Abstract

A new recognition memory model is proposed which differs from the existing memory models in that it operates on natural input. Therefore it is called the natural input memory (NIM) model. A biologically-informed perceptual pre-processing method takes local samples from a natural image and translates these into a feature-vector representation. The feature-vector representations reside in a similarity space in which perceptual similarity corresponds to proximity. By using the similarity structure of natural input, the model by-passes assumptions about distributional statistics of real-world input. Our simulations on the list-strength effect, the list-length effect, and the false memory effect support the validity of the proposed model. In particular, we conducted a face recognition simulation with the NIM model and found that it is able to replicate well-established recognition memory effects that relate to the similarity of the input.

Memory Representation

Many computational memory models represent an item by a vector of abstract features (e.g., the SAM model, Raaijmakers & Shiffrin, 1981; the REM model, Shiffrin & Steyvers, 1997, the model of differentiation, McClelland & Chappell, 1998). The feature values are usually drawn from a mathematical distribution (e.g., a geometric distribution). Since the computational models artificially generate vector representations, they do not address the contribution of the similarity structure intrinsic to natural data. However, we believe that the similarity structure contains important information. Therefore, we propose a memory model that operates on natural data and represents the similarity structure of these data.

The similarity structure of natural data can be represented in any type of space that fulfills the compactness criterion (Arkadev & Braverman, 1966). This criterion is fulfilled when similar objects in the real world are close in their representations. Several researchers developed so called 'similarity spaces', in which representations of similar items are in close proximity of each other (e.g., Nosofsky, 1986; Steyvers, Shiffrin, & Nelson, in press). An analysis of human similarity judgments or of free association data often forms the basis of a similarity space. However, we propose to derive the similarity space from the natural data by employing a biologically-informed transformation.

In the next section, a new recognition memory model that operates on natural images is introduced and described. We call this model the natural input memory (NIM) model. We will conduct a face recognition simulation with the NIM model and will evaluate its ability to replicate findings from recognition-memory studies. Finally our main conclusion will be given.

The NIM Model

The NIM model encompasses the following two stages.

1. A perceptual pre-processing stage that translates a natural image into a number of feature vectors.
2. A memory stage comprising two processes:
   (a) a storage process that simply stores feature vectors;
   (b) a recognition process that compares feature vectors of the image to be recognized with previously stored feature vectors.

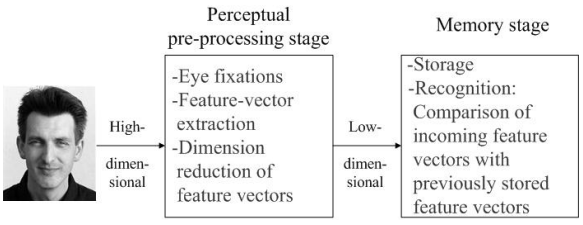

Figure 1: The natural input memory (NIM) model.

Figure 1 presents a schematic diagram of the NIM model. The face image is an example of a natural image. The two boxes correspond to the perceptual pre-processing stage and the memory stage.

The Perceptual Pre-Processing Stage

In this section, we first provide some background on the sources of biological inspiration and on the computational considerations. Then, we discuss some relevant implementation details.

Biological Inspiration and Computational Considerations
The human visual system is our main source of biological inspiration. The eye sequentially fixates on those parts of a visual scene that are most informative for recognition (e.g., Yarbus, 1967). Early visual processing in the brain leads to the activation of millions of optic nerve cells (Palmer, 1999). The nerve-cell activations may be conceived as a high dimensional vector. The high dimensionality enables the representation of a large amount of information without suffering from interference (Rao & Ballard, 1995), but it also hampers the memory performance, as the number of examples

that is necessary for a reliable generalization performance grows exponentially with the number of dimensions. This phenomenon is known as the 'curse of dimensionality' (Bellman, 1961; Edelman & Intrator, 1997). In coping with the curse of dimensionality, subsequent stages in the visual system are assumed to reduce the dimensionality of the high-dimensional input (e.g., Hubel, 1988; Tenenbaum, Silva, & Langford, 2000). The assumption is supported by findings of Edelman and Intrator (1997), who showed that the human visual system is able to retrieve the intrinsic low-dimensional structure of the high-dimensional visual input.

In the NIM model, dimension reduction of high-dimensional natural input is achieved in two sequential steps: (1) a biologically-informed feature-vector extraction (Freeman & Adelson, 1991) followed by (2) a principal component analysis (Pearson, 1901). The feature-vector extraction method employed by the NIM model operates directly on a high-dimensional natural image. The image has a high dimensionality because it is treated as a vector, the elements of which are the constituent pixel values. Motivated by eye fixations in human vision, the feature-vector extraction method takes samples from randomly-selected locations along the contours in the image. To emphasize the parallel with human vision, we refer to the samples as 'fixations'. For each fixation, the NIM model extracts features (i.e, a feature vector) from the image area centered at the fixation location. Since the feature vector contains a limited number of features, it is of a much lower dimensionality than the image. The feature-vector extraction method is based on the visual processing generally believed to occur in the visual area V1. The responses of neurons in V1 are modeled by a multi-scale wavelet decomposition (described later). Several studies showed that the biologically-informed multi-scale wavelet decomposition results in a representation space that accurately represents similarities as perceived by humans (e.g., Kalocsai, Zhao, & Biederman, 1998; Lyons & Akamatsu, 1998; Bartlett, Littleworth, Braathen, Sejnowski, & Movellan, 2003). After extraction of feature vectors, principal component analysis represents the feature vectors by their projection onto a number of orthogonal basis vectors which are ordered according to the amount of variance they explain. The dimensionality of the feature vectors is reduced by taking the projection onto the first p basis vectors. The low-dimensional feature vectors reside in a similarity space where visual similarity translates to proximity of feature vectors. Translating a two-dimensional image using a multi-scale wavelet decomposition followed by a principal component analysis, is an often applied method in the domain of visual object recognition to model the first three stages of processing of information in the human visual system (i.e., retina/LGN, V1/V2, V4/LOC; Palmeri & Gauthier, 2004). In contrast, existing memory models lack such a pre-processing method and often make simplifying assumptions about object representations.

Implementation The input image is translated into a multi-scale representation at four spatial scales. At every scale, the image is processed by four oriented filters in the orientations 0°, 45°, 90°, and 105° using the steerable-pyramid transform (Freeman & Adelson, 1991). This processing results in sixteen (four scales times four orientations) filtered images. From each of the sixteen images a 7×7 window is selected at a fixation point and the 16×49 pixel values are placed in a vector. In addition, the pixel values of a 7×7 low-resolution subimage centered at the fixation point are appended to the vector. Fixation points are randomly drawn from the contours of the face. The result is a feature vector for each fixation. As mentioned before, a principal component analysis was used to reduce the dimensionality of the feature vectors by taking the projection onto the first p basis vectors.

The Memory Stage

The Storage Process In the NIM model, the storage process straightforwardly stores an item (i.e., a pre-processed natural image). A pre-processed natural image is represented by a number of low-dimensional feature vectors in the similarity space, each corresponding to an eye fixation. The storage strength, S, is defined as the number of feature vectors stored for an image.

The Recognition Process In the NIM model, the recognition process determines the familiarity of an image to be recognized by comparing feature vectors of the image to be recognized with previously stored feature vectors. Models with a recognition process based on comparing items to previously stored exemplars can provide an accurate quantitative account of recognition performance (Medin & Schaffer, 1978; Nosofsky, 1986; Nosofsky, Clark, & Shin, 1989). In the NIM model, the recognition process uses a nearest neighbor classifier method, which takes each feature vector of the image to be recognized and then determines the number of previously stored feature vectors, f, that fall within a hypersphere with radius r, centered around the feature vector of the image. The familiarity, F, of the image is defined as $\sum f_i/T$, with f_i the value of f for the i^{th} feature vector of the image, and T the total number of feature vectors of the image.

We expect that the similarity-space representations employed by the NIM model will deepen our understanding of human recognition memory. Moreover, they may effectively support a number of memory effects often obtained in recognition memory studies. The latter studies are described in the next section.

Human Recognition Memory Studies

Three recognition memory effects often found in recognition memory studies are: the list-strength effect, the list-length effect, and the false memory effect. In general, recognition memory studies provide subjects with a study list of items and test their recognition memory for (some of) the studied items (i.e., targets) and a number of non-studied items (i.e., lures). We will emphasize the relation between the similarity structure of the targets and the lures used in the experiments on the one hand and the memory effects on the other hand.

The List-Strength Effect

A list-strength effect is defined as: a decrease in memory performance for a given set of study list items when other items of the study list are "strengthened" (i.e., the amount of time or the number of times the items are studied is increased) (Ratcliff, Clark, & Shiffrin, 1990). While some researchers failed

to find a list-strength effect for recognition memory (e.g., Ratcliff et al., 1990), recent findings showed that a list-strength effect can be obtained when there is a high degree of similarity between targets and lures. Norman (2002) tested whether strengthening some words of the study list affected a subject's recognition performance for other (non-strengthened) studied words. In the experiments, a significant list-strength effect was obtained only when targets and lures were similar. For dissimilar targets and lures, no list-strength effect was found. Moreover, recognition scores were significantly higher for dissimilar targets and lures than for similar targets and lures.

The List-Length Effect

A list-length effect is defined as: a decrease in memory performance for the items of the study list when additional items are added to the study list (Ratcliff et al., 1990). List-length studies yielded contradictory results. While some researchers failed to find a list-length effect (e.g., Dennis & Humphreys, 2001), others did obtain it (e.g., Cary & Reder, 2003). Recent experimental results indicate that the similarity between targets and lures can affect the degree to which a list-length effect occurs (MacAndrew, Klatzky, Fiez, McClelland, & Becker, 2002). In a study examining the effect of phonological similarity on recognition memory, MacAndrew et al. (2002) tested subjects' recognition memory for letters on a study list of four or six letters. The results showed that a larger list-length effect occurred for similar targets and lures than for dissimilar targets and lures. Also, overall recognition scores were higher for dissimilar targets and lures than for similar targets and lures.

The False Memory Effect

A number of experimental studies showed a false memory effect, which holds that the recognition of a lure (i.e., a false memory or a false alarm) is more likely to happen when the lure is similar to (one of the) studied items (e.g., Postman, 1951; Dewhurst & Farrand, 2004). For instance, the results by Dewhurst and Farrand (2004) show that the number of false memories increases together with the number of targets on the study list that are similar to the lures.

In a similarity space, representations of similar targets and lures show more overlap than representations of dissimilar targets and lures. Similar targets and lures are thus more difficult to discriminate than dissimilar targets and lures. Therefore, we expect that list-strength effects and list-length effects will be more pronounced and there will be more false alarms when targets and lures are similar than when targets and lures are dissimilar.

We hypothesize that the similarity structure of the perceived targets and lures can give rise to the recognition-memory effects discussed above. To test this hypothesis, we conducted a face recognition simulation with the NIM model, which employs similarity-space representations of perceived natural images.

Simulation

In our simulation, we investigated the ability of the NIM model to produce the following effects: (1) the effect of the similarity between targets and lures on the list-strength effect, (2) the effect of the similarity between targets and lures on the list-length effect, and (3) the false memory effect. The NIM model was repeatedly provided with a study list of face images and tested for recognition of the studied images (i.e., targets) and a number of non-studied images (i.e., lures). The images were gray-scale images of human faces taken from the FERET database (Phillips, Wechsler, Huang, & Rauss, 1998) of facial images. Male and female Caucasian faces without beards or glasses were selected. An example of such an image is shown on the left hand side of Figure 1. In this simulation, recognition memory was tested in two different conditions: (1) the dissimilar condition that employed lures dissimilar from the targets, and (2) the similar condition, that employed lures similar to one of the targets. In the NIM model, similar images are separated by a small distance in the similarity space. List-strength effects and list-length effects were assessed in both conditions and compared to determine whether the similarity between targets and lures had affected the degree to which the list effects occurred. Moreover, a comparison of the recognition results in the dissimilar condition and the similar condition revealed whether a false memory effect had occurred. Below we describe the calculation of recognition scores, the paradigms, the conditions, the procedure, and the results.

Calculation of Recognition Scores

The familiarity values, F, were used in a signal detection analysis to determine the recognition scores. The appropriate measure for the recognition score (d_a) was based on the normalized difference between the average F values of the targets ($\overline{F}(I_T)$) and the average F values of the lures ($\overline{F}(I_L)$):

$$d_a = \frac{\overline{F}(I_T) - \overline{F}(I_L)}{\sqrt{\frac{\sigma^2_{[F(I_T)]} + \sigma^2_{[F(I_L)]}}{2}}}$$

(Simpson & Fitter, 1973). Each d_a value was calculated on the basis of the familiarity values for targets ($F(I_T)$) and the familiarity values for lures ($F(I_L)$) of ten recognition tests.

Paradigms

The List-Strength Effect We used the mixed-pure paradigm first proposed by Ratcliff et al. (1990). It is used in many list-strength studies. The mixed-pure paradigm employs three types of study lists: pure weak lists (N weak images), pure strong lists (N strong images), and mixed lists ($N/2$ strong and $N/2$ weak images). A list-strength effect is said to occur (1) when the recognition score for weak images on a pure list is higher than the recognition score for weak images on a mixed list or, (2) when the recognition score for strong images on a mixed list is higher than the recognition score for strong images on a pure list. The pure/mixed ratio for weak images (i.e., the recognition score for weak images on a pure list divided by the recognition score for weak images on a mixed list) thus is an indication for the degree to which a list-strength effect occurs for weak images. Likewise, the mixed/pure ratio for strong images is an indication for the degree to which a list-strength effect occurs for strong images.

The List-Length Effect A list-length effect is said to occur when the recognition score for images on a shorter list is higher than the recognition score for images on a longer list. To assess the occurrence of a list-length effect we compared recognition scores for images on study lists of different lengths.

The False Memory Effect A higher false alarm rate (together with no difference in the hit rate) for the similar condition than for the dissimilar condition is said to indicate the occurrence of a false memory effect. However, using the general performance measure d_a (as described in the previous subsection) to determine recognition scores, the NIM model produces no false memories (and thus no false memory effect), simply because no recognition decisions are made. Most computational memory models, however, make recognition decisions based on the comparison of an obtained familiarity value to a given criterion (e.g., Busey, 2001). When the familiarity value exceeds the criterion, the item is recognized, if not, the item is not recognized. To assess the false memory effect, we also applied a decision criterion to the familiarity values, F, obtained for the dissimilar condition and for the similar condition. As a criterion we used: $C = S \times (0.02 + N/500)$, with S the storage strength of the images, and N the number of images on the study list.

Conditions

We distinguished two conditions: the dissimilar and the similar condition. For the dissimilar condition, recognition performance for targets versus dissimilar lures was tested. Targets and lures were selected from a subset of dissimilar images. The images in the subset of dissimilar images were selected in such a way that the clusters of their feature vectors in the similarity space showed relatively little overlap. Hence, dissimilarity for a subset of images, D, is defined as: $\sum f_{B,A_i}/T_A \leq d_1, \forall A,B \in D$, with f_{B,A_i} the number of feature vectors of image B that fall within a hypersphere with radius r centered around the i^{th} feature vector of image A, T_A the total number of feature vectors of image A, and d_1 a dissimilarity constant. For the similar condition, recognition performance for targets versus similar lures was tested. Pairs of similar targets and lures were selected in such a way that the clusters of their feature-vector representations in the similarity space showed relatively much overlap. Hence, similarity for two images, A and B, is defined as: $\sum f_{B,A_i}/T_A \geq d_2$, with f_{B,A_i} the number of feature vectors of image B that fall within a hypersphere with radius r centered around the i^{th} feature vector of image A, T_A the total number of feature vectors of image A, and d_2 a similarity constant, with $d_2 > d_1$.

Procedure

We provided the NIM model with (1) pure weak study lists, (2) pure strong study lists, and (3) mixed study lists of lengths $N = 4$, 8, and 12, in both the dissimilar and the similar condition. Weak images were stored with storage strength $S = 5$ (i.e., five feature vectors were stored, corresponding to five fixations) and strong images were stored with storage strength $S = 10$. For each feature vector, the first $p = 50$ dimensions were stored. After the last image of a study list had been presented to the model, the N images of the study list (i.e., targets) along with N new images (i.e., lures) were presented for recognition. Lures in the dissimilar condition were selected with dissimilarity constant $d_1 = 0.26$ and lures in the similar condition were selected with similarity constant $d_2 = 0.8$. Recognition tests and the selection of targets and lures were performed using the radius parameter $r = 5.0$.

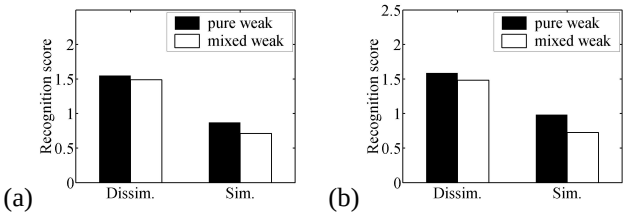

Figure 2: (a) Norman's (2002) results, and (b) Recognition scores (d_a) for weak images on pure lists (black bars) and on mixed lists (white bars) of length $N = 12$ for the dissimilar condition and for the similar condition.

Results

Table 1 presents the results for the dissimilar and similar conditions, respectively. The rows show the recognition results for lists of lengths $N = 4$, 8, and 12. The columns labeled w show the recognition scores for the weak images and the columns labeled s show the recognition scores for the strong images. The columns labeled pw/mw show the pure/mixed ratio for weak images and the columns labeled ms/ps show the mixed/pure ratio for strong images (both of which are indications of the degree to which a list-strength effect occurred). Figure 2(a) presents a bar graph of the results reported by Norman (2002) (described previously). Figure 2(b) presents a bar graph of the recognition scores produced by the NIM model in conditions analogous to the conditions in Norman's experiment. Since results were similar for lists of different lengths N, only the results for lists of length $N = 12$ are shown. A comparison of the graphs in Figures 2(a) and 2(b) reveals a close correspondence between Norman's results and the results produced by the NIM model.

Table 1: The average recognition scores produced by the NIM model for the dissimilar and the similar condition.

Dissimilar condition						
	Pure lists		Mixed Lists		ratios	
N	w	s	w	s	pw/mw	ms/ps
4	1.81	2.39	1.78	2.41	1.01	1.01
8	1.65	2.18	1.54	2.28	1.07	1.05
12	1.59	2.11	1.48	2.15	1.07	1.02
Similar condition						
	Pure lists		Mixed Lists		ratios	
N	w	s	w	s	pw/mw	ms/ps
4	1.38	1.83	1.14	1.97	1.21	1.08
8	1.12	1.52	0.87	1.78	1.29	1.17
12	0.98	1.35	0.73	1.61	1.36	1.20

Similarity and the List-Strength Effect List-strength effects for the dissimilar condition were significantly smaller than list-strength effects for the similar condition as indicated by the higher pw/mw and ms/mw values for the similar condition compared to those for the dissimilar condition. This was supported in a two-way analysis of variance (ANOVA) by the interaction between list type (pure or mixed) and condition. Calculated F values for lists of lengths $N = 4$, 8, and 12 ranged from $F(1,159) = 4.97$ to $F(1,159) = 9.62$, $p < 0.05$ for weak images and $F(1,159) = 4.52$ to $F(1,159) = 12.02$, $p < 0.05$, for strong images.

Similarity and the List-Length Effect The list-length effects for the dissimilar condition were significantly smaller than those for the similar condition. This was indicated in a two-way ANOVA by the interaction between list length and condition for pure weak lists, $F(2,239) = 4.61$, $p < 0.05$, and for pure strong lists, $F(2,239) = 3.68$, $p < 0.05$.

The False Memory Effect Table 2 presents the hit rates and false alarm rates for pure strong lists of lengths $N = 4$, 8, and 12 for both the dissimilar and the similar condition. Since the results were similar for pure weak lists and pure strong lists, we only present the results for pure strong lists. The results show that a false memory occurred: false alarm rates were higher for lists in the similar condition than for lists in the dissimilar condition (while hit rates were not significantly different). In an ANOVA, calculated F values for the false alarm rates ranged from 163.38 to 384.74, $p < 0.05$, while F values for the hit rates ranged from 2.08 to 2.24, $p > 0.05$.

Table 2: The average hit rates and false alarm rates produced by the NIM model for the dissimilar and the similar condition.

	Dissimilar condition		Similar condition	
N	Hit rate	F/A rate	Hit rate	F/A rate
4	0.84	0.01	0.86	0.14
8	0.76	0.02	0.78	0.17
12	0.69	0.02	0.70	0.15

Discussion

Based on recent experimental findings (Norman, 2002), we assumed that the degree to which a list-strength effect and a list-length effect occur varies with the degree of similarity between targets and lures. The NIM model produces this effect, as well as a false memory effect. Below we discuss the single-process NIM model in relation to other memory models and the ability of the NIM model to simulate mirror effects.

Comparison to Other Models

The NIM model differs from existing memory models in that it operates on natural input and employs a single process for recognition.

A Perceptual Process Operating on Natural Input The NIM model encompasses a transformation that yields the similarity structure of natural images. So far, existing memory models have been tested with artificial data (e.g., the REM model, Shiffrin & Steyvers, 1997), with predefined similarity spaces (e.g., the SimSample model, Busey, 2001), or with synthesized natural images (Kahana & Sekuler, 2002). The predictions these models make for recognition memory performance can be similar to the predictions the NIM model makes, provided that a representation space is employed that accurately reflects the similarity structure of the input. However, these models fall short in constructing a representation in an *a priori* manner. In contrast, the NIM model remedies this. Therefore, we expect that the NIM model provides us with a useful tool for making predictions about the effects of varying similarity of natural input on memory.

Single versus dual-process models Several memory models assume two processes for recognition to explain recognition results. These dual-processing models assume that recognition involves (1) a familiarity process, i.e., a context insensitive automatic process, and (2) a recollection process, i.e., a context sensitive strategic process (see Yonelinas, 2002, for a review of dual-processing models). Norman (2002) explains his experimental findings on the similarity effect by a dual-processing approach. He argues that the degree to which a list-strength effect occurs depends on the extent to which recollection drives recognition. While there might be good biological evidence that more than one process is involved in recognition, our results show that a single straightforward process for recognition suffices to produce Norman's and other findings on recognition memory.

Mirror Effects

In addition to the list-strength effect and the list-length effect, memory models are often tested for two related effects consistently obtained in experimental studies: the strength-mirror effect and the length-mirror effect (e.g., Murnane & Shiffrin, 1991). Simulation results, reported elsewhere (Lacroix, Murre, Postma, & Herik, submitted), showed that the NIM model exhibits these effects.

Conclusion

We have seen that the NIM model is able to build a similarity space from perceived natural data. Moreover, it successfully replicated recognition findings on list-strength effects, list-length effects, false memory effects, and mirror effects. Though it is at present not clear to what extent these results emerge from the use of natural images, it does increase the validity of the model by by-passing assumptions about distributional statistics of real-world perceptual features. Future studies aim at extending the NIM model to simulate a wider variety of findings on recognition memory.

Abstract

In this paper, we examine approaches to representing and utilizing hierarchical skills within the context of a cognitive architecture. We review responses to this issue by three established frameworks – ACT-R, Soar, and PRODIGY – then present an alternative we have developed within ICARUS, another candidate architecture. Unlike most earlier systems, ICARUS lets skills refer directly to their subskills and communicate within a single recognize-act cycle. This assumption has implications for the number of cycles required to complete complex tasks. We illustrate our approach with the domain of multi-column subtraction, then discuss related methods and directions for future work in this area.

Introduction and Overview

Human skills are organized in a hierarchical fashion. There seems to be general agreement with this claim, as it is consistent not only with experimental findings about the execution and acquisition of skills, but also with introspection about our everyday behavior. Upon request, most people can describe their complex skills at successive levels of aggregation, whether these involve how they drive to work each day, how they cook a meal, or how they write a technical article.

What remains an open question is how we should model such skill hierarchies in computational terms. Alternative approaches to modeling cognition encode the notion of hierarchy in distinct ways that have different implications for performance and learning. The most interesting positions are those which are embedded in theories of the human cognitive architecture, such as Soar (Laird et al., 1987), ACT-R (Anderson, 1993), and EPIC (Kieras & Meyer, 1997). These frameworks make strong commitments to both the mental representations of knowledge and to the processes that operate on them.

In the pages that follow, we consider the challenge of modeling hierarchical skills within a unified theory of cognition. We begin with a brief review of three such architectures and their responses to this issue, then turn to ICARUS, an alternative framework that approaches hierarchical skills from a different perspective. The key issue involves whether one can traverse levels of a hierarchy within a single cognitive cycle. Our illustrative example comes from a familiar cognitive skill that has a hierarchical organization – multi-column subtraction – but we also consider other models that incorporate multi-level skills. We conclude by discussing related work and our plans to extend the architecture's capabilities.

Previous Research on Hierarchical Skills

A cognitive architecture (Newell, 1990) specifies the infrastructure for an intelligent system, indicating those aspects of a cognitive agent that remain unchanged over time and across different application domains. Many proposals for the human cognitive architecture take the form of a production system, which stores long-term knowledge as a set of condition-action rules, encodes short-term elements as declarative list structures, and relies on a recognize-act cycle that matches against, and executes rules that alter, the contents of short-term memory. Soar, ACT-R, and EPIC are all examples of the production-system paradigm, although other architectural frameworks are also possible.

Despite the general agreement that cognitive skills are organized hierarchically, there exist different ways to implement this basic idea. Within a production-system architecture, the most natural scheme involves communication between skills and their subskills through the addition of elements to short-term memory. For instance, ACT-R achieves this effect using production rules that match against a generalized goal structure in their condition sides, such as the desire to prove that two triangles are congruent, and, upon firing, create new subgoals, such as the desire to prove that two lines have the same length. This approach requires the explicit addition of goal elements to short-term memory, since this is the only mechanism through which other production rules can be accessed.

Soar takes a somewhat different approach to encoding hierarchical skills that relies on multiple problem spaces. For instance, Jones and Laird (1997) report a detailed model of ying an aircraft in combat training scenarios. This system organizes its capabilities in a hierarchical manner, with each node implemented as a Soar problem space with associated states, operators, and goals. To invoke a lower-level problem space, the system adds a new element to short-term memory that refers to that space, and it must take similar action in order to exit. The details differ from those in ACT, but the passing of messages through short-term memory is similar.

The PRODIGY architecture (Minton et al., 1989) produces cognitive behavior in yet another manner. The system represents knowledge about actions as STRIPS-like operators, and the central module utilizes means-ends analysis to decompose problems into subproblems. This gives PRODIGY the ability to generate hierarchical

structures dynamically for each problem it encounters, and it can use control rules to select among candidate operators, states, and goals that determine the decompositions. However, these hierarchical structures do not remain in memory after a problem has been solved; instead, the system stores its experience in generalized control rules that let it reconstruct them for new problems. Again, this requires adding explicit elements to short-term memory that serve as mediators.

Thus, despite their diversity, these three frameworks share a basic assumption about how communication occurs among skills and subskills. This tenet has implications for the cognitive behavior of systems cast within them, including whether intermediate results are available, the time required to execute complex skills, and the effects of learning on hierarchical structure. We will see shortly that another response to this issue is possible.

Hierarchical Skills in ICARUS

ICARUS (Choi et al., in press) is a cognitive architecture that shares some central features with its predecessors. For instance, it relies on symbolic list structures to encode information, and it makes a clear distinction between long-term and short-term memories, with the former storing generic knowledge and the latter containing specific beliefs. Moreover, ICARUS assumes a recognize-act cycle, which relies on matching patterns in long-term memory against elements in the short-term store, to determine behavior over time. The framework also comes with a programming formalism for building knowledge-based systems.

However, ICARUS has other characteristics that distinguish it from earlier frameworks in significant ways. One such feature is its commitment to embodied cognition, which requires that all symbols in ICARUS programs be grounded in sensori-motor primitives.[1] A second key assumption is that each long-term memory structure may have not only a symbolic description but also an associated numeric function that computes its value as a function of sensory attributes. A third novel feature is that ICARUS contains distinct long-term memories for skills, which store its knowledge about action, and for concepts, which specify its knowledge about states and relations. Yet another contribution lies in the strong correspondence between long-term and short-term memory, specifically that every element in the latter must be an instance of some structure in the former.

A fifth important assumption, which is our focus here, is that hierarchical structures play a central role in cognition. Although production systems and related architectures allow hierarchies, many do not encourage them, and we maintain that ICARUS supports them in a sense that is stronger and more plausible psychologically than do frameworks like ACT and Soar. To understand this claim, we must first examine the architecture's representation for skills and the relations among them.

[1]Some recent architectural variants, like ACT-R/PM and EPIC-Soar, incorporate sensori-motor modules, but these were grafted onto systems based on theories of human problem solving, whereas ICARUS included them from the outset.

ICARUS skills bear a strong resemblance to production rules, but they have an even closer kinship to the operators in PRODIGY and STRIPS. Each skill has a name, arguments, and some optional fields. These include:

- a `:start` field, which encodes the situation that must hold to initiate the skill;
- a `:requires` field, which must be satisfied throughout the skill's execution across multiple cycles; and
- an `:effects` field, which specifies the desired situation the skill is intended to achieve.

For example, Table 1 shows a complete set of ICARUS skills for the domain of multi-column subtraction, including *borrow*, which has the objective of getting *?digit1* to be greater than *?digit2*. This skill can start only if *?digit2* is greater than *?digit1* and if a third element, *?digit3*, is nonzero. Moreover, its execution requires that *?digit1* be above *?digit2*, that *?digit3* be in the top row, and that *?digit3* be left of *?digit1*.

In addition, each ICARUS skill includes another field that specifies how to decompose it into subskills or actions. This may be either:

- an `:ordered` field, which indicates the agent should consider the components in a specific order;
- an `:unordered` field, which identifies a choice among skill components; or
- an `:actions` field, in which a primitive skill specifies one or more actions that are directly executable.

For example, *borrow* states that one should invoke *decrement* on one digit and call *add-ten* on another, in that order. These are both primitive skills that play the same role as STRIPS operators in a traditional planning system, with their `:start` fields serving as preconditions and their `:effects` fields specifying the desired results of execution.

The table also clarifies that ICARUS can specify multiple ways to decompose each skill in this manner, much as a Prolog program can include more than one Horn clause with the same head. Different decompositions of a given skill must have the same name, number of arguments, and effects. However, they can differ in their start conditions, requirements, and subskills. The skill *borrow* has two such expansions, one for borrowing from nonzero elements and another for borrowing across zero, which involves a recursive call to itself.

Each skill decomposition may also include a numeric function that encodes the utility expected if it executes this decomposition. This function is specified by a `:percepts` field that matches against the values of objects' attributes and a `:value` field that states an arithmetic combination of these quantities. The expected utility for a skill decomposition is a linear function of the numeric descriptors matched by that skill. Such functions are not required when the available skills specify deterministic behavior, as do those in the table, but we have used them in other domains and we mention them here for completeness.

We should note that ICARUS also organizes its long-term conceptual memory in a hierarchy, with higher-level concepts being defined in terms of lower-level ones, which

ultimately connect to perceptual elements. The literals that appear in the `:start`, `:requires`, and `:effects` fields must be defined concepts, thus linking the skill and conceptual memories in an interleaved manner. The architecture also incorporates three short-term memories. These include a perceptual buffer, updated on each cycle, that contains descriptions of perceived objects, a conceptual short-term memory that contains inferences derived from the perceptual buffer, and an intention memory that contains instances of skills the system intends to execute. The elements in these memories are simple literals but, because their predicates correspond to hierarchical structures in long-term memory, they encode substantial information about the agent's beliefs and intentions.

Distinctive Aspects of ICARUS Hierarchies

From the preceding discussion, it should be clear that ICARUS utilizes a more structured representation of knowledge than traditional cognitive architectures, but the implications of this structure depend directly on the processes that operate over them. Together, they enable cognitive processing that exhibits important differences from that in older frameworks.

One such characteristic involves the ability of ICARUS' skills to reference subskills by their names, rather than through the indirect references used in Soar, ACT, and PRODIGY. For example, the *borrow* skill in Table 1 calls directly on *decrement* and *add-ten*. ICARUS' approach has some aspects of subroutine calls in procedural programming languages but, when combined with multiple expansions for each skill (such as two variants for *borrow*), effectively embeds these calls within an AND/OR search. This makes our formalism a close relative of logic programming languages like Prolog, which uses a very similar syntax to support logical reasoning. But like other cognitive architectures, ICARUS is concerned with agents that exist over time, so it situates these computations within a recognize-act cycle.

As a result, ICARUS retains the overall avor of a production system but gains the ability to invoke subskills directly, rather than through the creation of short-term memory elements. This lets it execute complex skills in a top-down manner without having to descend through the hierarchy one step at a time. ICARUS can take advantage of this hierarchical organization without requiring the generation of explicit intermediate goal structures that are needed by production systems.

Recall that ICARUS includes a short-term memory that contains skill instances the agent considers worth executing. On each cycle, for each skill instance, the architecture retrieves all decompositions of the general skill and checks whether they are applicable. A skill is applicable if, for its current variable bindings, its `:effects` field does not match, the `:requires` field matches, and, if the system has not yet started executing it, the `:start` field matches the current situation. Moreover, at least one of its subskills must also be applicable. Since this test is recursive, a skill is only applicable if there exists at least one acceptable path downward to executable actions.

For each such path, the architecture computes the expected value and selects the candidate with the highest utility for execution. For a given path, it uses the value function stored with each skill and the numeric values matched in that skill's `:percepts` field to calculate the expected value at each level, summing the results along the path to compute the overall score. For instance, for the path *((subtract), (process digit11), (borrow digit11), (decrement digit21))*, the system would sum the expected value for all four levels to determine the utility of decrementing. This means that the same action can

have different values on a given cycle depending on which higher-level skill invokes it, providing a natural way for the hierarchy to incorporate the effect of context.

The architecture treats a skill expansion differently depending on whether its components appear in an `:unordered` set or an `:ordered` list. If they are unordered, the module considers each of the subskills and selects the one that yields the highest scoring subpath. If they are ordered, it instead treats the list as a reactive program that considers each subskill in reverse order. If the final subskill is applicable, then it expands further only down paths that include that subskill. Otherwise, it considers the penultimate skill, the one before that, and so forth. The intuition is that the subskills are ordered because later ones are closer to the parent skill's objective, and thus should be preferred when applicable.

We should clarify that ICARUS' consideration of alternative paths through its skill hierarchy does not involve generative planning. On each cycle, the architecture finds the best pathway through a set of exible but constrained structures. The process is much closer to the execution of a hierarchical task network (e.g., Myers, 1999) than to the construction of a plan from primitive operators. Such computation can be done efficiently within a single recognize-act cycle, at least for well-structured skill hierarchies. One can craft ICARUS programs that are expensive to evaluate, but the same holds for production systems with complex conditions on their rules.

An Illustrative Example

We can best clarify ICARUS' operation with an example that uses the skills from Table 1 on the subtraction problem 305 147. The system interacts with a simulated environment that, on each cycle, deposits perceptual elements such as *(digit digit11 col 1 row 1 val 5)* and *(digit digit12 col 1 row 2 val 7)* into the perceptual buffer. A conceptual recognition process draws inferences from these elements, such as *(greater digit12 digit11)* and *(above digit11 digit12)*, which it adds to conceptual short-term memory.

The model also begins with the single top-level intention *(subtract)*, which focuses cognitive behavior on the skills in the table even if others are present in long-term memory. On the first cycle, the system would consider both expansions of *subtract*, selecting the first one and binding *?digit* to *digit11*, the object in the top row and right column. This skill instance would in turn invoke *(process digit11)*, which would consider its subskills *find-difference* and *borrow*. Only the latter skill has its `:start` and `:requires` fields met, specifically by its second expansion, which handles situations that require borrowing from zero.

This skill instance, *(borrow digit11)*, then invokes itself recursively, producing the call *(borrow digit21)*, where the argument denotes the digit 0 in the top row and second column. Because the digit to its left is nonzero, this instantiation can only utilize the first expansion of *borrow*, which in turn calls on *(decrement digit31)* in its `:ordered` field, since its preconditions are satisfied, but those for *add-ten*, which occurs later in this ordering, are not. Because *decrement* is a primitive skill, it becomes the terminal node for an acceptable path through the skill hierarchy. Also, because this is the only such path ICARUS finds, it executes the instantiated actions *(*cross-out digit31)* and *(*decrement digit31 3)*.

These actions alters the environment and lead to another execution cycle. This time ICARUS again finds a single acceptable path that shares all but the last skill instance with that from the first round. The difference is that *digit31* has been crossed out, making *(decrement digit31)* inapplicable but enabling the skill instance *(add-ten digit21)*. Again this is the only acceptable path through the hierarchy, so ICARUS executes the action associated with this primitive skill, thus altering the simulated display so that *digit21*'s value is increased by ten.

On the third cycle, the architecture again finds only one path, in this case *((subtract), (process digit11), (borrow digit11), (decrement digit21))*, since the top number in the second column is no longer zero and can be safely decremented. This action enables execution of the path *((subtract), (process digit11), (borrow digit11), (add-ten digit11))* on the fourth cycle, after which (on the fifth cycle) the model selects the path *((subtract), (process digit11), (find-difference digit11))*, which writes the two digits' difference in the rightmost column.

This altered situation leads ICARUS to add the inference *(processed digit11)*, which on the sixth cycle causes it to select the second expansion of *subtract*; this invokes the skill instance *(process digit21)* on the revised top digit in the second row. Because this digit has already been incremented by ten, it is greater than the one below it, so the skill instance *(find-difference digit21)* is now applicable. Execution of this path produces an answer in the second column, which leads on the next cycle to processing of the third column and to an answer there as well. No paths are satisfied on additional cycles, so the system idles thereafter, waiting for new developments.

General Implications

The sample trace above does not illustrate all of ICARUS' capabilities, since it ignores details about the conceptual inference process and it does not utilize value functions. However, it should make clear that ICARUS operates over its skill hierarchy in a different manner than frameworks like Soar and ACT-R. They can model behavior on complex tasks in two distinct ways. One scheme assumes hierarchical rules or problem spaces, which require additional cycles for stepping downward through each level of the hierarchy. Another assumes that learning has produced compiled rules that eliminate the hierarchy and thus the need for intermediate goal structures. Such compilation methods have been used to explain both the power law of learning and reduced access to subgoals (e.g., Neves & Anderson, 1981).

However, it seems unlikely that the hierarchical structure of skills disappears entirely with practice, and ICARUS offers an account that avoids the above dichotomy. An architecture that traverses levels in a skill hierarchy within a single recognize-act cycle also predicts that intermediate structures will be inacessible, and the

power law follows from the construction of the hierarchy itself, which we discuss later. This account also makes different predictions than traditional schemes about the number of cycles, and thus the time, required to accomplish tasks with hierarchical and recursive structures.

Again, we can use multi-column subtraction to illustrate this point. A standard production-system model for this domain, like that described by Langley and Ohlsson (1984), finds the difference between two numbers in a column when the top one is larger but otherwise adds a goal to process or borrow from the adjacent column. Analysis reveals that such a model will take $5 \cdot b + 2 \cdot n$ cycles to complete a problem with b columns that require borrowing and n columns that do not. In contrast, the ICARUS model in Table 1 requires $3 \cdot b + 2 \cdot n$ cycles on the same problems. The two frameworks both indicate that solution time will increase with the number of borrow columns, but they predict quite different slopes.

