's screen was identical to the participant's card, except that the quadrant locations did not necessarily correspond and the target quadrant was not indicated in any way. The trial continued until the partner clicked on one of the quadrants.

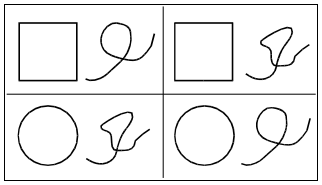

Figure 1: Target quadrant (top left hand corner) might be described as "the square and the squiggle" (with gesture)

Critically, for each trial there were 4 quadrants that the participant could potentially refer to, so the participants had to consider the contents of these quadrants when deciding what to say to their partner (Grice, 1975). Each quadrant contained two "features", which were usually separate objects. In each quadrant one feature would be easy to describe verbally and the other feature would be more difficult to describe verbally. There were a total of four features on each screen – two nameable features that never occurred in the same quadrant, and two less nameable features that never occurred in the same quadrant.

Results

We examined the gestures produced by the participants for each trial, focusing on the participants' first attempts to describe the target quadrant. Participants did produce co-occurring speech and gesture when describing the target quadrant. They were more likely to gesture for the feature that was more difficult to describe (83%) than for the feature that was easy to describe (21%). This pattern held for each individual subject, and for each individual item. We then tabulated the types of gestures that were produced in each case – gestures that were produced while the participant was describing the easy to describe entity were likely (75%) to be beats (McNeil, 1992) or tokens (Lidell 1994), specifically gestures that indicated that the co-occurring speech introduced a new entity to the discourse. They were less likely to be iconic gestures (25%). This pattern was reversed for the gestures that occurred while the participant was describing the feature that was more difficult to describe. In this case gestures were more likely (95%) to be iconic.

Influences of Knowledge on Eye Fixations While Interpreting Weather Maps

Matt Canham (canham@psych.ucsb.edu)
Mary Hegarty (hegarty@psych.ucsb.edu)
Department of Psychology, University of California, Santa Barbara
Santa Barbara, CA 93106-9660 USA

Theories of gaze control in scene perception predict that viewers will fixate on aspects of visual scenes that are either visually salient or informative. Thus far, research has focused mainly on the bottom-up processes that direct a viewer's gaze to salient aspects of a display. However, Semantic knowledge also plays a major role in directing attention toward the most relevant aspects. The current research applies this paradigm to graphical weather map interpretation.

Several studies involving experts from many domains have demonstrated that experts focus on the most relevant information of a display, and because of this they are able to process complex visual information related to their domain much faster than novices.

Although these effects have been well documented, it is still not well understood how these processes develop, or how much knowledge and experience are required before these processing differences begin to appear.

This study examined whether and how the process of focusing on the relevant graphical aspects (while ignoring the irrelevant), changes with a brief period of instruction. The main hypothesis tested was that after instruction in meteorological principles, novice participants would spend more time fixating on relevant aspects of a weather map, and less time fixating on irrelevant aspects.

Methods

Novice participants (N = 16), were shown a series of weather map displays, in which they were asked to determine whether an arrow shown within a target circle, see Figure 1, was showing the correct direction of wind in a target area (true), or the incorrect wind direction (false) .

Participants made judgments on an initial block of 30 trials, were then provided with training on the principles of surface air movement, and finally made judgments on a second block of 30 trials.

Throughout the experimental trials, participant's eye movements were tracked using an SMI EyeLink head mounted eyetracking system.

Eye fixations were analyzed using pre-determined regions of interest, which were assumed to have high or low relevance for successful task completion. These areas included the closest pressure system (relevant) and the temperature scale (irrelevant).

Results and Discussion

Participants showed a significant improvement in performance from before, to after instruction $F(1, 15) = 32.297$, $p < .001$, $\eta 2 = .683$, demonstrating that they learned how to make better judgments about surface wind direction. There was also support for the main hypothesis that after training novice participants would spend more time fixating on the relevant map aspects, and less time fixating on the irrelevant aspects. Participants spent more time fixating on the closest pressure system (highly relevant to the task) after training compared to before $F(1, 15) = 5.162$, $p = .038$, $\eta 2 = .256$, and spent less time fixating on the temperature scale (irrelevant to the task) $F(1, 15) = 5.162$, $p = .038$, $\eta 2 = .256$, after training compared to before. These results, suggest that participants interacted with the weather maps in a qualitatively different way as a result of training.

This study makes two significant contributions to this field of research. First it demonstrates that minimal instruction can influence novices to behave more like experts. Thus, the eye fixation analysis indicated that, participants were able to search the graphic more efficiently (and more like an expert) after a brief amount of instruction. Second this study demonstrates that semantic knowledge influences eye fixations on graphical displays, and not just on pictorial displays or real-world scenes, which have received much more attention in the literature. This research has implications for training of individuals who must interpret complex graphical displays, and for the design of these displays.

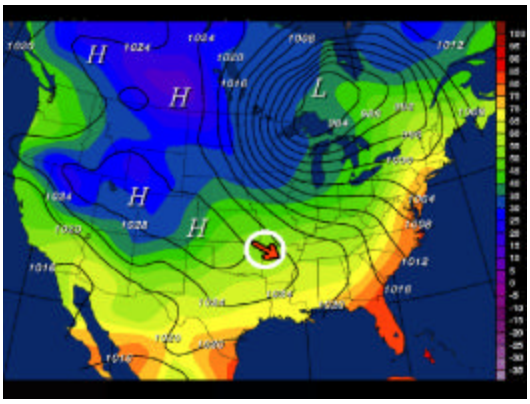

Figure 1. Sample weather map shown to participants. Their task was to judge whether the arrow displayed the correct or incorrect surface wind direction.

Representation of Intentions in Routine Skills

Richard A. Carlson (racarlson@psu.edu)
Daniel N. Cassenti (dnc112@psu.edu)
Lisa M. Stevenson (lms152@psu.edu)
Department of Psychology, The Pennsylvania State University
130 Moore Building, University Park, PA 16802 USA

Intentions can be represented theoretically as active, structured states of working memory. This approach is complementary to standard componential and capacity approaches to understanding executive control. We report the results of several studies examining hypotheses derived from this view of intentions.

Carlson (1997, 2002) described intentions as mental states that instantiate goals and have a schematic structure that specifies desired outcomes, operations for achieving those outcomes, and mental or physical operands. This structure is dynamic, such that instantiating a goal to apply a specific operator evokes a procedural frame to which operands can be assimilated. Instantiation as an intention is one phase of an intention-outcome cycle in which goals are first represented prospectively (Figure 1). In a complex activity, this intention-outcome cycle is embedded in a plan that represents a larger goal structure.

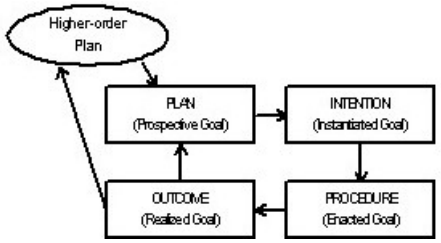

Figure 1: The intention-outcome cycle

Applying this analysis to routine skills with repetitive sequential structures (e.g., counting, running arithmetic) provides a basis for examining several specific hypotheses. The *deictic specification* hypothesis suggests that fluent performance is achieved in part by streamlining intention representations such that their elements are specified deictically rather than semantically, and error monitoring is implicit rather than explicit. The *temporal tuning* hypothesis suggests that instantiating a goal as an intention serves to establish a temporal frame of reference that can be used to coordinate cognitive processing with the perceptual pickup of information.

Deictic Specification

Carlson and Cassenti (in press) examined the deictic specification hypothesis in an event-counting paradigm. Participants counted visual events in a variety of timing conditions. We found support for a model in which events are specified by when they appear rather than by their identity, when temporal regularity makes that possible. This deictic specification allows intention-outcome confusions and promotes implicit error monitoring. Only disruptions to the flow of events (e.g., non-rhythmic trials) seem to trigger error detection, leaving errors in rhythmic trials largely undetected.

Temporal Tuning

Carlson and Stevenson (2002; Stevenson & Carlson, in preparation) examined the temporal tuning hypothesis in a running arithmetic paradigm. We found that preview of at least one upcoming operator seems to be necessary for participants to establish a temporal reference frame. This reference frame is adjusted to the structure of the task, and allows individuals to learn to coordinate self-paced displays with ongoing mental operations. Neither declarative nor procedural knowledge of upcoming operators appear to substitute for preview. Temporal tuning thus depend on environmental support for the specification of operators.

Conclusions

Analyzing intentions as active, structured states of working memory suggests new hypotheses about the control of routine activities. The experimental results reported here support several of these hypotheses, and suggest boundary conditions for them. Other results support hypotheses concerned with information-acquisition strategies and the coordination of information in working memory and in the environment. The present analysis can be related to recent work on the computational modeling of executive control.

Attention Unites Form and Function in Spatial Language

Laura A. Carlson*, Terry Regier, William Lopez*, and Bryce Corrigan****

Introduction

Traditionally, the processing of spatial terms has been explained independently of more general cognitive processes, operating upon strictly geometric representations of the objects being spatially related. Challenges to this idea have focused on either process or representation. Research on process has linked spatial language with attention, but has assumed only abstract representations of the objects; research on representation has shown that both geometric and functional information about the objects and their interaction influence spatial language – but the process by which this is accomplished is left largely unspecified. We bring together process and representation, and offer an extension of the Attention Vector-Sum (AVS) model (Regier & Carlson, 2001) in which geometric and functional information is integrated via the process of attention.

Two Assumptions

Carlson-Radvansky, Covey & Lattanzi (1999) observed that spatial terms are defined on the basis of both geometric and functional information. For example, given the instruction: *Place the tube of toothpaste above the toothbrush*, participants were biased to place the toothpaste away from the center toward the bristles of the toothbrush. This functional bias was mediated by the typicality of the relationship between the objects (i.e., a smaller bias with a tube of oil paint). The explanation of the functional bias relies on two critical assumptions: 1) attention can be allocated to a particular functional part of an object (Lin & Murphy, 1997), with a consequent bias to define spatial terms with respect to space around that part; and 2) that the amount of attention allocated to the part is mediated by the typicality of the interaction between the objects.

Empirical support

Empirical support for the first assumption was obtained by manipulating the location of attention within the reference object, and assessing whether there was a bias to define spatial terms around this locus of attention. In Experiment 1, we used an exogenous cueing task to anchor attention at various locations within a rectangle, and then presented a circle as the located object either at the attended location or elsewhere. In Experiment 2, we used a watering can as the reference object, and a plant as the located object; with attention presumably allocated to the spout. In both experiments, response times for verifying that the located object was above/below the reference object were faster when the placement of the located object coincided with attention. Empirical support for the second assumption was obtained by collecting ratings of the functional importance of the parts of the reference objects used by Carlson-Radvansky et. al. (1999) in the context of functionally typical located objects, functionally atypical located objects, or in isolation. Ratings of the functional part were greater in the context of the functionally typical located objects, and were significantly correlated with the linguistic functional bias, suggesting that the typicality of the interaction mediated the strength of the functional information.

Computational support

The Attentional Vector Sum (AVS) model of spatial language involves an attentional beam that is focused on the reference object, and extends outward toward the located object (Regier & Carlson, 2001). There is a vector-sum representation of the direction of the located object relative to the reference object, with vectors anchored at points within the reference object and pointing toward the located object, weighted by the amount of attention paid to the point on the reference object. In order to incorporate functional information about the reference object, the attentional weight in AVS was modified such that functionally important object parts receive greater attention (Lin & Murphy, 1997). With this change, AVS captures the two critical assumptions, and simulations successfully account for the functional bias effect (Carlson-Radvansky et al., 1999) and its dependence on the typicality of the interaction between the objects.

Introduction

An important dilemma to resolve in instruction is distinguishing between short-term performance and long-term learning in assessing students' progress. Conditions that appear favorable in acquisition are not always as effective at promoting subsequent retention and transfer, due to differences in the processing activities involved in training and at test; in some cases, poor performance in training produced better performance at test (Schmidt & Bjork, 1992). Since global measures of accuracy and speed are insufficient predictors of the effectiveness of training, we have used a modeling approach to draw inferences about the knowledge structures students use to solve problems both at test and in training. We will present the results from one study demonstrating the usefulness of such qualitative measures in predicting learning outcomes from training.

Method

We collected complete sets of data from 47 statistics-naïve undergraduate students in a five-day training study in which they received instruction and guided practice in solving exploratory data analysis problems. The focus of the instruction was to learn when and how to use pie charts, histograms, boxplots, scatterplots, and contingency tables to analyze a set of data. Following each lesson explaining and demonstrating how to use the new representation and method of data analysis, participants worked through a series of practice problems (30 problems in total). One group solved problems in which the problems' surface features were spuriously correlated with their deep structure (*S*-condition), while the other group solved problems whose surface features were varied across all the problem structures (*V*-condition). All participants received problems that were broken down into their individual steps, as well as correct-answer feedback on their solutions. On the final day, participants solved 25 new problems without any scaffolding or feedback. (See Chang, Koedinger, & Lovett, 2003, for a fuller description of a similar procedure.)

Results and Discussion

Consistent with the claim that good performance in training does not guarantee good performance at test, *V*- participants demonstrated a slight disadvantage at training but superior performance at test, in terms of their accuracies and latencies in selecting the appropriate representation type for analyzing the dataset given in the problem. Examining participants' actual answers revealed that *S*-participants' errors were not merely random, but reflected negative transfer from the surface features that had been incorporated into their training.

To assess the extent to which their answers were driven by surface features or by problem structure, we developed a model of participants' knowledge that specified the different possible features they could be using to choose the appropriate statistical display to answer each question. This model was fit to participants' data by adjusting the parameters indicating the degree to which different features were used. The best-fitting models indicated that at test, *S*-condition participants tended to derive their answers from surface features rather than deep structure, whereas *V*-condition participants made greater use of deep structure than surface features.

Analyzing the training data using the same modeling methodology showed that even during the learning phase, *V*-participants demonstrated stronger knowledge of deep structure, whereas *S*-participants exhibited a stronger influence from surface features. The contrast between the apparent performance of *S*- and *V*-participants according to the two different methods of assessment underscores the importance of measuring the target skills that students are intended to learn. Examining the accuracy data alone would suggest that the *V*-participants were performing more poorly than the *S*-participants, with average scores about half a standard deviation lower. However, examining the reasons why participants chose the answers they did reveals more sophisticated understanding in the *V*-condition. Revising our assessments of students' learning to reflect their knowledge representation, rather than relying merely on accuracy scores, may better inform instructional design by distinguishing more clearly between learning and performance.

Visual Cognition in Microanatomy

Julia H. Chariker (julia.chariker@louisville.edu) **John R. Pani (jrpani@louisville.edu)**

Much of a person's knowledgeable interaction with the world concerns the use of visual information. One useful place to expand our knowledge of visual cognition is in the study of what we will call visual symbol systems. These consist of visual domains that are used as sources of information about additional domains – target domains. Examples include the use of telescopes to study astronomy, aerial photographs, and microscopy.

We report here two studies aimed at understanding the use of microscopy in histology. Histology is the microanatomy of biological tissues. It is a core course in both the biology and medical curricula, and it is essential to the study and practice of pathology.

While the target domain in histology consists of three-dimensional structures, the information domain consists of thin sections through the interiors of these structures that have been treated with a variety of stains. The outcome is that: 1) Histology includes a visual information domain and an anatomical target domain that are both very large and complex. 2) The target domain and the information domain are related by a spatial transformation (taking thin slices) that does not generally preserve structure and appearance. 3) There is a one-to-many mapping from the target domain to the information domain. A single type of structure can have a wide variety of looks in a microscope. 4) There is a many-to-one mapping from the target domain to the information domain. Different structures often look alike.

An interview study was conducted with 5 pre-medical or pre-dental graduates of a college histology course. Participants viewed four different microscope slides. In a first phase, participants thought out loud. In a second phase, a structured interview followed up on statements from the verbal protocol. The view through the microscope and everything that was said was recorded with a digital video camera. The four slides varied in their complexity, their familiarity, and in whether the stain was a common one. The audio recordings were transcribed to written form.

This task was clearly challenging for the students. A correct identification of the whole tissue was made 12 times during the verbal protocol out of the possible 20 identifications. One of the slides was identified by everyone -- one was identified by four of the five people. A slide with an unfamiliar stain was identified by just two people, and a tissue that had not previously been seen in a slide was identified by just one person.

Two formal coding systems were developed to help guide exploration of the cognitive processes involved in the interpretation of histological slides. One system was used to characterize the content of the language used to talk about the slides. The second system was used to characterize the manner in which participants worked toward the goal of tissue identification.

The coding of the language revealed that nearly sixty percent of all propositions used by the participants referred to structures on the slide. Fourteen percent of all propositions were associated with reasoning. Almost sixteen percent of all propositions were expressions of prior knowledge.

A second coding system captured high-level goal-directed cognitive processes. First, a master list was composed of the types of elementary cognitive process used across participants to work toward the goal of identification. Second, for each participant and each slide, progress toward identification was diagrammed using the listed processes.

Across all participants and slides, 70 instances of 13 cognitive processes on the master list were recorded. There were 23 attempts at recognition that did not appear to include hypothesis generation. Thirteen of these consisted of a participant listing structures on the slide and then immediately inferring a whole tissue. There were 39 examples of hypothesis testing across all participants and all slides. Interestingly, disconfirming evidence was used more often than confirming evidence.

This investigation demonstrated that identification of histological structures in a microscope is an extremely challenging task, and individual differences among the students are large. In addition, identification of histological structures in a microscope is remarkable for the degree to which it forces an integration of visual knowledge, general (anatomical) knowledge, and reasoning into a single cognitive system. This includes the use of holistic visual information, analytical knowledge about the diagnostic structures in slides, and general knowledge of anatomy. These forms of representation combine to allow recognition and immediate inference when that is available and extensive processes of reasoning when they are needed.

You Write Better When You Get Feedback From Multiple Peers Than an Expert

Kwangsu Cho (kwangsu@pitt.edu) Christian D. Schunn (schunn@pitt.edu)
Learning Research and Development Center, University of Pittsburgh
3939 O'Hara St., Pittsburgh, PA 15260 USA

In colleges and universities content classes outside composition classes are providing *near-total neglect* of writing. This unfortunate situation appears to be caused by instructors' workload in generating feedback on student writing. As a result, students do not often practice writing. Therefore, it seems a natural choice to replace instructor or expert reviews with reciprocal peer reviews to remedy the problem. Fortunately, peer reviews seem to allow various advantages beyond the obvious fact that they help instructors spend more time on pedagogically desirable activities by reducing instructors' workload. However, reciprocal peer reviews may be fundamentally limited in that student peers are subject-matter novices in their disciplines and inexperienced in reviewing writing in their disciplines. To improve these issues, Cho and Schunn (2003) developed a web-based reciprocal peer review system called *SWoRD* (refer to the procedure section). The goal of this paper is to show the effectiveness of the SWoRD approaches.

Method

Participants. Participants included 28 students and a domain expert in a 12-week summer class at the University of Pittsburgh, USA. The students had an average of 3.4 college years (*SD* = 1.0). They as writers worked for their class credits. They individually wrote first drafts and final drafts on a topic '*informal science learning*'. They as reviewers also reviewed six peers' first and final drafts. The domain expert was a Ph.D. on the writing topic and had taught similar courses for the past eight years. She was not the instructor of the class but reviewed all of the drafts.

Design. Based on basic writing skill test scores, the students were matched into blocks and then randomly assigned to one of three different conditions: an expert feedback condition (SE), a single peer feedback condition (SP), and a multi-peer feedback condition (MP). The writers in SE received feedback and grades on their drafts only from the expert. Those in SP received them from a single best peer. Those in MP received them from six peers. Also, to get rid of reviewer's status effect, the writers and reviewers were blind to each other. The writers were told that they would not receive writing grades by their instructors, but by their reviewers. All procedures were undergone without marking any identity information.

Procedure. The general procedure of the experiment followed the built-in processes in SWoRD with some modifications for experimental purposes. All of the remaining procedure was managed online by SWoRD. After the writers turned in their first drafts, individual reviewers received a set of six drafts that were randomly selected by SWoRD. They individually generated written comments on six peer drafts and evaluated their qualities on 7-point rating scale (1:Disastrous to 7:Excellent). The same period, the expert reviewed all of the drafts. Then, the writers received selected feedback based on their feedback condition, revised their writing over a week period. Then, writers turned in their final drafts, which were reviewed by the same reviewers. Then, the writers back-reviewed their reviewers' feedback on a five-point rating scale in terms of how helpful it was/would be in revising their first drafts. The results of the back-review were not delivered to the reviewers unlike the SWoRD normal procedure. As a final cycle, the writers received the second round of feedback and back-reviewed the feedback.

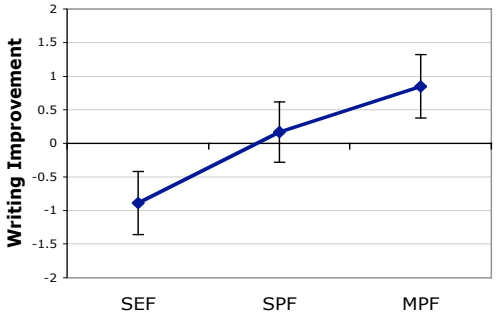

Figure 1: Writing quality improvement

Results

Based on the expert's blind evaluations on all of the papers, a two-way mixed ANOVA on the improvement of writing quality found a significant difference between the feedback conditions F (2, 25) = 3.50, $p < .046$ as in Figure 1. *Tukey* pairwiswe comparison found only the difference between SE and MP signficant, $p. = .015$. Thus, this result supported the SWoRD approaches in that student writers benefited from getting multiple peer feedback and rewriting practice.

Insight Problem Solving as Goal-Derived, Ad-Hoc Categorization

Evangelia G. Chrysikou (lila@temple.edu)
Robert W. Weisberg (weisberg@temple.edu)
Department of Psychology, Temple University
1701 N. 13th St., Weiss Hall 6th Floor, Philadelphia, PA 19122-6085 USA

Problem Solving and Categorization

Research on categorization suggests that, when facing a goal, people construct *goal-derived categories* through *conceptual combination*. These categories may be either well-established or ad hoc, constructed "on-the-spot" from elements from well-established or taxonomic categories. Under pressure or uncertainty people tend to employ taxonomic categories, that reflect world models (i.e., *primary categorizations*) and are denoted by lexemes (e.g., *cups*), as opposed to goal-derived categories, that are unstable, dependent on context, and are denoted by phrases (e.g., *things to pack when going on vacation*; Barsalou, 1983, 1991; Murphy & Ross, 1994).

Insight problem solving is an instance in which the solver, being in a state of uncertainty regarding the solution, is likely to form solution strategies based on primary categorizations. *Insight* is an abrupt and unanticipated shift in the solution path that leads the solver to success. Previous studies regard insight as the result of ordinary cognitive processes (e.g., Perkins, 1981; Weisberg & Alba, 1981) or as indicative of a special way of thinking, characterized by a *representational shift*, a restructuring of the elements of the problem (e.g., Knoblich, Ohlsson, & Raney, 2001). Research, thus far, has neither examined: (i) how solvers interpret insight problems *before* they proceed to a solution, or (ii) how category construction and categorical induction during problem solving are involved in the planning and evaluation of strategies to achieve the intended goal.

This study examined the effects of training to construct goal-derived categories on solving insight problems. We hypothesized that participants who received training in considering secondary, goal-derived categories, in addition to primary, taxonomic categories of items, would exhibit better performance on insight problem solving.

Method

Thirty-six undergraduates were randomly assigned to one of three conditions: (i) Control (n = 12), (ii) Alternative Categories Task [ACT] (n = 12), and (iii) Alternative Categories Task with critical items [ACT-C] (n = 12). The Control condition was administered a word association task and then received six insight problems. The ACT condition was given the Alternative Categories Task and then received the six problems. The ACT-C condition received a version of the Alternative Categories Task, which included six items, each critical for the solution to the problems that followed. The six insight problems were *Charlie, Fake Coin, Candle, Two-Strings, Ten Coins, and Nine-Dots*. Participants in the ACT and ACT-C conditions also received a hint concerning the relevance of the categorization task to the problem-solving task. Participants were tested individually. Sessions were videotaped with subjects' consent. Participants were given specific instructions to *think aloud* during the experimental tasks (Perkins, 1981).

Results and Discussion

A contrast-based ANOVA on solution rates and times revealed that the ACT and ACT-C conditions outperformed the Control condition, with the ACT-C condition exhibiting the highest performance. Results suggest that the construction of goal-derived, ad hoc categories and the ways these categories are used to guide participants' inferences may predict problem solving. The primary aim of this study was to consider problem solving as an instance of goal-derived categorization. Our findings may offer a new perspective on the mechanisms underlying insight. In addition, although much previous research on categorization focuses on the taxonomic organization of isolated items, this study examined categorization in an ecologically valid and dynamic problem-solving task.

Instructions

The motion aftereffect (MAE) is a powerful of motion in the visual image caused by prior exposure to motion in the opposite direction (Anstis et al, 1998). The study with use of MAE provides information of motion direction property.

This study was conducted to investigate an effect that shape information of stimulus affects orientation discrimination of windmill pattern with use of MAE. In according to the prior study of visual pathway, shape information of objects is processed to separates from motion information (Lenny, Trevarthen, 1990). Recently, however, there were reports on the interaction between two visual pathways. Kim (2001) proposed that the interaction chromatic and luminance modulation. Nisida (2001) proposed that our brain may process different sensory modalities and attributes in an integrative fashion on the unified spatiotemporal coordinates.

Experiment 1: the effect of stimulus property

In the first experiment, we investigated the effect of stimulus shape in case of adapted stimulus is same with test stimulus, by measuring the orientation discrimination of MAE on windmill pattern. We measured the perceived orientation on test stimulus and the duration time of MAE in different shapes of stimulus.

Stimulus and Method

There were two stimuli in experimental 1. One stimulus was a shape of circle and the other stimulus was a shape of ring.

An adapted stimulus was same with test stimulus. An adapted stimulus was presented on monitor during 15sec. And then test stimulus was presented. Observers experience the MAE. They pressed space bar on keyboard when MAE finished. It was measuring the duration time of MAE. After duration time was measured, observers reported the perceived orientation discrimination. Four observers, native to the purpose of the study and with normal or corrected-to-normal vision were participated.

Results

All observers reported that the orientation of MAE by the shape of circle was different with the orientation of MAE by the shape of ring. The orientation discrimination of MAE by the shape of circle was higher than the shape of ring, which was significant ($F(1,3) = 53.53$, $p < .005$). However MAE duration difference was not significant ($F(1,3) = .422$, $p < .562$). The results suggest that motion information is affected by shape property of object.

Experiment 2: the effect of adapted stimulus

In the second experiment, we investigated only the effect of adapted stimulus in case of an adapted stimulus was different with a test stimulus. We measured the perceived orientation on test stimulus and the duration time of MAE for different shapes of adapted stimulus.

Stimulus and Method

There were three stimuli in experimental 2. An adapted stimulus was circle or a ring and a test stimulus was adding shape. A test stimulus was same each condition. A procedure was same experiment 1.

Results

All observers reported that the orientation discrimination of circle shape MAE was higher than ring shape MAE, which was significant that the difference of orientation discrimination ($F(1,3) = 11.457$, $p < .043$). But it was not difference for duration time within each observer. The results suggest that the shape of object affect the motion information. And it implies to attribute integration.

Language-Specific Grammatical Attention in Second Language Proficiency

Wai Men Noel Chung (wmn_chun@alcor.concordia.ca)
Norman Segalowitz (norman.segalowitz@concordia.ca)
Department of Psychology & Centre for the Study of Learning and Performance, Concordia University
7141 Sherbrooke Street West, Montréal, QC H4B 1R6 Canada

Introduction

The present study investigated whether attention control for grammatical elements plays a role in second language (L2) proficiency. The meanings of grammatical elements (e.g., grammatical morphemes, inflections, and word order patterns) derive from how they relate various message elements to each other. Unlike nouns, adjectives and other content words, the referents of grammatical elements cannot be "experienced directly in our perceptual, sensorimotor, and practical dealings with the world" (Slobin, 1996, p. 91). For instance, in *The teacher was reading a new book*, the elements (*the/a, was, -ing*) refer to definiteness, time, and how the action unfolded. These meanings are not directly available to perception in the same way as are those of *teacher, read, new*, and *book*. Because not all languages use grammatical elements in the same way, L2 learners may experience particular difficulty in their use (Slobin, 1996).

Chung and Segalowitz (2003), using *a non-matching to sample task*, found that L2 proficiency correlated positively with performance in a task of L2 attention control for grammatical elements (pronouns, prepositions, copula forms, and conjunctions). A potential confound, however, was that subjects (Ss) may have used meta-linguistic knowledge about grammatical categories to perform the task, knowledge that may possibly be correlated with L2 proficiency. The present study attempted to replicate that study by removing the metalinguistic confound. In the grammatical condition, only spatial prepositions were used, divided into four subsets (e.g., *above/over/…*; *below/under/…*; *far/beyond/…*; and *close/near/…*). Two control conditions used non-grammatical words unrelated to language structure: concrete words, subsets of "animal" (*cat/dog/…*; *ant/bee/…*; *trout/salmon/…*; *sparrow/eagle/…*) and abstract words, subsets of "qualities" (*happy/glad/…*; *smart/clever/…*; *polite/honest/…*; and *beautiful/pretty/…*).

Method

Bilingual undergraduates (n=32; First language (L1) = English; L2=French) performed the following tasks.

Proficiency was operationalized as efficiency of accessing word meaning in a *lexical categorization task*. In separate L1 and L2 blocks, bilinguals were required to panel press to indicate whether a word referred to a living or non-living object (136 trials in each language). Intra-individual variation in reaction time (based on the coefficient of variation—CV) was the measure of processing efficiency (Segalowitz & Segalowitz, 1993). L2-specific measures were obtained by partialling out L1 from L2 measures.

Attention control was operationalized as efficiency of attention shift judgments in a *non-matching-to-sample task*. In a Non-Match condition, Ss saw a sample word at the bottom of the screen and 4 display words across the top. They had to press one of 4 buttons to indicate the position of a word belonging to a different subcategory than the sample. L1 and L2 versions of the task were created to measure attention control for grammatical (GRAM), concrete (CONC), and abstract stimuli (ABST) (40 experimental trials each). In a Match condition, Ss had to select a stimulus that matched the sample. CVs provided the measure of processing efficiency. Attention control indices were computed by partialling out Match CVs from Non-Match CVs. L2-specific measures were obtained by partialling out L1 from L2 attention indices.

Results

The data were submitted to hierarchical multiple regression with L2-specific proficiency as the dependent measure. In Step 1, measures of L2-specific attention control for abstract (ABST) and concrete (CONC) stimuli were entered. In Step 2, measures of attention control for grammatical stimuli (GRAM) were entered. For the 16 most proficient Ss, in Step 1 (CONC, ABST), R^2= .110 (*n.s.*), and in Step 2 (GRAM), R^2 change = .428 (p = .005). For the 16 least proficient Ss, total R^2 = .020 *(n.s.*).

Discussion

In more highly proficient bilinguals, efficiency of L2 attention control for grammatical elements accounted for 42% of unique variance of L2 proficiency, after controlling for non-grammatical attention. Because all L2 measures had been residualized against L1, the results reflect a language-specific form of attention, not general processing abilities. This replicates Chung and Segalowitz (2003), without the potential metalinguistic confound.

Managing Multiple Tasks: Reducing the Resumption Time of the Primary Task

Jonathan D. Clifford (cliffo44@msu.edu)
Erik M. Altmann (ema@msu.edu)
Department of Psychology
Michigan State University
East Lansing, MI 48824 USA

The instinctive way in which people use notes to augment their memory suggests one way in which they might manage the disruptive effects of multi-tasking. In this study we investigated whether mental notes and/or physical notes taken before an interruption would reduce time to resume the interrupted task afterwards. Imagine that you are writing email to a colleague when the telephone rings. The *interruption lag* – the time from when the ringing starts until you pick up the phone – is an opportunity to make notes that might help shorten the *resumption lag* – the time from when the phone call ends until you resume the preexisting cognitive state required to compose the email message. A physical note would be some contextual information recorded on a physical medium, whereas a "mental note" would be such contextual information encoded in memory. The current study indicates that resumption lag is indeed reduced by having cues available during the interruption lag (to facilitate mental note taking), but is *increased* by requiring participants to take physical notes.

Participants

Participants were 48 undergraduate psychology students.

Task and Materials

Two tasks were used in the experiment. The *tank task* was a complex resource-allocation task that involved planning simulated missions to defeat targets using tanks (Brock and Trafton, 1999; Trafton, Altmann, Brock, and Mintz, 2003). The *radar task* was a simulated tactical assessment task that involved classifying "tracks" on a radar screen (Ballas, Kieras et al. 1999; Brock, Ballas et al. 2002; Brock, Stroup et al. 2002; as cited in Trafton, Altmann et al. 2003).

Design and Procedure

Participants performed the tank task for three blocks of 20 minutes each. At 12 random points during each block, a visual alert would appear indicating that the secondary task was about to start. The interruption lag following this alert lasted six seconds, during which input to the tank-task interface was frozen (meaning that no actions were possible). After the interruption lag, the tank task display was replaced by the radar task display. The radar task lasted 30 to 45 seconds, after which the tank task display was immediately restored.

There were two between-participants factors: Cue or No Cue, and Record or No Record. The Cue/No Cue variable probed mental note taking, on the assumption that mental notes are easier to make when cues from the interrupted task are perceptually available. In the Cued condition, the tank task display was preserved throughout the interruption lag, whereas in the No Cue condition the tank task display was erased at the start of the interruption lag, so that participants saw a blank screen for six seconds until the start of the radar task. In the Record condition, participants were instructed to use the interruption lag to record data on a prepared form positioned next to the keyboard.

Measures

The resumption lag was computed as the interval from the moment the tank task interface was restored following the interruption to the first mouse click or key press a participant make to resume the primary task.

Results

Each participant's 36 individual resumption lags were extracted from the log files, and the medians entered into an analysis of variance (ANOVA). There was a significant increase in resumption lag for participants in the No Cue condition, $F(1,44)=6.551$, $p=.014$. In the No Record condition the resumption lag was significantly lower than the participants in the Record condition, $F(1,44)=8.332$, $p=.006$. There was no significant interaction between the Cue and Record manipulations, $F(1,44)=1.238$, $p=.272$. The first finding was that visual cues available in the brief transitional period before an interruption speeded resumption of the primary task afterwards. The second finding was that the act of writing contextual information on a form hindered the resumption of the primary task.

Part-Set Cuing: A Connectionist Approach to Strategy Disruption

Edward T. Cokely (cokely@psy.fsu.edu)
Department of Psychology, Florida State University
Tallahassee, FL 32306

Roy W. Roring (roring@psy.fsu.edu)
Department of Psychology, Florida State University
Tallahassee, FL 32306

Part-Set Cuing

In a part-set cuing paradigm, when part of a previously studied list of words is provided as a memory aid, a reliable and robust impairment of the non-cued list items results. Since its discovery (Slamecka, 1968; as cited in Nickerson, 1984), this paradoxical phenomenon has been characterized as a persisting enigma in memory research (Nickerson, 1984), of both theoretical and practical concern. One leading informal model, the strategy disruption interpretation (Basden & Basden, 1995), suggests that the part-set cuing impairment results because one's retrieval strategy is changed and differs from the original encoding strategy, following the presentation of cues. The strategy disruption account is thoroughly supported by empirical evidence; however, it has been criticized as theoretically vague and poorly defined. In contrast, the other leading account, a formal model using SAM (Raaijmaker & Shiffrin, 1981), while precise, has been criticized as overly defined, theoretically inconsistent, and unable to account for the full range of findings (Roediger & Neely, 1982). In an attempt to more precisely identify and extend the strategy disruption interpretation, we examine and compare both neural network simulations and human experiments in a part-set cuing paradigm.

The Neural Network

The artificial neural network used was a fully-connected, auto-associative, three-layer perceptron, using a backpropagation algorithm with a learning rate set to 0.1. The network used 15 input and 15 output nodes with a bias, 10 hidden, and 10 context units. The context layer used a 1 to 1 association from hidden units to context units and was fully connected from context to hidden units.

Experiment 1: Human Results

A within-participant (N=24) design was used and counterbalanced for list-order, list-cue-order, and randomized part-set cuing. A typical and robust part-set cuing impairment was observed for cued (M=.35) verses non-cued (M=.40) items, $F(1,23) = 4.99$, $p < .05$.

Experiment 2: Simulation Results

A within-simulated-participant (N=24) part-set cuing design was used and counterbalanced for list-order and list-cue-order, with randomized part-set cues. Output vector error served as the dependent variable and was summed and analyzed for cued and non-cued states. A typical and robust part-set cuing impairment was observed, $F(1, 23) = 24.00$, $p < .05$, without evidence of catastrophic interference.

Conclusion & Discussion

The neural network was consistent with the observed human performance, providing a good fit across a number of analyses. The findings suggest that the neural network formalism is consistent with and may serve as an extension of the Basden and Basden strategy disruption account of part-set cuing. That is, following cuing, different study and activation patterns disrupt the subsequent process of recall. This disruption is caused by a change in the availability and accessibility of cued items, altering the retrieval process and thus the retrieval strategy.

Although the experimental evidence is from a small set, results suggest that the neural network can provide an increasingly precise mechanistic account of part-set cuing impairment that is consistent with the leading informal theoretical account. Future simulations should attempt to replicate key findings including part-set cuing facilitation and category-cuing impairment.

Setting of Goals in Museum Websites: General and Specific Influence of Previous Knowledge

Javier Corredor (jac11@pitt.edu)
Learning Research and Development Center, University of Pittsburgh
3939 O'Hara St., Pittsburgh, PA 15260 USA

Introduction

Both general and domain-specific knowledge influence human performance in tasks as different as scientific discovery (Shunn,1999), social science reasoning (Voss, Tyler & Yengo, 1983) and web-based search (Hsieh-Yee, 1993). These types of knowledge are also crucial for learning in open-ended, ill-structured situations to the extent that domain-specific knowledge and general metacognitive skills are critical to the acquisition of complex knowledge (Lawless & Kulikowich,1996). It is also the case that learners who have either general or domain-specific skills seem to be able to learn in new, open online situations but the absence of either knowledge resource requires that the environment be well-structured (Steinberg, 1989).

Museum websites are open tasks designed to fit the expectations and backgrounds of multiples audiences. Goal-setting for either a web or physical visit is a critical process for the success of both visits and learning in museums because goals determine visitors' paths and learning. Clear goals can make the difference between a superficial drifting visit and a meaningful learning experience. Previous research in real museums shows that visitors develop specific sets of goals to drive their interaction with the exhibitions. Visitors attend to three elements: the content knowledge provided by the exhibitions, the navigational clues provided by the museum environment and the goals they have (Leinhardt, Tittle, & Knutson 2002). Here we explore how visitors to museum websites, with different backgrounds, set goals, make navigational decisions, and attend to the exhibition content in the service of learning.

Method

Eight graduate students were asked to think aloud while they surfed freely through two museum websites of different domains for 20 minutes (anthropology and natural sciences). Half (4) of the participants had robust domain-specific backgrounds in anthropology and half were social science graduate students in other domains. Within each half, two had more than four years of graduate study, while the remainder had less than a year. They were instructed to explore each of two web sites freely and to think aloud while doing so. No specific goals or tasks were given to the visitors. The data were the pages that they visited, the order of the visits, and the comments made while visiting. The online pages were classified as: content pages that presented domain-specific information (e.g. exhibits, articles), and navigational pages that presented information about what could be found in the museum (e.g. link pages). Comments made by participants were coded as to whether or not the visitor was attending or searching for navigational support, were setting goals, or if they were elaborating on content.

Results

For this ill-structured task of visiting a web-based museum, it appears that having high levels of general knowledge (high experience) has the greatest impact on surfing and reasoning behavior. The evidence for this is that high experience visitors *elaborated* more deeply on *conten*t pages than did non-experienced visitors. However, visitors with high content knowledge combined with high experience produced more immediate *clear-cut goals* and used fewer moves to meet them than all other groups. Low-experience higher knowledge visitors seemed to support the establishment of goals but not the actions of elaboration, thus they did not benefit as much from meeting goals; while low knowledge-low experience visitors showed a more random, rapid "click" behavior. We take this to mean that high experience positions individuals learn more through elaborating while high content and experience combined positions individuals learn more about the content domain offered by the museum because they are more effective goal setters in that context.

A Contingent Response Analysis of Negative Feedback

Andrew Corrigan-Halpern (ahalpe1@uic.edu)
University of Illinois at Chicago, Chicago, IL

Introduction

Negative feedback is information provided by a teacher or other instructional agent given to correct the errors a learner has committed. One might expect that corrective feedback is effective because it helps learners alter their performance. In fact, it has been suggested that negative feedback should be given immediately, so that it can more easily be tied to the cognitive structures responsible for the error.

It is then expected that negative feedback decreases the chance of committing the same error in future situations when the error could occur (i.e. due to the *corrective effect*). While this position makes intuitive sense, it has been largely untested. Studies that compare a negative feedback group to control often use global performance measures and have not considered why feedback is effective. Feedback effects, when obtained, could be due to the corrective effect, or they might be due to other factors.

To consider the question more carefully, we tracked individual responses made in a learning experiment involving multiple trials. We provided feedback for some errors, but allowed others to go uncorrected. It was then possible to consider whether feedback facilitated the correction of errors.

Method

Task

A letter extrapolation task was used, similar to those used by Kotovsky and Simon (1973) and Restle (1970). To make letter extrapolation into a task with multiple opportunities to receive feedback, we presented the given sequence via several short presentations and asked for a response after each one. The subjects viewed the given sequence for 20 seconds, and then attempted to extrapolate it. They were asked to reproduce as much of it as they could, guessing the letters for which they were uncertain. They received feedback on their extrapolation as described below. Then the next trial (20 second study period, plus extrapolation attempt) began. The subjects went through 8 such trials.

The sequence used was [MKNPPNKMNLOQQOLN]. This pattern is composed of the four-letter chunk 'MKNP', which is then reversed to form the chunk 'PNKM'. The Chunks 'NLOQ' and 'QOLN' are translation of the other two chunks.

Feedback and Design

Two negative feedback conditions were used. In the *local* condition, feedback was given for each letter response. In the *global* condition, feedback was given for the 4-letter chunks below. Subjects were told that they would not receive feedback for all errors. They were instructed that a 'none' message would appear below some responses. This message appeared below 25% of all errors, as well as below all correct responses. When the subject received this message, they received no useful information. The study was completed on a Macintosh computer using the Pyscope software. Feedback was given after all responses were made and remained on the screen for 45 seconds.

Results

We have previously reported that subjects in the local condition outperform those in the global condition. (Corrigan-Halpern & Ohlsson, 2002). The current goal is to better understand the source of this effect.

Subjects in the global condition were significantly better at correcting errors after receiving feedback, $F(45,1) = 4.59$, $p < .05$. After receiving negative feedback, subjects in the local condition corrected errors 26% of the time, compared to the global condition where correction occurred 32% of the time.

Subjects in the local group were more likely to correct errors after 'none' messages, $F(37,1) = 68.46$, $p < .001$. After receiving the 'none' feedback, subjects in the local condition corrected errors 92% of the time, compared to 28% of the time for the global group.

Subjects in the local condition were more likely to maintain correct responses, $F(43,1) = 5.02$, $p<.05$. Subject in the local condition reproduced a correct response 71% of the time, compared to 53% for the global condition.

Discussion

Despite the fact that the local feedback condition resulted in superior performance, this effect could not be attributed to the corrective effect. Subjects in the local condition perform well because they are able to correct errors made for responses where feedback was *not* provided. This result suggests that negative feedback achieves its effect indirectly or in a more cumulative fashion.

Anaphora and Indefinite Noun-Phrases

Maria Luiza Cunha Lima (marialuizacl@yahoo.com)
and
Edson Françozo (edson@unicamp.br)
LAFAPE, State University of Campinas (UNICAMP)
C.P. 6045 Campinas, SP (CEP 13084-971) BRASIL

Introduction

Indefinite NPs are usually taken to introduce new referents and, thus, are not deemed capable of acting as anaphors. Recent research, however, has attested the occurrence of indefinite anaphoric expressions (Schwarz, 2000), which occur (cf. Cunha Lima, 2004) (i) when the anaphor expresses part-whole relations, including partitive and specifying relations; and (ii) when the sentence or phrase containing the indefinite NP does not enclose a finite VP expressing an event which is different from the one in relation to which the antecedent was introduced.

Consider:

(1) O gato caçou um rato na cozinha. Um rato grande e gordo. *(The cat chased a mouse in the kitchen. A big, fat mouse)*

(2) O gato caçou um rato na cozinha. Um rato saiu pela porta dos fundos. *(The cat chased a mouse in the kitchen. A mouse left by the back door)*

(3) O gato caçou um rato na cozinha. O rato saiu pela porta dos fundos. *(The cat chased a mouse in the kitchen. The mouse left by the back door)*.

In (1) there is no doubt that the second occurrence of *a mouse* refers to the very same mouse mentioned previously. In (2), however, the second occurrence of *a mouse* is not co-referential with the first – it introduces an unmentioned referent in the discourse. Contrast this with (3): now, *the mouse* is old information.

One way to explain the difference between (2) and (3) above is to postulate that the verb following an indefinite NP forces its re-interpretation as not co-referential with the previously focused entity. If this is so, we can predict that processing the verb following an indefinite NP will be costlier than processing the verb following definite NP.

Method

Thirty-six students (native speakers of Brazilian Portuguese) at the State University of Campinas took part in the experiment. Twenty-four pairs of sentences ("texts") were constructed. In a self-paced reading experiment [1], the stimulus texts were chunked as follows: "Meu gato / caçou / um rato / na cozinha. / Um rato (1) / saiu (2) / pela porta (3) / traseira (4)"; and responses were recorded in points (1)-(4).

[1] The experiment was run using the DMDX software, developed at Monash University and at the University of Arizona by K.I.Forster and J.C.Forster

Results and Discussion

Reading times for the verb position (see Table 1) was significantly slower following indefinite than definite NPs. That is, following indefinites, verbs took longer to read.

Table 1: Mean reading times (ms) for tensed sentences

	1	2	3	4
Definite	484,13	387,86	684,08	757,20
Indefinite	519,68	445,67	723,92	795,83
Difference	-35,55	-57,81*	-39,84	-38,63

*F_1=(1,99)7.0379, p=0.009 and F_2=(1,123) 3.9192, p=0.049.

This result is consistent with the prediction that verbs following indefinite NPs are costlier than verbs following definite NPs. The source of such cost may be in the mechanism which bridges referring exp ressions to discourse (Almor, 1999). Recent data (Nadig et al., 2003) indicate that children, in a truth-value judgment test, tend to bridge indefinites to previously mentioned entities; similarly, adults also bridge indefinites to previously focused referents in a forced choice task. It seems that, at least in the case of children, bridging is driven by attention, rather than by type of referring expression. One can hypothesize that, in the present study, referring expressions, either definite or indefinite, were bridged to given/focused referents; when the verb incrementally makes its contribution, the need for re-interpretation becomes apparent – and exerts its tolls.

The Effects of Self-Explanations of Correct and Incorrect Solutions on Algebra Problem-Solving Performance

Laura A. Curry (lac@ichp.edu)
Department of Psychology, University of Florida
Box 112250, Gainesville, FL 32611

Various strategies such as self-explanation (Chi, 2000), collaborative problem solving (Ellis, Klahr, & Siegler, 1993), scaffolding (Vygotsky, 1978), reciprocal teaching (Brown & Palinscar, 1989), and learning from worked-out examples (Mwangi & Sweller, 1998), have been used successfully to facilitate learning and understanding. Psychologists are particularly interested in the cognitive processes underlying and affected by these methods, the varying effectiveness of each across different domains, and the mechanisms that are associated with the learning that results from the utilization of each. Although these techniques are different in form, each one encourages the student to engage in learning during which knowledge is actively processed, and mental models and schema are constructed and reconstructed. The goal of this study was to extend our knowledge of the mechanisms by which students acquire knowledge and the strategies that could be used to facilitate these processes.

The effects of feedback and self-explanation have been examined under various conditions, and within various domains (Chi, de Leeuw, Chiu, & LaVancher, 1994; Mwangi & Sweller, 1998; Tudge, Winterhoff, & Hogan, 1996). Because both have shown to have advantageous effects under many circumstances, they were used together in this study of algebra problem solving. To extend prior research, both the self-explanation of correct and incorrect solutions was elicited and compared to the condition in which only the correct answer was self-explained. It was hypothesized that students who received feedback and were asked to explain both correct and incorrect solutions would demonstrate the most improvement in solving algebra word problems.

Method

Participants included 80 college students (60 females, mean age = 19.73 years, *SD* = 2.05), including 50 Caucasians, 12 African Americans, 10 Hispanics, 6 Asians, and 2 "Others".

An algebra pretest consisting of 14 multiple-choice compare word problems (4 simple-direct, 5 simple-indirect, and 5 complex) was used to assess algebra problem-solving abilities. Participants then participated in a directed practice session during which they were randomly assigned to one of four experimental conditions (No feedback/"Explain own" (Control), Ambiguous feedback/"Explain own and alternative", Feedback/Explain correct, and Feedback/Explain correct and incorrect"). Students were asked to provide algebraic equations for each of 10 problems, and to explain why they thought these equations were correct (or incorrect). Finally, an algebra post-test, identical in form to the pretest, was administered.

Results & Discussion

Pre- to post-test improvements in performance for students in each of the experimental conditions exceeded those for students in the control condition. Results indicated that feedback and self-explanation conditions positively affected post-test performance. Students who self explained both correct and incorrect solutions outperformed all others, and students in the control group had the smallest increase in performance between pre- and post-tests.

This study extends our knowledge of the strategies that could be used to facilitate the processes by which students learn, and offers insights that could prove valuable to educators in selecting task appropriate instructional techniques.

Towards a Model of the Prime-Retention Effect

Eddy J. Davelaar (e.davelaar@bbk.ac.uk)
School of Psychology, Birkbeck, University of London
Malet Street, WC1E 7HX, London, UK
http://www.geocities.com/ejdavelaar

The semantic priming effect has been central in many debates on the structure and dynamics of semantic memory. One view states that concepts in the memory system are interconnected via links of variable strength through which activation spreads. On presentation of a word (prime), its semantic representation will increase in activation, which then spreads via the semantic connections to related concepts. When a second word is presented, whose semantic representation is close to the prime word, shorter lexical decision or naming latencies are observed; the basic semantic priming effect.

This simple semantic network (SSN) model predicts that the more activation is given to the prime, the larger the priming effect. However, it was found that when the prime word had to be retained in short-term memory (STM) while a lexical decision was being made, the priming effect was absent (Davelaar, 2004). This *prime-retention effect* is modulated by semantic distance and the stimulus-onset asynchrony (SOA) between the prime and the target, with weak associates being more affected than strong associates and especially at long SOAs. In order to account for this finding, an extension to Dagenbach and Carr's (1994) Center-Surround hypothesis was proposed. Here, a computational structure is sketched that implements this hypothesis and is easy to incorporate in a recent connectionist models of priming (Huber & O'Reilly, 2003; Plaut & Booth, 2000).