Experiments with human subjects should reveal which alternative offers a better explanation of skilled behavior in this arena. We have not yet carried out such studies, but to test our framework's generality, we have developed ICARUS models for behavior in other domains that appear to have hierarchical organizations. One involves the well-known Tower of Hanoi puzzle, which can be solved using a hierarchical strategy. Our model for behavior on this task includes three primitive skills for lifting, lowering, and moving a disk sideways, along with one high-level skill for moving a disk to a target peg that, in two expansions, calls itself recursively. However, the Tower of Hanoi is like subtraction in that the environment changes only when the agent takes some action.

To ensure that ICARUS can also support behavior in more dynamic domains, we have developed two additional models. One involves hierarchical skills for balancing an upright pole by moving its lower end back and forth. This system includes two high-level skills with knowledge about the order in which the four primitive skills should be invoked. As described elsewhere (Choi et al., in press), we have also constructed a system that drives a vehicle and delivers packages in a simulated in-city environment. This model includes 46 skills that are organized in a hierarchy five levels deep. The high-level skills let the agent drive straight in lanes, get into rightmost lanes, slow for intersections, drive through intersections, turn at intersections, and make U turns. These terminate in actions for changing speed and altering the wheel angle. Another 13 skills support the delivery of packages to target addresses.

We have not attempted to compare the details of these systems' operations to human behaviors on the same tasks. Nor have we attempted to show that ICARUS produces more robust behavior than programs cast in earlier frameworks like Soar and ACT-R. Rather, our goal has been to demonstrate the same broad functionality as we observe in humans, including their apparent organization of complex skills into hierarchies. We have also aimed to show that ICARUS constitutes a viable point in the space of cognitive architectures, which we believe has been too thinly explored to date.

Related Efforts and Future Research

Although ICARUS incorporates a number of features that distinguish it from typical cognitive architectures, some related ideas have appeared elsewhere under different guises. For instance, our framework has much in common with the 'reactive planning' movement, which often utilizes hierarchical procedures that combine cognition, perception, and action in physical domains.[2] Examples include PRS (Georgeoff et al., 1985), teleoreactive programs (Nilsson, 1994), and the 3T robotic architecture (Bonasso et al., 1997), and some case-based planners (e.g., Hammond, 1993) embody similar notions.

However, within this paradigm, only Freed's (1998) APEX has been proposed as a candidate architecture for human cognition. This framework shares ICARUS' commitment to hierarchical skills, but it has a more procedural flavor and it does not incorporate a separate conceptual memory or enforce a correspondence between long-term and short-term structures. Another kindred spirit is Albus and Meystel's (2001) RCS architecture, which organizes knowledge hierarchically and makes a clear distinction between logical structures and value judgments. ICARUS and RCS share many common features, but they also retain many differences due to their origins in cognitive modeling and control theory, respectively.

We should clarify that, as a cognitive architecture, ICARUS still requires some development. The framework lacks many processing assumptions that would make it more plausible as a general theory of human behavior. For instance, it lacks any limits on perceptual bandwidth that require attention, which arises even on routine tasks like subtraction. We intend to model such behavior by introducing an action that focuses the agent's attention on an object and deposits its description in the perceptual buffer, with ICARUS being able to apply this action to only one visible object per cycle. This should produce longer subtraction runs that require additional steps for attentional events, much as in Anderson, Matessa, and Lebiere's (1997) ACT-R model of visual attention.

We should also extend our models for subtraction and other domains to handle lower levels of behavior more faithfully. The skills in Table 1 terminate with actions for decrementing, adding ten, and finding a difference, but these can be further decomposed into subskills for writing specific digits and even drawing individual lines. Our claim to model embodied cognition would be stronger if we extended the skill hierarchy downward in this fashion. We should also extend the hierarchy upward to model choices about which problem to tackle when many are present on the page. Such an expanded system would model subtraction behavior in a more complete way than do most accounts.

However, a more important omission concerns the origin of ICARUS' hierarchical skills. To handle this, we hypothesize a mechanism that is related to chunking in Soar and production composition in earlier versions of ACT. Although humans prefer to use routine behaviors when possible, they can, within limits, combine

[2] Our model of subtraction skills also has similarities to VanLehn's (1990) hierarchical treatment of this domain.

knowledge elements when needed to solve novel problems. Means-ends analysis has been implicated in such situations, so we plan to incorporate this method into future versions of the architecture. The generalized results of means-ends problem solving would be cached as a new skill. However, unlike chunking and composition, which produce at rules that eliminate structure, ICARUS would store a new hierarchical skill that refers to the original ones as components. This method should lead to the construction of skill hierarchies in a gradual, bottom-up manner as an agent learns about a domain.

Concluding Remarks

In closing, we should review the main claims we have made about hierarchical skills and their treatment within various cognitive architectures. There seems to be general agreement that skills are organized in some hierarchical fashion, but most existing models implement the invocation of subskills through goal structures that are deposited in short-term memory. In contrast, ICARUS produces hierarchical behavior by letting skills communicate directly with their subskills, as in procedural languages and logic programming formalisms.

We illustrated this idea by presenting an ICARUS model for multi-column subtraction and tracing its behavior on a specific problem. We saw that this system takes the same basic steps as a production-system model, but that steps involved in traversing the skill hierarchy occur within a single recognize-act cycle rather than across successive cycles. This theoretical difference leads to different predictions about the time required to execute complex skills. Future research should test these predictions and extend ICARUS to incorporate mechanisms for attention and construction of skill hierarchies.

The Role of Prior Learning in Biasing Generalization in Artificial Language Learning

Jill Lany (lany@u.arizona.edu)

Rebecca Gómez (gomez@u.arizona.edu)
Department of Psychology, The University of Arizona, Tucson, AZ 85721-0068

Abstract

Because unbiased learners are unlikely to arrive at the appropriate generalizations of their language (Gold, 1967), accounts of acquisition must examine the nature of learning biases. One form of bias is learners' prior learning experience. Adult participants familiarized with a category-induction language learned a language with the same underlying structure but novel vocabulary much more rapidly than naïve learners (Lany, Gómez, & Gerken, 2004). In the present experiments, we extend our investigations of prior learning experience by manipulating whether learners were initially exposed to fully- or partially-cued structure. Generalization is hindered by prior exposure to fully-cued structure, but enhanced by prior exposure to structure that is partially-cued. The results are important for understanding of the role of prior experience in constraining language acquisition.

Introduction

The syntax of natural languages is highly complex. Without corrective feedback, unconstrained learners are unlikely to converge on the grammar of their linguistic community (Gold, 1967). However, language learners regularly manage to discover the underlying patterns of their language while ignoring irrelevant structure, suggesting that they are constrained. Recent work in artificial language learning has begun to investigate forms of learning constraints, or ways in which learning processes might be guided.

Saffran (2002) demonstrated modality constraints on learning an artificial language by exposing adult learners to a phrase-structure language in which the presence of one item in a phrase predicted the presence of another item (Language P), or to a phrase-structure language in which predictive relationships were absent (Language N). Participants were presented with either an auditory or visual version of Language P or N. Learning of Language P was better when presentation was auditory. Visual language learners acquired the predictive and non-predictive languages equally well, suggesting that learners' sensitivity to patterns and relationships varies as a function of modality.

Recent work by Gómez (2002; Gómez, Welch, & Lany, 2003) speaks to another way learning may be guided. Gómez' studies suggest that learners selectively tune in to regularities by seeking out the most reliable structure in their input. While learners are highly sensitive to conditional probabilities of adjacent elements (e.g., Saffran, Aslin, & Newport, 1996), Gómez demonstrated that when conditional probabilities between adjacent elements are low or unreliable, learners attend to relationships between non-adjacent elements. These findings indicate that learners are biased to take the statistical reliability of a structure into account. Importantly, languages make use of various cues highlighting relevant structure, not just statistical ones[1].

Saffran's (2002) work suggests that learners are biased before they even begin to learn language. Gómez's work (2002; Gómez et al., 2003) suggests that statistical characteristics of the input itself can bias learning. Research also suggests learners can be biased by prior experience.

Saffran and Thiessen (2003) provided evidence that once infants form phonological generalizations based on regularities in their input, those generalizations influence how they parse new speech materials. Lany, Gómez, and Gerken (2004) demonstrated that generalization occurs at the abstract level of syntax-like structure. In these experiments, adults were exposed to a language consisting of categories of words, with restrictions on how categories could combine (see Braine, 1987; Frigo & MacDonald, 1998; Gerken, Wilson, & Lewis, in press; Gómez & Lakusta, in press). The language is composed of words belonging to the categories *a*, *b*, *X*, and *Y*. As in natural languages, the rules

[1] For example, languages are rich with prosodic cues to syntactic structure, and learners are sensitive to such cues beginning in early infancy (see Jusczyk, 1997 for an overview).

involve relationships between word categories. Specifically, the language has restrictions on how categories of different types can be combined within a string, such that *a* elements are paired with *X* elements and *b* elements with *Y*s, but not vice versa. (See Figure 1.)

	$\mathbf{X_1}$	$\mathbf{X_2}$	$\mathbf{X_3}$	$\mathbf{X_4}$	$\mathbf{X_5}$
$\mathbf{a_1}$	a_1X_1	a_1X_2	a_1X_3	a_1X_4	a_1X_5
$\mathbf{a_2}$	a_2X_1	a_2X_2	a_2X_3	??	a_2X_5

	$\mathbf{Y_1}$	$\mathbf{Y_2}$	$\mathbf{Y_3}$	$\mathbf{Y_4}$	$\mathbf{Y_5}$
$\mathbf{b_1}$	b_1Y_1	b_1Y_2	b_1Y_3	b_1Y_4	b_1Y_5
$\mathbf{b_2}$	b_2Y_1	b_2Y_2	b_2Y_3	??	b_2Y_5

Figure 1. A typical *aX bY* paradigm. Learners are exposed to a subset of the grammatical pairings of markers and content-words then are tested for generalization to the withheld (??) pairings.

Learners exposed to 18 or 6 minutes of the *aX bY* language successfully acquired the language in the former but not the latter condition. However, learners exposed to 18 minutes of one language, and then transferred to a second language with the same underlying pattern, but none of the same words, learned the pattern with just 6 minutes of exposure.

The findings of Lany et al. (2004) demonstrate that learners do not remain the same over the course of acquisition. Rather, the learning process changes them, constraining the ways they perceive and learn about subsequent input. Thus, prior experience represents an additional constraint enabling learners to successfully acquire language.

Using this procedure, we can begin to investigate other ways learning might be facilitated by prior experience. In doing so, it is important to explore the extent to which this process might be useful in natural language acquisition.

In English, consistency in head direction results in a co-occurrence relationship between determiners and nouns, and also between auxiliaries and verbs. These relationships both involve a functional element preceding a lexical one, and restrictions on co-occurrences of categories of functional and lexical elements (similar to the *aX bY* structure used by Lany et al., 2004). Importantly, learners only truly acquire categories, and their co-occurrence restrictions, when there are cues indicating category membership (Frigo & McDonald, 1998; see also Gerken et al., in press). However, cues in natural language are variable, differing with strength according to category. For example, a corpus analysis (Lany et al., 2004) showed that in infant-directed speech, a greater proportion of nouns are marked with morpho-syntactic cues than verbs – e.g. nouns were fully cued by a determiner and a plural or diminutive ending 20% of the time and partially cued by either a determiner or an ending 60% of the time. Verbs were fully cued both by an auxiliary and inflectional ending 1% of the time and by one or the other 20% of the time. Thus languages contain different degrees of fully- and partially-cued structure.

In this study, we asked whether learners with prior exposure to a well-cued pattern have an advantage over naïve learners in acquiring a version of that pattern in which the cues highlighting relevant structure are diminished. In Experiment 1, we exposed a control group to 18 minutes of a partially-cued *aX bY* language, in which only 60% of the *X* and *Y* words had cues to category membership. We exposed an experimental group to 18 minutes of a fully-cued *aX bY* language, in which 100% of the *X* and *Y* words had cues to category membership, and then transferred them to 18 minutes of the partially-cued *aX bY* language. Interestingly, learners with prior exposure to a fully-cued language did not subsequently learn a partially cued language better than the control group. However, in Experiment 2, learners with prior exposure to a partially-cued language learned a second partially-cued language better than naïve learners. Why might this be the case? Learners initially exposed to the fully-cued language may have learned the perfectly predictive surface regularities resulting from the underlying structure, as opposed to the category relationships. These surface regularities were probabilistic in the partially-cued language, and thus a focus on this aspect of structure would not result in successful learning at transfer. In other words, perhaps learners of the fully-cued language were hindered by their focus on the surface regularities of the strings. Learners of the partially-cued language were not led to rely exclusively on a cue that would later be less reliable. We speculate on factors facilitating this group's transfer in the discussion.

Experiment 1

Method

Participants Ninety-five University of Arizona undergraduate students participated for course credit, forty-eight in the experimental condition.

Materials Learners in these experiments were exposed to category-induction languages of the form *aX bY*. We constructed both a fully-cued and a partially-cued *aX bY* language. The fully-cued language had two versions which shared the same underlying structure, but had none of the same words (two versions were necessary to test transfer). The vocabulary of each version of the language consisted of two *a* elements (*ong* and *rud* in Version A, and *ush* and *dak* in Version B) and two *b* elements (*alt* and *pel* in Version A, and *erd* and *vot* in Version B). The vocabulary of each version also consisted of six bisyllabic *X* words and six bisyllabic *Y* words. The *X* words all ended with the same syllable ("-ul" in Version A and "-it" in Version B). Similarly, all *Y* words shared the same final syllable ("-ee" in Version A and "-oo" in Version B. Additionally, each version had two variants, or grammars. The two grammars of a version were composed of the same set of words, but differed in how they were combined – strings from Grammar 1 (G1) took the form *aX bY* and strings from Grammar 2 (G2) took the form *aY bX*. For example, strings from Version A, G1were *ong bivul* and *erd suffee*, and strings from G2 were *ong suffee* and *erd bivul*. In Version B, G1 strings were *ush zamit* and *alt wifoo*, and G2 strings were *ush wifoo* and *alt zamit*. The fully-cued versions of the language consisted of 24 possible strings (12 *aX* strings and 12 *bY* strings), however, 4 strings (2 *aX* and 2 *bY* strings) were withheld from familiarization to be presented at test, so the familiarization set consisted of 20 strings.

The test materials for the fully-cued languages consisted of 16 strings, half grammatical and half ungrammatical. Four grammatical strings had been withheld during familiarization, four strings had been presented during training, and eight strings were ungrammatical strings (these were from the unheard language). Strings that were grammatical for one group of participants were ungrammatical for the other.

The materials for the partially-cued languages were the same as those of the fully-cued languages, with the exception that only 60% (four of six) of the *X* and *Y* words had endings cueing their category membership. Uncued words were bisyllabic, and each had a distinct ending (i.e. an ending that was not present on any of the other words, cued or uncued). Examples are *jeeloff*, *skyjer*, *bowda*, and *pefto*. These uncued words replaced four of the cued words from the fully-cued version of the language. The partially-cued versions of the language consisted of 24 possible strings (12 *aX* strings and 12 *bY* strings), however, 8 strings (4 *aX* and 4 *bY* strings) were withheld from familiarization to be presented at test, so the familiarization set consisted of 16 strings.

The test materials for the partially-cued languages consisted of 32 strings, half grammatical and half ungrammatical. Eight grammatical strings had been withheld from familiarization (four were cued and four were uncued). Eight strings had been presented during familiarization (four were cued, four were uncued). There were also 16 strings from the grammar of the unheard language.

The process underlying successful learning of this language is twofold (Braine, 1987; Frigo & MacDonald, 1998). Learners must first discover that there are different categories of words, which requires that words from different categories be differentiable based on their semantic or phonological characteristics. Once learners are sensitive to the categories, they can then learn that there are restrictions on how categories co-occur. Learners with knowledge of co-occurrence restrictions can generalize to novel combinations that respect these restrictions. When cues to category membership are present, generalizations can be accomplished through attention to the pairing of *a*s and *b*s with the endings of the *X* and *Y* words. Additionally, learners exposed to the partially cued language, can generalize to novel combinations involving uncued words by noting that if an *X*-word is paired with a particular *a* word, it can co-occur with other *a* words, but not with *b* words.

Procedure There were eight conditions in this experiment, resulting from the between-subjects manipulations of familiarization type (Transfer vs. Control), version (Version A vs. Version B), grammar (Grammar 1 vs. Grammar 2), Aside from instructions at the start of the familiarization phase, which were delivered by the experimenter, the entire experiment was conducted on a Hewlett Packard Brio PC running SuperLab 2.01 software.

In the Transfer condition, participants listened over headphones to 18 blocks (approximately 18 minutes) of randomly ordered strings from their fully-cued training language, and then answered two iterations of 16 test

questions, each in a different random order and separated from each other by a brief pause. Using the "Y" and "N" keys on their keyboard, participants made yes/no judgments on the grammaticality of each string. They then repeated this familiarization and test procedure for a partially-cued version of the language with novel vocabulary. In the Control condition, participants were familiarized with 18 blocks of the partially-cued language before test.

For the fully-cued language, participants sensitive to the *aX bY* structure should endorse grammatical test strings, including those withheld during training, more often than they endorse ungrammatical ones. Similarly, for participants familiarized with a partially-cued language, sensitivity to the *aX bY* structure would be indicated by higher endorsement rates to withheld grammatical strings (both cued and uncued) than to ungrammatical ones.

Results and discussion Preliminary analyses indicated that there were no differences in learning as a function of language version or grammar, so we collapsed across these variables. Mean endorsement rates to test strings are found in Table 1.

We tested whether participants in the Transfer group learned the partially-cued language better than Control participants. We did a three-way mixed ANOVA, with a between-participant factor of familiarization type (Transfer vs. Control), and the within-participant factors of test string familiarity (heard vs. unheard), and test string cues (cued vs. uncued). The dependant measure was the difference in endorsement rates to grammatical test strings and their ungrammatical counterparts.

There was a main effect of test string familiarity, $F(1, 92) = 88.89$, $p < .001$, with the difference in endorsement rates to heard grammatical strings and ungrammatical ones ($M = .27$, $SE = .026$) more than to unheard ones ($M = .05$, $SE = .022$). There were no other main effects or interactions. Thus, both Transfer and Control participants endorsed heard grammatical test strings more often than unheard grammatical strings, but the Transfer group did not perform better than the control group. Neither group showed differences in endorsement rates to *unheard* grammatical and ungrammatical strings, ts ≤ 1.82, ps $\geq .076$. Thus there was no generalization to unheard items.

These findings suggest that Transfer learners did not benefit from their prior exposure to a fully-cued *aX bY* language. One explanation is that learners cannot acquire an *aX bY* pattern with only partial cues, regardless of their prior experience. However, given that other studies provide evidence of learning partially cued *aX bY* structure (e.g. Frigo & McDonald, 1998), this explanation seems unlikely. An alternative explanation is that learners exposed to a fully-cued language focused only on the surface relationship between the *a* and *b* elements and endings on the *X* and *Y* words, essentially learning a co-occurrence relationship between the first word in the string and the ending on the second. If this were the case, they would learn only the surface regularities resulting from the underlying structure as opposed to the category relationships. Experiencing a perfectly predictive relationship between the first word and the ending of the second may have led Transfer learners to tune-in to this aspect of the partially-cued language as opposed to the abstract structure.

We next tested whether learners would transfer from a partially-cued *aX bY* language, by exposing them to a partially-cued *aX bY* language before transferring them to another version of this partially-cued language. Because the initial language does not have a perfect correspondence between the initial word and ending of the final word of a string, learners would not likely focus solely on it, and thus might perform differently than the Experiment 1 learners at transfer.

Table 1: Endorsement Rates to Test Items with Standard Errors in Parentheses

	Grammatical Heard		Grammatical Unheard		Ungrammatical	
Expt 1	Cued	Uncued	Cued	Uncued	Cued	Uncued
Transfer	.76 (.028)	.77 (.031)	.54 (.029)	.60 (.028)	.50 (.031)	.55 (.032)
Control	.80 (.020)	.75 (.026)	.62 (.025)	.56 (.031)	.56 (.029)	.59 (.026)
Expt 2						
Transfer-2	.83 (.028)	.80 (.026)	.59 (.036)	.54 (.031)	.48 (.033)	.48 (.032)

Experiment 2

Method

Participants Forty-eight University of Arizona undergraduates participated for course credit.

Materials The language materials were the two partially-cued versions of the language used in Experiment 1.

Procedure The procedure for Experiment 2 participants was the same as for the Transfer group in Experiment 1, such that participants were familiarized and tested on one version of the language in Phase 1, and then transferred to the other version in Phase 2. Half of the participants were exposed to Version A of the partially-cued language and then Version B, and half to Version B and then A. This group is referred to as the Transfer-2 group.

Results and discussion We wanted to determine whether participants in the Transfer-2 group learned the partially-cued language they heard in Phase 2 better than the control participants from Experiment 1. Thus, we did a three-way mixed ANOVA, with the between-participant factor of familiarization type (Transfer-2 vs. Control), and the within-participant factors of test string familiarity (heard vs. unheard), and test string cues (cued vs. uncued). The dependant measure was the difference in endorsement rates to grammatical and ungrammatical test strings. Mean endorsement rates to test items can be found in Table 1.

We found that the difference in the Transfer-2 learners' endorsement rates to grammatical vs. ungrammatical test items ($M = .21$, $SE = .030$) was higher than that of the control group from Experiment 1($M = .11$, $SE = .031$), $F\,(1, 93) = 5.69$, $p = .019$. There was an effect of test string familiarity, with the difference in endorsement rates to heard grammatical test strings and ungrammatical ones ($M = .27$, $SE = .026$) greater than the difference between unheard grammatical test items and ungrammatical ones ($M = .05$, $SE = .022$), $F\,(1, 93) = 102.45$, $p < .001$. There was also an effect of test string cues. The difference in endorsement rates to grammatical test strings with cues and ungrammatical strings ($M = .20$, $SE = .026$) was significantly greater than the difference to grammatical test strings without cues and ungrammatical strings ($M = .13$, $SE = .023$), $F\,(1, 93) = 6.50$, $p = .012$. There were no interactions between any of the three variables, suggesting that learning in the Transfer-2 group was generally better than the Control group.

Paired-sample *t* tests comparing endorsement rates for each of the four types of grammatical strings and ungrammatical ones indicate that the Transfer-2 group learned the underlying structure of the language (see Table 1 for means and standard errors). Endorsement rates to grammatical heard test strings, cued and uncued, were higher than those to ungrammatical ones, ts $(47) \geq 6.36$, ps $\leq .001$. Critically, endorsement rates to *unheard* grammatical strings with cues were higher than those to ungrammatical strings, $t\,(47) = 2.10$, $p = .04$. (Recall that control subjects in Experiment 1 did not show such learning). Endorsement rates to grammatical unheard strings without cues did not differ from those to ungrammatical ones, $t\,(47) = 1.68$, $p = .1$.

In sum, learners with prior exposure to a partially-cued language subsequently learn a new version of such a language better than naïve learners. Thus, these findings shed light on how learners might acquire patterns in the absence of robust cues typically necessary for successful learning.

General discussion

In this set of experiments, we demonstrated that what learners can acquire from their input changes as they gain experience with a particular type of structure. Our results suggest that learners exposed to a fully-cued category-induction language become sensitive to a phonological pattern in the form of a perfect correspondence between *a* and *b* words and the endings on the *X* and *Y* words. Because they have not become sensitive to the underlying category relationships, only to the surface correlates of this pattern, their learning of a partially-cued language in which this relationship is probabilistic is not enhanced relative to controls. However, exposure to a partially-cued language facilitates subsequent acquisition of another partially-cued language. What is the basis for generalization in these learners? Recall from Experiment 1 that control participants exposed to a partially-cued language do not generalize to new strings. Tranfer-2 learners, whose initial learning phase was identical to controls', are also unlikely to have learned the *aX bY* structure. While neither the Transfer nor the Transfer-2 group appeared to successfully

acquire the structure of their initial training language, unlike learners transferred from a fully-cued language, Transfer-2 learners were not led to rely on a cue that would later be disrupted. While we cannot precisely determine what aspect of their exposure to the partially-cued language facilitated generalization, it is clear that strong sensitivity to the underlying category relationships does not drive the effect. Generalization may be driven by sensitivity to the underlying pattern learners acquire in their initial exposure. Generalization may also be influenced by other similarities between languages. In these experiments, strings from both versions of the language were composed of two words, the first monosyllabic and the second bisyllabic, and most *X*s and *Y*s in both versions of the language had distinctive features in the form of endings on the words. If some or all of these similarities were absent, transfer of structure might be less likely to occur, thus raising important questions about constraints on transfer. We might test this by transferring learners to languages in which some of these similarities are removed.

These results add to our previous work (Lany et al., 2004) by providing information about how prior learning experience can interfere with generalization (Exp. 1) or enhance it (Exp. 2). We plan to extend this work by asking whether prior exposure to one of the partial-structure languages facilitates acquisition of a language in which the cues are even further diminished. This would be analogous to asking whether the higher incidence of partially cued noun phrases found in English child-directed speech could help learners acquire verb phrases (in which category structure is less reliably marked). This manipulation should also provide information about how prior learning affects the flexibility of later learning.

In conclusion, learners' prior experience can be instrumental in shaping what they acquire from their input. Learning biases of other sorts have also been proposed, such as constraints on the kinds of computations likely to be performed based on the modality of the input (Saffran, 2002), and the tendency to acquire the most reliable or statistically predominant structure from indeterminate input (Gómez, 2002; Gómez et al., 2003). Prior experience is yet another source of bias constraining language learners. Understanding the scope of these biases will contribute importantly to our theories of language acquisition.

Abstract

This article presents the results of a two stage investigation about how linguistic quantifiers are used to summarize expressions of quantity. In the first step subjects were asked to give verbal descriptions of arrays of percentages. Then a second group of subjects was asked to reproduce the original array from the verbal description. The second group produced quantities extremely similar to the original percentages even though the verbal descriptions they used did not describe all categories within the arrays. We shall show that quantifiers have implied meaning (e.g., between *a large number* and *most*) and that similar linguistic constructions may refer to amounts that are noticeably different (e.g., *the principal* vs. *principally*). Finally we highlight the importance of the implicit, topic-related meaning in the choice of spoken complements by showing how the concept of fuzzy quantifiers can be applied not only to their modeling, but also to their use in multi-dimensional data searches.

Cognitive semantic approaches of Quantifiers

For Cognitive semantic approaches of Quantifyers have also been quite rare. Just, (1974) defined cognitive traits within three dimensions (Universal-Specific, Large-Small, Negative, Positive) which serve to categorize and give meaning to quantifiers. Quantifiers also project a representation of quantity which influences how information is perceived. The statement " few dots are blue (or red)" with a visual image of two dots of one color and 12 dots of another, will result in attention being focussed on the two dots. If the statement were "a lot of dots are blue (or red)", attention would be focussed on the group of 12 dots (Just & Carpenter, 1971). Quantifiers also carry implied meaning and lead to making inferences about other quantities. This is the case for distinctions based on the positive ("a few of") or negative ("few of") polarity of quantifiers (Paterson, Sanford, Moxey & Dawydiak, 1998). The statement, "there are a few people in the train" designates the amount of people in relation to an empty train, whereas "there are few people in the train" refers to the number of people missing in relation to how many the train should carry.

How much meaning can be inferred from quantifiers? How many bottles of soda should you buy when a friend asks you to pick up "a few"? The analogous approach of Holyoak & Glass, (1978) is based on the idea that there is a direct correspondence between terms and a numerical scale. They showed that confusion arises when the quantifiers are very close in scale, as did Anderson (1981). Furthermore, with their approach it is not possible to evaluate the question when maximum values are unknown (the maximum amount of bottles of soda, for example). The adverbs "generally" and "usually" can be accepted as covering almost all the people or things in consideration. The adverb "often" refers to either the majority of the individuals ("children are often bright") or the majority of occurrences and can thus convey repetition ("demonstrations are often violent"). Continuing in this vein, Hörmann, Cascio & Bass O' Connor, (1974) sought to define how quantifiers would be spread on a scale with class intervals. Unfortunately quantifiers denoted values that varied in relation to what was being quantified. For example "frequently" corresponded to 70% (on average), when referring to how often Miss Sweden was judged attractive, but only to 30% when used to refer to the frequency of airplane crashes (Newstead, 1988). In natural language semantics, where quantifiers denote relations between groups (Geurst, 2003), "a lot" corresponds to the majority. Thus "a lot of A's are B's" can mean that there a more A's that are B's than there are A's that are not B's. This interpretation nevertheless is not valid for the statement "in the last elections a lot of (A: electors) were (B: electors that didn't vote)" which actually refers to the number of non-voters (Barwise & Cooper, 1981). The adverbs "sometimes"' and "rarely" appear to designate respectively a small, but non-negligible frequency, and a quite negligible frequency. Still, it is difficult to say what is "small" or "negligible", as in (1) and (2) where "sometimes" probably is not the same. What a quantifier denotes is therefore dependant on the various elements of the situation being described.

(1) Sometimes I watch the evening news.
(2) Sometimes I go to the movies.

The vast majority of studies have confined themselves to the quantifiers "all", "none" and "some", but even with these most simple cases the process which generates inferences from their meanings remains unclear. In function of given statements 49 to 75% of respondents infer from "all A's are B's" that "all B's are A's" (Newstead, 1988; Chater & Oaksford, 1999). Applying pragmatic linguistics theory,

Grice (1975) similarly found that while "all" should logically encompass "some", it is possible for "some" to be restrictive and exclude "all". Interestingly enough, it has been observed that children do not have the same understanding of quantifiers as adults. Although at 3 years of age children do not differentiate between "all" and "some" (Hollander, Gelman & Star, 2002), by the time they are seven and even though they have not learned all rules of conversation, their answers are logically more valid than adults' are (Smith, 1980).

A question remains as to the information the adult is using to make an inference. Are they saying "some" because they know they cannot include "all" the objects (3), in which case the restrictive interpretation is pragmatically valid, or, are they saying "some" because they have no more information about the other objects (4), in which case a non-restrictive interpretation is more accurate.

(3) There are some broken eggs in this carton

(4) I took some eggs from this carton and they weren't fresh

In contrast to studies which have used ad hoc statements, in this article we have sought to potentially include all the values and expressions that "some - not all" can have in relation to a real situation (results of the 1998 French high school graduation standardized examination, the "baccalauréat"). There were 1,277,282 students in the class of '98. The data from this group are multidimensional; they can be arranged according to many factors: pass rate, gender, age, nationality, region, type of school, presence during the exam, which specialized baccalauréat was taken, which foreign languages were studied, etc.

From the 18 independent dimensions used (each containing 2 to 13 terms), more than 300 million relations are possible when only considering the intersection of the dimensions' terms, because relations may also derive from the fusion of exclusive terms. Our objective was to investigate quantifiers both in terms of their production and their interpretation.

The first step was to observe an initial group of students producing quantifiers (experiment 1). In step two a second group of students was given the opposite task of assigning numerical percentages to the verbal descriptions which were summarized by group 1.

Experiments

In order to assess the wide range of quantifiers used, in experiment 1 we allowed the free production of verbal descriptions for the percentage distributions. In order to assess how often certain quantifiers were used for each distribution, participants then selected terms from a list

Experiment 1: production and choice of quantifiers

Method

Participants. 83 university students in psychology and computer sciences responded to the questionnaires either in writing or via the Internet. In the later case students had to access the research lab's site. All the participants had passed their *baccalauréat* examination one or two years previouslySecond-level headings should be 11 point, initial caps, bold, and flush left. Leave one line space above and 1/4 line space below the heading.

Questionnaires. 18 percentage distributions generated from a database concerning the 1998 baccalauréat, constituted the basic information in the questionnaires. The distributions were selected to include the largest range possible of cases in terms of dimensions, number of variables (from 2 to 13) and values. They were as follows:

D-1: very close values all around a half,
D-2: very different values; one very large, one very small,
D-3: many values; one very large, one small and all others very close and very small,
D-4: many values, but none large (i.e. near a half) and all others very small but not as close as in D-3,
D-5: five not very high values; two quite close, one not very distant and two others quite close and very low,
D-6: three values close to a third and two other very weak ones (almost null),
D-7: data in absolute values (to compare with the first distribution),
D-8: one very strong value, one very weak,
D-9: two strong proportions (above 50%), neither very, nor too distant,
D-10: on two lines, a strong imbalance between columns with a rather large difference between lines with intersections as well,
D-11: two rather close proportions near 50%, but one was 10 points over and the other 10 points below,
D-12 : many very small and close values with two other values close to 20% and a third near 40%,
D-13: two close values, both quite average,
D-14: two high and close values,
D-15: two very weak, close values,
D-16: five values; one near a half, two others near 20%, and two very weak others
D-17: three very weak and close values (two almost equal and the third a little higher)
D-18: two strong, very close values (in comparison to D-14).

*Procedure.*The instructions on page one of booklet one were as follows: "Without using any of the figures in the tables, in a few lines, write what you can say about the table. You have 20 minutes for this task." The second booklet had the same instructions with the constraint to use words from the quantifiers list given: "Without using any of the figures in the tables, in a few lines, use words from the list below to say what you can about the table. If a non-included term seems absolutely necessary you may add it to the list. You have 20 minutes for this task".

Results and Discussion

Quantifier production. The participants' responses fell into two contrasting types of verbal statements summarizing the given distributions. The first type consisted mostly of describing the dominant term(s) and its(their) impact by using quantifiers, like "half". Modifiers like "very" were used extensively. These kinds of responses were particularly common when the distribution table had only two variables and/or when the table had one very high level, very different from the other levels.

The other type of verbal summary was used when there were many variables and when no one term was prominent. The statements first purpose was to organize and structure the data, that is, to make comparisons (especially of near equality) between the different terms, for example by contrasting the girls' results to the boys'. This process can be seen as a relative analysis of the results. Sequencing terms like "first" and "then" were prevalent and no indication in either quantitative or qualitative terms was given for evaluating proportions. When statements of this type set hierarchical relations between variables, they did not on the other hand, establish orders of magnitude. For D-13 and D-14 for example, all the respondents ordered the success rates, but only one gave an indication of the actual values of the scores.

The principal terms found fall into four categories:

Ordering numerical values
- More ___ than ___ and less ___ than ____
- first ... next/then ... the rest ...
- best/better than ...
- many ... few

Quantifiers
- principally, in general, the majority, frequently, often, almost/almost all, a good part
- (very) few of, a minority of
- a third, (nearly) half, more than a million
- about x%

Relations (fuzzy
- about the same, (a little) more often, almost as much, no major difference, lower, raise, constantly, bigger, below, above, …

Modifiers (fuzzy)
- just about, almost, lightly, clearly, noticeably, approximately, (very) (low) minority, large majority, …

It quickly appeared that certain quantifiers were not used as often as would have been assumed. This was the case for the expressions of proportion other than "about half" (i.e. "about a quarter", "about a third") and it was also true for "most of" which wasn't often produced spontaneously, but was chosen when included on the list (see next section). In general the respondents preferred the expression "a lot of". Comparisons and ordering seemed of primary interest and thus, the term "more" was used extensively.

Finally, we observed in most cases that the verbal summary descriptions were incomplete: the respondents only focussed on certain variables in each distribution. It is true that for inter-dimensional variables, orders of magnitude cannot be deduced. However, our distributions were for the most part intra-dimensional. For this reason it was often possible to infer and reconstruct the numerical values of the proportions in the tables (all proportions summed to 100%), from the verbal summaries.

The choice of quantifiers. The quantifiers the respondents chose for summarizing the data are as follows. When more than 75% of the participants chose a certain quantifier, it was then associated with the distribution

If we consider only the data compiled from the Internet questionnaires, only distributions 4 and 10 generated a disparate choice of quantifiers. For the majority of the other cases, three groups of quantifiers stand out; the first being simply "almost all", the second being proportional ("about half", "about a quarter", "about a third", etc.), and the third being composed of quantifiers that describe either the general case ("most of"") or particular cases ("few").

The option "If a non-included term seems absolutely necessary you may add it to the list" was chosen most often to differentiate (and provide a substitute for) descriptions that used the terms "as many/much as", "equals", "similar", "almost equal", "more than", etc., found with test booklet version 1

Items (D-1) and (D-7) presented the same information in numerical values and as a proportion, respectively. For D-7 the participants massively chose the same quantifiers as in the distribution, whereas for the absolute values there was a much greater diversity in the quantifiers selected.

Items (D-14) and (D-18) represent approximately the same numerical data (strong proportions near 75%), but with different dimensions. The temporal dimension is more salient with quantifiers like "constant over time" or "rose by" for D-18, (which described baccaulareat rates by years), than for D-14 (pass rates vs. gender), even though for version 2 the results were quite similar.

Finally, it was noted that although version 2 had different quantifiers added to its list which did not necessarily appear on version 1, the answers concerning the same subject were often very close, for both versions of the questionnaire**.**

Experiment 2: understanding quantifiers

The objective of this second investigation was to determine whether respondents would be able to reconstruct tables of numerical data from the series of verbal summaries containing quantifiers which the subjects in experiment 1 defined.

Method

Participants. As with the first test, the participants were university students in psychology or computer sciences (N=116), who all had passed their baccalauréat one or two years previously. All students used printed questionnaires (none responded via the Internet***).***

Questionnaires. The questionnaire used in experiment 2 contained nine (D-1, D-2, D-3, D-4, D-11, D-13, D-15, D-16 and D-17) of the original 18 distribution tables, without their numeric values. Hereafter they will be designated as D-1 through D-9. Each distribution is associated with a verbal description containing the quantifiers that the majority of the subjects in test one chose. The descriptions are as follows:

D-1: "There are a few more girls than boys",

D-2: "There are very few foreigners enrolled",

D-3: "The test candidates mainly came from public schools, if not, they came principally from state accredited private schools",

D-4: "About half the candidates have no possible area of specialization. Most of the others chose mathematics or a modern foreign language",

D-5: "The majority of test passers were girls",

D-6: "The pass rate was higher (quantifier=more) for the French than for the foreigners and represents the majority",
D-7: "The pass rate was higher (quantifier=more) for the girls than the boys",
D-8: "A quarter of the test takers fail. Half receive no honors. 1/5 receive the honorable mention - good. Very few receive the highest distinction - excellent".
D-9: "The excellent honors rate was very weak for the baccalauréats specialized in economics and social sciences. It is 3 times higher (quantifier=more) for the literary baccalauréats (a little less than double) and it is 4 times higher (quantifier=more) for the scientific baccalauréats".

The tables and their descriptions were on one sheet of paper. On the top of the paper the following instructions appeared: "Use the corresponding summaries to reconstruct tables of numerical data (percentages)".

Procedure. Each participant received the questionnaire sheet with the nine distributions to fill in according to its corresponding verbal summary. They were allotted a maximum of 30 minutes to complete the task.

Some of the tables submitted did not present a total of 100, so they were proportionally corrected to reach 100. In this manner the quantitative values obtained in experiment 2 could be compared to the initial numeric information the subjects used in experiment 1.

Results and Discussion

Item D-7 introduced a comparison with a conditional frequency. The number of boys receiving highest honors was 7.6%; for girls it was 7.8%. This relationship was interpreted by the respondents as being complementary and thus, they furnished values that summed to 100%. Setting aside this distribution, the results demonstrate that the subjects were able to reconstruct numeric tables from the textual summaries. Variation around the average response was quite low in the majority of answers (Figure 1).