Proposed Model Architecture

The single-layer SSN is changed into a two-layer network and augmented with two types of inhibitory connections that correspond to known anatomical connections in the human cortex (local and global inhibition). The architecture is depicted in Figure 1 and is presented as having a columnar structure, where every column represents a separate concept. Within each column, the input unit (bottom unit) sends activation to the corresponding output unit (top unit) and to the local inhibitory unit (filled circle). The output and inhibitory units are reciprocally connected, which lead to the output unit exhibiting adaptation; with increase in stimulus duration the activation increases from baseline to a maximum and then drops to an intermediate level (cf. Huber & O'Reilly, 2003). Between columns, input units are connected to output and inhibitory units of related concepts, where the connection strength reflects the semantic distance. This inter-columnar organisation implements a semantic on-center/off-surround receptive field. All output units feed into a common global pool of inhibitory units that feeds back to the output units (depicted by the circle-headed arrow). This dynamically enforces a limitation on the maximum number of concepts that can be active simultaneously (cf. Davelaar, et. al., in press). In order to model the prime-retention effect, the output unit of the prime word has a self-recurrent connection (dashed arrow) whose strength affects the probability that the prime remains in STM (conceptualised as sustained activation).

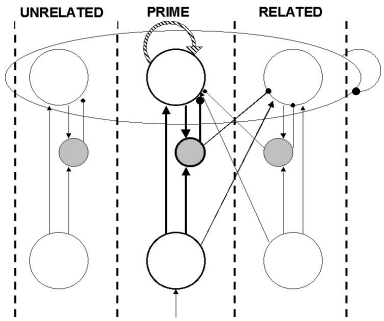

Figure 1. Architecture of a proposed model that captures the prime-retention effect.

Reexamining the "Distinctiveness Effect": Poorer Recognition of Distinctive Face Silhouettes

Nicolas Davidenko (ndaviden@psych.stanford.edu)
Michael Ramscar (michael@psych.stanford.edu)
Department of Psychology
450 Serra Mall, Stanford, CA 94305 USA

The distinctiveness effect in face processing

A recognition advantage for distinctive faces has been widely reported (e.g., Valentine, 1991). In such studies, distinctive faces produce more hits and fewer false alarms than typical faces. Although the finding is robust, the mechanism for this advantage has not been carefully explored. The choice of distractors in these studies does not guarantee equivalent target-distractor distances for typical and distinctive faces. In fact, because typical faces lie in a denser, more central region of face space (Valentine, 1991), they will be on the whole more similar to the distractor set than distinctive faces. The location of distractors may thus be sufficient to explain the distinctiveness advantage. In fact, theories of perceptual learning would predict a processing *disadvantage* for distinctive faces that we have less experience with. To control for the effect of unevenly spaced distractors, we constructed a parameterized face space and created equally spaced targets and distractors.

Parameterized face silhouettes

Forty-eight face profiles from the FERET database were reduced to two-toned silhouettes (Figure 1 A and B). The position of 18 key points was recorded for each silhouette from which a 32-dimensional set of principal components (PCs) was computed to fully describe the shape of each silhouette, up to rotation and dilation (Figure 1 C).

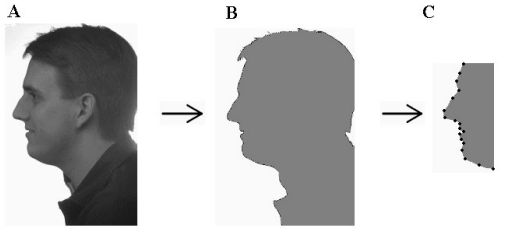

Figure 1. Silhouette parameterization

Experiment 1

From this parameterization, 100 typical and distinctive silhouettes were constructed by setting two of the first 10 PC values to +/- 1 (for typical faces) or +/- 3 (for distinctive faces) standard deviations from the mean. This resulted in distinctive faces being farther from the origin of face space (see Figure 2A), a measure that correlated highly with rated distinctiveness. Distractors were constructed for each face by varying two orthogonal PC values to +/- 1 and +/- 2. In a 3AFC recognition task, 16 Stanford undergraduates observed the randomly presented faces, each followed by a 2-second mask and a choice of three faces (the target and two distractors). Performance was coded as percent identification of the target face. Mean performance was 61% for typical and 56% for distinctive faces, a significant disadvantage for distinctive faces ($p<.05$). To control for the possibility of biased online learning of the typical region of face space, we conducted a second experiment where the size and density of the two regions were matched.

Experiment 2

The design was the same as above except that the set of distinctive faces was defined as a translation in face space from the set of typical faces. Each distinctive face corresponded to a typical face translated by a fixed number of units on a set of eight orthogonal PCs. To control for item effects, the direction of translation was reversed in two between-participant conditions (see Figure 2 B and C).

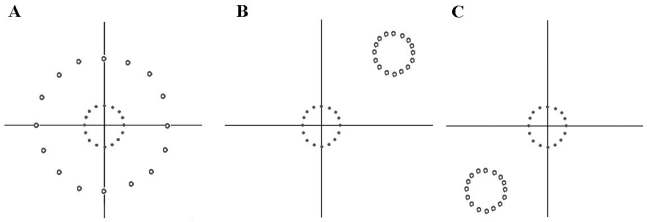

Figure 2. Relative sizes of typical (dots) and distinctive (rings) face regions in Experiments 1 (A) and 2 (B and C)

In conditions 1 (N=16) and 2 (N=14), typical faces were correctly identified more often than distinctive faces (62% vs. 57% and 64% vs. 59% respectively; $p<.05$ in each case).

Discussion

By using parameterized silhouettes, we were able to construct distractors that were equally spaced from their respective targets, across typical and distinctive faces. In two experiments, we found that when controlling for distractor distance, the advantage associated with distinctive faces *reverses*. This "reverse distinctiveness effect" is consistent with the notion that people have less experience with distinctive regions of face space.

Lexical decision and semantic categorization: age of acquisition effects with students and elderly participants

Simon De Deyne (simon.dedeyne@psy.kuleuven.ac.be)
Department of Psychology, University of Leuven
Tiensestraat 102, 3000 Leuven, Belgium

Gert Storms (gert.storms@psy.kuleuven.ac.be)
Department of Psychology, University of Leuven
Tiensestraat 102, 3000 Leuven, Belgium

Introduction

Age of acquisition (AoA) effects have often been found in a large variety of tasks involving word processing. One of the ongoing discussions remains the confounding of AoA effects with word frequency (e.g. Morrison & Ellis, 1995). In this study we removed possible frequency confounds by comparing AoA and word familiarity differences with young and older participants. A lexical decision experiment was conducted to test if reaction time (RT) differences of both age groups might be explained by differences in AoA of the words.

Previous research (Brysbaert, Van Wijnendaele, & De Deyne, 2000) has shown that AoA effects might also have a semantic origin, apart from proposed origins at the word output or word form access level. To further test this hypothesis we adapted the lexical decision procedure to become a semantic categorization task.

Method

Norms

Subjective ratings of AoA and word familiarity ratings were gathered for 309 Dutch words from students (18 to 23 years old) and older persons (52 to 56 years old). The rated stimuli consisted of early acquired nouns (e.g. apple) and late acquired nouns (e.g. radar), of which some are acquired only recently by the older participants (e.g. modem) and were used for selecting stimuli for the RT experiments. Results showed that not only AoA differed significantly, but also familiarity differed between both age samples.

Lexical Decision

A lexical decision experiment with 108 Dutch words was conducted with young (n = 22, 18 to 23 years old) and older participants (n = 20, 52 to 56 years old). Due to the significant differences between the rated familiarity of words for both groups a factorial design was undesirable and correlational designs were used.

Semantic Categorization

Subjects from both age groups were required to make a categorization between manmade concepts and natural concepts for 160 Dutch words. Ages varied in the young group (n = 21) from 18 to 23 years and from 52 to 56 years in the older group (n = 21).

Results and Conclusions

Results from the lexical decision experiment showed that there was an effect of difference in AoA but not familiarity when predicting RT differences for the young and older participants. The results were complete analogues in the semantic categorization experiment. In both experiments no effects were found for AoA and familiarity when predicting error rates.

The main conclusions of this study are threefold. First, the data show that the normation of words depends on age, both for AoA and familiarity. In this respect it is the first study where age-specific norms are used. Second, our study clearly demonstrates, by only manipulating the age between subjects, that AoA is an important factor in lexical decision. Third, we provide further evidence for an interpretation of the AoA effect as a general effect of learning systems. More specifically, besides the proposed effects on word output or word form access level, AoA plays a significant role in processing the meaning of words.

Cognitive Style and Integration of Verbal and Visual Information

Kyung Soo Do (ksdo@skku.edu)
Hye-ran Hwang (5823305@hanmail.net)
Department of Psychology, Sungkyunkwan University
Seoul 110-745, KOREA

Cognitive style refers to an individual's preferred and habitual approach to organizing and representing information (Riding & Rayner, 1998). One of the most widely used cognitive styles is the distinction between verbalizers and visualizers. If the verbalizer/visualizer distinction were valid, the presentation order of verbal and visual information should affect learning differently. That is, verbalizers should learn better when verbal information is presented prior to the visual information, whereas visualizers would benefit when visual information is presented prior to the verbal information.

Methods

Ninety-eight Sungkyunkwan University students, selected out of 160 students based on their scores on a cognitive style questionnaire (Kirby, Moore, & Schofield, 1988), participated in the experiment. They studied three Korean historic sites using two different versions of instructional material. Forty-eight students, twenty four verbalizers and twenty-four visualizers, studied using text with video clips presented on computer monitors (text condition). Text and video clips were presented on the monitor screen. Fifty students, twenty-five visualizers and twenty-five verbalizers, studied with narrations and video clips on monitor screens (narration condition). Instructions for each site consisted of seven segments, each of which lasted twelve to fourteen seconds. In the visual first condition, video clips for each segment started three seconds prior to the start of text presentation, and the screen for the video clips remained blank after the end of the segment until the presentation of the text segment ended. In the simultaneous condition, both text (or narration) and the video clips of the segment started simultaneously. In the verbal first condition, text (or narration) started to play three seconds prior to the start of the video clips, and the monitor screen for the text remained blank or silent until the video clips of the segment ended. After students finished studying three sites, they answered twelve retention questions, four for each site, for four minutes, and twelve integration questions, four for each site, for eight minutes.

Results and discussion

The number of correct answers for the retention questions and the integration questions were analyzed. The interaction effect of cognitive style and the presentation order in the retention test was significant in the narration condition ($F(2,96)=6.97$, $p<.01$), and marginal in the text condition ($F(2,92)=2.84$, $p<.06$). The pattern of the interaction effect in the integration test was similar to that of the retention test, but failed to reach statistical significance. As was shown in Fig. 1, visualizers got the most benefit when the visual information was presented first, compared to the simultaneous and verbal first condition ($F(1,24)=3.04$, $p<.09$, and $F(1,24)=3.61$, p,.07, respectively). Whereas verbalizers retained more information when the verbal information was presented first, compared to the visual first condition and simultaneous condition ($F(1,24)=8.35$, $p<.01$, $F(1,24)=6.68$, $p<.02$, respectively). The results suggested that the multimedia instructional material would be better if separately prepared for visualizers and verbalizers.

Segmenting Everyday Actions: an Object Bias?

Rebecca E. Dowell (rebecca.dowell@stanford.edu)

Bridgette A. Martin (martin@psych.stanford.edu)

Barbara Tversky (bt@psych.stanford.edu)
Department of Psychology, Bldg. 420 Jordan Hall
Stanford, CA 94305 USA

Introduction

Recognizing and understanding observed actions is critical to effective social interaction. To do this, observers must segment complex and continuous human behavior into discrete events. Newtson (1973) developed a paradigm for measuring behavior segmentation, in which participants observed films of everyday behavior and used a key to mark off separate events. Zacks, Tversky and Iyer (2001) showed that people segment observed action according to a *hierarchical* structure: larger (coarse) action units were defined by changes in the object being manipulated, whereas smaller (fine) units were defined by changes in actions performed upon the same object. Zacks et al. suggested that this organization reflected a cognitive bias to relate objects to goals and actions to subgoals. Because Zacks et al.'s findings could be due to the organization inherent in their stimuli, the present study examines the possibility of an object bias by asking observers to segment differently organized tasks.

Methods

We filmed two familiar activities: packing a suitcase and washing dishes, according to two different organizations. One version organized larger goals by object changes and subgoals by action changes (*object* films), and the other organized larger goals by action changes and subgoals by object changes (*action* films). Participants viewed both object films or both action films and segmented them according to the Newtson paradigm. In Experiment 1, thirty-two participants viewed the films twice, marking off coarse units on one viewing and fine units on the other. In Experiment 2, sixteen participants segmented the same films into whatever events felt natural.

Results and Discussion

For Experiment 1, linear regression analyses revealed that observers changed their segmentation criteria based on the organization of the films they observed. For *object* films, changes in objects were the best predictor of coarse event boundaries, $F(1,560) = 76.2$, $p < 0.001$, and changes in actions on the same object were the best predictor for fine boundaries, $F(1,560) = 96.2$, $p < 0.001$. For *action* films, this pattern reversed: changes in actions predicted coarse segmentation, $F(1,552) = 125.8$, $p < 0.001$, and changes in objects predicted fine segmentation, $F(1,552) = 27.5$, $p < 0.001$. Although segmentation followed event organization by action or object, there was greater agreement on segment boundaries and greater hierarchical alignment for events organized by objects than events organized by actions (Fig 1). To further test whether objects bias segmentation, participants in Experiment 2 segmented the films into natural units. Object changes were the best predictor of event boundaries for both *object*, ($F(1,560) = 51.068$, $p < 0.001$) and *action* conditions ($F(1,552) = 72.244$, $p < 0.001$). Furthermore, participants in the object condition produced segmentation patterns suggesting that they monitored both coarse and fine levels of action. Participants in the action condition did not show this pattern, suggesting poorer identification of hierarchical structure. Taken together, these data suggest that while observers are adept at uncovering the structure in different task organizations, there is a bias towards object-based segmentation

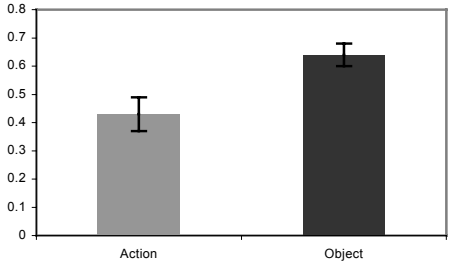

Figure 1: Hierarchical Alignment for *action* and *object* films.

The Creativity of Invented Alien Creatures: The Role of Invariants

Yana Durmysheva (YanaD@brooklyn.cuny.edu)
Aaron Kozbelt (AaronK@brooklyn.cuny.edu)
Department of Psychology, Brooklyn College, CUNY
2900 Bedford Ave., Brooklyn, NY 11210 USA

Purpose

In his study on structured imagination, Ward (1994) found that in general people are not very creative. When asked to imagine alien creatures, participants usually draw beings that resemble common animals and stereotypical science-fiction characters. However, this result does not address why some aliens might be judged as creative, or if creativity can be enhanced, e.g., by certain instructions. Kaplan and Simon (1990) suggested that creative insights may be achieved by actively noticing "invariants," i.e., characteristics that attempted solutions all have in common. Ward (1994) found that most invented creatures had two eyes, four limbs and bilateral symmetry. If these invariants are given to participants in Ward's creature generation task, do they boost creativity? Also, what aspects of the drawing or description of the creature predict its judged creativity?

Method

Creation Task

Sixteen undergraduate students at Brooklyn College participated in the Creation Task, which was similar to that of Ward (1994). The session consisted of six trials (seven minutes each) in which participants were asked to imagine, draw, and describe an alien creature. Participants invented a new creature on each trial. In trials 1-3, participants were given "General" instructions, without any constraints or suggestions. In trials 4-6, they were given "Invariants" instructions and told that their creature should not have 2 eyes, 4 limbs, or bilateral symmetry.

Coding

Coding systems were developed for the drawings and paragraphs. Two raters independently coded each creature. One coding system categorized each drawing in terms of following each of the three invariants. Drawing coding was mostly high (Cohen's kappa = .88 and .79, and .56, for eyes, limbs, and symmetry, respectively). In the paragraph coding system, each proposition in each paragraph was coded into one of 14 categories, e.g., Analogies, Extraordinary abilities, Planet conditions, etc. Inter-rater reliability on coding paragraph categories was also high: r (1342) = .85, p < .0001. All coding was done prior to the Evaluation Task.

Evaluation Task

Ten undergraduates at Brooklyn College participated in the Evaluation Task. Participants were asked to rate the creativity of each of the 96 creatures from the Creation Task, taking into account both the drawing and the paragraph, on a scale from 1 (very low creativity) to 6 (very high creativity). Participants rated the creatures by sorting them into six piles. They could define creativity any way they liked, but they were advised to think about the originality of the drawings and paragraphs.

Results

Performance in the General condition replicated Ward (1994): participants mostly drew creatures with two eyes, four limbs, and bilateral symmetry. In the Invariants condition, almost all participants avoided two eyes and four limbs; fewer followed instructions to avoid bilateral symmetry. In general, there was a strong association between instructions and invariants: for eyes, χ^2 (4 df, N = 96) = 42.5, p < .001, for limbs, χ^2 (4 df, N = 96) = 27.8, p < .001, and for symmetry, χ^2 (4 df, N = 96) = 49.3, p < .001.

Do instructions affect creativity? Evaluations were refined using Rasch analysis (Wright & Masters, 1982), which generates an interval-scale dependent measure of creativity for each creature. A paired t-test, conducted using each participant's average rating for the three creatures in the two conditions, showed no reliable difference, t (15) = 1.06, p = .30. Therefore, the instructions had no discernible effect on the judged creativity of the creatures.

If instructions do not predict creativity, what does? To assess this, a multiple regression was performed using drawing and paragraph coding categories for each creature. The full 17-predictor regression was highly significant, F (17, 78) = 3.66, p < .0001, adjusted-R^2 = .32. Non-significant predictors were dropped, yielding a final 5-predictor model, F (5, 90) = 9.86, p < .0001, adjusted-R^2 = .32. Significant predictors (Betas) were: Activities (.21), Explanations (.26), Extraordinary abilities (.27), Feature description (.19), and Personality characteristics (.32).

Conclusion

Results suggest that constraining participants to avoid common invariants does not enhance the creativity of their productions. However, creativity can be predicted by a several verbal description categories given by participants.

Introduction

We are developing a system, Cassie, that defines unknown words from their linguistic context combined with background knowledge [Ehrlich & Rapaport, 1997; Rapaport & Ehrlich, 2000]. This work is of significance for cognitive science, education, computational linguistics and philosophy of mind.

Cassie is built on SNePS, a semantic-network-based knowledge representation and reasoning system developed by Stuart C. Shapiro and the SNePS Research Group [1999], with facilities for parsing and generating English and for belief revision. SNePS has been and is being used for several natural language research projects.

Cassie Learns as Humans Learn

When asked to define of a word, Cassie reports relevant aspects of her experience with that word. Which aspects are chosen depends upon the type and quantity of her exposure to the word, and the contexts in which it occurs, as well as what background knowledge she has.

Our algorithms for selecting information salient to a good definition have been drawn, in large part, from observation of humans with very strong verbal skills. These humans were asked to reason aloud as they read a series of passages containing an unfamiliar word, or a familiar word used in a new sense. It was observed that certain types of information were almost always regarded as salient, while other items would be reported when the preferred data was lacking, but would be dropped from the definition (even if still believed) once the more important information could be observed or inferred.

Though monotonic reasoning is preferred where possible [Ehrlich, 2004], it is at times necessary to withdraw or modify previously held beliefs. Therefore, Cassie has been given an ability to analyze her beliefs, and to select (from among the beliefs supporting a conclusion shown to be erroneous) a belief most likely to be at fault. Cassie then withdraws or modifies the belief according to pre-defined algorithm. This allows her to revise an incorrect definition (as opposed to the more typical case of an incomplete definition).

Cassie's ability to define nouns, verbs, and adjectives has been developed and refined through work on a number of examples, following protocols taken from several readers. Current work includes the further development of a rudimentary discourse analysis for finding the effects of verbs and further development of case-based reasoning.

Humans Learn as Cassie Learns

Meanwhile, the algorithms we have developed and tested on Cassie are being used to formulate an educational curriculum [Rapaport & Kibby, 2002]. It is well-known that the majority of a person's vocabulary is obtained from context, but to date there has been little in the way of instruction in methods of acquiring vocabulary from context. The explicitly formulated algorithms needed to allow Cassie to learn word meanings, however, provide what appear to be a useful set of techniques that can be explicitly taught to secondary school and college students. Investigation is ongoing into how helpful these techniques may be in improving reading comprehension, especially in reading scientific or technical materials that may include a variety of new terms.

A Coupled Oscillator Model of Creative Cognition Process for Emergent Systems

Tetsuji Emura (emura@kinjo-u.ac.jp)
College of Human Sciences, Kinjo Gakuin University
Omori 2-1723, Nagoya 463-8521, Japan

Introduction

Psychologists (e.g., Wallas 1926; Guilford 1959; Finke et al. 1992) have clarified the existence of a process controlled by imagination that precedes what is called design, which are deductive logic operations, for the act of creation, in which things that had hitherto not existed are created; a creative act absent this process in mental space is not possible. In other words, a process that could be perceived as what is called insight or idea generation before deductive logic operations substantially controls the creative process. However, research proposing mathematical models for such as the creative cognition process for direct linkage to creativity has seldom been conducted.

When, analyzing the musical work's structures of Brahms, Wagner, for example, a melody is present here, although the melody and harmony are inseparable; there is absolutely no way to first have the melody and then harmonization with it. Moreover, the melody and harmony are allocated to individual instruments for respective sounds and with harmonic progression are changed to be extremely effective as melody; if melody and harmony do not exist simultaneously and if changes in both harmonic progression and timbre in the process of creation do not exist simultaneously in the brain of the composer as a sound image, then creation of a work like this would be close to impossible. That is, harmony, melody, and timbre are in a mode where they are blended into one another and creation must be interpreted to progress with simultaneous processing of these in parallel in the brain of the composer. However, the music theory proposed until now is only static system theory (e.g., Lerdahl & Jackendoff 1983; Forte 1973) and dynamical system theory is not proposed yet.

A Device for Emergent Systems

Two continuous-time autonomous dynamical systems $\mathbf{X_a}$ and $\mathbf{X_b}$ are considered in n-dimensional Euclidean space $\mathbf{R}^n$.

$$\dot{\mathbf{X}}_\mathbf{a} = \mathbf{F}(\mathbf{X}_\mathbf{a}), \quad \dot{\mathbf{X}}_\mathbf{b} = \mathbf{F}(\mathbf{X}_\mathbf{b}) \quad \cdots(1)$$

Here, $\mathbf{F}$ is considered to be the Lorenz system for both with n=3, when considering the $\mathbf{X_a}$ and $\mathbf{X_b}$ in bi-directionally coupled by $0<c_{1,2,3}<1$ are temporal coupling coefficients and $0<d_{1,2,3}<1$ are spatial coupling coefficients, where individual vector components are

$$\mathbf{X}_\mathbf{a} = [x_1, x_2, x_3], \quad \mathbf{X}_\mathbf{b} = [x_4, x_5, x_6] \quad \cdots(2)$$

$$\begin{pmatrix} \dot{x}_{1,4} \\ \dot{x}_{2,5} \\ \dot{x}_{3,6} \end{pmatrix} = \begin{pmatrix} \sigma(x_{2,5} - x_{1,4}) \\ x_{1,4}(r - x_{3,6}) - x_{2,5} \\ x_{1,4}\, x_{2,5} - b\, x_{3,6} \end{pmatrix} + \mathbf{D} \begin{pmatrix} x_4 - x_1 \\ x_5 - x_2 \\ x_6 - x_3 \end{pmatrix} \quad \cdots(3)$$

$$\mathbf{D} = \begin{pmatrix} c_1 & d_2 & d_3 \\ d_1 & c_2 & d_3 \\ d_1 & d_2 & c_3 \end{pmatrix} \quad \text{: excitatory connection}$$

$$\tilde{\mathbf{D}} = \begin{pmatrix} c_1 & d_2 & 1-d_3 \\ 1-d_1 & c_2 & d_3 \\ d_1 & 1-d_2 & c_3 \end{pmatrix} \quad \text{: inhibitory connection}$$

Discussion

The presented Lorenz model having two parameters c and d is a device that has coupled three one-dimensional information codes of $\{x_1$-x_4, x_2-x_5, x_3-$x_6\}$. This device can be used as an emergent device for three channels through control of on-off intermittent chaos as observed in this model with the c and d as parameters. The c and d control on-off intermittent chaos, although they have no direct effect on individual vectors and work as independent parameters without providing internal disturbance. The wandering on the three one-dimensional information coded space in the burst phase with seeking and gathering of valuable information from this, synchronized stabilization on a point in the laminar phase can be modeled as a process that intermittently and irregularly repeats and the phase transition between laminar phase and burst phase simultaneously occur in three dimensions. Figure 1 shows the phase transition from chaos→limit cycles→intermittent chaos → laminar phase with increase of the value of d=d_1=d_2=d_3 in case as constant of c=c_1=c_2=c_3. The figure is plotted in t=0~100000, d=0~1. The d is changing linearly with t, where d=0.00001t.

A Model of Analogical Retrieval Using Intermediate Features

Mark Alan Finlayson (markaf@mit.edu)
Patrick Henry Winston (phw@mit.edu)
Computer Science and Artificial Intelligence Laboratory, MIT
32 Vassar St., Cambridge, MA 02139 USA

We present a model of analogical recall in people which draws inspiration from recent work in visual classification by Ullman (2002). Our model is intended to unify two bodies of evidence regarding recall in people: on the one hand, we seek to cover a body of evidence that indicates people drawn from a population without regard to task expertise are heavily influenced by surface similarity during retrieval; on the other hand, we also seek to account for the fact that experts are able to achieve analogical recall on a consistent basis. Our model works by breaking the symbolic graph representation of an input situation into sub-graph structures (structures we call *features*), and looking for these features in other situations. By varying the informativeness of the features we use to retrieve situations, we are able to promote or suppress analogical retrieval.

Our model is consistent with previous models of recall (Thagard, Holyoak, Nelson, & Gochfeld, 1990; Forbus, Genter, & Law, 1994) which indicate object similarity, first-order relations, and some small amount of structure dominate recall in normal subjects. These models were primarily intended to account for evidence of the predominance of so-called "mere-appearance" matches in normal recall (Gick & Holyoak, 1980; Rattermann & Gentner, 1987), while still acknowledging some structural effects (Holyoak & Koh, 1987; Wharton et al., 1994)

In contrast to these previous models, however, our model indicates an explanation for certain results in the field of expert problem-solving and retrieval, which has received less attention to date. Evidence drawn from this literature (Chi, Feltovich, & Glaser, 1981; Schoenfeld, 1982; Shneiderman, 1977) indicates that certain sorts of people do consistently achieve analogical recall in particular domains: while these people often fall under the heading "expert," non-experts are also able to attain structural reminding under particular circumstances.

We run our model on a dataset of descriptions of complex political scenarios, and show the predicted switching of preference from mere-appearance to analogical matches when moving from low average feature informativeness to high average feature informativeness. Furthermore our results indicate, as Ullman's did, that features of an intermediate size and complexity provide the most robust recall within analogical category.

A Morpheme-Specific Constraint Approach to Vowel Harmony in Korean

Sara Finley (finley@cogsci.jhu.edu)
Department of Cognitive Science, Johns Hopkins University
3400 N Charles St. Baltimore, MD 21218 USA

The problems with previous analyses of Korean vowel harmony are solved when harmony is treated as a consequence of morphological alternation rather than a purely phonological process. This morphological alternation is best accounted for using morpheme-specific correspondence constraints in an Optimality-Theoretic Analysis.

In Korean, vowel harmony occurs in the semantic contrasts of sound symbolic (SS) words. SS words are words whose sound bears some symbolic meaning, and are extremely productive in Korean (Cho, 1994). The majority of SS Korean words alternate between LIGHT and DARK, which have fast and slow connotations, respectively. Alternations between LIGHT and DARK are based on the vowels that can occur in these forms. DARK forms harmonize to contain only DARK vowels: [i, y, ɨ, e, ə, u] (as in [t**e**ŋg**ə**ŋ] 'chopping slowly'). LIGHT forms harmonize to contain only LIGHT vowels: [ɛ, ø, a, o] (as in [t**ɛ**ŋg**a**ŋ] 'chopping quickly').

Phonological analyses of vowel harmony must use one harmonic feature to capture vowel alternations. The problem in Korean is that there is no single harmonic feature. Some alternations involve only a change in height, as in [u] to [o] in [h**u**llə**ŋ**]/[h**o**lla**ŋ**] 'take off clothes'. Some alternations involve only a change in advanced tongue root (ATR), as in [e] to [ɛ] in [t**e**ŋgə**ŋ**]/[t**ɛ**ŋga**ŋ**] 'chopping'. Other alternations involve both changes in aTR and HIGH. Analyses using one harmonic feature ([low] or [ATR] (see Chung, 2000)) cannot completely capture the distinction between DARK and LIGHT without significant restructuring or arbitrary assignment of phonological features. This problem can be solved if this instance of vowel harmony is treated as a morphological process whereby morphemes for DARK and LIGHT bear phonological features that are in correspondence with the output surface form.

The feature associated with DARK is [+ATR] while the features associated with LIGHT are [−ATR] and [−HIGH]. Using both [HIGH] and [ATR] captures the fact that the phonological alternations result in changes in one or both features. The presence of a DARK or LIGHT morpheme triggers morpheme-specific correspondence constraints which restrict the occurrence of vowels in the output. Correspondence between the morpheme and the output is governed by left/right anchoring constraints and output-contiguity. These constraints represent the drive for the morpheme to be in correspondence with all vowels in the output. The interaction of the correspondence constraints with IO-Faithfulness and markedness constraints gives the expected outcome, including an account of high vowels, which do not undergo harmony after the first syllable. The analysis presented also accounts for unexpected behavior, such as the absence of [o] in DARK forms and alternations of [u] and [o] after the first syllable.

Use of correspondence constraints to account for morphologically controlled harmony as opposed to agreement (Bakovic, 2000) is in line with work on featural affixation (Akinlabi, 1994), and is part of a larger project involving the use of morpheme-specific faithfulness constraints to account for morphologically controlled harmony.

When Mats Meow: Phonological Similarity of Labels and Induction in Young Children

Anna V. Fisher (fisher.449@osu.edu)
Department of Psychology & Center for Cognitive Science
Ohio State University

Columbus, OH 43210 USA

The ability to make inductive inferences is crucial for humans, and it has long been demonstrated that labels play an important role in induction. However, the mechanism by which labels contribute to induction remained unclear. According to one theoretical position, often referred to as the *naïve theory*, even for young children labels presented as count nouns are special properties: even young children understand that count nouns denote categories, communicating what the things are (Keil, et al, 1998; Gelman & Coley, 1991). According to a recently proposed alternative model SINC (Similarity, Induction and Categorization in Children), children perform induction on the basis of the overall similarity among compared entities, and labels are features contributing to the overall similarity (Sloutsky & Fisher, in press). If labels are features contributing to the overall similarity then not only identical, but phonologically similar labels should contribute to the overall similarity, and therefore to induction. This research was designed to test this prediction of SINC, which, if supported would present challenges to the naïve theory position. Results of two experiments supported the prediction.

Experiment 1: Inductive inference with similar, identical, and different labels

Participants (N = 67, *M* = 4.9 years; *SD* = 0.34) were presented with an induction task in one of the three between subject labeling conditions: identical, similar, and different labels. Children were presented with triads of animal pictures introduced by identical, similar, or different labels, and informed about pseudo-biological properties of two members of each triad. Then children were asked to generalize these properties to the third member of the triad. If labels are category markers as the naïve theory suggests, then identical labels should be fully predictive (thus promoting inferences), while similar labels should be completely non-predictive (thus promoting no inferences). According to the SINC model identical, but also similar labels should promote inductive inferences (i.e., similar labels should be at least partially predictive). Results of Experiment 1 supported predictions of the SINC model: similar labels were found to be partially predictive and likely to promote inductive inferences.

Experiment 2: Label Verification

Results of Experiment 1 could be due to children treating similar novel labels as mispronunciations of identical labels. Experiment 2 was designed to eliminate this potential confound. Participants (N = 29, *M* = 4.8, *SD* = 0.45) were presented with sets of pictures consisting of a Target and four Test stimuli of various degree of similarity to the Target (i.e., identical, very similar, less similar, and dissimilar). On each trial a Target and one of the Test stimuli was labeled with similar labels used in Experiment 1. Children were asked whether the labeled entities had the same name. If children consider similar labels as mispronunciations, then, at least when pictures are identical, they should respond that similar labels were the same. However, the majority of children considered similar labels as different words, and their responses were not affected by picture similarity.

A Critique of the Small Sample Account of Covariation Detection

Wolfgang Gaissmaier (gaissmaier@mpib-berlin.mpg.de)
Lael Schooler (schooler@mpib-berlin.mpg.de)
Jörg Rieskamp (rieskamp@mpib-berlin.mpg.de)
Center for Adaptive Behavior and Cognition, Max Planck Institute for Human Development
Lentzeallee 94, 14195 Berlin, Germany

The starting point for this project was the finding that people with a low working memory capacity perform better in a covariation detection task (Kareev, Lieberman, & Lev, 1997). In the task people successively encountered envelopes with two different colors and each time had to decide which out of two objects they think they will contain. The explanation for the low capacity advantage is that people with a lower working memory capacity have to rely on smaller samples when they make decisions. This helps them to detect a correlation earlier, because statistically small samples are more likely to indicate a correlation that exceeds the correlation in the population (Kareev, 1995b).

Experiments

We conducted two experiments with an extended version of the original task to test and model the original finding that low capacity people perform better in a covariation task. An implication of the small sample account is that they are also better in detecting a change in the correlational structure of the environment. As in the original experiment, working memory capacity was assessed with a digit span test. The original finding was replicated in the first but not in the second experiment, thus it seems to be a weak and unstable effect. It is worth noting that the probability of replicating a result at the same or a higher level of significance (and in the same direction) is only 50% (Goodman, 1992). Contrary to the predictions by the small sample account there was a high capacity advantage after a change in the first experiment. In the second experiment we did not find any differences between low and high capacity people, neither before nor after a change. Therefore, we focus on the first experiment with regard to modeling.

Modeling

Two different models have been tested, a naïve window model and a reinforcement learning model. Every model was fitted to each individual separately since we wanted to relate capacity to model parameters. The naïve window model that tries to translate the small sample idea directly could not capture the low capacity advantage. But we were able to model it with the reinforcement learning model (Camerer & Ho, 1999) with a decay, a sensitivity and an initial attraction parameter, where we forced the variance in each of the parameters separately by fixing the other two to their means. All three versions were able to capture the low capacity advantage on covariation detection, but only the initial attraction version was related to capacity *and* could predict behavior after a change.

Conclusions

The small sample account is not clearly supported by our data. First, the deduced hypothesis of a low capacity advantage after a change does not hold, we find either no effect or the opposite. Second, the naïve window model and the reinforcement learning model version with the decay parameter which has the strongest connection to memory have to be rejected. Instead, an initial attraction parameter model is successful, indicating a faster learning process of low capacity people in the beginning, but not later on. Still, faster learning can be interpreted as relying on smaller samples. But it is also congruent with the finding of Weir (1964) that children use the simple but most successful payoff maximization strategy (i.e. always choose the more frequent option given a color) earlier in a similar task because they are simply reinforcement driven. Adults, in contrast, develop complex hypothesis and apply complex strategies because they believe that there exists a perfect solution, but they end up worse. As capacity differs between children and adults (Kail, 1984) and plays an important role in hypothesis generation (Dougherty and Hunter, 2003) this could be an explanation for the low capacity advantage.

Dynamical Field Theory Predicts a Developmental Reversal in an A-not-B-like Task

Joshua Goldberg (joshgold@cs.indiana.edu)
Department of Computer Science, Indiana University, Bloomington
125 South Woodlawn Ave., Bloomington, IN 47401 USA

The A-not-B Error

Since Jean Piaget's observations of the A-not-B error in his own children, a great deal of scientific effort has been applied to understanding how the error occurs and how children overcome it. The error occurs when a young infant (around 10 months) watches a toy being hidden and then reaches for it. First the child retrieves the toy, hidden a few times at a location A. Then, when the toy is hidden at a new location B and the child must wait a few seconds before retrieving it, she will reliably *perseverate,* reaching to the old location for the toy (often with great frustration.) By about 14 months, infants no longer perseverate in this task.

Dynamical Field Theory And A-not-B

Dynamical Field Theory has been a source of many validated predictions of infant behavior in the A-not-B task (Thelen et al., 2001). These have included manipulations of age, number of practice trials, delays, spacing between target locations, and distinctiveness of hiding boxes. Field theory's lack of dependence on the object concept in conceptualizing the A-not-B error has led to demonstrations that the same patterns of behavior are evident even without a hidden toy, using only light-up buttons for example.

The field model accounts for the dynamics of the A-not-B task by postulating a nonlinearly interactive activation field isometric to the space in front of the infant (Erlhagen & Schöner, 2002). This field, with local excitation and distal inhibition, builds up activation into a peak that indicates where the baby will reach. It is driven by perceptual inputs as well as bias from motor memory of past reaches. Young infants differ from old in that they are less able to maintain a stable reach decision (a peak in the activation field) in the absence of a cue. Therefore, after a short delay, they forget the cue at B and reach to A because of motor memory from practice trials.

A New Task

The A-not-B task does not exhaust the dynamical possibilities that the field model is equipped to handle. Specifically, the A-not-B task does not lead to inhibitory competition between multiple peaks in the activation field. (The competition between a peak in activation and a peak in motor memory is of a different sort with different dynamics.)

A new task we are exploring consists of a cue at A, followed by a delay during which there is a "distractor" cue at B before the baby's turn to reach. We manipulate the duration and timing of the distractor within the delay, as well as the number of training A-trials before this test.

Predictions

Computer simulations of the model allow testing how changes in experimental conditions will affect behavior. More training trials lead to more perseveration to A. A longer distractor more effectively draws the infant to B. A later distractor is more effective because it occurs closer to when the infant may reach.

More striking predictions derive from the differing dynamics of the older versus younger infants. Since young infants cannot maintain a reach decision over a delay, a distractor that is too early is not effective, even if it is long. By the end of the delay, they forget B and are dominated by motor memory at A. Older infants do maintain stable decisions, so a distractor must compete against the cued, stable peak at A. Thus, for older infants, duration is crucial. In the case of a late, short distractor, old infants perseverate more than young—a reversal of the classical A-not-B effect. As illustrated in Figure 1, each condition follows a different dynamical "story," even if the resulting reach is the same.

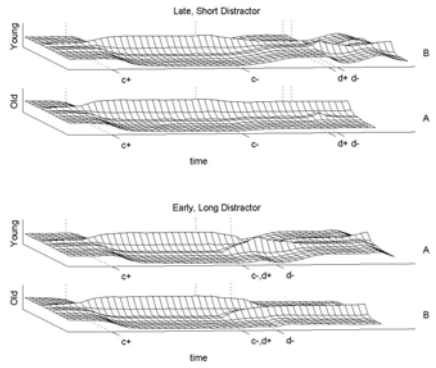

Figure 1: Simulations of four conditions. The first test-trial after 3 A-trials. (c+/c- is cue at A. d+/d- is distractor at B.)

A Simple Model of Encoding and Judgment about Non-Adjacent Dependencies

Pablo Gómez (pgomez1@condor.depaul.edu)
Trisha Hinojosa (tripp@condor.depaul.edu)
Department of Psychology, 2219 N Kenmore
Chicago, IL 60614 USA

Studies with adult and infants have shown that subjects can learn fairly complex probabilistic relationships. Researchers have used statistical learning as a laboratory to explore issues like word segmentation (Saffran, Aslin & Newport, 1996) and the acquisition of grammar (Morgan, Meier & Newport, 1987). Statistical learning has become a scenario for an argument between the two competing views about language acquisition: the view that assumes that humans have some innate ability to acquire grammar (cf., Chomsky, 1965); and the view that claims that statistical learning is based on the same learning mechanisms (e.g., distributed supervised learning) as other domains (see Seidenberg, 1997).

Of particular relevance to our research program are the studies that focus on learning of relationships between non-adjacent speech elements. Newport & Aslin (2004) and R. Gomez (2002) have shown that, only under some special circumstances, participants learn relationships between non-adjacent speech elements (e.g., syllables and words). Here, we present the first version of a model that can account for that data. The model uses a simple encoding process, and a decision mechanism inspired in signal detection theory (Green & Swets, 1966). Our mode supports the notion that very simple mechanisms are enough to explain non-adjacent dependency learning without resorting to special language learning modules.

R. Gomez (2002) has shown that adults and infants can learn non-adjacent regularities when the set size of the intermediate element is large (24 elements), but not when the size set is small (e.g., 2). In a follow up study, she showed that participants could learn non-adjacent dependencies if the intermediate element set size was 1. In these studies, words from an invented language were used in utterances of the form $a_1\ X_{1\ to\ N}\ b_1$, where the dependency was between elements (words) a and b, and the set size of the intermediate element was N.

Newport & Aslin (2004) showed that participants could learn non-adjacent dependencies between letters, but not between syllables. For their experiment with syllables, the stimulus had the form $CV1_1\ CV2_{1\ to\ 4}\ CV3_1$, where the dependency was between the consonant-vowel syllables CV1 and CV3. For the experiment with letters, their experiment had the form $C_1V_{1\ to\ 2}\ C_2V_{3\ to\ 4}\ C_3V_{4\ to\ 5}$, where the dependency was between the consonants C_1, C_2 and C_3.

Description of the Model

The model assumes that subjects use a minimalist approach when they encode the training stimuli. If in their subjective estimation, the adjacent (first order) relationships are informative about the rules to form the artificial language, they will tend not to encode the nonadjacent (second order) relationships.

How informative the first order relationship (say, between the first and second elements in Gomez's studies) is can be determined by a very simple computation:

$$I_{X,b}=p(X_j|a_i)\ (1-p(X_j|a_i)), \qquad (1)$$

where $I_{X,b}$ is a measure of how informative the first order relationship is, and $p(X_j|a_i)$ is the estimated conditional probability of element X_j given element a_i. This measure of informativeness can be thought of as the probability to encode the next order of (non-adjacent) relationship.

The grammaticality judgments are based on familiarity (cf. Signal Detection Theory) at the order of relationship that the learner estimated as informative using Equation 1.

This simple model can account for the u-shaped pattern of accuracy that Gomez found as a function of set size in the intermediate component. In addition, it accounts for the difference between the syllable and letter conditions found by Newport and Aslin; this, because the first order relationship between consonants and vowels had some level of subjective informativeness in the syllable condition.

From Beetle to Bug: Progression of Error Types in Naming in Alzheimer's Disease

Laura M. Gonnerman[1], Justin M. Aronoff[2], Amit Almor[3], Daniel Kempler[4], & Elaine S. Andersen[2]
[1]Department of Psychology, Lehigh University, Bethlehem, PA 18015
[2]Program in Neuroscience, University of Southern California, Los Angeles, CA 90089-2520

The distributed feature approach to semantic memory organization has been supported by data from patients with Alzheimer's disease (AD) (e.g., Gonnerman et al., 1997). This account makes specific predictions about the types of errors one would expect in AD as semantic memory deteriorates, with initially more contrast coordinate errors, followed by superordinates, and finally an increase in unrelated responses. We investigate these predictions using a picture naming task, with both natural kinds and artifacts.

Method

Participants

The young normal (YN) group included 25 USC undergraduates, the old normal (ON) group 24 healthy elderly, and the Alzheimer's (AD) group 15 individuals diagnosed with AD, matched with the ON group for age.

Materials and Procedure

Participants named 144 color pictures, with 12 items each from six natural kinds and six artifacts categories, controlled for familiarity, imageability, frequency, and typicality.

Results & Discussion

The YN group correctly named 86% of the pictures, ON 85%, and AD 62%, indicating a significant impairment in naming for the AD group, (t (15) = -4.15, p < .0009), but no significant difference between YN and ON controls.

To examine the types of errors AD patients made as their naming impairment progressed, errors were coded into three categories: 1) *contrast coordinate*, giving the name of another category member (e.g., calling a *zebra* 'horse'); 2) *superordinate*, giving the category label rather than the object name (e.g., 'bug' for *beetle*); and 3) *unrelated*, where the response was not from the same category (e.g., 'flute' for *cucumber*). No responses, 'I don't know', and machine errors were not included in the analysis.

To determine if the prevalence of a given error type was affected by the degree of damage, ratios of each error type over the total number of errors were calculated. Overall, there were initially significantly more contrast coordinate errors than superordinates (t(327)=-4.7, p <.00001), followed by unrelated responses (t(190)=-3.5, p <.001). This is consistent with the progression of errors in studies of patients with semantic dementia (Hodges et al., 1995).

We were most interested in the progression of errors within natural kind versus artifact categories (see Figure 1 below). The pattern of change varied by domain. As expected, there were more contrast coordinate errors in both natural kinds and artifacts early on, declining with increasing damage. Interestingly, while superordinate errors increased for natural kinds, they decreased for artifacts. The distributed feature approach provides a natural account of this pattern. As damage increases, the core features of natural kinds concepts are still available because they have more intercorrelations. The activation of these core features permits activation of the superordinate name, whereas the lack of similar correlations in artifact categories leads to a steady decrease in superordinate responses for artifacts. Finally, there is a greater increase in unrelated responses in artifacts compared to natural kinds in later damage stages.

Probing the Paradox of the Active User: Asymmetrical Transfer May Produce Stable, Suboptimal Performance

Wayne D. Gray, V. Daniel Veksler, & Wai-Tat Fu

Cognitive Science Department
Rensselaer Polytechnic Institute
[grayw, vekslv] @rpi.edu

Psychology Department
Carnegie Mellon University
wfu@cmu.edu

The "paradox of the active user" (Carroll & Rosson, 1987) is the persistent use of inefficient procedures in interactive environments by experienced or even expert users when demonstrably more efficient procedures exist. In this study we examine the procedures that people adopt in response to minor changes in interface design and how these procedures adapt, or do not adapt, when the design changes.

Prior Knowledge versus Perceptual-motor Effort

For this work, subjects programmed one of two nearly identical VCR simulations. To program a setting, the subject must first click on the setting's radio button and then use the up or down arrow to reach the target value. As suggested by Figure 1, to set the start time the subjects must set start-hour, start-10min, and start-min. To set the end time, they set end-hour, end-10min, and end-min. In the interface used here the three radio buttons to set start time are in one row and the three buttons to set end time are in another row.

In this study we manipulated whether or not the interface had buttons above each column of radio buttons. For the button (BTN) condition (shown in the Figure 1), if a subject had just finished programming, for example, start-hour and now wished to program start-10min, they would first have to deselect the current column button and then select the next column button before they could click-on the "Start-10min" radio button. In the no button (noBTN) condition, subjects could select any radio button at any time.

How easy is it to manipulate the decomposition of the task-to-device rule hierarchy for a particular device? How persistent would the influence of practice in one task environment (either BTN or noBTN) be when subjects were transferred to the other task environment?

We hypothesized that due to the role of prior knowledge, subjects in the noBTN condition would adopt a *by-row* strategy in which they would program all of start time (hour, 10min, and min) before going off to program something else. In contrast, the BTN condition increases the perceptual-motor cost of this "natural" by-row strategy by requiring subjects to click column buttons on and off prior to selecting a radio button in another column. Consequently, the BTN interface would seem to encourage an unnatural *by-column* strategy (i.e. setting start- and end-hour, then start- and end-10min, and then start- and end-min).

Strategies Adopted on BTN and noBTN intefaces

Each subject programmed 8 different shows to the criterion of two successful trials per show. Half of the subjects (32) programmed the first four shows with BTN and half with noBTN. For the last four shows they switched interface conditions. The dependent variable in this report was the strategy used by subjects to program time; either by-row or by-column.

By trial 4, 30/32 noBTN(tr4) subjects used the by-row strategy. With all else equal, subjects preferred to program time as a unit. In contrast, 21/32 BTN(tr4) subjects used the by-column strategy. A very simple manipulation of the perceptual-motor cost resulted in dropping a strategy that was congruent with prior knowledge for a strategy that in some way ran contrary to prior knowledge.

Moreover, further analysis revealed that such minor interface differences affect effort and performance, as well. The average time spent memorizing the target values on the hard interface (BTN) was ~10.4% higher than on the easy interface (noBTN). This resulted in *~20% less programming errors on the hard interface than on the easy*.

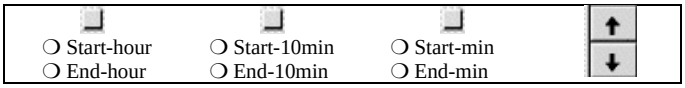

Figure 1. Partial simulated VCR 3.0 BTN interface.

Transfer from BTN to noBTN and vice versa

The results for trial 8 (see Table 1) show that when transferring from a hard interface (BTN) to an easy interface (noBTN), the methods acquired with the hard interface persist. However, in going from easy to hard, subjects quickly adapt to the hard interface.

From the subject's perspective, during the second phase of the study (shows 5-8) the perceptual–motor cost of the by-column strategy greatly decreased and the memory cost stayed about the same. Hence, a strategy that worked well under the conditions of the BTN task environment still worked and was easier to implement under the noBTN task environment.

	Trial 4	Trial 8
noBTN-BTN group	~94% used by-row	75% used by-column
BTN-noBTN group	~66% used by-column	~44% used by-row

Table 1. Strategy use on Trials 4 and 8.

Summary

People do not use one tool or one piece of software. Rather, we work in multiple task environments and our cognitive processes seem adapted to these environments, as opposed to particular subtasks in any given environment.

Towards an Affective Cognitive Architecture

Markus Guhe, Wayne D. Gray, Michael J. Schoelles, Quiang Ji
(guhem, grayw, schoem, jiq@rpi.edu)
Rensselaer Polytechnic Institute

Affective state can influence users' cognitive processing capabilities and hence their productivity (Picard 1997). The first goal of our research is to develop methods to timely and efficiently recognize negative user affective states, model their influence on cognition and behavior, and provide the most appropriate intervention in a timely manner to return the user to his/her productive state. The second, more distal, goal is to develop an integrated architecture of affect and cognition. There are four challenges facing this initiative. (1) Users' affect develops over time, and its expressions vary significantly with individual and context. (2) Affective state observations from a given sensory source are ambiguous, uncertain, and incomplete. (3) The influence of cognition on affective state and vice versa is not well understood. (4) Interventions to improve user performance must be timely and effective.

Our approach contrasts with the state-of-the-art in augmented cognition as well as in affect-based augmentation. The former assumes normative performance and fails to adapt to the user's current affective state. The latter tends to have low-to-no cognitive fidelity, failing to understand the cognitive activities that lead to the observed user state. (But see Hudlicka 2003 for an overview of recent approaches.) Our framework addresses both sets of challenges.

The proposed framework has five major parts: data sensing, user affective modeling, user cognitive modeling, an integrated affective–cognitive model, and a probabilistic user assistance model. Data sensing entails various visual, physiological, and behavioral data.

The *Rensselaer Bayesian Affect Recognition System* (R-BARS) determines the user's most likely affective states using both current and stored sensory data. The model's *context component* represents information about relevant environmental factors such as time of day and type of work. The *affective state component* represents the affective states the system can infer. The affective state we are currently investigating is confusion. The *profile component* may include experience, skill level, etc. It enables us to adapt the model to individual differences. Finally, the model's *observation component* integrates current data with the longitudinal data record collected during the session.