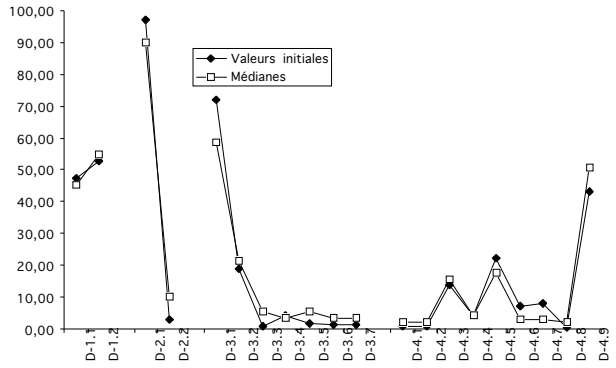

Figure 1: Comparison of the initial values and the reconstructed values.

It is clear that although the verbal descriptions were often incomplete, the participants were capable of filling in the distribution tables with values quite similar to the original ones. Aside from D-7, the averages of the quantities generated by the respondents correlate to the initial values at 0.89 ($p<0.0001$) and the medians correlate at 0.875 ($p<0.0001$). The greatest differences occurred with items D-6 and D-9. In D-6 as in D-7, the participants produced complementary percentages that totaled to 100%. In D-9, they greatly overestimated the percentage of *excellent* honors.

General Discussion

Despite the variances in D-6, D-7 and D-9, the students were able to produce a very good approximation of the initial quantitative data and the question remains as to how they managed this using just the quantifiers in the verbal descriptions.

Abstract

Concept mapping is widely used in educational and other settings to aid knowledge construction, sharing, and comparison; concept maps are also used as a vehicle for assessing understanding. To aid the concept mapping process, projects at Indiana University and the Institute for Human and Machine Cognition (IHMC) are developing "intelligent suggesters" to support users as they build concept maps, by presenting them with relevant information from existing knowledge models and the Internet. This depends on identifying important concepts in the concept map under construction. This paper presents and evaluates models of the influence of concept map layout and structure on the selection of concepts expected to be relevant to the topic of concept maps. It presents and assesses a set of potentially-relevant structural factors and evaluates how these factors combine to affect human judgments of concept importance. Twenty subjects were asked to judge the relative importance of concepts in concept maps selected to highlight particular characteristics, and three models were compared to their judgments. Analysis of the results shows that subjects were significantly influenced by concept map topology, but little influenced by other aspects of concept map layout. The results suggest that layout-independent models of concept maps can provide a suitable representation for guiding retrieval of topic-relevant information to support concept map construction, provided that the representation reflects topologically-based influences. The results are applied in the design of the suggesters' similarity assessment procedures for retrieving relevant concept maps.

Introduction

Concept mapping [Novak and Gowin, 1984] has been widely used to elucidate humans' knowledge and to facilitate knowledge elicitation, construction, and comparison and sharing. In concept mapping, users construct a two-dimensional, visually-based representation of concepts and their relationships. The concept map representation encodes propositions describing two or more concepts and their relationships, in simpli ed natural language sentences. In educational settings, concept mapping exercises have been used to encourage students to actively construct an understanding of concepts and relationships within domains of interest. To facilitate concept map construction and sharing, the Institute for Human and Machine Cognition (IHMC) has developed CmapTools, publicly-available tools to support generation and modi cation of concept maps in an electronic form (http://cmap.ihmc.us/). CmapTools enable interconnecting and annotating maps with material such as other concept maps, images, diagrams, and video clips, providing rich, browsable knowledge models available for navigation and collaboration across geographically-distant sites. The CmapTools software has been downloaded by users in approximately 150 countries, and has been used in major educational initiatives, such as the Quorum project [Canas et al., 1995], which involved more than one thousand schools in Latin America. It has also been used for modeling and sharing the knowledge of human experts, for example, for modeling NASA experts' knowledge of Mars (http://cmex-www.arc.nasa.gov/).

CmapTools provides a convenient framework for knowledge construction, but users may have dif culty nding relevant resources, remembering speci c aspects of a domain to include, or locating relevant concept maps to compare. To alleviate this problem, projects are under way at Indiana University and the IHMC to develop intelligent suggesters to support users by retrieving resources such as prior concept maps and multi-media materials [Leake et al., 2003]. Figure 1 shows a screenshot of a Mars knowledge model under construction, with suggestions of propositions, resources, and topics to consider. The suggesters' effectiveness depends on their ability to retrieve topic-relevant information, which in turn depends on modeling users' own judgments as they examine concept maps. Thus modeling users' judgments of the importance of concepts to a map's topic has practical value for suggester software to support concept mapping and scienti c value, for better understanding what in uences human understanding of the knowledge that concept maps convey.

The assessment of concept importance may depend on the concepts they include (based on their labels in the concept map), on the concept map topology, or on layout differences between isomorphic maps. Especially for users unfamiliar with a domain, we would expect topology and layout to play an important role in their assessment of the topic of a concept map. However, to our knowledge, no previous studies have investigated whether/how the topology and layout of a concept map actually in uence judgments of its topic. To hypothesize candidate topological and layout factors that might in uence decisions of which concepts are most topic-relevant, we considered general structure and layout guidelines for building good concept maps in the concept mapping literature, as well as methods for identifying important nodes from the structure of hyperlinked environments. These were used to develop candidate models for the in uence of structural features on identifying the concepts most important to the topic of a concept map. We then performed experiments in which twenty paid subjects judged the relative importance of concepts in concept maps selected to investigate particular structural in uences. We used this data to set pa-

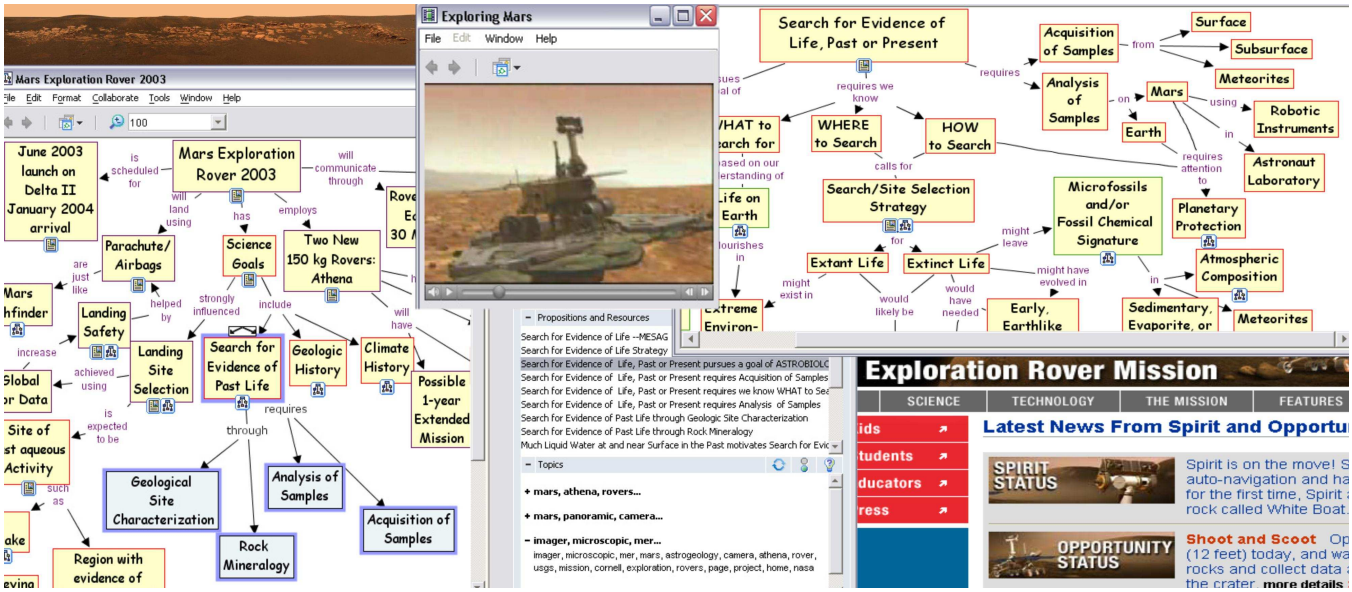

Figure 1: Portion of a Knowledge Model developed by the NASA Center for Mars Exploration, with Sample Suggestions.

rameters in the models and to assess the ability of the models to predict the subjects' performance. Our results suggest that topology is important; the structure of concept maps plays an important role in assessments of concept importance. However, they also suggest that layout plays a less important role. Methods suggested by the models have been implemented in the suggesters to provide support for students and experts' concept map construction.

Modeling Concepts and their Relationships

Concept mapping was developed in an educational setting by Joseph Novak, in an effort to design better teaching and learning activities [Novak and Gowin, 1984]. Novak based the approach on Ausubel's cognitive learning theory[Ausubel, 1963], which proposes that meaningful learning requires deliberate effort by the learner to connect new concepts to relevant preexisting concepts and propositions in the learner's own cognitive structure. Concept mapping was designed to support the learner's effort by externalizing concepts and propositions known to the student, making them visually apparent to facilitate their connection with newly acquired concepts. Concept maps have been used by teachers to assess students' understanding, by students to compare their knowledge and collaboratively re ne their understanding, and by experts as a vehicle for modeling and sharing their knowledge.

Concept maps relate to several other frameworks developed in cognitive psychology and arti cial intelligence to model concepts and their relationships. Schemes based on graphs or networks are commonly used as models of human memory organization, to account for phenomena such as similarity judgments or hierarchical category structure. Early examples include the hierarchical network model [Collins and Quillian, 1969], semantic memory [Tulving, 1972] and conceptual structures [Ausubel, 1963]. More formal approaches to graph-based representations, such as conceptual graphs [Sowa, 1984] or semantic networks [Quillian, 1968], attempt to provide a representation suitable for machine processing. Proposals for non graph-based representations to model concepts and their relationships include formal concept analysis [Ganter and Wille, 1999], which models the organization of concepts in terms of lattice theory, and the geometric structure of conceptual spaces [Gärdenfors, 2000].

Despite the many differences among theories of knowledge organization, they share a fundamental assumption that knowledge can be modeled in terms of a set of components and their relationships. Concept mapping is a method for externalizing such a structure in an individual, making concepts and relationships explicit. Thus examination of concept maps can be used to assess subjects' knowledge [West et al., 2002], and support for the usefulness of this approach has been provided by empirical studies[Aidman and Egan, 1998, Michael, 1994]. However, there has been little study of what affects subjects' judgments of the topic of a concept map, how to determine topic similarity from concepts maps, and the types of representations that may support computer models of concept map retrieval. In previous studies using similar types of representations, topological information about graphs has been used to de ne measures of graph similarity [Goldsmith and Davenport, 1990] and for concept clustering [Esposito, 1990]. These frameworks are based on the premise that the closer the relationship of two concepts the closer they are in cognitive structure the closer they will be in the graph representation. This has been used to induce concept proximity or relatedness. Our study investigates a complementary question, the in uence of other structural factors, such as the numbers of incoming and outgoing links. How graph topology and layout affect assessments of concept importance is central to understanding the information conveyed by concept map structure, as well as for developing models of topic similarity for concept maps.

Models for Analyzing Concept Maps

We developed four candidate models of the in uence of structural and layout characteristics on expectations for the importance of particular concepts to the topic of concept maps. In the models, concepts are represented as nodes in the concept map graph. The baseline model treats map topology and layout as unimportant. The three remaining models use the topology of the concept map to compute a weight predicting each concept's importance in describing the topic of the map.

To determine which factors to include in the models, we rst considered factors from the concept mapping literature. Novak proposed that meaningful learning is facilitated when new concepts or concept meanings are subsumed under broader, more inclusive concepts, which suggests that concept maps should have a hierarchical structure. All of the non-baseline models can re ect such a structure, with weighings re ecting that important concepts are at the top of the map, and less important at the bottom. However, the models are parameterized so that the actual contribution of hierarchical structure if any can be determined empirically. We also considered the applicability of topological analysis methods from other domains, in particular, Kleinberg's algorithm[Kleinberg, 1999] for topological analysis of graphs, used to identify important nodes in a hyperlinked environment. Kleinberg's work characterized nodes on the World Wide Web as hubs and authorities based on their interconnections. When applied to concept maps, we expected hub and authority concepts to be especially important to determining the topic of concept maps.

Connectivity Root-Distance Model (CRD)

The connectivity root-distance model is based on two observations. First, concepts that participate in more than one proposition, as indicated by their connectivity the number of incoming and outgoing connections may be more important in de ning a map's content than concepts with lower connectivity. Second, Novak argues that concept maps are best constructed if a focus question or a single root concept guides the selection of concepts and their hierarchical organization in the map. The root concept, typically located at the top of a map, tends to be the most general and inclusive concept and to specify the map's topic. This suggests that concept importance may increase with proximity to the root concept.

The CRD model determines proximity by counting the number of direct links between the map's root concept and a given concept. For example, in gure 2, the concept masses of ice has a connectivity of four (one outgoing and three incoming links) and a distance of one to the root concept glaciers . If concept k in a map has o outgoing and i incoming connections to other concepts and is d steps distant from the root concept of the map, then the weight assigned to k by the CRD model is

$$W(k) = (\alpha \cdot o(k) + \beta \cdot i(k)) \cdot (1/(d(k)+1))^{1/\delta}$$

The model parameters α, β, and δ determine in uence of the incoming connections, outgoing connections, and distance to the root concept. The formula implies that the higher a concept's connectivity and the shorter its distance to the root concept, the larger its weight and therefore relevance in the topic of the map.

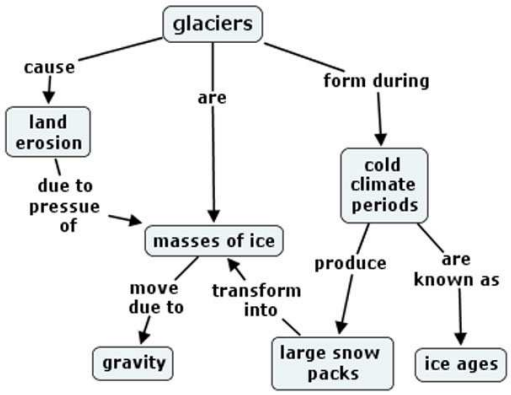

Figure 2: A simple concept map about glaciers.

Hub Authority and Root-Distance Model (HARD)

The Hub Authority and Root-Distance Model also explores the importance of the root node and the hierarchical organization of concepts in maps. However, while CRD performs a local analysis, only taking immediate neighbors into account, HARD performs a global analysis on the in uences of the concepts on each other. Its analysis centers on three different types of concepts that may be found in a concept map:

- *Authorities* are concepts that have multiple incoming connections from hub nodes.
- *Hubs* are concepts that have multiple outgoing connections to authority nodes.
- *Upper* nodes include the root concept and concepts closest to the root concept.

To determine a node's role as a hub or authority, we adapted Kleinberg's algorithm for analyzing hyperlinked graphs to concept maps. Our algorithm, described in detail in [Canas et al., 2001], associates each concept with three weights between 0 and 1, each re ecting the concept's role as a hub, authority, or upper node. A given concept may simultaneously have properties of all three, but in Figure 2, glaciers is primarily a hub concept, due to the number of outgoing connections, and masses of ice is primarily an authority, due to its mostly incoming connections. Among the three concepts with outgoing links to the concept masses of ice , glaciers is the one with the greatest in uence in making masses of ice an authority node, because of the comparative strength of glaciers as a hub.

In the HARD model, the three weights of a selected concept k are combined into a single weight as follows:

$$W(k) = (\alpha \cdot h(k) + \beta \cdot a(k) + \gamma \cdot u(k))$$

In the above formula a, h, and u are the corresponding authority, hub, and upper node weights of a concept in a map and α, β, and γ are the model parameters. As above, the parameters re ect the in uences of the different roles that a concept may play.

Path Counter Model (PC)

The Path Counter Model, like the CRD model, re ects the expectation that concepts participating in more propositions will tend to be more important to the topic of a map. However, instead of considering only a concept node's immediate connectivity, like the CRD model, the PC model considers indirect relationships as well. It counts all possible paths that start from the root and either (1) end on a concept with no outgoing connections, or (2) end on a concept that has already been visited in a path. We note that if a concept has high connectivity (which allows for many paths through the map to include that concept), then the number of paths crossing concepts indirectly linked to the high-connectivity concept increases as well. For example, the PC value for the concept gravity in gure 2 is three, because there are three paths extending from the root concept to gravity, due to masses of ice which is well connected in the map. Formally, to determine the weight $W(k)$ of a concept k in a map, assume that n is the number of paths crossing k. Then the weight is computed as $W(k) = n$. Unlike the previous two models, this model considers only a single in uence on concept weight, and consequently requires no parameters.

Experiments and Results

We conducted a human-subjects experiment to study the in uences of the hypothesized factors on human judgments of concept importance, and the overall t of the four models' predictions to human judgments, with the parameter settings that best t the CRD and HARD models to the subject data.

Method

Twenty paid subjects, all students admitted to Indiana University, were recruited by postings on electronic message boards and bulletin boards for a one-hour experiment conducted on the Web. In a training phase, participants were given a brief description of concept maps and their applications and asked to write a short summary of two concept maps from different domains. In the test phase, subjects answered 56 questions about a total of 12 small concept maps (fewer than 15 concepts each). The maps were designed with controlled differences in their topological structure and layout, to investigate the presence or absence of in uences from particular types of changes (e.g., changing position of a node without affecting topology). Each question presented a concept map and two concepts selected from that map. Participants were asked to examine a map and to answer which of the two concepts best described the map's topic, or whether both described it equally well.

To allow participants to rst practice decision making on regular concept maps, the rst 2 of the 12 concept maps used regular words in the concepts. To prevent domain knowledge from in uencing participants' decisions, concept labels were replaced with arti cial terms in the remaining 10 maps, and only responses concerning the latter 10 test maps were used in evaluating the models. To minimize the in uence of previously-seen concept maps on new responses, different arti cial labels were used for each map, and both the ordering of options for questions and ordering of topological and layout changes between successive concept maps was randomized. The concept maps in the experiment were designed to test speci c hypotheses about the topological and layout factors that may in uence subjects' evaluation of relevance of concepts to a concept map's topic; the absence of domain information forced subjects to rely entirely on topology and layout.

Results

To test whether subjects' judgments of the importance of two concepts changed signi cantly from one map to another, we used a χ^2 test of independence when comparing the subjects' selections from two different maps. Table 1 summarizes the statistical results.

Distance to root concept: To test the in uence of distance to the root concept, subjects evaluated two concept maps in which the distance from a test concept to the root concept was changed from 2 to 1, by inserting an intermediate node. In a series of questions, subjects were asked to compare importances of the test concept, which was moved in the map's hierarchy, to the root concept and neighboring concepts of the moved concept. The results show that the root concept was considered most important compared to the other concepts, and that the importance of the test concept increased as it moved up the hierarchy. The differences in the selection of the moved concept over its neighboring concepts between the two concept maps were statistically signi cant.

Connectivity of a concept: To test the in uence of connectivity, we used two concept maps which differed by increasing a test concept's connectivity the number of incoming and outgoing connections to neighboring concepts from 1 in the rst map to 6 in the second. Subjects were asked to compare importances of the test concept to the root concept and the neighboring concepts of the modi ed concept. When the test concept's connectivity was increased, participants favored it over neighboring concepts and sometimes even over the root concept. All differences were statistically signi cant except for the preference over the root concept.

Layout of a map: To test whether a difference in layout affects subject's selections, two concept maps were constructed with identical topology but substantially different layout. The layout changes primarily involved horizontal organization, but in one instance a single concept was moved from the center right to the bottom left position. The questions asked for both layouts compared the concept that changed its position to its neighboring concepts. The statistical evaluation revealed that the layout changes had no signi cant affect on the concept ratings.

Direct and indirect influences of hub and authority nodes in a map: To test the effects of direct and indirect in uences, a total of four concept maps were constructed with strong hub and authority concepts connected to other concepts in the map. The results showed that hub and authority concepts have an in uence on the selection of concepts, and that authorities play a stronger role than hubs. However, the indirect in uence of either a hub or authority concept on other concepts (when a hub or authority is indirectly connected to a test concept) did not signi cantly affect concept importance.

Fitting the Models to the Data

A hill-climbing algorithm was used to determine the parameter settings for the CRD and the HARD models which gave

In uence	Signi cant	χ^2 Test of Independence
distance to root concept	yes	$(1, N = 40) = 17.04, p < 0.05$
concept connectivity	yes	$(1, N = 40) = 19.37, p < 0.05$
map layout	no	$(1, N = 40) = 0.23, p > 0.05$
direct, hub concept	yes	$(1, N = 40) = 7.74, p < 0.05$
direct, authority concept	yes	$(1, N = 40) = 15.93, p < 0.05$
indirect, hub concept	no	$(1, N = 40) = 3.73, p > 0.05$
indirect, authority concept	no	$(1, N = 40) = 3.73, p > 0.05$

Table 1: Statistical evaluation of in uences on concept importance.

Model	Parameters for Best Fit			RMSE	Cumul. Error
	α	β	γ / δ		
CRD	0.930	4.959	3.603	0.072	27.5%
HARD	0	2.235	1.764	0.1487	32.8%
PC	N/A	N/A	N/A	0.170	27.8%
Baseline	N/A	N/A	N/A	0.564	66.8%

Table 2: Summary of model parameters and RMSE.

the best t between the models and user data. Table 2 summarizes the chosen parameter values, the root-mean-square error (RMSE) of user and model data, and the cumulative error. The cumulative error is the percentage of the total questions (44 questions per subject, involving the 10 test concept maps) for which the models determine different responses from the subjects. To determine a model's preference between two concepts in a concept map, we compared the model's importance values for the two nodes. The model was considered to treat the concepts as equally relevant when their relevance values were within a xed threshold of each other, for a threshold distance determined by hill-climbing. The last row of the table shows the RMSE and the cumulative error for a baseline model. In this model each concept in a map is rated equally important by assigning it a weight of 1.

The results show that the CRD model provides the best t to the user data, followed by HARD and PC. All models except the baseline agree with more than 67% percent of the decisions reached by the participants, who were in a few cases strongly divided in their vote for the best topic-describing concepts. For the remaining 33%, in most cases the models' predictions match the decisions of some subjects. Only once for the CRD model, twice for the HARD model, and four times for the PC model were model and user predictions entirely disjoint. Overall, CRD, HARD, and PC perform better than the baseline model.

Further analysis of the best- t parameters for the CRD and HARD models supports the importance of authority nodes (nodes with incoming connections). For the CRD model, nodes with incoming connections (nodes that play the role of an authority) are more relevant than nodes with outgoing connections (nodes that play the role of a hub) because their β is greater than α. With the best- t parameters for the HARD model, hub nodes are not considered relevant when computing the weight of a node. However, we note that hub nodes still play an important role when computing the level of authority of other nodes in the map.

Discussion

The experiments studied how topology and layout affect assessments of the importance of concepts within concept maps. They compared four candidate models which, using only analysis of a map's topology, compute a weight for each concept in a map. The computed weights provide an estimate of the importance of each concept as a descriptor of the topic of the map, according to subjects' judgments of topic importance.

The studies highlighted the importance of topological information; to our knowledge, this is the rst study to show this effect. They also suggested that speci c layout does not have a signi cant effect. This is important for being able to recognize similarity across concept maps developed by different individuals, despite super cial differences that might affect user judgments. It is also interesting to note that despite the importance of topology, local information alone was suf cient to account for the observed results. The CRD model, which considers distance from the root node and local connectivity, outperformed the HARD model, which takes indirect in uences into account as well.

The current study did not examine interobserver variation; this is an interesting area for future work. Also, the experiment used small concept maps, and considered only the topological and layout factors of the maps, rather than their content. We are conducting additional studies to explore the role of content in assessments of concept importance. However, preliminary results suggest that structure plays a surprisingly strong role, with structural information alone often suf cient to make high-quality predictions.

Application in the Suggesters

The experimental results are re ected in the design of the CmapTools suggesters, two of which are shown in use in the lower center of Figure 1. The rst suggester uses the calculated importance values to weight keywords from concept labels in a concept map, in order to retrieve similar prior concept maps for comparison and to suggest propositions from those maps. This approach to supporting concept map generation is inspired by case-based reasoning [Kolodner, 1993]; concept maps constructed by different users are considered as case-bases of their concept-mapping activity, with each concept map considered to be a separate case. When a user wants to extend a concept to add a new connected concept the system draws upon prior concept maps that include the original concept, as examples of how that concept was extended in similar past contexts. The second suggester uses the similarity weighting to weight keywords for Web search,

to derive topics for the user to consider when starting a new concept map to broaden the knowledge model. These and other implemented suggesters are described in detail in [Leake et al., 2003].

Conclusion

This paper explores factors affecting human judgments of concept importance in determining the topic of concept maps. Modeling such judgments helps elucidate the knowledge captured in concept maps, provides information to guide the design of concept maps in educational settings, and aids the development of intelligent support systems to provide relevant material during concept mapping. Our experiments assessed the in uence of speci c factors and examined the ability of four different models to re ect human assessments of concept importance.

Among the three models, the CRD model, which considers connectivity and distance to the root concept, provided the best match to human data: Its predictions were consistent with the average predictions made by the participants for forty-three out of forty-four questions. The results highlight the importance of local topology and suggest that human topic decisions are robust to layout differences, which is encouraging for the generality of concept mapping for knowledge sharing and the development of support tools to retrieve similar concept maps and topic-relevant information. We are performing followup studies to examine the role of domain content and the t between the predictions of these models and the concept maps developed by domain experts for sample domains.

Principles suggested by the results have been applied to intelligent suggesters to aid the human knowledge modeling process, and the implemented systems appear to give good results in practice. We consider the type of evaluation presented here as important step for guiding the design of such tools, and are now designing experiments to more formally test the relevance of the suggester systems' recommendations during the concept map construction process.

Acknowledgments

This research is supported by NASA under award No NCC 2-1216. We thank Alberto Canas and the IHMC CmapTools development team for their many contributions to the project, Tei Laine for her comments on a draft of this paper, and John Kruschke for assistance on experimental design and analysis.

Abstract

What are the problems faced by artists in real-life contexts? By what processes do they solve these problems? In this paper, work on scientific discovery (e.g, Klahr, 2000; Kulkarni & Simon, 1988; Langley, Simon, Bradshaw, & Zytkow, 1987) and a situated perspective on creative cognition (e.g., Csikszentmihalyi, 1988, 1999; Nersessian, 2004) are brought together into a unifying framework for studying the processes of artistic creativity in real-life. Within this framework, artistic creativity is viewed as *situated problem solving*. We illustrated our approach by applying it to Isabelle Hayeur, a successful Canadian visual artist.

Introduction

In this paper, work on scientific discovery and a situated perspective on creative cognition are brought together into a framework for studying the processes of artistic creativity. Everybody is interested in art, but up until now few have examined the problem-solving processes that provide support for the artistic process and the production of works of art; almost no one has looked at real-life artistic practices.

We begin by reviewing work on scientific discovery processes. We then present a current definition of creativity that parallels work on situated and distributed cognition. We then go on to describe part of an ongoing field study we are conducting, a study of creative artistic processes in a contemporary visual arts practice, within our framework. Finally, we discuss the potential of this approach for future studies of artistic creativity.

Artistic Practice and Creativity as Situated Problem Solving

Artistic Creativity as Problem Solving

There is now a tradition of studying creativity from a problem-solving viewpoint (e.g., Klahr, 2000; Kulkarni & Simon, 1988; Langley, Simon, Bradshaw, & Zytkow, 1987; Newell, Shaw, & Simon, 1962). The processes of scientific discovery, especially, have been studied from this perspective.

In an excellent review, Klahr and Simon (1999) present the four major approaches of these studies: historical, laboratory, direct observation, and computational. What Klahr and Simon note is that all these approaches to the study of scientific creativity have led to convergent findings about discovery processes.

Klahr and Simon propose that by using the concepts and vocabulary of human problem-solving theory "we may be able … to converge toward a common account of discovery in many areas of human endeavor: practical, scientific and artistic, occurring both in everyday life and in specialized technical and professional domains" (p.524). Here, these concepts and vocabulary are those of problem spaces – states, operators and goals –, heuristic rules, weak and strong search methods – hill-climbing, means-end analysis, planning (Newell & Simon, 1972). Discovery is thus viewed as a search process in a problem-solving space, composed of goals, rules and other aspects of the task and situation.

Up until now, artistic creativity had almost never been studied from a problem-solving perspective. There are a few exceptions (e.g., Weisberg, 1993), but a lot of groundwork still needs to be done. So far, the studies of artistic creativity based on this approach have mainly addressed creative processes in relatively general terms; they have not produced specific descriptions of problem spaces and heuristics in specific artistic practices.

Search Spaces in Scientific Discovery *Search spaces* or *problem spaces* are abstract – representational, conceptual – spaces explored by a 'problem solver' during the problem-solving process. In the case of scientific discovery, scientists have been found to work in two, three, four, and even in search spaces of greater dimensionality (e.g., Klahr & Dunbar, 1988; Kulkarni & Simon, 1988; Schunn & Klahr, 1995; Thagard, 1998; Wolf & Beskin, 1996; see also Klahr & Simon 1999; Klahr, 2000). The traditional two-space view of scientific discovery has its origins in Simon and Lea's (1974) work on problem solving and rule induction; it was first proposed by Klahr and Dunbar (1988). According to this model, in the process of scientific discovery, search happens in two coordinated spaces: (1) the hypothesis space, and (2) the experiment space. Thus, scientific discovery involves generating new hypothesis and experiments; then these experiments serve to evaluate the hypothesis and further generate new ones. This can be considered a problem-solving process.

Similarly, we may ask: what problem space is explored by an artist in the course of the artistic work and practice? In what problem space, and by what processes, is this search conducted? And, of course, there is the possibility that the artist is working through multiple search spaces, corresponding to diverse subproblems involved in artistic creativity.

Artistic Creativity as Situated Activity

According to Csikszentmihalyi (1999), "For creativity to occur, a set of rules and practices must be transmitted from the domain to the individual. The individual must then

produce a novel variation in the content of the domain. The variation then must be selected by the field [the social organization of the domain] for inclusion in the domain" (p. 315; see also Feldman, Csikszentmihalyi, & Gardner, 1994).

From this point of view, creative cognition is not just "in the head" (Norman, 1993a), it is a computational process involving domain and field, as well as the individual. The parallels with situated or distributed approaches to cognition are obvious (e.g., Hutchins, 1995; Nersessian, Kurz-Milcke, Newstetter, & Davies, 2003; Thagard, 1999). Nersessian et al. (2003), for example, studied innovation – creativity – in biomedical engineering research laboratories as a situated and distributed process. The view of creativity as situated, contextual, points toward individual, field, and domain-specific studies of creativity (Csikszentmihalyi, 1988, 1999; Li, 1997; Mace & Ward, 2002).

A lot of recent work in cognitive science explores the situated nature of cognition and action (e.g., Clancey, 1997; Hutchins, 1995; see Nersessian, 2004; Norman, 1993b). Nersessian summarizes the challenges posed to traditional cognitive science by this *environmental perspective* with three interrelated questions: "1) What are the bounds of the cognitive system? 2) What is the nature of the processing employed in cognition? and 3) What kinds of representations – internal and external – are used in cognitive processing?" This perspective effectively poses challenges to cognitive science; the same challenges are also implicit in current models of creativity.

Thus, as with the problem-solving approach, situated and distributed cognition approaches have been used to study processes of scientific discovery (e.g., Nersessian et al., 2003).

Within our framework for studying processes of artistic creativity, in accord with problem-solving theory, recent approaches to situated and distributed cognition, and with current definitions of creativity, we view artistic creativity as *situated problem solving*. We are interested in finding out what problem-solving processes are involved in artistic creativity and in situating these – computations, rules – within the larger system involved in an artistic practice.

Contemporary Visual Arts Practice: The Case of Isabelle Hayeur

To illustrate this approach, we will briefly present preliminary results obtained from the study of a contemporary Canadian visual artist's work and practice. The main focus of this first phase of analysis is on determining the *search spaces* involved in a real-life artistic work and practice.

Isabelle Hayeur[1] is a professional Canadian artist. She is a *professional artist* in the sense of Quebec's law on the *Professional status of artists in the visual arts, arts and crafts and literature, and their contracts with promoters* (R.S.Q., c. S-32.01); she has received multiple grants from both the Canada Council for the Arts and the Conseil des Arts et des Lettres du Québec, and her work has been shown nationally and internationally.

Isabelle Hayeur works mainly with digital photography and video. Her digital photomontages and videos have been shown in solo and group exhibitions, and festivals, in Australia, Belgium, Canada, Chile, Croatia, Denmark, England, Estonia, France, Finland, Germany, Italy, Japan, Malaysia, Mexico, Portugal, Poland, Serbia, Spain, and the United States. She also produces Internet art projects and site-specific works. Her artistic work deals mainly with the impact of the Western model of development on the environment. Her images often display landscapes, part idyllic, part disenchanted, amid man's interventions. Based on a major sociological survey[2] of Québec's visual artists' conditions of practice (Bellavance, Bernier, & Laplante, 2001), she can be considered representative of other successful visual artists in that context.

At the time of writing we had been conducting a field study of this artist's creative processes and practice for a ten-month period; the study is ongoing. Kulkarni and Simon (1988) discussed the use of different kinds of data for building models of processes that span many months or years (e.g., discovery processes in science), where gathering continuous protocols is not practical; in such contexts, recourse to other kinds of data is required. Data about this artist's creative processes were collected on-site, at the artist's studio, through interviews, recording of her artistic activity at the computer, and photographs taken of her work space and tools. Extensive field notes were also taken. The combined data collection allows for the recording of cognitive processes involving a distributed set of activities and tools (see Clancey, 2001). All data was digitally recorded (except for the field notes); the total archived data volume amounts to close to 30 gigabytes.

Our study is at the crossroads of the observational and computational approaches to discovery and creativity processes (Klahr & Simon, 1999); we are using observational and interview data to build a computational description and model of processes of artistic creativity.

Here we will focus on the interview data. Eight semi-structured interviews were conducted over a six-month period, at the artist's studio (Leclerc & Gosselin, 2003). We took inspiration from the traditional protocol analysis methodology (Ericsson & Simon, 1993) for eliciting verbal reports; interviews were thus conducted with the goal of producing information resembling what Ericsson and Simon call "Level 2 verbalizations". This type of verbalization involves descriptive information; Isabelle Hayeur was therefore asked for descriptions of her activities as an artist, not for explanations. Interviews were digitally recorded and were 30 to 60 minutes long each. These were transcribed verbatim and represent a total of 74,507 words. Interviews were organized, stored, and analyzed using Atlas.ti, a computer package designed for qualitative data analysis.

[1] Her work, artist's statement, and resume can be found on her Web site: isabelle-hayeur.com.

[2] This study was commissioned by Québec's main group of professional visual artists, the *Regroupement des Artistes en Arts Visuels du Québec*.

Problem Spaces in Isabelle Hayeur's Creative Process

Viewing artistic creativity as a special case of human problem solving, we have to ask what are the problems solved by an artist? More precisely, what are the problems solved by Isabelle Hayeur? Finding what problems she solves means finding out what problem spaces she explores in the course of her artistic practice. Problem spaces are defined in terms of states, operators, goals, and constraints (Klahr & Simon, 1999, citing Newell & Simon, 1972); we have coded and analyzed our interviews in these terms.

Recently, some researchers have also started to redefine the concept of *problem space*, putting the emphasis not just on internal representations, search, and operations on these representations, but also on the physical space, and the context, involved in real-life problem-solving activity. For example, Nersessian et al. (2003), in their study of innovative practices in biomedical research laboratories, considered the "lab-as-problem-space"; the laboratory, with its resources, people, technology, equipment, etc., is thus considered as a 'problem space'. Similarly, in contemporary visual arts practice, the artist, work space, tools, technologies, technical knowledge and skills, environment, partnerships with other artists, relations with galleries, art centers, funding agencies… constitute the problem space of an arts practice (e.g., see Figure 1). Our analysis is thus based on identifying states, goals, operators, and constraints, in this sense – in a situated artistic practice.

Figure 1: The artist's "studio-as-problem-space"

Criteria for Proposing New Search Spaces Schunn and Klahr (1996; see also Klahr, 2000) have suggested three criteria for proposing new problem spaces: (1) logical, (2) empirical, and (3) implementational. The logical criterion refers to logical coherence of the categories – spaces – proposed; spaces must be mutually exclusive. The empirical refers to the fact that there must be some activity going on in the proposed spaces. And, the implementational criterion allows precise characterization of the proposed problem spaces.

Given the preliminary nature of our research, we have relied mainly on the empirical and on the logical criteria. We have analyzed transcripts from the interviews and coded those in terms of rules (i.e., production rules), condition-action rules. And based on these rules, we have identified goals and heuristic operators[3]; these define the spaces searched by Isabelle Hayeur in the course of her creative process.

Artistic Practice and Career Search Spaces Following coding and analysis of the interviews, two main spaces emerged as the ones most actively searched in the course of Isabelle Hayeur's account of her creative activity: the *artistic practice space* and the *career space*. Throughout the interviews she describes both areas of activity. For example:

> Interview 2
> (28:30) I always plan, I plan moments where I concentrate on my [artistic] production. And there are moments where I put together my artist's dossiers; it is rather dull, but it has to be done. I put together those dossiers [for submission calls]. *You see, there really is the creative work, you know what this is, and there is also everything surrounding that, which takes about half my time* [italics added][4].
>
> Interview 3
> (29:49) I find myself putting more time on my artistic work… the artistic work, and the career.
>
> Interview 5
> (01:08) Already, I am very busy, with things related to the dissemination [of the artistic work], but which I must do, everything surrounding the artistic practice.

In the following sections, we will look at the organization and role of the artistic practice and the career search spaces.

Artistic Practice Search Space: Goals and Heuristics Table 1 shows the main set of goals found to operate in the artistic practice space. These high-level goals shape Isabelle Hayeur's artistic practice. Heuristic operators searching through the artistic practice space apply these goals; these play a role in many heuristic rules used by Isabelle Hayeur to accomplish the tasks associated with this space.

Table 1: Artistic practice space main goals

[gR2-12; gR2-13] Doing my work as an artist seriously, full time.
[gR2-14; gR2-15] Living with less money, in order to put more time into my artistic practice (and less time into 'bread-and-butter' jobs).
[gR2-17; gR2-28] Having more time for my artistic practice.

[3] Goals are labeled gR and rules R. A rule is given the number of the interview in which it first appeared; goals are constitutive parts of rules.

[4] For this paper, interview excerpts, goals, and rules were translated from the French language.

[gR2-30; gR2-32] Working on my images, especially after a few weeks of not working on them.
[gR2-31] After a long time working on my images, taking some time away from the work, doing something else.
[gR2-33; gR-35] Putting time into my practice, taking up and continuing work on projects, planning time when I concentrate on my production.
[gR2-38] Art must remain a calling, it must remain research; the career side must not take too much time.
[gR2-38; gR3-06] I want my images, series, artistic work and career to succeed.
[gR2-39] Doing art for the knowledge it brings in my own life, and for what it may teach or give to others.
[gR3-04] Not stopping my artistic work.
[gR3-07] Being an artist; doing this my entire life.
[gR5-01; gR5-02] Creating strong works, strong images; saying things in a strong way, a stronger way.

Among the goals defining the artistic practice space, some appear to play a major role because they call upon many other goals to search the problem space. For example, gR3-07 calls on a host of activities to reach its aim (see Tables 1 & 2, [gR2-33; gR2-35; gR2-36; gR2-37; gR2-38; gR3-01, gR3-02; gR3-05; gR3-06], for an example of subgoals – heuristics – called by gR3-07).

The artistic practice space is divided further in a number of important subspaces. Among these figures the *image-generation space*. Of great importance, it is the very basis of Isabelle Hayeur's artistic practice; this subspace includes all the knowledge and skills actually involved in the image production activity. Another subspace would be a 'project-management' subspace. We will not expand on these here.

The task achieved through the artistic practice problem space is the task of being an artist, of focusing on one's artistic practice and of producing art works.

Career Search Space: Goals and Heuristics This is the main set of goals found to operate in the career space. Goals gR2-36, gR3-01, gR3-06, gR3-07, and their associated heuristic rules, are the most significant; these actually call upon every other goal and heuristic in the career space.

Table 2: Career space main goals

[gR2-01; gR2-03] Sitting on panels, juries, etc., with other artists.
[gR2-01; gR2-02] Learning. Learning how other artists talk about their work, getting ideas about how to present your work, how art councils work, etc.
[gR2-26; gR2-27] Being represented by a private art gallery, in order to sell my work.
[gR2-34; gR6-01] Sending my work to art centers, galleries, and obtaining exhibitions.
[gR2-35; gR3-05] Putting together "artist's dossiers" – artistic projects and related documents about my practice (to be sent to art centers when there are calls for submissions).
[gR2-36] Doing the things that make a difference in an artist's career, in order to have a successful career.
[gR2-37; gR3-02; gR3-05] Taking care of the career side – everything that surrounds the creative work: searching for submission-call deadlines, new places and centers to show my work, residencies, putting together my "artist's dossiers" according to grants and submission-call deadlines, also answering specific requests for exhibitions and, at some point, sending a set of dossiers – around ten at a time – to art centers I want to reach in a given year, etc. I put half of my total work time as an artist on these activities (when I do not have other contracts, 'bread-and-butter' jobs to do).
[gR2-38] Not putting too much time on the career side; leaving aside some activities if necessary, even if I miss out on some opportunities.
[gR3-01; gR3-06] Being entrepreneurial; sending out a lot of artist's dossiers in order to have exhibitions.
[gR3-01; gR3-07] Having success as an artist; being an artist my entire life.

The career space is further subdivided in two main subspaces: the dissemination and the promotion spaces. These serve to solve the 'problem' of making the artistic work known and seen.

Some of the career goals are related to the same rules as some of the artistic practice goals. This is because certain heuristics operators mediate activity between these two search spaces. The task achieved through the career problem space is the task of making one's work known and seen, thereby building up a successful career.

Heuristics Coordinating Search We have found some heuristic operators, some rules, to be of special importance in Isabelle Hayeur's creative process because they coordinate the search between the artistic practice and career spaces. Here is such a heuristic operator associated with the recurrent goal gR3-07:

> [R3-07] If I want to be an artist and I want to be an artist my entire life, and I know what I have to do, then I do it immediately (i.e., gR2-33, gR2-35, gR2-36, gR2-37, gR2-38, gR3-01, gR3-02, gR3-05, gR3-06).

R3-07 coordinates a lot of activity related to the artistic practice and the career spaces. In fact, it links vocational goals, wanting to live the life of an artist, with very practical career goals and activities.

Here is another example of a heuristic operator linking artistic practice and career:

> [R2-38] If I want art to remain a calling as it must, and if at a certain point I realize that the 'career' side takes too much of my time, then I just don't do it, that activity (even if it means missing opportunities).

Identifying coordination between search spaces is an important part of modeling problem-solving processes; as Klahr (2000) notes, "One must … distinguish search in a particular space from coordination among multiple spaces" (p. 215).

An Additional Search Space This additional space, the *economic space* is not directly part of Isabelle Hayeur's process of artistic creativity, although, as we will see, it is essential for it. This space could also be called the 'working for a living' or the 'bread-and-butter job' space. Table 3 shows a sample of goals from this space.

Table 3: Some economic space goals

[gR2-07] Taking small jobs, contracts, especially in my domain or related to my practice, the arts, and the art milieu.
[gR2-07] Trying to find more gratifying, better paid, and a little bit more interesting jobs.
[gR2-13] 'Bread-and-butter' jobs must not take away from my hours of artistic work.
[gR2-14; gR2-16] To live with less money, in order to need to work less (in order to have more time for my practice).
[gR2-23; gR2-24] Not putting time into searching for bread-and-butter jobs; taking what comes.
[gR2-27; gR2-28] To sell my art work, in order to spend more time on my production and less on contracts outside my practice.

Some rules related to these goals show an interaction between the artistic practice, career, and economic spaces. Here are some examples:

> [R2-07] If you are an artist, and you (necessarily) need to pay for your own production (e.g., the high cost of printing large format photographs), and you have the chance to work in your own domain, then generally you accept these small jobs.
> [R2-14] If I cannot live solely from my art, and I have to take 'bread-and-butter' jobs, and I do not want this to replace my hours of artistic practice, then I decide to live with less money, in order to need to work less.
> [R2-28] If I sell my art work, even if just one image a month, then for each picture sold, I have one less contract to do, and I have more time for my practice.

These rules show that artistic creativity – artistic practice and career – is supported by the economic space. Search, minimal search in Isabelle Hayeur's case, in this space aims at finding the necessary resources to allow most of the artist's activity to be focused on her professional life and artistic production. The main task achieved through the economic problem space is finding (minimal) financial resources to support artistic and career related activities.

In Isabelle Hayeur's life and developmental trajectory as an artist, less and less time is spent on the economic space and more is spent on the actual artistic practice and career (see goals gR2-12, gR2-13, gR2-14, gR2-15, gR2-16, gR2-17, gR2-23, gR2-24, gR2-27, gR2-28, gR2-33, gR2-35, gR2-38, gR3-04, in Tables 1, 2, & 3). The rules that coordinate the artistic practice, career, and economic spaces aim at: (1) diminishing economic space activity, (2) maintaining career activity at a balanced level, and (3) maintaining or augmenting artistic practice activity level. According to Bellavance, Bernier, and Laplante's (2001) survey, few professional artists manage to achieve these goals in Québec's and Canada's socio-cultural and economic context. One measure of an artist's success, at least in regard to the interplay between practice, career, and economic spaces, seems to be his or her ability to do just that, focus on the artistic life rather than just on sheer survival.

Our situated problem-solving perspective on artistic creativity has shown that two main spaces are directly involved in a contemporary visual artist's creative process: the artistic-practice-as-problem-space and the career-as-problem-space. When Nersessian (2004) describes the challenges posed by the environmental perspective to the traditional view of cognition, she mentions considerations of the boundaries of cognitive systems; according to this perspective, cognition is situated and distributed in a complex cognitive system, a system that includes environment and individual. In this first part of Isabelle Hayeur's case study, we found a number of environmental elements playing a role in the artistic practice space (e.g., the artist's studio, equipment, time and financial resources, knowledge and skills needed to produce art works, etc.) and the career space (e.g., relationships with other artists, art centers and galleries, funding agencies, etc.), and defining the complex cognitive space of her artistic creativity.

Conclusions

The project of modeling Isabelle Hayeur's processes of artistic creativity is ongoing. What was outlined here is meant as an illustration of our framework for studying real-life artistic creativity; our preliminary results suggest a well-integrated set of search spaces and processes involved in real-life, situated, artistic practice and cognition. Further work will involve collecting verbal protocols related to the image-generation search space – the actual picture producing process; we have already recorded more than 100 hours of her image-generation activity.

Within the *artistic creativity as situated problem solving* framework, it is possible to study real-life artistic practices. The product is a descriptive model of search spaces, goals, and heuristic operators involved in artistic creativity. Dasgupta (1994, see also 2003) has done something of the kind in the context of science and technological innovation. The type of studies provided by our framework may lead to computational models of historical instances of artistic creativity, as studies in science have led to computational models of historical scientific discoveries (Langley, Magnani, Cheng, Gordon, Kocabas, & Sleeman, 2001). Such studies may also serve an educational purpose by providing information about real-life processes of artistic creativity.

Acknowledgments

We thank Isabelle Hayeur for her generous participation in this research project and for graciously giving her consent to the disclosure of confidential information. This research was supported by an Excellency Scholarship from the University of Montreal awarded to Jude Leclerc, and by an NSERC

(R0010085) and an NATEQ (R0010287) grant awarded to Frédéric Gosselin.

An Efficient Method for the Minimum Description Length Evaluation of Deterministic Cognitive Models

Michael D. Lee (michael.lee@adelaide.edu.au)
Department of Psychology, University of Adelaide
South Australia, 5005, AUSTRALIA

Abstract

The ability to evaluate competing models against noisy data is central to progress in cognitive science. In general, this requires advanced model selection criteria, such as the Minimum Description Length (MDL) criterion, that balance goodness-of-fit with model complexity. One limiting property of many of these criteria, however, is that they cannot readily be applied to deterministic models. A solution to this problem, developed by Grünwald (1999), involves a process called 'entropification' that associates deterministic models with probability distributions, and allows MDL criteria to be calculated. However, a potential practical difficulty with this approach is that it requires a multidimensional summation over the data space that can be prohibitively computationally expensive in realistic situations. This paper derives a simpler version of the MDL criterion for deterministic models in the important special case of 0-1 loss functions that is computationally feasible. Two concrete applications of the simpler MDL criterion are presented, demonstrating its ability to consider model fit and complexity in selecting between competing models of cognitive processes. The first application involves three different heuristics for a problem solving task, while the second involves three different models of forced-choice decision making.

Introduction

To a large extent, progress in cognitive science relies on the development of better models of cognitive phenomena. Models provide a formalized representation of theoretical explanations, and make predictions that can be tested empirically. For this reason, the ability to evaluate competing cognitive models against noisy data in a complete and meaningful way has been a central concern recently in mathematical psychology (e.g., Myung & Pitt 1997; Myung, Balasubramanian & Pitt 2000; Myung, Forster, & Browne 2000; Pitt, Myung, & Zhang 2002).

In particular, there has been a strong (and overdue) focus on balancing the goodness-of-fit of models with their complexity. These ideas have been applied to core topics in cognitive science such as models of psychophysical discrimination (e.g., Myung *et al.* 2000), stimulus representation (e.g., Lee 2001; Navarro & Lee 2003; in press), inference and generalization (e.g., Tenenbaum & Griffiths 2001), and decision-making (e.g., Myung & Pitt 1997).

Probabilistic Models

For the most part, however, these recent development have been restricted to considering *probabilistic* cognitive models. This class of models has the property that any parameterization (or, more generally, any probability distribution over the parameter space) corresponds to a probability distribution over the data. That is, the model corresponds to a parametric family of probability distributions over the data. This means that considering a probabilistic model at a particular set of parameter values makes some data quantifiably more likely than others. In turn, for probabilistic models the likelihood of any observed data having arisen under the model at any parameterization of interest can be evaluated.

Many cognitive models are probabilistic in this way. For example, models of memory retention (e.g., Rubin & Wenzel 1996) usually consist of parameterized functions that specify the probability an item will be recalled correctly after a period of time. As another example, the ALCOVE model of category learning (Kruschke 1992) also produces a probability, that depends upon the values of a number of parameters, for each possible category response on any trial. For these models, their probabilistic nature allows likelihood to be measured against any pattern of observed data.

Many advanced model selection criteria, such as Bayes Factors (e.g., Kass & Raftery 1995), Minimum Description Length (MDL: e.g., Grünwald 2000), Stochastic or Geometric Complexity (Myung, Balasubramanian & Pitt 2000; Rissanen 1996), and Normalized Maximum Likelihood (Rissanen 2001), rely on this property. This is because they integrate the probabilities of the data across the parameter space of the models, or the maximum likelihoods across all possible data sets, and so require non-zero probabilities over a subset of the parameter space that has measure greater than zero to be meaningful.

Deterministic Models

As Myung, Pitt and Kim (in press) note, however, there are many important cognitive models that belong to the alternative class of *deterministic* models. These models specify differently how to assess the relationship between data on the one hand, and model predictions at different parameterizations on the other. For example, a sum-squared loss or error function might be proposed, so that increasingly large differences between model predictions and observed data are penalized more heavily in evaluating the model. Alternatively, a 0-1 loss function might be proposed, so that models are evaluated as being correct only if they predict data exactly, and are wrong otherwise. What deterministic models do not specify, however, is an error theory that describes the likelihood of data that differ from model predictions. This means that, when a deterministic model makes incorrect predictions, it is not possible to assign the probabilities needed by many modern model selection criteria.

A good example of a deterministic cognitive model is the 'Take the Best' model of decision making (Gigerenzer & Goldstein 1996). This model takes the form of a simple algorithm, searching a fixed stimulus environment in a deterministic way, so that it will always make the same decisions. One way of interpreting the model in relation to empirical data is that it has probability one when it makes the same decision as that observed, but probability zero when it makes a different decision. Adopting this approach, however, any evaluation of the model against human data involving multiple decisions is very likely to find an overall probability of zero, because at least one of the model's decisions will disagree with the data.

Other deterministic models that face similar problems include the memory models surveyed by Pietsch and Vickers (1997), axiomatic theories of judgment and choice (e.g., Luce 2000), and various lexicographic decision models (e.g., Payne, Bettman & Johnson 1990). For these sorts of models, the natural assessment is in terms of the proportion of correct decisions it makes, or some such error function, but this measure is not the same as the probabilities from likelihood functions used in probabilistic model selection. In particular, it is not clear how the error function measuring goodness-of-fit should be combined with measures of model complexity to undertake model selection.

Recently, however, Grünwald (1999; see also Myung, Pitt, & Kim in press), has developed a model selection methodology that overcomes these difficulties. He provides a principled technique for associating deterministic models with probability distributions, through a process called 'entropification', that allows MDL criteria for competing models to be calculated. There is a potential practical difficulty, however, in using this approach to evaluate cognitive models. The MDL criterion involves multidimensional summations over the data space that could be prohibitively computationally expensive in some realistic situations. This paper derives and demonstrates a reformulation of the MDL criterion for deterministic models in the important special case of 0-1 loss functions that is much less computationally expensive.

The MDL Criterion

In this section, Grünwald's (1999) formulation of the MDL criterion based on entropification is described, and a computationally simpler form is then presented. In one sense, the reformulation is just a straightforward algebraic manipulation, and has probably been noted (but not published, as far as we are aware) by others. In another sense, making the reformulation explicit, and demonstrating its advantages, is a useful contribution. There are many cognitive models that are deterministic and naturally assessed under 0-1 loss[1], for which the MDL method described here ought to find wide application.

Original Formulation

Suppose a deterministic model M is being evaluated using a dataset D that has n observations, $D = [d_1, \ldots, d_n]$. Each of the observed data are discrete, and can assume only k different values. The model uses P parameters $\theta = (\theta_1, \ldots, \theta_P)$ to make predictions $Y = [y_1, \ldots, y_n]$. To evaluate any prediction made by the model, a 0-1 loss function is defined as $f(D, Y) = \sum_{i=1}^{n} \gamma_i$, where $\gamma_i = 0$ if $d_i = y_i$ and $\gamma_i = 1$ otherwise. By considering all possible parameterizations, the model makes a total of N different predictions. In other words, there are N different predictions, $Y_1, \ldots, Y_N$, the model is able to make about the data by choosing different parameter values. In general, the relationship between parameterizations and predictions will be many-to-one. This means that every unique model prediction is naturally associated with one or more parameterizations of the model.

Under these assumptions, Grünwald (1999) shows that using entropification the model making prediction Y can be associated with a probability distribution, parameterized by the scalar w, as follows:

$$p(D \mid M, Y, w) = \frac{e^{-wf(D,Y)}}{\sum_{x_1=1}^{k} \cdots \sum_{x_n=1}^{k} e^{-wf(D,[x_1,\ldots,x_n])}}.$$

Determining the MDL criterion for the model requires finding the model predictions Y^* and scalar w^* that *jointly* maximize $p(D \mid M, \theta, w)$ to give the value p^*.

[1] All of the deterministic decision making, memory and judgment models already mentioned effectively have 0-1 loss when they are restricted to two choices. There are other models, such as the optimal stopping models considered later, that are also naturally associated with 0-1 loss despite having a larger number of choices.

Once this is achieved the MDL criterion for the model is given simply by $\text{MDL} = -\ln p^* + \ln N$.

Besides automatically balancing the competing demands of model fit and complexity, this MDL criterion has at least two attractive properties for model selection in cognitive science. First, differences in MDL values, through their natural probabilistic interpretation, can be assessed as odds, in much the same way as Bayes Factors. This allows the assessment the 'significance' of different MDL values for different models to be done meaningfully as a question of the standards of scientific evidence required for the problem at hand, using a scale that is calibrated by betting. Secondly, as Grünwald (1999, pp. 24-28) discusses, the information theoretic or coding approach used by MDL means that results are available for cases where the data generating process that is being modeled has statistical properties that are not perfectly represented by the models being considered. We would argue this is inevitably the case for cognitive models, and so the ability of the MDL approach to address this problem is an important one.

Despite these attractions, however, there is an obvious difficulty in maximizing $p(D \mid M, \theta, w)$. The problem is that the denominator given by $Z = \sum_{x_1=0}^{k} \cdots \sum_{x_n=0}^{k} e^{-wf(D,[x_1,\ldots,x_n])}$ involves considering every possible data set that could be observed, which involves a total of k^n terms. In cognitive science, where it is possible for a deterministic model to be evaluated using many data points, each of which can assume many values, the repeated calculation of Z may be too computationally demanding to be practical.

A Simpler MDL Computation

A simpler form for Z can be derived by noting that $f(D, Y)$ can only take the values $0, \ldots, n$, in accordance with how many of the model predictions agree with the data. Since Z considers all possible data sets, the number of times $n-x$ matches (i.e., x mismatches) will occur is $\binom{n}{x}(k-1)^x$. For a prediction Y that has $n-m$ matches with the data (i.e., there are m mismatches and $f(D, Y) = m$), this leads to the simplification

$$p(D \mid M, Y, w) = \frac{e^{-wm}}{\sum_{x=0}^{n} \binom{n}{x} (k-1)^x e^{-wx}},$$

which has a denominator that sums $n+1$ rather than k^n terms.

The computational efficiency offered by this reformulation means it will generally be possible to find the w_i^* that maximizes $p(D \mid M, Y_i, w_i)$, giving p_i^*, for all N model predictions. The p^* required for MDL calculation is then just the maximum of $p_1^*, \ldots, p_N^*$.

Finding each w_i^* can also be done efficiently by observing that

$$\partial p / \partial w = \frac{1}{Z^2} e^{-wm} \sum_{x=0}^{n} \binom{n}{x} (k-1)^x (x-m) e^{-wx}.$$

This derivative is clearly always positive if $m = 0$ and always negative if $m = n$. This means, if a model predicts all of the data correctly, $w_i^* \to \infty$, and if a model fails to predict any of the data correctly $w_i^* \to -\infty$. Otherwise, if $0 < m < n$, the substitution $u = e^{-w}$ allows w_i^* to be found from the positive real roots of the degree n polynomial

$$\sum_{x=0}^{n} \binom{n}{x} (k-1)^x (x-m) u^x.$$

by standard numerical methods (e.g., Forsythe, Malcolm, & Moler 1976).

Grünwald (1999, pp. 98-99) notes, with particular reference to the 0-1 loss function, that the case $w < 0$ corresponds to 'inverting' models. For example, if a model only makes two choices, and so considers binary data (i.e., $k = 2$), the inverted model changes all of the model predictions to the alternative possibility. We would argue it will generally be the case in cognitive modeling that it is not appropriate to consider inversion, because this manipulation will require the model to be interpreted in a substantively different and unintended way. If this is the case, it is necessary to restrict consideration to $w \geq 0$ in finding the MDL value.

With this restriction in place, the Y^* and w^* learned from data for qualitative model selection convey useful information in their own right. In particular, as Grünwald (1999, pp. 94-95) explains carefully, the value of w^* measures the 'randomness' of the data with respect to the model Y^*, so that smaller values of w^* indicate that the the model provides relatively less information about the data.

Demonstrations of the MDL Criterion

In the remainder of this paper, we present two concrete examples of the MDL criterion evaluating cognitive models, in situations where there is a clear need to assess whether the better goodness-of-fit of some models warrants their additional complexity. The first involves different heuristics for a problem solving task, while the second involves different models of forced-choice decision making.

Optimal Stopping Problem

As a first demonstration of the MDL criterion for deterministic models, consider three different account of human decision-making on an optimal stopping task sometimes known as the full-information secretary problem (see Ferguson 1989 for a historical overview).

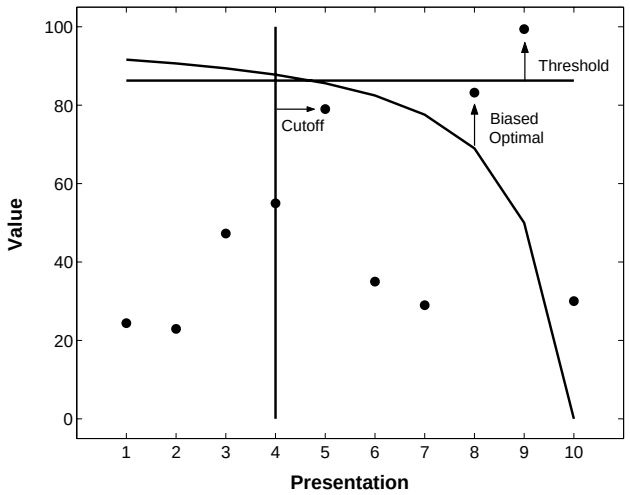

Figure 1: An optimal stopping problem of length 10, with the sequence of values shown by circles, demonstrating the operation of the biased optimal (curved line), threshold (horizontal line) and cutoff (vertical line) models.

Background In these problems, a person presented with a sequence of numerical values, and told to select the maximum. They must decide whether to accept or reject each possibility in turn and, if a possibility is rejected, they cannot select it at some later point. The number of choices in the complete sequence is fixed and known, and the distribution from which the values are drawn (usually a uniform distribution on the interval $[0, 1]$) is also known. Performance is assessed using a 0-1 loss function, so that if choosing the maximum is regarded as correct, but any other choice is regarded as incorrect.

From the mathematical (e.g., Gilbert & Mosteller 1966) and psychological (e.g., Seale & Rappoport 1997) literature, there are at least three plausible accounts of how people might make decisions on these problems. The first 'threshold' model assumes people simply chooses the first value that exceeds a fixed threshold. The second 'biased optimal' model assumes people choose the first value that exceeds a threshold level, where the threshold level changes for each position in the sequence. The threshold levels correspond to the mathematically optimal values (see Gilbert & Mosteller 1966, Tables 7 and 8), for the given problem length, all potentially biased by shifting by the same constant. The third 'cutoff' model assumes people view a fixed proportion of the sequence, remember the maximum value up until this cutoff point, and then choose the first value that exceeds the maximum in the remainder of the sequence. Each of these models has one parameter, giving the threshold, the bias, or the cutoff proportion respectively. For all three models, if no value meets the decision criterion, the last value presented becomes the forced choice.

Figure 1 summarizes the three models on a secretary problem of length 10. The sequence of values presented is shown by the filled circles. The horizontal line shows the constant level used by the threshold model. The threshold levels for the optimal model with no bias follow the solid curve. The vertical line shows the proportion used by the cutoff model. Under these parameterizations, the biased optimal, threshold, and cutoff models choose, respectively, the eighth, ninth, and fifth values presented.

Application of MDL Lee, O'Connor and Welsh (this volume) administered $n = 20$ problems of length $k = 10$ to a number of subjects. For this set of problems, the threshold, biased optimal, and cutoff models are able to predict, respectively, 60, 78, and 9 data sets by varying their parameters. As a concrete example of how the MDL criterion can balance these different model complexities against the fit they are able to achieve, consider the decisions made by one subject from the experiment. For this subject, the best-fitting parameterizations of the threshold, biased optimal, and cutoff models correctly predict, respectively 14, 17, and 10 of the 20 decisions. This is an interesting case to consider, because increases in model complexity lead to increases in model fit.

The MDL criteria values for each model, in relation to this subject's data, are 29.5, 19.4 and 38.0 respectively, showing that, despite its increased complexity, the biased optimal model provides a better account than the threshold and cutoff models. This superiority can be quantified in terms of naturally interpretable odds, because differences between MDL values lie on the log-odds scale. For example, the biased optimal model provides an account that is about $e^{29.5-19.4} \approx 24,000$ times more likely than that provided by the threshold model.

Sequential Sampling Processes

As a second example, we consider the sequential sampling model of decision making developed by Lee and Cummins (in press).

Background Lee and Cummins (in press) proposed that an evidence accumulation approach can unify the 'Take the Best' (TTB: Gigerenzer & Goldstein 1996) model with the 'rational' (RAT) alternative to which it is usually contrasted. The cognitive process being modeled involves choosing between two stimuli on the basis of the cues or features that each does or does not have. In essence, TTB searches the cues until it finds one that only one stimulus has, and then simply chooses that stimulus. The RAT model, in contrast, forms weighted sums across the cues for both stimuli,

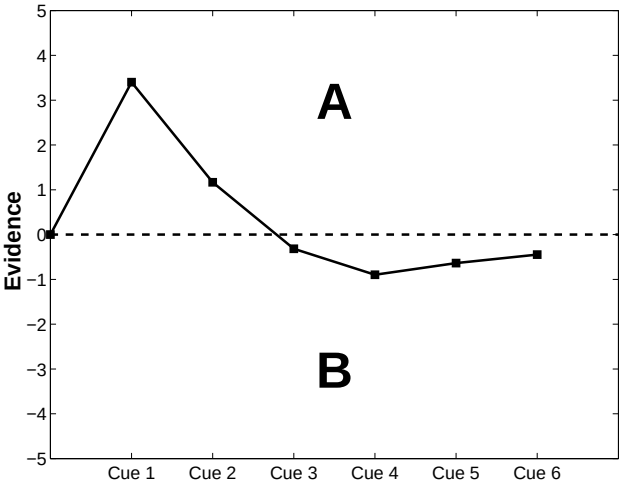

Figure 2: A sequential sampling process using evidence accumulation to decide between choices A and B. Successive evidence values are shown as cues are examined from highest validity to lowest. A decision is made once the evidence exceeds a threshold value.

and chooses the one with the maximum sum.

Figure 2 shows a sequential sampling process accruing information in making this sort of decision. Each of the cues is examined and the evidence provided by that cue is used to update the state of the random walk in favor of choosing stimulus A or stimulus B. If stimulus A has the cue and stimulus B does not, the random walk moves towards choosing A. If stimulus B has the cue and stimulus A does not, the random walk moves towards choosing B. If both stimuli either have or do not have the cue, the state of the random walk is unchanged.

The important observation about Figure 2 is that the TTB and RAT models correspond simply to different required levels of evidence being accrued before a decision is made. If a very small evidence threshold were set, the sequential sampling process would choose stimulus A, in agreement with the TTB choice. Alternatively, if a very large evidence threshold were set, the sequential sampling process would eventually choose stimulus B (because the final evidence is in its favor), in agreement with the RAT model. In general, if a threshold is small enough that the first discriminating cue is guaranteed to have evidence that exceeds the threshold, sequential sampling corresponds to the TTB decision model. If a threshold is large enough that it is guaranteed never to be reached, the final evidence is used to make a forced decision, and sequential sampling corresponds to the RAT decision model.

Application of MDL For the 200 decisions collected from 40 subjects by Lee and Cummins (in press), the TTB model made 36% correctly, while the RAT model made 64% correctly. The sequential sampling model, at the best-fitting value of its evidence threshold parameter, made 84.5% of the decisions correctly. Of course, the sequential sampling model, through its use of the parameter, is more complicated than both the TTB and RAT decision models, which are parameter-free. This raises the issue of whether the extra complexity is warranted by the improved accuracy. Using the model selection method developed here, Lee and Cummins (in press) found MDL values of 87.6, 138.6 and 130.7 for the sequential sampling, TTB and RAT models respectively. The much smaller MDL value for the unified model indicates that it provides a better account of the data, even allowing for its additional complexity.

Conclusion

These demonstration of the MDL criterion provides clear practical examples of how it can be used to evaluate competing deterministic models of human cognitive processes. It also highlights the contribution of this paper, which is a simpler form of the MDL criterion for the special case of 0-1 loss functions. For the optimal stopping problem example, the original MDL formulation involves summing 10^{20} terms in the denominator to find $p(D \mid M, Y, w)$ for each combination of m and Y that needs to be evaluated in optimization. The simpler form given here requires summing only $n + 1 = 21$ terms each time. For the sequential sampling problem, the original formulation involves $2^{200} \approx 10^{60}$, while the simplification involves 201 terms. As these comparisons make clear, the drastic reduction in computation offered by the simplification developed here makes the MDL evaluation of deterministic cognitive models under 0-1 loss feasible for most (if not) all empirical data collected in cognitive science.

Abstract

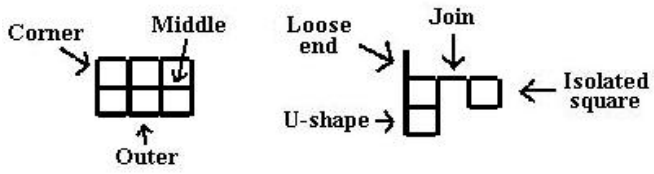
Three experiments investigated how individuals solve "shape" problems. These problems are not susceptible to a means-ends strategy. They consist of a configuration of squares, whose sides consist of separate pieces; and the task is to remove a given number of pieces to leave behind a given number of squares. The paper presents a theory of how individuals develop strategies for these problems. Experiment 1 explored the constraints of symmetry and visual saliency in shape problems. Experiment 2 corroborated the theory's prediction of a major shift in which knowledge acquired during the evaluation of tactical steps comes to govern the generation of these steps. Experiment 3 showed that participants could be biased to adopt strategies making use of specific tactical steps.

Introduction

How do individuals develop strategies to solve problems? The question arises crucially for those problems that come in a series of different instances (e.g. Luchins's, 1942, water jug problems). Our aim was to answer this question for problems that do not have a unique solution and for which individuals cannot develop a simple deterministic strategy guaranteeing an error-free solution. We therefore studied what we refer to as "shape" problems (see Katona, 1940). Figure 1 presents an example of such a problem. There is an initial shape made out of separate pieces (matchsticks) and the goal is to remove a given number of pieces to leave a given number of squares. There are two constraints: the resulting squares should be of the same size as the initial squares, and the solution should not have any loose ends (pieces with an end not connected to any other piece).

Figure 1: On the left is a shape problem in which the task is to remove five matches so that only ten squares remain. A solution is shown on the right.

An important feature of shape problems is that naïve individuals cannot use a means-ends strategy in which they work backwards from the desired goal (Newell & Simon, 1972). The goal merely specifies how many squares should remain, but not how they are arranged. Likewise, individuals cannot always tell if a tactical step in a shape problem makes progress towards the goal. The discovery of the tactical steps in shape problems is accordingly a discovery of the problem space. There are, in fact, seven distinct tactical steps for removing pieces, which are summarized in Figure 2.



1. To remove 1 piece & 0 squares, remove *loose end*
2. To remove 1 piece & 0 squares, remove *join*
3. To remove 1 piece & 1 square, remove *outer*
4. To remove 1 piece & 2 squares, remove *middle*
5. To remove 2 pieces & 1 square, remove *corner*
6. To remove 3 pieces & 1 square, remove *U-shape*
7. To remove 4 pieces & 1 square, remove *isolated-square*

Figure 2: The seven tactical steps for shape problems.

In what follows, we outline a theory of how individuals explore these tactical steps, and how they use these explorations to develop strategies. We then report three experiments that test the predictions of this theory.

The theory

Problem solving is a creative process, and we distinguish three main sorts of algorithm for creativity (e.g., Johnson-Laird, 1993). First, a *neo-Darwinian* algorithm consists of a stage in which ideas are generated followed by a stage in which they are evaluated. Generation depends on arbitrary combinations and modifications of existing elements; evaluation depends on the use of knowledge as constraints to filter out useless results. Any ideas that survive can be recycled recursively through the generative stage again, and so on. Second, in a *neo-Lamarckian* algorithm, all the knowledge acquired from experience constrains the generation of ideas. If alternatives are created, then choice amongst them can only be arbitrary, because all the

constraints have already been used in their creation. When individuals have the requisite knowledge, the algorithm is highly efficient, because there is no need for recursion. Third, in a *multi-stage* algorithm, some knowledge is used to constrain the creation of ideas and some knowledge is used to evaluate the results – with the option of recursion. In sum, according to this account, constraints govern the evaluation of ideas, or their generation, or both.

The algorithm that individuals use to solve shape problems should depend on their experience. Naïve individuals are likely to tackle their initial problems using a strategy that is close to neo-Darwinian. They should be constrained solely by the statement of the problem, the problem shape itself, and their existing perceptual and cognitive processes. As they try out the various possible tactical steps, they learn their consequences, which are summarized in Figure 2. Learning occurs whether or not a tactical step turns out to be useful in solving a problem. Any problem allows only a limited set of tactical options, and so individuals should gradually narrow down the steps that are left to explore. Likewise, granted that the problem is within their competence, they should at length hit upon a sequence of steps that leads to a solution. In addition, some pieces in the problem shape are visually salient, and they may bias participants to attempt certain tactical steps first. Saliency is likely to depend on the perimeter of the shape. Any piece in the perimeter should be *visually salient* if it has at least one adjacent piece that is also in the perimeter and is at right angles to it. In addition, a piece should be more salient if both adjacent pieces are at right angles. A visually salient *component* comprises a group of such visually salient pieces that are adjacent to each other. These principles are probably special cases of broader factors governing visual salience. The acquisition of tactical knowledge depends on perceptual abilities, e.g., subitizing a small number of squares, and conceptual and inferential abilities, e.g., a grasp of the concepts of *squares* and *pieces*, and relevant arithmetical operations.

According to the theory, as tactical knowledge is acquired, it shifts from the evaluative stage of the creative process to the generative stage. Individuals accordingly shift from using a neo-Darwinian algorithm to a multi-stage algorithm, and may even converge on a neo-Lamarckian algorithm. This strategic shift enables them to avoid useless tactical steps and thereby to make more efficient progress towards solutions. They may proceed at once to correct tactical steps. A central component of an efficient strategy for shape problems is the *ratio* of the number of pieces to remove to the number of squares to remove (henceforth, the "p/s" ratio). It constrains the appropriate tactical steps from those afforded by the current configuration of the problem (see Figure 2). But, its optimal use depends on knowledge of the full variety of tactical steps. Conversely, a limited knowledge of these steps yields limited strategies for coping with the problems. Yet, the shift of tactical knowledge to the generative stage of problem solving should still occur, albeit with a restricted repertoire of tactical steps. Hence, it should be possible to bias the development of strategies by giving individuals only a limited experience of tactical steps in an initial set of problems.

Experiment 1

This experiment explored two factors that should affect shape problem solving: whether the initial shape is symmetrical or asymmetrical, and whether the solution is salient or not in the shape.

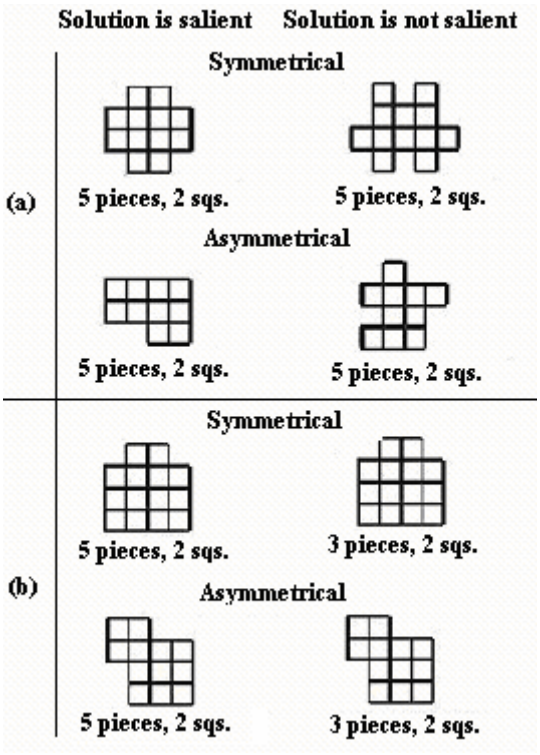


Figure 3: The eight problems used in Experiment 1. We manipulated symmetry and the presence of a salient solution.

Method and procedure

Twenty Princeton University students carried out eight problems, which manipulated symmetry and the presence or absence of salient solutions. Figure 3 presents the eight problems used in the experiment. In order to counterbalance the manipulation, one set of four problems (see Figure 3a) called for the same number of pieces and squares to be removed. This condition is feasible only by changing the shapes from the cases in which the solution is salient to the cases in which it is not. Hence, a second set of four problems (see Figure 3b) used the same shapes in these two cases but changed the number of pieces and squares that had to be removed. The experiment employed a block design: half of the participants carried out the four problems in Figure 3a first, and the other half carried out the four problems in Figure 3b first. The assignment of block

presentation, as well as the order of problems within each block, was random.

On each trial, the participants constructed the shape in a given diagram using matchsticks. They then tried to solve the problem. They were told that they should not leave any loose ends, and that each square must consist of four pieces. They had to say "done" at the end of each trial to the experimenter, who recorded the latencies.

Results and discussion

Figure 4 presents the mean latencies to solve the eight problems. The two blocks did not differ reliably ($z = 1.61$, n.s.), and therefore we collapsed their latencies for analysis. Participants solved problems with a salient solution reliably faster than those without a salient solution (Wilcoxon signed-rank test, $z = 3.85$, $p<.001$). In addition, they also solved problems with a symmetric initial shape reliably faster than those with an asymmetrical initial shape (Wilcoxon signed-rank test, $z = 2.09$, $p<.05$). The two variables did not interact. These results demonstrate that existing factors in the problems can constrain problem solving strategies. To investigate how people develop strategies to cope with shape problems, however, participants would need to solve a series of problems calling for the removal of different numbers of pieces, and to think aloud as they solve the problems. Experiment 2 employed this procedure.

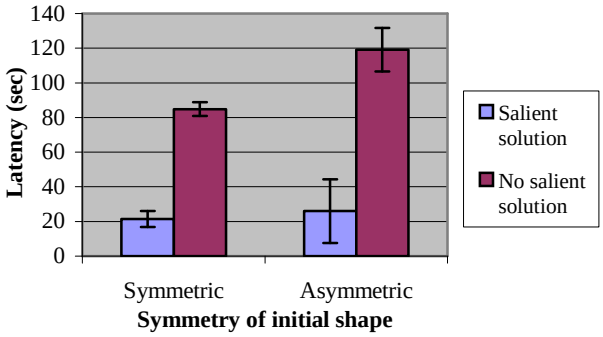

Figure 4: Experiment 1: Mean latencies as a function of symmetry and the presence of salient solution.

Experiment 2

This experiment tested the key prediction of a shift in strategy from a neo-Darwinian exploration of steps to their use in constraining the generation of steps. As a corollary, there should be a reduction in the number of steps that individuals take to solve problems.

Method and procedure

Fourteen Princeton University students carried out 12 problems presented in a random order. The problems (see Figure 5) varied in terms of symmetry, number of matches to be removed, and tactical steps, but they all called for removing two squares. The experimental procedure was the same as that in Experiment 1. However, there was an additional requirement: participants had to think aloud as they solved the problems. We video-recorded what they did and what they said.