The *Rensselaer Cognitive Architecture of Cognition* (RAAC) is based on ACT-R (Anderson & Lebiere, 1998). Our current focus is on "model tracing"; i.e., the step-by-step tracing of human performance in real-time. Although model tracing in real-time has been repeatedly demonstrated at the 10s level of analysis (Anderson, 2002), behavior at the 100ms level, such as point-of-gaze, is viewed as non-deterministic.

We use a dual-task to induce confusion in the user. The math task is a simple addition/subtraction of two-digit numbers. The user must decide whether the result presented on the screen is correct. The audio task is to determine whether a letter is lower or higher in the alphabet than the previously presented one. For example, for the sequence a–c–b the user must press the ⟨higher⟩ key first and then the ⟨lower⟩ key. The tasks are presented in eight 10min blocks that are subdivided into 36s intervals. For each task, one stimulus is presented every 2s, 4s, or 6s, so that there are 18, 9, or 6 stimuli per interval. By varying the rate of presentation between intervals for each task we get 9 different combinations, e.g. 6–18: 6 stimuli per interval in the math task and 18 stimuli in the audio task. Varying these combinations varies the user's level of confusion, which is confirmed by pilot data. Although performing the audio task at a rate of 2s is manageable, the math task proves very challenging – in particular in conjunction with the audio task. On trials with challenging (18–18) schedules the performance over a 10min block can drop below 20% for the math task (it is typically around 60%). The audio task is usually significantly better; even for challenging schedules the performance hardly drops below 80%.

The cognitive implications of the user's affective state are established by analyzing the deviation of user behavior from the optimal path determined by the model. We will interpret the difference between expected and observed behavior as the influence of affect on cognition and behavior.

In combining R-BARS with RAAC our proximal goal is to mimic the *effect of affect* by identifying low-level parameters of the cognitive architecture that, when varied, mimic the cognitive and behavioral consequences of affective state. Candidate parameters include noise in memory activation and noise in production choice, cf. Belavkin (2001).

We face a profound challenge. Even developing a reliable affective–cognitive model for the task at hand is demanding. Yet, even a partially validated integrated affective–cognitive model would be an important step forward for understanding of the relationship between cognition and affect.

Cognitive Science Needs Powerful Research Strategies

Bernadette Guimberteau (Bern0@mac.com)
Graduate School of Education, UC Berkeley
4533 Tolman Hall #1670, Berkeley, CA 94720 USA

It seems reasonable to believe that problem solving with the Tower of Hanoi (TOH) task has been studied thoroughly enough to be well understood. Yet, the discovery of a new class of affordance-based strategies was reported recently (Guimberteau, 2003), with the finding that problem solving strategies issued from that class are capable of explaining the famous TOH protocol from Anzai & Simon (1979).

The above discovery enriches the set of known strategies for the task, formalized several decades ago (Simon, 1975). Importantly, it also raises an issue, given the prolific nature of the research area concerned with problem solving with the TOH task: Why has not the new class been specified earlier?

Such a question may be dismissed on the grounds that certain aspects of scientific inquiry are not explainable. Another approach is to consider that question closely, as an opportunity to learn from the past. The present analysis takes a first step in the latter direction. It examines past modelizations of Anzai & Simon (1979)'s first problem solving episode (Episode 1), looking for clues to explain why those modelizations have not considered the affordance-driven explanation of the learner's problem solving behavior.

The strategy put forth to explain Episode 1 – Selective Search – constitutes a classic result in the cognitive science literature. The strategy simplifies search by not repeating moves (Anzai & Simon, 1979; Ruiz & Newell, 1989; VanLehn, 1991). It is made of three heuristics: "Don' t reverse a move just made", "Don' t move the same disk twice in a row," and "Don' t transfer the smallest disk and later return it to its previous peg." Those heuristics constrain move selection in such a way that search becomes unnecessary after the first move.

Good fits and convergence of results form the basis of the credibility of the Selective Search strategy. Past accounts simulate problem solving in Episode 1 using the Selective Search strategy and show that they can reproduce the transitions between the learner's strategies (Anzai & Simon, 1979), with a good fit to the learner's moves (Ruiz & Newell, 1989), and to her goal utterances as well (VanLehn, 1991). Specifically, Anzai & Simon (1979) build a production system that can make the same strategy transitions as the ones they hypothesize for their human learner. The Soar simulation from Ruiz & Newell (1989) produces moves that correspond to 77% of the subject's observed moves in her first problem-solving episode. The production system from VanLehn (1991) accounts for all but one of the subject's 130 observed moves and all but 3 of her 41 goal utterances.

A close examination of the Selective Search modelizations reveals three observations. Certain aspects of the episode (e. g., a bottom-disk focus) are not explained by the Selective Search strategy, requiring additional modeling mechanisms. In addition, two conflicts between the heuristics and data from the episode need addressing Finally, the fact that those simulations overlook certain aspects of the data raises the possibility that other mechanisms may be able to explain both the unexplained and the explained data. Indeed, a stronger explanation of the problem solving strategies used in Episode 1 is affordance-driven, and not based on the above Selective Search heuristics: The subject recognizes task-specific affordances during problem-solving, from which she devises affordance-driven strategies (e.g., moving the second smallest disk first because that disk affords moving less than the smallest one.) In other words, the Selective Search characterization rests on a foundation that does not address issues of exhaustive protocol coverage, conflict prevention, and parsimony.

The Selective Search strategy discussed here constitutes one of the classic results of cognitive science. Yet, the two major criteria underlying its credibility – good fits with the protocol data and convergence of past analyses of those data – are insufficient. Other classic results may suffer from similar limitations. The present finding calls for the definition of powerful strategies for cognitive science research.

Probability Intervals and Sample Constraints

Patrik Hansson (patrik.hansson@psy.umu.se)
Department of Psychology, Umeå University
SE-901 87, Umeå, Sweden

Peter Juslin (peter.juslin@psyk.uu.se), Anders Winman (anders.winman@psyk.uu.se)
Department of Psychology, Uppsala University
SE-751 42, Uppsala, Sweden

The success of on agents realistic probability assessment for an unknown quantity are greatly enhanced if a pre-stated interval is evaluated, rather then produced by the same agent (Hansson, Winman and Juslin, 2004). In order to explain this *format dependence effect* we have developed what we call a *Naive Sampling Model* (here after NSM) (Juslin, Winman and Hansson, 2004).

The NSM assumes that a Subjective Probability Distribution for an unknown quantity is assessed by a retrieval of similar objects from memory which provide a sample distribution. This sample distribution is directly taken as an estimate of the corresponding population distribution. With interval production the sample dispersion is interpreted as an estimate of the population dispersion, with the fractiles in the distribution defining the upper and lower limit for the interval. Because of the fact that sample dispersion is a biased estimator of the population dispersion, failing to correct this bias (Kareev et al, 2002) leads to intervals that are too narrow, thereby producing overconfidence.

The current study tests the NSM with a special eye on sampling constrains. We manipulate how much knowledge (possibly sample size) that participants could use to make these inferences.

Experiment

The stimuli used in the current experiment were fictive income figures for 136 different companies. The companies were divided in to five different fictive regions (the regions were supposed to function as cues). Two conditions (13 participants in each) were used: one (4XTraining) where the participant trained on 4 x 136 trials, the other (2XTraining) where the participants trained on 2 x 136 trials. Feedback was given under the training phase. After going trough the training phase participants in both conditions completed a test phase consisting in making point estimates and producing intervals under three different confidence levels (50, 80 and 100%) regarding the income of the 136 companies.

Results and Discussion

Participants in the 4XTraining condition produced significantly more correct point estimates in the test phase than the participants in the 2XTraining condition ($t(24)=2.38$, $p=.03$). This indicated that they had received more knowledge (i. e. larger sample). Figure 1 (Left Panel): although the participants in the 2XTraining condition had learned less, they were not worse calibrated then those who participated in the 4XTraining condition. Both groups are overconfident in their interval productions. Monte Carlo simulation of the NSM on the same database used in the experiment showed that sample size (n) = 5 fitted the data best for both groups. One interpretation of these results is that the sample used to make these kinds of inferences is constrained by working memory limitations and that knowledge produced by the long-time summarizing of the complete sample of the observation experienced plays no part. One limitation with the model is that it does not predict the difference between the two conditions regarding the interval width (see Figure 1, Right Panel).

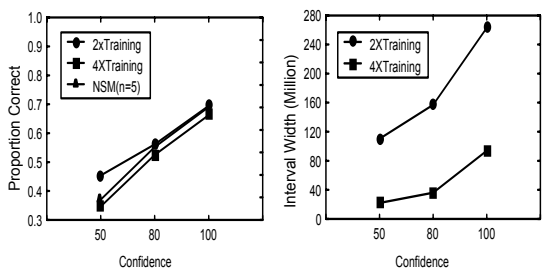

Figure 1: Left Panel: Mean proportion of correct values included in each confidence intervals in the two experimental conditions and the models performance with sample size (n) =5. Right Panel: Interval width (upper minus lower limit) for the produced interval by the participants in the two conditions

Analysis of Attention Networks and Analogical Reasoning in Children of Poverty

Ruby C Harris (rcharr02@louisville.edu)

Introduction

Researchers describe the development of analogical reasoning as a shift from similarity judgments based on simple perceptual feature comparisons to more complex reasoning based on common relational structures (Gentner, 1989). Given that this shift entails a selective focus on relational information, perhaps attentional development affects the development of analogy.

Recently attentional processes have been examined in terms of three networks of attention; orienting, alerting, and executive (Posner & Petersen, 1990). The executive network, an attentional control network required for the resolution of cognitive conflict, may be particularly important for analogical reasoning tasks. Recent research has shown that the same neurological pathways are activated in selective attention activities of the executive network and analogical reasoning (Duque & Posner, 2001; Luo, Perry, Peng, Jin, Xu, Ding, & Xu, 2003).

Children from low-income backgrounds have been shown to have impaired attentional and cognitive abilities (Norman & Breznitz, 1992). In the current study, individual differences in children's skills on the three attention networks are studied in order to understand the relationship between specific attentional processes and analogical reasoning in the context of poverty.

Methods

Participants were 78 children (Mean age = 56.88 mos, SD = 5.97) from low-income backgrounds. Children were assessed on computerized attention tasks designed to tap the three attention networks (Berger, Jones, Rothbart, & Posner, 2000) Analogical reasoning was assessed using the Matrices Subtest of the Kaufman Brief-Intelligence Test (Kaufman & Kaufman, 1990).

Results

Hierarchical regression was performed to predict analogical reasoning ability using median reaction time on the attention tasks. Controlling for cognitive ability, the overall model was significant, F (4, 72) = 4.091, $p < .005$. Performance on the executive attention task added a significant amount of variance (6.4%) to the model.

Discussion

The present study is unique in its examination of the relation between attention and analogical reasoning in the context of a high-risk environment. Future studies should examine how these findings relate to Halford's (1989) proposals about the impact of processing capacity on the development of analogy. Further, studies should examine how executive attention interacts with changes in domain knowledge to affect analogy task performance. The present results suggest that high functioning executive attention may be a protective factor in a high-risk environment.

Biological Limbic Systems: A Bottom-Up Model for Deliberative Action

Derek Harter (dharter@memphis.edu)
Department of Computer Science, University of Memphis
Memphis, TN 38152 USA

Evolution of Deliberative Actions

While bottom-up approaches to studying cognition have proved insightful in many ways, top-down approaches are still better at explaining deliberative cognitive processes. Deliberative actions are those that go beyond simple sensory-motor loops and seem to require some type of internal model, map or logical reasoning. Examples of deliberative actions include planning a route to navigate to a goal or performing a chain of logical inference to determine a likely course of action.

Bottom-up approaches such as Walter's tortoise (1951) and Braitenberg's vehicles (1984) are excellent models of how simple sensory-motor loops can combine to produce complex intentional behavior. Such behaviors are still mainly of the tropic type (e.g. phototropic, chemotropic), which rely on detecting and following some type of perceptual gradient in the environment. More recently, models such as Brook's (1990) subsumption architecture have shown us how collections of behavior patterns can combine in relatively flexible chains, in an emergent manner, to produce even more complex behaviors. Simple tropic behaviors are present in even the simplest of single celled organisms, while the more complex collection, chaining and combining of such sensory-motor behavior patterns appear with fish and insects.

Deliberative actions appear to require the development of more long-term memory mechanisms that allow for the storage of past experiences and for these experiences to be brought to bear on current situation. Evolutionarily, the development of the limbic system in simple vertebrates, such as amphibians, marks the first appearance of primitive hippocampal structures. The hippocampus plays the role of forming and remembering more long-term representations of experiences. It is known to participate in the formation of episodic memory, logical reasoning and cognitive maps (Dusek & Eichenbaum, 1997; Arbib, Érdi & Szentágothai, 1997). Building more deliberative systems in a bottom-up whole-system approach would therefore appear to potentially benefit from a more complete understanding of the biological limbic system.

K-IV: Basic Limbic System Model

The K-IV architecture is a model of what biologists believe may be the simplest neural architecture capable of basic intentional and deliberative actions, the limbic system (Kozma, Freeman & Érdi, 2003). The purpose of the K-IV is to model a complete autonomous organism, in a bottom-up manner, to understand better the neurodynamical mechanisms involved in intentional and deliberative behavior. The K-IV uses a neural population model (called K-sets) to describe the activity of large populations of neurons (as opposed to single unit or more abstract ANN models). It is a highly-recurrent multi-layer model of the important neurological structures of the basic limbic system.

We have been developing pieces of the K-IV for use as control mechanisms in autonomous vehicles for exploration and navigation problems for NASA. We have developed discrete simplifications of the K-set neural population models for use in such autonomous agent simulations (Harter & Kozma, submitted). In this work we will present some of our results on modeling and implementing pieces of the K-IV model, including how nonconvergent dynamics form perceptual categories (Harter & Kozma, in press) and how such dynamics may be used to learn and control behaviors in an autonomous agent (Harter & Kozma, 2004).

What Exactly Do Numbers Mean?

Yi Ting Huang (huang@wjh.harvard.edu)
Jesse Snedeker (snedeker@wjh.harvard.edu)
Elizabeth Spelke (spelke@wjh.harvard.edu)
Department of Psychology, Harvard University
33 Kirkland Street, Cambridge, MA 02138 USA

The correct semantics for number words has been a topic of much dispute in linguistics. This controversy bears directly on our understanding of the development of numerical concepts. The Neo-Gricean theory (Horn, 1989) posits that number words, like other scalar terms, possess a lower-bounded semantics and only receive exact interpretations pragmatically via scalar implicatures. For example, "two" would mean AT LEAST TWO and would only be interpreted as referring to exactly two entities because the speaker could use stronger terms such as "three" or "four" to refer to larger quantities. A second theory (Koenig, 1991) states that numbers have an exact semantics ("two" means EXACTLY TWO) that can generate both a set reading ("two" establishes numerosity of the set) and a distributed reading ("two" predicates the existence of two individuals of a given type). Situations that are compatible with the set readings of a number are also typically compatible with the distributed readings of all smaller numbers, leading to what appear to be lower-bounded interpretations of number words (e.g. if the number of fish in the bowl is four, then there are also three/two/one fish that are in the bowl). The salience of these distributed readings will depend heavily on the context in which the number word occurs. But critically the meaning of number words remains the same across contexts.

To test these theories we examined children's early interpretation of numbers words. Children acquire number words in a gradual and predictable sequence (Wynn, 1990) providing ample opportunity to test the initial semantics of each term. Previous research (Noveck, 2001) demonstrates that scalar implicatures appears relatively late in development. Therefore, if numbers are semantically lower bounded, we would expect to find evidence for this in children's interpretation prior to implicatures.

In Experiment 1, we presented 10 children (2;6 to 3;5) who have demonstrated knowledge of "two" but not "three" (i.e. "2-knowers") with a card displaying 1 fish and another with 3 fish and asked them to select the card with two fish. A similar procedure was repeated for 3-knowers (2;8 to 3;7) and 4-knowers (2;9 to 3;9) using their most recently acquired number. 2-knowers overwhelmingly chose the card with 3 fish, an interpretation that is consistent with lower-bounded semantics without implicatures. While these results support the Neo-Gricean account, two pieces of evidence lead us to refrain from that conclusion. First, according to an Exact Semantics account, 2-knowers in this task may assign "two" to mean EXACTLY TWO but simply select out a subset of two fish from a card with three fish using a distributive reading. Consistent with this idea, 7 out of 10 2-knowers pointed specifically to two fish on the three fish card. In addition, 4-knowers, who did not differ in age from 2-knowers, rejected both card choices, consistent with exact semantics.

In Experiment 2, we minimized the possibility of a distributive reading by pushing for the perception of stimuli as a bounded set. We also provided a way for children to demonstrate an exact interpretation without having to reject both choices. First, we taught 10 2-knowers (2;6 to 3;5) to find target animals that were located in uncovered or covered boxes. Then, in the test phase, we asked them to find the box with two fish when presented with uncovered boxes with one fish and three fish and a covered box (see figure 1). 2-knowers overwhelmingly selected the covered box, suggesting that they interpreted "two" as "exactly two" and inferred that this quantity must be in the covered box. A Neo-Gricean theory would have to provide an account for why children failed to select the visible option compatible with lower bounded semantics (3 fish) when they fail to show evidence of scalar implicatures for other terms until 7-9 years of age. The Exact Semantics account provides the most natural and parsimonious explanation of these results.

Introduction

Finding our way from place to place is essential to everyday functioning. Often, we rely on information from others to help us navigate. For example, people follow directions to get to unfamiliar destinations, such as airports and hospitals. One important goal is to determine the most effective way to give and follow directions.

What types of information are most effective? Previous research has focused on two common direction types: those using landmark descriptors (e.g., go toward the arena on Main St.) and those using cardinal descriptors (e.g., go east on Main St.). In general, landmarks are helpful naviagation tools. For instance, routes with landmarks are learned more quickly than routes without landmarks (e.g., Jansen-Osmann, 2002; McFadden, Elias, & Saucier, 2003; Saucier et al., 2002). Many studies have also examined the effects of gender on navigation (e.g., Lawton, 2001; Sholl, Acacio, Makar, & Leon, 2000). Findings have revealed gender differences in navigation tasks, with men often outperforming women.

The present experiment investigated whether landmarks or cardinal directions were more effective as navigation tools and whether there were gender differences in navigation efficiency using these cues. We predicted that people would navigate faster and more accurately when given cardinal directions than when given landmarks and that men might navigate more efficiently than women.

Method

Ninety-two undergraduate students (46 males, 46 females) participated for extra credit in psychology courses.

A fictitious model town (6 ft. 6 in. x 4 ft.) served as the experimental space. The town contained 17 landmarks marked by unique pictures and labels (e.g., hospital). The town also contained 30 streets marked by blue tape and street names (e.g., Memory Lane). Bound sets of note cards contained directions for navigation: one with landmark directions and another with cardinal directions. A toy car was used during navigation.

Participants were randomly assigned to either the landmark condition or the cardinal condition. Participants in the landmark condition received directions involving landmarks (e.g., go toward the arena on Main St.), whereas participants in the cardinal condition received directions involving cardinal descriptors (e.g., go east on Main St.). The routes were identical in both conditions; however, the descriptions differed based on condition. Routes started at a landmark, included four turns, and ended at a destination. The order of routes was counterbalanced across participants.

During the familiarization phase, the experimenter pointed out the four cardinal directions and the 17 landmarks. Then, participants were given 30 seconds to familiarize themselves with the town. On each trial, the experimenter placed the toy car at a starting location and said, "Go." Participants read a set of directions and moved the car so it followed the directions to the destination.

Navigation time was calculated by averaging the time for all 17 trials. The total number of errors was calculated by summing the errors for all 17 trials. Errors included reversing, making a wrong turn, ending at the wrong destination, and not finishing the route.

Results and Discussion

Our main objective was to examine how quickly and accurately men and women navigated based on cardinal and landmark directions. As predicted, participants were significantly faster and more accurate when following cardinal directions than when following landmark directions. In addition, men navigated significantly faster than did women. These findings generally support our predictions, providing valuable information about the processes by which men and women use landmarks and cardinal directions to navigate from here to there.

Background

The inverse base-rate effect (Medin & Edelson, 1988) is a paradoxical result in human category learning. It occurs, see Figure 1 left, after participants have been trained over a series of trials with corrective feedback to categorize pairs of features into high-frequency (C) and low-frequency (R) categories, where each category has a perfectly predictive feature (PC or PR) and a shared, imperfectly predictive feature (I). The term "inverse base-rate effect" reflects the fact that when tested with the conflicting cues together (PC+PR, Figure 1 left), participants non-normatively tend to respond with R despite its low frequency relative to C even though both cues are otherwise equally predictive of their categories.

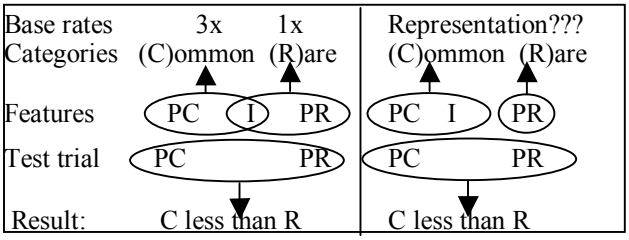

Figure 1: Left: Abstract category structure plus test trial (terminology from Kruschke, 1996). Right: Hypothesized asymmetric representation in relationship to the test trial.

Experiments

One of the most persistent theoretical explanations (e.g. Kruschke, 1996; Medin & Edelson, 1988) of the inverse base-rate effect is that the learned category representations are asymmetric, Figure 1 right, (for any of several reasons which we don't have space to describe) but that, based on similarity to this representation, the decision-making at test is normative. The purpose of our research was to evaluate whether asymmetric representation is a necessary and sufficient condition for the inverse base-rate effect in either a trial-by-trial category-learning task with corrective feedback or a purely decision-making task based on a single presentation of summary information: base-rate information together with feature-category relationships as specified in either the left or right hand sides of Figure 1, symmetric or asymmetric respectively. The four experimental conditions are in Table 1. Note that the results for the trial-by-trial learning of the symmetric structure are from Kruschke (1996).

Results

The results, see Table 1, for the pure decision-making task (N=33) on the summary information for the Symmetric structure indicate strong use of the explicitly presented base-rate information (C=0.94 > R=0.06) compared to the results from trial-by-trial learning of the Symmetric structure (C=0.35 < R=0.61). The results of trial-by-trial learning on the Asymmetric structure (N=16) show a significant inverse base-rate effect (C=0.27 < R=0.63) indicating that asymmetric representation in the context of the learning task is sufficient to produce an inverse-base rate effect. However, the results of the pure decision-making task on the Asymmetric summary information (N=33) show the absence of an inverse base-rate effect (C=0.58 > R=0.42). This indicates that asymmetric representation is not by itself sufficient to produce an inverse base-rate effect, possibly because the base-rate information is presented explicitly. Nevertheless, the fact that the results for the pure decision-making task on the Asymmetric structure are qualitatively closer to an inverse base-rate effect than the results for the Symmetric structure is consistent with Asymmetric representation being a necessary condition whose impact is overcome by the influence of the explicitly summarized frequency information.

In summary, asymmetric representation of the categories may be a necessary condition for the inverse base-rate effect, but it is not by itself a sufficient condition.

Table 1: (**C**)ommon and (**R**)are response proportions for perfectly conflicting cues (trials PC+PR) by task

	Task category structure			
Learning procedure	Symmetric		Asymmetric	
	C	**R**	**C**	**R**
Pure Decision Making	0.94	0.06	0.58	0.42
Trial-by-Trial Learning	0.35	0.61*	0.27	0.63

*Kruschke (1996) sum < 1 because of other possible responses.

Introduction and Background

If a knowledge representation and reasoning (KRR) system gains *new* information that, in hindsight, might have altered the outcome of an earlier belief change decision, the earlier decision should be re-examined. We call this operation *reconsideration* (Johnson & Shapiro, 2004), and the result is an optimal belief base regardless of the order of previous belief change operations. This is similar to how discussion in a jury room can help jurors to optimize their interpretation of the evidence in a trial, regardless of the order in which that evidence was presented.

To simplify our example, we assume a global decision function is used in the belief change operations, and it will favor retaining the most preferred beliefs as determined by a linear preference ordering ($\succeq$). Any base can be represented as a sequence of beliefs in order of decending preference: $B = p_1, p_2, \ldots, p_n$, where p_i is preferred over p_{i+1} ($p_i \succeq p_{i+1}$).

Reconsideration requires maintaining a set of all beliefs that have ever been in the belief base at any time (effectively, the union of all past and current bases), $B^{\cup}$. The base produced by reconsideration is defined as $B^{\cup}!$ where $!$ is a consolidation operation (which eliminates *any and all* inconsistencies) (Hansson, 1999).

A base, $B = p_1, p_2, \ldots, p_n$, is optimal if it has the most credible beliefs possible without raising an inconsistency: i.e. it is consistent and there is no $B' = q_1, q_2, \ldots, q_m$ s.t. $B' \subseteq B^{\cup}$, B' is consistent, and either $B \subset B'$ or $\exists q_i$ s.t $q_i \succeq p_i$ and $p_1, p_2, \ldots, p_{i-1} = q_1, q_2, \ldots, q_{i-1}$.

Dependency-Directed Reconsideration

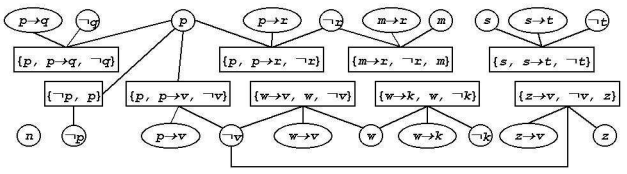

Figure 1: A graph showing the elements of $B^{\cup}$ (circles/ovals) of a KS connected to their minimally inconsistent sets (rectangles), where $B^{\cup} = \neg p, p, p \rightarrow q, p \rightarrow r, m \rightarrow r, s \rightarrow t, w \rightarrow v, w \rightarrow k, p \rightarrow v, z \rightarrow v, n, \neg q, \neg r, w, s, \neg v, m, z, \neg t, \neg k$.

Consider the base beliefs in Figure 1 *prior* to the addition of $\neg p$. The optimal base would be $B1 = \{p, p \rightarrow q, p \rightarrow r, m \rightarrow r, s \rightarrow t, w \rightarrow v, w \rightarrow k, p \rightarrow v, z \rightarrow v, n, w, s, m, z\}$, with $\neg q$, $\neg r$, $\neg v$, $\neg t$, and $\neg k$ removed. Adding $\neg p$ to $B1$ now forces the retraction of p. MOST SYSTEMS STOP HERE.

A literal implementation of reconsideration would examine *all* removed beliefs. Dependency-Directed Reconsideration (DDR), however, only reconsiders removed beliefs whose inconsistent sets have had *changes* in the belief status of their elements. It reconsiders these beliefs in decending order of preference, updating the base as it goes and maintaining a global priority queue of beliefs yet to be reconsidered. A removed belief can return as long as any inconsistency it raises is resolved through the removal of a *less preferred* belief.

As with a literal implementation of reconsideration, DDR first produces the following changes: (1) $\neg q$ returns to the base, and (2) $\neg r$ returns to the base with the simultaneous removal of m, because $\neg r \succ m$ (consistency maintenance). However, once DDR determines that $\neg v$ cannot return to the base (due to its being the culprit for the inconsistent set $\{w \rightarrow v, w, \neg v\}$), it would would prune off the examination of the inconsistent sets containing $\neg k$ and z. The inconsistent set containing s would also be ignored by DDR — it is not connected to p in any way. This latter case is representative of the possibly thousands of unrelated inconsistent sets for a typical belief base which *would* be checked during a literal $B^{\cup}!$ operation of reconsideration, but are ignored by DDR.

DDR is an anytime algorithm: if starting with a consistent base, a consistent base is always available, and the optimality of that base improves with increased execution time. Additionally, an interrupted DDR can be continued at a later time as long as the priority queue has been maintained. If run to completion, the base will be optimal (as with reconsideration) — thus, the KRR system can make the most reliable inferences, and belief change operation order will have no effect.

Beyond common features: The role of roles in determining similarity

Matt Jones (mattj@psy.utexas.edu) and Bradley C. Love (love@psy.utexas.edu)
Department of Psychology, The University of Texas at Austin. 1 University Station A8000; Austin, TX 78712 USA

A common assumption underlying most category learning research has been that category information is represented in terms of intrinsic properties or features (cf., Nosofsky, 1986; Shepard, Hovland, & Jenkins, 1961). However, recently there has been a growing awareness that many concepts are determined not by features but by the relationships between category members and members of other categories (Gentner & Kurtz, in press; Markman & Stilwell, 2001). For example, while a *game* cannot be defined in terms of features (Wittgenstein, 1968), it has a simple definition as something that can be *played* (Markman & Stilwell, 2001).

One intriguing implication of this idea is that relational information may be a central component of object representations (in addition to feature information), with objects playing the same roles in predicates or events being perceived as similar. For example, the concepts *hammer* and *baseball bat* might be similar because they both regularly hit other objects. A further question is whether similarity is affected by roles per se, or whether involvement in the same relationship is all that matters. For example, are hammers and baseballs similar because they both participate in the relation *hit*(*x*, *y*)? This is the prediction made by models of word learning such as LSA (Landauer & Dumais, 1997) that derive meaning from co-occurrence statistics. Because these corpus approaches are insensitive to the role an object plays in an utterance, they predict that similarity will be thematically determined, in that objects that participate in common relations will be similar regardless of the correspondence between their roles.

Method

The present experiment tests the potential contributions to similarity of roles and relations independently. In the first phase of the experiment, each subject read 16 atomic sentences and rated them according to how realistic and interesting they were. Certain nouns varied between subjects in the relations they participated in and the roles they played within their relations. The second phase consisted of a series of forced-choice similarity comparisons among these nouns, in which subjects selected which of two base words was most similar to a target word.

Results

The effect of common role was assessed using similarity comparisons in which one base word played the same role as the target and the other base played the opposite role in the same relation. For example, among subjects who read "The polar bear chases the seal" and "The collie chases the cat," 65% later selected *cat* over *collie* when asked which was more similar to *seal*. Among subjects who instead read "The seal chases the fish," only 29% chose *cat*. An analysis combining eight contrasts of this type showed a significant effect of common role ($\chi^2[1] = 64.8$, $p < 10^{-15}$) with 73% of subjects choosing the base that matched the target's role.

Tests for the effect of common relation involved comparisons in which one base word matched the target in relation but not in role, and the other base was involved in a different relation. The analysis showed a significant effect of common relation ($\chi^2[1] = 7.43$, $p < .01$) with 61% of subjects selecting the base that had appeared in the same relation as the target.

Discussion

The present results demonstrate that similarity is affected by relational information in at least two ways. First, participation in the same relation increases the similarity between objects, even if they play different (or opposite) roles. Second, people are sensitive to structure within relations, such that playing the same role further increases similarity. This structure-sensitivity implies that word learning models like LSA need to be modified to discriminate among sentential contexts, according to the role (e.g., agent vs. patient) played by the word in question.

These results also support the claim that the processes by which humans learn similarity and categories extend beyond the purely feature-based approaches currently assumed. Incorporating relational information into experiments and models will lead to a more encompassing theory that may shed light on many current unsolved problems.

Attentional shift within an object and between objects in 3D space

Tetsuko Kasai (tetsu@edu.hokudai.ac.jp)
Graduate School of Education, Hokkaido University, Sapporo 060-0811, Japan
Takatsune Kumada (t.kumada@aist.go.jp)
Institute for Human Science and Biomedical Engineering,
National Institute of Advanced Industrial Science and Technology, Tsukuba 305-8566, Japan

Introduction

Object-based attention can be indexed by an advantage of attentional shift along the same object relative to that across different objects in the pre-cuing paradigm (Egly, Rafal, & Driver, 1994). There are two accounts of the effect: within-object benefit (WOB) and between-object cost (BOC). The former is explained by prior covert scanning of a cued object (Shomstein & Yantis, 2002); the latter is by a switching cost from the cued object to the other (Lamy & Egeth, 2002). So far, these accounts are indistinguishable because the object-based attention effect is defined by relative difference in RTs between the within-object and between-object conditions. This study examined the WOB and BOC separately presenting stimuli in 3D space and showed that these can operate in different space/object coordinates respectively.

Methods

Subjects: Twelve healthy volunteers participated in Exp.1 (6 females, 19-25 years) and Exp.2 (5 females, 19-28 years).
Stimuli: Fig.1 shows stimuli presented stereoscopically, using shutter goggles (frame rate: 60 Hz per eye) with a viewing distance of 57 cm. A square (16°×16°) was overridden by a bar (17.4°×3.6°) with horizontal or vertical orientation located in back of (segmented condition), the same as (flat condition), or front of (completed condition) the square. All stimuli had crossed binocular disparity, 27.4', 13.7', 41.0', and 45.6' (Exp.1, near space) or uncrossed disparity, -27.4', - 41.0', -13.7', and -9.1' (Exp.2, far space) relative to the CRT display for the square, bar in back, bar in front, and fixation, respectively. **Procedure:** An experimental block of each condition consisted of 640 target-present trials and 128 catch trials. After presentation of the bar and square for 1,000 ms, the cue (flashed at one corner of the square) was superimposed for 100 ms. After another 200 ms, a target (dot diminishment) was superimposed at one of the corners until the subject responded. The intertrial interval was 1000 ms with blank screen. The task was to detect a target as rapidly and accurately as possible by pressing a key. On target-present trials, the target appeared at the cued corner on 75 % (valid cue) and at an uncued corner on 25 % (invalid cue).

Results and Discussion

Mean hit and FA rates were 95.9 % and 5.4 % in Exp.1, and 97.9 % and 3.2 % in Exp.2. Summary of RT results is shown in Table 1. RTs for valid trials were faster than for invalid trials, confirming pre-cueing effects. Attention shift (indexed by (invalid – valid)) were faster for the within-region than between-region conditions in the segmented condition, replicating a typical object-based attention effect. Comparing with the flat and completed conditions, the object-based effect was due to WOB in Exp. 1, but to BOC in Exp. 2.

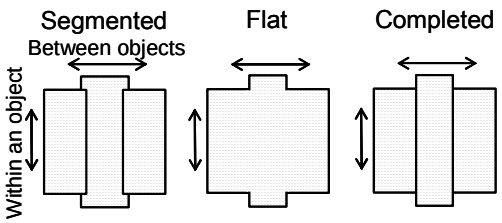

Fig.1 Schematic illustration of stimuli.

Table 1: Summary of mean RTs (ms).

	Valid	Invalid-Valid Within	Invalid-Valid Between	Object effect	WOB	BOC
Exp.1						
Segmented	300.8	3.4	12.9	9.5*	---	---
Flat	303.3	16.4	10.1	-6.3	13.0*	2.8
Completed	303.0	7.6	13.7	6.0	4.2	0.8
Exp.2						
Segmented	295.4	16.9	27.6	10.6*	---	---
Flat	293.4	17.5	20.0	2.5	0.6	7.6
Completed	297.6	17.0	19.7	2.7	0.1	7.9*

Note: WOB and BOC are shown for segmented display relative to flat and completed displays; * indicates significant effect ($p < 0.05$).

The present results showed separable mechanisms for WOB and BOC of attention. The benefit and cost may be associated with habits in different space regions (Previc, 1998): analyses of object shapes for action in near space associated with a WOB; search and orienting of objects in far space associated with a BOC. Different mechanisms to scan visual field can be driven according to stimulus context.

Introduction and Method

This experiment was designed to investigate the roles of interactivity and spatial visualization ability in the comprehension of 3D computer visualizations.

Undergraduates were presented with a fictitious anatomy-like structure in the form of both printed 2D images and a 3D computer visualization that could be rotated in *x*, *y* and *z* dimensions. A superimposed vertical or horizontal line on the printed images indicated where they should imagine the structure had been sliced. The task was to draw the cross-section at that point. The drawings were assessed for spatial understanding using a standardized scoring scheme.

Sixty participants were randomly allocated to one of two conditions. The *active* group was allowed to rotate the computer visualization at will via keyboard controls during the drawing task. The *passive* group had no control over the movements. Using a yoked pairs design, the manipulations performed by the active participants were recorded and later played back to the passive participants, so that both members of each pair received the same visual information.

Spatial ability was measured via the Mental Rotation Test (Vandenberg & Kuse, 1978) and a modified version of Guay's Visualization of Views test (Eliot & Smith, 1983).

Results

There was no main effect of condition, indicating no significant difference between the active and passive control conditions. However, a main effect of spatial ability was found (median split; F=9.38, p<.005; Figure 1). Although the interaction between these two factors did not reach significance, pairwise comparisons revealed that high- and low-spatial participants differed significantly in the passive condition (t=2.80, p<.01), but not in the active condition (t=1.47, p>.1; Figure 1). In line with this finding, the correlation between spatial ability and performance was relatively attenuated under active control (r=.29, p>.1), compared to passive viewing (r=.51, p<.005; Figure 2).

Discussion

The data indicate that having active control of the computer visualization did not benefit overall performance. A more important predictor of success was individual differences in spatial ability. However, the contribution of this factor was stronger in the passive condition than in the active condition, i.e. when participants were allowed to manipulate the 3D model, the performance means of high and low spatial individuals were brought closer together. While low-spatial participants were helped by interactivity, this benefit did not extend to high-spatial individuals. We are currently undertaking a replication study with a more intuitive control mechanism, to establish whether these findings arose from the nature of the interface or from interactivity *per se*.

Exploring the Bases of Causal Inferences

Say Young Kim (syk2@pitt.edu), Francisco J. Morales, & Erik D. Reichle (reichle@pitt.edu)
Learning Research and Development Center, University of Pittsburgh
3939 O'Hara St., Pittsburgh, PA 15260, USA

Myers, Shinjo, and Duffy's (1987) paradoxical results showed that the degree of causal relatedness affected the likelihood of participants making causal inferences: Whereas memory for the sentences exhibited an inverted-U shape function, with participants showing the best performance in the case of moderate relatedness, sentence reading times increased linearly as the degree of causal relatedness decreased. Although recent efforts to explain these results implicate causal relatedness as being important (Reichle & Mason, in press), the factors that mediate this causal relatedness remain under-specified.

In this paper, we report the results of an experiment that examined one variable that also affects perceived causal relatedness and the propensity to make inferences—the topicality of discourse. Kim, Cho, and Han (2002) showed that topicality (a global variable that reflects overall text coherence) affects how well a topic maintains continuity in a text. In the present experiment, we manipulated the topicality of short passages by augmenting the Myers et al. sentence pairs so that they were preceded by four sentences that either did or did not maintain continuity (i.e., weak vs. strong topicality, respectively). Our main objectives were to determine if topicality affects the likelihood of making interferences, and to determine if topicality modulates the perceived causal relatedness of the actual sentences that were used by Myers et al.

Method

Participants. Thirty-eight University of Pittsburgh undergraduate students participated for extra class credit.

Stimuli Materials. Thirty of the sentence "pairs" from Myers et al. (1987) was adapted for our study. Each "pair" consisted of an outcome sentence and a sentence preceding it that could be highly, moderately, or distantly related to the outcome sentence. Each sentence "pair" was preceded by four sentences that maintained a strong or weak topicality. (Topically was assessed through ratings collected in an earlier normative study.) Six filler stories similar to the test items were also included.

Design. There were six different versions of each story, with each version being defined by the factorial combination of two within-subjects variables: relatedness (highly vs. moderately vs. distantly) and topicality (strong vs. weak). Stories were counter-balanced across participates using a Latin Square design so that each participant read five stories from each of the six conditions, plus six fillers.

Procedure. Participants read the stories in a self-paced manner as they were displayed sentence-by-sentence on a computer monitor. After reading each story, participants judged the degree of relatedness between the last two sentences (which were re-displayed in isolation) using keys corresponding to a 7-point Likert scale. After reading all of the stories, participants completed a recognition task in which they viewed 45 sentences (30 story-final sentences and 15 distractors) that were displayed one-at-a-time. Four dependent measures were recorded: (1) sentence-reading times; (2) relatedness judgments; (3) recognition accuracy; and (4) recognition latencies.

Results & Conclusions

Nine participants failed to comply with task instructions and were excluded from our analyses; data from the remaining 29 participants were analyzed using within-subjects ANOVAs. The degree of causal relatedness affected sentence reading times [$F(2,56) = 7.39$, $p < .01$], with reading times increasing linearly with decreasing relatedness. Although topicality did not reliably affect reading times ($F < 1$), it did lead to differences in the perceived relatedness, as indicated by the relatedness judgments [$F(1, 28) = 17.82$, $p < .001$]. Importantly, the Relatedness × Topicality interaction was not significant ($F < 1$), suggesting that these two variables differentially influence initial sentence processing and perceived relatedness. This finding suggests that local (inter-sentence relatedness) and global (topicality) variables independently affect the likelihood of a reader making an inference during reading. Finally, although recognition accuracy was at ceiling and hence did not differ condition ($F < 1$), the reliable Relatedness × Topicality interaction in the recognition latencies [$F(2, 56) = 3.49$, $p < .05$] suggests these variables may contribute similarly to text memory.

Recency judgments and list context

Krystal A. Klein (krklein@indiana.edu)

Most memory experiments require participants to remember *what* events occurred, indirectly providing a measure of context availability. A more direct approach requires participants to remember *when* events occur. In Judgment of Recency (JOR) paradigms, participants study a list of stimuli and are asked to judge the recency of items from the list. In life, recency judgments can be made by associations to dates or autobiographical timelines. Although such cues are probably absent in list studies, participants can nonetheless make such judgments (Yntema & Trask, 1963), and the results can be used to make inferences about temporal context and its changes.

The current experiments utilize a study-test variant of the forced-choice judgment of comparative recency paradigm (Flexser & Bower, 1974). In each experiment, participants viewed lists of words on a computer monitor, and were subsequently tested in the following manner: two words from the list were presented, and participants indicated with a keystroke which word they had seen most recently.

A pilot study was completed in an attempt to obtain baseline data for JORs. Study lists were 90 items in length. Following the study phase, participants completed the forced-choice JOR for each of 20 pairs of words from the study list. Factors were lag (number of words studied between the two test items) and list type (fast or slow presentation time; each participant received one list of each type). Both factors were manipulated within-subjects. To our surprise, we found performance did not differ significantly from chance (50% accuracy) overall or in any of the individual experimental conditions.

Given that above chance performance had been found in earlier studies using a continuous study-test paradigm, we generated two hypotheses that might help explain this null result. First, the longest lag used in the study was 24 items, and context may change too slowly in a random word list without breaks for tests to allow above chance performance at short lags. Second, we had excluded the first ten and last ten study items from testing, in order to avoid any contamination by special strategies or effects due to primacy or recency. It could be that it is only during these parts of the list that context changes rapidly enough to allow for temporal discrimination.

Experiment 1 used longer lags (36) and compared performance between pairs in three conditions: those that contained one primacy item (primacy-middle), one recency item (middle-recency), or neither (middle-middle). Primacy and recency regions were set at length 12. The testing procedure was the same as in the pilot study. The longer lags did facilitate recency discrimination, illustrated by above-chance performance in the three conditions. However, the three conditions did not differ, even when the primacy and recency regions were limited to include only four items on each end of the list. These results suggest that while primacy and recency items receive a benefit in item encoding (as seen in recall), they do not receive better temporal encoding than other list items.

Because longer lags produced above chance performance, the hypothesis that context changes quite slowly during list presentation received some support. Nonetheless, the results seemed weaker than in earlier continuous study-test paradigms, leading us to ask what factors induce context change. In Experiment 2, participants studied a long list of items that was broken in half by the insertion of a 90-second task. There were four such tasks: 1) study of a list of faces; 2) a math task; 3), an old-new recognition test (on a subset of first-half items that would not be later tested for recency); 4) answering the following question (aimed to change internal context): "What would you do if you were invisible?" (Sahakyan & Kelley, 2002). For pairs containing one item from the first half (before the break) and one item from the second half (after the break), participants who received the recognition test performed best, followed by the 'invisible' answer condition. Performance in the face study and math problem conditions was not different from chance. These results are consistent with the idea that different tasks cause differential context change, and the pattern of results is consistent with certain puzzling results from standard memory paradigms (e.g., Shiffrin, 1970).

Osaka (2001) suggested that imitative words would be processed verbally and mimetic words would be processed visually. This study investigated whether visual or verbal second task would interfere with the processing of imitative or mimetic words. Our hypothesis was visual task would interfere with recognition of mimetic words, whereas verbal task interfere with recognition of imitative words.

Method

Experimental Design

The design used the reading span (high, low) as a between-participants variable, and the stimuli of memory task (figures, words) and the target word of sentence recognition task (imitative, mimetic) as within-participants variables. Dependent variables were reaction times and error rates for memory task and sentence recognition task.

Stimuli

Forty sentences including one imitative word and forty sentences including one mimetic word were used in sentence recognition task. In the half of the sentences, these sentences made sense and else did not make sense. In memory task, twenty combinations of three words or figures were used.

Participants

Participants were thirty-five female undergraduate students. All were Japanese native speakers and had normal or corrected vision.

Procedure

Reading Span Test. We measured each participant's working memory capacity by Japanese reading span test (Osaka, 2002).

Sentence Recognition Task and Memory Task. The fixation point was presented for 3000ms. After that, three figures or words were presented for 3000ms, so participants were required to memorize these stimuli. Participants answered whether the sentence presented after the figures or words could make sense as quickly and accurately as possible (sentence recognition). Three figures or words were presented again, participants answered whether these stimuli were presented previously by pressing allocated keys (memory task).

Results

Seventeen participants with a high reading span (more than six sets) and eighteen with a low reading span (less than five sets) were assigned to the high and low groups, respectively.

Recognition Task

The mean reaction times for correct responses were shown in Figure 1. Interaction between the target word (imitative, mimetic) and the stimuli of memory task (figures, words) were significant ($F [1, 33] = 7.85$, $p < .01$). Other main effects and interactions were not significant. About error rate, no main effect and interaction was significant.

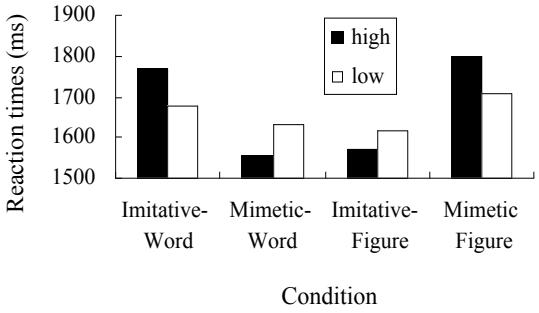

Figure 1: Reaction times for recognition of sentences (ms).

Memory Task

In word condition, reaction times for mimetic words were significantly longer than imitative words ($F [1, 33] = 4.75$; $p < .05$). In figure condition, error rate for imitative words were significantly higher than mimetic words ($F [1, 33] = 5.25$, $p < .05$).

Discussion

The results of sentence recognition task showed that verbal dual task interfered with the memory of imitative words and visual task interfered with the memory of mimetic words. These results support our hypothesis. The results of memory task suggested that there was a tradeoff between primary task and secondary task, however. The task switching between phonological loop and visuo-spatial sketchpad would affect these results. Working memory capacity did not related with performance of words' maintenance.

The relationship between Japanese spatial terms and visual factors in three- dimensional virtual space

Takatsugu KOJIMA (kojima@cpsy.mbox.media.kyoto-u.ac.jp)

Introduction

How spatial terms correspond to visual factors has been a topic of interest (e.g. Regier & Carlson, 2001). In particular, how a spatial term categorizes a space is an important problem (Hayward & Tarr, 1995). Most studies have considered a line as a prototype of a spatial term. In this view, some spatial terms have the same prototypical line. However, it is possible to choose an appropriate spatial term from similar spatial terms that are based on a line. Therefore, a spatial term also has a prototypical point on a prototypical line that distinguishes it from another spatial term, also categorized by a line (Kojima & Kusumi, 2002).

This study examined the prototypical points for three Japanese spatial terms categorized by a spatial line, which are recognized as differing from each other, by using a method of adjustment instead of rating tasks. We also examine the effects of visual factors on choosing a spatial term.

Method

In this experiment, we focused on three Japanese spatial terms, *mae* (front), *ushiro* (back), and *saki* (ahead), and three visual factors, the distance between objects, the height of the viewing point, and the position of the viewing point.

Forty-five Japanese graduate or undergraduate students participated in this experiment. They were divided into three groups of fifteen, and each group participated in each session.

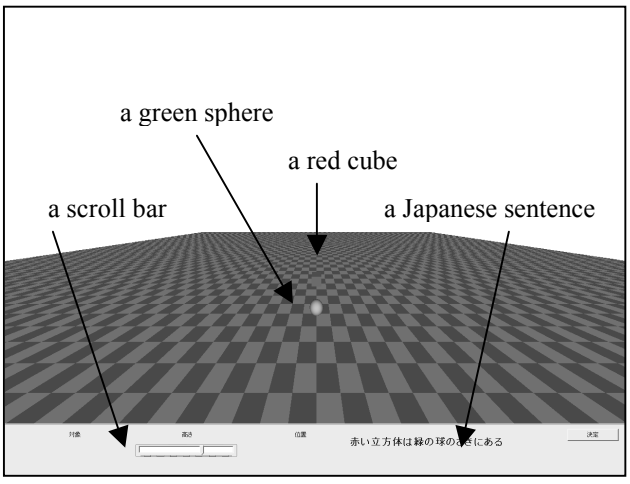

Fig.1. An example of a stimulus in the experiment

The experiment was run on a computer with a 17-inch monitor (Fig. 1) and consisted of one session for each of the three spatial terms. In any trial, only one of three scroll bars was shown and used to adjust a different factor: the distance between the green sphere and the red cube, or the height or the position of the viewing point. A Japanese sentence including a spatial term was presented in the lower part of the screen (*e.g.*, in English the sentence might be "A red cube is in front of a green sphere."). When the participant adjusted one factor, the coordinates of the other two factors remained fixed. Seven patterns were used in each session. The participants adjusted the pattern for each sentence.

Results and Discussion

The point of subjective equality (PSE) was computed from the data. The PSE values for each condition for the three spatial terms were analyzed using one-way ANOVA and Tukey's HSD. We found significant differences between all of the conditions: the position of the viewing point ($F(2,447)=54.06$, $p<.01$); the height of the viewing point in the near ($F(2,447)=92.28$, $p<.01$), middle ($F(2,447)=75.42$, $p<.01$), and far ($F(2,447)=48.27$, $p<.01$) distance conditions; and the difference in the distance between the green sphere and red cube in the near ($F(2,447)=58.22$, $p<.01$), middle ($F(2,447)=53.32$, $p<.01$), and far ($F(2,447)=68.75$, $p<.01$) distance conditions. Tukey's HSD indicated a significant difference between all but four of the conditions with respect to the spatial terms. The exceptions were the height in middle and far distance conditions, and the distance in middle and far distance conditions.

The result indicated that three visual factors affect the choice of spatial terms. It follows that humans can distinguish one spatial term from another, based on certain visual factors, even if the spatial terms are linked to a similar prototypical line in space. In addition, considering the values of the mean PSEs, it may be said that human beings choose an appropriate spatial term by differentiating visual differences accurately.