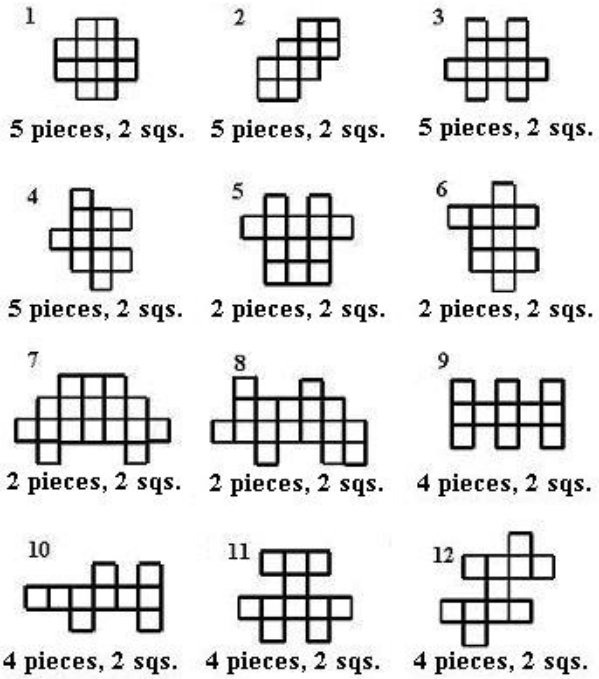

Figure 5: The 12 problem shapes used in Experiment 2.

Results and discussion

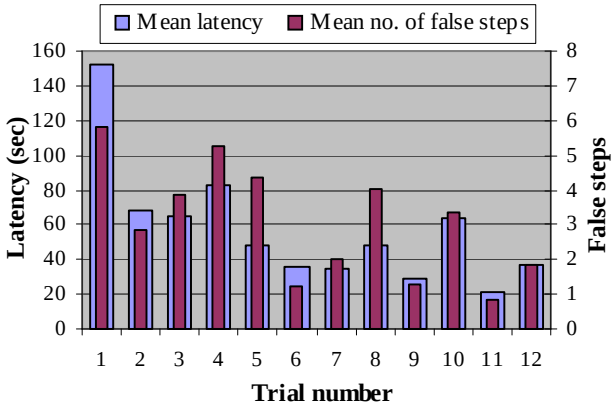

Figure 6: Experiment 2: Mean latencies and numbers of false steps across trials.

Figure 6 presents the mean latencies to solve the problems, and the mean numbers of false steps, over the 12 trials. A false step was one that the participants subsequently undid. As predicted, the participants were able, with experience, to solve the problems faster (Page's $L = 7882.5$, $z = 4.86$, $p <<$

.001), and to make fewer false steps (Page's L = 6750.0, z = 2.16, p <.05). These two variables correlated reliably for all but two of the problems (Pearson's r ranged from .65 to .95, with p <.05 to p <.001). In addition, in a post-experimental questionnaire, the participants were most likely to identify those tactical steps that they had used during the experiment: they all mentioned the *outer* and the *U-shape*, but none identified all seven tactical steps (see Figure 2).

The transcriptions of the video-recordings showed that the participants relied mainly on a single strategy, but there were other two strikingly different strategies. The main strategy has two stages. The first stage is exploratory: the participants try out various tactical steps, which they usually subsequently undo. They are acquiring knowledge of these steps, including steps irrelevant to the present problem. They are also acquiring knowledge of the *p/s ratio*, i.e., the ratio of pieces and squares to be removed (see the previous section). They grasped its relevance, but rarely in a complete way. The duration of this stage depends on the participants' experience with the problems. It accordingly shrinks in proportion over the problems as the participants acquire knowledge. The second stage of the strategy is the application of tactical knowledge. The participants consider the *p/s ratio*, often mentioning it explicitly, and use their tactical knowledge to select an appropriate tactical step. The shift has occurred from a neo-Darwinian strategy to a multi-stage strategy. Hence, the participants are able to make rapid progress to the solution. For some problems, they make no false steps. Likewise, they can combine tactical steps into a single step that solves the problem at a stroke. In other cases, they apply their knowledge recursively, removing a correct piece, re-assessing the number of pieces and the number of squares to be removed, and, as result, selecting a further tactical step, and so on, until they solve the problem. They are converging on a neo-Lamarckian strategy for solving shape problems.

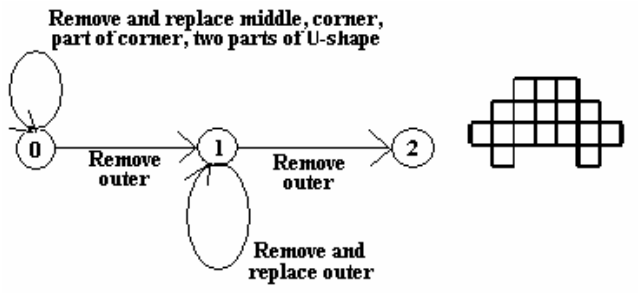

Figure 7: An example of the main strategy in a non-deterministic finite-state automaton. On the right, is the shape problem in which the goal is to remove 2 pieces and 2 squares (Problem 7).

Figure 7 shows an example of the main strategy. The participant started in an exploratory state (state 0) and tried various steps, which she immediately undid. She then correctly removed an *outer* (shifting to state 1), and then removed another outer to solve the problem. On some subsequent trials, e.g., with problem 5, she proceeded at once to the correct solution with no false steps. The protocol is typical in that it appears to reflect the use, not of a simple deterministic strategy, but one in which various steps are tried out in a way that appears to be non-deterministic.

One participant used a quite different sort of strategy. During the first stage of tackling a problem, the participant removed some pieces – often the required number – in an apparently arbitrary way, sometimes leaving several loose ends. The participant then carried out one of three actions: removing a new piece, replacing a piece removed earlier, or moving a piece from one position in the shape to fill the position of a piece that had been removed. The participant persisted in these steps until the solution emerged. The strategy was inefficient, yielding many more false steps than other participants. Yet, the participant gradually acquired some tactical knowledge, which became evident in both a more judicious initial removal of pieces and in more efficient steps in the second stage.

Another participant used a strategy that depended on the initial shape. The participant used the statement of the problem to divide the initial shape into two or three conceptual parts. For example, for Problem 2 (remove five pieces to remove two squares), the participant identified the number of squares to remain in the solution (eight), and then partitioned this number into two parts (three squares plus five squares). The participant then searched for ways to eliminate all but these configurations. Unfortunately, the attempt ignored the number of pieces to be removed. The strategy was inefficient, and yielded little tactical knowledge.

All three strategies stabilized as instances of the multi-stage algorithm outlined earlier. No-one developed a neo-Lamarckian strategy that guaranteed that they could proceed directly to the solution of a problem without any false steps.

Experiment 3

When individuals acquire a deterministic strategy, it transfers to new problems (see, e.g., Luchins, 1942). With shape problems, however, individuals do not acquire a deterministic strategy guaranteed to lead to solution, but instead acquire a tactical knowledge that constrains the generation of steps. Their resulting strategy does not appear to be deterministic (see Figure 7). Nevertheless, it should be possible to bias the development of strategies by giving participants an experience of only certain tactical steps in the initial problems. Experiment 3 tested this prediction.

The participants first encountered a series of four problems that could be solved only by using certain tactical steps. These tactics differed between two groups of participants. Both groups then tackled two "ambiguous" problems that could be solved using either set of tactics. A final unambiguous problem could be solved only with novel tactics, i.e., a problem used to train the participants in the other group. Such a problem should force the participants

back to a greater use of the exploratory stage of their strategy.

Method

Twenty Princeton undergraduates were assigned at random to one of two groups: both carried out seven problems calling for the removal of four pieces to eliminate two squares. In Group 1, participants tackled four problems that could be solved only by removing two *corners*; in Group 2, they tackled four problems that could be solved only by removing a *U-shape* and an o*uter*. Each participant carried out these trials in a different random order. Both groups then attempted two ambiguous problems, and finally a problem chosen randomly from the first four problems given to the other group. Figure 8 shows the complete set of problems. The experimental procedure was the same as that in Experiment 1.

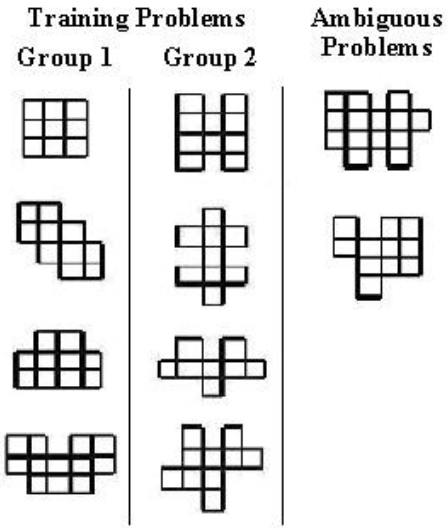

Figure 8: The problems used in Experiment 3. Each problem called for the removal of four pieces and two squares.

Results

Figure 9 presents the mean latencies of the two groups to solve the problems. The participants took progressively less time to solve the problems over the seven trials (Page's L = 1618.0, z = 4.23, p <<.001). The ambiguous problems took slightly longer than the last training problem, though the difference was only marginally significant (Wilcoxon test, z = 1.64, p >.05). However, the choice of pieces to be removed showed that both groups persevered with the same tactics that they had used in training: overall, 92% of solutions were based on the same tactics; 14 out of the 20 participants used these tactics on both ambiguous problems, and the remaining participants were ties (Binomial test, p << .001). The final control problem took significantly longer to solve than the last training problem (Wilcoxon test, z = 2.61, p < .01).

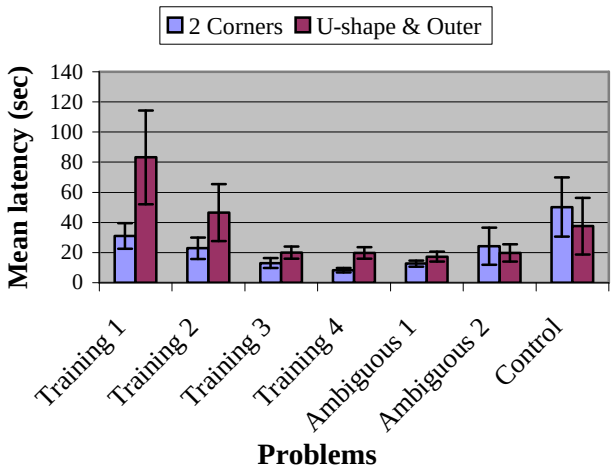

Figure 9: Mean latencies of the two groups in Experiment 3.

The results show that even when individuals have not acquired a deterministic strategy, their knowledge of tactics transfers to new problems. The training trials sufficed for the participants to develop tactical knowledge, and this knowledge constrained their search for solutions to the subsequent problems. With ambiguous problems, they readily succeeded though there was a marginal tendency for them to be slightly slower. In the case of the final problem, the tactics were inappropriate, and so they had to revert to a longer exploratory stage, which slowed them down.

General Discussion

Problem solving calls for creativity, because it calls for the generation of ideas that are novel (at least for the individual). In the case of, say, Duncker's X-ray problem (Duncker, 1945), psychologists can study only how individuals solve the problem for the first time. Hence, in order to investigate the development of strategies for solving problems, it is necessary to use problems that can be presented in a series that call for distinct solutions. In the past, such problems have been open to solution by a simple deterministic strategy of one sort or another (see, e.g., Luchins, 1942). In contrast, our goal was to examine the development of strategies for coping with problems that lie outside the bounds of a deterministic strategy – at least for our participants. We therefore studied problems that come in a series, just as many problems in daily life do – from the writing of computer programs to the search for a job.

Experiment 1 explored two constraints in shape problems, and found that symmetry of the initial problem shape, and the presence of salient solutions in the shape, facilitated problem solving. Experiment 2 showed that individuals do indeed normally begin to tackle such problems by exploring

the consequences of various tactical steps in a way akin to a neo-Darwinian procedure. They choose a step arbitrarily, and then evaluate its consequences in relation to the solution of the problem. More importantly, however, they acquire knowledge of the number of squares that the step removes. They pick up this knowledge whether or not the step is useful in the solution of the problem. And, as the think-aloud protocols also showed, they acquire some understanding of the importance of the p/s ratio in determining appropriate steps for a given problem. This ratio, between the number of pieces to be removed and the number of squares to be removed, constrains the set of useful steps at any point in solving a shape problem. As the theory postulates, a strategic shift then occurs. Individuals start to use their knowledge of tactical steps and the ratio to govern the generation of tactical steps. In this way, they are able to avoid useless false steps in the solution of problems. No participant, however, was able to converge completely on a neo-Lamarckian strategy that guaranteed a solution to any problem without false steps. Indeed, it is an open question whether such a strategy is possible for shape problems of any degree of complexity.

Experiment 3 corroborated the prediction that constraints in the form of tactical knowledge do transfer to new problems. Participants acquired tactical knowledge during training trials, and they continued to use these tactics for problems that could be solved in other ways. When the tactics were inappropriate, they were slowed down because they had to revert to a longer exploratory stage to find the right tactics. Luchins (1942) discovered that deterministic strategies transfer in this way. Our results generalize his findings to show that even when experience leads at best to a strategy that is not deterministic, the strategy nevertheless transfers.

Is the strategic shift an instance of *insight*? The answer depends on what one takes insight to be (cf. Weisberg, 1986; Kaplan & Simon, 1990; Isaak & Just, 1995; Ormerod, MacGregor, & Chronicle, 2002). When the current constraints fail to yield a solution, the shift yields new constraints on the generation of tactical steps. This change, in turn, can yield the solution of a problem. The development of strategies for shape problems accordingly reflects a series of small insights in which constraints are changed as a result of strategic shifts.

Ackowledgments

This research was supported by a grant from the National Science Foundation to the second author to study strategies in reasoning (BCS-0076287). We thank Sam Glucksberg, Geoffrey Goodwin, Uri Hasson, Cathy Haught, Sanna Reynolds, and three anonymous reviewers for helpful comments.

Abstract

The secretary problem is a recreational mathematics problem, suited to laboratory experimentation, that nevertheless is representative of a class of real world sequential decision-making tasks. In the 'full information' version, an observer is presented with a sequence of values from a known distribution, and is required to choose the maximum value. The difficulties are that a value can only be chosen at the time it is presented, that the last value in the sequence is a forced choice if none is chosen earlier, and that any value that is not the maximum is scored as completely wrong. We report a study of human performance on full information secretary problems with 10, 20 and 50 values in the sequence, and considers three different heuristics as models of human decision-making. It is found that some people achieve near-optimal levels of accuracy, but that there are individual differences in human performance. A quantitative evaluation of the three heuristics, using the Minimum Description Length criterion, shows inter-individual differences, but intra-individual consistency, in the use of the heuristics. In particular, people seem to use the heuristics that involve choosing a value when it exceeds an internal threshold, but differ in how they set thresholds. On the basis of these findings, a more general threshold-based family of heuristic models is developed.

Introduction

Many real world decision-making problems are sequential in nature. A series of choices is made available over time, and it is often efficient (and sometimes even necessary) to make a selection without waiting to be presented with all of the alternatives. On long cross-country drives, for example, people refill their cars at one of a sequence of towns on the route, without knowing the price of fuel at subsequent towns. This type of sequential decision has a continuous utility function. People aim to choose the cheapest price, and measure their success by how much their purchase exceeded this minimum.

Other sequential decision-making tasks have binary utility functions, where any incorrect decision is equally (and completely) incorrect. For example, consider being a witness for a police line-up, where, because of the circumstances of the case, the offender is known to be in the line-up. Police line-up policy demands that suspects are presented one at a time, may only be viewed once, and that a suspect must be identified at the time they are presented (e.g., Steblay, Deisert, Fulero, & Lindsay 2001). Suppose also (unrealistically, we hope) that the police insist that a suspect be identified, and indicate that they will force the identification of the last person in the line-up if none of the previous people are chosen. The aim is to choose the offender, and any misidentification has the equally bad outcome of selecting an innocent suspect.

This decision-making scenario has the same essential features as a recreational mathematics problem known as the 'secretary problem' (see Ferguson 1989 for a historical overview). In secretary problems, an observer is presented with a sequence of possible choices, and must decide whether to accept or reject each possibility in turn. The number of choices in the complete sequence is fixed and known, and only the rank of each possibility, relative to those already seen, is presented to the observer. If the observer chooses the best possibility in the sequence, their decision is correct, and any other choice is regarded as incorrect.

Variants of the secretary problem have been considered that change or relax different parts of the problem. In particular, the full information version of the secretary problem, sometimes known as the 'Cayley' problem, presents observers with a score from a known distribution for each possibility, and the goal is to choose the maximum score in the sequence. Rank information corresponds to the assumption that witnesses keep a relative ordering of people in line-ups, whereas value information corresponds to the assumption that witnesses evaluate some continuous measure of the probability that a person is the offender. In either case, the secretary problem has the important feature of using the same binary utility function as the line-up decision. The goal is to choose the actual offender, and any incorrect decision is equally wrong.

Problem Solving and Secretary Problems

Human performance on secretary problems is an interesting topic for cognitive science, for a number of reasons. It offers a well defined task, suited to labora-

tory experimentation, that nevertheless is ecologically representative of a class of real world situations. Because of their inherent complexity, secretary problems also provide an opportunity to study the relationship between rational analysis and heuristic strategies in human problem solving.

Most laboratory research on human problem solving has relied on artificial problems that are characterized by well-defined initial and terminating states that must be linked by a systematic, finite series of steps. Typically, these problems, like the 'Towers of Hanoi' or 'Cannibals and Missionaries', are deterministic, and have state spaces with combinatorially limited possibilities. A major focus of studying people's abilities to solve these tasks involves examining under what circumstances, if any, people make rational decisions. Violations of rationality are easy to measure, because the tasks permit a complete formal analysis. This approach to studying human problem solving assesses what Simon (1976) terms 'substantive' rationality: the ability of people to produce optimal final decisions. Typically, they do not address what Simon (1976) terms 'procedural' rationality—the efficiency of the processes required to make the decision—because of the limited combinatorial complexity of the problem.

More recently, however, some research has studied human performance on difficult combinatorial optimization problems, such as visually presented Traveling Salesperson Problems (TSPs), that have very large state spaces, and resist complete formal solution (e.g., MacGregor & Ormerod 1996; Vickers, Butavicius, Lee, & Medvedev 2001). In attempting to solve these problems, subjects are constrained both by the nature of the task (e.g., limited time), and by their cognitive capabilities (e.g., limited memory). In other words, their performance is constrained not only by the need to achieve a substantively rational outcome, but also by the need to use procedurally rational heuristic processes that are sufficiently fast and accurate, and are implementable with available cognitive resources. Procedural rationality offers an important additional constraint for understanding human problems solving processes, and for the development and evaluation of cognitive models of decision-making.

Secretary problems provide an opportunity to continue and extend this line of study. Because they are not inherently perceptual, secretary problems allow consideration of whether results obtained with problems like TSPs generalize to cognitively-based problem solving. Secretary problems also introduce uncertainty, and place demands on memory. While visual problems like TSPs are combinatorially large, the basic information about distances between points is always perceptually available in a complete and certain form to subjects. In contrast, the sequences of information in secretary problems are stochastic and presented only temporarily, requiring people to deal with uncertainty and rely on their memory.

Previous Research

Gilbert and Mosteller (1966) provide a thorough and useful overview of early mathematical analysis of several versions of the secretary problem. When only rank information is provided, the optimal decision rule takes the form of observing some fixed proportion of values in the sequence, remembering the maximum presented, and then choosing the first subsequent value that is greater, if one exists. Gilbert and Mosteller (1966, Table 2) detail the optimal 'cutoff' proportion for the initial sequence of observations, which depends upon the length of the sequence, but converges to the value $1/e \approx 0.368$. They also give the associated probability of making a correct decision using the optimal decision rule.

For the full information version, where values rather than ranks are presented, the optimal decision rule requires choosing the first value that exceeds a threshold level for its position in the sequence. Gilbert and Mosteller (1966, Tables 7 and 8) detail these optimal thresholds and the associated probabilities of making a correct decision. Since Gilbert and Mosteller's (1966) seminal work, a large literature has developed on mathematical analyses of a large number of variants on the secretary problem, often with a focus on the performance of heuristic decision rules (e.g., Freeman 1983).

Relatively less attention has been given to studying human performance solving secretary problems. Seale and Rapoport (1997) consider the rank information version of the problem with lengths of 40 and 80, and focus on the evaluation of plausible heuristic models of human decision-making. In an individual subject analysis, they found a parameterized version of the optimal cutoff rule provided the best fit. Kahan, Rapoport and Jones (1967) studied human performance on full-information versions of the problem with length 200, where the values were drawn from either a positively skewed, negatively skewed, or a uniform distribution. They found no evidence for the different distributions affecting the decisions made. They also compared individual and group decision-making, and found that decisions were made earlier in the sequence by individuals. Other empirical studies (e.g., Kogut 1990), make a large methodological departure by requiring subjects to sacrifice explicitly held resources to view additional presentations, usually because they are interested in applications of the problem to economic decision-making.

In this paper, we study human performance on the full information version of the secretary problem, where values are chosen from a uniform distribution. We consider problems of length 10, 20 and 50, under the binary utility function, but without any explicit

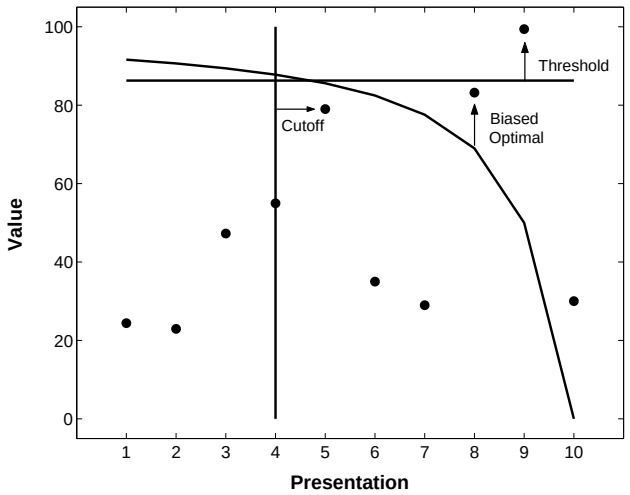

Figure 1: A sample secretary problem of length 10, with the sequence of values shown by filled circles, demonstrating the operation of the biased optimal (curved line), threshold (horizontal line) and cutoff (vertical line) heuristics.

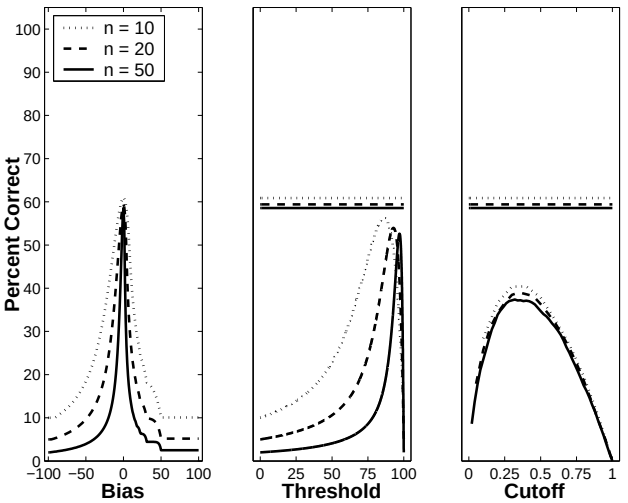

Figure 2: The accuracy of the heuristics, across their parameter spaces, for 10, 20 and 50 sequence length problems.

search cost. Our primary interest, like that of Seale and Rapoport (1997), is to develop and evaluate competing cognitive models of human decision-making.

Three Heuristics

We consider three possible heuristics as models of human decision-making. The first is a biased version of the optimal decision rule. This heuristic chooses the first value that exceeds a threshold level for its position in the sequence. The threshold levels correspond to the optimal values, for the given problem length, all shifted by the same constant. The second heuristic is inspired by Simon's (1956) notion of satisficing. It simply chooses the first value that exceeds a single fixed threshold. The third heuristic is inspired by the optimal decision rule for the rank information version of the secretary problem. It observes a fixed proportion of the values in the sequence, and remembers the maximum value up until this cutoff point. The first value that exceeds the maximum in the remainder of the sequence is chosen. For all three heuristics, if no value meets the decision criterion, the last value becomes the forced choice.

Figure 1 summarizes the functioning of the three heuristics on a problem of length 10. The sequence of values presented is shown by the filled circles. The threshold levels for the optimal heuristic (with no bias) follow the solid curve. The horizontal line shows the constant level used by the threshold heuristic. The vertical line shows the proportion used by the cutoff heuristic. Under these parameterizations, the biased optimal, threshold, and cutoff heuristics choose, respectively, the eighth, ninth, and fifth values presented.

The left panel of Figure 2 shows the accuracy of the biased optimal heuristic for bias values between -100 and 100 for problems of length 10, 20, and 50, calculated using the analytic method of Gilbert and Mosteller (1966, p. 55). At zero bias, the heuristic corresponds to the optimal decision rule, and so the maximum possible accuracy is obtained. The middle panel of Figure 2 shows the accuracy of the threshold heuristic for threshold values between 0 and 100 for problems of length 10, 20 and 50, calculated using the same analytic method. The maximum possible accuracy, corresponding to the use of the optimal decision rule, is shown for each problem length by the horizontal lines. Finally, the right panel of Figure 2 shows the accuracy of the cutoff heuristic for proportions between 0 and 1 for problems of length 10, 20 and 50, generated by simulation on a large sample of independently generated problems. Once again, the maximum possible accuracies are shown by the horizontal lines.

There are two observations worth making about the accuracy of the heuristics shown by Figure 2. It is clear that the threshold heuristic is capable of making better decisions than the cutoff heuristic. This is interesting, given that the cutoff heuristic is optimal for rank information secretary problems. It is also clear that the accuracy of both the biased optimal and threshold heuristics are very sensitive to their parameterizations, particularly for larger problem lengths.

Experiment

Participants Ten participants completed the experiment. There were 4 males and 6 females, with a mean age of 26.1 years.

Method Each participant completed the same three sets of problems. The first set contained 20 problems of length 10. The second contained 20 problems of length 20. The third set contained 20 problems of length 50. Participants always did the three sets in the same order—length 10, then 20, then 50—but the order of the 20 problems within each set was randomized across participants.

For each problem, the participants were told the length of sequence, and were instructed to choose the maximum value It was emphasized that (a) the values were uniformly and randomly distributed between 0.00 and 100.00, (b) a value could only be chosen at the time it was presented, (c) the goal was to select the maximum value, with any selection below the maximum being completely incorrect, and (d) if no choice had been made when the last value was presented, they would be forced to choose this value. As each value was presented, its position in the sequence was shown, together with 'yes' and 'no' response buttons. When a value was chosen, subjects rated their confidence in the decision on a nine point scale ranging from "completely incorrect" to "completely correct".

Results Table 1 summarizes the accuracy of the decisions made by all of the subjects for all of the problems. The average accuracy for the 20 problems in each set is given, together with averages across all problems for each subject, and across all subjects for each problem length. There are three observations worth making about these results. First, some subjects achieve levels of accuracy competitive with the optimal decision rule. Secondly, there appear to be individual differences between the subjects, with a range in average accuracy from 33% to more than 60%. Thirdly, there is some suggestion that human performance worsens as the problem length increases, even after accounting for the slightly decreased accuracy of the optimal decision rule.

Table 1: Accuracy of human decisions, showing the percentage of correct answers for each participant on each set of problems. Average accuracy for each participant, and for each problem length are also shown.

Participant	$n = 10$	$n = 20$	$n = 50$	Mean
1	65	65	55	61.37
2	45	45	20	36.67
3	55	45	50	50.00
4	40	35	25	33.33
5	55	35	55	48.33
6	65	45	20	43.33
7	45	60	50	51.67
8	55	50	45	50.00
9	70	55	55	60.00
10	50	35	55	46.67
Mean	54.50	47.00	43.00	

Model Evaluation One compelling aspect of the model evaluation undertaken by Seale and Rapoport (1997) is that it was done at the level of individual subjects, rather than by averaging decisions across subjects. As noted by Estes (1956), averaging non-linear decision processes in the presence of noise, and with significant individual differences, acts to corrupt the form of the empirical data being modeled. Because these criteria are likely met in the current problem, we also undertook individual subject evaluation of the biased optimal, threshold and cutoff heuristics.

A potential criticism of Seale and Rapoport (1997) is that the quantitative component of their model evaluation relied solely on the ability of a heuristic, at one or more parameterizations, to match the decisions made by a subject. As argued by Roberts and Pashler (2000), measures of goodness-of-fit fail to account for important quantifiable components in model selection. In particular, it is important also to assess the complexity of parameterized models, to ensure that good fit to empirical data does not merely arise because a model is so complicated that it can fit any data, including data that are never observed.

In model theoretic terms, there are clear differences in the complexity of the three heuristics being considered. For the set of 20 length 10 problems given to subjects, there are 10^{20} possible combinations of decisions. The biased optimal, threshold, and cutoff heuristics can predict, respectively, 78, 60, and 9 of these possibilities by varying their parameters. Similar differences in complexity hold for the longer problem lengths, with 88, 70 and 17 data distributions being indexed by the parameters for the length 20 problems, and 121, 90 and 30 for the length 50 problems. Accordingly, any superiority in the ability of the biased optimal heuristic over its competitors, or in the threshold over the cutoff heuristic, could possibly be due to greater complexity, rather than fundamentally capturing regularities in the empirical data.

These concerns are best addressed using advanced model selection methods (e.g., Pitt, Myung, & Zhang 2002), which provide criteria for choosing between models in ways that consider both goodness-of-fit and complexity. One interesting challenge in doing this is for the current models is that they are deterministic, and do not specify an error theory. This means that various probabilistic model selection criteria, such as Bayes Factors (e.g., Kass & Raftery 1995), Minimum Description Length (MDL: e.g., Grünwald 2000)

Table 2: Minimum Description Length (MDL) criteria values for the Biased Optimal (BO), Threshold (Th) and Cutoff (Cu) models, measured against the decision made by the ten participants on each problem length. Bold entries highlight strong evidence in favor of the preferred model.

	$n = 10$			$n = 20$			$n = 50$		
	BO	Th	Cu	BO	Th	Cu	BO	Th	Cu
1	32.7	**26.3**	40.1	34.4	**25.6**	52.6	34.6	**23.2**	60.6
2	**19.4**	32.4	33.2	38.0	40.4	45.0	34.6	32.8	60.6
3	35.4	**26.3**	35.7	38.0	29.7	35.2	29.7	32.8	47.5
4	**15.3**	35.1	42.0	26.3	25.6	47.8	**18.7**	32.8	44.1
5	32.7	32.4	40.1	30.4	29.7	50.3	52.0	48.9	60.6
6	**19.4**	29.5	38.0	**21.8**	29.7	42.1	29.7	28.1	43.8
7	26.6	22.9	40.1	26.3	21.2	41.5	18.7	17.8	35.8
8	32.7	26.3	40.1	41.5	**33.5**	50.3	**12.5**	23.2	47.8
9	26.6	32.4	38.0	26.3	25.6	52.6	24.4	23.2	36.0
10	**29.8**	37.6	40.1	**21.8**	37.0	52.6	34.6	**28.1**	43.8

or Normalized Maximum Likelihood (Rissanen 2001), are not immediately applicable. Grünwald (1999), however, develops a model selection methodology that overcomes these difficulties. He provides a principled technique for associating deterministic models with probability distributions, through a process called 'entropification', that allows MDL criteria for competing models to be calculated.

Table 2 shows the MDL values found by applying Grünwald's (1999) method to all three heuristics, taking each subject individually, and considering each problem length separately. Lower MDL values indicate better models, and differences between values can be interpreted on the log-odds scale. This means, for example, that the threshold heuristic (MDL value 26.3) provides an account that is about 600 times more likely than that provided by the biased optimal heuristic (MDL value 32.7) for the decisions made by the first subject for the length 10 problems, since $e^{32.7-26.3} \approx 600$. Kass and Raftery (1995) suggest, without being prescriptive, that a difference of six or more in the log-odds given by MDL values corresponds to 'strong' evidence in favor of the preferred model. Adopting the same standard, Table 2 highlights in bold those instances where the MDL for one of the heuristics provides strong evidence in its favor compared to both of the others.

There are several conclusions that can be drawn from this analysis. First, despite its simplicity, the cutoff heuristic does not provide a good model of the human decisions. For almost every subject and every problem length, it has the greatest MDL value, and often is so much larger as to provide strong evidence against its suitability. Secondly, there is clear evidence of inter-individual differences in the use of the biased optimal or threshold heuristics. There are approximately as many instances, for each problem length, where the biased optimal or threshold heuristic is strongly favored as an account for an individual subject. Thirdly, there is also some evidence of intra-individual consistency in using the biased optimal or threshold heuristic. This is because, in most instances, strong preferences favor the same heuristic for the same subject on different problem lengths.

Once the MDL criteria have been used to control for effects of model complexity, it is sensible to examine the goodness-of-fit of the heuristics. This was done by considering the average percentage of correct predictors made by each heuristic, for just those participants with MDL values favoring the heuristic. The biased optimal heuristic correctly predicted an average of 81%, 78% and 88% of participant decisions for, respectively, the 10, 20 and 50 length problems. The threshold heuristic correctly predicted an average of 74%, 78% and 79% of decisions. These results suggest that, while the heuristics may not provide a complete account of human performance, they do capture important regularities in the decision-making data.

Where there is strong evidence for a participant using either the biased optimal or threshold heuristic, it is also worthwhile to examine the parameter values used. For participants using the biased optimal heuristic, the bias parameter was always negative, indicating they underestimated the optimal threshold value for each position in the sequence. As the problem length increased from 10 to 20 then 50, however, the average bias changed from -5.1 to -1.8 then -1.9. This suggests that, for the longer sequences, participants were better calibrated to the optimal curve. For participants using the threshold heuristic, the average best-fitting threshold increased from 88.1 to 93.2 then 94.6. These values compare to theoretically optimal thresholds of 86.4, 92.6 and 97.2, as shown in the middle panel of Figure 2. It is clear that participants are sensitive to the need to increase the threshold as the length of the sequence increases, and do not seem either to under- or over-estimate the optimal value. It should be acknowledged, however, that these parameter values analyses are based on limited data, and additional data are required to confirm the suggested trends in this experiment, as well as to ascertain whether there are significant individual differences that also need to be considered.

Discussion

This study constitutes a first attempt to understand human decision-making on the full information version of the secretary problem. A first contribution of the study is to reject the usefulness of the cutoff heuristic, on both theoretical and empirical grounds, as an

account of human decision-making. This is a worthwhile finding, given that Seale and Rapoport (1997) found good evidence for people using this strategy on the rank information version of the secretary problem.

More importantly, it seems clear that both the biased optimal and threshold heuristics do capture something fundamental about human decision-making on the full information version. Both heuristics take the form of choosing the first value that exceeds a threshold, with the key difference being that the biased optimal heuristic uses thresholds that are sensitive to the position in the sequence, rather than being fixed.

Indeed, the biased optimal and threshold heuristics represent the two extremes of a continuum of threshold-based decision-making heuristics. Instead of using a constantly changing or a fixed threshold, it is possible for a decision process to use a small number of thresholds, and apply each to a sub-sequence of the presented values. For example, for a problem of length 10, a heuristic might apply one threshold for the first five values, decrease it for the next three values, and finally decrease it again for the penultimate value[1]. These sorts of heuristics seem likely to have complexity that lies somewhere between that of the biased optimal and threshold heuristics. It may well be the case that human performance is best explained by an account that is more sophisticated than the threshold heuristic, but does not have the full complexity of the biased optimal approach.

A final interesting problem for future research is whether the observed individual differences in accuracy are related to more traditional measures of problem solving ability and psychometric intelligence. In the everyday world, the ability to solve practical problems is generally regarded as an expression of intelligence. There is some evidence (e.g., Vickers *et al.* 2001) of a relationship between solution quality on TSPs and measures of IQ. Given that secretary problems are representative of a class of real world sequential decision-making tasks, they allow the possibility that there is a similar relationship for non-perceptual tasks to be examined.

Abstract

This paper presents a computational model of the incremental construction of an associative network from a corpus. It is aimed at modeling the development of the human semantic memory. It is not based on a vector representation, which does not well reproduce the asymmetrical property of word similarity, but rather on a network representation. Compared to Latent Semantic Analysis, it is incremental which is cognitively more plausible. It is also an attempt to take into account higher-order co-occurrences in the construction of word similarities. This model was compared to children association norms. A good correlation as well as a similar gradient of similarity were found.

Introduction

A computational model of the human semantic memory may be valuable for its ability to mimic the human semantic representations, but also for its ability to mimic the *construction* of these representations over a long period of time. Not all models possess both features. For instance, symbolic formalisms like semantic networks had proven to be interesting for representing human knowledge but they do not tell us how human beings build such representations over their life. Several computational models of both the representation and construction of the human semantic memory have been proposed in the recent years. Some of them are based on a general common mechanism that rely on a huge input, composed of examples of associations between words. The statistical analysis of the occurrences of each word within well-defined units of context leads to a computational representation of association links between words. The representation of word meanings per se is not of significant interest, it is rather their association links which combined will form a model of the long-term semantic memory.

These models can be distinguished along six features:

1. the kind of input they are based on (either a corpus or word association norms);
2. the knowledge representation formalism (either vector-based or network-based);
3. the way a new context is added to the long-term semantic memory (incrementally or not);
4. the unit of context in which co-occurrence information is considered (either a paragraph or a sliding window);
5. the use or not of higher-order co-occurrences;
6. compositionality: the way the meaning of a text can be inferred from the meaning of its words.

After a description of existing models, we will discuss these features, present our model and describe an experiment that aims at comparing our model to human data.

Existing computational models of the construction of semantic representations

Latent Semantic Analysis

LSA (Landauer, 2002) takes as input a corpus of free texts. The unit of context is the paragraph. The analysis of the occurrences of each word within all paragraphs leads to a representation of the meaning of words as vectors, which is well suited for drawing semantic comparisons between words. The underlying mechanism (singular value decomposition of the word-paragraph occurrence matrix) implicitly takes into account higher-order co-occurrences (Kontostathis & Pottenger, 2002). Compositionality in this model is straightforward: the meaning of a text is a linear combination of the meaning of its words. There is however no way of updating the semantic space with a new unit of context without redoing the whole process. LSA's semantic representations have been largely tested in the literature (Foltz, 1996 ; Wolfe et al., 1998). This model can account for some mechanisms of the construction of knowledge (Landauer & Dumais, 1997).

Hyperspace Analogue to Language

HAL (Burgess, 1998) is also a model of the semantic memory. It is similar to LSA except that (1) it does not take into account higher-order co-occurrences since vectors are just direct co-occurrence vectors; (2) the unit of context is a sliding window of a few words which takes into account the lexical distance between words and (3) updating the semantic space with a new paragraph can be done easily.

Sparse Random Context Representation

SRCR (Sahlgren, 2001, 2002) is also based on the use of a sliding window applied to a large corpus. Words have an initial random vector representation (1,800 dimensions), which is updated with the vectors of the co-occurring words: they are all added to the current word, but with a multiplying factor which depends on their distance to the current word within the window. The way the initial

representation is computed is important: all 1,800 values are set to 0 except eight which are randomly selected and set to 1. This method is intrinsically incremental. It has better results than LSA on the famous TOEFL test. However, it does not take into account higher-order co-occurrences.

Word Association Space

WAS (Steyvers, Shiffrin & Nelson, in press) is not based on a corpus but on association norms providing associates for 5,000 words. The authors applied scaling methods to these data in order to assign a high-dimensional representation to each word. In particular, they relied on singular value decomposition, the mathematical procedure also used by LSA. The idea is similar to LSA: words that appear within similar contexts (i.e. words with similar associative relationships) are placed in similar regions in the space. WAS appeared to be a better predictor of memory performance than LSA.

Features

We will now discuss the six previous features in order to sketch out a model of construction and representation of the long-term semantic memory that would attempt to overcome existing limits.

Input

A corpus of free texts as input is cognitively more plausible than association norms or even a sublanguage of a few propositions (Frank et al. 2003). As humans, we do not obviously construct our semantic representations solely from written data (Glenberg & Robertson, 2000), but there is currently no formalism able to model all perceptual data such that they can be processed by a computational model. In addition, written data, although it is not perfect, seems to cover a large part of our semantic representations (Landauer, 2002).