The effect of a character's emotional shift on narrative comprehension

Hidetsugu Komeda (komeda-h@xk9.so-net.ne.jp.ac.jp)
Takashi KUSUMI (kusumi@educ.kyoto-u.ac.jp)

Sakyo-ku, Kyoto 606-8501 Japan

While reading a story, readers feel happy when good things occur and worry when characters are in danger (Zwaan, 1999). When readers understand the narrative, they construct situation models (Kintsch, 1998). Situation models are multidimensional representations consisting of five dimensions: time, space, causation, intentionality, and the protagonist (Zwaan & Radvansky, 1998). Zwaan, Langston, & Graesser (1995) developed the event-indexing model to explain how readers construct coherent multidimensional representations of situations. According to the model, events and the actions of characters are important in situation model construction. Readers can represent and update characters' emotions (de Vega, Le'on, & Diaz, 1996). The present experiments focus on the effect of a character's emotion when people read a story in which a change in the character's emotion is induced.

Method

Participants. Thirty Japanese speakers were recruited at Kyoto University.

Materials. The materials were 16 stories (4 themes × 4 emotional states: worry-relief, relief-worry, worry-worry, and relief-relief). Emotional-shift versions were worry-relief and relief-worry. No-shift versions were worry-worry and relief-relief. There were 24 sentences in each story. Presentation of the versions of the stories was counterbalanced with a 4 × 4 Latin square. Each participant read four stories.

Procedure. Participants were instructed to read the stories in order to appreciate the story and sympathize with the characters. Stories were presented one sentence at a time on a CRT. Reading was self-paced; readers pressed the space bar to proceed. Reading time of each sentence was collected. After finishing each story, readers rated their emotional response to each on five 7-point scales (sympathy, similarity between the character and the reader, experience, interest in the theme, and readability of the story).

Results and Discussion

We performed multiple regression analyses of reading times to assess that reading times could be predicted by the temporal breaks, causal breaks, and a character's emotional shift. Table 1 presents the b-weights from the multiple regression analyses. As Table1 indicates, temporal discontinuities caused sentence reading times to increase, suggesting that the temporal dimension is crucial. The result is consistent with Zwaan, Magliano, & Graesser's (1995) study. A character's emotional shift also caused sentence reading times to increase. Words and serial positions have consistently been robust predictors of reading times (e.g., Zwaan et al., 1995). These current results indicate that readers monitor temporal continuity and represent a character's emotion. The multiple regression analyses suggested that a character's emotional shift caused sentence reading times to increase; therefore, readers monitored a character's emotional shift during the on-line reading process. We conclude that, when readers monitor the dimensions of the protagonist in an event-indexing model, emotions similar to those of that character are invoked.

Table 1 B-Weights

Variable	B-Weights
Temporal breaks	134.0*
Causal breaks	8.6
Emotional shifts	209.1*
Words	49.5***
Serial positions	-32.2***
R^2	.30

p < .05, ** p < .01, *** p < .001

Table 2 The difference of score in characters' emotional shifts (standard deviation) range: 1-7

Theme	Examination		Moving		Party		Marriage	
	S	N	S	N	S	N	S	N
1	4.7 (1.3)	4.5 (1.7)	4.1 (2.2)	2.9 (1.8)	3.4 (2.0)	4.3 (2.2)	1.6 (.96)	1.2 (.58)
2	4.0 (1.5)	4.4 (1.8)	4.7 (1.8)	4.1 (2.1)	5.1 (1.3)	5.1 (2.2)	2.5 (1.1)	2.9 (1.4)
3	5.7 (1.1)	5.4 (1.4)	5.6 (1.1)	5.5 (1.3)	5.9 (.89)	6.5 (.76)	4.8 (1.4)	3.9 (1.7)
4	4.5 (1.6)	4.0 (1.7)	5.6 (1.2)	4.0 (1.5)	4.0 (1.3)	5.1 (1.8)	4.9 (1.6)	3.9 (1.4)
5	3.9 (1.5)	4.2 (1.6)	5.3 (1.4)	4.0 (1.9)	3.7 (1.3)	4.6 (1.4)	4.7 (1.6)	4.2 (1.4)

Note. S: shift, N: no-shift

1: sympathy, 2: similar thinking and action to the character 3: experience, 4: the interest in the theme, 5: the readability of the story.

Table 2 displays the score differences in characters' emotional shifts. As Table2 reveals, interest in the story theme was higher in the shifting version than in the no-shift version, for the moving and the marriage story (t (28) =3.3, p =.003, t (28) = 1.9, p = .074). Interest in the theme was higher in the no-shift version than in the shifting version, for the party story (t (28) = -1.9, p =.069). The readability of the story was higher in the shifting version than in the no-shift version for the moving story (t (28) =2.1, p =.043). On the other hand, the readability of the story was higher in the no-shift version than in the shifting version for the party story (t (28) =-1.8, p =.078). Because the reader's experience was higher in the no-shift version than in the shifting version (t (28) =-2.1, p=.049), the party theme exhibited a pattern different from that of the other two themes. The present findings suggest that a character's emotional shift influences the reader's on-line and off-line processes.

When Coordination is Worth a Thousand Words: the Role of Gesture in Grounding

Meredyth Krych Appelbaum (krychm@mail.montclair.edu)
Joan Schultheiss (schultheisj1@mail.montclair.edu)
Julie Banzon (banzonj1@mail.montclair.edu)
Department of Psychology, Montclair State University
1 Normal Avenue, Montclair, NJ 07043 USA

Introduction

In most conversations, people rely on a process of grounding, in which people establish the mutual belief that they have been understood (Clark, 1996). While the majority of research on grounding has focused on speech in conversation, we examine the grounding process when people may coordinate only through gesture, compared to speech + gesture, and to speech-only conditions.

Grounding is fundamentally about coordination between people. Clark & Krych (2004) demonstrated how speaking and listening are incremental processes and how many of those increments are determined jointly—whether through speech or gesture.

In this study, our aim is to achieve a better understanding of the role of gestures and speech in communication and what gesturing alone can further inform us of the grounding process.

Lozano and Tversky (2003) have studied gestures and speech+gestures when people are videotaped assembling a TV cart for an undefined audience who would later view the videotape. In our research, we are interested in how two participants interact and coordinate with one another under different conditions.

While one might predict that not being allowed to talk with one another would be a disadvantage, resulting in more time to achieve understanding, we predict that the gesture-only and speech + gesture conditions should be equivalent in timing, while the speech-only condition should take significantly longer.

Methods

Pairs of students worked together as one participant, the director, instructed the other participant, the builder, how to create duplicate models of Lego blocks. Their goal was for the builder to create identical models as efficiently as possible based on the director's instructions. Each pair had a practice trial to orient them to the task and then constructed nine other models. The models used were the same as in Clark & Krych (2004) and Krych & Clark (1997).

Thirty-nine subject pairs participated in one of three separate conditions. Each condition consisted of 13 subject pairs who were all undergraduate students. In one condition, the director could see the builder's workspace and they could converse normally using both speech and gesture as they wished (speech + gesture). In a second condition, the builder's workspace was not visible to the director, so participants could only communicate with speech (speech-only). A third group of subject pairs participated in a gesture-only condition in which the workspace was visible to the director, but the subjects could not use any words at all. They could communicate only by gesturing to one another and pointing to objects.

Results and Discussion

As predicted, there was a large difference in the average amount of time to complete each model, $F(2, 36) = 27.64$, $p < .001$). The speech-only condition took much longer-- 181 seconds compared to 94.5 seconds in the Speech + Gesture condition and 112 seconds in the Gesture-only condition. The latter two conditions were statistically equivalent to one another. This pattern held true even if the practice trial was included. Thus, participants who were restricted to gesturing were not at a disadvantage compared to participants who could speak and gesture. These results appear consistent with the findings of Lozano and Tversky's non-interactive study (2003) that language and gesture can supplement as well as complement each other.

In the future, we plan to focus on the process of how people ground information in the gesture-only condition. We suggest that studying the process of grounding when people may only gesture to one another will shed further information on the underlying processes involved in achieving understanding in face-to-face conversation.

Acknowledgments

We would like to acknowledge Montclair State University for funding some of this research. We also thank Joanna Musial and Cecilia Sullivan for their dedicated work.

Adaptation Effects on Word Recognition Times: Evidence for Perceptual Representations

Christopher A. Kurby (ckurby@niu.edu)
Katja Wiemer-Hastings (Katja@niu.edu)
Department of Psychology, Northern Illinois University
DeKalb, IL 60115 USA

Abstract

We present evidence for the involvement of perceptual feature detector cells in the initial stages of processing lexically activated concept knowledge. Participants were slower to respond to names for oriented objects after being adapted to gratings of matching orientation, relative to opposite orientation. The data are consistent with the view that knowledge is perceptually based at a fundamental level, and inconsistent with alternative views that perceptual representations are generated at a later stage based on amodal representations.

Perceptual Representation: Adaptation Effects

The view that knowledge representations have a perceptual basis has been supported in a variety of methodological approaches. However, many of these studies may provide limited evidence for the importance of perceptual processing. Perceptually based aspects of knowledge may be generated in a later phase based on an initial, perhaps perception-unrelated representation, or they may be the knowledge that gets activated initially. Influential theories in this domain (e.g., Barsalou, 1999) assume the latter, and need to be tested accordingly.

With the goal to test whether perceptual representations are the foundation of knowledge processing as opposed to a by-product, we examined participants' response times to names for objects that had standard, vertical or horizontal orientations after exposing them to grating patterns that were in the same or opposing orientation as the object. When processing such grating patterns, specialized orientation detector neurons in the visual cortex become activated (Hubel & Wiesel, 1959). After certain exposure times, these neurons adapt, leading to lower sensitivity. We predicted that if access to a perceptual representation is by necessity part of accessing object concepts, response times to object names should be slowed down after adaptation of neurons that process critical object primitives (Treisman, 1986). Specifically, adaptation to matching orientations should slow responses relative to adaptation to the opposite orientation. In contrast, response times should be equal (or faster via priming) for matching grating patterns if such cells are not involved in initial processing.

Method

Twelve graduate students who volunteered to participate in the experiment viewed grating patterns for time durations that have been shown to create and maintain adaptation of the feature detectors for vertical and horizontal orientations. Subsequent to viewing patterns, they performed a lexical decision task on names for vertical vs. horizontal objects.

A set of items with standard vertical or horizontal orientations was rated with respect to variables that may influence perceptual processing, such as their height to width ratios and view invariance. These ratings served as covariates in the analyses.

Results & Discussion

Adaptation effects were observed for items with strong view invariance and high ratios. A 2 (grating orientation: vertical vs. horizontal) x 2 (word orientation: vertical vs. horizontal) repeated measures ANOVA revealed an interaction of grating orientation and word orientation on response time, which was slower when grating and object orientation matched (Table 1).

Table 1: Response Times per Syllable (in msec.)

	Grating	
Object	Vertical	Horizontal
Vertical	463.40	326.30
Horizontal	294.58	435.74

Conclusions

Our data suggest that perceptual representations are an integral part of knowledge activated during the initial processing of words for oriented objects. These data are consistent with the assumption that conceptual processing activates brain regions that are involved in processing of the actual related percepts. This finding lends stronger support to theories of perceptually based representations than other, related studies because the adaptation effects on response times are inconsistent with the view that perceptual representations are activated at a later stage and are merely by-products of a potentially amodal representation.

What drives learning by classification?

Kenneth J. Kurtz (kkurtz@binghamton.edu)
Department of Psychology, Binghamton University (SUNY)
P.O Box 6000, Binghamton, NY,13905 USA

Elizabeth Gonzalez (bj90475@binghamton.edu)
Department of Psychology, Binghamton University (SUNY),
P.O Box 6000, Binghamton, NY,13905 USA

The classification learning paradigm has been the dominant technique across decades for the study of categorization (Murphy, 2002). The learning procedure consists of passes through a set of training items presented one at a time in random order. On each trial, an example is displayed with a forced-choice classification question. Responding elicits corrective feedback followed by an inter-stimulus interval.

The goal of this research is to look inside the classification trial in order to identify the locus of learning. The roles of feedback and intentionality have been investigated elsewhere (e.g., Love, 2002). The factors addressed here are: 1) unlimited access to the stimulus during responding; 2) availability of the stimulus during feedback; and 3) generation of a classification response.

In the Init+During condition, the classification trial is executed in standard fashion except the stimulus is removed during feedback. This allows us to evaluate the importance of coordinated evaluation of the stimulus and the correct label at the end of the learning trial. In the Init+Final condition, each stimulus is presented for 3s and then removed when the classification question appears. After the response, the stimulus re-appears along with corrective feedback to allow coordinated evaluation. Speeded classification has been a topic of past research (e.g., Nosofsky & Palmeri, 1997), but the present question is about limiting access to the perceptual stimulus without any requirement of fast responding. In the Init-Only condition, we test the combined effect of limited initial access plus absence of the stimulus during feedback.

Finally, in the No-Response condition, each trial consists of presentation of the stimulus and its correct category. The learner observes the association and presses a button to continue. This allows us to address the common intuition that generating a response and evaluating success plays a critical role in classification learning. Many models of category learning operate on the basis of error correction between an output and a feedback signal.

In order to compare these conditions, three category prototypes were designed using 4x4 grids of half gray and half white squares. The training set consisted of 16 examples of each category generated by distorting the prototype with exactly two squares of reversed color. Participants (n=199) were randomly assigned to one of five conditions. The study phase consisted of a maximum of 192 trials. After every twelve trials, performance was evaluated against a 90% criterion for stopping learning. The test phase consisted of standard classification of all items.

Ease of learning was measured by percentage of participants reaching criterion and performance on the test phase common to all conditions. Impaired performance in any experimental condition relative to the control group would highlight a critical aspect of classification learning.

Approximately half of all learners reached criterion (11/12 correct). In the test phase, participants were well above chance (33%), though quite far from ceiling.

Table 1: Learning performance across conditions

Condition	% Ss reach criterion	% correct at test
Standard	54	69
Initial Only	40	63
Init+During	47	69
Init+Final	65	72
NoResponse	--	72

To our considerable surprise, none of the experimental conditions differed reliably from the control group on either measure. The only significant difference was between the Initial-Only and Initial+Final groups. This appears to be attributable to a slight disadvantage in the Init-Only condition combined with a slight advantage in the Init+Final. We draw the preliminary conclusion that none of the elements considered, i.e., extended evaluation of the stimulus during responding, coordinated evaluation during feedback, nor response generation can be considered critical components of classification learning. Learners are able to adapt fairly seamlessly in each case. These data suggest that as long as the learning trial includes the item and its label, the rest is more or less bells and whistles.

Representations in Simple Recurrent Networks Which are Always Compositional

David Landy (dlandy@indiana.edu)
Departments of Computer Science and Cognitive Science, Indiana University
107 S. Indiana Ave., Bloomington, IN 47405-7000

In classical cognitive models, representations of inputs are deliberately built into the operational structure by a model's designers. Network systems by contrast usually automatically construct responses following some generic learning scheme, and consequently lack overt representations altogether. Instead, the system's representations are read off the system according to a chosen analytical methodology. The performance of such models is therefore independent of how their representations are labeled.

Simple recurrent networks (SRNs) are among the most successful network models of cognition (Elman, 1990, 1995). These networks are often taken to represent inputs in the values of their hidden layer nodes, which can be analyzed using principal component analysis or hierarchical clustering. Under this interpretation, representations in networks are context-sensitive, static, and non-compositional. Significantly different properties result from taking as the representation of a sequence the function which that sequence causes the network to compute.

Consider a typical SRN with input weights W_{in}, output weights W_{out}, and recurrent connections in the hidden layer with weight matrix C, and call the vector of weights in the hidden layer H. Let S denote the closure of the set of legal inputs to the network under concatenation, so that S contains all legal sequences (and also an empty input, ε). Call the set of possible output vectors O, and call the function which maps input sequences to output vectors $i:S \rightarrow O$, so that $i(s)=o$ exactly when o is the output resulting from running sequence s through the network. Consider the following function:

$$r'(s,h) = \begin{cases} h & \text{if } s = \varepsilon \\ r'(u, Sigmoid(C \cdot h + W_{in} \cdot t) & \text{if } s = t.u \end{cases}$$

r' can be interpreted as the function which computes, for an initial value on the hidden layer, h, the value on the hidden layer which results after processing input sequence s. Define the family of functions which results from currying r' over s: $r_s(\vec{h}) = r'(s,\vec{h})$, $r_s \in R$. Then R is the representation scheme of the SRN. $i(s)$ can be easily reconstructed from r_s.

A straightforward homomorphism can be constructed between concatenation over S and function composition in R, making the representations of any SRN classically compositional, regardless of the prior training of the network (see Fodor & Lepore, 2002; Zadrozny, 1994). This analysis also reveals a limited form of inherent systematicity, in that the same representation function, and hence the same causal mechanism, is employed in processing a particular lexeme or sequence regardless of the context in which it appears (see Davies, 1991).

If the computation specified by r_s picks out a type of representation, then any particular application of that function can be taken to be a token. The computation performed is independent of its context, but the specific hidden layer value which results will not be. Therefore, tokens of computations can be picked out by specifying the input/output pair (where both input and output are hidden layer values) which that application involved. The method of hierarchical clustering which is so useful in analyzing hidden layer values can then be performed on this pair, and so this technique can be applied essentially unchanged. Additionally, the extra information stored in the source values allows the method to be applied to sequences as well as single inputs.

Since these representations are the system's disposition to respond to a particular lexeme, rather than the residue of state information which results from that response, these representations are active processes rather than static data structures. Since the important

Therefore, representations capture all of the knowledge which is involved in generating the internal state of the network.

Because the representation scheme given here appropriately encapsulates an SRN's knowledge and presents representations as dynamic processes rather than static structures, it is intuitively appealing as a model for how SRNs represent. Inasmuch as it is appealing, SRNs represent compound phrases compositionally and context-independently, which implies that these properties may not account for some of the interesting properties with which they have been credited (Fodor & Lepore, 2002).

Categories among Relations

Levi B. Larkey (larkey@mail.utexas.edu)

Introduction

Much research has been devoted to the way that categories are represented. Two of the most influential theories argue that concepts are represented by prototypes (e.g., Rosch & Mervis, 1975) or exemplars (e.g., Medin & Schaffer, 1978). While these views are typically analyzed in terms of their differences, they share the assumption that category coherence is a function of intrinsic features of category members.

In contrast, recent theories have proposed role-governed categories (Markman & Stilwell, 2001; Gentner & Kurtz, in press). Members of role-governed categories cohere because they fill similar roles within a relational structure. Role-governed categories differ from feature-based categories in that membership is determined according to external relations between categories rather than intrinsic features.

One reason for the prevalence of feature-based categories in the literature is that typical laboratory tasks are well matched with this type of category. The majority of categorization experiments employ artificial categories that are composed of entities isolated from any relational context. A critical problem with this approach is that it may not capture the essence of categorization outside of the laboratory; natural categories occur in relational contexts. We present an experiment that addresses whether artificial role-governed categories can be learned and manipulated in the lab.

Method

The experiment consisted of a learning phase and two transfer phases. Each trial, subjects were shown two objects that varied in size (big or small), color (blue or orange), shape (circle or square), and relational role (object that pushed or was pushed). After one of the objects was briefly highlighted, one of the objects moved across the screen and pushed the other object. In all phases, the task was to classify the highlighted object as type F or G. Subjects were given feedback in the learning phase, but not in the transfer phases. The learning phase lasted until subjects correctly classified 10 consecutive objects or 50 trials had been given. Each transfer phase was 10 trials. Taken together, the transfer phases were constructed to control for the presence of non-relational spatial and temporal cues.

There were two between-subjects conditions. In the first condition, categories were defined by a Shepard Type I rule (i.e., a unidimensional rule) involving a relational role and a redundant Type I rule involving a feature dimension (cf. Shepard, Hovland, & Jenkins, 1961). For example, an object could be classified as type F based on being a pusher or based on being blue. In the second condition, categories were defined by a Type I rule involving a relational role and a redundant Type II rule involving two feature dimensions. In the transfer phases of both conditions, the Type I rule involving the role was reversed such that subjects using the role would reverse their classifications while subjects using the features would not. In other words, the rule involving the role and the rule involving the features were deconfounded.

Results and discussion

In the Type I condition, 20 out of 39 subjects (51%) used the role, 11 (28%) used the feature, and 8 (21%) did not meet the learning criterion or could not be clearly classified. In the Type II condition, 28 out of 41 subjects (68%) used the role, 4 (10%) used the features, and 9 (22%) did not meet the learning criterion. In addition, subjects were more likely to use relational roles when the rule involving the features was more complex (51% for Type I versus 68% for Type II).

These data suggest that artificial role-governed categories can be learned and manipulated in the lab. The majority of subjects (51% in the first condition and 68% in the second condition) used relational roles to classify the objects. This manipulation sets the stage for a systematic set of laboratory studies to explore the acquisition of feature-based and role-governed categories.

Understanding and Modifying Procedural Versus Object-Oriented Programs: Where Does Domain Knowledge Help More?

Thomas LaToza (Student Member CSS) and Alex Kirlik (Member CSS)
Department of Psychology and the Beckman Institute
University of Illinois at Urbana-Champaign
<latoza, kirlik>@uiuc.edu

Software bugs are an ever-increasing societal problem as computers become more prevalent in our homes and workplaces, and programs grow in size and complexity. In response, many in the software engineering community have advocated a shift in the way programs are written: away from procedural (plan-like) code (e.g., Pascal, Fortran) and toward more declarative (map-like) Object-Oriented (OO) code (e.g., C++, Java). A central claim is that more declarative, map-like code allows developers to better deploy their knowledge of a problem domain (what the code is 'about') than does procedural code. The latter typically consists of a compact plan for solving a problem (such as a recipe or driving directions), rather than a more declarative description of domain entities and their relationships (OO). To test this claim, we conducted an experiment requiring experienced programmers presented with procedural and OO code *isomorphs* of the same algorithm to perform code modification tasks, and crossed this manipulation with whether or not participants were primed on the domain knowledge of the actual problem solved by the algorithm (scoring ten-pin bowling). In contrast to the claims of the OO community, our findings revealed that priming domain knowledge helped those modifying procedural, rather than OO, code: The procedural group whose knowledge of how bowling is scored was primed created significantly fewer bugs than the non-primed procedural group, while priming the OO group led to perhaps even slightly more bugs. This finding suggests that, when trying to modify or "tweak" problem solutions, knowledge of the problem domain is more important when trying to amend existing procedural solutions (e.g. a route given as a list of directions) than when trying to amend more descriptive, declarative solutions (e.g. a map to a destination). Implications for both software engineering and cognitive science will be presented.

Content with Causal Complexity

Daniel Hsi-wen Liu (hwliu@pu.edu.tw)
Division of Humanities, Providence University
200 Chung-Chi Rd, Shalu, Taichung County 433, Taiwan

Internal representation and causal relations have been generally taken as polemically contrasted in the cognitive architectures. Representation bears content; whereas, a causal line does not, which at best can be seen as its (the representation's) implementation. In discussing the nature of a certain type of low-level processes, such as those in the Watt Governor, that they are 'mere transition of forces' is taken as a reason to deny the existence of an immanent role of representation (Haselager *et al*. 2003). To think of it more sympathetically, causal complexity and content together can be seen as two separate strands to be reconciled (Wheeler and Clark 1999). The possibility of *content with causal complexity* has rarely been considered, as it is not easy to figure out a substantial sense of content bound intrinsically with the complexity of a causal line.

As an attempt, Bechtel (1999) argues that there is a legitimate sense of representation immanent in the control of the Watt Governor. The reason of its existence is grounded on the isomorphism between representation and the machine states. Such a reason, however, is challenged by Haselager *et al*. (2003) that it is risky to incur overwhelming representations. A problem facing a loose account of representation is "how a system can be shown not to be representational" (Haselager *et al*. 2003, p. 18). This paper will present a sense of content with causal complexity but avoid the aforementioned problem of overwhelming representations.

It is easy to understand that the content of intentional states *arises from* machinery with causal complexity, yet this is not the attempt of this paper. Alternatively, in this paper I will make clear the existence of a type of content that is immanent in the dynamic states of certain complex cognitive processes, with those states being possibly scattering across intentional states or spreading across a line of cognitive control. Such a special type of content can be named *dynamic content*.

Sub-symbolic Features with Complex Connections

Consider two examples of dynamic content. Firstly, units of the connectionist network represent certain sub-symbolic features, according to Smolensky (1988), which together represent intuitive cognitive content. Consider the role of sub-symbolic features in the representation of those units. Those features interact mutually under the connecting control of the connectionist network, with various weights in different between-units connections and certain algorithms controlling the activation of units. When the information transformation is in process, the network has not yet presented clear intentional (possibly conscious) content, but those sub-symbolic features really undergo transformation. That network, meanwhile, is by no means empty (though possibly unconscious) in its maintenance of cognitive features. The envisaged content, unlike the higher-level content manifested in the output layer, does not pertain to a cognitive state under a functional analysis. Rather, its nature causes it exist *in process*.

Motor Control

Secondly, motor control is the paradigmatic example of *dynamic content*. Dynamic content is conceived of as consisting of standing-ins of a system that serve as *guidance of that system's behavioral control*, and in turn as a way to supply the maintenance (with its causal power) of that system's performance in its environment with a certain degree of flexibility. Those standing-ins work systematically under a scheme which is non-isomorphic but can engage external conditions. Those standing-ins qualify the system as content-bearing because they enhance its capabilities of performance. The role of standing-ins in the constitution of content is to provide mediating entities for the systematic use in the course of behavioral generation.

A system's dynamic content *qua* content, as we can see, rests on the amenability of its behavioral guidance in the light of enhancing its performance. Because the amenability is a capacity of fine-tuning the causal connections of a system's complex behavioral control, dynamic content qualifies as content on grounds of its potentiality of amending complex causal connections.

The Hippocampus: Where a Cognitive Model meets Cognitive Neuroscience

Bradley C. Love (love@psy.utexas.edu) and Todd M. Gureckis (gureckis@love.psy.utexas.edu)
Department of Psychology, The University of Texas at Austin; 1 University Station A8000; Austin, TX 78712 USA

Models and Cognitive Neuroscience

The goal of the present work is explore possible mappings between an existing model from cognitive psychology and functional brain regions. There are numerous possible mappings between these somewhat different levels of analysis. For the the Supervised and Unsupervised STratified Incremental Network (SUSTAIN; Love, Medin, & Gureckis, 2004; Sakamoto & Love, in press) model, the mapping is straightforward: aspects of the model appear to map onto functional structures in the brain.

SUSTAIN holds that humans represent category information in terms of natural bundles of information, referred to as clusters. For example, knowledge of mammals might be represented by several clusters (e.g., primates, four-legged mammals, whales, bats, etc.). SUSTAIN posits that learners form new clusters in response to surprising events, such as when a child is first told that a whale is a mammal and not a fish.

In this poster, we will focus on SUSTAIN's cluster formation process. Our hypothesis is that a healthy and intact hippocampus is necessary for forming new clusters to support cortical learning in the temporal lobe (cf., Gluck & Myers, 1993). Forming new clusters can be seen as constructing conjunctive codes. A wide variety of tasks rely on the formation of conjunctive codes such as episodic memory (a conjunction of item and context), sequence memory (item and position), list discrimination (item and list), and item relations (item and item). All of these tasks appear to rely heavily on the hippocampus (see Brown and Aggleton, 2001, for a review). Assuming reduced ability to form new clusters, SUSTAIN has been able to model developmental trends in infant learning (hippocampus not fully developed) and performance by amnesiacs with hippocampal lesions (Gureckis & Love, 2003).

Rules and Exceptions: An Aging Study

Our account of hippocampal function predicts that normal aging will disproportionately affect performance for exception items in rule-plus-exception classification studies. To master an exception, a cluster must be recruited to encode it, despite the fact that similar clusters or conjunctive codes likely already exist in memory. As we age, an accumulation of cortisol released in response to stressful events differentially leads to atrophy and reduceas the functioning of the hippocampus (Lupien et al., 1998). In the study design, three items from category A and three items from category B followed a simple rule (e.g., if large, then category A. if small, then category B.). The exception items ran counter to these rules. SUSTAIN predicts that older adults will form one cluster for category A and B, leading to increasing rule application and insensitivity to old vs. novel rule-following items with increasing age. In contrast, SUSTAIN predicts younger adults will recruit one cluster for each exception, storing them apart from rule-following items, which leads to predictions counter to those of the older population.

Human Results

Thirty-seven University of Texas undergraduates and thirty-seven healthy older adults (51-84 years-old, mean=67.9) recruited from the Austin VA outpatient clinic participated in the study. All of SUSTAIN'S predictions held. Only a subset of results are reported here. In the learning phase, item type (rule vs. exception) and population interacted such that the younger population exhibited a smaller difference in accuracy (.27 vs. .61) for exception and rule-following items than did the older population, $F(1, 72) = 35.39$, MSe = 1.09, $p < .001$. For the older population, performance on rule-following and exception items for the learning and test phase negatively correlated (r=-.38 and -.72, respectively), whereas these correlations were positive for the younger population (r=.52 and .49, respectively). In transfer, subjects from the older population made rule consistent responses to studied rule-following items and all novel items at about the same rate, .70 vs. .69, $t < 1$, whereas the younger population applied the rule more frequently (.88 vs. .77) to the studied examples, $t(36) = 4.99$, $p < .001$.

Thinking With and Without Words: A New Model of Cognition, Language and Mind

Jack Lynch (jlynch2@comcast.net)
200 Lake View Avenue
Cambridge, MA 02138 USA

Viewing the mind as a sophisticated processor of analog signals rather than as a processor of symbolic information has led me to conclude that human intelligence emerged from nonhuman primate intelligence as a consequence, and only as a consequence, of the evolution of natural language. A nonhuman animal's primary cognition processes endow it with a sophisticated means of extracting useful features of its environment from the signals from its sensors, such as the eyes and ears, that enable, some species, flexible survival-enhancing and even innovative behavior.

The powerful primary cognitive system was greatly enhanced by the hominid and human species evolving natural syntactic speech—a two-tiered system of auditory communication. Meaningless sounds combine in restricted ways to produce words and words combine in restricted ways to form sentences. The secondary cognition system, also called the human reason system, not only allows the expression of internal representations of the primary cognitive system, it has created a new way of thinking that has resulted in a entirely new culture on the planet that has produced Shakespearian sonnets, jumbo jet aircraft, international corporations and a cure for infectious diseases.

This new model of cognition is presented in two books, *I am not a machine—Book I: Thinking without words* (Lynch, 2004) and *I am not a machine—Book II: Thinking with words* (Lynch, expected late in 2004) and is introduced on the website, NOTaMACHINE.org. Under the proposed model of cognition, there is no inner language of thought (mentalese), no formal computational rules and procedures underlying thought and no inner "engine of reason" that controls or guides our behavior or utterances.

This paper starts with a description of the primary cognition system upon which the new conceptualization of human intelligence rests. The first of four parts of the primary cognition model is a neural network pattern classification system (association). In addition, primates have a second-order pattern classification system (also called relational matching or tertiary cognition). This second-order process cannot be implemented by a feedforward neural network because the similarities to be noted are not in the patterns themselves but in the higher-order relationships in the patterns.

The second part of the model is a mental representation system that can be best understood by introducing a new term, *cogject* that labels how minds from hamsters to primates mentally represent physical objects, actions and events. A critical property of *cogjects* is that they are singular and affirmative—a dog cannot represent, *The cat is not on the mat*. Unlike the popular inner language of thought hypothesis, these internal representations are not more precise than natural language—they are much less precise than natural language. This primary representation system has evolved the capability to chunk perceptions and representations in appropriately sized "bins," so that a creature can gather statistical information of its world via neural network pattern classification processes.

The third part of the model includes the well-documented specialized core knowledge systems. Also known as a cognitive toolkit, this system includes know-how about objects, navigation skills and a number sense.

The fourth part of the primary cognition model is an action planning and evaluation system. An animal's next immediate motor control movements are planned by sequencing representations of action control signals, that is, *cogjects*, in a buffer. Evaluation of a planned action is by an additional pattern classification process that operates on the *cogject* contents of the action buffer. The result of the evaluation process is either a go-ahead or an abort response that is simply based on pattern classification. If an action is aborted, another action can be planned and perhaps also aborted, leaving a human observer to conjecture that the momentarily inactive animal is "thinking."

Human cognition is modeled by three systems, the primary cognition system just outlined, a language cognition system, and a secondary cognition or human reason system. Language cognition includes those cognitive processes that support natural language. I endorse the cognitive linguists' theory based on patterns and spaces rather than rules, procedures, symbols and formal systems.

The third human cognitive system called, "human reason," may be the least intuitive. Based on natural language, it establishes a new world of complexity by allowing us to create, name, describe, explain and communicate intricate concepts, procedures and theories. What can the human mind do with words? My answer is that we can tell stories, period. Human logic and truth are Greek myths that need comprehensive revision. Even the "truth" of science is a value we bestow on a story that has been corrected many times by many people who look for consistency with other stories (theoretical import) and consistency with their observations of the world (empirical import). Truth is based upon group consensus and is always subject to change and revision.

Human intelligence is built upon animal intelligence and natural language and not on a separate engine of reason.

A Model of Novel Compound Production

Dermot Lynott (dermot.lynott@ucd.ie)
&
Mark T. Keane (mark.keane@ucd.ie)
Department of Computer Science, University College Dublin, Belfield, Dublin 4, Ireland

PUNC: Producing and Understanding Novel Combinations

The PUNC model (Producing and Understanding Novel Combinations) is the first model to capture both production and comprehension aspects of conceptual combination within the same theoretical framework. The comprehension side of PUNC has been detailed elsewhere (see Lynott, Tagalakis & Keane, 2004), so here we give a brief overview of the production side of the model.

Lynott (2004) has proposed the Integrated Production and Comprehension (IPAC) Theory of conceptual combination. The IPAC theory seeks to describe the two sides of the conceptual combination coin, comprehension and production, within the same theoretical framework. Lynott draws together several factors that have been shown to influence both sides of conceptual combination in similar ways. Central to this view are the factors of Diagnosticity, Informativeness and Plausibility (inspired by earlier work by Costello & Keane, 2000). PUNC is a computational implementation of this theory, with the model taking as input short descriptions of novel entities (e.g., "a beetle that eats cacti" or "a prickly beetle") and, using the aforementioned factors, outputs candidate labels together with an overall acceptability score for each label. Below, we provide a brief description of the stages the model undergoes, from taking in an entity description to outputting candidate labels and assigning acceptability scores.

A description is input to PUNC (e.g., a beetle that eats cacti; a beetle that is prickly). Concepts are activated either by being explicitly mentioned in the description or through the description containing a feature that is diagnostic of another concept. So, the "is prickly" feature would also activate the concept *cactus*. Each of these concepts forms part of a set of candidate modifiers for the head concept (e.g., *beetle*). The individual concepts' features are then activated, prioritised by their diagnosticity. For example, for the concept *cactus* "is prickly" is more diagnostic than "can conserve water" and so has greater activation. These features are used to determine whether a modifier is informative with respect to the head concept as PUNC considers each candidate modifier in turn and whether it can form part of a valid, acceptable label for the entity being described. For example, *cactus beetle* is output as a valid label for the described entity since "is prickly" is a highly diagnostic feature of the concept *cactus* and this feature is also informative with respect to the head concept *beetle* (i.e., beetles are not by default prickly). Labels are considered informative if they incorporate some new information relative to the head concept. In this way, the informativeness of a label is a binary affair. A label such as "wood tree" meaning "a tree made from wood" would not be considered informative and so would be rejected as a possible label. As such, informativeness is a primary pragmatic constraint within the theory and model.

PUNC assigns overall acceptability scores to each of the candidate labels, based on the relative diagnosticity of the features used, the informativeness of the label and the plausibility of the relation that links the two concepts in the compound. For example, using a highly diagnostic feature of *cactus* to form a label contributes positively to the acceptability of a compound; if a less diagnostic feature had activated *cactus* the resultant score would be reduced.

Finally, the plausibility of the relation linking the head and modifier concepts contributes to the acceptability of the label. For the description "a beetle that eats cacti", the label *cactus beetle* would be considered highly plausible since there is a reciprocal "eats" relation between the concepts – beetles can eat things, and cacti, as vegetative matter can be eaten. On the other hand, *brick beetle* as a label for "a beetle that eats bricks" is considered less plausible as bricks are not usually considered edible.

Lynott (2004) has found that by using such pragmatic constraints in an integrated fashion PUNC not only reflects people's choice of label for novel entities, but its overall acceptability scores correlate highly with people's ratings of how good specific compounds are as labels for entity descriptions.

Integrating Planning, Creativity and Exploration in Motivational Agents

Luís Macedo (lmacedo@isec.pt)

Abstract

Although, planning and exploration of unknown environments has been previously addressed in multi-agent environments, we believe that in addition to these activities, agents may also benefit from exhibiting creativity so that they are able to imagine or invent new things (objects) that may be helpful or simply pleasant for the agents that inhabit the environment. Psychological and neuroscience research (e.g.: Damásio, 1994) over the past decades suggests that motivations (emotions, drives and other motivations) play a critical role in these activities that involve decision-making, and action, by influencing a variety of cognitive processes (e.g., attention, perception, planning, etc.).

We have developed a multi-agent environment (Macedo & Cardoso, 2004) in which, in addition to inanimate agents (objects), there are two main kinds of animate agents interacting in a simple way: the creators, whose main function is to create things (objects, events), and the explorers whose goal is to explore the environment, analyzing, studding and evaluating it. In spite of this classification, there are agents that may exhibit the two activities, exploration and creation. In addition to these two activities, animate agents are able to generate plans. Planning plays a central role in the reasoning/decision-making by supporting the other two activities: exploration and creativity. Actually, in our approach, creativity and exploration involve planning: when exploring the environment an agent has to plan a sequence of actions required to visit an unknown region or entity; when creating, an agent has to plan the sequence of actions required to come up with an original and valuable object.

The architecture of an agent includes the following modules: memory (for entities, plans, and maps of the environment), goals/intentions, desires, motivations (emotions, drives and other motivations), and reasoning/decision-making. The planner is the core of the deliberative reasoning/decision-making module. The agent uses a planner that combines the technique of decision-theoretic planning with the methology of HTN planning in order to deal with uncertain, dynamic large-scale real-world domains. Unlike in regular HTN planning, the planner can generate plans in domains where there is no complete domain theory by using cases of previously successful plans instead of methods for task decomposition. It generates a variant of a HTN - a kind of AND/OR tree of probabilistic conditional tasks - that expresses all the possible ways to decompose an initial task network. The expected utility of alternative plans is computed beforehand at the time of building the HTN and it is based on the expected positive and negative feelings that the agent feels if the plan is executed. Plans that are expected to elicit more positive feelings (happiness, surprise, etc.) and less negative feelings (e.g.: hunger) are assigned a higher expected utility.

When performing exploration, the aim of an agent is twofold: (i) acquisition of maps of the environment – metric maps – to be stored in memory and where the cells occupied by the entities that populate that environment are represented; (ii) construction of models of those entities. Exploration may be performed by single or multiple agents. Each agent autonomously generates goals for visiting unknown entities or regions of the environment (goals of kind *visitEntity* or *visitLoc*) and builds a HTN plan for each one. Goals and plans that are expected to cause more positive feelings and less negative feelings are preferred. Thus, each agent performs directed exploration using an action selection method based on the maximization of the intensity of positive feelings and minimization of negative ones. Relevant motivations for directing exploration are for instance curiosity, surprise and hunger. The exploration strategy for multiple agents relies on considering a team leader that, based on the information provided to it by the members of the team as they perform their single exploration, builds a joint metric map, a joint episodic memory and a joint plan in order to be shared by all the members of the team.

When performing creativity, an agent generates goals for the creation of novel, original and valuable entities (goals of kind *createObj*) and builds a plan for each one. Like in exploration, goals and plans that are expected to cause more positive feelings and less negative feelings are preferred. Motivations such as surprise and curiosity that capture variables such as novelty or unexpectedness, respectively, are hence important for creativity.

Word Order Effects in Conceptual Combination

Phil Maguire (phil.maguire@ucd.ie)
Arthur Cater (arthur.cater@ucd.ie)
Department of Computer Science, University College Dublin,
Belfield, Dublin 4, Ireland.

The combination of two existing words is a productive strategy used by speakers to convey new concepts and extend the limits of their vocabulary. In English compounds, the first word or modifier attaches further meaning to the second word or head, thus creating a reference to the intended concept. According to Gagné and Shoben's (1997) Competition Among Relations In Nominals (CARIN) theory, there is a fixed, relatively small taxonomy of standard relations that can be used to link the modifier and head noun concepts. According to this theory, the most available standard relation is the one most frequently used to interpret other compounds containing that same modifier. We investigated whether the alleged importance of the modifier in relation selection is due to the fact that it comes first or whether it can be attributed to the modifier's functional role. Accordingly, we conducted our study in French, a language in which the order of the nouns is the reverse of that in English.

Priming Experiment

We carried out two experiments using French noun-noun combinations which parallel a speeded sensibility study carried out by Gagné (2001). Gagné's study investigated the way in which recent exposure to a similar combination influences the processing of a subsequent combination. She found that when the prime and the target had the same head noun, there was no significant different in reaction times between cases where they shared the same relation and cases where they did not. However, when the modifier was the repeated constituent, primes that used the same relation were more effective than those that used a different relation. Gagné took this as evidence that the modifier is paramount in relation selection. We investigated whether the same effect would be apparent in a language in which the order of the constituent nouns was reversed.

No Evidence of Word Order Effects

As predicted by the CARIN theory, we found no influence of the prime's relation on reaction times when the prime and target shared the same head noun. However when the modifier was a shared constituent, reaction times were slower when the target was preceded by a combination with the same relation than when it was preceded by a combination with a different relation. Participants responded to targets following a same-relation prime 45ms quicker than they did to targets following a different-relation prime, $F_{subject}(2, 34) = 4.349$, $p < .05$; $F_{item}(2, 118) = 4.194$, $p < .05$. Hence *"ruisseau de montagne"* (mountain stream) was more effective than *"chaussures de montagne"* (mountain shoes) at priming *"glacier de montagne"* (mountain glacier) while *"sac de voyage"* (travel bag) and *"sac de cuir"* (leather bag) were equally effective at priming *"sac de sport"* (sports bag).

Table 1: Response Times for Same-Head Targets.

Prime			Target Response Time (ms)
Same Head	Same Modifier	Same Relation	
✓	×	✓	994
✓	×	×	999
×	×	NA	1153

Table 2: Response Times for Same-Modifier Targets.

Prime			Target Response Time (ms)
Same Head	Same Modifier	Same Relation	
✓	×	✓	998
✓	×	×	1043
×	×	NA	1062

Our results follow a similar pattern to those of Gagné (2001). They indicate that people's ability to select a relation that was used in a recently viewed combination is influenced by whether that combination shares the same modifier but not whether it shares the same head. Since these effects have been replicated in a language in which the order of the modifier and head are reversed, this suggests that modifiers and heads maintain the same role in the process of interpretation regardless of the order in which they are realized. Additionally, it appears as if relational information is predominantly associated with the modifier.

Introduction

The search for universally shared elements of word meaning can shed light on how human languages are shaped as well as on shared aspects of human cognition: Do any such elements arise from a universal appreciation of structure that exists in the world, from universal properties of human information processing, or from universal human needs, interests, and concerns? Likewise, understanding how and why languages diverge in their word meanings can reveal how languages evolve word meanings and how cognitive processes shape this evolution.

We studied naming patterns across three languages in the domain of human locomotion (walking, running, skipping, etc.). This domain is universally experienced and highly structured, and there is an independent biomechanical description of that structure. Any universality is not likely determined at the level of the sensory apparatus (cf. the much-studied domain of color). These features allow us to ask whether a shared perception of structure in the world provides a constraint on the development of word meanings.

Portions of this domain vary in their centrality to human experience: Walking and running are universally the primary gaits, whereas hopping, skipping, etc. are more peripheral. And languages differ in how manner of movement is lexically encoded. Some typically encode manner in the verb ("She ran out of the room" [the English pattern]); others more typically encode path in the verb and manner only optionally in an adverbial phrase ("She exited the room {optional: running} [the pattern of e.g., Romance languages]. These features allow us to ask whether centrality to human experience and differences in verb lexicalization patterns across languages influence the degree of shared meaning.

We predicted that: (a) Strong universality would be found in the central portions of this domain; all languages tested would have manner verbs closely equivalent to "walk" and "run" in English. (b) Greater diversity would be found in more peripheral parts of the domain. (c) Manner verb languages would show greater linguistic differentiation of the more peripheral parts of the domain than other languages.

Experiment 1

Monolingual native speakers of English, Spanish, and Japanese named 24 video clips of a student locomoting on a treadmill that varied systematically in speed and slope from low to high. Speakers of all three languages showed strong within-language agreement on names for clips and switched from one label to a different one at exactly the same points in the stimulus continuum -- points that corresponded to biomechanical discontinuities in the movements produced.

Experiment 2

Monolingual native speakers of English, Spanish, and Japanese named 36 video clips of a student locomoting on a static walkway. The student performed a range of examples of various biomechanically distinct gaits (e.g., several different versions each of walking, marching, and jumping). The central biomechanical distinction of walking vs. running was largely observed by speakers of all the languages. However, there were points of between-language disagreement on exemplars even here. The between-language disagreement for gaits more peripheral to human experience was greater, and speakers of English (a manner verb language) showed greater linguistic differentiation of the more peripheral gaits than did speakers of Spanish (a path verb language) and Japanese (a path-and-ground language).

Discussion

These results indicate that structure in the stimulus array provides a constraint on the cross-linguistic construction of meaning, but not an absolute one. Even in a strongly structured domain, some diversity in the meaning of terms can arise. The formulation of meaning is less constrained by stimulus structure in parts of the domain that are more peripheral to human experience, and independently existing typological differences in verb lexicalization patterns are a force that can contribute to diversity in meaning.

Effect of Presentation Style on Children's and Adults' Use of Data Characteristics

Amy M. Masnick (psyamm@hofstra.edu)

In two studies, we examined children's reasoning in the interpretation phase of an experiment: data were presented as results of a completed experiment, and participants were asked to draw conclusions based on the information they had available. We set up situations with minimal theoretical background information, to make the variation in data characteristics particularly salient.

Two of the most important ideas about data involve expectations about data distribution and expectations about the effect of sample size, and we used these variables as the focal variables in our study. We asked participants to draw conclusions about whether there was a difference between two sets of data and to explain their reasoning (Masnick & Morris, 2002).

In the current study, we wanted to explore how the style of presentation might influence children's and adults' conclusions. Presenting all of the data to be considered at one time could be difficult to process. In addition, the pairwise presentation of data could facilitate comparisons of pairs of data points instead of comparisons of the entire column of data. We used the some of the same datasets as in Masnick and Morris (2002) but presented information in a different format.

Method

Twenty-two third grade students, 29 sixth-grade students, and 50 undergraduate students participated in this study. All participants were shown a cover story describing two engineers testing sports balls. The engineers programmed robots to throw or kick balls a certain number of times to test if they were different. Participants were then presented with three datasets, in one of two conditions.

In the pairwise condition, participants saw data presented in two columns. First, they were shown one pair of data points, then two, four, and then six pairs. After each presentation, participants were asked if there was a difference between the two variables, how sure they were of this difference, and whether they thought the engineers should test the balls again.

In the column condition, participants saw six data points in one column, and one in the other column. They were asked the same questions as in the pairwise condition, and then were presented with additional data points in the second data column (1, 2, 4, and 6 data points at a time). This condition was included to see if reasoning changes when pairwise comparisons are less salient.

Results and Discussion

The results of this study replicated the major finding of Masnick and Morris (2002): Across all grade levels, there was a significant effect of sample size and level of data variation that affected students' sureness that the two columns of data were different.

In this study, participants were asked if they thought the engineers should test the balls again. There were no differences between conditions in the frequency of replies: with fewer data points, most participants wanted more data. When there were six pairs in each column, about 40% of participants still thought more data should be collected.

Participants' justifications for their reasoning were most frequently based on data characteristics such as sample size and the magnitude of differences. There were large age differences, with older participants more likely to name more characteristics. Participants in the column condition were more likely to comment on an outlier affecting their judgment. These participants also said that the inequality of the number of data points in each column was the main reason for wanting the engineers to test at least one ball again.

The findings from this study suggest that students pay attention to data characteristics as early as third grade, and are able to use this information in drawing conclusions. Further, the presentation style of the data affects reasoning about only a small subset of features, suggesting that students are responding not just to the demands of the task, but are interpreting data however they are presented.

How the Central System Works? It Uses Fast and Frugal Heuristics

Rui Mata (mata@mpib-berlin.mpg.de)
Max Planck Institute for Human Development
Lentzeallee 94, 14195 Berlin, Germany

There are two serious contestants as to how the mind works: the Modularity (MT; Fodor, 1983) and the Massive Modularity theses (MMT; Tooby & Cosmides, 1992). Both visions have been targets of criticism Decision making research suggests that one criticism faced by the MT can be overcome by assuming the central system relies heavily on simple heuristics. In this paper fast and frugal heuristics are presented. It is argued that fast and frugal heuristics are the unencapsulated solutions to the central system's potential computational tractability problem, thus supporting MT. Moreover, it is discussed how these heuristics are task-specific but not domain specific, thus undermining MMT.

Modularity vs. Massive Modularity

The MT (Fodor, 1983) is the thesis that the mind is made up of a few modular systems plus a domain-general, unencapsulated central system that serves higher-order functions, like decision-making. The MMT (Tooby & Cosmides, 1992) is the idea that the mind is like a Swiss Army knife, a collection of specialized tools designed to solve adaptive problems. MMT contrasts with MT in that it claims that central capacities can also be divided into domain-specific mechanisms. The two approaches are at opposing sides of a debate and yet they share concerns like computational tractability and domain-specificity. However, for MMT domain-specificity is non-negotiable at all levels. For MT unencapsulation of the central system is the non-negotiable item.

Both visions face challenges. MT faces the obvious criticism that an unencapsulated central system is prone to computational intractability problems. MMT has been criticized for being based on the unwarranted premise that domain-specific mechanisms outperform domain general ones in principle, and for not accounting for the holistic nature of human thinking (Fodor, 2000).

Fast and Frugal Heuristics

The idea that individuals have limited resources, such as time, money, and cognitive capacity, has lead some to propose that people often rely on simple but accurate, fast and frugal heuristics (Gigerenzer, Todd, & The ABC Research Group, 1999).

Different fast and frugal heuristics have been so far identified and tested, including the Take-the-Best and the Recognition heuristics for pair-comparison tasks, and the Quickest heuristic for estimation tasks. These heuristics have been proven to be accurate (i.e., providing more often right than wrong decisions), but also faster (i.e., requiring less computations) and more frugal (i.e., requiring less information) than more standard decision models like multiple regression. Moreover, fast and frugal heuristics are more robust than these latter models when cross-validation is concerned. The reason simple heuristics are so successful is they exploit the structure of decision environments. Importantly, it has been shown that people use such simple heuristics (for a review see Gigerenzer et al. 1999).

Unencapsulated, Domain-general Heuristics

Crucial to the argument exposed here is that simple heuristics can be conceptualized as decision devices which are both information- and processing-frugal without being encapsulated. The fact that they are not encapsulated supports MT. The fact that they are not domain-specific contradicts MMT. Let us evaluate these claims by considering one prototypical heuristic, TTB.

In order to arrive at a decision about which of two objects scores higher on a criterion TTB does the following: (1) it retrieves the cue values of the best predictive cue for that criterion from memory; (2) assesses if one object has a higher value on that cue than the other; (3) if the cue discriminates it chooses the object with the highest value, if the cue does not discriminate, TTB looks up the second best cue, and so forth, until it makes a decision. If no discriminating cues are available TTB guesses.

TTB is not encapsulated in the sense that it has access to all beliefs *in principle* (e.g., beliefs about the value of a cue). However, for TTB there is a limited set of beliefs that it needs to use to reach a decision. In sum, TTB makes decisions in a computationally tractable way not by being encapsulated but by having a stopping rule (i.e., stop search and decide after finding a discriminating cue).

TTB is task-specific because it can only be applied to pair-comparison tasks. However, TTB is domain general because it can be applied to any domain (e.g., social, food choice). Importantly, it has been shown that people use TTB across domains (see Gigerenzer et al. 1999).

From this perspective, one might be lead to think that the central system is but a collection of simple heuristics. However, we still need MT's concept of a central system that chooses between heuristics and reasons about which cues are the best and should therefore be considered first (see also Payne, Bettman, & Johnson, 1993).

The Levels of Processing influence the Mere Exposure Effect on Incidental Concept Formation

Ken MATSUDA (ken@p01.mbox.media.kyoto-u.ac.jp)
Takashi KUSUMI (kusumi@educ.kyoto-u.ac.jp)
Faculty of Education, Kyoto University
Sakyo-ku, Kyoto 606-8501 Japan

We investigated the effect of perceptual and semantic processing on concept and preference formation. Matsuda & Kusumi (2002, 2003) found three effects using a mere exposure (e.g., Zajonc, 1968) and concept formation paradigm (e.g., Barsalou et al., 1999). The first effect, concept formation by repeated exposure, is based on the event; the concept builds the prototype. The second, prototypical stimuli integrated dimension of each individual, are preferred if the value of that dimension is weighted. Finally, although formed concepts decrease cohesiveness as a function of interval, the prototype is retained.

In the present study, the learning condition was changed from intentional (Matsuda & Kusumi, 2002, 2003) to incidental learning. Category classification performance using incidental learning was found superior to performance based on intentional learning in Parkinson's disease patients (Reber & Squire, 1999). Because the typicality effect on learning by semantic processing is higher than that achieved with perceptual processing (Fujita & Shimizu, 1990), we also examined levels of processing (perceptual vs. semantic) as an independent variable.

Method

Design. A 3 (typicality of stimuli: high, medium and low) × 4 (exposure frequency: 0, 1, 3 and 5 times) × 2 (levels of processing: perceptual vs. semantic)× 2 (interval: 5 min vs. 2 weeks) design was used, with interval and levels of processing manipulated between participants, and typicality of stimuli and exposure frequency manipulated within participants.

Participants. Ninety-six Japanese university students participated in the experiment.

Material. Unfamiliar fish pictures based on Barsalou et al.(（1999) were used. The pictures were classified into types A and B. All stimuli consisted of 10 dimensions (D1-D10), and all stimuli shared D7-D10 dimensionality. Shared dimensions operated typically as independent variables. High-typical stimuli shared D3-D10, medium-typical stimuli shared D5-D10, and low-typical stimuli shared D7-D10. No-shared dimensions had a unique value. Within-distracters were unpresented prototypical stimuli that were integrated with the value of the same- exposure frequency condition. Between-distracters were non-presented stimuli integrated with A and B types.

Procedure. Participants studied unfamiliar fish pictures that consisted of 10 dimensions (0, 1, 3, 5 times incidentally), and classified the fish into two categories (A or B), based on perceptual (shape: round vs. slender) or semantic processing (nature: gentle vs. fierce). Each stimulus was successively displayed for 7 sec; response times were 2 sec, feedback times were 1 sec, and ISIs were 1 sec. After an interval (5 min or 2 weeks), the participants judged the typicality, familiarity, liking, prettiness, and nostalgia of each picture, using a nine-point scale, as well as indicating recognition of new and old items.

Results and Discussion

A. Typicality and Familiarity Judgment In the 5-min interval condition of the present stimuli, the main effects of stimuli typicality and exposure frequency were significant, but the main effects of levels of processing and interaction were not. In the 2-week condition, the effect of exposure frequency was not significant. The results suggested that interval effected a judgment criteria shift from episode to knowledge base. Based on analysis of the within-category distracters, the judged value was higher in the semantic processing condition than in the perceptual processing condition. The data suggest that semantic processing integrates each stimulus and, thus, promotes prototype formation. (Figure 1A).

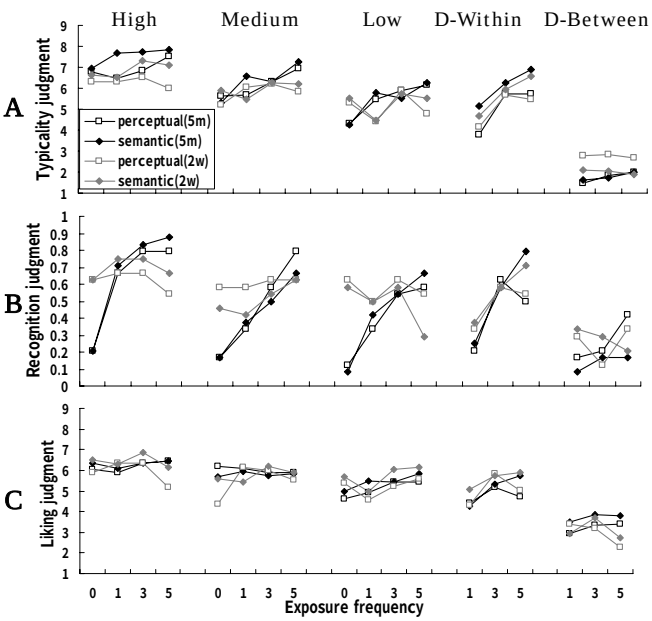

Figure 1 Typicality, Recognition, and Liking judgment scores

B. Nostalgia and Recognition Judgment The effect of exposure frequency on presented stimuli was significant in the 5-min condition but not in the 2-week condition. There was no effect of intention or levels of processing. Analyzing the data from the within-distracter condition revealed that recognition was higher in the semantic processing condition, which integrates high-frequency dimensions, than in the perceptual processing condition (Figure 1B).

C. Liking and Prettiness Judgment High-typical stimuli were preferred, and there was a significant effect of exposure frequency for the low-typical stimuli, as well as for intentional learning (Matsuda & Kusumi, 2002, 2003). There was no effect of levels of processing. The judged value of within-category distracters in the semantic processing condition was high, as compared to that in the perceptual processing condition (Figure 1C).

In conclusion, the effects of intention and levels of processing on judgments were weak. Furthermore, semantic processing in the study phase (compared with perceptual processing) enhanced typicality and affective judgments for the non-presented prototypical stimuli (within-category distracters).

Event-based Priming

Ken McRae (mcrae@uwo.ca)
Department of Psychology, University of Western Ontario
Social Science Centre, London, Ontario, N6A 5C2 Canada

Mary Hare (hare@rowan.bgsu.edu)
Department of Psychology, Bowling Green State University
Bowling Green, OH 43403-0228 USA

Several recent articles have emphasized event representations and their role in language processing. For example, Vu et al. (2003) used subject nouns such as *astronomer* versus *director* to promote a situation model that led to disambiguating the meaning of a sentence-final word such as *star*. They found that their manipulation was sufficient to activate selectively the dominant or subordinate meaning of the ambiguous noun. Ferretti, McRae, and Hatherell (2001) used short stimulus onset asynchrony priming to provide evidence that verbs denoting events quickly activate knowledge of typical aspects of those events (verbs primed typical agents, patients, and instruments). McRae et al. (2004) found that nouns denoting typical aspects of events activate verbs, thus suggesting that event knowledge is computed quickly via means other than the name of the event (i.e., a verb). The goal of the present study was to extend this research by testing for priming between nouns that denote events or typical aspects of them.

We used generation norms to select six groups of items. For event nouns such as *baptism*, subjects were asked to "List the types of people and/or animals that are typically found at these events." The norming produced 18 prime-target pairs such as *baptism-priest*. A separate norming study asked subjects to "List the types of things that are typically found at these events." This produced 26 event-thing pairs such as *trip-luggage*. For location nouns such as *tavern*, subjects were asked to "List the people and/or animals that you commonly see in/at each of these locations." This produced 24 items such as *tavern-bartender*. This norming also was conducted for locations and things, producing 30 items such as *garage-car*. Similar norming was also conducted with instrument nouns such as *wrench*. These norming studies produced 24 instrument-living thing pairs such as *wrench-plumber* and 24 event-thing pairs such as *key-door*. Care was taken to exclude event and instrument nouns that are often used as verbs, and to exclude prime-target pairs that form common phrases.

We hypothesized that if people's memory representations are shaped by their experiences with events, then common aspects of events should activate one another. In our priming task, the prime was presented visually for 200 ms, followed by a blank screen for 50 ms, and then the target word was presented until the subject responded. For the people/animals experiments, subjects decided as quickly and accurately as possible whether or not the target referred to a living thing. For the "thing" experiments, subjects decided whether or not the target referred to a concrete object.

There was a 32 ms priming effect for event-people/animal pairs (related: M = 590 ms; unrelated: M = 622 ms; $F_1(1, 18)=5.30$, $p < .05$, $F_2(1, 16) = 7.74$, $p <. 05$), and a 32 ms priming effect for event-thing pairs (related: M = 738 ms; unrelated: M = 771 ms; $F_1(1, 18) = 7.74$, $p < .05$, $F_2(1, 24) = 4.71$, $p < .05$). Both priming effects for locations were also significant: 37 ms for location-people/animals (related: M = 728 ms; unrelated: M = 765 ms; $F_1(1, 20) = 4.39$, $p < .05$, $F_2(1, 22) = 5.29$, $p < .05$); and 29 ms for location-things (related: M = 646 ms; unrelated: M = 675 ms; $F_1(1, 18) = 8.60$, $p < .01$, $F_2(1, 28) = 5.16$, $p < .05$). Finally, there was a significant 58 ms priming effect for instrument-things (related: M = 735 ms; unrelated: M = 793 ms; $F_1(1, 16) = 9.59$, $p < .01$, $F_2(1, 28) = 10.72$, $p < .01$), but a nonsignificant -10 ms effect for instrument-people (related: M = 766 ms; unrelated: M = 756 ms; both F's < 1).

The present study provides additional evidence that semantic memory is organized so that knowledge regarding various aspects of common events can be computed quickly from multiple types of linguistic cues, thus providing valuable information for interpreting language on-line and generating expectancies during language comprehension. As Sanford and Garrod (1981) have stated, "we use a linguistic input to call up representations of situations or events from long-term memory as soon as we have enough information to do so" (p. 115). The present studies, and other recent ones related to them, suggest that nouns that denote typical aspects of common events are often "enough information".

Two stages of visual feature binding: inside and outside the focus of attention

David Melcher (dmelcher@brookes.ac.uk)
Department of Psychology, Oxford Brookes University,
Oxford OX3 0BP, UK

Zoltán Vidnyánszky (vidnyanszky@ana.sote.hu)
Neurobiology Research Group, Hungarian Academy of Sciences
Semmelweis University, 1094 Budapest, Hungary

Despite of the fact that visual features are processed separately in specialized subsystems in the brain, our perceptual experience is of coherent objects. It has been suggested that visual attention acts as a "glue" to bind separate features–such as color, shape, size, motion, and location—into objects (Triesman & Gelade, 1980). This theory would suggest that features outside of visual attention remain unbound perceptually. We tested (1) whether binding occurs outside the focus of attention, and (2) whether feature binding was automatic or dependent on top-down attention to each feature individually. To determine whether two features were bound together, we probed whether paying attention to one feature (color) would also influence the processing of another, task-irrelevant feature (motion) of the same stimulus (cross-feature attention: CFA: Sohn et al., in press). These CFA effects were tested both within the focus of attention (focal attention) and outside the spatial location of attention (global attention).

Methods

The first test was to detect a luminance change in one of two colors of dots (red or green) clustered in one visual hemifield. After a beep, the subject was cued to pay attention to a cluster of dots in the opposite hemifield for a motion direction discrimination task. Unbeknownst to the subject, a brief (150 ms) sub-threshold motion prime was present in the unattended dots during the first (luminance) task (for details of the motion prime, see Melcher & Morrone, 2003). The use of a sub-threshold prime excluded the possibility that the motion signal was attended directly. The prime was presented either in same color of dots attended for the luminance task or in the other color.

In addition to this test of the influence of the prime outside the focus of attention, separate blocks were run in which the prime was in the same dots as those attended for the luminance task. In this case, only the dots in one hemifield were attended during the trial.

Results

We found that global CFA modulation outside the focus of attention spreads to spatiotemporally co-localized features, while inside the focus of attention CFA modulation spreads between all features belonging to the same surface or object. In other words, CFA effects outside the focus of attention were color-specific. An influence of the prime was found only when the prime dots were the same color as those attended in the opposite hemifield for the luminance test. When both tasks were in the same dots, however, the prime dots in the cluster always influenced the later motion test, suggesting that the entire cluster of dots was bound together as a surface.

Conclusions

These results suggest several implications for the role of attention in feature binding. First, these findings imply the existence of a binding mechanism at the local stages of visual processing that links spatiotemporally co-occurring features across the visual field, and that this mechanism is independent of attention. Secondly, these results support previous suggestions of another binding mechanism that acts at the level of coherent surfaces and links all features of the same surface (object-based attention: Duncan, 1984; O'Craven et al., 1999). Third, the CFA effects found here suggest that features are bound automatically, rather than depending on top-down attention to each feature separately. The use of the sub-threshold stimulus showed that attention influences visual processing even when the feature is below the level of conscious awareness.

The View Association Model of Embodiment Effects in Spatial Learning

Gareth E. Miles (GMiles@Glam.AC.UK)
School of Humanities, Law and Social Science, University of Glamorgan,
Pontypridd, S. Glamorgan, UK.

The View Association Model (VAM) is a novel account of how interacting with a spatial layout in different ways can lead to differing representation of the space. VAM provides an account of data demonstrating the learning of different spatial associations when the same layout is learnt through 3D Virtual navigation and 2D map navigation.

Embodied views of cognition suggest that representations of the environment can be understood by examining how they complement the perceptual-motor programs used to interact with the environment (Ballard et al., 1997). Inherent in this perspective is the suggestion that different environments will typically require different perceptual-motor programs that will in turn require different internal representations.

Miles & Howes (submitted) found that spatially close items became associated when participants learnt a space by navigating through it in a 3D Desktop Virtual Environment (DVE), but not when the space was a learnt by navigating a 2D map. The data presented by Miles & Howes suggest two questions. Firstly, what are the differences in the way the DVE and 2D map were learnt? Secondly, how do these differences lead to spatial association in the DVE condition, and its absence in the 2D Map condition? The View Association Model (VAM) attempts to explain these data and provide answers to both of these questions.

The View Association Model

VAM learns the locations of items in a space by learning the visual location of an item in a particular view of the space. A view is defined as a single static depiction of a space (or a portion of that space) from the viewer's perspective. In the plan view condition used by Miles & Howes participants only see a single view of the space. However in the DVE condition a large number of possible views of the environment are possible. A consequence of the views available in the DVE and 2D Map conditions is that different perceptual-motor programs are required for successful navigation.

Although, VAM moves around the DVE and Plan View in similar ways, the motor actions needed to facilitate movement are different. To move in the DVE VAM must point the direction of view toward the item it wishes to move to and press down the space bar. Subsequently VAM adjusts the direction of motion by moving the mouse. When VAM interacts with the 2D view a similar mode is adopted, but key presses are used to navigate. VAM presses a key to start moving in a desired direction and that key remains depressed until another key is preferred.

As VAM moves toward an item in both conditions a course correction algorithm is periodically engaged. VAM searches for the target item in the current view and then compares its current heading with the heading needed to get to the item. In the DVE it will then adjust the view so the target item is in the centre of the view (thus correcting the heading). When interacting with the 2D Map VAM will simply decide which key will move the red dot closest to the target item.

The algorithms used by VAM to move toward an item rely on bottom up processing to initiate course correction. The bottom up processing not only focuses attention on the target item but, by default, focuses attention periodically on other items that happen to appear in the current view. This occurs when VAM searches the current view for the target item, rejecting non-target items before it locates the target item. When attention is focused on these non-target items then there is a chance that VAM will elaborate the name of the item and an associative link will be formed between the item and the current goal item.

Crucially, only items that appear in view will be elaborated. Hence associative links will tend to form between items that appear in the same view. In Miles & Howes' 2D map condition all items are always in the same view. But in the DVE condition only subsets of items appear in any given view and typically items appearing in the same view will be proximal. Hence the interaction of the course correction algorithm and perceptual display lead VAM to predict the pattern of data observed by Miles & Howes.

Attentional Modulation of Lexical Effects in an Interactive Model of Speech Perception

Daniel Mirman (dmirman@andrew.cmu.edu)
James L. McClelland (jlm@cnbc.cmu.edu)
Lori L. Holt (lholt@andrew.cmu.edu)
Center for the Neural Basis of Cognition & Department of Psychology, Carnegie Mellon University

A number of studies have demonstrated that the strength of lexical effects on phoneme processing can be modulated by attention (e.g., Cutler et al., 1987; Eimas, Hornstein, & Payton, 1990; Vitevitch, 2003). The TRACE model (McClelland & Elman, 1986) posits direct feedback from lexical processing to phonemic processing, thus accounting for lexical influences on phoneme identification. However, the TRACE model lacks a mechanism for modulation of this feedback through attention. Some researchers (Norris, McQueen, & Cutler, 2000) have argued that this is a weakness of the interactive view of speech perception and is one reason to prefer an autonomous model.

We consider biased competition (Desimone & Duncan, 1995) as a possible attention mechanism that fits within the interactive framework of TRACE. In the context of TRACE, when an input is presented, phonemes that are partially consistent with the input compete through lateral inhibition. This competition is biased by lexical feedback proportional to the magnitude of lexical activation. Activation of lexical items is based on excitatory input from the phoneme layer and lateral inhibitory interactions among lexical items. The magnitude and rate at which lexical items become active can be manipulated by a scaling factor on the lexical units' response to input. This, in turn, influences the strength of lexical influences on phoneme perception. That is, task or stimulus conditions that cause participants to direct attention away from lexical processing may operate by causing a dampening of lexical layer activity and thereby reducing lexical biasing of phoneme processing. To implement this mechanism in TRACE, an attentional scaling parameter (α) was added to the function specifying the change in activation for lexical units for each processing cycle. When α=1.0, this is the standard TRACE model as implemented by McClelland and Elman (1986), when α<1.0, the lexical activation is dampened and lexical effects should be reduced.

This mechanism was tested in two cases of lexical effects on phoneme identification. Ambiguous phonemes tend to be perceived as lexically consistent (Ganong, 1980), but the strength of this effect varies with task and stimulus differences (see Pitt & Samuel, 1993, for review and meta-analysis). The attention parameter captured this variability. When lexical attention is high, lexical items become more active more quickly, thus providing stronger and earlier feedback to the phoneme level and biasing perception of the ambiguous acoustic input. When lexical attention is very low, lexical items become active more slowly, thus providing less feedback to the phoneme level and causing a small and late-developing lexical bias.

A second lexical effect on phoneme recognition is that phonemes are recognized more quickly in words than nonwords. This word advantage has also been shown to be affected by task and stimulus factors (e.g., Cutler et al., 1987). Variation of the attention parameter also captures this variability: at high α values, TRACE is faster to recognize phonemes that are embedded in words; at lower α values, the word advantage disappears. This is because lexical items are less active, thus they provide less support to their constituent phonemes.

The addition of a scaling parameter that dampens overall lexical layer activation provides a simple mechanism that works within the interactive framework of the TRACE model to modulate the strength of lexical influences on phoneme processing.

The aim of this research is to evaluate the extent to which Thesaurus allow us to modify a researcher's knowledge frame. A well calculated Thesaurus has the power to overwrite existent knowledge frames, or habitual "heuristics" for the humanities, if word occurrence data are rigorously manipulated by the algorithms of statistical linguistics. However, even if all targets and means of data gathering and analyzing are readily available, there remains behind various interpretations of subjects a sort of Frame question of how we partition off the texts and documents to avoid arbitrary text segmentation. Frames are needed before we can gather and interpret the data for a word occurrence computation.

If the problem of text segmentation remains unresolved, any experiment in quantitative text analysis will be still far from being realized. We need a sort of "TextTiling" methodology enabling an objective segmentation based on objective criteria.

This holds true for the frame setting in parallel and variant texts as the synoptic Gospels. We have to point out that the basic frame for Biblical research was taken from second hand data called the Parallel Synoptic Table (in abbreviation, PST), which shows the order and arrangement of the "pericopes" belonging to the Synoptic Gospels. The frame traditionally prepared was built only by a "Form Criticism", which divided the texts into parts by the arbitrary unities coming from tradition or reduction.

The purpose of the PST framework has been the resolution of the problem of "who quoted whom" in writing respectively the first three Gospels. However we propose an alternative and more objective way of segmenting the parallel texts by using our web-based biblical software, named "Tele-Synopsis", which is designed to gather information of the word usage under various conditions and to help further statistical approach to the origin of the variant texts. A quantitative analysis (factor analysis) is applied to the lexical datasets obtained by changing framing conditions in order to verify some traditional hypotheses made to explain the mutual relationship of the synoptic Gospels. Our framing principle is that the entire texts can be classified into the following 7 categories which are A: common part of the three Gospels, B: part common to Matthew and Mark, C: part common to Mark and Luke, D: part common to Matthew and Lukas, E: part peculiar to Matthew, F: part peculiar to Mark, G: part peculiar to Luke. It is natural that the category to which each instance of word has to belong for constructing a biblical Thesaurus varies according to the way in which we partition off the parallel texts. But the results of the factor analysis applied to the multiple datasets showed high robustness in the sense that the types of loading matrix are more or less similar *except* for the dataset depending on the traditional PST.

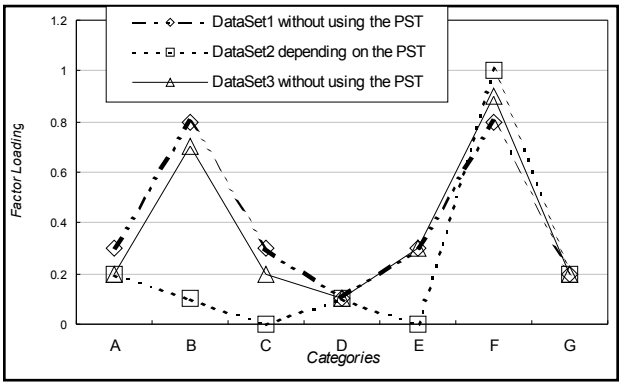

Figure 1: One of the factor patterns for the identical variables with different datasets.

Learning through verbalization (2): Understanding the concept of "schema"

Naomi Miyake, Hajime Shirouzu, & Yoshio Miyake ({nmiyake; shirouzu; ymiyake}@sccs.chukyo-u.ac.jp)
School of Computer and Cognitive Sciences, Chukyo University
101 Tokodate, Kaizu-Cho, Toyota, 470-0393 JAPAN

When one starts to learn a new topic, it is essential to understand the terminology, to the point where one can use them comfortably. For such learning, balance is required between concrete experiences and their abstract verbalization, but how to achieve the balance has not yet been studied systematically. In this report we compare three sets of learning activities to see the effects of the amount of concrete experiences and their verbalization on learning. While a short demo with high demand on abstraction does not yield significant verbalization, ample practices with reflection appear to solicit natural generalization.

Comparison of three classes

Three undergraduate classes were taught the concept of schema through structured activities around the "Day arithmetic" (Lindsay & Norman, 1977), where the students were to solve problems like

When Wednesday + Tuesday = Friday,
what is Tuesday + Friday?

The classes differed in the amount of practices of the problem, as well as in the types of verbalization required to summarize this experience. In Class 1, students solved three problems, while Class 2 solved 3 and then 20, and Class 3 solved 3, 72, 60, and 60 problems in chunks. This practice was followed by the question of what strategy they would choose to solve many Day arithmetic problems. After that, a transfer problem, "m+b=?" was posed. At the end of the unit, each class was asked to summarize their experiences. For the numbers of the students, see Table 2.

Amount of experiences and choice of strategies

Table 1 shows the students' choices of strategies to tackle many problems, either rote memorization of the answers, use of a table of answers, or of rules such as "to add a Monday, answer the next day of the addend." Rules are highly effective, but this fact was only graspable after a relatively many practices.

Table 1: Strategy choice

Class	No. of Trials	Strategy choice		
		Memory	Table	Rules
1	3	20.0%	70.0%	10.0%
2	23	16.2%	32.3%	51.5%
3	195	15.2%	15.2%	69.6%

Micro-generation of a schema

To the transfer problem of m+b, many students answer "o," paralleling this to the Day arithmetic. Some even extended its rule and solved this by just going down the alphabet two more letters from m, without counting. Both cases indicate that the students generate a schema-like understanding, applicable to a similar problem. Table 2 itemizes the ratio of types of this micro-generation. The success rate of the micro-generation of the schema is quite high, and sparing the practice time does not affect the generation pattern.

Table 2: Answer types of "m+b"

Class	Count-up	Transfer	No answer
1 (n=81)	50.6%	44.4%	4.9%
2 (n=71)	59.2%	38.0%	2.8%
3 (n=92)	63.0%	35.9%	0%

Abstraction at the end of the unit

At the end of this unit, the students were asked to summarize their experiences, in different instructions. The answers were categorized as "Concrete" when they only referred to specific examples and/or procedures; as "Moderate" when they referred to the strategies and effects; as. "High" when they included explicit comments on their commonality and/or generalizability. Class 1 students were asked to describe what kind of knowledge their rules were, which was too difficult to answer, particularly after a short demo. Class 2 students were encouraged to explain the Day arithmetic to their friends. Most students chose to stick to concrete procedures, ignoring the schemas. Contrastingly in Class 3, the students were asked to comment on the most important points of the unit. Possibly scaffolded by the ample amount of experiences as a base for reflection, this attempt was most successful among the three classes.

Table 3: Abstraction levels of summaries

	Ratio of answerers	Answer abstraction levels		
		High	Moderate	Concrete
1	23.4%	15.8%	42.1%	42.1%
2	91.5%	6.2%	1.7%	92.3%
3	100%	24.7%	25.9%	49.4%

The overall pattern indicates the importance of concrete experiences, as a basis for significant reflection. A short demo with highly abstracted explanation might appear to save time, but could impair the quality of learning.

Cognitive Style, Gender, Alignable Differences and Category Sorting

Marnie L. Moist (mmoist@francis.edu)

Introduction

Witkin et al. (2002) notes that field independents process analytically, whereas field dependents process globally. Markman and Genter (1993) define alignable differences (AD) as arising from an underlying commonality (e.g.,'one has more legs' arises from 'both have legs'). It follows that:

1) Field independents may produce fewer AD, sort more categories, and create less variable-sized categories than field dependents.
2) Cognitive style may interact with artificial stimulus sets, which vary in shared attributes (characteristics true of multiple category members). Specifically, the "mixed" set, the only one of the three sets allowing selective attention to vary between either "common" (i.e., majority shared) or "idiosyncratic" (i.e., minority shared) attributes, may elicit the largest difference in AD production between field independents and dependents.
3) There should be gender differences in cognitive styles (Witkin et al., 2002), number of categories sorted, and/or category size variability (Pettigrew, 1958).

Methods

Participants

87 (23M/64F) college students (98% Caucasian; M age = 19) from a Catholic school, participated for extra credit.

Materials

The Group Embedded Figures Test (GEFT) by Witkin et al. identified cognitive style. Nine stimulus sets, each with 20 artificial animal line drawings, allowed category sorting. Four "common" sets each consisted of 8 common attributes (e.g., "tail") with varying values (e.g., 'peacock') shared by 16/20 animals. One "mixed" set consisted of 8 common attributes; 4 shared by 16/20 and 4 shared by 4/20. Four "idiosyncratic" sets each consisted of 8 common attributes shared by 4/20 pairs. All sets were counterbalanced to ensure the same attributes/values were used across all sets. Response sheets were used to record category sort answers and the first difference noticed for each of 20 animal pairs.

Design and Procedure

All individually tested participants were randomly assigned one ordered stack of 20 animals, which they sorted into as many categories as they wanted. Then they listed the first difference they noticed for the same 20 animal pairs, followed by a second, identical category sort task with the same 20 animals. Finally, all were timed and scored on the GEFT test as instructed by Witken et al.

Results and Discussion

GEFT inter-rater reliability was 99%; AD reliability was 95%. *Hypothesis 1*: A multiple regression analysis (see Table 1) predicting AD, model $F(4,71) = 4.30$, adj.$R^2 = .15$, $p = .004$, showed that alignable differences decreased as field independence increased and as animal pairs became more different from each other (i.e., shared fewer attributes). A simple correlation, $r(74) = -.31$, $p = .003$, showed that as field independence increased, the sorted category size variability at Time 2 decreased.

Table 1: Multiple regression on alignable differences (AD).

Four I.V.s	Stand. *B*	*SE*	*p*-value
GEFT scores	**-.31**	.01	**.009**
Categ. sorted Time 2	+.06	.01	.608
Stimulus Set	**-.26**	.04	**.021**
Categ. variab. Time 2	-.18	.03	.156

Note: 11 participants' data were removed here due to uncorrected vision.

Hypothesis 2: There was no cognitive style X stimulus set interaction, though a corrected confound and more equal numbers tested per condition may change this in the future. *Hypothesis 3*: An unequal variance independent t-test, $t(55) = 2.32$, $p = .024$, showed that females ($M = 6.20$, $SD = 2.3$) sorted more categories at Time 1 than males ($M = 5.17$, $SD = 1.61$). However, for the Time 2 category sort, a 2-way ANOVA, $F(5,81) = 2.46$, $p = .04$, showed a significant gender X stimulus set interaction, $F(2,81) = 4.88$, $p = .01$. Females ($M = 7.59$, $SD = .48$) sorted more categories for "common" stimuli than males ($M = 5.20$, $SD = .78$), but males ($M = 7.63$, $SD = .88$) sorted more categories for "idiosyncratic" stimuli than females ($M = 5.78$, $SD = .58$). No gender differences in cognitive styles or sorted category size variability occurred.

Very Brief Interruptions Result in Resumption Cost

Christopher A. Monk (cmonk@gmu.edu)

Washington, DC 20375 USA

Introduction

Recent research suggests that the disruptive effects of interruptions arise from decay of the activation associated with the primary goal while attending to the interrupting task (Altmann & Trafton, 2002; Monk, Boehm-Davis, & Trafton, in press; Trafton et al., 2003). This disruption is seen in the additional time required to resume a task after it has been interrupted; that is, in the reaction time (RT) from the onset of a display after an interruption until the first keypress is made (this RT is called the *resumption lag*). The purpose of this study was to test this interpretation by looking at the resumption costs associated with very brief interruptions, where the model predicts minimal goal decay.

Method

Twelve undergraduates from the George Mason University psychology subject pool participated for course credit. The experiment was a single factor within-subjects design with three interruption lengths (1/4 s, 1 s, and 5 s) and an uninterrupted condition. The dependent measure was the post-interruption *resumption lag*, which was the reaction time from the onset of the VCR display (after an interruption) to the first click on a VCR button.

The primary task was to program a simulated VCR, which consisted of four subtasks: entering the show's start-time, end-time, day of week, and channel number. The screen was blank during the interruptions (there was no task) and the participant was required to wait until the VCR was displayed again before resuming the programming task. The target information was posted next to the monitor on a 3x5-index card at all times.

The experimenter trained the participants through demonstration and practice of uninterrupted and interrupted trials. Each participant completed 20 experimental trials (five trials for each of four conditions). For each interruption trial, participants began with the VCR task and were interrupted every five seconds until the VCR program entry was completed.

Results and Discussion

The time between keypresses (*lag*) was measured every five seconds in the uninterrupted condition to provide a baseline comparison for the resumption lags in the interruption conditions. Figure 1 shows the mean resumption lags and confirms a significant main effect of interruption condition, $F(3, 33) = 48.88$, $p < .001$, $MSE = 7{,}190$. Paired comparisons showed that the 5-second interruption condition ($M = 1115$ ms, $SD = 129$) took significantly longer than the other three conditions, and the uninterrupted condition ($M = 706$ ms, $SD = 80$) was significantly shorter than each of the interrupted conditions. The resumption lags for the 1/4 s ($M = 974$ ms, $SD = 79$) and 1 s conditions ($M = 974$ ms, $SD = 107$) were not reliably different.

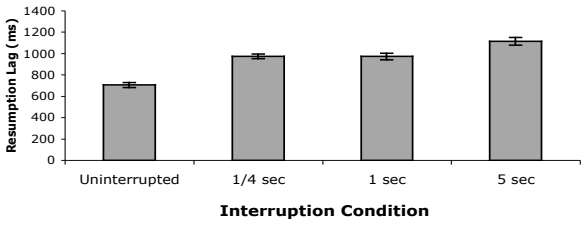

Figure 1. Mean resumption lags.

The difference between the interrupted and uninterrupted conditions confirms the prediction from the goal-activation model (Altmann & Trafton, 2002). Further, the presence of a resumption cost for both the 1/4 s and 1 s interruption conditions shows that goals decay quite rapidly. Even for the briefest interruptions, there is a penalty to be paid when resuming the primary task.

Evidence for Multiple Strategy Use Within a Single Logic Problem

Bradley J. Morris (morrisb@gvsu.edu)
Grand Valley State University
One Campus Drive, Allendale MI, 49506

Christian D. Schunn (schunn@pitt.edu)
Learning Research and Development Center, University of Pittsburgh
3939 O'Hara St., Pittsburgh, PA 15260 USA

When solving a logic problem, do reasoners use a single processing step or do they use a series of steps? Further, are these steps derived from the same inferential mechanism or different inferential mechanisms? Traditional models of logical reasoning posit a single solution using one mechanism (e.g., rules, models). A modification of this model, the dual processing model, suggests that logical inferences are the result of a competition between two different mechanisms. Though there are two mechanisms, a single inferential step is executed based on a decision between two candidate solutions. A third possibility, the Logical Strategy Model (LSM), suggests that logical reasoning makes use of more than one inferential step making use of a variety of inferential mechanisms (i.e., strategies).

The LSM predicts that reasoners use strategies based on task demands such as believability. For example, given familiar content, a reasoner will likely use a knowledge-based heuristic. Reasoners may use multiple strategies at different points within a single problem. For example, reasoners might (1) begin with one strategy and shift to another strategy or (2) begin using one strategy and revise their approach using the same strategy. In either case, reasoners would be using a dynamic process in which they may begin with a strategy and change their approach based on changing problem factors and goal states (see Epstien, 1994). To examine this, we performed a verbal protocol study of a series of logical syllogisms.

Method

Subjects. Five University students were recruited from Introductory Psychology courses.
Materials. A series of 32 logical syllogisms were created varying the following dimensions: Abstract v. Concrete, Unfamiliar v. Familiar, Valid v Invalid X True v. False.
Procedure. Subjects were asked to "think-aloud" as they solved 32 syllogisms. As a warm-up, subjects were given a series of multiplication and word scramble problems to practice the verbal protocol.
Coding. Once completed, the session was transcribed. The resulting protocol was coded for strategy use. Strategy use was coded by matching elements of subject discourse to salient elements of proposed strategies. For example, a Token-Based strategy involves the creation (and search) of models derived from premises (e.g., "Some X are Y, so some X are not Y"). A Knowledge-Based strategy derives inferences from a match between problem elements and current knowledge (e.g., "It's not true that some fish have legs so this is false"). Finally, each problem was coded for cues indicating a change in current strategy (e.g., "that can't be right").

Results

All subjects used more than one strategy on a single problem, most (4/5) for each problem type. Subjects were most likely to use multiple strategies when validity and truth or falsity of the conclusion was in conflict (Valid & False, Invalid & True, see Table 1). In these cases, subjects were likely to re-examine their initial conclusion by using a new strategy than by using the same strategy in light of new information (i.e., a putative conclusion). Table 1 also reports whether the second strategy used was the same or a different than the initial strategy. The results indicate that reasoners commonly use multiple strategies in a single problem and that the type of strategies used can be predicted on the basis of task demands.

Table 1- Strategy use by problem type

Problem Type	Mean Number of Strategies	Most frequently used first strategy	Used Same	Used New
A	1.4	Token-based	**65%**	35%
C + U	1.4	Token-based	**70%**	30%
C + F + V + T	1.2	Knowledge-Based	**65%**	35%
C + F + I + T	1.9	Knowledge-Based	25%	**75%**
C + F + V + F	2.3	Knowledge-Based	40%	**60%**
C + F + I + F	1.4	Knowledge-Based	**80%**	20%

The Effect of Spatial Ability on Learning from Text and Graphics

Julie Bauer Morrison (morrison@bryant.edu)
Department of Applied Psychology, Bryant College
1150 Douglas Pike, Smithfield, RI 02917-1284 USA

Introduction

Previous research has shown that participants' comprehension of spatial information described in text improves when either graphics or animation accompanies the text (Morrison & Tverksy, 2001). This relationship was found to be true in all cases for low spatial ability participants; however, it was only true under the most difficult conditions for high spatial ability participants. When given enough time to do so, high spatial participants were able to mentally imagine what was described in the text, and therefore did not need externally provided graphics.

The high and low spatial ability distinctions described above were based on a median split of scores on the Vandenberg and Kuse (1978) Mental Rotation Test. The study was conducted with undergraduate students from Stanford University, raising concerns about the accuracy of the categorization and the generalizability of the results. The study presented here replicates the original with a more typical college population.

The Learning Study

Method

Fifty-nine Bryant College undergraduates participated in the study. Although specific GPA data was not available for the participants, the average high-school GPA of an entering student is 2.95 at Bryant and 3.90 at Stanford (Undergraduate Guide, 2003). After completing a test of spatial ability, the Vandenberg and Kuse (1978) Mental Rotation Test, participants began the learning phase of the experiment. They read through a learning interface with 7 novel rules four times, studying for as long as they wished. The interface included text, text plus static graphics, or text plus animated graphics. Following the learning phase of the experiment, participants completed three timed performance tests requiring applications of the rules. The scores on these tests have been combined into a composite Problem-Solving Score, which can range from 0-100.

Results

As with previous analyses, due to a lack of difference between the static and animated graphics conditions, these conditions were combined into a text plus graphics condition. The problem-solving data was analyzed with a one-way (text vs. text plus graphics) ANOVA with spatial ability as the covariate. Participants performed better in the graphics condition than in the text condition, $F(1,56)=21.1$, $p<.01$. High spatial ability participants performed better than their low spatial counterparts, $F(1,56)=16.0$, $p<.01$. Participants were separated into low and high spatial ability groups according to a median split of spatial ability scores. Figure 1 displays the Problem-Solving Score earned by the low and high spatial ability groups across the text and text plus graphics conditions.

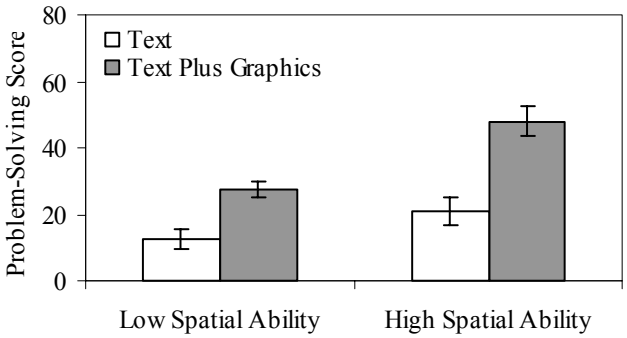

Figure 1: The relationship between spatial ability and interface type for Bryant students.

Discussion

Participants with high spatial ability and those who studied static or animated graphics were better able to learn the spatial rules described in the interface. These results replicated the previous research, in part. In the Stanford version of this study, the low spatial text participants performed more poorly than the three other groups, which did not differ, showing that graphics have benefits, but only for low spatial participants (Morrison & Tversky, 2001). However, the pattern of data seen above is identical to the performance of Stanford participants when limited to studying the interface a single time and with instructions to do so quickly. This suggests that when spatial ability decreases (MRT Score: Bryant M=7.53, SD=3.4; Stanford M=9.17, SD=4.2) and/or when the task becomes more difficult, the benefits of graphics become more pronounced. Although the participants in both studies were college students who may have higher aptitude than the general population, it is clear that there is a learning advantage when spatial material is presented with accompanying graphics.

Baseline Explorations in the Spatial Construal of Time

Benjamin A. Motz (bmotz@cogsci.ucsd.edu)
Rafael E. Núñez (nunez@cogsci.ucsd.edu)
Department of Cognitive Science, University of California, San Diego

Introduction

Due in part to theoretical advances in cognitive linguistics (e.g., Lakoff & Johnson, 1980; Núñez, 1999) and recent studies in cognitive psychology (Boroditsky, 2000; Gentner, 2001), it has become well accepted that humans apply spatial principles to their conception of time. Statements such as, "Cogsci 2004 has arrived," reflect a mental model in which temporal abstractions are given meaning via spatial metaphors. Examining these metaphors, Boroditsky (2000) used spatial priming to influence subjects' interpretation of "forward" (as earlier or later) when disambiguating the meaning of *Move the meeting forward*. She reported the baseline interpretation of "forward" to be "about evenly split" (p. 9) between earlier (45.7%) and later (54.3%) when subjects received no priming.

As part of a larger research project, the present report focuses on these baseline interpretations. In order to standardize the responses and improve replicability, subjects were shown a graphic display with no reference to objects moving toward an observer, or an observer moving toward objects—the two situations widely believed to exclusively influence conceptual models when disambiguating the meaning of "forward" (Gentner, 2001).

Methods

66 undergraduate students at the University of California, San Diego participated in the study as part of their course requirements. Subjects were shown a static display of five stationary colored boxes. Two of the boxes contained balls; the others were empty. During this presentation, subjects were asked to respond to five questions, including: *What is the color of the box containing the black ball?* and *How many boxes are in the display?*

Immediately following these presentations, subjects were instructed to turn to subsequent pages in their questionnaires containing the following two target questions, the order of which was balanced across subjects.

Next Wednesday's meeting has been moved forward two days. On what day will the meeting now take place?

Tomorrow's 12:00 (noon) meeting has been moved forward two hours. At what time will the meeting now take place?

Results and Discussion

Subjects' responses to the target question are shown in Table 1. Chi-square analyses indicated that responses are significantly different from those expected by chance when the question on the scale of days is asked first ($p < 0.005$). This is not the case when preceded by the question on the scale of hours.

Table 1: Number of responses by order of target questions.

	Day then Hour	Hour then Day
Monday	8	17
Friday	24	16
10:00am	7	16
2:00pm	25	18

It is widely believed that time is construed specifically in terms of observers and motion (Gentner, 2001). Our methodology, which bore no explicit reference to such concepts, elicited responses significantly different from those expected by chance. Furthermore, this difference is sensitive to the time scale of the target question. These findings suggest that the specific spatial metaphors for time are more complex than previously assumed.

The data in the upper left cells of Table 1, which are analogous to Boroditsky's (2000) baseline data, can hardly be interpreted as "about evenly split." This suggests that there may be many pragmatic constraints to be considered and that there are more complex variations of conceptual mappings from space to time. Without making claims as to exact baseline responses to ambiguous questions about time, the present findings suggest a reconsideration of what is necessary and sufficient to elicit priming effects in the spatial construal of time.

Low Frequency Waves on EEG Recordings during Stimulation of Sound

Hiroyuki Murakami (murakami@otsuma.ac.jp)
Department of Social Information Studies
Otsuma Women's University
2-7-1 Karakida, Tamashi, Tokyo 206-0035, Japan

Introduction

It has been reported that delta band waves were observed during sleep (Gevins & Cutillo, 1986; Melnechuk, 1988), during altered states of consciousness (Jovanov, 1997) and during hypnagogium (Faber et al., 2003). In this article, the delta band waves are shown in spectral power of EEG recordings during sensory stimulation of sound. Four patterns of spectral power are shown in stimuli of Song and Talk by female and male participants.

While the participants were stimulated by sound, the EEG data were recorded into ESA-16 (Musha, 2000) from 10 electrodes according to the international 10-20 system. We present the content and the strength of the delta (1/4 ~ 5 Hz), theta (5 ~ 8 Hz), alpha (8 ~ 13 Hz) and beta band (13 ~ 20 Hz) waves from the spectral power of EEG recordings.

Experiment

Eight university students (4 females and 4 males) aged between 21 and 23 years participated to the experiment. The materials were song and talk.

Song Boy Soprano: Green grasslands in England (60"), by Anthony Way. Rock: Why I'm me (60"), by RIZE. Cheer Song: Aida! Decide a goal! (60"). Chorus: Barbie Girl (60"), by AQUA. Hip Hop: Return of the Ripper (1'29"), by LL Cool J.

Talk Man's DJ: The voice of the man in the 40's who talks slowly and softly in a low voice can be heard (60"). Woman's DJ: The voice of the woman in the 20's who talks clearly in a cheerful voice can be heard (24"). Woman's Voice: The voice of the woman in the 20's who talks fast in a high-pitched voice can be heard (30"). Conversation: The voice of two native speaker men who talk fast in a low voice in English can be heard (60").

Results

We obtained the following four patterns of spectral power.

Pattern 1 (Song, female participants): The delta band waves of the content 21.0% with small strength were observed on the frontal region, the theta band waves of the content 13.6% with rather large strength on the lateral and back regions, the alpha band waves of the content 57.6% with large strength on the frontal, lateral and back regions, and the beta band waves of the content 7.8% with small strength on the lateral and back regions.

Pattern 2 (Song, male participants): The delta band waves of the content 44.6% with rather large strength were observed on the frontal region, the theta band waves of the content 3.3% with very small strength on the frontal region, the alpha band waves of the content 47.6% with large strength on the frontal, lateral and back regions, and the beta band waves of the content 4.5% with very small strength on the lateral and back regions.

Pattern 3 (Talk, female participants): The delta band waves of the content 16.9% with very small strength were observed on the lateral and back regions, the theta band waves of the content 9.7% with small strength on the lateral and back regions, the alpha band waves of the content 66.7% with large strength on the frontal, lateral and back regions, and the beta band waves of the content 6.7% with very small strength on the lateral and back regions.

Pattern 4 (Talk, male participants): The delta band waves of the content 41.8% with small strength were observed on the frontal region, the theta band waves of the content 6.7% with very small strength on the frontal region, the alpha band waves of the content 37.5% with large strength on the lateral region and with small strength on the frontal and back regions, and the beta band waves of the content 14.0% with very small strength on the lateral and back regions.

The effect of repeated presentation and aptness of figurative comparisons on preference for metaphor forms

Keiko Nakamoto (kenakamoto@nifty.com)

Takashi Kusumi (kusumi@mbox.kudpc.kyoto-u.ac.jp)

Department of Cognitive Psychology in Education, Graduate School of Education, Kyoto University,
Yoshida-Honmachi, Sakyo-ku, Kyoto 606-8501, Japan

Introduction

Figurative comparisons consisting of two nouns (a target and a base) can be expressed in two grammatical forms, i.e., in simile form (X is like Y), or in metaphor form (X is Y).

Recently, many studies have shown that there are substantial differences between metaphors and similes. In particular, much evidence has been found for people's grammatical preference for figurative comparisons (e.g., Chiappe & Kennedy, 1999). Among hypotheses proposed for explaining this grammatical form preference in relation to figurative comparisons, we focused mainly on the career of metaphor hypothesis, proposed by Bowdle & Gentner (1999). The career of metaphor hypothesis suggests that the repeated use of a particular base term, as intending a certain metaphorical sense, will result in lexicalization of the metaphoric sense as a secondary meaning to that of the base term, and that this conventionalization process causes the metaphor form preference. In contrast, Chiappe & Kennedy (1999, 2001) have claimed that the metaphor form might be preferred when a comparison is highly apt, because the metaphor form implies that the target will inherit almost all the features of the base term. In other words, the metaphor form implies the category assertion.

In this study, we conducted an experiment to test the career of metaphor hypothesis, based on Bowdle & Gentner's (1999) "in vitro conventionalization". In addition, we observed the interaction between the aptness of comparisons and the repeated presentation of the base terms.

Method

Design Aptness of comparisons (High/Moderate) X The number of repetition of base terms in the study phase (0 /5 times). Both were within subject variables.

Participants Thirty-six undergraduates participated in the experiment. All were native Japanese speakers.

Materials and Procedures The experiment consisted of two phases; the study and the test phase.

For the test phase, we prepared 16 comparisons as the test items in the test phase. Half of the test items were rated as highly apt, and the other half as moderately apt in a preliminary study (M=3.52 and 2.39 on a 5-point scale, respectively). We defined the aptness according to Chiappe & Kennedy (1999). For each comparison, two grammatical forms, a metaphor and a simile, were prepared.

For the study phase, we prepared five target terms for each base of the comparison in the test phase. For example, for the test "An encyclopedia is (like) a goldmine", the new target terms such as {library, book…} were selected. These terms were combined with the base (goldmine) and made up the comparison in simile form. Filler statements were prepared for both phases: 40 comparisons for the study phase, and two category-pairs (e.g., elephant-animal) and two literally-similar-pairs (e.g., lemon-orange) for the test phase.

In the study phase, the participants were presented with the study items in random order and required to write down their interpretation of the comparison in a few words; they were also required to rate the comprehensibility on a 5-point scale. After a five-minute delay, they were asked to rate which grammatical form (metaphor or simile) was more natural or reasonable for each target – base pair, on a 7-point scale.

Results and Discussion

The mean grammatical preference rating for the comparisons in the test phase are shown in Table 1, transformed so that higher numbers indicate a preference for the metaphor form over the simile form. Table 1 shows that previous repetition of the base term increased the participants' preference for the metaphor form. Moreover, a tendency emerged, in that the effect of the repetition differs by the aptness of the comparisons. A 2 X 2 repeated measures analysis of variance on the subject means showed that the main effect of repetition was significant ($F(1,35)=11.52$, $p<.01$). The interaction between repetition and aptness was marginally significant ($F(1, 35)=3.03$, $p<.10$).

Table 1. Mean metaphor form preference ratings (and standard deviations) as a function of repetition

Aptness of comparison	Repetition in Study Phase	
	None	5 times
High	3.13 (.86)	3.77 (1.41)
Moderate	3.17 (.82)	3.35 (1.03)

In summary, these results support the career of metaphor hypothesis. Furthermore, they suggest that the aptness of a comparison promotes the conventionalization of the base term. The implication of this interaction is that the newly created metaphoric meaning is more likely to be lexicalized when it is highly apt, that is, when it has more metaphoric implications.

Eye-tracking and Simulating the Temporal Dynamics of Categorization

Marissa Nederhouser (mneder@usc.edu)
Department of Psychology, University of Southern California

Temporal Dynamics of Categorization

Recent research in categorization has seen a growing emphasis on the temporal dynamics of classification responses (e.g., Lamberts, 1998, 2000; Nosofsky & Palmeri, 1997). These dynamic models generally predict that the degree of fit between an exemplar and the possible categories to which it might belong is a gradually increasing function over hundreds of milliseconds for the correct category and a gradually decreasing function for the incorrect category (or categories).