Representation

Most models are based on a vector representation of word meaning. Dimensions of the semantic space can be the result of a statistical analysis which keeps hundreds of dimensions like in LSA or SCRC (they are therefore unlabelled), the most variant words as in HAL, the most frequent ones (Levy & Bullinaria, 2001) or even a predefined subset of words, either taken from a thesaurus (Prince & Lafourcade, 2002) or selected as being the most reliable across various sub-corpora (Lowe & McDonald, 2000).

One major interest of the vector representation is that it offers a simple way to measure the similarity between words. The angle between the corresponding vectors or its cosine are generally used.

One drawback of the vector representation however is the difficulty to determine the words that are similar to a given word or, say differently, the words that are activated in memory. It requires the scanning of all vectors in order to find the closest ones, which is both computationally and cognitively not satisfactory. A direct link between a word and its associates should exist in a plausible model of the semantic memory.

Another problem with the vector representation is that similarity is symmetrical: similarity(A,B)=similarity(B,A). This is not coherent with psycholinguistic findings showing that semantic similarity is not a symmetrical relation (Tversky, 1977). For instance, *bird* is a very close neighbor of *swallow*, but the opposite is not so obvious.

A network of words with simple numerical oriented links between nodes (what is called an oriented graph in graph theory) would be better for that purpose. Numerical links would represent semantic similarities. Such a basic network would offer a direct connection between a word and its neighbors and represent differently similarity(A,B) and similarity(B,A).

Memory updating

A model of the construction of the semantic memory should describe the way processing a new piece of written data affects the representation of the long-term memory. Some models like Latent Semantic Analysis are not incremental, which means that the whole process needs to be restarted in order to take into account a new context. Actually, a new paragraph can easily be represented by a vector in this model, by a simple linear combination of its words, but this operation does not affect at all the semantic space. Incremental models are much more cognitively plausible: processing new texts should modify, even slightly, the semantic memory.

Unit of context

The semantic relations between words are constructed from the occurrences of words within contexts. The size of such contexts plays an important role. Psychological experiments as well as computer simulations (Burgess, 1998) tend to consider that a context composed of a few words before and after the current word is reasonable. However, computational constraints have led some models to consider a whole paragraph as a unit of context, which is probably a too large unit. Latent Semantic Analysis is such a model. The use of a sliding window allows models like HAL or SRCR to take into account the distance between words within the window, whereas approaches based on paragraphs deal with bags of words.

Higher-order co-occurrences

It has been shown that higher-order co-occurrences play an important role (Kontostathis & Pottenger, 2002) in the latent structure of word usage. Two words should be considered associated although they never co-occur in context units, provided that they occur within similar contexts. A is said to be a second-order co-occurrence of B if it co-occurs with C which also co-occurs with B. If C were a second-order co-occurrence of B, A would be considered as a third-order co-occurrence of B, etc.

By means of the singular value decomposition procedure, LSA semantic similarity indeed involves higher-order co-occurrences (Lemaire & Denhière, submitted). Other approaches such as SCRC or HAL do not.

Table 1: Features of different models

	Input	Representation	Memory updating	Unit of context	higher-order co-occurrences	Compositionality
LSA	corpus	vectors	not incremental	paragraph	yes	easy
HAL	corpus	vectors	incremental	sliding window	no	easy
SCRC	corpus	vectors	incremental	sliding window	no	easy
WAIS	association norms	vectors	not incremental	N/A	no	easy
ICAN	*corpus*	*network*	*incremental*	*sliding window*	*yes*	*hard*

Compositionality

Compositionality is the ability of a representation to go from words to texts. The vector representation is very convenient for that purpose because the linear combination of vectors still produces a vector, which means that the same representation is used for both words and texts. This might be a reason why vector representations are so popular. On the contrary, symbolic representations of word meaning like semantic networks do not offer such a feature: it is not straightforward to build the representation of a group of words from the individual representations of words, especially if the representation is rich, for instance with labelled links.

Summary

Table 1 describes some of the existing models along the previous six features. We present ICAN, our proposal, at then end of the next section.

ICAN

Basic mechanisms

Like others, this model takes as input a corpus of free texts and produces a computational representation of word meanings. This model is based on a network representation, which we believe is more accurate in modeling the process of semantic activation in memory. The idea is to associate to each word a set of neighbors as well as their association weights in [0..1], exactly as in rough semantic network. The model is incremental which means that the set of connected words for each word evolves while processing new texts. In particular, new words can be added according to the co-occurrence information and other words can be ruled out if their association strengths with the current word become too low.

Links between words are updated by taking into account the results of a previous simulation on 13,637 paragraphs of a corpus (Lemaire & Denhière, submitted), which showed that:

- co-occurrence of W_1 and W_2 tends to strongly increase the W_1-W_2 similarity;
- occurrence of W_1 without W_2 or W_2 without W_1 tends to decrease the W_1-W_2 similarity;
- second and third-order co-occurrence of W_1 and W_2 tends to slightly increase the W_1-W_2 similarity.

In our model, a sliding window is used as a unit of context. Therefore, each word of the corpus is considered with respect to its preceding and following contexts. The size of the window can be modified. For the sake of simplicity, we will not use the third-order co-occurrence effect. The algorithm is the following:

For each word W, its preceding context $C_1..C_k$ and its following context $C_{k+1}..C_{2k}$ (the sliding window therefore being $[C_1\ C_2\ ...\ C_k\ \mathbf{W}\ C_{k+1}\ C_{k+2}...\ C_{2k}]$):

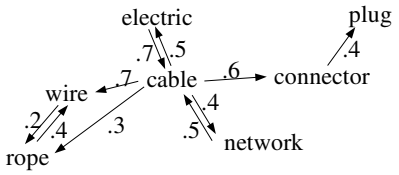
Direct co-occurrence effect: reinforce the link W-C_i (if this link does not exist, create it with a weight of 0.5, otherwise increase the weight p by setting it to $p+(1-p)/2$;

Second-order co-occurrence effect: let p be the weight of the W-C_i link. For each M linked to C_i with weight m, reinforce the link W-M (if such a link does not exist, create it with a weigth of $p.m$, otherwise, increases the weight q by setting it to $q+A(1-q)(p.m)$, A being a parameter;

Occurrence without co-occurrence effect: reduce the links between W and its other neighbors (if the weights were p, set them to a fraction of p, e.g., $0.9p$). If some of them fall under a threshold (e.g., .1), then remove these links.

Example

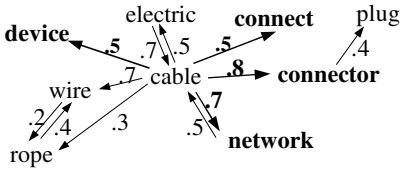
As an example, consider the following association network, which is the result of processing several texts:



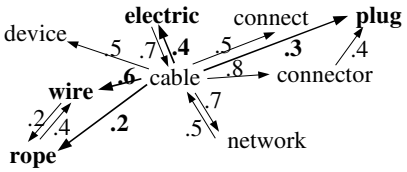
The new text being analyzed is:

... if you have such a device, connect the cable to the network connector then switch...

We now describe how this text will modify the association network, according to the previous rules. Suppose a window of size 5 (2 preceding words, 1 current word, 2 following words). Since functional words are not taken into account, the current window is then [device, connect, **cable**, network, connector], *cable* being the current word. The direct co-occurrence effect leads to reinforce the links between *cable* and the four co-occurring words. Two of them are new links, while others are existing links whose weights are simply increased. The network becomes:



The second-order co-occurrence effect reinforces the links between *cable* and all words connected to one of its four co-occurring word. In this small example, this is only the case for the word *plug*. Finally, the occurrence without co-occurrence effect leads to a decrease of the links between cable and its other neighbors. The network is then:



The next current word is *network*, the window is [connect, cable, **network**, connector, switch] and the process repeats again.

Measure of similarity

Similarity between words W_1 and W_2 is the combination (i.e. the product) of the links of the shortest path between W_1 and W_2. If W_2 is connected to W_1, it is just the weight of the link; if W_1 is connected to Z which is connected to W_2, it is the combination of the two weights. If W_2 does not belong to the neighbors of W_1's neighbors it is probably sufficient to set the semantic similarity to 0. Since the graph is oriented (the link weight between A and B might be different from the link weight between B and A), this way of measuring the similarity mimics the asymmetrical property of the human judgment of similarity better than the cosine between vectors.

Tests

Comparison to association norms

In order to test this model, we compared the association links it provides to human association norms. The corpus we relied on is a 3.2 million word French child corpus composed of texts that are supposed to reproduce the kind of texts children are exposed to: stories and tales for children (~1,6 million words), children productions (~800,000 words), reading textbooks (~400,000 words) and children encyclopedia (~400,000 words). All functional words were ruled out. Words whose frequency was less than 3 were not taken into account. The program is written in C, it is available on demand. Processing the whole corpus takes a few hours on a standard computer, depending on the window size.

Once the association network was built, we measured the similarity between 200 words and 6 of their associates (the first three and the last three), as provided by the de la Haye (2003) norms for 9 year-old children. The association value in these norms is the percentage of subjects who provided the associate. For instance, the six associates to *abeille(bee)* are:

- miel(honey): 19%
- insecte(insect): 14%
- ruche(hive): 9%
- animal(animal): 1%
- oiseau(bird): 1%
- vole(fly): 1%

Actually, 16 words were not part of the corpus. Only 1184 pairs of words were therefore used.

We then compared these values to the similarity values provided by the model. We had two hypotheses. First, the model should distinguish betwen the three first associates and the last ones and there should be a gradient of similarity from the first one to the last ones. Second, there should be a good correlation between human data and model data.

Several parameters have to be set in the model. The best correlation with the human data was obtained with the following parameters (see the algorithm presented earlier):

- window size = 11 (5 preceding and 5 following words);
- co-occurrence effect: $p \rightarrow p+(1-p)/2$;
- 2nd-order co-occurrence effect : $p \rightarrow q+.02(1-q)(p.m)$;
- occurrence without co-occurrence effect : $p \rightarrow .9p$.

Using these parameters, the average similarity values between stem words and associates, as well as the children data, are the following:

	1st associates	2nd associates	3rd associates	Last associates
ICAN	.415	.269	.236	.098
Norms	30.5	13.5	8.2	1

All model values are highly significantly different, except for the 2nd and 3rd associates which differ only at the 10% level. Our model reproduces quite well the human gradient of association.

We also calculated the coefficient of correlation between human data and model data. We found an interesting significant correlation: $r(1184)=.50$.

The exact same test from the same corpus was also applied to Latent Semantic Analysis. Results are the following:

	1st associates	2nd associates	3rd associates	Last associates
LSA	.26	.23	.19	.11

Similarities between the stem word and the first associates appear stronger in the ICAN model. LSA' scorrelation with human data is $r(1184)=.39$, which is worse than our correlation.

Similarity as direct co-occurrence

One can wonder whether the similarity could be mainly due to the direct co-occurrence effect. Similarity between words is indeed often operationalized in psycholinguistic researches by their frequency of co-occurrence in huge corpus. Experiments have indeed revealed the correlation between both factors (Spence & Owens, 1990). However, this shortcut is questionable. In particular, there are words that are strongly associated although they never co-occur. Burgess & Lund (1998) mentioned the two words *road* and *street* that almost never cooccur in their huge corpus although they are almost synonyms. In a 24-million words French corpus from the daily newspaper *Le Monde* in 1999, we found 131 occurrences of *internet*, 94 occurrences of *web*, but no co-occurrences at all. However, both words are strongly associated. Edmonds (1997) showed that selecting the best typical synonym requires that at least second-order co-occurrence is taken into account. There is clearly a debate: is the frequency of co-occurrence a good model of word similarity?

In order to test that hypothesis, we modified our model so that only direct co-occurrences are taken into account: the 2nd order co-occurrence effect as well as the occurrence without co-occurrence effect were inhibited. Results are the following:

	1st assoc.	2nd assoc.	3rd assoc.	Last assoc.
ICAN (only direct co-occurrences)	.903	.781	.731	.439

The gradient of similarity is still there but the correlation with human data is worse ($r(1184)=.39$). This is in accordance with our previous findings (Lemaire & Denhière, submitted) which show that the frequency of co-occurrence tends to overestimate semantic similarity.

Effect of second-order co-occurrence

Another test consisted in measuring the effect of second-order co-occurrences. This time, we only inhibited this effect in order to see whether the loss would be significant. Results are presented in the next table:

	1st assoc.	2nd assoc.	3rd assoc.	Last assoc.
ICAN (no 2nd-order co-occurrences)	.371	.225	.191	.056

Correlation with human data was not significantly different from the full model. It only decreased from .50 to .48. This means that second-order co-occurrences do not seem to have much effect in this simulation. One reason might be due to the mathematical formula we used to model higher-order co-occurrences. It might not be the right one. Another reason could be that we only implemented second-order co-occurrence effects. Third and higher-order co-occurrence effects might play a much more significant role than could be expected. A final reason could be that higher-order co-occurrence does not play any role. But, how then could we explain the high similarity between words that almost never co-occur? More experiments and simulations need to be carried out to investigate this issue.

Window size

We also modified the model in order to shed light on the role of the window size. Results are as follows:

Window size	Correlation with human data
3 (1+1+1)	.34
5 (2+1+2)	.38
7 (3+1+3)	.44
9 (4+1+4)	.48
11 (5+1+5)	.50
13 (6+1+6)	.49
15 (7+1+7)	.47

We found that the best window size is 11 (5 preceding words and 5 following words). This is in agreement with the literature: Burgess (1998) as well as Lowe and McDonald (2000) use a window of size 10, Levy and Bullinaria (1998) found best performance for a window size from 8 to 14, according to the similarity measure they relied on.

Conclusion

This model could be improved in many ways. However, preliminary results are encouraging: the model produces better results than the outstanding Latent Semantic Analysis model on a word association test. In addition, it adresses two major LSA drawbacks. The first one has to do with the representation itself: the fact that LSA's associations are symmetrical is not satisfactory. A network representation seems better for that purpose than a vector representation. The second limitation of LSA concerns the way the semantic space is built. LSA is not incremental: adding a new piece of text requires that the whole process is run again. Like HAL or SCRC, ICAN has the advantage of being incremental.

ICAN's main limitation is related to compositionality. The construction of a text's representation is not straightforward, given the representation of its words. Representing every text as a simple function of its words, and in the same formalism, as in the vector representation, is very convenient since text comparisons are then easy to perform. Compared to other approaches, LSA is for instance very good at simulating the human judgment of text comparisons (Foltz, 1996). However, the cognitive plausibility of such a representation can be questioned. Do we really need the exact same representation for words and texts? Is it cognitively reasonable to go directly without any effort from words to texts? Why having two ways of processing texts: one which would be computationally costly (singular

value decomposition in LSA) and another one very quick (adding its words)?

A solution could be to process each new text by the mechanism described in this paper: a text would then be represented by a subgraph, that is by a small subset of the huge semantic network, composed of the text words, their neighbors and their links. An information reduction mechanism like the integration step of the construction-integration model (Kintsch, 1998) could then be used to condense this subgraph in order to retain the main information. This smaller subgraph would constitute the text representation. This way, there would be a single mechanism used to process a text, construct its representation and update the long-term semantic memory. However, much work remains to be done in that direction.

Once a corpus was processed, it would be interesting to study the resulting network structure. In particular, this structure could be compared to existing semantic networks, in terms of connectivity or average path-lengths between words, much like Steyvers & Tenenbaum (submitted) did recently.

Acknowledgements

We would like to thank Maryse Bianco, Philippe Dessus and Sonia Mandin for their valuable comments on this model, as well as Emmanuelle Billier, Valérie Dupont and Graham Rickson for the proofreading .

Integrating Spatial Language and Spatial Memory: A Dynamical Systems Approach

Abstract

The domain of spatial language is an ideal testing ground for proposals addressing the representational gap between perceptual-motor and language systems precisely because it is an unambiguous case of these systems coming together. To date, however, efforts addressing this representational gap within the domain of spatial language have generated conflicting results. Focusing on an "above" ratings task, we provide here a dynamical systems approach to spatial language performance and supporting empirical results that address this impasse. The development of a dynamical systems model linking spatial language and spatial memory is also discussed.

Representation and Spatial Language

A current focus in cognitive science is understanding how the sensory-motor and linguistic systems interact. Because spatial language brings words and physical space together so directly, it is the ideal vehicle for exploring this interaction. To date, two general approaches to representation speak to this issue of interaction in spatial language (Barsalou, 1999): amodal symbolic systems and perceptual symbol systems.

Amodal symbolic systems presume representational independence between symbolic processes like language and sensory-motor systems (Harnad, 1990; Anderson, 2000). The amodal view thus requires a transduction process that permits "communication" between linguistic and non-linguistic systems. This transduction process is best described by Jackendoff's representational interface (1992; 1996; 2002) in which communication between different types of representations (e.g. auditory and visual) is achieved through a process of schematization─ the simplifying and filtering out of information within one representational format for use in another representational system (Talmy, 1983). The representational interface approach ultimately permits abstract conceptual structures that can encode spatial representations but still capture the core characteristics of the symbolic view (e.g. pointers to sensory modalities, type-token distinctions, taxonomies).

There is significant empirical support for this perspective. Talmy (1983), for example, showed that language uses closed-class prepositions (such as "above", "below", or "near") to provide an abstracted, skeletal structure of a scene that narrows the listener's attention to a particular relationship between two objects by disregarding other available information (Talmy, 1983; Hayward & Tarr, 1995). Thus, in the sentence "The bike stood near the house", all of the specific information about the bike (e.g. size, shape, orientation) is disregarded and the bike is instead treated as a dimensionless point (Hayward & Tarr, 1995). As a result of this schematization, linguistic representations of relational states can be extended to a variety of visual scenes and objects with little regard to the individual object characteristics.

In contrast to transduction and the amodal approach, Barsalou's Perceptual Symbol Systems (1999) posits perceptual symbols: "records of neural states that underlie perception" (p.583) that are both inherently grounded in the given sensory modality and capable of replicating the flexible, productive, and hierarchical capacities of amodal symbolic systems. These perceptual symbols are implemented when top-down processes partially reactivate sensory-motor areas and organize the perceptual components around a common frame. Ultimately, perceptual components implement a simulator that captures both perceptual memories and core symbolic behaviors (e.g. type-token distinctions, hierarchies). Because these symbols are grounded in sensory-motor processes, they do not require pointers or transduction to become "meaningful".

A growing empirical literature supports Barsalou's (1999) PSS as well. For example, Stanfield and Zwaan (2001) argued that if symbolic, linguistic representations are integrated with perceptual symbol systems, people should be faster to recognize visual objects described in a sentence as the similarity between the perceived object and the description increase. Consistent with this prediction, they found that people were faster to recognize an object (e.g. a vertically oriented pencil) as part of a previous sentence when that sentence matched the orientation (e.g. He placed the pencil in the cup) than when it conflicted (e.g. He placed the pencil in the drawer). Visual information has also been shown to facilitate real-time resolution of temporarily syntactically ambiguous sentences (Tanenhaus, Spivey-Knowlton, Eberhard, & Sedivy, 1995), further evidence against a hard separation between linguistic and sensory systems. Finally, recent work by Richardson et al. (2003) shows that verbal stimuli interact with visual discrimination performance, additional evidence that linguistic processing can directly impact the processing of visual space.

In summary, the contrasting amodal and modal perspectives both appear to be substantially supported.

iven the clear contrast between the two theories, however, both cannot be correct. Thus, despite a vigorous debate and valuable empirical data on both sides, the fundamental question of how linguistic and non-linguistic systems relate remains unanswered.

Limits of the Current Approaches

Further consideration suggests two critical limits of the proposals and empirical support discussed above. First, they rely on descriptive, conceptual accounts of representational structure. Though critical at initial stages of theory development, the flexibility of conceptual accounts makes them ultimately difficult to critically test and falsify. Consequently, data collected in support of one view can be reinterpreted by the other view. Jackendoff (2002), for example, incorporated the resolution of syntactic ambiguity through visual processing (Tanenhaus, et al., 1995) using characteristics of a syntax-semantics interface.

The second, related limit of the current literature is treatment of representational structure in the abstract. In particular, with the exception of recent tests of the PSS theory (e.g. Richardson et al., 2003), spatial language studies have tended to focus on the nature of representational structure without considering the second-to-second processes that give rise to those structures. This can lead to an impasse because representations are not strongly grounded in task-specific performance. Consideration of an ongoing debate within spatial language illustrates this point. Because this debate is central to our empirical work, it is considered in some detail.

Evidence for Shared Representations

In order to explore the possible correspondence between the linguistic and sensory-motor representations of space, Hayward and Tarr (1995) conducted a series of experiments designed to compare how object relations are linguistically and visually encoded. In the first experiment, participants were presented with a visual scene depicting a referent object and a target object and asked to generate a preposition describing the relationship. Results suggested that the prototypical spatial positions for "above" and "below" lie along a vertical reference axis and prototypical spatial positions for "left" and "right" lie along a horizontal axis. In addition, use of these terms declines as target positions deviate from the horizontal and vertical reference axes.

Next, Hayward and Tarr built on these findings by using a preposition ratings task. In the ratings task, participants were asked to rate on a scale of 1 (least applicable) to 7 (most applicable) the applicability of a given spatial term (e.g. above) to a relationship between two objects. This ratings task is particularly valuable because it permits quantification and metric manipulation of an otherwise gross measure of linguistic output (e.g. above/not above). As such, this task provides a means of empirically bridging the continuity of sensory-motor representations with the discreteness of linguistic representations. Results from this ratings task showed strong metric effects of spatial language use around the vertical and horizontal axes. For instance, "above" ratings were highest along the vertical axis and systematically decreased as the target object's position deviated from the vertical axis. Hayward and Tarr concluded that this ratings gradient across spatial positions reflected the use of prototypical vertical and horizontal reference axes.

To compare the representational prototypes of spatial language with visual representations of space, Hayward and Tarr compared these findings with performance on location memory and same-different discrimination tasks. Importantly, the areas of highest spatial recall accuracy were vertically aligned with the reference axes used as prototypes in the ratings task. Performance in the same-different location task yielded similar findings, showing that discrimination was best along the vertical and horizontal axes. Collectively, data from these four experiments point to a shared representational spatial structure between linguistic and sensory-motor systems, a result consistent with Barsalou's PSS approach.

Evidence Against Shared Representations

Follow-up results from Crawford, Regier, & Huttenlocher (2000) present a different picture. To probe both linguistic and visual representations of space, they analyzed "above" ratings as well as spatial memory performance. Although results showed an "above" ratings gradient aligned with the vertical axis similar to that of Hayward and Tarr (1995), Crawford et. al. also found location memory bias away from the vertical axis when participants had to recall the locations of targets to the left and right of this axis. These researchers proposed that the cardinal axes that appear to function as prototypes in the linguistic task instead serve as category boundaries in the spatial memory task. Thus, while both linguistic and sensory-motor spatial representations use the same cardinal axes, these axes serve functionally distinct representational roles in the two tasks. It therefore appears that the linguistic and sensory-motor representations of space differ in critical ways, a conclusion consistent with an amodal representational interface perspective.

Considered together, these results illustrate the limits of dealing with representation in the abstract: both sets of researchers used similar experimental tasks and reported largely similar findings, yet they draw starkly different conclusions, conclusions that depend critically on abstract definitions of representational structure. Because we do not yet know the process that selects, creates, and encodes spatial prototypes nor the process used to create a spatial rating, we cannot go beyond abstract representational descriptions to make predictions about the similarities and differences across tasks. Notably, the failure to resolve this particular debate within spatial language mirrors the larger failure to resolve the modal-amodal conflict. In most general terms, the empirical support offered in both cases fails to delineate between the proposed accounts.

A Process Approach to Spatial Language

The theory and data discussed so far appear to be at an impasse, due in part to an emphasis on descriptive accounts of representational systems and a focus on representation in the abstract. To move beyond these fundamental limitations, the current proposal seeks to establish and test a process model that relates spatial memory and verbal performance. Such a process model can move beyond description and representation in the abstract and provide strong, testable predictions.

To lay the foundation of this proposed model, consider again the results of Crawford et al. (2000). The distinguishing result was the finding of spatial memory biases away from the vertical axis. They interpreted this movement away from midline to be a function of bias towards spatial categories. This interpretation is derived from Huttenlocher et al.'s (1991) Category Adjustment (CA) model. According to the CA model, people encode spatial location at two levels. The first level encodes fine-grained information about target location (e.g. angular deviation), while the second level encodes the region or category of target location. Specifically, the CA model proposes that people represent a central or prototypical value within a category that is most representative of that category. To remember a location, these two levels of detail are then combined to produce a remembered target location. Importantly, fine-grained and categorical information can be weighed differently. If, for example, the fine-grained detail is less certain, the prototype can be given more weight, resulting in a bias away from midline. Moreover, evidence from Huttenlocher et al. (1991) indicates that these spatial prototypes lie along the diagonal axes. According to Crawford et al. (2000), these spatial prototypes along the diagonals are the source of the observed spatial memory biases away from midline. Recall, however, that spatial prepositions maintained their highest applicability ratings along the vertical and horizontal axes. Thus, spatial prepositions appear to maintain prototypes along vertical and horizontal axes while spatial categories appear to maintain prototypes along the diagonal axes.

But must the drift away from midline observed in spatial memory performance result from spatial prototypes along the diagonal? A recent model suggests no. Specifically, the Dynamic Field Theory (DFT) (Spencer & Schöner, 2003; Schutte, Spencer, & Schöner, 2003) provides a formalized process account of spatial memory bias away from reference axes without positing prototypes. This model specifies how location-related activation is maintained in spatial working memory (SWM) during short-term delays and how perception and memory are integrated within this single representational system.

The DFT can be best understood within the context of a location memory task used to test predictions of the model. In this task, participants are seated at a large empty table and a spaceship-shaped object is flashed for 2 seconds on the table. After a variable delay, participants are asked to indicate the location of the ship using a computer mouse. Participants in this task show the same biases away from midline reported by Huttenlocher and colleagues. The focus of the DFT is to explain this performance through activation in the SWM field.

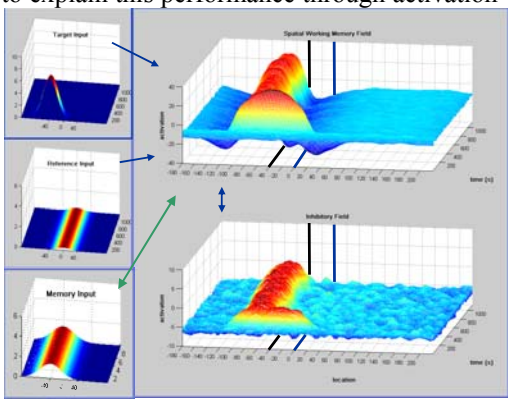

Figure 1 Dynamic Field Theory of spatial working memory

Figure 1 shows the structure of the DFT model. The large box shows the excitatory and inhibitory layers of neurons that together form the SWM field. Each layer has a collection of spatially tuned neurons that respond selectively to a specific location. Spatial location is indicated by position along the x-axis, where 0˚ is the center of the space; positive locations are rightward, and negative locations are leftward. The y-axis represents time which is moving away as a particular experimental trial proceeds from start to finish. The z-axis captures the activation of each neuron in the field.

In addition to the excitatory and inhibitory layers of the SWM field, there are input fields: target input, reference input, and memory input. The upper left portion of Figure 1 shows the target input which feeds into the excitatory layer of the SWM field. This target input turns on when the target is visible and turns off when the target is hidden. Figure 1 also shows the reference input. This reference input captures perception of the midline or vertical symmetry axis, the same axis central to the linguistic and non-linguistic representations of space discussed above. The third input is the long-term memory field which reflects the activation history of the SWM. This field also reciprocally feeds into the SWM field to impact real-time spatial memory processes.

The integration of these inputs in working memory is governed by an interaction function that determines how activation at one site in the SWM field influences activation at other sites. The DFT uses a local excitation and lateral inhibition function. Thus, activation at one site increases the activation of its neighbors and decreases the activation of sites further away. There are two main consequences of the interaction function. First, strong target input can lead to a self-sustaining peak of activation. These self-sustaining peaks of activation maintain themselves even after the target input is removed. In this way the field can maintain a memory of the target location during short-term delays.

The second consequence of the interaction function is that self-sustaining peaks can drift away from reference axes such as midline during memory delays. The process that gives rise to such delay-dependent spatial drift is illustrated in Figure 2. The short activation profile in this figure was generated by running a simulation of the model shown in

Figure 1 with only a single input—the reference input—and taking a time slice through the excitatory layer (top layer in the large panel of Figure 1) of the resultant SWM field (at time 8.00 s). Thus, this short activation profile reflects the influence the reference input has on each neuron in SWM at a particular moment in time (note that, because the reference input in Figure 1 is constant throughout the memory delay, the short activation profile actually captures the resultant influence of the reference input throughout the trial).

As can be seen in Figure 2, the resultant reference profile has stronger activation around midline; however, there are also two troughs in activation to the left and right of midline. These troughs cause systematic delay-dependent drift away from midline when targets are positioned to the left and right of this axis. This is captured schematically by the tall activation profile in Figure 2. As can be seen in Figure 2, this tall activation profile receives slightly more reference-related input on its left side than its right side. As a consequence, neurons on the left side of the activation peak will tend to join into the locally-excitatory interaction, while neurons on the right side of the peak will tend to be laterally inhibited.

The excitatory (top) layer of the SWM field in Figure 1 shows that as this interactive process propagates through time, activation peaks can spatially drift. In particular, Figure 1 shows a simulation of the model during a single trial to a -40º location. At the start of the trial, activation in the excitatory layer of SWM is relatively uniform because no strong inputs are present. At 2 s, the target appears at -40º and the strong target input associated with this event builds a peak of activation in SWM. Importantly, this activation peak sustains itself even after the target disappears at 4 s. And, during the ensuing memory delay, the peak drifts systematically away from midline (i.e., away from 0º). Note that this effect is partially counteracted by the long-term memory input at -40º.

In summary, the DFT provides a process-based alternative to Huttenlocher et al.'s (1991) category adjustment model. Critically, this model links spatial memory biases to a process that integrates remembered information in working memory with perceived reference frames, the same reference frames implicated in research by Hayward and Tarr (1995). As a result, the central argument against Hayward and Tarr's claim of shared structure between linguistic and non-linguistic representations of space—that memory is biased away from a category boundary—no longer follows obligatorily from the data. This provides the impetus to once again consider the potentially rich and direct connections between spatial memory and spatial language.

Connecting the DFT with Spatial Language

Inspired by our model of spatial working memory, we recently conducted a set of experiments designed to investigate Hayward and Tarr's (1995) claim that linguistic and non-linguistic representations overlap, not by examining representational structures in the abstract, but by considering the specific representational structures that emerge in our formalized process model. In particular, we asked whether the processes that create delay-dependent spatial drift in spatial working memory might also leave some empirical signature in a spatial language task. Toward this end, we used the ratings task from Hayward and Tarr given its capacity to reveal quantifiable metric effects and its centrality in the spatial language literature (e.g., Hayward & Tarr, 1995; Crawford et al., 2000; Logan & Sadler, 1996; Regier & Carlson, 2001).

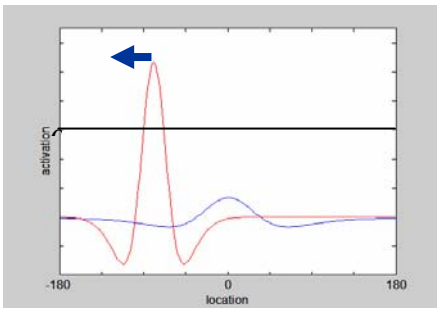

Figure 2 Local excitation/ lateral inhibition

To relate the DFT to performance in the ratings task, we borrowed an idea from Regier and Carlson's (2001) Attentional Vector Sum model and scaled verbal ratings for "above" by the angle between the representation of the target location and the representation of the reference axis, that is, by the spatial distance between the center of the activation peak in SWM and the midline axis (0º). Ratings should be highest when activation is centered at 0º and should fall off systematically as the activation peak is shifted to the left or right. Based on this proposal and the dynamic properties of the DFT, we predicted that if spatial language and spatial memory use the same representational system—spatial working memory—then ratings performance should show delay-dependent "drift", giving systematically lower "above" ratings as memory delays increase (i.e. as the distance between the activation peak in SWM and the midline axis increases).

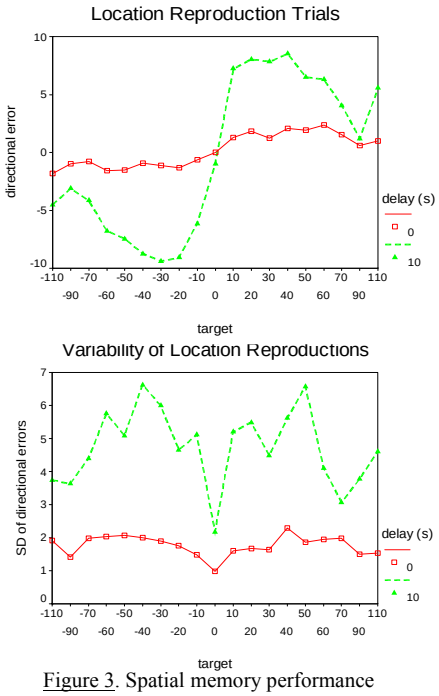

Figure 3. Spatial memory performance

Experimental Support

Subjects. 15 University of Iowa undergraduates participated in this study in exchange for class credit or payment.

Method. Experimental sessions were conducted in dim lighting in a room with black curtains covering all external landmarks. A curved border occluded the corners of the table (and therefore the diagonal symmetry axes).

A single referent disc appeared at midline 30cm in front of the participant and remained visible throughout each presentation trial. At the start of each trial the participant moved a computer mouse to this disk. A number (100-500) then appeared and participants begin counting backwards by 1s aloud until they made a response. This counting task prevented the verbal encoding and maintenance of the spaceship position or rating. A small, spaceship-shaped target then appeared on the screen for two seconds.

Trial Types For spatial memory trials, participants were instructed to move the mouse to the location corresponding the ship's location when the computer says "Ready-Set-Go". For spatial language rating trials, on the other hand, participants are instructed to rate on a scale of 1 ("definitely not above") to 9 ("definitely above") the extent to which the word "above" describes the spaceship's location relative to the reference disk and say their rating when the computer says "Please give your 'Above' rating." The spoken stimuli that indicated which response to provide were each 1500ms in duration. In No Delay conditions, completion of the spoken stimulus was timed to coincide with the offset of the spaceship target. In the 10s Delay conditions, completion of the spoken stimulus occurred exactly 10 seconds after the disappearance of the spaceship target. Spaceship targets appeared at a constant radius of 15cm at 19 different locations relative to the midline axis (0º): every 10º from -70º to +70º as well as ±90º and ±110º to map onto previous research.

Results

Participants in our modified spaceship task either gave a spatial memory response or a verbal ratings response (1 = "definitely not above", 9 = "definitely above") after a 0 s or 10 s delay. The top portion of Figure 3 shows directional errors on the memory trials across target locations and delays. Positive errors were clockwise, while negative errors were counterclockwise. Consistent with previous work (Spencer & Hund, 2002), directional error was larger in the 10 s delay condition and responses were systematically biased away from midline (responses to negative or leftward targets showed counterclockwise bias; responses to positive or rightward targets showed clockwise bias). Similar effects were found for variable error (see lower portion of Figure 3). Specifically, variability was higher in the 10s delay condition, and responses to targets to the left and right of midline were more variable than responses to the target aligned with 0º.

Critically, we also found the predicted delay-dependent drift effect in participants' ratings performance. The top portion of Figure 4 shows that "above" ratings in the spaceship task followed a gradient similar to that obtained by Hayward and Tarr (1995) and Crawford et al. (2000). However, there was a systematic and significant decrease in ratings in the 10 s delay condition. Examination of ratings variability revealed effects of delay comparable to those found on the spatial memory trials (see Figure 4). Specifically, ratings variability was higher at the long delay and lower for targets near the midline axis.

In a final analysis, we compared spatial memory and ratings responses directly by converting the ratings "drift" apparent in Figure 4 into a spatial deviation measure (e.g., deviation at 10º target = (change in 10 s delay rating between 10º and 20º) * 10º / (change in 0 s delay rating between 10º and 20º)). This analysis revealed a high degree of overlap in delay-dependent spatial drift across the two tasks (see Figure 5). These results support the prediction we generated from the DFT and suggest that a shared working memory representation underlies performance in both tasks.

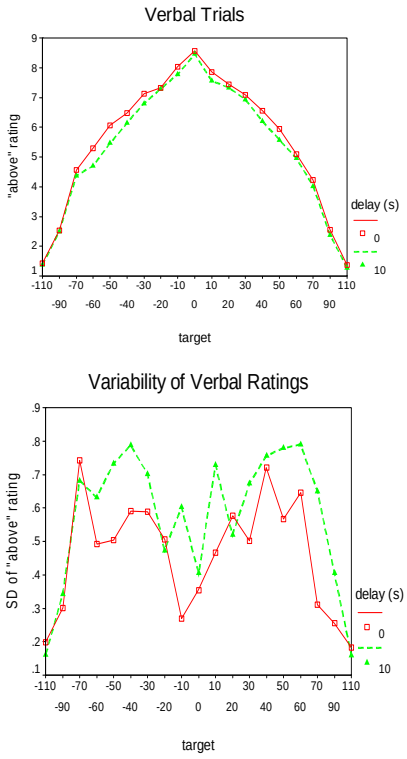

Figure 4 Ratings performance

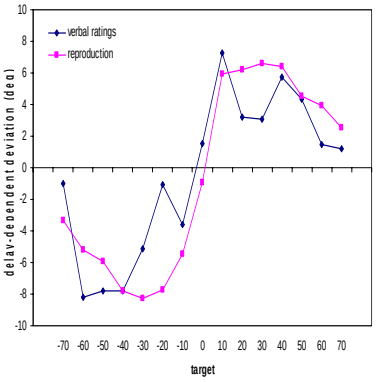

Figure 5 Ratings and drift

Towards a Dynamic Field Model of Spatial Language Performance

Given that we have a formal theory of SWM and encouraging preliminary data, we are in a unique position to develop a process model of both spatial memory and verbal behavior in spatial tasks. The starting point of such a model will be a modified dynamic field model that links two dynamic fields—the SWM field discussed previously and a new spatial prepositions field. Although this new spatial prepositions field has yet to be formalized, the current data suggest two important features. First, this field must be alignable with particular locations in SWM, in particular with perceived reference frames. We are currently developing a process within the field theory that handles the alignment of multiple fields, including the anchoring and scaling necessary in such situations. Critically, these processes must be developed in a way that allows for

generalizability to spatial prepositions beyond "above" such as "left", "right", and "below".

Second, consistent with the dynamic nature of the tasks employed here, and cognition more generally, the two fields should be dynamically coupled. This means that activation in SWM can serve as input to the spatial preposition field and vice versa. This dynamic coupling is critical given the presented evidence that verbal ratings reflect the same dynamic processes underlying spatial working memory performance. If these layers are indeed dynamically coupled as we suggest, then establishment of stable activation peaks within one layer should give rise to stable peaks in the other. Similarly, instability and drift within one layer should give rise to a instability and drift within the other layer. Experiments are currently underway to test these specific predictions.

Although this provides only a limited window onto the dynamic processes that underlie a very flexible spatial cognitive system, we contend that this is an appropriate starting point given the novelty of our general theoretical approach. Indeed, the results of our current experiments will provide the empirical foundation for a more extensive formal model that links spatial working memory with spatial language processes.