The development of experimental techniques that can provide evidence for these simultaneously partially-active category representations during the early moments of the categorization process has faced some methodological obstacles, such as imprecision in response deadlines, or limited reaction-time ranges, extensive repetition of stimuli, and potential strategies resulting from speeded classification instructions. The present work recorded eye movements as a semi-continuous, real-time measure of partially activated categories during a normal-speed categorization task (cf. McMurray, Tanenhaus, Aslin, & Spivey, 2003).

Eye Movements During Categorization

Participants were presented with a pair of category bins and given several toy animals sequentially. Eye movements were recorded while they placed the toy animal in one or the other category. We were thus able to calculate an indirect estimate of the moment-by-moment partial activation of the categories being adjudicated among. Figure 1 shows example data (averaged over 17 subjects) for two of the eight critical toy animals used in this experiment.

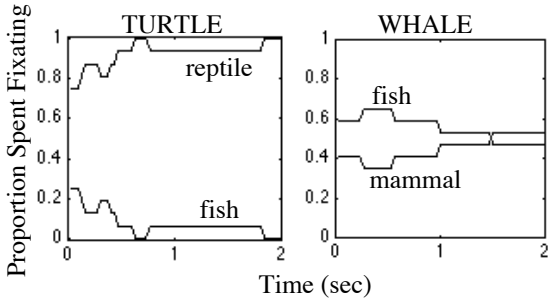

Figure 1: Proportion of time spent fixating two different classification bins while categorizing a toy animal.

Localist Attractor Network Simulations

A simple version of the normalized recurrence competition algorithm (Spivey & Tanenhaus, 1998) was constructed with five feature banks (limb type, environment, blood temperature, oxygen source, birth method) and four taxonomic classes (mammal, reptile, bird, fish). The resulting activation curves over time approximated the eye movement data (compare example items from Figures 1 and 2). Thus, experimental data and network simulations coincide with the general predictions of current temporally dynamic models of categorization (Lamberts, 1998, 2000; Nosofsky & Palmeri, 1997).

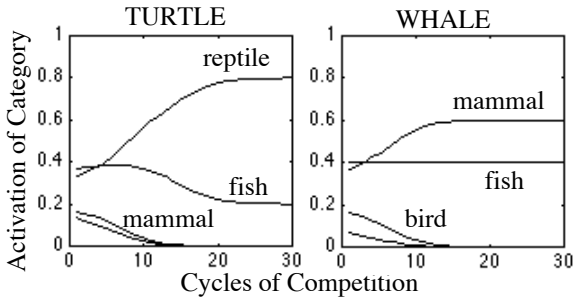

Figure 2: Activation of taxonomic classes as normalized recurrence settles into a stable state.

Finding useful questions in a natural environment

Jonathan D. Nelson (jnelson@cogsci.ucsd.edu)
Cognitive Science Dept., University of California at San Diego
9500 Gilman Dr., Dept. 0515, La Jolla, CA 92093-0515 USA

Identifying useful questions (tests, experiments, or queries) is important for a host of situations, including scientific reasoning, word learning, and vision. If a probabilistic belief model is used to describe an inquirer's knowledge, then each question's usefulness may be calculated using an explicit sampling norm (utility). Prominent sampling norms in psychological literature include Bayesian diagnosticity and log diagnosticity (Good, 1950), information gain (mutual information or Kullback-Liebler distance: Oaksford & Chater, 1994, 1996), probability gain (minimal error: Baron, 1985), and impact (absolute difference: Klayman & Ha, 1987). Strong claims about both the psychological reality and normative basis of particular norms have been made, in papers that calculate only a single sampling norm. Yet a literature review produced no treatment of when the sampling norms disagree with each other, and whether there are theoretical or empirical reasons to prefer a particular norm.

Skov & Sherman (1986) provided an early probabilistic study of information gathering. Participants were told (for instance) that on the planet Vuma 50% of creatures are gloms and 50% are fizos; that 28% of gloms and 32% of fizos wear a hula hoop; and that 10% of gloms and 50% of fizos smoke maple leaves. Given the goal of finding out whether a novel Vumian was a glom or fizo by asking either whether they wear a hula hoop or whether they smoke maple leaves, most participants asked about maple leaves. Skov & Sherman took this as evidence that people are sensitive to diagnosticity. Unfortunately, this result does not show what sampling norm is closest to people's intuitions, because diagnosticity, log diagnosticity, information gain, Kullback-Liebler distance, probability gain, and impact make the same prediction. Other studies have also made claims about particular sampling norms' psychological reality or normative preeminence, without considering other sampling norms.

One frequent task in daily life is to visually ascertain a person's gender. A simplified version of this task (which negates low-resolution information available from outside the center of gaze) is to learn a person's gender by viewing one feature at a time. This task is formally equivalent to the Vuma task. We collected statistics of the gender and features of interest of about 500 passerby, 51% of whom were male, in one natural environment (Table 1). Goals were to determine (1) whether different sampling norms make contradictory claims about what features are most useful, and (2) what sampling norms would best serve in this task.

Results showed that asking about hair length maximizes information gain, Kullback-Liebler distance, probability of correctly identifying the gender, and impact (absolute change in beliefs). Skirt and beard, however, have infinite diagnosticity and log diagnosticity. This is because in the rare event that a person is wearing a skirt or dress, or has a beard or other facial hair, their gender is known with certainty. Using diagnosticity or log diagnosticity to select questions would be inefficient in this environment.

Future work will examine what sampling norms' predictions best match human questions, and whether human questions are sensitive to symmetries and other class-conditional feature dependencies of natural objects.

Table 1: Features' distribution and usefulness.

	Skirt/ dress		Glasses (s=sun)			Beard		Earring		Short hair	
	n	y	n	s	y	y	n	y	n	y	n

Fluency in Categorization

Daniel M. Oppenheimer (Oppenheimer@psych.stanford.edu)
Stanford University, Department of Psychology
Building 420 – Jordan Hall, Stanford, Ca 94305 USA

The meta-cognitive experience of ease of processing, also known as fluency, is a central element of our reasoning repertoire and influences a wide array of judgments. Fluency has been shown to have an effect on a wide array of judgments such as intelligence (Oppenheimer, under review), frequency (Tversky & Kahneman, 1973), familiarity (Monin, 2003), risk for disease (Rothman & Schwarz, 1998) and confidence (Norwick & Epley, 2002).

As the widespread impact of fluency becomes more recognized, researchers have begun accumulating evidence that fluency plays a part in classification. For example Whittlesea and Leboe (2000) have proposed a heuristic model of categorization learning in which fluency plays a central role. In an elegant set of experiments, Whittlesea and Leboe (2000) constructed a set of words that varied in fluency and demonstrated that the fluency of an item had a tremendous impact on categorization judgments.

One potential shortcoming of this set of studies is that Whittlesea and Leboe (2002) restricted their stimuli to artificial words. While this was essential to ensure rigor and avoid confounds, it leaves open the question of what would happen if participants had access to more information than fluency and perceptual similarity of features. When people reason about categories about which they already know a great deal, will fluency still play a role, or is it only used in novel situations when there are few other cues available? This question is the impetus for the current study.

Method, Results, and Discussion

71 Stanford University undergraduates participated as part of a course requirement. Participants rated how good a category member a given exemplar was on a nine-point scale. Four categories (bird, mammal, vehicle, and unusual foods) with 15 exemplars each were used. Exemplars were selected so as to vary in both typicality and commonness.

A standard font manipulation was used to operationalize fluency (Norwick & Epley, 2002). A third of the questionnaires were printed in standard 12 point, Times New Roman font. A reduced fluency condition was created by printing a third of the questionnaires in 10 point, Mistral font. An example of the fonts can be seen in Figure 1.

Times New Roman Font
Mistral Font

Figure 1: Examples of the different fonts used.

Results are summarized in Figure 2. For all categories, participants in the fluent condition rated the exemplars as better category members than participants in the nonfluent conditions. ($t(14) = 4.7$ to 1.5, $p = .000$ to .07).

These results suggest that even in a domain about which individuals know a great deal and likely have pre-experimental notions about what features are relevant to category membership, fluency still plays a significant role.

The Memory Consequences of Study after Successful Recall

Philip I. Pavlik (ppavlik@andrew.cmu.edu)
Department of Psychology, Carnegie Mellon University
Pittsburgh, PA 15213 USA

John R. Anderson (ja+@cmu.edu)
Department of Psychology, Carnegie Mellon University
Pittsburgh, PA 15213 USA

Introduction

Our lab has been investigating data and models of spaced memory practice with the long-term goal of applying these models to optimizing the learning of material like vocabulary items. These continuous paired-associate experiments have utilized a recall-or-study trial procedure on both of 2 sessions. On first sessions (Session 1), items are randomized into conditions where they will receive a number practices at various spacing intervals. The memorial consequences of these conditions (distributed continuously across Session 1) are assessed during second sessions (Session 2) in which all of the items are retested several times to determine the effects of the practice by spacing conditions.

The procedure in these experiments was to introduce each paired-associate with an initial 5-second study presentation of the cue-response pair. Subsequent trials were then presented as tests of this knowledge. Because we wanted each trial to count as a single practice in the model, we provided a restudy presentation only when participants responded incorrectly. If the response was correct, we assumed that the correct response constituted a practice of the item. We felt that this recall-or-study procedure resulted in roughly equal practice for each trial.

However, a review of our work suggested that our assumption might not be so uncontroversial. Because of this we designed an experiment where we compared our procedure with a more typical test-and-study procedure where a study opportunity was always presented after a test.

Experiment

The basic procedures for the experiment are described above. The retention interval was 2 days. We looked at our results in terms of both session 1 and session 2 performance. On session 1, we compared recall performance for the two procedures for test trials 2 and 3 (where the effect should be strongest since it had not yet approached ceiling). The first test was excluded because the difference between conditions occurs depending on the success of this test. Means for test 2 and 3 performance were .684 and .639 for the test-and-study and recall-or-study procedures, respectively. This was significant $t = 2.372$, $p < .05$. However, a follow-up conditional analysis suggested that some portion of this effect was merely noise.

Not surprisingly, very little of this benefit persisted into Session 2 in which performance averages were .9 and .883 respectively, and the difference was not significant. Furthermore, session 2 first test results, which were farther from ceiling (*M*s = .760 and .746 respectively for test-and-study and recall-or-study conditions) also showed no significant difference.

Discussion

Subsequent to the experiment an ACT-R (Adaptive Character of Thought – Rational) (Anderson and Lebiere, 1998) model was created using modifications designed to capture the spacing effect described in Pavlik and Anderson (2003). This model captures the small differences in performance by proposing that study trials immediately following successful recall have little effect on long-term memory because the effect of these studies decays more quickly.

The data and model have implications for teaching material such as vocabulary items because they showed that in the typical paired-associate procedure the study trial after a correct recall is redundant and thus inefficient. Further, the data suggest that it is not crucial for models to consider the study after successful recall because its effect is so small. Finally, the model was shown to agree with arguments and data from Kimball and Metcalfe (2003) which proposed a theory of why delayed judgments of learning (JOLs) are more effective than immediate JOLs. The model agrees that this effect, which occurs only when there is no study after the JOL, is not due to enhanced metamemory.

Traditionally language models have been evaluated by testing their ability to mark sentences as grammatical or ungrammatical. But with the emergence of probabilistic, connectionist models etc. on the computational side and magnitude estimation tests etc., on the linguistic side, it might make sense to go all the way and evaluate the models graded predictions.

We present a language acquisition algorithm that can learn structural regularities from raw data without any prior knowledge about the data. When trained on corpora the extracted language structures can be tested with new sentences to which a graded score is assigned.

Three experiments were conducted. The algorithm was trained on text from the English CHILDES database [MacWhinney and Snow. 1985. The child language exchange system] and then tested on linguistic acceptability data collected by Keller [Keller, Frank. 2000. Gradience in Grammar: Experimental and Computational Aspects of Degrees of Grammaticality. PhD Thesis, University of Edinburgh] and the algorithm was partially successful on these.

A linguistic acceptability experiment was performed on a large set of well controlled data from an ESL multiple choice (English as Second Language) test and a modest but highly significant correlation with the algorithm score was found.

Finally a linguistic acceptability experiment was performed on sentences generated randomly from a small CFG. 25% of the sentences had 2 neighbor words permuted and another 25% of them had 2 random words from anywhere in the sentence permuted. Both groups got, as expected, significantly lower acceptability score but furthermore the latter had a significantly lower score and a higher variance suggesting that global permutations are more violating but also sometimes by chance get acceptable. The algorithm gives a more clear cut division of the permuted and non-permuted sentences (when trained on similar sentences) but it remains to be investigated whether it can distinguish the two different permutations.

These experiments show that our scoring function is still somewhat unstable and only performs well when variations are small or the data is highly structured as in the CFG experiment. But it also shows that the algorithm is productive under even slightly absurd circumstances like when we train it on CHILDES and test it on the more complex sentences from the ESL data. Furthermore, if we administer the ESL sentences as a multiple choice test the algorithm performs as "intermediate" according to the norms for that test.

What's in a Name?
The effect of sound symbolism on perception of facial attractiveness

Amy Perfors (perfors@mit.edu)
Department of Brain and Cognitive Sciences, Massachusetts Institute of Technology
77 Massachusetts Ave, Rm NE20-388, Cambridge, MA 02139

Introduction

The Saussurean assumption that there is nothing inherent in the relation between a sound pattern and a concept is taken for granted in most of cognitive science. Though the notion that sound-meaning pairings are arbitrary is rarely challenged, there is some evidence indicating that this conjecture may not be wholly true. Sapir (1929) first suggested that cross-linguistically, front and back vowels are robustly associated with specific connotations: front vowels like [i] and [ɪ] are perceived as "smaller" than back vowels like [u]. Other researchers have further explored this idea, documenting that the same association occurs in many languages and cultures (e.g. Ultan 1978; Jakobson 1937). A non-arbitrary sound-meaning relation has also been suggested of some consonants: for instance, Kelly, Leben, and Cohen (2003) suggest that obstruents like [g], [b], and [k] are perceived to be 'hard' and masculine, while sonorants like [l], [n], and [r] are 'soft' and feminine.

Most of these findings, though intriguing, rely on asking subjects what connotations they associate with certain sounds. To date, there is little research that rigorously uses implicit and unconscious measures to study whether sound symbolism is a psychologically real and robust phenomenon. This work does so.

Method and Results

24 photos of men and women paired with names of varying phonology and gender connotation were rated for attractiveness on a 10-point numerical scale on the website *hotornot.com*. Each photo consisted of a frontal shot taken in a naturalistic background; names were saliently located in the upper corner of each photograph. Each photograph was posted multiple times (though never simultaneously) with names that differed systematically in gender connotation, vowel type, and consonant type. As a control, each name was ranked on a 7-point Likert scale by 14 English-speaking subjects based on how much they "liked" it, in general as well as when considered specifically for a male or a female.

Results indicated that phonology played a significant role in perception of facial attractiveness. (see Figure 1). For men, pictures matched with names with front vowels were consistently perceived as more attractive than pictures with back vowels; for women the relation went in the opposite direction ($p<0.01$). Consonants played a smaller but still significant role, but only for women ($p=0.01$).

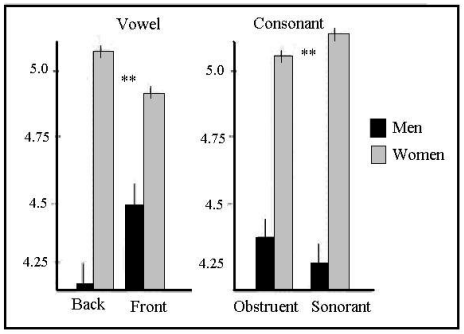

Figure 1: Effect of consonant / vowel type on attractiveness.

Interestingly, names with back vowels were liked less than names with front vowels, but only when the name was considered a guy's name – when the exact same name was considered for a girl, there was no effect of vowel type. (Males: 'back' mean 3.10, 'front' mean 3.59, $F=6.52$, $t=3.627$, $p<0.001$; Females: 'back' mean 2.86, 'front' mean 2.93, $F=2.748$, $t=-0.502$, $p=0.604$). This suggests that although some of the effect of sound symbolism on facial attractiveness may be mediated by how much a name is liked, it cannot be the full story.

Conclusion

This research argues against the Saussurean notion that word-referent associations are completely arbitrary pairings. It suggests that at least under some circumstances, there is a systematic and significant link between some sounds in a language and the semantic associations belonging to words with those sounds.

Task-Set Specific Preparation Prohibits the Expression of Repetition Benefits in Task Switching

Edita Poljac (e.poljac@nici.kun.nl)
Ab de Haan (dehaan@nici.kun.nl)
Gerard P. van Galen (vangalen@nici.kun.nl)
Nijmegen Institute for Cognition and Information, University of Nijmegen,
P.O. Box 9104, 6500 HE Nijmegen, The Netherlands

Task Switching: Top-Down or Bottom-Up?

The research on task switching has gained a lot of attention in cognitive psychology in the last decade. The phenomenon observed is the so-called switch cost, which is the decline in performance after a task switch, with the base-line performance being measured on task repetition trials.

Generally speaking, the theoretical interpretations for switch costs can be divided in two groups: top-down and bottom-up interpretations. One of the most prominent top-down interpretations is the reconfiguration theory proposed by Rogers and Monsell (1995), and one of the most recent bottom-up interpretations is the activation theory proposed by Altmann (2004). The reconfiguration approach assumes a functional switching process, with switch costs as an index of this process, while the activation approach assumes a more distributed, general activation of a task representation in memory, with switch cost as a side effect.

The aim of this study was to test the validity of predictions the reconfiguration and the activation theory make about task switching.

Methods and Results

In 2 experiments, the preparation interval duration and the preparation interval type (self-paced vs. externally paced) were manipulated. These manipulations occurred within subjects in Experiment 1 (900 and 200 ms) and between subjects in Experiment 2 (self-paced, 900, 600, 300 and 200 ms). Color and form matching tasks were presented repeatedly in switch and no-switch blocks of 8 trials each. A written cue specified the nature of the upcoming task. The cue appeared at the beginning of a task block and disappeared as soon as a preparation interval was over. No switching between the two tasks occurred within the blocks.

The results showed switch costs, restart costs, and generic performance improvement for longer preparation intervals. A task-switch specific preparation effect (reduction of switch costs with longer preparation intervals) was only observed in Experiment 1.

Conclusions

The data of this study can just partially be explained by the two approaches. On the one hand, our results showed that task-switch specific preparation effect is design dependent. This contradicts the assumption of reconfiguration theory for this effect being robust. On the other hand, the self-paced condition showed switch costs but no restart costs. This observation is at odds with the activation theory, which assumes that the basic processes involved in switch and repeat trials are qualitatively the same.

Therefore, we propose an alternative model of task switching (see Figure 1). The model focuses on processes taking place around the preparation interval, which starts with a cue and lasts until the first imperative stimulus. Generic preparation is the main part of this model, which activates the system if no task switch is required and inhibits this generic activation if a task switch is required. The generic activation compensates for costs accompanied with rule reactivation if the preparation period is sufficiently long. The generic inhibition reduces the chance of making errors but cannot compensate for rule activation costs. Therefore, irrespective of the preparation interval duration, the costs of rule activation become apparent if a task switches.

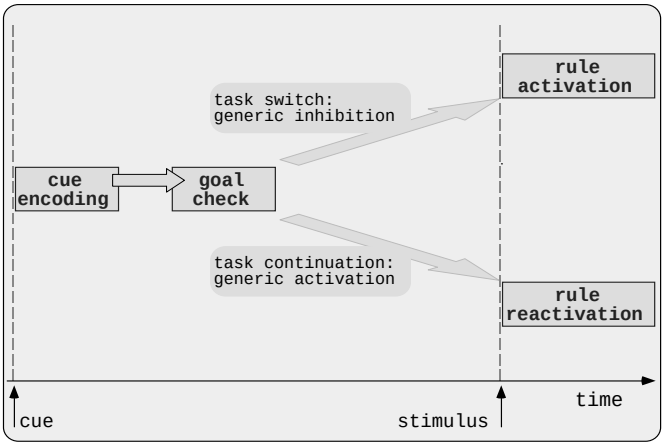

Figure 1: An alternative model of task switching, with generic preparation (activation for task continuation or inhibition for task switch) as its main part.

Localization of cognitive processes using Stroke patients and fMRI

V. Prabhakaran, S.P. Raman, M.R. Grunwald, A. Mahadevia, J.K. Werner, L. E. Philipose, N. Hussain, H.H.Alphs, P. Sun[+], H. Lu[+], B. Biswal*, B.Rypma*, P.C.M. van Zijl[+], A.E. Hillis,

Johns Hopkins University School of Medicine, Rutgers University*, Kennedy Krieger Institute[+]

Localization of cognitive processes to brain regions have mainly utilized the location of infarcted brain regions in stroke patients or fMRI in normal subjects. The BOLD effect in fMRI studies may be difficult to interpret in stroke patients who have areas of hypoperfusion (with resultant reduction in hemodynamic response) due to arterial stenosis. This study was undertaken to examine the influence of hypoperfused regions, in addition to the area of infarct itself, on cognitive processes and fMRI in stroke patients.

Methods

Subjects with subcortical strokes in the left MCA or right-MCA territories, along with normal controls, were imaged while performing a verbal fluency task. The experiments were performed on a 1.5 T whole-body scanner (Philips Medical System, Best, The Netherlands). The study population included six normal participants (3M, 3F, ages 24-57) and six stroke patients (3M, 3F, ages 28-58) with MCA distribution subcortical infarcts. Patients were given a verbal fluency task of 1 min. in duration, compared to rest of 30 secs, organized in an alternating block design, while being scanned with a whole brain fMRI/Stroke MRI-Protocol that included perfusion weighted imaging (PWI) that reveals areas of hypoperfusion as well as structural scans (FLAIR, DWI, T2 sequences)

Results

While normal subjects displayed a left-lateralized fronto-temporal and bilateral cingulo-striatal-thalamic-cerebellar network, the activation pattern of stroke patients was determined both by the hypoperfused regions and/or infarcted areas of the brain. Specifically, the left frontal-temporal network showed diminution of activity in our left MCA patients that had cortical hypoperfusion in the corresponding regions, although their infarcted areas were subcortical.

Table 1:

	Left Middle Cerebral Artery Stroke				**Right Middle Cerebral Artery Stroke**	
Patient	MS	SB	MZ	HS	TG	JH
Gender	Male	Female	Female	Female	Male	Male
Age,Race	58, W	34,AA	50, W	52, W	50, AA	28,W
Infarct **Perfusion Defect Occurence FMRI test**	Minimal left posterior temporo-parietal infarct Posterior temporo-parietal hypoperfusion 04/18/02 11/07/02	Minimal left frontal infarct Frontoparietal hypoperfusion 02/99 10/08/02	Left caudate and Centrum semiovale Fronto-temporo-parietal Hypoperfusion 08/18/01 12/12/03	Left basal ganglia and Centrum semiovale Frontal hypoperfusion 07/00 01/07/03	Right parietal watershed Fronto-temporo-parietal hypoperfusion 1990 02/05/04	Right anterior temporal lobe and basal ganglia Parietal Hypoperfusion 07/19/02 09/30/02
Signs and Symptoms	Impaired word retrieval Impaired sentence comprehension Right upper extremity tingling	Alexia, agraphia Minimal word retrieval difficulty Right-sided weakness	Impaired word retrieval Right upper extremity weakness	Impaired word retrieval Right upper extremity numbness Slurring of speech	**Impaired word retrieval** Right arm numbness Slurring of speech	Left-sided facial droop Slurring of speech Right temporal headache

Conclusions

The observation of a diminished BOLD signal in hypoperfused regions of cortex could either reflect reduced activation in these areas due to tissue dysfunction or reflect normal activation accompanied by increased oxygen extraction without a normal hemodynamic response. The results raise the possibility that localization studies should take into account brain regions that are hypoperfused, as well as infarcted brain regions, in trying to map cognitive processes to brain regions.

Understanding of Principles of Arithmetic with Positive and Negative Numbers

Richard W. Prather
University of Wisconsin
Department of Psychology, 1202 W. Johnson Street
Madison, WI 53706 USA

Martha W. Alibali
University of Wisconsin
Department of Psychology, 1202 W. Johnson Street
Madison, WI 53706 USA

Many models of problem solving include intuitive knowledge components such as principles. Principles are general rules that capture regularities within a domain. Principles reflect conceptual understanding of the underlying structure of a problem domain. For example, in arithmetic, when adding two positive numbers (A + B = X) the answer (X) will always be greater than both operands (A and B) (Dixon, Deets & Bangert, 2001). Problem solvers have been shown to use principles in a variety of problem domains, including counting and arithmetic.

Dixon et al. (2001) investigated participants' understanding of principles that apply to arithmetic operations involving positive numbers. In their study, participants viewed sets of sample problems that had been solved by hypothetical students, and rated the level of understanding that each hypothetical student appeared to have. The analysis compared participants' ratings of problem sets that violated principles and sets that did not violate principles.

The present study built on Dixon et al.'s prior work to investigate participants' understanding of arithmetic operations involving negative numbers. Problem sets were created to test participants' understanding of principles that apply to addition and subtraction with a positive and a negative number, as well as addition and subtraction with positive numbers. The specific principles tested were: (1) *Relationship to Operands*, which specifies the magnitude of the sum or difference relative to the operands, (2*) Direction of Effect*, which specifies how the magnitude of the sum or difference changes as the magnitude of one of the operands is changed, and (3) *Sign*, which specifies the sign of the sum or difference as a function of the relationship between the magnitudes of the operands. As in Dixon et al.'s study, participants rated problem sets that violated principles and sets that did not violate principles. Participants used a scale ranging from 1 (very bad) to 7 (pretty good) to rate the sets. In each case, the relevant analysis compares participants' ratings of violation and nonviolation sets.

As seen in Table 1, participants represented the Direction of Effect principle for operations involving positive numbers and for operations involving negative numbers. Participants represented the Relationship to Operands principle only for addition with positive numbers.

Table 1:
Mean Ratings Provided for Problem Sets
with and without Principle Violations
for Each Principle, Operation, and Number Type

Principle	Operation	No. Type	M Non	M Vio	T
RO	Addition	Positive	3.56	2.89	3.50**
RO	Addition	Negative	3.31	3.15	0.72
RO	Subtraction	Positive	3.11	2.92	0.82
RO	Subtraction	Negative	3.60	3.58	0.10
DE	Addition	Positive	3.89	2.34	6.26**
DE	Addition	Negative	3.06	2.63	2.46*
DE	Subtraction	Positive	3.69	2.53	4.66**
DE	Subtraction	Negative	3.68	2.79	4.75**
Sign	Addition	Negative	2.79	2.81	0.07
Sign	Subtraction	Positive	2.79	2.56	1.17

RO = Relationship to Operands, DE = Direction of Effect, Vio = Violation, Non = Non-violation
* $p < .05$, ** $p < .01$.

The work of Dixon et al (2001) laid a solid foundation for investigating the principles governing arithmetic operations. Our findings replicate some of Dixon et al.'s results, and expand this line of inquiry to negative numbers. Our findings suggest that adults' representations of operations with negative numbers are not as well-established as their representations of operations with positive numbers.

Part-Whole Statistics Training: Effects on Learning and Cognitive Load

Jodi L. Price (gtg231d@prism.gatech.edu) Richard Catrambone (rc7@prism.gatech.edu)
Georgia Institute of Technology, School of Psychology
654 Cherry Street, Atlanta, GA 30332-0170 USA

Part-Whole Presentations and Cognitive Load

The acquisition of a problem solving procedure is a challenging task often made more difficult by examples or presentation methods that heavily tax working memory and result in the learner being unable to identify and learn the key elements of the example. In general, cognitive load refers to the amount of mental effort required to complete a task within a given time frame (Xie & Salvendy, 2000). Cognitive load theory is based on the observation that working memory capacity is limited. Because of these limitations, cognitive load theory suggests that the methods used to present information should be designed to reduce the demands on working memory (Tindall-Ford, Chandler, & Sweller, 1997) to allow for better processing of examples and ultimately more learning. One technique shown to reduce cognitive load and improve learning is a part-whole (PW) presentation method (Mayer and Chandler, 2001). Mayer and Chandler suggest that initially studying a part (piece by piece) rather than a whole presentation allows the learner to progressively build a coherent mental model of the material without experiencing cognitive overload.

Overview of Experiment

To directly test how a PW presentation would affect cognitive load ratings and skill acquisition in the statistics domain (learning to calculate t-tests and ANOVAs) 84 undergraduate students at the Georgia Institute of Technology studied and completed statistical calculation training and testing materials. The training materials were paper based and consisted of 7 different portions, which contained a brief introduction to statistical calculations and worked examples of how to calculate a t-test and a 2-group ANOVA. Those in the PW condition initially received each of the 7 portions of the training materials one at a time (part) and then were given all 7 portions at the same time (whole). This order was reversed for those in the WP condition.

The test booklet contained three test problems: 2 near transfer problems that were isomorphs to those studied during training and a third far transfer problem that required participants to conduct an ANOVA with three groups.

Participants were asked to rate their cognitive load using the NASA-TLX (NASA Human Performance Research Group, 1987) three times: at the conclusion of the first presentation method (either P or W), at the end of the second presentation method but before testing began, and after they completed the test problems.

Results and Discussion

Contrary to expectations, those who studied the training materials in a PW order performed significantly worse on the test than those who received a WP presentation order, $F(1, 83) = 1.21$, $p = .07$; 4.34, $p < .05$; 4.12, $p < .05$, for the t-test, 2- and 3-group ANOVA problems, respectively. The mean NASA-TLX cognitive load ratings were also found to vary as a function of presentation order with participants in the PW condition rating the part as more difficult than the whole and those in the WP condition reporting the whole more difficult than the part. This yielded a significant main effect of ratings and a significant interaction between ratings and presentation order, $p < .01$ for both. Together these data suggest the PW benefit was not obtained in this experiment but it remains unclear whether this was due to the domain or our implementation of the PW method. Perhaps a paper-based implementation in the domain of statistics is too different from Mayer and Chandler's (2001) multimedia science lesson to obtain the PW benefit. Further research is necessary to tease apart these issues.

Table 1: Variables as a Function of Presentation Order

Presentation Order	Part First			Whole First		
	M	*SD*	N	*M*	*SD*	N
Test Performance (out of 6 possible)						
- T-test	5.38	1.21	41	5.65	1.02	43
- 2-group ANOVA	4.34	1.50	41	4.92	.99	43
- 3-group ANOVA	2.94	1.94	41	3.75	1.74	43
NASA-TLX Cognitive Load Ratings (100=greater load)						
- Part Portion	71.68	11.05	40	64.51	15.35	43
- Whole Portion	63.15	15.09	40	72.20	13.27	43
- Test	62.27	10.65	40	58.84	15.23	43

Topographic Map Learning Strategies

An important skill of geology is being able to visualize the landscape using contoured topographic maps. This study investigates how students develop topographic map learning strategies, and apply these strategies toward three-dimensional maps. Participants were geology students from an urban university in the Southwest. A topographic map memory test was developed by the authors using Authorware 6.5. One component of the test required participants to study a two-dimensional map, and then select the corresponding three-dimensional map representation from four possible choices. Another component of the test asked participants to describe their strategy for learning the two-dimensional map.

The results indicate differences between participant topographic map learning strategies. For example, participants who used directional terms (for example, North, South, or center) to describe their map learning strategy were more successful in selecting the corresponding three-dimensional map representation then participants who used geological terms (river, mesa, or hill). Gender differences of map learning strategy were also suggested. In conclusion, a better understanding of how students approach the learning of a topographic map is gained, and implications for further research are defined.

Analogy-making as Predication Using Relational Information and LSA Vectors

José Quesada, Walter Kintsch, Praful Mangalath ([quesadaj, wkintsch, praful]@psych.colorado.edu)
Institute of Cognitive Science, University of Colorado, Boulder
Boulder, CO 80309-0344 USA

Current models of analogy comprehension use hand - coded representations. As Hummel and Holyoak (2003) put it, "the problem pf hand-coded representations is among the most serious problems facing computational modeling as a scientific enterprise: All models are sensitive to their representations, so the choice of representation is among the most powerful wild cards at the modeler's disposal" (p. 247). French (2002) reviews different computational models of analogy-making, and points out one of the most fundamental problems of the field: case representations are authored (hand-coded) to make the model work. Between the challenges and future directions he presents "the systematic exploration of experimenter-independent representation-building and learning mechanisms" (p. 204).

In this poster, we propose LSA as a method to generate the much-wanted non-hand-coded representations. However, LSA has severe limitations to represent structure. Turney and Littman (2003) pointed out that the similarity of *semantic relations* between words is not directly reducible to the semantic similarity of individual words. This is also the leitmotiv of some analogy models like Gentner's (1983; 1989).Thus, LSA alone would fail to explain analogy, where relations (structure) between words are fundamental. We use a predication (Kintsch, 2001) to represent structure comparisons in the LSA semantic space. Predication is able to select the features (neighbors) of one component of the analogy (the source) that are relevant to the other (the target).

Table 1(a): a sample SAT question.

Ostrich : bird	
(a)	Lion : Cat
(b)	Goose : Flock
(c)	Ewe : Sheep
(d)	Cub : Bear
(e)	Primate: Monkey

Table 1(b): predication using analogy domains

	Number	Percent	T&L (2003)
Correct	157	41.20%	47.10%
Incorrect	150	40.10%	51.60%
Skipped	67	17.20%	1.30%
Total	374	100%	100.00%
Precision	157/307	0.51%	47.70%
Recall	157/374	0.42%	47.10%
F		0.46%	47.10%

We calculated the predication vectors for all the targets and alternatives of 374 items from the Scholastic aptitude test (SAT). This dataset of analogies was collected by Turney and Littman (2003). An example of a SAT item can be seen in Table 1(a). To calculate the correct alternative, we computed the cosine between the target vector and each alternative, and selected the alternative with the highest cosine. However, this method had poor results: using LSA this way leaves out most of the relational information. For example, relations such as is-a, part-of, causal-agent-of, etc. are all substituted by a very basic semantic distance measure when we compute the cosine between the target and the alternatives. To include this relational information in the comparison, we constructed a set of ten possible relations between the components in the 374 SAT analogies (table 2). Then we computed the cosine between the list of words that define the analogy domain and each analogy predication vector in the dataset. That is, for each analogy we created a vector of ten features, where each feature indicates how similar the analogy is to each of the analogy domains. For example, Ostrich::bird would load primarily in the taxonomy and Hyponymy domain components, but also in endonymy, synonymy, and degree. Then, we correlated these loading vectors for the target and each alternative, and selected the alternative that best correlated with the target to solve the SAT question.

Table 2: Ten analogy domains and their characteristic words

Hyponymy	X is a type of Y (for example - Maple:Tree)
[Subordinate of, superordinate to, rank, class, category, family, genus, variety, type of, kind of, hyponym]	
Degree	X means Y at a certain degree (Pour:Drip)
[level, stage, point, magnitude, extent, greater, lesser, intensity, severity, extreme, degree]	
Meronymy	The parts of X include the Ys (Body:Arm)
[part, whole, component, made up of, portion, contains, constituent, segment, piece of, composite, meronym]	
Taxonomy	X is an item in the category Y (Milk:Beverage)[classification, containing, structure, relationship, hierarchy, system, framework, taxonym]
Synonymy	is the same as Y (Work:Labor)
[equivalent, equal, likeness, match, interchangeable, alike, same as, similar, close to, like, synonym]	
Antonymy	is the opposite of Y (Find:Hide)
[opposite, unlike, different, antithesis, opposed, contradiction, contrast, reverse, anti, not the same as, antonym]	
Characteristic	X is a characteristic of Y (Dishonesty:Liar)
[indicative, representative of, typical of, feature, attribute, trait, property, mannerism, facet, quality, characteristic]	
Plurality	X is many Ys (Throng:People)
[mass, bulk, several, many, lots of, numerous, crowd, group, more, number, plural]	
Endonymy	X entails Y (Coop:Poultry)
[entails, require, evoke, involve, suggest, imply, presuppose, mean]	
Use	X is used to Y (Scissors:Cut)
[do with, manipulate, operate, function, purpose, role, action, utilize, employ, use]	

The results are displayed in Table 1(b). The performance of our model is very close to the state of the art in automatic analogy making when considering correct answers (42% vs. 47%, Turney & Littman, 2003), and precision, recall and F measures. Furthermore, our model is psychologically plausible.

Differentiating the Contextual Interference Effect from the Spacing Effect

Lindsey E. Richland (lengle@psych.ucla.edu)

Interleaving, as opposed to blocking presentations of stimuli sets, can impair learning during training yet enhance retention after a delay or on transfer tasks (Battig, 1972; Shea & Morgan, 1979). Since the initial studies, these effects have been shown in diverse cognitive and motor tasks. These studies have in common that two or three stimuli sets were developed such that materials within each set were distinct yet shared features with the other set(s) (e.g. two ball toss patterns). The similarity was designed to create competition for the learner, such that the learner had to both learn the sequences and distinguish them. Battig (1972) described this competition as the contextual interference effect (CI).

While the CI effect has been widely documented, a natural confound has been integral to the studies. Interleaving materials also introduces spacing between the presentations of each set of learning materials.

The current experiment addresses the relationship between the CI effect and the spacing effect. The spacing effect is one of the most robust cognitive scientific findings (see Dempster, 1990); however, its relationship to contextual interference is less well understood. In this study, foreign language vocabulary words were used to test the prediction that CI is distinct from spacing, and that the CI and spacing effects are additive.

Eighty undergraduates were taught translations of eight English words into both Swahili and Estonian, in a task designed to maximize CI (materials from Pashler, UCSD). Subjects completed six anticipation trials, (prompted generation with feedback) and after a brief delay completed a transfer test. The test required subjects to discriminate between the two languages and present both translations for an English word. During training, the languages were either interleaved (I) or blocked (B) between subjects. The spacing between repetitions of a word was kept constant (CS) across the blocked and half of the interleaved stimuli (7-10 items between repetitions) to isolate the effect of interleaving. Spacing was doubled for the other half of words in the interleaving condition (DS) (15-18 intervening items).

Learning curves and final test accuracies are shown in Figure 1. An interaction between performance at trial six and performance on the transfer test revealed that while accuracy during training was highest for B-CS items and lowest for I-DS items, the opposite was true on the test. Test performance was highest for I-DS items and lowest for B-CS items.

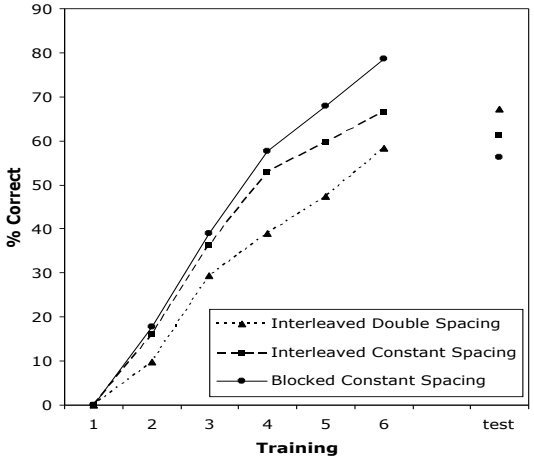

Figure 1. Interleaving and spacing effects during training and on a transfer test.

The data support the prediction that interleaving and spacing are distinct phenomena, and both impair performance during learning yet enhance retention and transfer. Further, the data suggest the effects are additive.

Abstract

A focus being defined as the part in a sentence where new information is given, it is assumed that foci in verbal communications show distinctive prosodic features as well as semantic ones. Sentences were given in pairs and each pair contained a question inducing a certain focus and an answer to it. Suprasegmental features were investigated in priority to detailed physical features of separate sounds.

Generally, a narrow focus didn't show any special correlation with stress. An accentual phrase before a focus showed 1onger duration in the ratio of 1:1.5, and 75% of accentual phrases were actualized as intonational ones. It is suggested that a focus in Korean sentences becomes distinct not by being embodied with stress, but by remarking an accentual phrase before it as pause in an intonational phrase, which is quite different from the cases in Indo-European language.

Methods and Analysis

Materials

1. 'What's up?'
2. 'Who give the TV to her mother?'
3. 'What is given by Sumi to her mother?'
4. 'To Whom Sumi give the TV?'

→ '**Sumi** give **the TV** to **her mother**.' (in Korean)

Participants

20 persons, male and female university students who were born in and grew up at Seoul, Korea.

Analysis

- Pitch tracks were made with the Praat program.
- A K-ToBI transcription was made by the author of the redorded sentences. Analyses of break indices were confirmed by other listeners.

Results

In this paper, there is no correlation between focus and accent. If an AP become focus, the AP and a AP in front of the AP is extended. And, in length, a length of the last syllable in the AP is very extended than a total length of the AP. Especially, at the front of focus, it is revealed IP(ex. complex tone etc.)

Therefore, it could be assumed that in stead of accent, focus appeared through breaking speech in Korean.

Type/Token Information in Category Learning and Recognition

Yasuaki Sakamoto (yasu@psy.utexas.edu)
Bradley C. Love (love@psy.utexas.edu)
Department of Psychology, The University of Texas at Austin
Austin, TX 78712 USA

Items that violate a salient category regularity are remembered better than items that follow the regularity (Palmeri & Nosofsky, 1995). A memory advantage for violating items is also found in the schema research (e.g., Rojahn & Pettigrew, 1992). Furthermore, work in the schema and category learning research suggests that the memory for inconsistent items is stronger when the violated regularity is more salient (e.g., Rojahn & Pettigrew, 1992; Sakamoto & Love, in press).

In Sakamoto and Love (in press), the salience of a regularity was manipulated by varying the number of items that conformed to it. Category A contained eight items that followed the regularity, whereas category B contained only four. The classification learning procedure encouraged subjects to entertain the rules "If value 1 on the first dimension, then category A" and "If value 2 on the first dimension, then category B." Each category contained an exception item that violated the rule (i.e., the regularity). The category B exception violated the category A rule, whereas the category A exception violated the category B rule. After learning, these exceptions were remembered better than the rule-following items, replicating Palmeri and Nosofsky (1995). Furthermore, following findings from the schema research, memory for the category B exception, which violated the more frequent category A rule, was enhanced (cf., Rojahn & Pettigrew, 1992). While SUSTAIN (Love, Medin, & Gureckis, 2004), a clustering model, correctly predicted these findings, current exemplar and hypothesis-testing models could not.

Type vs. Token

The category A rule-following items were more numerous in two ways. There were not only more rule-following tokens (i.e., instances of the rule) but also more rule-following types (i.e., distinct stimuli) in category A (cf., Barsalou, Huttenlocher, & Lamberts, 1998). Thus, the strength of the category A's regularity was attributable to both more tokens and more types. These two notions of "more" have perfectly co-occurred in the schema literature. The goal of the current research is to test the contributions of types and tokens independently of each other.

When repeating rule-following items from the category containing fewer types equated tokens, the exception that violated a regularity consisting of more rule-following types was remembered better (.86 vs. .65) than the exception that violated a regularity consisting of fewer rule-following types, $t(51) = 3.27$, $p < .01$. Preliminary results from experiments examining the effect of tokens independently of types are mixed across manipulations.

Discussion

The current results demonstrate that when tokens are held constant, items that violate a regularity consisting of many item types are remembered better than items that violate a regularity consisting of only a few item types. Future research will resolve the effect of tokens on recognition of violating items when types are equated. Stronger manipulations are currently being examined that avoid contrastive categories often used in category learning research. Work along these lines will illuminate future schema and category learning research and will advance our understanding of how humans represent rules, exceptions, and type/token information.

The Leverage of a Self Concept in Incremental Learning

Alexei V. Samsonovich (asamsono@gmu.edu)

George Mason University, 4400 University Dr., Fairfax, VA 22030 USA

Introduction

This work is an attempt to bring together three topics that belong to three different levels of science: (1) symbolic unsupervised learning, (2) the self of a cognitive system, and (3) a universal criterion for conscious experience. We study cases when a cognitive system develops new abilities by reinterpreting its own episodic memories, using the self-concept and the schema of a motivated voluntary action. Within our framework (Samsonovich & DeJong, 2003), the subject-self per se is not represented as a virtual entity in the cognitive system. Instead, the set of axioms that constitute a self-concept (Aleksander & Dunmall, 2003; Samsonovich & Nadel, in press) are implemented via dynamical rules and constraints. These principles are demonstrated in a model paradigm and have implications for the philosophy of mind.

Approach

The proposed approach is based on the general framework of schemas, charts and mental states described previously (Samsonovich & DeJong, 2003). The term "schema" was introduced by Kant (1781/1929). Here schemas are units of semantic knowledge, primitives of action, reasoning, sensation, etc. A schema has a header (specifying rules and conditions of binding and expected effects of execution) and a body (specifying how, if at all, the schema is executed).

Paradigm: Leveraging Self-Learning with the Self

In this paradigm, a set of specially designed virtual worlds is used as a "training facility" to help the virtual robot to develop useful and powerful schemas. Innate schemas may include elementary moves and senses, as well as relevant reasoning primitives. The robot "wakes up" in a first-level world and starts by repeating the following procedure:

1. Select an action schema and mutate its header to produce an idea of an action that is not straightforward.
2. Take the new header as a challenge and solve it in each of several encountered situations (execute the solutions).
3. Reinterpret own behavior: find an apparent common motivation in the performed intermediate steps in all cases.
4. Based on the above, write the body of the new schema and add the schema to semantic memory.

As the robot learns essentials at the first level, it is taken to the next level, and so on. At each new stage, previously developed schemas are used for solving new challenges.

Demonstration by Example

The scheme outlined above will be demonstrated in the poster by computer simulations based on a push-push puzzle setup. A minimal set of innate schemas includes a one-step move and some useful cognitive primitives, e.g., the notion of Euclidean distance. At the first stage the robot learns to move in an open space. Then it learns to navigate a maze, to push blocks, to avoid irreversible moves, etc. After that, when given a goal, it is capable of solving simple puzzle configurations and learns to deal with more complex ones.

Philosophical Implications

The above analysis has interesting implications for the philosophy of mind. Some philosophers believe that the phenomenon of conscious experience will always remain a mystery, while others maintain that this mystery is illusory. How can one decide, when and whether this phenomenon should occur? Chalmers (1994) answers with the Principle of Organizational Invariance. His answer sounds like this: *there is an abstract mathematical model M of a functional organization of a cognitive system, such that, whenever M can be mapped onto a given physical object, that object is conscious.* Therefore, a criterion for consciousness can be given in terms of *M*. We define it as follows: *M* must instantiate the self as a noumenon (a notion introduced by Kant, 1781/1929), which we understand as an imaginary thing that seems to determine system's dynamics, and yet it cannot be explicitly represented in the system due to its fundamental properties. The proposed framework in which the self is implemented via a set of self-axioms (constraints) about system's own dynamics conforms to this concept.

Individualization as influencing semantic alignment in mathematical word problem solving

Emmanuel Sander (emmanuel.sander@univ-paris8.fr)
University Paris 8, Department of Psychology, 2 Rue de la Liberte
Saint-Denis, 93526 France

Nadege Mathieu (nadege.mathieu@wanadoo.fr)
University Paris 8, Department of Psychology, 2 Rue de la Liberte
Saint-Denis, 93526 France

Several previous works from Bassok and colleagues (e.g. Bassok, Wu & Olseth, 1995) put in evidence that, when solving a mathematical word problem, content is used to interpret structure: surface features are used as semantic cues in order to induce an interpretative structure that the participant will rely on in order to solve the problem. For instance, a problem involving doctors choosing other doctors is likely to provoke the inducement of a symetrical structure wereas a problem involving secretaries choosing computers is likely to provoke the inducement of an asymetrical structure (Bassok, Wu & Olseth, 1995). These structures interfere with the mathematical ones and influence problem difficulty, solving procedures and analogical transfer. Bassok (2001) considered this phenomenon as a special case of the cognitive mechanism of structural alignment (Markman & Gentner, 1993) and refered to it as semantic alignment. Two dimensions, namely symmetry-asymmetry and continuity-discreteness, were identified by Bassok and colleagues as influencing semantic alignment for a large range of problems and identification of other dimensions is important for a better understanding of the phenomenon and it's range of application. We conducted 2 experiments in order to show that Individualization (I)-Non Individualization (NI) is also a relevant dimension.

In the first experiment, 80 undergraduate students were equally split among I and NI conditions and solved combinatorial problems in two contexts. For instance, one NI version involved four children choosing one after the other one strawberry among twelve strawberries wheras the I version was identical except that strawberries were replaced by explicitly individualized cakes (a cheese cake, an apple pie, a chocolate cake…). We found significant effect of the condition (Table 1). In the NI condition, students proposed significantly more partitive solutions (e.g. 12/4) which did not require individualizing objects such as sharing 12 objects among 4 people, than in the I condition. The reverse was true for the multiplicative solutions (e.g. 12x4) which required individualization, such as each child having 12 choices. With the same experimental design, we conducted a second experiment including two problems, the 'car problem' and the 'grocery problem' in which, contrary to combinatorial problems, individualization was not a relevant dimension in the mathematical structure.

Table 1: Rates of procedures used by participants (exp. 1)

Procedure	Indiv	Non Indiv
Correct	8%	10%
Partitive	25%	51% *
Multiplicative	28%	4% *
Other	39%	35%

We found again significant effects: Table 2 sums up the results of the 'car problem': John buys a car 10,000 Euros and sells it 12,000 Euros. He buys it back 14,000 Euros and sells it again 16,000 Euros (NI) and John buys a red car 10,000 Euros and sells it 12,000 Euros. He buys a black car 14,000 Euros and sells it again 16,000 Euros (I). We found also significant effect of individualization for the second problem (NI condition involved two kinds of figs wheras I condition involved figs and dates).

Individual protocol analyses confirmed that participants induced different structures depending on the condition. For instance, most of the participants who found 2000 in the 'car problem' considered that there was a loss of 2000 due to the buying of the same object sold for 2000 less. Those results encourage to carry out more extensive studies concerning the influence of individualization in problem solving.

Table 2: Rates of results obtained by participants (exp. 2)

Results	Indiv	Non Indiv
4000	53%	34% *
0	29%	12% *
2000	12%	46% *
Other	6%	8%

Abstract

In an event-related fMRI-experiment reading during a supposed inference generation period was compared to explicit reading. In a subsequent verification task, the verification of inference and explicit statements were compared. The results show systematic but minimal inference processing during encoding (BA 9) and supplementary activities of text related processes, additional inferencing, and situational elaborations when verifying inference as compared to explicit statements.

Introduction

Which brain areas are involved in predictions during reading and which areas in the subsequent utilization of predictive inferences in a verification task? While predictive inferences are supposedly only represented as part of the situation model, the sentences of a text are additionally encoded as text information (Schmalhofer et al., 2002). Previous fMRI experiments have shown involvement of the prefrontal cortex in establishing text coherence (Ferstl & von Cramon, 2001) and in generating inferential bridges (Mason & Just, 2004).

Experiment

In an event-related fMRI-experiment we investigated 1) the reading during a supposed inference generation period (see Table 1, words 13-18) in comparison to explicit reading and 2) the subsequent verification of the respective statement. (e.g. "wine spilled"). Four versions of texts were constructed so that the same statement constituted an explicit, a paraphrase, an inference or an incorrect statement. The collected data were analyzed by SPM2.

Table 1: Sample text material and test statement

Title: Air Travel
Words 1-12 (all conditions): While the flight attendant served the passenger a full glass of wine
Words 13-18 (explicit): turbulence caused the wine to spill.
Words 13-18 (paraphrase): turbulence caused the wine to splash.
Words 13-18 (inference): turbulence occurred which was very severe.
Words 13-18 (control) : the plane was at cruising altitude.
Test statement: wine spilled

13 students from the University of Osnabrueck participated. 108 reading passages and subsequent tasks were presented: The 4 experimental conditions with 18 trials each as well as 18 filler and 18 non-word trials. A trial lasted 27 seconds. Data were collected by a 1.5 Tesla Siemens Sonata scanner.

Results and Discussion

During reading of words 13-18, the comparison between the inference versus the explicit condition showed the medial frontal gyrus (L + R BA 9, 63 Voxels) to be active. For the statement verification, the contrast between the inference and explicit conditions showed three clusters predominantly in the left prefrontal cortex to be differentially active, as can be seen from Figure 1. For more details see Table 2.

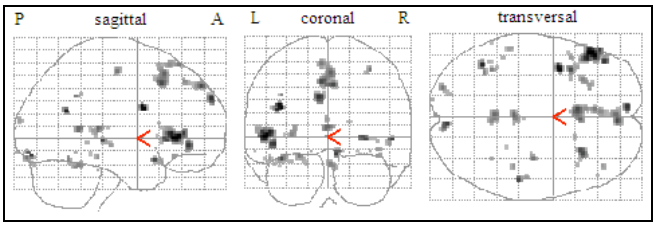

Figure 1: Statement Verification: Inference versus explicit

This experiment confirms previous behavioral results showing minimal predictive inferencing during encoding. It involves the medial frontal gyrus (bilateral). During verification, areas which can be attributed to semantics, inferencing and situational elaborations were observed.

Table 2: Statement Verification: Inference versus explicit

Location of Activated Areas	Z	Voxels
1. Cingulate Gyrus / Superior Frontal Gyrus Medial Frontal Gyrus (L + R BA 8; L BA 6, 32)	3.8	125
2. Medial Frontal Gyrus (L + R BA 9; L BA 6, 8)	3.8	67
3. Inferior Frontal Gyrus (L BA 10, 44, 45, 46, 47)	4.2	168

Consistent Argument-Predicate Binding Is Important for Predicate-Predicate Linking

Adam Sheya (aasheya@indiana.edu), Rima Hanania (rhanania@indiana.edu)
Department of Psychology and Cognitive Science, Indiana University

Hilmi Demir (hdemir@indiana.edu)
Department of Philosophy and Cognitive Science, Indiana University

The fundamental process of connecting instances to each other is essential to many types of learning: from generalization over instances, to category learning, to learning from analogies. The present work seeks an understanding of these processes by studying how adults learn about relations. Learning about relations requires learning about two kinds of entities: arguments and predicates.

Gentner (2003) proposes that arguments, and particularly arguments that take the form of concrete objects, are psychologically prior to predicates. Further, she has shown that object-object similarities play a key role in the relational mappings that both children and adults make. This suggests that when learners are presented with a set of instances in the form of arguments and predicates, the similarity among arguments may be more important than among predicates in connecting learning instances to each other.

However both Gentner (2003) and Billman and Knutson (1996) have also suggested that systematicity of predicates is important. More specifically, Billman and Knutson propose that what is important when learning is how many cues are systematically predictive of the categories. All cues – arguments and predicates – can contribute to systematicity with the critical issue being the degree to which cues are mutually predictive. Thus, it may be the systematicity relations across a set of instances and not specifically argument and predicate similarity that guides learning.

The present experiment uses a learning task in which object categories are defined by the relational roles of the objects and not by their properties. These relational categories have high systematicity: knowing that object X is in relation P to object Y determines both what other relation X enters into and the relational roles of all other objects. In order to learn this, learners must link one relation to another. In these experiments, we manipulate argument similarity and the systematicity of argument-predicate links; keeping predicate systematicity high and constant.

Design

The experiment consisted of a training and test phase. On each trial there were three objects: two actors (A_1, A_2) and one receiver (R). The actors each performed two actions relative to the receiver (e.g. A_1 might "jump over" R and also circle R). On each trial the actions that define A_1 and A_2 did not change. Participants were assigned to one of three training conditions: (1) low argument similarity (different objects each trial), (2) high argument similarity (same objects each trial) and (3) high argument similarity but low argument-predicate systematicity (same objects but different roles on each trial).

In the test trials, new object triads were used that were not superficially similar to the training objects. On each trial the experimenter demonstrated one of the actions for A_1 or A_2. Since the predicates (actions) are systematically related, if the argument-predicate structure has been learned then participants should infer the correct object and predicate pairs from this single cue. In order to measure learning, participants were asked to perform the demonstration object's second action and the two actions of the other actor.

Results and Discussion

A test trial was scored as correct if the actions were paired correctly and the correct receiver was used for every action. Participants failed to learn the argument-predicate structure in the low argument similarity condition (Mean percent of trials correct=16%) and in the high argument similarity and low argument-predicate systematicity condition (M=22%), but they did learn the argument-predicate structure in the high argument similarity condition with high argument-predicate systematicity (M=65%). Our results indicate that systematicity matters in learning. However systematicity of predicates alone is insufficient because this was present in all conditions. The systematicity that was crucial for learning in this case was the systematicity between arguments and predicates. This type may be critical to the learning process because it facilitates the linking of distinct temporal events. The arguments may thus serve as the indexes in working memory that bind one instance to another and thus enable learning across them. The next question is whether objects or arguments in general are privileged in this role or whether any common index to all learning instances would do.

Is Color Photography Flatter:
The Difference of Depth Perception between Chromatic and Achromatic Photos

Suejin Shin (sjshin@yonsei.ac.kr)
Center for Cognitive Science, Yonsei University
134 Shinchondong, Seodaemungu, Seoul, KOREA

Introduction

Expression of depth is one of the most important factors in constructing the creative vision of a photographer. Photographers usually know how to create, with certain artistic sense or taste, depth impression in the process of flattening objects in a three-dimensional space. To emphasis the feeling of depth, photographers tend to choose black and white processing. This is because there has been a myth: color photography is flatter than black and white. From the era of early color photography, pleasure of flatness has been pursued rather than feeling of depth(Newhall, 1982).

The aperture and focal length of lenses are the major factors in changing depth impression(London et al, 2002). Depth impression increases when the aperture size is enlarged, resulting in shallower depth of field. When the focal length of lens becomes longer making the discrepancy of relative size among subjects smaller, depth impression decreases (Shin, 2002). This study is performed to investigate the effects of the presence of color as a photographic technique on depth perception.

Method

Fifty (N=50) Yonsei University undergraduates and graduate students were assigned two experiments. The stimuli were taken in color using two techniques: (a) aperture; f/2.8, f/5.6, f/11, f/22, and (b) focal length of lens; 28mm, 50mm, 70mm, 105mm, which were then duplicated and transformed to gray scale images. The conditions were consistently maintained to reveal the effects of the specific techniques. Every photograph included two same-sized mannequins positioned at different distances from camera. Participants were asked to compare two photographs at a glance, and were forced to identify the photograph in which the two mannequins appear to be closer to each other.

Results and Discussion

The frequency was analyzed by the method of paired comparison(Thurstone1927a; 1927b). In the results(Figure 1, 2), the smaller aperture size and the longer focal length decreased depth perception in both chromatic and achromatic images. Color severely decreased depth impression at variations of focal length. In the mean time, the flattening effect of color was relatively weak along aperture variations. This implies that spatial frequency is a strong factor in giving a feeling of depth even in color photographs.

Black and white process is still common in the field of photography as fine art. From the results of this work, the relatively intense feeling of depth can be one of the reasons for that.

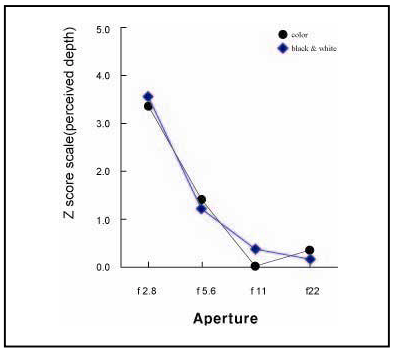

Figure 1: The effect of aperture on depth perception.

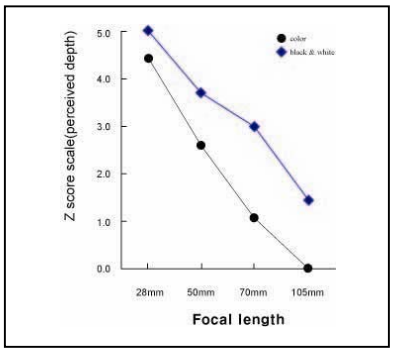

Figure 2: The effect of focal length on depth perception.

Learning through verbalization (1): Understanding the concept of probability

Hajime Shirouzu, Naomi Miyake, ({nmiyake; shirouzu}@sccs.chukyo-u.ac.jp)

Schematizing experiences plays a critical role in learning. Verbalizing experiences at a proper abstraction level has been identified as important for effective schematization (Shirouzu *et al.*, 2002), or learning (Chi *et al.,* 1989), but its details need to be studied further. For instance, in a statistics class, a dramatic demonstration can help students grasp basic concepts like the law of large numbers. Though the students remember them well, what they could verbalize differs depending on the class activities and has different effects on learning. We report here that the students asked to verbalize a demo one hour after could express the important aspects of the event 18% more than their counterparts who did the same twelve weeks later.

Learning the concept of probability

When asked what it means that "The probability of getting ONE pip when you roll a die is one-sixth," it is not rare that even a college student answers that you get ONE once per six rolls of a die. To change this misconception a curriculum was devised. In Activity 1 each student rolled a die 50 to 100 times, counted each pip, and the class tallied the results to yield a histogram of over 3000 trials. This was followed by Activity 2 using a deformed die, with four sides of 1.5 lengths of the other two. Each student rolled the die 200 times, checked the probability of appearances of the pips of ONE and SIX (on shorter sides). Then the class collected all the data to histogram them. The comparison of these two patterns aims to clarify the relationship between the probability and the likelihood of event occurrences, based on the law of large numbers.

Comparison of two classes

Using the curriculum, two undergraduate classes in cognitive science dept. were taught the concept of probability. Two classes were organized differently to compare the timing effect of abstracting the experiences. While Class 1 emphasized teacher-guided abstraction, Class 2, taught by the same teacher, focused more on the students' own verbalization. In Class 1, the teacher explained the law of large numbers, had the students engage in Activity 1. One week later, he showed to the class the histogram of all the data, explained the law, and engaged the class in Activity 2. The results were tallied three times, for 20, 200, and 1800 trials. The students were only explicitly requested to verbalize the meaning of their experiences twelve weeks later, at the term examination. In Class 2, the class did Activities 1 and 2 consecutively in one day (in two classes), without teacher's explanation of the law. Explicit verbalization was requested at the end of the class, in the form of revisiting the starting question. The students had a chance to discuss among themselves.

Results

The verbal reports of the two classes were categorized in terms of their degrees of abstraction. The reports of category "High" refer to the meaning of the law; "If you roll the die infinitely, the ratio of getting the pip ONE approaches 1/6." "Moderate" reports mention the effect of large numbers; "You get the pip ONE roughly 1/6 times if you roll the die many, many times." "Concrete" reports may refer to their class size as an example of a large number, but not its effects. "Others" often include their previous knowledge about the probability, "The pip ONE occurs 1/6 times because it is one of the equally possible six events." Table 1 summarizes the results.

Table 1: Abstraction levels of verbal reports

	Ratio of answerers	Answer abstraction levels			Other
		High	Moderate	Concrete	
1	85.3%	5.3%	16.0%	45.3%	18.7%
2	92.1%	0%	39.4%	10.5%	42.1%

In Class 2, more students moderately abstracted their experiences than concretely. Lacking the chance to do the same, some 45% of the students in Class 1 reverted to the concrete level answers when tested. In order to bridge concrete experience with abstraction, the "moderate" expressions may play an important role.

Requiring students only to verbalize from memory may have had them focus on resultant pattern of 1/6, bringing them back to their previous "common sense" from textbooks. There seems to be certain duration of time to properly ponder on the exact cause and effect of the "surprising" phenomena, to be able to scrutinize their newness carefully enough to be able to generalize them.

Basic Questioning Strategies for Making Sense of a Surprise: The Roles of Training, Experience, and Expertise

Winston R. Sieck (sieck@decisionmaking.com)
Deborah A. Peluso (debbie@decisionmaking.com)
Jennifer Smith (jsmith@decisionmaking.com)
Danyele Harris-Thompson (dharris@decisionmaking.com)
Klein Associates Inc.

Information operations (IO) specialists are like US political strategists in foreign lands, and they are concerned with affecting others' decision processes. In order to be effective, IO practitioners must be able to efficiently develop an understanding, frame or theory (i.e. "make sense") about how decisions are made in a particular locale. As in scientific reasoning, when IO specialists observe surprising events, they have an opportunity to dramatically improve their frames (cf. Dunbar, 1995). But to capitalize on such opportunities, they must acquire the skill to ask good questions; questions that admit to a basic lack of understanding or that specifically challenge their frames. In the current study, we ask, "What roles do training and field experience have in acquiring skills for questioning one's frames?"

Method

Participants (n=60) were either laypeople (L) with no military background, novices (N) who were trained in IO, or individuals who had training and IO field experience (F). Of the latter group, 4 were identified as IO "experts" (E) via peer nomination. Participants were presented with a 1-page scenario describing a real situation that had occurred in Kosovo, and that was obtained earlier from an IO expert by CTA elicitation. The synopsis was that buses with armed escorts were used to transport Serb college students to school from their family's enclaves. The regional commander made plans to reduce the escort due to costs. An IO campaign was conducted to convince the *students* that the buses would still be safe. However, once the escort was reduced, the vast majority of students quit riding the bus. This was quite a surprise to US personnel on the scene. The reason as eventually discovered was that, unlike in the US, the Serb *mothers* made the ride/no ride decision for the students. This reason was not disclosed to participants. Instead, they were asked to explain their understanding of the situation in a think-aloud procedure, as well as what they would want to know to inform their understanding.

Results

The protocols were coded for key kinds of inquiries participants made, in particular, inquiries that would lead directly to developing an accurate understanding of the scenario. The two key inquiry types are: "Why are the students not riding?" and "Is someone else influencing the student's decision?" The proportions of participants who asked each of these key decisions by experience level are presented in Table 1. As shown, participants with field experience were 3 to 4 times more likely to ask one of these critical questions than were those with no field experience (trained or not), $\chi^2(1) = 5.31$, $p = .02$ for the "why" question, and $\chi^2(1) = 5.31$, $p = .02$ for the "who" question. The results were not due to the experienced participants simply "knowing" the answer. Only 3 participants hypothesized the correct answer (coded liberally as "family decides" is the reason). Also, accuracy did not depend on field experience, $\chi^2(1) = 0.04$.

Table 1: Proportion who ask each question

	Experience Level			
Key Inquiries	L	N	F	E
"Why not ride?"	.10	.04	.23	.50
"Who decides?"	.05	.09	.23	.50

Discussion

Experienced IO practitioners were much more likely to question important aspects of their frames than laypeople and trained novices. At one level, the kinds of questions they asked were quite "basic," lacking the obvious technical sophistication that might often be assumed to be associated with experience and expertise. Nevertheless, these simple questions were exactly the kind needed to develop a useful frame on which to base decisions and actions, and are quite similar to questioning strategies of experienced scientists. Indeed, the current study represents an early step toward extension of work in scientific reasoning, situation assessment, judgment and other areas to a broader collective higher-order cognitive topic of "sensemaking" (Klein et al. 2004).

The Effects of Working Memory Load on Transitive Inference

Cynthia M. Sifonis (sifonis@oakland.edu)
Department of Psychology, Oakland University
Rochester, MI 48309 USA

William B. Levy (wbl@virginia.edu)
Department of Neurological Surgery, University of Virginia Hlth Sys

Introduction

Cognitive scientists are interested in the brain mechanisms supporting transitive inference (TI) reasoning. In a TI task, participants learn correct responses to premise pairs (A>B, B>C, C>D, D>E) from which they can infer a relational hierarchy (A>B>C>D>E). The hierarchy allows them to respond appropriately to novel pairings of non-adjacent members of the hierarchy (B>D). It has been demonstrated that both the hippocampus and the prefrontal cortex, with its ability to support working memory (WM) (Barrouillet, 1996) are necessary for successful TI in humans. However, the relationship between WM and TI has never been directly tested.

In the current experiment we examine the effect of a working memory load on TI. We load working memory in two ways – by preventing rehearsal with a math task and by using unfamiliar stimuli, making it more difficult to encode the information in WM. We hypothesized that loading working memory would impair participants ability to learn the premise pairs, their ability to engage in TI, and the degree to which they are aware of the TI hierarchy.

Methods

Stimuli and Procedure

During training blocks, Oakland University students learned the correct response to the premise pairs. The stimuli in the **Unfamiliar** conditions consisted of five hiragana characters. Those in the **Familiar** conditions consisted of five familiar shapes (See Figure 1). Following each premise pair, participants in the **Math** conditions were presented with a subtraction task. Feedback as to premise pair and subtraction task accuracy was provided for each of the 40 training trials in each training block.

Following completion of each training block, participants were tested on their discrimination of the four premise pairs, and the transitive inference pair (BD). Feedback was not provided during the testing blocks. If participants reached 80% accuracy on the premise pairs during testing, training ended. Otherwise, they continued on to the next training block. This continued until criterion performance was reached or four testing/training blocks were completed. After testing, all participants were given a questionnaire assessing their awareness of the hierarchical relationship between pairs.

Results

There were significant main effects of math task, $F(1,141) = 6.12$, $p < .05$, and familiarity, $F(1,141) = 8.14$, $p < .01$, on avg. premise pair performance during testing. Participants given the math task performed less accurately (72% correct) on the premise pairs than those not given a math task (77%). Those given unfamiliar stimuli performed less accurately (76%) than those given familiar stimuli (83%). There was a marginal main effect of familiarity, $p < .10$, on average TI performance during testing. Those given unfamiliar stimuli were less accurate on the BD pairs (68%) than those given familiar stimuli (75%). There was a marginal effect of familiarity on awareness of the TI hierarchy, $X^2 = 3.09$, $p = .10$. Participants given unfamiliar stimuli were more likely than those given familiar stimuli to engage in TI while reporting no conscious awareness of the hierarchy.

Discussion

Our predictions were confirmed. Both preventing rehearsal of premise pairs during the ITI and making it more difficult to encode the information in WM adversely affected participants' ability to engage in transitive inference. With a working memory load, participants were less accurate on both the premise and transitive inference pairs during testing. Additionally, loading WM affected participants' awareness of the TI hierarchy even when they performed accurately on the novel TI pair. This suggests that in humans the prefrontal cortex and the hippocampus interact to support deductive reasoning tasks such as transitive inference.

Now You See It, Now You Don't: Can People Mentally Impose Spatial Category Boundaries?

Vanessa R. Simmering (vanessa-simmering@uiowa.edu)
John P. Spencer (john-spencer@uiowa.edu)
Department of Psychology, University of Iowa
E11 Seashore Hall, Iowa City, IA 52242 USA

Introduction

Several accounts of spatial memory biases propose that people "mentally impose" spatial category boundaries (e.g., Huttenlocher, Hedges, & Duncan, 1991). However, in most tasks that have reported categorical biases, adults have used boundaries aligned with either visible lines or axes of symmetry. This raises a fundamental question: can people mentally impose a category boundary in the absence of perceptual structure supporting such a division? In our previous research, we have demonstrated that category boundaries can be created and destroyed in a spatial memory task by changing the perceptual cues available in the task space (Simmering & Spencer, 2004). Thus, in the present study, we added or deleted perceptual structure to see if people could maintain a categorical division in the absence of relevant perceptual information.

Method & Results

One behavioral signature of using a category boundary in spatial recall is drift away from the boundary over delay (e.g., Spencer & Hund, 2002). In the current experiments, we used direction of drift as an indication of whether participants were using the category boundary. In Experiment 1, the presence of perceptual support for the boundary alternated across blocks. Participants' responses showed drift away from the category boundary only when the perceptual support was provided. Figure 1 shows the switch in drift direction based on the presence of perceptual structure (negative values indicate drift away from the boundary). In both conditions (solid and dashed lines), performance depended on the available perceptual structure. This suggests that people need perceptual support to impose a category boundary.

In Experiment 2, the presence of perceptual support varied randomly across trials. Although imposing the category boundary should have been simpler in the experiment, participants were still unable to impose the reference without perceptual support (see dotted line in Figure 1). This provides further evidence that people need perceptual support to impose a category boundary.

Further analysis of the effects in Experiment 2 suggested that the order of trials may influence participants' ability to mentally impose the spatial category boundary. That is, whether support for the boundary was present on the just-previous trial seemed to influence performance, but the number of trials available for this analysis was too small to determine the reliability of this effect. Experiment 3 was designed to test this more directly by providing the most supportive conditions for mentally imposing the category boundary. In this experiment, we designed mini-blocks of trials in which a trial with no perceptual support followed sets of 1 or 3 trials with perceptual support. In the mini-blocks with 3 trials, the memory for the category should be strongest, and therefore easiest to impose on the following trial. Data collection for this experiment is in progress.

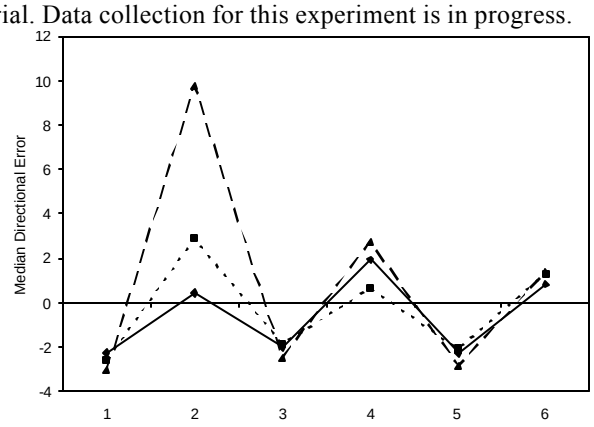

Figure 1: Directional error across blocks for Experiments 1 (solid and dashed lines) and 2 (dotted line).

Conclusion

This series of experiments suggests that adults are unable to mentally impose a category boundary without perceptual support. Even when a category boundary has been used on previous trials, when perceptual support is removed, adults' performance indicates a failure to impose the boundary.

Perception of temporal continuity in discontinuous moving images.

Tim J. Smith (tim.smith@ed.ac.uk)
Institute for Communicating and Collaborative Systems, School of Informatics, University of Edinburgh,
2 Buccleuch Pl., Edinburgh, EH8 9LW, UK

Introduction

The perception of short visual durations is dependent on the internal and external allocation of attention. When attention is concentrated on a single visual event the perceived duration of that event will be longer than if attention is divided or distracted ('Watched Pot Illusion': Block, George & Reed, 1980). Similarly, when we perform voluntary saccadic eye movements to an object with a discernible temporal signature we perceive the first duration following the saccade as being longer than the subsequent duration ('Stopped Clock illusion': Yarrow et al, 2001).

These effects show how ecological time perception can lead to perceptual discontinuities. The opposite effect can be seen in motion picture perception: the perception of temporal continuity from discontinuous visual events. An action filmed from two different camera positions appears temporally continuous if two frames (83.3ms) of the action are overlapped during the cut between shots (Anderson, 1996). This technique of 'continuity editing' is well established yet the perceptual foundations for it have rarely been empirically investigated.

The aim of this study was to show how 'continuity editing' can be explained as the natural result of time perception under different viewing conditions (fixation, peripheral change, and saccadic eye movements).

Methods

Twenty subjects (10 male, 10 female; 19-33 years) were shown animations depicting a series of letters within photo-realistic scenes and asked to judge whether the presentation duration of a target letter was longer or shorter than all other letters. A Modified Binary Search procedure (MOBS: Yarrow et al, 2001) was used to identify a presentation duration perceived by the subjects as being equal to 1000ms under nine viewing conditions: Saccade target relocation (3) x Background (3) (see Figure 1). The presentation order of the conditions was either blocked or randomized to create predictable and unpredictable viewing conditions.

Results and Discussion

The following effects were identified in this study:

- Predictable viewing conditions lead to perceptual extension of fixation duration (estimate = 898ms; t=-3.096 df=9 p=.013). Unpredictable viewing conditions lead to accurate fixation duration perception (estimate=991ms).
- Unexpected peripheral change leads to perceptual shortening of fixation duration (duration = 1049ms; t=-3.180 df=9 p=.011). This effect disappears when coinciding with an unexpected saccade target relocation.

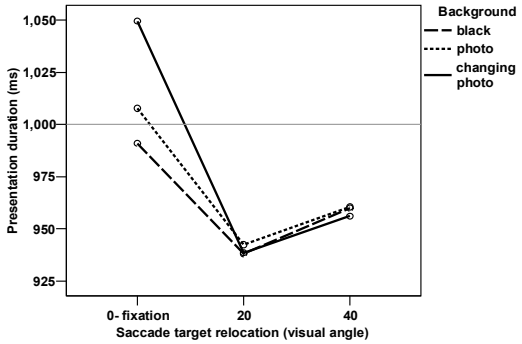

Figure 1: Presentation duration perceived as being equal to 1000ms under the nine randomized viewing conditions.

- Small saccade target relocations (20°) lead to the perceptual extension of post-saccadic durations (blocked: duration decrease=67ms, p=.041; random: duration decrease=53ms, p=.054, one-tail). Large target relocations (40°) only lead to a similar extension when they are unexpected (duration decrease = 57.2ms, p=.023).

These results show how involuntary capture of attention by peripheral change is perceptually under-compensated and voluntary redirection of attention (saccades) over-compensated when perceiving visual durations. These effects are moderated by expectancy.

This allows us to conclude in favour of and explain in more detail the ecological basis of 'continuity editing': perceived temporal continuity is created by overlapping one frame (42.5ms) of a visual event across a cut when the focus of attention remains in the same location but the periphery changes, and omitting one frame when the focus relocates.

Acknowledgments

This project was conducted under financial support from EPSRC and ICCS, and the supervision of John Lee, Helen Pain, and Graeme Ritchie.

Perceiving Narrated Events

Introduction

The perception of events, such as viewing a baseball game, is typically studied using movies of real-world events (e.g., Zacks, Tversky, & Iyer, 2001). However, people frequently perceive events by reading, hearing, or talking about events. Current models of text comprehension suggest that the process of perceiving events in narrated activity may be driven in part by changes in various dimensions of the narrated situation (e.g., Zwaan, Radvansky, Hilliard, & Curiel, 1998). Four experiments were conducted to determine a) whether people are able to reliably perceive event structure in narratives using a paradigm employed to study event structure in real-world activities, and b) which dimensions of the narrated situation are relevant to the perception of event structure in narratives.

Materials & Method

The stories used in all current studies were excerpts from *One Boy's Day* (Barker & Wright, 1951). Written in the style of a narrative, this book provides a detailed record of the activities of a 7-year old boy (Raymond) during a single day in the 1940's. The four stories used in these studies described Raymond waking up, playing in the schoolyard, working on an English lesson, and attending a Music class.

Task Design

In the first experiment, 32 participants were asked to listen to each narrative twice: Once while identifying large units of activity (coarse segmentation), and once while identifying small units of activity (fine segmentation). In the second experiment 32 participants were asked to read the narratives twice on paper, and place a line between words to identify coarse and fine segments of activity in the same stories. In a third experiment, clause-by-clause reading times were collected from 32 participants. In a final experiment, 32 participants used a 7-point scale to rate the predictability of the activity described in each clause given prior information from the story.

Analysis

For each study, the data were analyzed at the level of clauses. In the first two studies, clauses were considered to be event boundaries if a participant segmented at least once during that clause. Each clause was coded for changes on one of six dimensions: temporal references, changes in the foregrounding of characters, their spatial locations, the objects with which they were interacting, their goals, and the causal relations between their actions. The number of syllables (or the duration of the spoken clauses) and punctuation were also coded for each clause.

For each study, these variables were used to predict the patterns of large and small segmentation, reading time, or predictability ratings for each participant. The coefficients generated from these regressions were used to measure the influence of the independent variables in each study.

Results & Conclusions

Participants identified larger units of activity during coarse than fine segmentation, indicating that they were able to perceive structured activity in the narratives.

When identifying large units of activity, participants' patterns of segmentation were related to changes in the foregrounding of characters, their locations and goals, and the causal relations between their actions. In contrast, when identifying small units of activity, patterns of segmentation were more strongly related to changes in characters' interactions with objects. These results were consistent across presentation modalities, and suggest that fine-grained events are closely tied to physical interactions, whereas coarse-grained events are more tied to goals and plans.

Situational changes were also associated with slower reading times (see also Zwaan, et al., 1998) and lower ratings of predictability, suggesting a role for transient changes in predictability in the perception of event structure.

Laypersons Searching for medical information on the Web: The Role of Metacognition

Marc Stadtler (stadtlm@uni-muenster.de)
Rainer Bromme (bromme@uni-muenster.de)
Department of Psychology, University of Muenster
Fliednerstr. 21, 48149 Münster, Germany

Introduction

Today, the WWW is a very prominent resource of health-related information, both, for medical experts and laypersons (e.g. Fox, 2003). The latter often retrieve these information to make an informed decision. However, one cannot expect laypersons to deal with these information effectively offhand. We rather assume that to succeed, laypersons need to actively guide their search process on a metacognitive level, since metacognitive strategies are known to play an important role in the comprehension of complex documents (e.g. Hill & Hannafin, 1997). However, it is yet unclear whether laypersons spontaneously guide their web search on a metacognitive level and - in case they do so - whether the use of metacognitive strategies is related to search success.

Method

To answer this question we carried out a study in which 20 university students with little medical knowledge participated. Their task was to search the WWW for information on cholesterol in order to help a fictitious friend make a knowledge based decision: "Is a medical treatment of my high level of cholesterol necessary?". Participants were provided with 11 pre-selected websites containing controversial information on the topic. Search time was limited to 35 minutes. Knowledge acquisition, decision conflict and detailedness of written credibility assessments functioned as measures of search success. Cognitive processes were ascertained using a think-aloud procedure. Verbal protocols were analyzed using a category system which comprises the categories *Planning*, *Monitoring*, *Evaluation* and *Elaboration*. Inter-rater reliability was 82% across all categories.

Results

Results show that participants differ considerably in their metacognitive activity (see Table 1). Participants' metacognitive activity is rather consistent across the four categories (Cronbach's $\alpha = .78$). Interestingly, metacognitive activity is positively related to knowledge acquisition. Correlation coefficients range from $r = .45$, $p < .05$ (Monitoring), to $r = .57$, $p < .01$ (Evaluation). No significant correlation could be obtained for the relationship of Planning and knowledge acquisition ($r = -.18$, *ns.*).

Results concerning subjectively experienced decision conflict reveal a negative but nonsignificant correlation with metacognitive activity ($r = -.23$, *ns.*). The assumption that better knowledge of the topic cholesterol is related to subjectively experienced decision conflict could be confirmed only partially. While factual knowledge did not correlate significantly ($r = -.13$, *ns.*), comprehension of the subject matter was significantly correlated with scores on the Decision Conflict Scale ($r = -.49$, $p < .05$).

Table 1: Mean number of metacognitive statements and standard deviations for each category.

Category	*M*	*SD*
Planning	10.90	6.61
Monitoring	13.95	6.86
Evaluation	19.00	12.60
Elaboration	11.65	9.48

Finally, analysis of participants' written credibility assessments show that the more participants evaluate information during the search process, the better they are able to report on the credibility of information after their search ($r = .46$, $p < .05$).

To summarize, in the present study the importance of metacognitive strategies for a successful web search could be demonstrated. The results point to the need for metacognitive interventions which support laypersons in dealing with complex technical information on the WWW. Therefore, we have developed the computer based tool *met.a.ware.* The tool enables laypersons to systematically store the information they have found on the web. For this, laypersons have to assign the information gathered to different tabs, which are labeled with aspects of the topic cholesterol. Furthermore, laypersons are prompted to engage in metacognitive activities each time they add information to the system. In ongoing experiments, different types of metacognitive prompts (i.e. evaluating information and monitoring ongoing comprehension) are tested against each other. Thereby, we seek to seperately examine the contributions of different metacognitive activities to a successful web search. First results from our current experiments point to the supportive character of *met.a.ware*.

Introduction

A number of auditory tasks, including speech perception, require listeners to categorize stimuli on the basis of one or more features of the input. In many cases, especially speech, there is no one-to-one mapping between values along continuous features and discrete categories (e.g., phonemes). How then do perceptual systems categorize stimuli under uncertainty? One possible solution is that perceptual systems identify and use statistical information inherent in the acoustic environment. We propose that perceivers incorporate distributional knowledge about the acoustic environment with the information provided by the signal in order to make optimal (i.e., maximized accuracy) categorical decisions. Statistical approaches such as this are widely used in vision research but are rarely applied to auditory or speech perception. Our goal in this study was to develop a framework that will provide testable hypotheses about the nature of statistical (distributional) learning in auditory perception in general and specifically in speech perception.

Methods

In this experiment, participants were presented non-speech sounds sampled from two overlapping distributions. The sounds consisted of 25 narrow-band noise bursts varying in center frequency from 1000 to 1360 Hz. Three different conditions were created by varying parameters of the training distributions. The distributions varied in the ratio of stimuli in each category (i.e., prior probabilities of each category) as well as the amount of overlap between the two distributions. Figure 1 displays the distributions for one of these conditions. The listeners were asked to identify the sounds as belonging to one of two categories ("A" or "B") and feedback was provided after each trial. Due to the overlap between the distributions, there was no deterministic relationship between center frequency and category label for many stimuli.

Results

In decision tasks such as these, optimal performance requires listeners to create a criterion boundary on the dimension (i.e., a particular frequency). Stimuli on either side of this boundary should receive different category labels. Within as few as one block of training trials, most listeners displayed a stable category boundary. Boundaries were estimated from categorization functions averaged across several training blocks. These boundaries varied as a function of the distribution characteristics and were statistically equivalent to the point of distribution intersection. Slopes from categorization functions were steeper than the slopes of the training distributions; suggesting that listeners were more likely using a criterion bound as opposed to simply probability matching the distributions. In general, listeners were responding in a near optimal manner with minimal experience with the training distributions. The ability to use distributional information to map from continuous dimensions to category labels is also essential for speech sound categorization.

Implicitly Learned Sequences Structure the Perception of Human Activity

Khena M. Swallow (kmswallo@artsci.wustl.edu)
Jeffrey M. Zacks (jzacks@artsci.wustl.edu)
Department of Psychology, Washington University in St. Louis
Campus Box 1125, One Brookings Drive, St. Louis, MO 63112 USA

Introduction

People are able to learn and use temporal sequences to guide their perception and behavior. This ability has been demonstrated in visual search tasks (Olson & Chun, 2001) and is present in infants as young as eight months (e.g., Saffran, Aslin, & Newport, 1996). Does seeing the same sequence of activity repeated in different contexts cause that sequence to be treated as a coherent perceptual unit? If temporal sequence learning influences the perception of others' activity, observers should be able to use sequences of activity to prepare for an event predicted by those sequences. Furthermore, these sequences should have a direct effect on the structure people perceive in others' activity: implicitly learned sequences of activity should be perceived as units of activity. The goal of this study was to determine the consequences of temporal sequence learning for the way observers understand the actions of others.

Experiment 1

The first experiment addressed the hypothesis that participants can learn sequences of human activity and use those sequences to aid in a target detection task. A series of pictures (presented for 750 ms with no ISI) of a man with his arm in six different positions and forming thirteen different hand gestures were presented to participants. Eight participants were asked to monitor the gestures and press the correct button whenever they saw either of two target gestures. Within the series of pictures a sequence of seven arm positions was repeated 320 times. Each repetition of the sequence was separated by two to twelve pseudo-randomly selected arm positions. For the first three-quarters of the task, a target gesture immediately followed the sequence. In the last quarter of the task the sequence did not predict when the target would appear. Response times steadily decreased while the target followed the sequence but then increased once the target was no longer predicted by the sequence. None of the participants discovered the sequence nor were they able to demonstrate knowledge of the sequence in a cued-generation recognition test.

Experiment 2

The first experiment demonstrated that observers learn sequences of human activity and can use this knowledge to prepare for important, task-related activity. In a second experiment we sought to determine whether these learned sequences of human activity are treated as perceptual units and, if so, whether this perception depends upon the predictive value of the sequence. Twenty-four participants performed the same target detection task described in the first experiment. However, the predictiveness of the sequence was manipulated across two groups (predictive and nonpredictive groups) and the task was shortened. The performance of these two groups was significantly different: The group for whom the sequence was predictive showed better task performance than the group for whom the sequence was not predictive. Participants also performed a segmentation task in which they were asked to identify boundaries between units by pressing a button when one natural unit of activity ended and another began (Zacks & Tversky, 2001). This task used the stimuli and sequence from the target detection task (though no target gestures were presented). As they performed the segmentation task both groups of participants chose boundaries relative to the sequence of activity they learned in the first task.

Conclusions

As observers watch others perform everyday activities they build up structured representations of their behavior (Zacks & Tversky, 2001). These structured representations influence how they break behavior into smaller units of activity. The results of these experiments suggest that the structure people impose on their experience is in part due to implicitly learned sequences of human activity. These sequences are learned and used to predict the occurrence of important events. Moreover, these sequences influence the way we subsequently perceive the actions of others.

Within-Language Attention Control and Second Language Proficiency

Marlene Taube-Schiff (marlene_taubeschiff@yahoo.ca)
Norman Segalowitz (norman.segalowitz@concordia.ca)
Department of Psychology, and the Centre for the Study of Learning and Performance, Concordia University
7141 Sherbrooke Street West, Montréal, QC H4B 1R6 Canada

Introduction

This study investigated the role linguistic attention control might play in second language (L2) proficiency. Cognitive linguists have proposed that language, beyond referring to events, objects and their properties, also *directs attention* towards relationships between elements in a message (e.g., Slobin, 1996). This is especially true of function words, grammatical morphemes, etc. For example, in *The book is under the table*, the meaning of the preposition *under* is not represented by sensori-motor/perceptual experiences in the same way as it is for *book* and *table*. Instead, *under* directs attention to the relationship between *book* and *table*. Such grammatical elements pose challenges for L2 learners due to these attention-directing functions (Slobin, 1996).

This research used the *alternating runs paradigm* (Rogers & Monsell, 1995) to study attentional control when processing grammatical elements. This paradigm requires responses to two tasks that repeat and alternate predictably (e.g.,...AABBAA...), creating a sequence of repeat and shift trials. Typically, reaction times (RTs) are slower on shift than on repeat trials, resulting in *shift costs* that reflect the burden that shifting places on the attention system.

Decontextualized simple stimuli are often used to investigate attentional task shifting processes. Recently, Taube-Schiff and Segalowitz (2003) found significant shift costs during performance of first language (L1) grammatical judgment tasks involving contextualized sentence-like stimuli. The current two experiments aimed to clarify the specificity of linguistic attention in the grammatical domain by asking the following questions: (1) Does degree of grammatical similarity between tasks affect shift costs? (2) Does attention control in L2 differ for shifts between grammatical elements versus non-grammatical elements? (3) Are linguistic attention shift costs similar in L1 and L2?

Method

Bilingual undergraduate participants (Expt. 1: N=24; *M*=24 years and Expt. 2: N=32; *M*=22 years; L1=English; L2=French) performed an *alternating-runs task* involving 2-alternative forced choice conditions, with trials predictably alternating between repeat and shift trials. Stimuli were displayed on a computer screen and consisted of target words embedded in sentence-like fragments, appropriately counterbalanced for their occurrence in specific sentence contexts. In Experiment 1, participants were tested in two conditions in L1, each involving the following two tasks: In a Grammatically-Different (GDIFF) condition, verb targets were judged for temporal meaning (past versus present tense) and prepositions for location meaning (above versus below). In a Grammatically-Similar (GSIM) condition, prepositions were judged for either one type of location meaning (above versus below) or another type (near versus far). In Experiment 2, participants were tested in L1 and L2 in the GSIM condition (same as in Expt. 1) and in a Non-Grammatical (NOUN) condition in which noun targets were judged with respect to non-grammatical category membership (air versus water craft, and 2- versus 4-wheel vehicles).

Results

Repeated measures ANOVAs were conducted comparing shift and repeat trials to obtain shift costs. In Expt. 1, shift costs were significantly greater for the location task in the GDIFF versus the GSIM condition. In Expt. 2, a significant interaction effect revealed shift costs were significantly greater in L2 in the GSIM condition than in the NOUN condition. Finally, shift costs were significantly greater in L2 than L1, in the GSIM and not in the NOUN condition.

Discussion

The main findings from these studies were: (1) Increased grammatical similarity between tasks decreased shift costs, suggesting a lower attentional burden. (2) There was a greater impact on attention control in L2 when shifting attention between grammatical versus non-grammatical elements, and (3) Linguistic attention shifts costs were greater in L2 than L1, but only significantly so in the grammatical judgment tasks. Results speak to psychological distinctions within the grammatical system and provide additional support for the idea that grammatical elements are more difficult to master in L2 (Slobin, 1996).

Clauses in verbal protocols produced during reading reflect relationships among entities (e.g., arguments) and events (e.g., verb predicates) in the reader's unfolding situation model (e.g., Trabasso & Magliano, 1996). The content of the clauses come from three knowledge sources: the current sentence, the prior text, and the reader's world knowledge. In this study, the relative impact of text elements, as pertaining to dimensions of situation model construction during reading was examined (Zwaan & Radvansky, 1998). Specifically, we measured the extent to which producing an argument (or predicate) influences the likelihood of producing a predicate (or argument) within each knowledge source.

Method

The study included 64 participants enrolled in a critical thinking class at Northern Illinois University. Participants read and self-explained two of four science texts. The four texts were adopted from high-school textbooks on life sciences. Self-explanations were collected after each sentence was presented.

Protocol Analysis

Reader's utterances were parsed into clauses containing main verbs. The verb predicates and arguments within each clause were identified as belonging to one of three sources: the current sentence, the prior text, or world knowledge.

Results and Discussion

We computed the extent to which one constituent type (i.e., verb predicate vs. argument) determines the use of the other within a knowledge source with the following two equations:

Equation 1: Argument Determines Predicate (ADP) =
p (generate P | generate A) - p (generate P | not generate A)

Equation 2: Predicate Determines Argument (PDA) =
p (generate A | generate P) – p (generate A | not generate P)

Table 1 presents the mean constraint scores as a function of the source of a verb (i.e., current sentence, prior text, or world knowledge). A 2 (Constituent Constraint: argument or predicate) X 3 (Source: current sentence, prior text, or world knowledge) repeated measures ANOVA was conducted on the constraint scores. This analysis yielded a main effect for constraint score, such that ADP scores (M = .46) were significantly different from PDA scores (M = .51), $F(1, 126) = 32.03$, $MSE = .008$, $p < .01$. This main effect was qualified by a significant Constituent Constraint X Source interaction ($F(2, 126) = 142.94$, $MSE = .005$, $p < .01$). Post hoc analyses revealed that constraint scores differed across the knowledge sources. With respect to current sentence and prior text, verb predicates constrained the arguments more than arguments constrained the verb predicates. With respect to world knowledge, the opposite pattern was found.

These data suggest that intra-clause constraints may be source dependent. Specifically, when readers describe information from the current sentence, or are accessing information from the prior discourse, they tend to describe the events and entities associated with those events. On the contrary, when entities from world knowledge are activated, readers must construct the events which than link them to the current discourse information.

Table 1: Constraint scores as a function of source and constituent.

Source	ADP Score	PDA Score
Current sentence	0.47	0.52
Prior text	0.37	0.57
World knowledge	0.53	0.43

Eye Scanpaths Influence Memory for Spoken Verbs

Alexia C. Toskos (atoskos@indiana.edu)
Rima Hanania (rhanania@indiana.edu)
Stephen Hockema (shockema@indiana.edu)
Program in Cognitive Science, Indiana University
1033 E. Third St., Bloomington, IN 47405 USA

Introduction

The human body is designed to interact with its environment. Information from all sensory modalities is integrated to allow for navigation and decision making. Developing theories of embodied cognition suggest that thought may be grounded in low-level motor activity and sensory modalities.

The present study tests whether eye motion affects memory for spoken verbs. Vision is a dynamic process in which saccades are used to gather information from multiple points in space. However, these eye fixations are not random. Eye scanpaths are often consistent with thought during the absence of any visual stimulus (Spivey & Geng, 2001, & Laeng and Teodorescu, 2002). The present question is whether feedback from low-level motor activity also plays a role in high-level cognitive processes. If natural eye movements are congruent with thought, perhaps it is possible to influence thought by controlling eye motion.

Richardson, Spivey, Barsalou, & McRae (2003) found that certain verbs carry either a vertical or horizontal spatial orientation, and that spatial orientation is activated upon stimulus presentation. Thus, it is hypothesized that horizontal or vertical eye scanpaths will either enhance memory for words whose spatial orientation is congruent with that of the motion and/or inhibit memory for those words that are incongruent with the motion.

Method

Participants were 45 sighted undergraduates at Indiana University. Apparent motion software was used to create a black circle flipping back and forth vertically or horizontally. As participants tracked the stimulus, a pre-recorded list of verbs played. The list contained 20 of the verbs that Richardson et al. (2003) found to carry spatial meaning. Ten verbs were played while the participant observed apparent motion in one direction, and the next ten words were played while the participant observed apparent motion in the other direction. After a two minute pause, participants were given a list of 40 verbs and asked to circle those which appeared in the previously heard list.

Congruent instances consisted of "vertical" verbs that were presented while participants' eyes moved vertically or "horizontal" verbs while participants' eyes moved horizontally. Incongruent instances consisted of "vertical" verbs presented during horizontal motion or "horizontal" verbs during vertical motion. According to the hypothesis, performance on the recognition task should be better for congruent verbs than for incongruent verbs.

Results and Discussion

The results suggest that eye movements do prime memory for verbs, with vertical eye movements enhancing recognition of verbs with vertical spatial orientations over those with horizontal orientations. The effect was weaker in the horizontal condition. A 2(eye motion direction) x 2(order) x 2(congruency) analysis of variance for a within subjects design yielded a reliable interaction between eye motion direction and order, $F(1,43)=12.470$, $p<.001$. Horizontal eye movements only primed memory for horizontal verbs when this direction of motion was performed first. The analysis also yielded a reliable congruence x direction of motion interaction. The vertical condition yielded a greater difference between congruent and incongruent instances than did the horizontal condition, and the effect was reliable under both orders of presentation.

An ongoing study replicates these findings using a between subjects design (to eliminate order effects) and longer scanpaths. What one thinks is known to determine how one moves. The present findings show that how one moves (at least how the eyes move) determines what is remembered. Apparently, verb meanings are represented in a form close to the sensorimotor surface.

Use of Spatial Transformations in Graph Comprehension

Susan Bell Trickett (stricket@gmu.edu)
Department of Psychology, George Mason University
4400 University Dr., Fairfax, VA 22030 USA

J. Gregory Trafton (trafton@itd.nrl.navy.mil)
Naval Research Laboratory, NRL Code 5513
Washington, DC 20375 USA

Introduction

Current theories of graph comprehension are largely silent about the processes by which inferences are made from graphs (Freedman & Shah, 2002; Pinker, 1990), although it is apparent that people are able to make such inferences. In Trickett & Trafton (2004), we proposed that people use spatial reasoning, in the form of spatial transformations (Trafton et al., in press) to answer inferential questions. This paper is an extension of our earlier study, in which we standardized the graphs presented, so that the distance from the x and y axes was identical for all conditions, we removed typing time from the RT measure. Finally, we expanded the experiment with an additional "middle extension" condition.

Method

8 graduate students and faculty at GMU participated. Participants were shown 40 unlabelled line graphs presented in random order, 10 in each of 4 conditions. They were asked for the value of the y axis at a point on the x axis. The 4 conditions were: read-off (arrow beneath line), near (arrow slightly beyond line), middle (arrow a greater distance) and far (far beyond end of line) (see Figure 1).

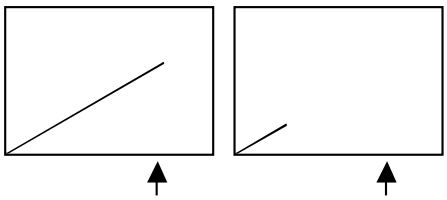

Fig. 1: Schematic of readoff (left) and far (right) conditions.

The readoff condition required no spatial transformations. However, in the near, middle and far conditions, we hypothesized that participants would mentally extend the line (i.e., use spatial transformation) to locate its intersection with the perpendicular from the red arrow. Spatial transformation theory predicts that longer extensions take longer; thus, we predicted that participants would be fastest in the read-off (no extension) condition, increasingly slower in the near and middle conditions, and slowest in the far (longest extension) condition. We also predicted that accuracy would decrease with increased use of spatial transformations, as people must move further from "anchor points" on the graph to obtain needed information—i.e, most accurate in the read-off condition, decreasingly accurate in the near and middle conditions, and least accurate in the far condition.

Results and Discussion

We measured accuracy as the absolute value of the correct response minus the participant's response. Response times (RT) represent the time taken to reach an answer.

Consistent with our hypothesis, participants were most accurate on the read-off task, decreasingly accurate on the near and middle tasks, and least accurate on the far task, repeated measures ANOVA $F(3, 15) = 12.43$, $p < .01$, linear trend $F(1, 5) = 13.93$, $p < .05$.

RT data also supported our hypothesis. Participants were fastest on the read-off task, increasingly slower in the near and middle tasks, and slowest on the far task, $F(3, 15) = 7.44$, $p < .05$, linear trend $F(1, 5) = 10.99$, $p < .05$. The linear trend is consistent with the idea that a longer extension takes more time to execute than a shorter one. If this is true, it should take a measurable amount of time more for each extension. In order to calculate how long each extra extension took, we did a linear regression, using the distance the participants had to extend the line (recall that the distance along the x and y axes was constant). This analysis was significant, $r = .43$, $p < .01$. The analysis yielded the following formula: Response Time = 4.8 + .63, where 4.8 seconds is the baseline time to read information from the graph and .63 is the amount of extra time required to extend the line each centimeter distance required. This result supports our hypothesis that participants used spatial transformations, by indicating a systematic relationship between response time and the distance mentally traveled. As participants had to draw longer mental extensions to the graph, their response times systematically increased. Thus, we propose that a comprehensive theory of graph comprehension should accommodate spatial reasoning.

Cross-Category Effects in Spatial Working Memory

Wendy W. Troob (wendy-troob@uiowa.edu)
Vanessa Simmering (vanessa-simmering@uiowa.edu)
John Spencer (john-spencer@uiowa.edu)
Department of Psychology, University of Iowa
E11 Seashore Hall, Iowa City, IA 52242 USA

Introduction

Most models of memory and spatial categorization predict that people select relevant categorical information at the time of stimulus encoding (e.g., Huttenlocher, Hedges, & Duncan, 1991). Following encoding, unselected category information has no influence on subsequent memory and categorization responses. In contrast, the Dynamic Field Theory (DFT), a neural network model of spatial working memory, suggests that unselected information can still exert an influence following encoding (Schutte, Spencer, & Schöner, 2004). In particular, the network's activation continues to be affected by "unselected" categorical information during memory delays.