Abstract

In this paper we explore the role of simplicity in choosing between competing explanations, and in particular how a preference for simplicity is integrated with information about the probability of particular explanations. In Experiment 1 we establish that all else being equal, people prefer explanations that are simpler in the sense of invoking fewer causes. Experiment 2 finds that people require disproportionate evidence in favor of a complex explanation before they will choose it over a simpler alternative. Experiment 3 suggests that this bias is not driven by assumptions about the probabilistic dependence of causes. Finally, Experiment 4 replicates the basic findings with a more ecologically valid computer task. We also find that participants who prefer a simpler but less probable explanation overestimate the frequency of events that would make the simpler explanation more probable. We conclude by suggesting that people believe simpler explanations are more likely to be true in virtue of being simple.

Introduction

Explaining the world around us is a fundamental part of everyday life. We wonder why objects have the properties they do, why people act in particular ways, and why things do or don't happen. But more often than not, explanations are vastly underconstrained by our knowledge and the available data. When more than one explanation is possible, how do we choose between them? A plausible constraint on competing explanations, often attributed to William of Occam, is simplicity. Here we explore whether people in fact prefer simpler explanations, and if so how they balance a preference for simplicity with the desire to maximize other virtues of explanation, like their probability of being true. We show that people do prefer simpler explanations, even when they are less probable than more complex alternatives. We also show that this preference can lead to systematic distortions in the perceived frequency of events.

A Metric for Simplicity

While simplicity is commonly invoked, it is notoriously difficult to formalize and justify. Several recently proposed approaches, like the Akaike Information Criterion (AIC) (e.g. Sober, forthcoming), Bayesian Occam's razor (e.g. Jeffreys & Berger, 1992), Minimum Description Length (MDL) and Kolmogorov Complexity (e.g. Chater & Vitanyi, 2003), nonetheless succeed in precisely specifying a metric for simplicity in the language of statistics and computer science. What's more, these metrics can be motivated on principled grounds. The AIC warrants a preference for simplicity by showing that simpler explanations are more likely to generalize. Similarly, Bayesian Occam's Razor shows that a simpler explanation will have a higher posterior probability. From a bottom-up perspective, considerations of processing constraints make measures like MDL and Kolmogorov complexity attractive.

While compelling, formal measures of simplicity are generally formulated over well-defined problems like line fitting, which bear little resemblance to the complex inductive leaps that characterize everyday explanatory judgments. For this reason we looked to the history of science for a more psychologically plausible metric. In the *Principia*, Newton wrote that "we are to admit no more causes of natural things than such as are both true and sufficient to explain their appearances" (1686). This maxim, similar to Occam's statement that entities should not be multiplied beyond necessity, suggests that explanations invoking fewer causes are to be preferred. We thus chose to quantify simplicity in terms of number of causes, where explanations involving fewer causes are simpler.

Simplicity and Probability

Newton's endorsement of explanations with fewer causes was likely grounded in metaphysical assumptions. After the quote above, he went on to suggest that "nature is pleased with simplicity and affects not the pomp of superfluous causes." If nature is in fact simple, then simple explanations are more likely to be true.

In the first experiments reported below we explore whether people prefer explanations involving fewer causes, but also if this preference is motivated by the belief that simpler explanations are more likely to be true. We examine the relationship between simplicity and probability both directly and indirectly. As a direct test, we look at people's justifications for choosing a simpler explanation. More indirectly, we look at whether people switch their preference from a simpler to a more complex explanation when provided with evidence that the more complex explanation is more likely.

Seeing how people balance the competing explanatory virtues of simplicity and probability can help distinguish

two possible hypotheses about the nature of a preference for simplicity. According to what we call the *probabilistic metric* hypothesis, people prefer simpler explanations, but represent this preference in terms of probability. That is, simpler explanations are believed to be more likely to be true in virtue of being simple. While choosing between competing explanations involves deciding which is most likely to be true, simpler explanations gain a probabilistic boost just for being simple. A second hypothesis is the *trade-off* hypothesis, according to which simplicity and probability are independent virtues of explanation that must be integrated according to some weighting function. The *probabilistic metric* hypothesis differs from the *trade-off* hypothesis in that the former claims the preference for simpler explanation is expressed in terms of probability, whereas the latter assumes that simplicity and probability trade-off in a way that is not commensurate.

In the final experiment we go on to explore the consequences of a tendency to favor simpler explanations. Specifically, does the preference for simpler explanations distort our perception of probability? If so, we would expect people's preferred explanations to influence their frequency judgments.

Experiments

All experiments we report involve a simple task adapted from Lagnado (1994) in which participants are asked to choose between one and two diseases to account for some symptoms. By varying the prevalence of the diseases we were able to manipulate the relative probability of the simpler, one-disease explanation to the more complex, two-disease explanation.

Experiment 1: Explanatory Virtues

Before examining how people integrate information about simplicity and probability in explanation, we wanted to confirm that simplicity and probability are indeed virtues of explanation.

Methods Twenty-four Boston-area undergraduate and summer school students completed a questionnaire in one of two conditions: the *simplicity* condition and the *probability* condition.

In the *simplicity* condition, participants read the following:

> There is a population of 750 aliens that lives on planet Zorg. You are a doctor trying to understand an alien's medical problem. The alien, Treda, has two symptoms: Treda's **minttels are sore** and Treda has developed **purple spots**.
>
> **Tritchet's syndrome** always causes both **sore minttels** and **purple spots**.
>
> **Morad's disease** always causes **sore minttels**, but the disease never causes **purple spots**.
>
> When an alien has a **Humel infection**, that alien will always develop **purple spots**, but the infection will never cause **sore minttels**.
>
> Nothing else is known to cause an alien's **minttels to be sore** or the development of **purple spots**.

They were then asked to choose the *most satisfying* explanation for Treda's symptoms among a list of possibilities that included every disease individually and every pairwise combination of diseases. Choosing Tritchet's syndrome would be the simplest option; choosing Morad's and a Humel infection is a more complex alternative.

In the *probability* condition, the cover story was similar, but participants were asked to choose between two diseases that each accounted for both symptoms. However, one disease was said to be present in about 50 of the aliens on Zorg, while the other was present in about 73 aliens on Zorg, making the latter choice the more probable option.

After choosing an explanation, participants were also asked to explain their reasoning. The names of the diseases were counterbalanced and we used three different sets of symptoms.

Results and Conclusions In the *simplicity* condition, 100% of participants chose the simpler explanation. They justified this choice about equally often by appeal to simplicity and probability: 50% explicitly said they chose it because it was simpler, while 42% said they thought it was more likely for the alien to have one disease than two. In the *probability* condition, 92% of participants chose the more probable explanation. All participants justified this choice by appeal to probability.

Experiment 2: Simplicity Versus Probability

Having established that people do prefer both simpler and more probable explanations, we went on to see how these virtues of explanations are traded off. To do so we had participants choose explanations in cases where the simplest was not the most likely to be true.

Methods One-hundred-thirty-seven Boston-area summer school and undergraduate students participated by completing a questionnaire. The questionnaire was like the *simplicity* condition from Experiment 1, but participants were additionally given information about the prevalence of each disease in the population. For example, one questionnaire read:

> There is a population of 750 aliens that lives on planet Zorg. You are a doctor trying to understand an alien's medical problem. The alien, Treda, has two symptoms: Treda's **minttels are sore** and Treda has developed **purple spots**.
>
> **Tritchet's syndrome** always causes both **sore minttels** and **purple spots**. **Tritchet's syndrome** is present in about 50 aliens on Zorg.
>
> **Morad's disease** always causes **sore minttels**, but the disease never causes **purple spots**. **Morad's disease** is present in about 225 of the aliens on Zorg.
>
> When an alien has a **Humel infection**, that alien will always develop **purple spots**, but the infection will never cause **sore minttels**. You know that Humel Infections are present in about 210 of the aliens on Zorg.

Nothing else is known to cause an alien's **minttels to be sore** or the development of **purple spots**.

As in Experiment 1, they were then asked to choose the most satisfying explanation and selected among six options, which included each disease individually and every pairwise combination. On a second page of the questionnaire they were asked to justify their choice, and also to complete a math problem. The math problem required participants to compute the joint probability of winning at two slot machines and compare this to the probability of winning at a different machine. We included this problem to see whether participants knew how to compute joint probabilities.

We varied the prevalence of the diseases to manipulate the relative probability of having the single disease causing both symptoms (D_1) to having both of the other diseases (D_2&D_3). Table 1 indicates the 8 sets of values we used, along with the corresponding probability ratios, which were computed on the assumption that the diseases are probabilistically independent. There were 14 to 18 participants per condition.

Table 1: Disease prevalence for each frequency condition.

D_1	D_2	D_3	$P(D_1):P(D_2\&D_3)$
50	50	50	15:1
50	197	190	1:1
50	195	214	9:10
50	225	210	4:5
50	250	220	2:3
50	268	280	1:2
50	330	340	1:3
50	610	620	1:10

Explanation justifications were coded into one of three categories: simplicity, probability, and other. Justifications were coded as 'simplicity' if (1) the participant explicitly mentioned simplicity, or (2) the justification emphasized that the *single* disease accounted for *both* symptoms, thus suggesting that it was unnecessary to invoke two diseases when one would do the trick. Justifications were categorized as 'probability' if the participant claimed their choice was more probable or seemed more likely to be true. Both participants who computed the joint probability of D_2&D_3 and those who went on a subjective feeling of probability were included in this category. Finally, participants whose justifications could not be classified as simplicity or probability were included in the 'other' category. Often these justifications included a restatement of the question ("it seemed best" or "it seemed most satisfying") or an appeal to general intuition ("I went with my gut feeling").

As before, the disease names were counterbalanced, and the explanation choices were presented in random order. In addition, we counterbalanced the order of the presentation of the diseases such that half the participants read about D_1 first and half read about D_1 last. We used three different sets of symptoms.

Results and Conclusions Figure 1 indicates the percentage of participants choosing the simpler explanation in each frequency condition. Nearly all participants chose the simpler explanation when the probability ratio of D_1 to D_2&D_3 was close, but this number steadily declined as it became increasingly probable that an alien had D_2&D_3. Even when it was ten times more likely for the alien to have D_2&D_3, however, over a third of participants were still choosing the simpler explanation. Nor was this preference for the simpler explanation due to participants' inability to compute joint probabilities. The correlation between explanation choice and answering the math problem correctly was small and not significantly different from zero ($r = .12$, $p > .15$).

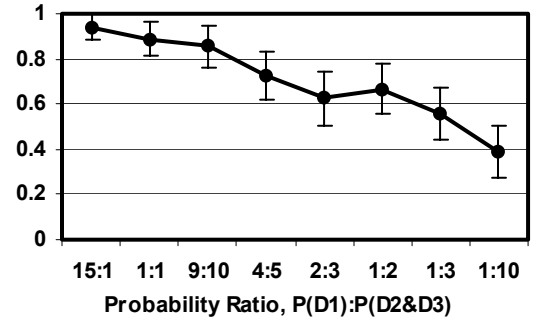

Figure 1: Percent of participants choosing simpler explanation as a function of the probability condition.

To better understand the data we conducted a logistic regression analysis. We used the natural log of the probability ratio as the predictor for the percentage of participants choosing the simpler explanation, as this choice results in a straightforward interpretation of the regression parameters. To understand why, it helps to consider how these parameters relate to the computations that would be performed by an idealized Bayesian agent. In our task, the ideal agent's data would result in a slope parameter of 1 and a constant of 0. A non-ideal agent could have a bias in favor of simplicity at either of two stages in the inference process, each corresponding to a parameter of the logistic function. A slope significantly less than 1 would suggest that the agent underweights the importance of probability: as evidence in favor of D_2&D_3 accumulates, the agent fails to reduce the probability of choosing D_1 accordingly. In contrast, a constant significantly different from zero reflects a bias at the level of the prior probability. The non-ideal agent could overweight, underweight, or appropriately weight probability information, but starts out with disproportionate confidence that D_1 is true.

The *probabilistic metric* and *trade-off hypotheses* make different predictions about the parameters of the logistic function resulting from this analysis. Specifically, the *probabilistic metric* hypothesis requires that the slope parameter be 1. If the preference for simplicity is represented in terms of probability, then probability information should be weighted appropriately. The constant, however, could be significantly different from 0. In contrast, the *trade-off* hypothesis makes no predictions about these parameters. Because simplicity and probability are

evaluated on different metrics, the bias could be reflected in either or both parameters.

The regression analysis resulted in a constant significantly different from zero, but a slope not significantly different from one. This provides some support for the *probabilistic metric* hypothesis. Specifically, the data suggest that as a group, participants think the simpler explanation is more likely than the complex alternative by a factor of about 4 (1.4 to 9, .95 confidence interval), and this belief influences what would be the prior probability in a Bayesian computation. When the probability ratio is 1:2, the percentage of subjects choosing the simpler explanation corresponds to the ideal Bayesian's posterior probability for D_1 at a frequency of 1:(2/4), and so on for the other values. As a result, participants require disproportionate evidence in favor of the complex explanation before it can rival the simpler alternative. Nonetheless, the slope of the regression suggests that participants incorporate probability information appropriately in making a decision.

We can also examine participants' beliefs about simplicity by looking at how they justified their explanation choices. When the simpler explanation was also more probable, a majority of participants justified choosing the simpler explanation by appeal to probability. However, 'simplicity' and 'other' explanations became increasingly common as the simpler explanation became less probable. These trends are illustrated in Figure 2, which indicates the percent of each justification type for the simpler explanation. Because there were few participants in some categories, the figure combines data from pairs of probability ratios.

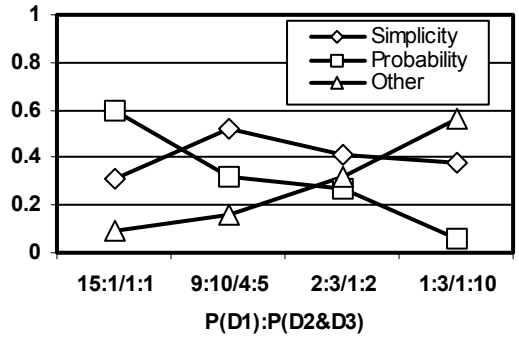

Figure 2: Distribution of justifications for choosing the simpler explanation.

Overall, the data suggest that many participants thought simpler explanations were more likely to be true. This is most apparent from the logistic regression analysis, but is also supported by the patterns of explanation justifications. In particular, many participants justified the choice of a simpler explanation by appeal to probability in conditions where the more complex explanation was as much as two times more likely. The data from the math problem suggest that this preference does not result from an inability to compute joint probabilities, but Experiment 3 considers and eliminates another alternative explanation.

Experiment 3: Independence Assumptions

In Experiment 2 we found that participants chose the simpler explanation well beyond the point at which a more complex alternative was more probable. However, the probability values against which we compared participants' choices were calculated on the assumption that diseases D_2 and D_3 are probabilistically independent—that is, that $P(D_2|D_3) = P(D_2)$ and $P(D_3|D_2) = P(D_3)$. As participants were told nothing about the dependence of the diseases, it's possible that they made a different assumption. In particular, if $P(D_2|D_3)$ is much smaller than $P(D_2)$, participants would be warranted in choosing D_1 on probabilistic grounds.

In Experiment 3 we were interested in determining participants' beliefs about the dependence of diseases. We also wanted to assess whether such beliefs influence explanatory preferences. To do so we found a domain involving dependence assumptions distinct from those for diseases, and examined whether more participants chose the complex explanation for this domain.

Methods Sixty-eight Boston-area undergraduate and summer school students participated. Twenty were in the *assumptions* condition, where we explicitly asked participants to provide a judgment of probabilistic dependence as follows:

> Suppose there are two diseases with similar symptoms, D_1 and D_2. Do you think someone who has D_1 is more or less likely to have D_2 than someone who does not have D_1?
> *Circle one*: **More** **Less**

In addition to asking about the dependence of diseases, we also wanted to find items with a different dependence assumption. We thus queried participants about books:

> Suppose there are two books on similar topics, B_1 and B_2. Do you think someone who has read B_1 is more or less likely to have read B_2 than someone who has not read B_1?
> *Circle one*: **More** **Less**

Participants in the *assumptions* condition saw both the disease and book questions, with the order counterbalanced.

The remaining 48 participants performed a task like Experiment 2 at the 2:3 probability ratio. However, half were asked about diseases, while the remaining half saw a formally identical question about books. Instead of reasoning about diseases causing symptoms, they were asked about books 'causing' knowledge of facts. For example, a passage read: "***The Zorgian Guide to Interplanetary Living*** contains the fact that **Planet Earth has an atmosphere** and the fact that **humans have two legs**. You know that about 50 aliens on Zorg have read ***The Zorgian Guide to Interplanetary Living***."

Results and Conclusions We first analyzed the data from the *assumptions* condition. Most participants (80%) claimed that having a disease makes someone *less* likely to have a similar disease, but 80% thought that having read a book makes someone *more* likely to have read a similar book.

These values were significantly different from chance, as well as being significantly different from each other ($\chi^2(1) = 14.4$, $p < .01$). Having thus established that people have different dependence assumptions about diseases and books, we went on to look at whether these assumptions affect explanatory preferences.

Replicating Experiment 2, we found that about half (46%) of participants chose the simpler explanation at the 2:3 probability ratio in the disease condition. In the book condition the results were identical, with 11 of 24 participants (46%) choosing the simpler explanation. There were also no differences between conditions in how participants justified their choice. The absence of a difference between the disease and book conditions suggests that beliefs about probabilistic dependence do not account for participants' preference for simpler explanations.

Experiment 4: Computer Replication

In the previous experiments participants were informed of the prevalence of each disease by being presented with a frequency. This method has two limitations. First, in the real world most frequency information is acquired through experience rather than a summary value, making the ecological validity of the task questionable. Second, having actual numbers allowed some participants to compute the joint probability of the diseases rather than relying on subjective judgments. For these reasons we decided to replicate the basic task in a computer format. Doing so also allowed us to examine whether explanatory preferences have consequences for perceived frequencies.

Methods One-hundred-and-eight Boston-area summer school and undergraduate students participated. The task was like Experiment 2, but on the computer. Instead of being told the prevalence of the diseases, for each disease participants saw ten screens containing a total of 75 aliens, some of which were marked as having a particular disease. In this way equivalent frequency information was communicated.

Participants were in one of four frequency conditions corresponding to probability ratios of 15:1, 9:10, 1:2 and 1:10, with 27 participants per condition. After being presented with the cover story and frequency information, participants were asked to choose the most satisfying explanation for the alien's symptoms and, as before, selected an answer among six options, which included every disease alone and each pairwise combination. They were then asked to explain their choice and to estimate the frequency of each disease in the Zorg population.

Counterbalancing and randomization was as in Experiment 2, with the additional control that the order of presentation of the disease frequencies was varied according to a Latin square.

Results and Conclusions The overall explanatory preferences in the computer task replicated those of Experiment 2, suggesting that the questionnaire format was methodologically sound (see Figure 3). Virtually all participants chose the simpler explanation when it was more likely, but nearly half continued to prefer the simpler explanation when it was as much as ten times more likely that the alien had two diseases.

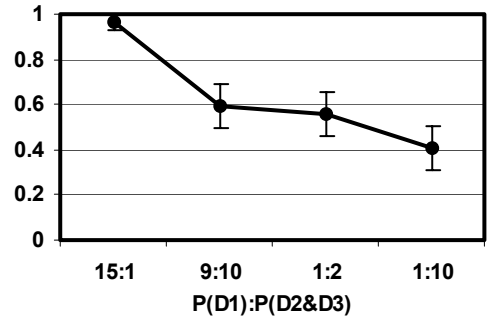

Figure 3: Percent of subjects choosing simpler explanation in computer task.

We also analyzed justifications for choosing the simpler explanation, using the coding scheme from Experiment 2. Not surprisingly, as the simpler explanation became less probable, a larger proportion of participants invoked simplicity rather than probability in their justifications (see Figure 4).

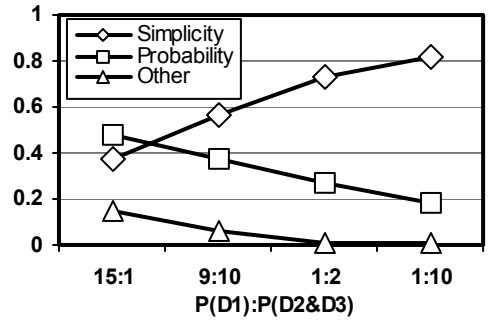

Figure 4: Distribution of justifications for choosing the simpler explanation in the computer task.

Using a computer task allowed us to examine an aspect of simplicity we couldn't address in the questionnaire format, namely how explanatory choices affect perceived frequencies. Figure 5 presents participants' estimates of the percentage of the Zorg population with each of D_1, D_2, and D_3. The average estimates are shown as a function of both frequency condition and explanation choice, with participants who chose the simpler, one-cause explanation distinguished from those who chose the more complex, two-cause explanation. Solid lines indicate the actual percentage of aliens with each disease.

While subjects were remarkably accurate overall, the data for D_1 suggest that those participants who chose the simple, one-cause explanation when it was less probable systematically overestimated the frequency of D_1. In both the 1:2 and 1:10 frequency conditions, the average estimate of participants who chose the simpler explanation were

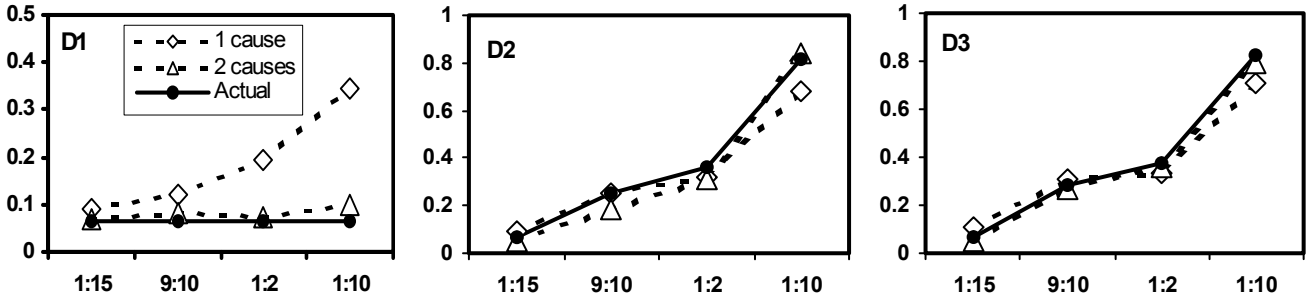

Figure 5: Average frequency estimates for each disease as a function of probability ratio and explanation choice.

significantly higher than that of participants who chose the more complex alternative ($p < .05$). One possibility, however, is that some subjects confused the frequency of D_1 with either D_2 or D_3, which would result in inflated D_1 estimates. If this were true we would expect to see systematic underestimation of D_2 and D_3. Moreover, only one subject provided a higher estimate for D_1 than either D_2 or D_3. This suggests that the overestimation of D_1 is not due to mismatching the frequencies and their corresponding diseases.

Another explanation for the D_1 overestimation is that participants who chose the simpler explanation were bad at estimating frequencies, and for this reason based their explanation choice on simplicity. This possibility is ruled out by the frequency estimation data for D_2 and D_3, where there were no differences between the estimates of participants who chose one or two cause explanations.

These data suggest that participants who chose the simpler explanation systematically overestimated the frequency of D_1 *as a result* of their explanation choice. However, it could be that some participants overestimated D_1, which in turn lead them both to choose the simpler explanation and to indicate a high prevalence of D_1. Evidence that the former interpretation is the correct one comes from the fact that participants never systematically overestimate D_1 in the 1:15 condition, when simplicity and probability converged on the same explanation.

Conclusions

We began by considering whether people prefer simpler explanations, and whether this preference is supported by a belief that simpler explanations are more likely to be true. We found overwhelming evidence for the claim that people do prefer simpler explanations, at least where simplicity is understood in terms of number of causes. Participants consistently chose a simpler explanation when provided no information about probability, and required a disproportionate amount of probability information in order to override this preference.

These findings are consistent with the idea that people believe simpler explanations are more likely to be true, albeit implicitly. Many subjects explicitly justified their choice of a simpler explanation by appeal to probability, but more telling is the fact that participants evaluated simplicity and probability as if they were commensurable quantities. The results from Experiment 2 tentatively support the *probabilistic metric* hypothesis over the *trade-off* hypothesis: people do prefer simpler explanations, but this bias manifests as a reweighing of priors rather than a failure to appropriately incorporate probability information.

The intimate relationship between simplicity and probability is most dramatically illustrated by the finding that committing to an improbable, simple explanation results in the systematic distortion of perceived frequencies. This result indicates that explanatory choices can have consequences for probabilistic judgments, and suggests that the study of explanation can provide a unique window into the mechanisms by which beliefs about the world influence decisions.

Abstract

This paper investigates the variation in cohesion across written and spoken registers. The same method and corpora were used as in Biber's (1988) study on linguistic variation across speech and writing; however instead of focusing on 67 linguistic features that primarily operate at the word level, we compared 236 language and cohesion features at the text-level. Variations in frequencies across these features provided evidence for six dimensions: (1) speech versus writing, (2) informational versus declarative, (3) factual versus situational, (4) topic consistency versus topic variation, (5) elaborative versus constrained, (6) narrative versus non-narrative. Our cohesion and linguistic analysis showed most variation in speech and writing, whereas the linguistic feature analysis operating at the word level did not yield any difference.

Introduction

One way to investigate similarities and differences between speech and writing is by using corpus linguistic methods. The most common and largest investigation of this kind is Biber (1988). Biber used 23 spoken and written registers. These registers are language varieties mediated by social situations and are similar to genres. Biber took these registers from the Lancaster-Oslo-Bergen (LOB) corpus and the London-Lund corpus, and computed the frequency of 67 linguistic features in these registers (see Table 1 for an overview of registers).

The linguistic features used for Biber's analysis primarily operate at the word level (e.g., parts-of-speech) and can be categorized as (1) tense and aspect markers, (2) place and time adverbials, (3) pronouns and pro-verbs, (4) questions, (5) nominal forms, (6) passives, (7) stative forms, (8) subordination features, (9) prepositional phrases, adjectives and adverbs, (10) lexical specificity, (11) lexical classes, (12) modals, (13) specialized verb classes, (14) reduced forms and dispreferred structures, and (15) coordinations and negations.

Table 1. The 23 registers used in Biber (1988)

Corpus	Register
Lancaster-Oslo-Bergen corpus	Press reportage, editorials, press reviews, religion, skills and hobbies, popular lore, biographies, official documents, academic prose, general fiction, mystery fiction, science fiction, adventure fiction, romantic fiction, humor
London-Lund corpus	Face-to-face conversation, telephone conversation, public conversations, debates, and interviews, broadcast, spontaneous speeches, planned speeches
(Additional)	Personal letters, professional letters

In Biber's study the normalized frequencies of these features in each of the registers were then entered in a factor analysis, from which six factors emerged. These factors can be seen as dimensions on which registers can be placed. Biber's analysis showed that no single dimension comprised a difference between speech and writing; As such, Biber defined the sets of relations among texts as follows:

1. Involved versus informational production
2. Narrative versus non-narrative concerns
3. Explicit versus situation dependent reference
4. Overt expression of persuasion
5. Abstract versus non-abstract information
6. On-line informational elaboration.

For example, registers such as romantic fiction, mystery fiction and science fiction were positioned high on the second dimension (narrative); whereas registers such as academic prose, official documents, hobbies, and broadcasts scored low (non-narrative).

Biber's (1988) study and the multi-feature, multidimensional approach have become a standard in corpus linguistics (McEnery, 2003), leading to various extensions (Biber, Conrad & Reppen, 1998; Conrad &

Biber, 2001), as well as to assessments of the validity, stability, and meaningfulness of the approach and its findings (Lee, 2004).

Measuring cohesion

Texts obviously consist of a large variety of linguistic features, many of which can be identified at a word level (e.g. morpho-semantics, syntactic category, frequency). Biber's study has shown that these linguistic features are powerful determiners of similarities and differences between registers. But despite these impressive results, the theoretical question that remains lurking is to what extent these linguistic features fully capture the nature of a text and thereby the nature of a register.

Although linguistic features operating at the word level may identify several register characteristics, we also know that one of the key features of a text is that it is not just a concatenation of words and sentences. Instead, there is a structure in the text that glues the various text components together. In comprehending the text, the reader or listener constructs a coherent, mental representation of the situations which have been cohesively described by the text. We have used the term "coherence" for the representational relationships and "cohesion" for the textual indications through which coherent representations should be built (Louwerse & Graesser, 2004). Cohesion, it should be noted, cannot be captured only by linguistic features at the word level. Instead, cohesion stretches to the inter-clause, inter-sentence and inter-paragraph level.

But if a key component in the nature of text consists of cohesion, a practical issue related to the theoretical question needs to be addressed. Linguistic features that operate at a word level can currently be reliably identified by regular expressions, part-of-speech taggers, and syntactic parsers. However, there is the practical question of whether automated techniques can also capture the cohesion of text. Recent landmark progress in computational linguistics has indeed allowed us to go far beyond surface level components into automating deeper and global levels of text and language analysis (Jurafsky & Martin, 2001). This progress has resulted in the cohesion and coherence measurement tool Coh-Metrix.

Coh-Metrix

Coh-Metrix was initially developed in order to replace readability formulas that exclusively focus on simple and shallow metrics. Instead, Coh-Metrix is sensitive to a broader profile of language and cohesion characteristics. It analyzes texts on 236 types of cohesion relations and measures of language, text, and readability (McNaramara, Louwerse, & Graesser, 2002; Graesser, McNamara, & Louwerse, in press). For this paper, we will only focus on the textual features (cohesion) of the tool.

The modules of Coh-Metrix use lexicons, part-of-speech classifiers, syntactic parsers, templates, corpora, latent semantic analysis, and other components that are widely used in computational linguistics. For example, the MRC database (Coltheart, 1981) is used for psycholinguistic information; WordNet (Miller, Beckwith, Fellbaum, Gross & Miller) for underlying lexical concepts; Latent Semantic Analysis (Landauer & Dumais) for the semantic similarities between words, sentences and paragraphs; the ApplePie parser (Sekine & Grishman, 1995) and the Brill (1995) part-of-speech tagger for a variety of syntactic categories.

Spatial restrictions do not make it possible to discuss all of the measures Coh-Metrix makes available. As such, a brief summary of key measures will have to suffice, whereas Graesser et al. (in press) has a more complete overview.

1. *Word information* includes word familiarity, word concreteness, word imageability, meaningfulness, and age of acquisition.
2. *Word frequency* includes four corpora-based standards: CELEX from the Dutch Centre for Lexical Information (Baayen, Piepenbrock & Van Rijn, 1993); the Kucera-Francis norms (Francis & Kucera, 1982); Thorndike-Lorge norms (Thorndike & Lorge, 1942) and the Brown norms (Brown, 1984).
3. *Part of speech* categories are adopted from the Penn Treebank (Marcus et al., 1993) and the Brill (1995) POS tagger.
4. *Pronoun density* is computed by taking the ratio of pronouns and nouns.
5. *Logical operators* are the incidence score of logical operators *or*, *and*, *not*, and *if-then* phrases
6. *Interclausal relationships* are the additive, temporal and causal cohesion based on connectives between clauses. These can be positive (extending) and negative (adversative), as outlined in Louwerse (2001).
7. *Type-token ratio* refers to the number of unique words divided by the number of tokens of the words.
8. *Polysemy* and *hypernym*: Polysemy is measured as the number of senses of a word in WordNet; whereas the hypernym count is defined as the number of levels in a conceptual taxonomic hierarchy that is superordinate to a word.
9. *Concept clarity* is a composite of multiple factors that measure ambiguity, vagueness, and abstractness.
10. *Syntactic complexity* refers to the noun-phrase density, the mean number of modifiers per noun phrase, the number of high-level constituents per word and the incidence of word classes that signal logical or analytical difficulty.
11. *Readability* scores are computed according to the Flesch Reading Ease formula and the Flesch-Kincaid Grade Level formula, the standard readability formulas.
12. *Coreference*: Three forms of coreference between sentences are computed, namely noun overlap between sentences, stem overlap, and stem-noun overlap.
13. *Causal cohesion* is interpreted as the ratio of causal particles to causal verbs.
14. *Latent semantic analysis*: LSA is a statistical, corpus based, technique used to represent world knowledge that computes similarity comparisons for terms and documents by taking advantage of word co-occurrences. LSA scores

can be computed for sentence to paragraph, sentence to text, paragraph to paragraph and paragraph to text. These measures can be used for measuring the local and global cohesion of the text (see Kintsch, 2002; Landauer & Dumais, 1997).

The advantage of the use of this wide range of computational linguistic tools is that Coh-Metrix is sensitive to variations in language, discourse, and cohesion. Such an analysis may not only help us to determine text difficulty, but may also help us with determining variations across registers.

Multi-dimensional study on cohesion

In our multi-feature, multi-dimensional approach we carefully followed Biber's study to allow comparison of his findings. We used the same fifteen written registers from the LOB corpus and the same six spoken registers from the London-Lund corpus. Two further non-published registers (professional and personal letters), which Biber had generated himself, were substituted with the *Compilation of Messages and Letters of the Presidents* Richardson (2003/1801) and *The Upton Letters* from Christopher Benson (1905), both downloaded from the Gutenberg text archives.

All textual coding other than alphanumeric characters and punctuation was removed. The 23 spoken and written registers were then processed through Coh-Metrix and the normalized frequencies for each of the 236 cohesion, language, and discourse features were saved. We followed Biber's approach in standardizing all frequencies to a mean of 0.0 and a SD of 1.0 and entered them in a factor analysis using the Promax rotation. Whereas Biber used a principal factor analysis to account for the shared variance, we opted for a principal component analysis to account for all the variances. Loadings with an absolute value of less than .35 were excluded from the analysis (Biber, 1988; Comrey & Lee, 1992). The scree plot of eigenvalues, illustrating the amount of variance accounted for by each factor, showed a clear break after six factors, explaining 88.3% of the total variance.

In order to translate the factor scores to the registers, we followed Biber by adding together the standardized scores of all linguistic features responsible for a factor in a particular text. This provides a measure of register's salience on a particular dimension given the presence of the linguistic features in that register. We deviated from Biber's approach in one important way: Whereas Biber removed the linguistic features from subsequent factors once it was used by a previous factor, we preferred to include these linguistic features in additional factors to account for the interactions between language, discourse, and cohesion features.

Dimensions

Space limitations dictate us to summarize the findings by presenting tables in which we have translated the ratio scale to an ordinal scale, thereby not serving full justice to the actual differences between the 23 registers.

Dimension 1: Speech versus writing. This dimension significantly accounts for 53.5% of the variance, (F (1, 22) = 35.61, $p < .001$, MSE = .721). When looking at the grouping of the registers, it immediately becomes apparent that spoken registers are distinct from written registers. In addition, the registers clearly show *the degree* to which the registers are speech-dependent. For example, fiction includes, or more closely reflects, spoken discourse, whereas this is far less likely to be the case with press reviews or professional letters.

The linguistic features with positive loadings are presented in the first data row of the table, signifying the higher presence in the register. They consist of concreteness, imageability, meaningfulness, polysemy, and frequency in the spoken discourse. Negative loadings relate to ambiguous quantification, pronoun density, argument overlap, and semantic similarity between sentences and paragraphs. Registers with a higher score on this dimension (like public conversations and face-to-face conversations) are characterized by frequent occurrences of concrete, imaginable, and meaningful language, together with higher pronoun density and ambiguous quantification. At the same time, occurrences of argument overlap and semantic similarities between text units are less prevalent. Registers with negative scores, presented in the second data row, have the opposite characteristics.

In Table 2 results are given for the Dimension 1. The first column presents the registers ranked by total scores and the second column presents the linguistic features ranked by factor loadings. Row separators mark the difference between positive and negative factor loadings. The same format is used for the remaining five tables representing the remaining five dimensions.

Table 2: Distribution registers and summary Coh-Metrix Dimension 1 (speech versus writing)

public conversations, face to face conversation, spontaneous speeches, telephone conversations, planned speeches, broadcast, mystery fiction	frequency, concreteness, imageability, meaningfulness, polysemy, Flesch Reading Ease, ambiguous quantification, pronoun density, higher level constituents per word, abstract nouns, hypernym, polysemy
Personal letters, general fiction, romantic fiction, religion, adventure fiction, skills and hobbies, official documents, humor, academic prose, editorials, popular lore, biographies, science fiction, press reportage, press reviews, professional letters	LSA sentence to sentence, ratio of causal particles to causal verbs, LSA paragraph to paragraph, paragraph to text, vague adverbs, type-token ratio for nouns, concreteness, argument overlap, average paragraph length, age of acquisition, average syllables per word, mean number of modifiers per noun-phrase, stem overlap, Flesch Kincaid Grade Level

Dimension 2: Informational versus declarative. The second dimension accounts for 16.3 % of the variance, but without significant differences between the registers (F (1, 22) = .93, p = .56, MSE = .968). This dimension shows many similarities with Biber's Dimension 6, with the majority of the registers positioned similarly along the axis in both studies. Biber tentatively labeled this "on-line informational elaboration marking stance" with registers such as planned speeches and public conversations being informational in focus and conveying the speaker's attitudes and beliefs. We come to a similar conclusion, interpreting the difference as informational and subjective versus declarative and objective. Informational registers are characterized by a higher occurrence of temporal cohesion, imageability, and concreteness, but a low occurrence of causality, whereas the opposite characterizes declarative registers.

Table 3: Distribution registers and summary Coh-Metrix Dimension 2 (informational versus declarative)

mystery fiction, religion, skills and hobbies, romantic fiction, spontaneous speeches, official documents, general fiction, popular lore, telephone conversations, adventure fiction, biographies, face to face conversation, broadcast, humor	Positive temporal connectives, polysemy (adjectives), meaningfulness, LSA paragraph to paragraph, familiarity, LSA sentence to sentence, negative temporal connectives, paragraph length, argument overlap, LSA sentence to paragraph, LSA paragraph to text, ratio of causal particles to causal verbs, LSA paragraph to paragraph, type-token ratio for nouns, LSA paragraph to text, imageability, concreteness, LSA sentence to sentence, LSA sentence to sentence, concreteness
planned speeches, public conversations, academic prose, personal letters, editorials, science fiction, professional letters, press reportage, press reviews	Negative causal connectives, frequency, (verbs), causal particles, average syllables per word, positive causal connectives, age of acquisition

Dimension 3: Factual versus situational. This dimension, explaining 7.7 % of the variance, shows similarities with Biber's Dimension 3: "explicit versus situation-dependent reference." Biber argues that the situation-dependent site of the dimension refers to places and times outside of the text (imaginary and real world), whereas the opposite side of the dimension has registers with elaborated explicit reference. Although we do not find evidence for the time or place reference, we do find a higher frequency of imageability and a lower frequency of clarification and causal connectives, with the opposite trend evident for the registers on the factual side of the dimension (F(1, 22) = 5.88, p < .001, MSE = .871). The labels "factual" and "situational" refer to the presentation, rather than the content. For instance, religion is located high on the factual dimension because this register is generally presented as factual. On the other hand, press reviews, reportages and fiction are presented in a less transparent way, often requiring the reader to imagine a situation.