To investigate this issue, memory targets were placed in separate spatial categories, but close to a category boundary (e.g. to the left and right of the midline axis of the task space). Participant's experience with the targets was varied by changing the relative frequency of trials to each target. The critical question concerned whether or not the longer-term memory of items in the unselected (e.g., right) category would affect memory for items in the adjacent (e.g., left) category during memory delays. If the predictions of the DFT are correct, such cross-category interactions would be expected.

Method

Participants were seated at a table with a homogeneous surface in a dimly lit room. Two dots aligned with the table's vertical axis were presented 15cm to right of midline. Previous work has demonstrated that these dots form a salient reference axis in spatial recall tasks (Simmering & Spencer, 2004). A target appeared for 2s and participants were asked to recall the location after delays of 0, 10, or 20s. We examined performance in four conditions: no bias (targets -5° to the left of the axis and 5° to the right of the axis), bias right (targets at -5° and 5° with twice as many trials to 5°), plus 10 (targets at -5°, 5°, and 10°), plus 80 (targets at -5°, 5°, and 80°). Importantly, participant's experience responding to the left (-5°) target was the same in all conditions.

Results

According to the DFT, performance to the left target should differ across conditions based on the frequency and spatial distribution of targets in the unselected, right category. This is precisely what we found. Repeated and different exposures to targets in the right category exerted significant effects on responses to items in the left category, even though the number and type of trials to items in the left category was identical across all conditions.

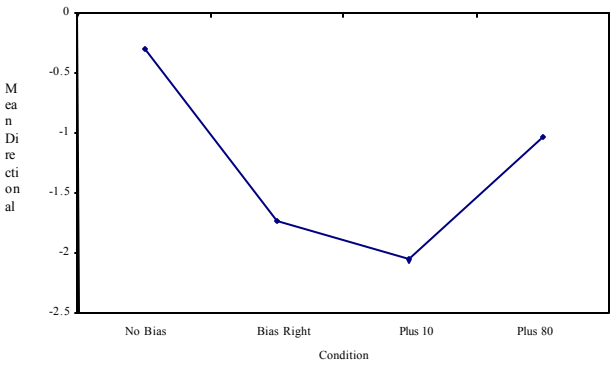

Figure 1: Directional error at the left target across conditions. As predicted, Bias Right and Plus 10 differs significantly from No Bias.

Discussion

Our results are consistent with the proposal that information from both selected and unselected categories can exert an influence on spatial memory performance. Current studies are examining these cross category effects more closely. For instance, the DFT predicts that memory biases to the left target should vary systematically with the distance between the left and right targets.

Computational Accuracy and Conceptual Understanding of Statistics: Effects of Thinking Before Plugging and Chugging

David L. Trumpower (trumpower@marshall.edu)
Department of Psychology, Marshall University
One John Marshall Drive, Huntington, WV 25755 USA

Introduction

Mathematics in general and statistics in particular are notoriously difficult topics for many students. Part of the difficulty may be that students view unfamiliar equations and procedures as being extremely complex and, as a result, focus on learning the computational procedures involved in solving problems at the expense of developing a conceptual understanding of the principles which underlie those procedures. One remedy for this situation is to present conceptual, rather than computational, equations to students. Atkinson, Catrambone, and Merrill (2003) found that learners who were trained to perform t-tests using conceptual equations were better able to transfer their knowledge to solve Analysis of Variance (ANOVA) problems than were learners trained to solve t-tests using computational equations.

Even students who posses both computational skill and conceptual knowledge, however, often fail to make use of their conceptual knowledge (Trumpower, 2003). Anecdotal evidence is provided by students who are able to perform a particular statistical computation accurately, but who then fail to draw accurate conclusions based on the computation. It is possible that this situation is caused by students' tendencies to solve statistics problems by immediately looking for appropriate equations and then plugging numbers into those equations (i.e., "plugging and chugging") before thinking about what the equations and numbers actually represent. If so, then forcing learners to answer some simple conceptual questions before performing computations may create links between conceptual and procedural knowledge, and thus allow them to draw more accurate conclusions. This hypothesis was tested in the present study.

Method

Twenty-eight undergraduate psychology students at Marshall University who had not previously taken any statistics courses served as participants. All participants were first asked to study a booklet that described a procedure for performing an independent-groups t-test and provided a solved example. Participants were then asked to perform 2 independent-groups t-tests and to state their conclusions based on the results of the tests. Half of the participants were randomly assigned to a conceptual condition in which they were asked to answer a series of conceptual questions before performing the t-tests. The other half were assigned to a procedural condition in which they performed both t-tests before answering the conceptual questions.

Results

Participants' computations and conclusions for the two t-tests were scored for accuracy. Also the percentage of conceptual questions answered correctly was determined for each participant. A one-way ANOVA revealed no significant difference between the percentage of conceptual questions answered correctly by participants in the conceptual and procedural conditions, $F<1$. A 2 Condition (conceptual, procedural) x 2 Assessment Type (computations, conclusions) mixed factorial ANOVA with repeated measures on the second factor revealed a significant main effect of Assessment Type, $F(1, 26) = 58.40$, $p < .001$, that was qualified by a significant Condition by Problem Type interaction, $F(1, 26) = 8.03$, $p < .01$. Participants in the procedural condition made more accurate computations than participants in the conceptual condition, whereas participants in the conceptual condition drew more accurate conclusions than participants in the procedural condition.

Discussion

Although participants in both conditions were equally capable of answering simple conceptual questions, those who answered them before performing computations were better able to draw accurate conclusions from the computations than those who performed the computations first. However, answering the conceptual questions first appears to have interfered with performing the computations. This latter finding may have been due to increased cognitive load of participants in the conceptual condition, as they may have been thinking about implications of the conceptual questions while performing computations.

Learning To Be Fluently Disfluent

Mija M. Van Der Wege (mvanderw@carleton.edu)
Department of Psychology, Carleton College
One North College Street, Northfield, MN 55057 USA

E. Christena Ragatz (christa.ragatz@highstream.net)
School of Education, Hamline University
1804 West 138th Street, Burnsville, MN 55337 USA

Introduction

Disfluencies are a normal part of everyday conversation, yet until the past few years, they were viewed only as speech errors and little attention had been paid to their potential functions. Recent research has determined that some of these disfluencies help to coordinate conversational processes. For example, speakers use both *um* and *uh* to indicate a delay in speech production, with *um* indicating a longer delay than *uh* (Smith & H. H. Clark, 1983; H. H. Clark & Fox Tree, 2002). These signals not only are systematically conveyed by the speaker but also appear to be used by the listener when recognizing words (Fox Tree, 2001).

Children are observed to use *um* and *uh* as young as two-years-old, about the same time that they are starting to learn many other content and function words (Van Der Wege, 1996). However, the proper adult-like use of these disfluencies requires cognitive abilities that most other words do not. A child must conceive of a listener as a separate being with a separate understanding from his own.

Preschool-aged children are often described as egocentric, unable to take another's perspective when reasoning or using language (Flavell, 2001; Glucksberg, Krauss, & Weisberg, 1966). Nevertheless, two-year-old children frequently make spontaneous repairs to their speech for the benefit of their listener, indicating that they have an awareness both of the communicative purpose of language and of what their listeners may or may not understand (E. V. Clark & Anderson, 1979).

The current study addresses whether this level of metalinguistic awareness is sufficient for the child to use disfluencies in systematic ways or if the ability to take another's perspective is critical.

Method

Sixty children between the ages of 3 years, 11 months and 6 years from two different preschools were interviewed. All children completed two tasks with a familiar adult. First, they recounted the details of a story, heard for the first time the morning of the interview. Second, they described and discussed a favorite toy.

All conversations were transcribed and digitized. Using a sound editing computer program, the lengths of the pauses surrounding all *um*s and *uh*s were measured and recorded.

Results and Discussion

When talking about their toys, older preschool children (age 5-6 years) used *um* and *uh* systematically, in the same way that adults do (i.e., *um* preceded longer pauses than *uh*). Younger children (age 3-4 years) did not appear to distinguish between their use of the two disfluencies. The distinction was also not seen when the children were recounting the details of the story that they had heard. This was a significant three-way ANOVA interaction ($F[4,2210] = 4.01$, $p < 0.01$).

Apparently, children begin to use *um* and *uh* early in their linguistic lives, recognizing the need to mark speech difficulties. However, they do not have the ability to use these disfluencies in an adult-like manner until later, when they have sufficient cognitive resources to take another's perspective.

Toward a Graded Model of English Phonology

Introduction

Traditional linguistics seeks to specify the universal and absolute properties of phonology and produce a set of inviolable rules. These rules serve to make binary distinctions between allowable forms and disallowed ones. In a thoughtful analysis by Harris (1994) such a set is described. However, this approach has difficulty accounting for graded differences in frequency among phonological forms that do not violate the rules, except to acknowledge certain preferences. For example, post-vocalic stops are more frequent in the context of a short vowel than a long vowel, though they occur with both.

The alternative approach taken in this investigation is to use a set of graded constraints to determine the frequency of a phonological form. This single mechanism captures both the binary and graded patterns assuming that the degree of concordance with the constraints is what determines the frequency. The less concordant a form is with the constraints the lower its frequency, and an unattested form is one that is extremely discordant. The approach taken here is similar to a graded version of Optimality theory (Boersma, 2000; Prince & Smolensky, 1993). In the following model, concordance with constraints is motivated by the observation that more complicated forms tend to be less frequently used than simpler forms, perhaps because as more phonetic material is added to a syllable there is an overall compression that makes articulation and perception difficult.

Graded Model

Phonotactic constraints differ in word internal and word-final contexts, and weaken both across morphological boundaries and from onset to rhyme. Rather than deal with all the sources of complexity at the outset of the investigation we limit our analysis to the rhymes of monosyllabic monomorphemic words. Furthermore, only those rhymes that contain a stop and follow principles of sonority sequencing (Harris, 1994) were considered. Vowels were categorized as either long or short with further distinctions ignored. So, rhymes under consideration have the following form: a long or short vowel followed by an optional liquid, optional nasal, or optional coronal fricative followed by a requisite stop followed by an optional coronal fricative or optional coronal stop. This yields a set of 64 possible rhymes, consisting of a vowel plus up to two additional phonemes, of which 38 are realized in English.

Each rhyme was characterized as a set of complexity-adding features, such as the presence of a fricative after the stop. The frequency of occurrence, measured as the average number of words that use the rhyme per vowel, was then predicted by a linear function which starts with a positive baseline and assesses a weighted penalty for each of the features. The weight was adjusted so that the model would predict the average number of words that use each rhyme type per vowel. Only those forms that occur in the language were allowed to contribute to weight adjustment.

The features used in the model and their final weighted penalty values were: presence of a long vowel (-5.46), stop voicing (-4.79), features to indicate whether the stop is labial (-4.75) or back (-3.22), the presence of a pre-stop homorganic nasal (-10.06), a pre-stop liquid (-13.96), a pre-stop coronal fricative (-12.93), a post stop coronal fricative (-12.80), and a post-stop coronal stop (-15.93). The positive baseline was 21.21. In terms of predicting which terms are attested in English, the model predicts a positive frequency of occurrence for 32 of the 38 that do occur, and a zero frequency of occurrence for 21 the 26 forms that do not. Among the forms that actually occur in English the model predicts 89% of the variance in the frequency per vowel.

Discussion

Previous linguistic work characterized phonology using a set of rules remaining largely unconcerned with graded patterns in the language. The goal for this investigation was to formulate a simple graded constraint model that could account for the binary distinction of which forms are attested in English and which are not, as well as account for the variations in frequencies among occurring forms. Based on the results from this simple model, continued development seems justified.

Natural language computer tutoring vs. human tutoring vs. text studying□□

VanLehn, Kurt
vanlehn@cs.pitt.edu□□

Studies of human tutoring suggest that the participants' use of natural language might be crucial to the effectiveness of human tutoring. In order to study the impact of natural language on learning, we compared 2 kinds of human tutoring (spoken and computer-mediated) with 2 kinds of natural-language-based computer tutoring (Why2-Atlas and Why2-AutoTutor) and 2 kinds text studying. Students solved qualitative physics problems by writing paragraph-long explanations and (in some conditions) discussing them with a tutor. Results from 5 experiments suggest that natural language tutoring is more effective than studying a text without a tutor unless (a) the students are motivated to self-explain the text thoroughly, (b) they have the prior knowledge to successfully self-explain the text, and (c) the content of the text matches the content of the assessments. If all three conditions are met, as they were in some of our experiments, then studying a text elicits the same learning gains as tutoring, even human tutoring. These results are consistent with current theories of cognitive skill acquisition, and with the benefits of tutoring in practical settings where students often lack appropriate engagement, prior knowledge and texts.

Sufficiency: A surprisingly stretchy concept.

Introduction

The concepts of necessity and sufficiency play a central role in explaining the reasoning performance. It is often argued that how people interpret the necessity and sufficiency expressed by a conditional relation has a causal impact on the number and types of inferences that are drawn (see e.g. Thompson, 2000). It is however not yet clear whether the formal definitions of necessity and sufficiency reflect the way reasoners use and interpret these concepts.

In logic, one proposition is a necessary condition of another when the second cannot be true while the first is false, and one proposition is a sufficient condition for another when the first cannot be true while the second is false. Research on conditional reasoning revealed that logical conceptions and definitions are not necessarily psychologically relevant or valid. The current experiment will verify whether participants adhere to the logical definitions of the concepts of necessity and sufficiency.

Experiment

A total of 28 first-year psychology students were asked to indicate whether each of four cause-effect combinations are possible or impossible. Figure 1 gives an example of the task for sufficiency. According to the logic definition, we should observe the pattern listed in Table 1 (the definition of sufficiency does not relate to the third combination). For necessity, participants should accept the first and the last combination and reject the third. When a reasoner considers a cause-effect combination possible, the answer is scored as 1; when it is considered impossible it is scored as 0

Figure 1: Example of the possibility-task.

The cause is sufficient for the effect		
Combinations	Possible	Impossible
1. Cause occurs – Effect occurs	x	
2. Cause occurs – No effect		x
3. No Cause – Effect occurs		
4. No Cause – No effect	x	

Table 1 displays the results. According to the formal conceptualisation of necessity the 'no cause-effect' combination is illegal, whereas the combination 'cause–no effect' is irrelevant. As expected, the irrelevant combination was more often considered possible than the illegal combination, *Wilcoxon T* = 15, *Z* = 2.35, *N non-ties* = 14, $p < .05$. For sufficiency, the difference between the irrelevant 'no cause – effect' and illegal 'cause–no effect' combination was not significant. Surprisingly, the illegal combination was considered possible by 60.7% of the participants.

Table 1: Percentage of trials in which each combination was considered possible.

	Cause Effect	Cause No Effect	No Cause Effect	No Cause No Effect
Sufficient	100	**60.7**	46.4	85.7
Necessary	96.4	57.1	14.3	92.9

When we look at the patterns of relevant combinations for a sufficient cause, there were 8 participants (29%) who considered the 'cause–effect', 'cause– no effect' and the 'no cause–no effect' combinations respectively possible, impossible and possible, whereas there were 16 participants (57%) who found all three combinations possible. For necessity, there were 22 participants (79%) that considered the 'cause-effect', 'no cause-effect' and 'no cause- no effect' respectively possible, impossible and possible, whereas only 3 participants (11%) considered all three combinations possible. The 'no cause–effect' combination is thus understood as a combination that contradicts necessity, the combination 'cause–no effect' does not contract sufficiency.

Conclusion

Whereas the subjective conceptualisation of necessity parallels the formal definition, the subjective concept of sufficiency is less stringent than the formal concept. A cause can be considered sufficient to grant the effect, even when the effect does not always follow. However, when causal rules are used to make predictions, it can be adaptive to label a cause that increases the probability of the effect as subjectively sufficient. The observed divergence between the subjective and formal definition raises doubt on the claim that reasoners assess the formal level of sufficiency to derive conditional conclusions.

Toward an Integrated Understanding of the Generation of Place-Fields in the Different Sub-fields of the Hippocampal Region.

Renan W.F. Vitral.[1,2] (renan@cns.bu.edu)
[1]Department of Cognitive and Neural Systems, Boston University.
677 Beacon Street, Boston, MA, 02215. USA

[2]NIPAN – CNPq, Department of Physiology,
Federal University of Juiz de Fora, Brazil.

Introduction

The generation of the "Place Fields" in the hippocampal region is a fundamental phenomenon for the processing of the declarative memory. The electrophysiological attributes are associated to the concomitant generation of theta-gamma activity, while, at the behavioral level, they are expressed as environmental exploration and attention phenomena, when studied in animals. However there were not described robust topographical pathways that sustain a direct association of the afferent pathways from hippocampus to specific cortical regions that would be recipients of the functional processes for the consolidation of memory and the navigational abilities.

Another topic refers to the generation of the "Place Fields" in the several sub-fields of the hippocampal region: the integrated role of these attributes still stays obscure.

Methods

In previous studies we developed a computational neural net based on mathematical attributes of the Gated Dipoles and the opponent processing for the modeling of the generation of place fields. We showed on this model that the temporary entrance of frequencies at the net, more than the topographical organization, would sustain a memory system for the construction of place fields. We used also attributes of self-organizing maps to construct the system.

In this work we expanded the developed net, with the integration of the several hippocampal sub-fields, based on anatomical and electrophysiological data, trying to get a more reliable model of the hippocampal function when working on the cited frequencies.

Results

In our results the concomitant generation of the Place Fields in different sub-fields and in an independent way would work in a combinatory system. So, while the afferent connections to the hippocampus show a progressive topographical condensation with a transduction for aleatory functional patterns in each sub-field, it happens a temporary filtration and accentuation of the developed information based on the temporal properties of the little variations on each frequency arriving the hippocampus. These attributes, associated with the internal abilities of frequency generation, could create a combinatory amplification of the capacities of storage of information that temporally would construct a diverse and accentuated basis for the efferent processes of the hippocampal system.

Conclusions

Finally, our suggestion is that the hippocampal complex functions as a transduction system from topographical to frequency-dependent abilities with a combinatory generation of memory traces based on the temporary weight of the established connections among cells and subfields to subserve the several roles attributed to it, as the participation on the memory consolidation, navigational abilities, emotional expressions, and so, adaptively timed learning.

Early Word Learning: How Infants Learn Words that Sound Similar

Julia Wales (jwales@purdue.edu)
Department of Psychological Sciences, 703 Third St.
West Lafayette, IN 47907 USA

George Hollich (ghollich@purdue.edu)
Department of Psychological Sciences, 703 Third St.
West Lafayette, IN 47907 USA

Introduction

The development of both phonological perception and semantic acquisition has been well studied, yet the connection between these remains a mystery. Research in phonological perception has demonstrated that infants are born with the ability to make fine phonetic discriminations (Cristophe, Jacques, & Sebastian-Galles, 2001). However, word-learning research has suggested infants do not make use of this knowledge in learning similar sounding words (Werker & Tees, 2002). Why? The current study suggests that infants have detailed phonetic representations for newly acquired words but suppress this information under certain circumstances.

Method

Infants from the West Lafayette/Lafayette area were tested at four different ages: 14, 18, 22, and 26 months.

The present study used the splitscreen preferential looking paradigm. This paradigm presents two objects, one on each side of a screen while audio stimuli requests one of the objects. The experiment consisted of two sequences. The first sequence attempted to teach infants a novel word (e.g. "chab") while the second sequence attempted to teach a second novel word that was phonologically similar to the previously taught word (e.g. "chas"). The auditory stimuli for this sequence were presented in a different voice (differing in gender) from the second sequence. The order of voices and specific words were counterbalanced across subjects.

Each sequence consisted of four types of trials. Infants first had a training trial where they were presented with a single object on the screen and the novel label for that object. This was always followed by a salience trial where the object the infant heard labeled was presented on one side of the screen and another object was presented on the other side. Auditory stimulus was played that was not intended to direct attention to either object (e.g "What do you see?"). The infants then saw the two test trials (label and similar), the order of which were counterbalanced to control for order effects. In the label condition, the object that the infants saw in training was requested. In the similar condition, the similar word was requested. The logic of the procedure was that if infants learned the word in the test phase, they should look longer at it during the label trials than in the salience trials or the similar trials.

Results and Discussion

Although performance did increase with age, even at 14 months, infants looked significantly longer at the labeled object when it was requested during the first sequence. Furthermore, they did not look longer at the label object in the salience or similar trials. In those trials, infants looked longer at the unlabeled object. This switch in looking suggests that infants noticed and rejected phonetic differences when the voice was the same, demonstrating that they can make fine phonetic discriminations in the context of a word-learning task. However, infants did not notice the same phonetic differences when the talker was changed in the second sequence of trials.

There are two logical explanations for the results from the second sequence of trials. Perhaps infants pragmatically noticed the switch between voices and assumed that the phonetic differences in this case were not meaningful. This strategy may cause mislabeling when the task is to learn similar sounding words, but it may ultimately lead to more successful labeling in the real world where phonetic signals are more variable and normalization is key. Alternatively, it is possible that the task of attaching meaning to the second word caused the difficulty. Specifically, it is possible that infants lost track of which word went with which object (something even adults will do, on occasion). In this case, the switch in voice was irrelevant. Even if the voice had been the same, infants would have had the same difficulties in the second block of trials.

Ongoing studies are examining whether it was the change in talker or the learning of a second word that caused the difficulties in the second block of trials. However, the current results suggest that infants do posses fine phonetic distinctions in a word learning task, even at 14 months, and that they will ignore these distinctions when memory or pragmatic conditions dictate.

Learning OT Grammars of Syllable Structure

Adam T. Wayment (awayment@jhu.edu)
Department of Cognitive Science, Johns Hopkins University
3400 N. Charles St. Baltimore, MD 21218 USA

1. Introduction

Optimality Theory (OT) (Prince & Smolensky 1993) has been widely adopted in phonology and has also been successfully applied to syntax, semantics, and pragmatics. One reason OT has been so rapidly accepted is that its initial presentation was closely tied to a connectionist realization (Blutner, et al. forthcoming). Goldwater and Johnson (2003) suggest that another reason for OT's recent dominance is that there are algorithms for learning constraint rankings. However, these elements of OT's success (learning algorithms and connectionist realizations) have not yet been unified in a connectionist network that learns constraint rankings.

A grammar in Optimality Theory is defined by a set of ranked violable constraints. The function GEN takes a base form as input and generates an infinite set of candidates. EVAL then selects the optimal realization from among these candidates, obeying the criterion that the ordering of constraints is strictly dominant. Archangeli (1997) reviews how re-ranking a few violable constraints (ONSET, PEAK, NOCODA, *COMPLEX, FAITHC, AND FAITHV) accounts for a large number of the syllable structures attested in the languages of the world. Within this domain of syllable structure, we explore the dilemma of learning a constraint ranking in a connectionist network. The goal is to design a network that can learn the well-formedness of test syllables, based on positive training data generated from a particular ranking of the violable constraints.

2. Fixed-Point Membership

Now, let **G** be a harmonic grammar. The task is to determine if an input form w is in $L(\mathbf{G})$. Define language membership as follows $w \in L(\mathbf{G})$ iff EVAL(GEN(w)) = w. In words, membership is equated with being a fixed-point of OT generation. This concept of membership provides a powerful framework, in which recognition can be performed via a fixed point test on an input form.

Translating this notion to a Harmonic Network—where input is equivalent to clamping the initial activation state—if, after the network is allowed to harmonize, the input pattern is the same as the output pattern, then the input form is in the language of the harmonic grammar described by the weights of the network. If however, the input and output pattern differ, then the input form is not in the language prescribed by the grammar because the more harmonic activation state corresponds to some other output form, so the form fails the fixed-point test. Thus, learning well-formedness is tantamount to learning the identity map. Poverty of the stimulus issues bear heavily on this problem because we require that the identity map be learned from only positive data.

3. Data, Representation, and Learning

Sample data consists of valid phonetic combinations of consonants and vowels, e.g. for a CV language, [ba], [mi], and [po] may be present in the training. Network evaluation is determined by way of the well-formedness scores of a random collection of test syllables of various structure (CV, CVC, CCV, etc.). Only those syllables that are in the language of the net's grammar will be fixed points, and all forms that are not in the language will not.

We represent syllables in a fully connected-symmetric network made by copying a set of fillers (one unit per consonant or vowel) for every role position (peak, onset, etc.). We allow for complex onsets and codas, by placing multiple filler sets in a position. Thus, 'tint' =[tInt], is represented by activating the *t* unit in the Onset filler set, the *I* unit in the Nucleus filler set, the *n* unit on in the first coda filler set, and the *t* unit in second coda filler set.

We compare two different algorithms for learning the weights of the network: backpropagation through time and Boltzmann learning. Preliminary experiments show that the first is unsuccessful at learning the elements in the complement of the training set are ungrammatical, whereas because of its negative phase of training, Boltzmann learning can learn the well-formedness of syllables.

Emergence of features in visual stimuli

Alice Welham (a.k.welham@ex.ac.uk) and A.J. Wills (a.j.wills@ex.ac.uk)
School of Psychology, University of Exeter, Perry Rd., Exeter, EX4 4QG. UK.

It has been suggested that new perceptual features can be "created" when they are necessary for a particular task. For instance, by "unitization" (Goldstone, 2000), components which were previously processed separately become represented as a wholistic unit. Certain associative theories (McLaren, Kaye and Mackintosh, 1989) explain unitization as the establishment of connections between reliably co-occurring elements of a stimulus. By this account, after unitization, sampling a subset of featural elements causes retrieval of the whole feature. Given that the model assumes that only a proportion of elements are sampled on any presentation, unitization could lead to an increase in subjective salience of a feature.

This account does not require that the feature is necessary for a task (e.g., diagnostic of a category) for unitization to occur, merely that its elements co-occur. Experiments 1 and 2 indicate firstly that features emerge through simple pre-exposure as well as when they are diagnostic, and secondly, that the process of emergence may increase the collective salience of the feature's components.

Method

Our stimuli consisted of 75% trial-unique random noise, and 25% "feature", which could occur in any of the four corners of a stimulus. There were four "non-obvious" features (NOF condition) and four "control features" (control condition), which were horizontal lines, vertical lines, and two types of square. Figure 1 shows an example of each, with the feature in the top left.

Forty-eight undergraduate students from Exeter University participated in each of Experiments 1 and 2, for course credits or 4 GBP. In both experiments, half of the participants were in the NOF condition and half in the control condition. Every participant completed a training phase followed by a test phase. The training phase consisted of repeated exposure to two of the four features (of the participant's feature type condition). Stimuli were displayed one after another on a computer monitor, and each stimulus contained one feature, in variable location. In Experiment 1, the training phase was a binary choice category learning task in which each feature was diagnostic of a category, and in Experiment 2, participants had to judge the aesthetic appeal of each stimulus on a 9-point scale.

The test phase (identical for both experiments) involved all four features (two trained and two untrained) from that participant's condition. In the first task, pairs of stimuli containing a common feature (the remainder of each stimulus was independently randomly created) were presented for 2 seconds each, after which a similarity judgment was made on a scale of 1 (not at all similar) to 9 (very similar). This was followed by a triad task, in which

Figure 1: Non-obvious feature stimulus (left) and control stimulus (right)

participants were presented with three stimuli (X, Y and Z) simultaneously, and had to decide which two were the most similar. X and Y shared 25% in the form of one of the "features", and X and Z shared 75% but in the form of trial-unique, randomly created noise. Of principle interest are differences in test phase performance with features that have been trained as opposed to untrained.

Results and discussion

In the NOF condition of both experiments, the number of times that the X and Y pair in the triads task was chosen as more similar than the X and Z pair was significantly greater for trained than untrained features. Contrastingly, training had no effect on control features' salience. The sequential similarity judgment task showed similar results. In the NOF condition of both experiments, similarity judgments were higher for pairs of stimuli containing trained than untrained features. This was not seen for the control features, whose salience significantly *decreased* with training in Experiment 2 (and did not change in Experiment 1). For both test phase tasks, effects of training were not significantly different for the two experiments.

The results indicate that novel features, which are presumably not represented prior to the experiment, became more salient through training. This is not dependent on their explicit usefulness. Theories of the allocation of attention to existing attributes (e.g., Kruschke 1996) would have trouble accounting for the increase in salience due to simple pre-exposure of a feature, and the McLaren et al. model can predict that the unitization process itself may be responsible.

The ability to assess the similarity of objects in the world is fundamentally important to our survival. Many theories have been proposed for modeling human similarity judgments. Most of these theories involve comparing the sets of features of the compared items to determine the overlap between them. Many of them completely ignore the structure of the objects and the relationships between the parts. Goldstone (1994) showed that such systems fail to account for human similarity ratings of structured data. His SIAM system used a (non-learning) connectionist architecture to create correspondences between objects and their features in different scenes. Excitatory connections reinforced coherent mappings between objects (e.g. ObjectA to ObjectC and ObjectB to ObjectD). Inhibitory connections fought against redundant or contradictory mappings. Likewise, connections between the features of objects either supported or inhibited each other and the corresponding object–object connections. SIAM's connectionist architecture allowed it to take into account the structure of the scenes and the objects as well as the similarity of the features.

Goldstone examined similarity ratings of visual scenes. His approach represented a scene as a spatially related set of objects (for example, pairs of schematic butterflies). Each object has a set of parts each of which has some value. For example, one of Goldstone's butterflies could be represented as: `(object1 (head square) (tail zig-zag) (body-shading white) (wing-shading checkered))`.

In previous research, we have explored the use of Latent Semantic Analysis (LSA) for judging the semantic similarity of a given sentence to a set of alternative target sentences. Although LSA has been shown to match the reliability of raters with intermediate domain knowledge, the correlation between LSA and human ratings is still somewhat disappointing, generally below 0.5 in a number of studies (Wiemer-Hastings, Wiemer-Hastings, & Graesser, 1999). In recent research, we have pursued the general hypothesis that including structural knowledge would improve the correspondence between human and LSA ratings. We found that by performing syntactic analysis of the source and target sentences and separately comparing their subjects, objects, and verbs with LSA, we could reduce the error by over 10% (Wiemer-Hastings & Zipitria, 2001).

In the current research, we explored the use of SIAM to combine the analysis of the structural aspects of the sentences with the semantic similarity ratings provided by LSA. To map this approach to sentences, we broke the inputs into subject, verb, object, and indirect object parts. Thus, a simple representation of the sentence "The dog bit a man" as an object would be: `(object1 (verb "bit") (subject "The dog") (object "a man"))`. The advantage of SIAM-LSA over the previous model (Structured LSA, or SLSA) is that its connectionist architecture allows the different components to "compete" for correspondence, instead of relying on a direct mapping of subject, verb, and object segments. Our basic hypothesis was that SIAM-LSA would provide a closer match to human ratings than SLSA. A secondary hypothesis was that providing a salience value to give differential weight to the different structural components of the sentences would better match human ratings.

In our experiment, we compared human ratings with the basic SIAM-LSA system and the system augmented with salience values. Our results did not support the basic hypothesis. In fact, SIAM-LSA performed worse than LSA or SLSA. When we included empirically derived weights which accentuated verb and object matches but completely devalued subject matches, the ratings correlated with human ratings $r = 0.59$, another 10% reduction in the error over SLSA. In accordance with (Resnik, 1993), this suggests that humans essentially ignore the role of syntactic subjects when matching sentence meanings.

Background

Food in a natural environment is often distributed in patches, spots of higher resource abundance than in the surrounding area. For an animal or human searching on the sea shore, each patch might be a rock pool. Models of animal foraging have considered the situation where such patches vary in their initial quality (return rates), where this may be hard to judge because food items are hidden, and where foraging progressively depletes the resource. As animals learn about and simultaneously deplete a patch they should eventually decide to move because greater success is expected elsewhere.

The optimal strategy in such a situation is given by the *Marginal Value Theorem* (MVT): leave a patch when the instantaneous rate of return falls below the long-term return rate in the whole environment when following the optimal policy (Charnov, 1976). However, the MVT does not offer a mechanistic solution if mean return rate in the environment is not known and if foraging is a succession of discrete events in which items are encountered stochastically (McNamara, 1982). Behavioural ecologists have both derived optimal departure rules in these circumstances and investigated the performance of sub-optimal rules of thumb (such as giving up after a constant time) which may be computationally simpler (Iwasa, Higashi & Yamamura, 1981; Green, 1984; Bell, 1991). Which rules perform well depends on whether patches are evenly dispersed in quality or some are very good and the others very poor. In the former environment finding an item should decrease the tendency to stay, whereas in the latter the opposite is true. This theory indeed explains why related species of insect utilising differently dispersed resources use different rules.

Hypotheses

We propose that humans also should be adapted to decide when to give up on one food patch and move to another, and that they may apply similar simple heuristics as animals have been shown to use. But because humans are intelligent generalists, feeding on some foods which are evenly dispersed across patches and on some which are aggregated in a few better patches, we further predict that humans are sensitive to this aspect of our environment and are able to adapt our heuristics accordingly. Additionally we propose that the patch-leaving heuristics that we use in foraging tasks are also used to decide when to give up on other tasks. We have designed two computerised experiments to test these hypotheses.

Methods

External search: the fishing task

Participants are given a virtual landscape in which they have to monitor ponds (i.e. patches), forage for fish and decide on how long to stay at each pond. All ponds appear equal, but the number of fish in each varies. Each participant experiences either a dispersed, aggregated or Poisson distribution of fishes per patch, and we will also vary the mean travel time between ponds. The probability of finding a fish is proportional to the number left in the pond. Participants see only the number of fish caught at the current pond (and must judge times and rates without reference to a clock). They receive payment at the end depending on the total number of fish caught at all ponds in a fixed time.

Internal search: the word puzzle task

Participants are presented with a modified anagram task in which they search for words from memory. Meaningful words must be generated out of meaningless sequences of letters. Analogously to the first task, participants experience one of three types of patch quality distribution, must decide when to switch to the next sequence, and are paid by their overall success. We attempt to match the environmental parameters in these two tasks as closely as possible.

Acquisition of polymorphous concepts

A. J. Wills (a.j.wills@ex.ac.uk), Lyn Ellett and S. E. G. Lea
School of Psychology, University of Exeter, Perry Rd. Exeter. EX4 4QG. ENGLAND.

In a polymorphous concept, features are characteristic rather than defining. In Figure 1a, a triangle, an upwards arrow and a pound sign are characteristic of category A. Stimuli are members of category A if they contain more features characteristic of A than features characteristic of B. Dennis, Hampton and Lea (1973) found that polymorphous concepts took considerably longer to acquire to an errorless criterion than either conjunctive or disjunctive rules; conjunctive rules being precisely the sort of structure rejected as "unnaturalistic" by much of contemporary categorization research.

Humans are not the only species to find the acquisition of polymorphous concepts very difficult. In one study with pigeons (von Fersen & Lea, 1990), separate training on each of the stimulus feature-pairs was eventually required in order to train the concept. If it could be demonstrated, with appropriate control groups, that this sort of pre-training was more effective than an equal length of training on the full problem, this would present a challenge to some theories of learning in both pigeons and in people.

Method

The left-hand panel of Figure 1b shows a stimulus containing all five features characteristic of category A. From the outside in, the five feature-pairs are a) flankers (fine/coarse), b) trapezium, c) stars/blobs, d) colored square (yellow/blue), and e) lines (orientation).

Sixty undergraduate students from Exeter University participated for course credit or 4 GBP. Standard category acquisition procedures were followed throughout - stimuli were presented one at a time, a category decision requested ("category A or B?") and feedback given immediately after each decision.

There were three between-subject conditions. In the SINGLE condition, feature pairs were trained one at a time. For example, a participant might first be trained on the problem "stars -> category A / blobs > category B", and would then move on to the next feature-pair. The order in which the five feature-pairs were trained was randomized across participants. Once all five feature-pairs had been trained individually, participants were moved, in the second phase, to the full polymorphous set of 32 (2^5) stimuli for four blocks of trials. Subjects in the POLY condition received the same total number of training trials as the subjects in the SINGLE condition, but all trials were with the full polymorphous stimuli.

Subjects in the SINGLE (REV) condition received single-feature training in the same manner as the SINGLE group. The difference was that the category associations of three out of the five feature pairs were (unbeknownst to the subject) reversed prior to the polymorphous training phase. Thus, if they had initially been trained that "stars -> category A / blobs > category B", then in the polymorphous phase, "blobs" were characteristic of category A and "stars" were characteristic of category B.

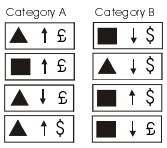

Figure 1a

Figure 1b

Results and discussion

Participants in SINGLE condition were considerably more accurate on the polymorphous problem than participants who had done that problem throughout, but they were also slower (longer RTs).

If these results were entirely due to general motivation or strategic factors then one might expect the reversal in the SINGLE (REV) condition to have relatively little effect. In contrast, if the SINGLE group is more accurate and slower because specific categorical knowledge acquired in phase one is transferred to phase two, then this reversal between the phases should dramatically affect performance. In fact, participants in the SINGLE(REV) condition were significantly worse at the polymorphous problem than participants in either of the other two conditions, but their reaction times were comparable to those in the SINGLE condition. Our working hypothesis is that the specific categorical knowledge acquired in the single feature-pair phase does indeed facilitate polymorphous categorization, but that there may also be important strategic/motivational effects.

Exemplar models (e.g. Nosofsky, 1986) explain aquisition of categorical knowledge by stating that we store labelled instances of categories. In "broad-brush" terms, it seems difficult to explain, from an exemplar-based account, why trading an exact copy of the stimulus you need to make a decision about for stimuli that contain only small parts of it would be beneficial to categorization accuracy.

Are Relations Directly Detected at Initial Encoding?

Aaron S. Yarlas (yarlasa@gvsu.edu)
Department of Psychology, Grand Valley State University
1 Campus Drive, Allendale, MI 49401 USA

Vladimir M. Sloutsky (VSloutsky@hec.ohio-state.edu)
Center for Cognitive Science, The Ohio State University
1961 Tuttle Park Place, Columbus, OH 43210 USA

This study examines how representations for relations are formed during initial stimulus encoding. One possibility is parallel encoding of elements and relations, such that detection of relations does not require binding, but rather involves matching a new stimulus to a relational template or schema that is retrieved from LTM. A second possibility is a serial account: that there is no direct detection of relations, but rather binding occurs only after elements have detected, at which point their configuration is encoded.

These two possibilities make differing predictions regarding the encoding of elements and relations. First, the first possibility predicts that elements and relations should be represented comparably, whereas the second possibility predicts that relations should be represented less often than elements. Second, the two possibilities differ in their expectation of illusory binding (i.e., binding of target elements to a distracter relation, or distracter elements to a target relation). The first possibility predicts that illusory binding should be symmetrical: given that both elements and relations are identified, there should be both binding of distracter elements to a target relation and binding of a distracter relation to target elements. On the other hand, the second possibility predicts that illusory binding should be asymmetrical: given that elements, but not relations, are identified prior to binding, there should be binding of distracter elements to a target relation, but not binding of a distracter relation to target elements, since this latter case requires an identified relational schema.

To distinguish between the two possibilities, we incorporated an immediate recognition procedure. The general procedure involved subjects receiving on each trial two study items in succession (presented on a computer screen), one a target and one a distracter, with order of presentation randomly counterbalanced across trials. Subjects then received two recognition items simultaneously on the screen, with one of these items being an old item (i.e., identical to the target study item), and the other a foil. Subjects' task was to choose which of these items had been presented during the study phase (i.e., the target). Subjects' choices and latencies were recorded.

The stimuli used were three horizontally-aligned shapes, with elements being shapes of objects and relations being the patterns among 3 shapes within each arrangement. Three relations were used (ABA, AAB, and ABB), with A and B representing different shapes (e.g., an ABA relation might be circle-square-circle). A second within-participants factor was the type of foil paired with an Old target (in the forced-choice recognition task). There were 5 types of foils: E_{New}/R_{Target} foils (same relation as target, but new elements), E_{Target}/R_{New} foils (same elements as target, but a new relation), $E_{Target}/R_{Distractor}$ foils (same elements as target, but relation from the distracter item), $E_{Distractor}/R_{Target}$ foils (same relation as target, but elements from the distracter item), and E_{New}/R_{New} foils (new elements and relations).

The two possibilities predict different patterns of accuracy across foil types. If relations are detected directly, then there should be no difference in accuracy between E_{New}/R_{Target} foils and E_{Target}/R_{New} foils, since participants should be equivalently sensitive to violations of both elements and relations. However, a different pattern was found: participants made fewer choices of E_{New}/R_{Target} foils than E_{Target}/R_{New} foils, indicating that they were more likely to have encoded elements than relations.

Comparisons among foils also afford examination of illusory binding for elements and relations. If participants directly detect elements during encoding, they should be more likely to choose a foil containing elements from the distracter study item ($E_{Distractor}/R_{Target}$ foils) than elements not presented in the study phase (E_{New}/R_{Target} foils) of that trial. At the same time, if participants directly detect relations during encoding, they should be more likely to choose a foil containing relations from the distracter study item ($E_{Target}/R_{Distractor}$ foils) than relations not presented in the study phase (E_{Target}/R_{New} foils). Consistent with both possibilities, there was evidence of illusory binding for distracter elements onto target relations; however, consistent only with the second possibility, there was not symmetrical illusory binding for relations. In other words, participants were not more likely to choose the foil containing distracter relations than the one containing new relations, indicating that distracter relations were not represented above and beyond relations never presented during the trial.

Thus, data clearly support the second possibility, that unlike elements, relations are not detected directly during encoding, but more likely representations for relations emerge from configural binding of elements. Of course, it could very well be the case that this is only true for unlearned relations such as those used here. Future studies will involve training of relations to examine whether well-learned relations are detected directly at encoding.

What is similar in phonological-similarity effect?

Michael C. W. YIP

School of Arts & Social Sciences, The Open University of Hong Kong

myip@ouhk.edu.hk

Introduction

A robust finding in working memory research is that to recall a set of phonologically similar words is much more difficult than to recall a set of phonologically dissimilar words, which is the well-known phonological-similarity effect (Conrad & Hull, 1964). This finding points out that the capacity of information retention in our working memory store more or less depends on the phonological nature of the to-be-memorized information. The more similar (phonologically) of the to-be-memorized item, the more difficult to retain in the working memory store. However, most of the Chinese people have the subjective experience that to immediately recall a set of colloquial slogans in television advertisement is much more easier than to immediately recall a set of common sentences due to the similarity of prosody. There is also evidence showing that rhyming of verbal information usually enhances our memorization ability (Fallon, Groves, & Tehan, 1999). Therefore, how to explain these contradicting observations is very important in order to get a fuller understanding to the operation of the working memory model (Baddeley, 1992).

In the memory study done by Saito (1998), he reported that intonation of a sentence might make a contribution to participants' recall performance (see also Pennington & Ellis, 2000). Following to this point and together with our aforementioned subjective experience, we can see that prosodic information may be useful to our recall performance to the verbal information to an extent, simply like to recall a colloquial slogan in advertisement for a brief period of time. Reviewing the relevant literature so far, there are a lot of empirical works conducted on this issue in the domain of language research: comprehension and production (Sevald & Dell, 1994; Slowiaczek, McQueen, Soltano, & Lynch, 2000; Soto-Faraco, Sebastián-Gallés & Cutler, 2001). However, little consideration has been given to how these different phonological characteristics of a word affect the recall performance in working memory so far despite of their interdependency.

Hence, the major objective in the present study is to examine how the phonological characteristics of a word influence the recall performance in working memory, which is a theoretically interesting but still unexplored question.

Experiment

A typical word span task with Chinese words as the materials was used to examine the phonological characteristics of a word on the recall performance. The main variable in the present experiment is the different degree of phonological similarity, whether those Chinese words presented in the testing lists shared any phonological characteristics (onset, rime and tone) among themselves or not (see Yip, 2004 for details).

Procedure

Participants were asked to read aloud lists of displayed Chinese words on the computer screen one by one. And then, they were asked to recall the Chinese words from the list out loud as many as possible, and the experimenter counted the correctness of their verbal responses at the end of each list. Altogether, each participant received forty lists with a total of 400 Chinese words in the experiment within two sessions with a break. Each session included 100 phonologically similar items and 100 phonologically dissimilar items. The order of presentation for the lists was randomly assigned in the two sessions. The whole experiment lasted for forty minutes.

Results and Discussion

Two main findings in the present study were concluded.

First, the present results indicate that one major source of phonological-similarity decrement comes from the overlapping of the segmental information of the to-be-memorized materials. This phonological overlapping among the to-be-memorized words poses difficulties for participants to perceive and to rehearse because of the acoustic confusion among the words, which is consistent with the previous research findings.

Second, the prosodic information of the to-be-memorized materials seems to be retained longer in the working memory. This overlapping of tonal information among words even produces a phonological-similarity facilitatory effect. Finally, based on the present results, the traditional concept of the term "similar" in the phonological-similarity effect should be re-conceptualized. Because similarity in prosodic information, unlike the similarity in segmental information, will not create any interference effect in working memory, but a facilitatory effect will occur in working memory instead.

Computing Semantic Representations: A Comparative Analysis

How can we formally capture the complex semantic relationships of the human lexicon? This question has been the focus of much recent computational studies. The ability to represent semantics faithfully in formal mechanisms not only is important for understanding the nature of the lexical system of natural languages, but also has significant implications for understanding the mental representation of meaning and its processing and acquisition.

Two best-known models in this regard are the Latent Semantic Analysis (LSA; Landauer & Dumais, 1997) and the Hyperspace Analog to Language (HAL; Burgess & Lund, 1997). Both of them are based on large-scale computational analyses of human speech corpora. The LSA model represents the corpora as a high-dimensional co-occurrence matrix of words in texts, and reduces its dimensions using singular value decomposition. The HAL model builds a semantic word co-occurrence matrix, which is weighted according to co-occurrence frequency. In contrast to these two models that automatically extract meanings by computational algorithms, a third model, the WordNet (Miller, 1990), is a computational thesaurus that provides semantic classification of the English lexicon in terms of hyponyms, synonyms, and antonyms, as well as searchable word entries with semantic definitions. Harm (2002) developed a system to extract the semantic features of the WordNet definitions so that lexical entries can be represented as feature-based vectors. In this study, we examine the virtues and drawbacks of the three models with respect to their ability to represent semantics accurately.

Because of our interest in modeling a developmental lexicon, we selected as our test vocabulary 600 words from the MacArthur Communicative Development Inventories (CDI; Dale & Fenson, 1996). The vocabulary can be divided into four major grammatical categories (nouns, verbs, adjectives, and closed-class words). The nouns can be further divided into 12 subcategories according to their meanings (e.g., clothes, toys, food, etc). The LSA, HAL and WordNet matrices used in our analyses were made available either by the authors or by their electronic distributions.

To examine the accuracy of word classification and representations of the three models, we used a simple k-nearest neighbor (kNN) classifier (Duda, Hart & Stork, 2000). The average classification rates of 4 grammatical categories and the 12 noun subcategories were treated respectively with a 5NN classifier. Figure 1 presents the results. It shows that the WordNet vectors give the best classification rates overall, followed by HAL and then LSA for the 4 grammatical categories, and by LSA and then HAL for the 12 noun subcategories. The best performance of the WordNet model indicates that the lexicographic and psycholinguistic analyses of words can yield accurate lexical-semantic representations, although it comes with a price: a significant amount of work is required to hand-code the features of words by human researchers. The better performance of HAL for the major grammatical categories indicates that HAL captures important information about grammatical relationships of words because of its representation and weighting of word sequences (word-to-word co-occurrence matrices). Finally, the better performance of LSA for the noun subcategories indicates that LSA is able to capture more subtle semantic differences and relationships among words, because a word's representation in this model involves a large number of other words in text (word-to-text co-occurrence matrices).

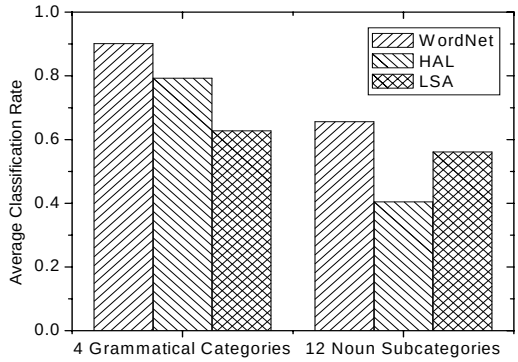

Figure 1: Average classification rates by a 5NN classifier

Reasoning about Ecological Systems

Introduction

Ecological systems are quite complex and dynamic, and are often poorly understood (Groves & Pugh, 2002). The multiple cause-and-effect relationships and second-order effects in such systems are difficult to learn and teach (Hogan, 2000). One example is the use of "bio-control," where the introduction of a species to prey or feed on an unwanted species is used as an alternative to chemical herbicides or pesticides. Because of the complexity of ecological systems and the potential side effects and long-term consequences of such actions it is often difficult to predict precisely the how the system will change over time. Therefore, it is important to understand how individuals think about the ecological systems and the environmental problems that they are being asked to make decisions about.

The purpose of this study was to examine students' reasoning about an ecological management proposal. Such reasoning can be influenced by many factors including conceptual understanding of ecological systems, perceived and actual scientific knowledge, the way information is presented and the influence of other individuals who support or oppose the proposal. In the current study, we focus on two of these factors. First, we were interested in exploring whether the process of self-evaluation (i.e., making students aware of their perceived and actual scientific knowledge) would affect reasoning and decision making. Attitudes, thoughts and beliefs are often automatic or non-conscious, but the conscious evaluation of one's own beliefs or attitudes may be one method for changing thoughts or behaviors (e.g., Bargh & Chartrand, 1999) and so requiring individuals to reflect on their current understanding of science could affect beliefs, reactions, or decisions. Second, we wanted to determine if an ecological management proposal described as a species *introduction* would invoke different mental models than one described as a species *reintroduction*. We hypothesized that the word "reintroduction" may support the inference that the species was "meant" to be part of the ecosystem.

Methods

Eighty undergraduates read and evaluated a brief news article (294 words) that described a proposed initiative to introduce wolves to the Rocky Mountain region. The article was adapted from an online newsletter ("Poll shows strong support for wolves," 2001). Two versions were created with the initiative described as either an introduction or a reintroduction. Participants were asked a number of questions, including whether or not they would support the initiative if required to vote today, their certainty and confidence in their decision, and whether they felt qualified to vote on such an issue. Students also completed a questionnaire to assess perceived and actual background knowledge either before or after reading and evaluating the proposal. Five items assessed perceived scientific knowledge. Actual background knowledge was assessed with a 20-item multiple-choice test covering basic ecological knowledge. Participants were randomly assigned to one of four conditions created by crossing *topic* (introduction vs. reintroduction) with *order of self-evaluation* (before or after evaluating the proposal).

Results

A relationship between the *topic* and voting decision was evident. Participants in the reintroduction condition were more likely to vote in support of the initiative (87.5%) than those in the introduction condition (62.5%) (χ^2 (1) = 6.67, $p < .01$), supporting the idea that this subtle, one-word manipulation may invoke different mental models. *Order of self-evaluation*, however, did not influence voting decisions. We predicted that people who took the test before making a decision would be less certain, confident, and feel less qualified than people who took the test after they made their decision. There was a main effect of order (F (1,76) = 7.21, $p = .009$) on this composite variable, but no main effect of topic or interaction between order and topic (Fs ≈ 1). This effect was not due to differences in either perceived or actual knowledge (Fs ≈ 1). Making individuals aware of their own knowledge did not affect the decision itself, but it did affect certainty and confidence with which they made their decisions.