Table 4: Distribution registers and summary Coh-Metrix Dimension 3 (factual versus situational)

academic prose, official documents, religion, skills and hobbies, popular lore, biographies, spontaneous speeches, personal letters, face to face conversation	Clarification connectives, causal particles, negative causal connectives, noun overlap, ratio of causal particles to causal verbs, vague adjectives, negative additive connectives, positive causal connectives, ambiguous quantification, argument overlap, vague verbs, vague nouns,
telephone conversations, humor, editorials, public conversations, press reviews, press reportage, professional letters, planned speeches, general fiction, broadcast, mystery fiction, romantic fiction, adventure fiction, science fiction	polysemy, imageability, causal verbs, mean hypernym of verbs

Dimension 4: Topic consistency versus topic variation. This dimension explains 4.6% of the variance with significant differences between the registers (F(1, 22) = 3.76, p < .001, MSE = .870). It marks the consistency of topics across and within instances of a particular register. For instance, personal and professional letters often have a similar set of topics that are used, as do biographies and spontaneous speeches. Face-to-face conversations, interviews, public debates, press reportages and editorials on the other hand, have more topics and are less predictable, often switching between different instances. In the registers located high in the topic consistency (e.g. personal letters and professional letters), semantic similarities marking global cohesion and local cohesion are higher, but noun density and type-token ratio are lower than the topic variation registers (e.g., reportages and editorials).

Table 5: Distribution registers and summary Coh-Metrix Dimension 4 (topic consistency versus topic variation)

personal letters, spontaneous speeches, professional letters, biographies, broadcast, academic prose, religion, official documents, skills and hobbies, romantic fiction, mystery fiction	frequency conditionals, frequency negations, causal verbs, positive additive connectives, polysemy, LSA paragraph to paragraph, positive causal connectives, LSA sentence to text, LSA paragraph to paragraph, LSA paragraph to text
telephone conversations, general fiction, press reviews, popular lore, planned speeches, humor, adventure fiction, science fiction, face to face conversation, public conversations, press reportage, editorials	type-token ratio, noun density

Dimension 5: Elaborative versus constrained. This dimension is harder to interpret and explains only 3.7 % of the variance. Differences between registers ($F(1, 22) = 3.55$, $p < .001$, $MSE = .866$) suggest that personal letters and press reviews for instance are more opinion-based and have a closer distance between writer and reader, whereas professional letters and press reportages, are more fact and evidence driven. It is almost as if there is more space in personal letters and press reviews to compare ideas. This conclusion is supported by the factor loadings of the linguistic features, which show a prominent role for additive cohesion, vague adjectives and adverbs, along with a high type-token ratio and an accompanying low semantic similarity in the case of the personal letters and the press reviews. It is as if many ideas are juxtaposed within these registers.

Table 6: Distribution registers and summary Coh-Metrix Dimension 5 (elaborative versus constrained)

personal letters, press reviews, biographies, skills and hobbies, religion, humor, popular lore, academic prose, official documents, editorials, general fiction	type-token ratio, negative additive connectives, vague adjectives, vague verbs, positive additive connectives
mystery fiction, science fiction, romantic fiction, telephone conversations, broadcast, adventure fiction, face to face conversation, press reportage, planned speeches, public conversations, spontaneous speeches, professional letters	LSA paragraph to text, LSA paragraph to paragraph, LSA sentence to text

Dimension 6: Narrative versus non-narrative Although significant differences were found between registers (F (1, 22) = 1.64, p = .037, MSE = .991) only 2.5 % of the variance was accounted for by this dimension. Dimension 6 is virtually identical to Biber's Dimension 2. In registers such as fiction and biographies, a narration of events is prominent, whereas narration is less obvious in press reviews and professional letters. Linguistic features like temporal connectives are primarily responsible for this dimension. Despite the similarities with Biber's dimension, there are also some important differences. For instance, in our findings, science fiction scores low on narrative but face-to-face conversations score high, whereas in Biber's analysis the opposite is the case. The clear similarities between the two studies (e.g., the clustering of the fiction texts) support this interpretation of the dimension.

Table 7: Distribution registers and summary Coh-Metrix Dimension 6 (narrative versus non-narrative)

Romantic fiction, mystery fiction, face to face conversation, general fiction, adventure fiction, biographies, religion, public conversations, telephone conversations, official documents	ambiguous temporal relation, vague nouns, positive connectives, temporal connectives
Editorials, academic prose, press reportage, skills and hobbies, humor, spontaneous speeches, popular lore, personal letters, broadcast, planned speeches, science fiction, professional letters, press reviews	LSA sentence to text, LSA paragraph to text, LSA sentence to sentence

Discussion and conclusion

The present study has investigated the multi-feature, multi-dimensional corpus linguistic approach initially outlined by Biber (1988). We have used the same corpora and the same methods as Biber, but instead of including linguistic features that primarily operate at the word level, we have included a large variety of language, discourse and cohesion features. These features ranged from the word level, to sentence, paragraph and discourse level. Six dimensions emerged from a factor analysis: (1) speech versus writing, (2) informational versus declarative, (3) factual versus situational, (4) topic consistency versus topic variation, (5) elaborative versus constrained, (6) narrative versus non-narrative. Three of these dimensions (Dimension 2, 3 and 6) show strong similarities with the distributions of registers as well as the interpretations of dimensions in Biber's study.

Results showed one crucial difference with Biber's finding. Whereas Biber was not able to find one single dimension that determined the difference between speech and writing, we found a very prominent difference in linguistic features between spoken and written discourse (Dimension 1). The most plausible explanation for this

result is the contrast between Biber's focus on the linguistic features operating at the word level and our study which included a much wider range of language and discourse characteristics that we have called cohesion.

What is Universal in Perceiving, Remembering, and Describing Event Temporal Relations?

Abstract

What temporal relations do humans use to form dynamic mental representations of events? In the fields of artificial intelligence and computational linguistics, some have proposed an interval based representation, in which two events could be related in time by seven primitives. The seven primitives are BEFORE, MEET, OVERLAP, START, DURING, FINISH, and EQUAL. In the present study, perception, memory, and language about event temporal relations were investigated. The results showed that BEFORE, MEET, and DURING seem to be prevalent in the temporal experiences across a range of cognitive tasks, despite that there is variability with respect to different cognitive tasks.

Event Temporal Representation

Time is an inherent dimension of event representations (Freyd, 1987; Lu, 2003; Schank & Abelson, 1977; Zacks & Tversky, 2001; Zwaan, Magliano, & Graesser, 1995). In everyday life, there are many goal oriented activities that require an understanding of fine-tuned and subtle timings of events, as in the case of *making chicken soup*, *operating certain mechanical devices,* and *making a camp fire*. There are also many events that are loosely related, as in the case of *recalling some quarreling couple while dinning at a restaurant, hearing a loud sound from a house while taking a walk,* and *seeing a squirrel running on the electrical wire while walking past a fence.* How do people construct the temporal relations of events that may or may not be related in an overarching conceptual structure? For the purpose of this paper, the term event will be used as a covering term for both intentional actions (as in the case of an agent *making chicken soup*) and events that are not governed by the goals of an agent (as the in the case of *oil turning smoky*).

Previous research suggests that the plan and goal structures of everyday activities play an extremely important role in the encoding and retrieval of event temporal relations (Lichtenstein & Brewer, 1980). When people are asked to recall the sequence of events, they often place events in an order that maps onto the logical inferences derived from the goal and causal constraints instead of the actual order in time (Bauer & Mandler, 1989; Lichtenstein & Brewer, 1980). It is notable that the type of the events investigated in these studies tends to be the case where one agent manipulates one object and enacts one action at a time (Lu, 2003), whereas the examples in the previous paragraph seem to suggest that humans often experience events that have overlap in time. Additional research is needed to specify the details of how the plan and goal based theories could account for events overlapping in time.

How are events represented in temporal dimension? There are two types of primitives for temporally representing events (Allen, 1984; 1991). A point based representation captures events as being indexed as points in time. One event can be a single point in time, as in the case of *a sunrise at 4:30* or a *hiccup.* There are many singular point expressions in natural language (Moens & Steedman, 1988; TerMeulen, 1995); the events described in these point expressions appear to be conceptually instantaneous. A point based representation can also represent non-instantaneous events with a set of points in time. For example, a person's cleaning the fish tank can have a beginning at 2:15 and an end at 2:35 p.m. Its sub-event *getting the supplies* begins at 2:16 and ends at 2:19 p.m. Each of these events has points in time marking the beginning and the end.

In contrast, an interval based representation captures events as durations that may gloss over exact time points. Thus, the interval of *getting the supplies* occurred during the interval of *cleaning the fish* tank, without any specification of the exact points in time that mark the beginning and end points of events. Psychological studies have reported that people have a grasp of the range of time during which an event occurs (Golding, Magliano, & Hempill, 1992; Loftus, Schooler, Boone, & Kline, 1987). For example, John may not know exactly at which points of time he opens his car door, yet he knows it takes two or three seconds to open it. The chief theoretical challenge lies in specifying how to relate the intervals of events and how to draw inferences about the relative timing of events on the basis of interval constraints.

In the fields of artificial intelligence and computational linguistics, Allen (1984; 1991) developed a formalism that captures the various temporal relations between two events that are represented in intervals. Figure 1 provides an illustration of these seven relational structures: BEFORE, MEET, OVERLAP, START, DURING, FINISH, and EQUAL. In Figure 1, each double-headed arrow represents an event that occurs over some time interval, and each arrow-head represents either the beginning or the end of an event. The relation between each pair of events is described by one of the seven predicates. The BEFORE relation means that one event is prior to another event and that two events do not overlap in any way, whereas the MEET relation means that one event starts at the time another event ends. START means that two events share the same

beginning, but one ends before another, whereas EQUAL means that two events share the same interval and the same beginning and end. These primitives are essential for constructing a computational system of event representations (Allen, 1984). To what extent are Allen's seven relations used as conceptual primitives in event temporal representation?

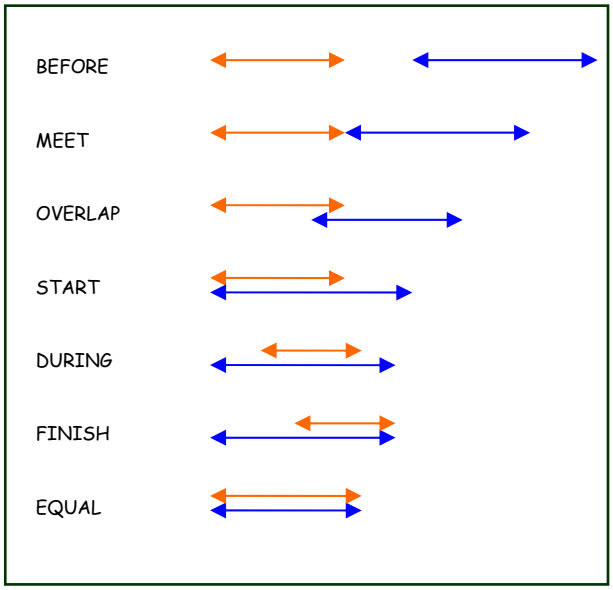

Figure 1: Temporal Representations by Allen (1991).

The formalism laid out in Figure 1 may capture some intuitive aspects of human temporal reasoning. For example, there is some evidence that endorses the distinction between BEFORE and MEET. Kate, a language found in Papua New Guinea, makes grammatical distinctions between the following two types of events: (a) events that are separated by a period of time with nothing significant, and (b) events that have successive temporal relations (Grime, 1975; but see Zwaan & Radvansky, 1998, pp. 176). In the Newtson task, participants are asked to segment a videotape of an activity into events and their parts (Newtson & Engquist, 1976). Participants are told to press the spacebar when they think one event ends and another begins. This methodology implicitly endorses MEET as the typical temporal experience encountered in the world.

Gestalt laws of perception postulate that forms are easier to process psychologically if they have more redundancy in pattern and permit fewer alternative forms. Conversely, forms are harder to process psychologically if they have less redundancy in pattern and render more alternative forms (Garner, 1974; Rock & Palmer, 1990). Examining Figure 1 based on Gestalt laws of perception, the complexity of the seven temporal relations seems to vary. For example, EQUAL may not have alternative forms, whereas START may have several alternative forms pending on the intervals of events. It is reasonable to infer that humans may capture some relations easily, but have some other relations confused (Lu, Graesser & Wolff, 2003).

In this paper, four experiments are reported to investigate the temporal relations people tend to construct. In Experiments 1 and 2, animated events of fish swimming were presented, and judgments of temporal relations were made. In Experiment 3, events were presented linguistically, and a production task was used. In Experiment 4, three separate sentence sorting tasks were conducted to see what semantic distinctions humans make when they describe events and their temporal relations.

Experiment 1: Perception of animated events

Experiment 1 investigated which temporal relations humans tend to construct out of the 7 primitives in the context of event perception. Participants were presented with animations of fish swimming events made in an animation program, called 3D Studio Max. Participants were asked to make judgments about which temporal relation out of the 7 choices best captures the animated events they saw.

Participants There were 51 college students at the University of Memphis who participated for course credit.

Materials Forty-two 3D animations were made using an animation program called 3D Studio Max release 5. Each animation depicted two fish of different colors and sizes swimming in the water. The spatial trajectory of the fish swimming was a straight line. For each relational structure in Allen's scheme, there were two sets of animations. One set of animations holds the distances of fish swimming constant but varies the speed of fish swimming, whereas the other set of animations holds the speed of fish swimming constant but varies the distances. For each set, there were three different perspective combinations: horizontal – horizontal, vertical - vertical, and horizontal - vertical.

The animation quality is near photorealistic. Each animation was 25 seconds in length and was run at approximately 30 frames / second.

Procedure Each participant was seated in front of a Pentium computer, which used MediaLab 2000 (Jarvis, 2000) to display the materials. Participants were asked to make judgments concerning how fish swimming events were related in time, as discussed below.

Participants were shown Figure 1 (without linguistic labels), and steps were taken to make sure they understood Figure 1. Participants were instructed to choose one relation out of the seven which best captured how two animated events were related in time. Before the animations were launched, participants were told that they could only have one viewing of each animation and that the screen with 7 choices would automatically pop up after each animation. Participants made choices by clicking a number that was next to the temporal relation.

Each participant received the same order of the temporal relations depicted in a diagram throughout the experiment. There were 20 sets of orders in which the temporal relations were presented. For each participant, the animations were presented in a random order.

Confusability Analysis Entropy was used to calculate the conceptual distance between each pair out of the 7 temporal

relations. The construct of entropy originated in information theory, which is a mathematical formulation of the uncertainty in a data set (Shannon, 1948). In the current study, each item may have 7 types of responses. For a given item, the following formula computes how likely one relation is confused with another one.

$$E_i = -\frac{\sum_{i=1}^{N} p_i \ln p_i}{\ln N}$$

The p_i refers to the proportion of times a given choice is selected out of the N possible choice items.

The entropy gives an index of how similar any two given structures (e.g. BEFORE and MEET) appeared to participants. A similarity matrix can thus be constructed, and then entered into the multidimensional scaling program implemented in SYSTAT version 9 with Young's S-STRESS scaling method (Wolff & Song, in press).

Results and Discussions The probability of people making the correct judgment of temporal relations was .80 on average. The error rates of the seven relations were the following: BEFORE (.20), MEET (.29), OVERLAP (.33), START (.15), DURING (.29), FINISH (.26), and EQUAL (.07). The EQUAL relation has the lowest error rates.

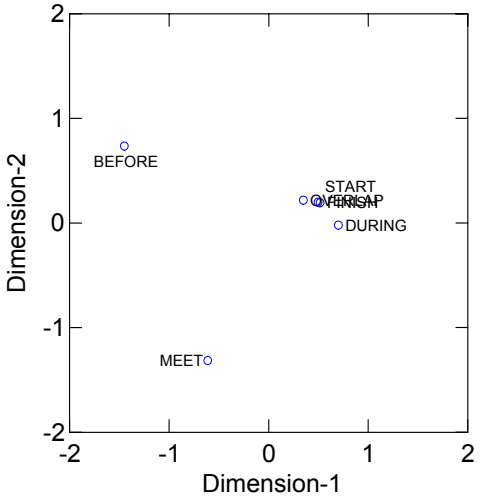

Figure 2: MDS Solution of Perception Task.

The confusability index was computed in entropy E_i. The similarity matrix was constructed using the entropy formula. This similarity matrix was submitted to the multidimensional scaling program. The MDS solutions in Figure 2 showed the following pattern of structure clustering yielded from the perception task. The similarity matrix was fit by a 2-dimensional MDS solution, with a very low stress value (.01), and a high proportion of variance accounted for (R^2 = 0.99). The seven temporal relations in Figure 1 were clustered into three main groups: BEFORE, MEET, versus (OVERLAP, FINISH, START, EQUAL, DURING).

The results showed that people tend to make distinctions whether events have overlap in time, as BEFORE and MEET stand out from the rest of the five temporal relations. People seem to make mistakes often among the five temporal relations that have overlap in time.

Experiment 2: Perception of animated events in the speeded condition

In Experiment 1, participants were given the luxury of focusing on two events. Experiment 2 investigated whether the effects observed in Experiment 1 are the result of people having enough attentional and cognitive resources during event perception. The animations used in Experiment 1 were presented at a faster rate (see Graesser & Nakamura, 1982; Reiger & Zheng, 2003, for the same method). Participants made judgments of the animated events in the same way as Experiments 1.

Participants There were 40 college students at the University of Memphis who participated for course credit.

Materials The same set of 42 3D animations used in Experiment 1 was used in Experiment 2. The animations were speeded up using an animation program called VirtualDub. The animations were displayed 30 frames / second in Experiment 1, whereas the animations was speeded to 75 frames / second in Experiment 2.

Results and Discussions The probability of people making the correct judgment of temporal relations was .66 on average. The error rates of the seven relations were the following: BEFORE (.34), MEET (.40), OVERLAP (.40), START (.23), DURING (.41), FINISH (.43), and EQUAL (.10). Compared with Experiment 1, the error frequency increased in Experiment 2.

The similarity matrix was constructed in the same way as Experiment 1, and then was submitted to the multidimensional scaling program. The MDS solutions showed the same pattern of structure clustering yielded as in Experiment 1. The seven temporal relations were clustered into three main groups: BEFORE, MEET, versus (OVERLAP, FINISH, START, EQUAL, DURING). The relational clustering in Experiment 2 did not differ from Experiment 1. Whether two events had overlap in time was again used to distinguish BEFORE and MEET from the rest of the temporal relations. Experiment 2 ruled out the possibility that the pattern observed in Experiment 1 was merely the effect of attentional allocation.

Experiment 3: Memory of everyday event time using a drawing task

Experiments 1 and 2 investigated the perception of events and their temporal relations. The question at this point is whether the relational clustering in the perception of everyday events will also be observed in the memory of everyday activities. In the perception judgment experiments, participants were provided Allen's seven relations. We were curious to find out whether the same pattern will be observed if Allen's seven relations are not provided. Participants were presented pairs of everyday events that were coded to have the temporal relations in Allen's representation. Participants read pairs of events, and then

drew which temporal relation in Allen's representation best captures the events they read.

Participants There were 34 college students at the University of Memphis who participated for course credit.

Materials A sample of events from everyday activities were collected. To ensure generality, the events were chosen from a wide range of everyday activities. Some examples include: driving a car, grocery shopping, cashing a check, and so on. Three raters were trained to understand Allen's representation, and made judgments on how each two events were related in time separately. The materials used in the experiment were the items agreed upon by all three judges.

For every pair of events, a supporting context was provided. An example is below:

Context: Imagine a passenger at an airport.
Events: She went through the security screening.
Her carry-on bags were x-rayed.

For each of the 7 temporal relations in Allen's proposal, there were 10 test items. There were 70 test items in total.

Procedure Participants were introduced how to represent an event occurring over some time with beginning and end points. Then they were given two examples: one indicating one event occurring before another, the other indicating one event occurring in the middle of another. The events were presented on A4 size papers, and space was provided for drawing. Allen's 7 temporal relations were used to code the drawings. The inter-rater agreement was 96%.

Results and Discussions The probability of people making the correct judgment of temporal relations was .29 on average. The error rates of the seven relations were the following: BEFORE (.31), MEET (.83), OVERLAP (.82), START (.95), DURING (.73), FINISH (.83), and EQUAL (.51). The probability of drawing START was significantly lower than chance, whereas the probability of drawing other six relations was higher than chance. For example, compared with the probability of drawing FINISH, the probability of drawing START are significantly lower, $t(33) = 3.021$, $p < .005$, using Bonferroni correction.

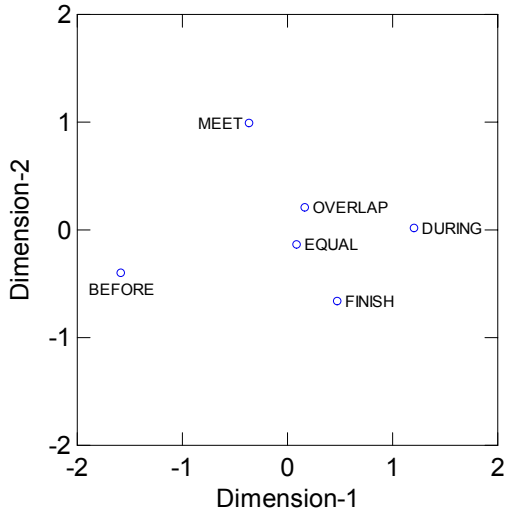

Figure 3: Drawing MDS Solution.

The similarity matrix, which was used to fit a 2-dimensional MDS solution, does not include START. The resulting MDS solution had a very low stress value (.01), and a high proportion of variance accounted for ($R^2 = 0.99$). The six temporal relations were clustered into three main groups with varying distances: BEFORE, MEET, versus (OVERLAP, FINISH, DURING, EQUAL). Compared with the MDS solution in the perception experiments, the distances among the four relations that have overlap in time are farther apart in the drawing task. Nonetheless, the clustering formed by the rest of the 6 temporal relations, are not incompatible with the previous perception tasks. Whether two events have overlap in time continued to be an important dimension in the memory of everyday events.

Experiment 4: Semantic organization of temporal lexemes

Children tend to describe an event when they answer questions about time (Nelson, 1996). Consider such an example. *When do you go to bed? When mommy comes to get me.* The child did not say something like *at night*. This example suggests that how we talk about time is correlated with how we think of time (Gentner & Boroditsky, 2001). Does the pattern of event temporal relations observed in the perception and memory of events reflect in the language about event temporal relations?

Experiment 4 investigated the semantic clustering of temporal event language when college students performed linguistic sorting tasks. Participants were presented sentences with temporal words embedded in them. They sorted the sentences into groups which shared similar meanings of the embedded words. The central question is whether the words would cluster according to theoretically interesting dimensions. Three experiments were conducted separately for verbs, adverbs, and prepositions plus conjunctions.

Experiment 4 (a): Verb sorting

Participants There were 27 college students at the University of Memphis who participated for course credit.

Materials A list of verbs and their synonyms encoding how two events are related in time was assembled from several thesauruses. Each of the 17 verbs in (4a) was printed at the top of a 4" x 6" index card. Below each verb were printed two sentences that illustrated the use of the verb. The example sentences were selected from the British National Corpus.

Procedure Participants were asked to read the sentences on the verb index card, and then sort the verb index cards into as many or as few groups as they felt appropriate. They were told that the cards in each group should have "essentially the same meaning".

Results The frequency of each pair of words co-occurring in the same group was scored and assembled in a word-pair co-occurrence matrix. The MDS solutions showed a pattern of verb clustering. The sorts were fit by a 2-dimensional MDS solution, with a very low stress value (.18), and a high proportion of variance accounted for ($R^2 = 0.87$). The verbs

in (4a) were sorted into three main groups as shown in Figure 4:
BEFORE – type verbs (anticipate, be before, foresee, go before, and precede);
AFTER – type verbs (come after, go after, follow after, succeed, and result);
DURING – type verbs (coincide, concur, co-occur, ensue, fall together, go with and overlap).

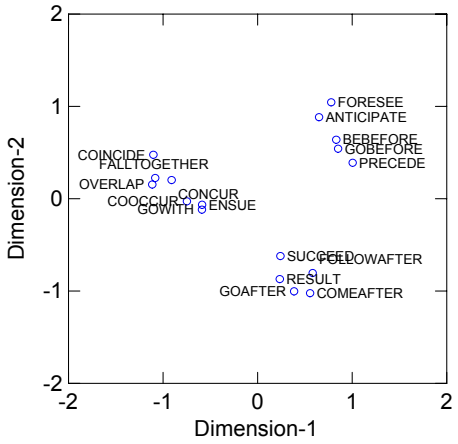

Figure 4: Verb Sorting MDS Solution.

Experiment 4 (b): Adverb sorting

There were 58 undergraduates at the University of Memphis who participated for course credit. Materials and procedure were the same as Experiment 4 (a).

Results The MDS solutions showed a pattern of adverb clustering. The sorts were fit by a 2-dimensional solution, with a very low stress value (.13), and a high proportion of variance accounted for (R^2 = 0.94). The adverbs in (4b) were sorted into three main groups:
BEFORE – type adverbs (before, beforehand, earlier, formerly, in advance, previously and sooner;
AFTER – type adverbs (after, afterwards, later, later on, next, sooner or later, and subsequently);
DURING – type adverbs (at the moment, at the same time, concomitantly, concurrently, contemporaneously, for now, in chorus, in concert, in the meantime, in the same breath, in time, in unison, instantaneously, meanwhile, on the beat, simultaneously, synchronously).

Experiment 4 (c): Preposition sorting

There were 76 undergraduates at the University of Memphis who participated for course credit.

Results The MDS solutions showed a pattern of preposition clustering. The sorts were fit by a 2-dimensional solution, with a very low stress value (.14), and a high proportion of variance accounted for (R^2 = 0.91). The prepositions in (4c) were sorted into three main groups:
BEFORE – type prepositions (before, prior to);
AFTER – type prepositions (after, soon after, as soon as, until, pending, by);
DURING – type prepositions (just as, when, as, along with, while, amid, during, in the course of, throughout, over).

Discussions of Experiment 4

Across grammatical categories, Experiment 4 showed that people are predisposed to three types of temporal relations when they talk about time. The results are compatible with the proposals by Wierzbicka (1973) in linguistics and Graesser et al. in psychology (Graesser, Wiemer-Hastings, & Wiemer-Hastings, 2001). The mapping between linguistic primitives and Allen's primitives may be more complex than the MDS solutions suggested. Nonetheless, the evidence in linguistics may indicate some alignment between the linguistic clustering and the conceptual clustering that emerged from the previous experiments.

The linguistic primitive AFTER may correspond to some aspects of MEET. Wierzbicka and others have noted that BEFORE and AFTER encode somewhat different temporal conceptions of events (Thompson & Longacre, 1985, but see Wierzbicka 2002; Wierzbicka, 2002). One difference is that the event in the BEFORE clause usually does not begin until the event in the main clause ends, whereas AFTER does not have this constraint. Consider the following two examples: (a) *John took out the water pipe before he drained the fish tank* and (b) *John washed the dishes after he cooked the dinner*. The two events in example (a) have to occur one before another, whereas *washing the dishes* in example (b) could occur before *finishing the cooking*. There is some empirical evidence in support of this conjecture. In a separate sentence rating task we conducted, two types of *after* sentences were selected from a corpus. One type refers to the situation where one occurs after another with a time interval in between, whereas a second type refers to the situation where the beginning of one event is after another event but both events have overlap in time. There were significant differences between the likelihood ratings of whether the two events described in each sentence have overlap in time.

Summary and Discussions

Four experiments investigated how people piece together events that may or may not have an overarching conceptual structure in a range of cognitive tasks. The results suggested that the distinctions made among BEFORE, MEET, and DURING seem to be prevalent when people perceive, remember, and describe how events are related in time.

However, there is apparently some variability in the MDS solution yielded from different cognitive tasks. When people had to linguistically encode and retrieve events, the event temporal representations may be harder to construct. The MDS solution in Figure 3 indicated the trend that BEFORE, MEET, and EQUAL are more likely to be constructed than other temporal relations. BEFORE, MEET, and EQUAL may be easier for humans to process because they have inherent simplicity, symmetry, and good forms, which are hallmarks of the Gestalt Law of Prägnanz (Rock & Palmer, 1990).

It is not clear at this point how the linguistic primitives map onto the primitives in perception and memory tasks. According to the relational relativity hypothesis, language

affects thought in more abstract domain (Gentner & Boroditsky, 2001; Gentner, 2003). Temporal constructs are abstract, this points to the possibility that the way we talk about time affects how we encode the temporal aspects of events. The MDS solutions in the current study indicate some alignment among the primitives across different cognitive tasks. However, the alignment may be more complicated and needs further investigations.

It appears that BEFORE, MEET, and DURING are used in the perception, memory, and linguistic experiences of temporal representations. When the representations are harder to construct, for example, in the case of linguistic retrieval of event representations, people are more likely to mistake one temporal relation with another. In further studies, it is necessary to investigate the cognitive principles that constrain the constructions of temporal event relations.

Acknowledgments

The research was supported by a grant from the National Science Foundation (REC0106965). We thank Phillip Wolff for discussions of this work, Srinivas Achunala for 3D animations, and Zhiqiang Cai for discussions on entropy. Abstract

A corpus consisting of eighty-one one-on-one tutoring sessions with first-year medical students carried on by two professors of physiology at Rush Medical College was analyzed for the use of analogies to facilitate understanding of the topics covered. Analogies were infrequently used, but had a positive effect on improving student comprehension of the topics tutored. The human tutor's goals, topics, discourse strategies, follow-up, and clarification in the presence of misunderstanding were analyzed with the long term goal of implementing analogies in an intelligent tutoring system.

Introduction

Analogies play a major role in learning. Eighty-one one-on-one tutoring sessions carried out by two professors of physiology at Rush Medical College were extensively marked for analogies using SGML. Instances of analogies were then classified in terms of the goals, targets, bases, and whether they were proposed by the student or the tutor.

Current advances in education, cognitive science, linguistics, and expert systems make it feasible to generate analogies in an intelligent tutoring system using a computational model. To date, as far as we know, no one has used full-scale natural language generation to implement analogies in an electronic tutoring system. The goal is to use computational models of memory retrieval and analog mapping to simulate the human tutor's behavior in our intelligent tutoring system, CIRCSIM-Tutor.

Analogies in Cognitive Science

Gentner defines analogies as:

> partial similarities between different situations that support further inferences. Specifically, analogy is a kind of similarity in which the same system of relations holds across different objects. Analogies thus capture parallels across different situations (Gentner, 1998, p.107).

Analogical reasoning is essential to cognitive ability (Gentner, 1998; Kurtz, Miao, & Gentner, 2001), and scientific inquiry and study (Dunbar, 1993; Goldblum, 2001; Michael & Modell, 2003; Modell, 2000; Thagard, 1997). Research studies exist that:

- analyze the way humans store and retrieve analogues from memory (Forbus, Gentner, & Law, 1995; Hofstadter, 2001; Holyoak, Gentner, & Kokinov, 2001; Holyoak & Thagard, 1995; Kokinov & Petrov, 2001; Kolodner, 1993)
- use computational models to simulate the results of human studies (Forbus, 2001; Forbus, Gentner, & Law, 1995; Holyoak, & Thagard, 1995)
- analyze the use of analogy in problem solving/reasoning (Holyoak & Thagard, 1985; Holyoak, Gentner, & Kokinov 2001; Kolodner, 1993; Thagard, 1997)
- analyze the use of analogies in education, medicine, and scientific inquiry (Dunbar, 1993, 1995; Goldblum, 2001; Thagard, 1997)

Gentner's (1983, 1998) structure mapping theory (Gentner & Markman, 1997; Holyoak, Gentner, & Kokinov, 2001; Holyoak & Thagard, 1995; Kurtz, Miao, & Gentner, 2001) seems to closely match the way our expert tutors work. New knowledge (the target) is learned by mapping its structure to existing knowledge (the base). Inferences are made from these mappings. The representation of mappings is discussed in length in Yan, Forbus, & Gentner (2003). When retrieving possible analogs from memory, the goal is to find mappings that have predictive value (Gentner, 1983).

Further studies have demonstrated that analogical encoding—the "process of comparing two examples and deriving an abstraction on the basis of their commonalities" (Loewenstein, Thompson, & Gentner, 1999, p. 586)—can be effective in facilitating the learning of similar problems. Abstractions of schemas gained through the intensive comparisons of two analogous concepts that are not fully

understood not only facilitate the understanding of the new pieces of information, but the general schemas derived can be applied to similar problems encountered later (Gentner, Loewenstein, & Thompson, 2003; Kurtz, Miao, & Gentner, 2001; Loewenstein, Thompson, & Gentner, 1999). Studies involving the learning of negotiation skills in undergraduates and graduate management students (Loewenstein, Thompson, & Gentner, 1999) and presentation of heat flow scenarios to teach the concept of heat flow (Kurtz, Miao, & Gentner, 2001) demonstrated that the intentional and intensive comparisons of two concepts that are not fully understood are as effective in knowledge transfer as structural alignment. Gentner (1983) demonstrated that this approach to teaching by analogy bypasses the common problem that humans have when trying to retrieve relevant information from memory to connect to new knowledge that one is attempting to learn. Mutual alignment is especially relevant to electronic tutoring systems that cannot always rely on the presence of existing knowledge when presenting new concepts.

Possible problems resulting from misunderstandings when reasoning analogically in a scientific domain are well-recognized (Feltovich, Spiro, & Coulson, 1989). Holyoak and Thagard (1995) have studied misconceptions and devised the multiconstraint theory that addresses the problems resulting from the use of inappropriate analogies. They recommend placing certain restrictions—of similarity, structure, and purpose—on the analogy. If all three constraints are met, only one interpretation of the analogy can be gleaned from the mapping. In cases where the three constraints are not met, misunderstandings can be identified and corrected. We have observed this behavior in our expert tutors' human sessions, as discussed below.

Analysis of Analogies Found in the Corpus

In order to understand our human tutoring session, one must first have background information on what is being tutored. The human body requires a blood pressure within a certain range to sustain life. The baroreceptor reflex is a negative feedback system that controls blood pressure in the cardiovascular system to ensure that the pressure remains within this range. When a perturbation in the system occurs, the response has three phases: direct response (DR) of the system to the perturbation, the reflex response (RR) to the new values of affected variables, and the steady state (SS), or state of the system after it has re-stabilized. CIRCSIM-Tutor asks the student to predict the qualitative changes in several important variables at all three stages. The variables are: Heart rate (HR), Cardiac Contractility (CC), Stroke volume (SV), Cardiac output (CO), Mean arterial pressure (MAP), Total peripheral resistance (TPR), Central venous pressure (CVP). Eighty-one hour-long tutoring sessions with first year medical students solving problems about the baroreceptor reflex were conducted by our experts, two professors of physiology at Rush Medical College, Joel Michael and Allen Rovick. Face-to-face sessions were recorded and transcribed. Keyboard-to-keyboard sessions were recorded using Computer Dialogue System (CDS) discussed in Li, Seu, Evens, Michael, & Rovick (1992). CDS forces each person to take turns typing. An annotation language based on SGML (Kim, Freedman, Glass, & Evens, 2002) was used to mark up the human sessions by hand. The following examples (discussed in Lulis & Evens, 2003; Lulis, Evens & Michael, 2003) were selected from the analogies found in these expert human tutoring sessions. They are representative of sessions where the tutor uses analogies: new material is explained, misconceptions are corrected, and prompts—successful and unsuccessful—are made to the student to make analogies and inferences. In each of the examples listed, the tutors used analogies after the student made an incorrect inference. The identifiers at the beginning of each sentence make it possible to find the original context at any time: initial F or K indicates whether the session was face-to-face or keyboard-to-keyboard; the session number comes next; st (student) or tu (tutor) indicates who is speaking/typing; this is followed by the turn number and the number of the sentence within the turn. A complete set of marked-up transcripts will be provided on request.

Example 1. Face-to-face session number one (F1) contains examples of the use of analogy to explain domain material and a correction by the tutor. The analogy of comparing the heart to a sink is proposed by the student (st). However, the sink is not a compliant object and the heart is. As a result, the tutor (tu) offers a better analogy—the heart is like a balloon.

F1-st-62-1: If I make an analogy of you try to fill a sink with water and you...
F1-tu-63-1: Try to fill a balloon with water, since that's what we're dealing with, a distensible object.
F1-st-64-1: OK.

After making a one-to-one mapping of the base (balloon) to the target (heart), a correct inference is made. In accordance with Holyoak and Thagard (1995) and Gentner's (1983) theory of structure mapping, the following structures underlie what the tutor does (as discussed in Lulis & Evens, 2003; Lulis, Evens, & Michael, 2003):

Structure for the balloon
- fill a balloon with water
- it will distend
- the pressure in the balloon increases as it distends

Structure for the heart
- fill the right atrium
- the right atrium will distend
- the pressure will increase as it distends

The above example demonstrated the effectiveness of the accepted structure mapping approach of connecting new knowledge to knowledge already understood by the student.

As a result, the student develops a better understanding of the new concept (Gentner, 1983, 1998; Goldblum, 2001; Holyoak & Thagard, 1995).

Example 2. We see the tutor correcting a misconception in face-to-face session #7.

F7-tu-267-1: Well, let's give it another thought, OK?
F7-tu-267-2: We can look at that central blood chamber that means the big veins and the atria together as though they were an elastic chamber.
F7-tu-267-3: Is that not correct?
F7-st-268-1: Yeah, and the heart is the pump.
F7-tu-269-1: Well, let's stick to this elastic chamber and look at it first more or less in isolation.
F7-tu-269-2: If you have an elastic chamber what are the things that determine the pressure inside that chamber.
F7-st-270-1: Size.
F7-st-270-2: No.
F7-st-270-3: I mean if you..
F7-st-270-4: I mean...
F7-st-270-5: Area is one but I gather for the heart..
F7-tu-271-1: Area of what?
F7-st-272-1: Area that..
F7-st-272-2: I mean if you want to know what the pressure is of a gas or well liquids aren't that...
F7-st-272-3: We're not talking about gas, we're talking about liquids.
F7-st-272-4: And liquids are not affected by size because you can't compress the molecules that much.
F7-tu-273-1: Oh, you mean the volume occupied by the liquid, expansion and condensation of the liquid.
F7-tu-273-2: No.
F7-tu-273-3: That's not an issue.
F7-st-274-1: No, because we're talking about liquids and liquids aren't affected.
F7-st-274-2: Like with gas, besides the container matters a lot....
F7-tu-275-1: Let's throw away this atria central venous system and take instead something inanimate elastic stretcher, say like a balloon.
F7-tu-275-2: Right?
F7-tu-275-3: What determines what the pressure is inside the balloon?

In the above example, an analogy of the atria as an elastic chamber is proposed by the tutor, but the structure of the intended base analog—the atria or central venous system as a reservoir—is not understood by the student resulting in a failure to make the connection between existing knowledge and the new knowledge. The tutor suggests a base that the student is familiar with—a balloon to compare the atria to. A correct structure mapping is made allowing the student to understand the new concept.

Example 3. In keyboard-to-keyboard session number one (K1), the tutor prompts the student to make an analogy between neurally controlled variables in the DR (direct response) period. The behavior of the variable TPR during the DR period has already been tutored. The inference is that all neurally controlled variables will behave similarly during this period. The student makes the connection between the analogs resulting in a correct inference.

K1-st-29-1:During the DR period it would remain unchanged.
K1-tu-30-1: Correct.
K1-tu-30-2: What other variables are neurally controlled?
K1-st-31-1: CC, HR
K1-tu-32-1: Again correct.

Example 4. An example of the student not getting the point of the analogy is seen in keyboard-to-keyboard session #5 (K5). After tutoring the neurally controlled variable CC, the tutor attempts to get the student to make an analogy between it and other neurally controlled variables. The student fails to make the analogy and the tutor finally tells the student the analogy that he is seeking.

K5-tu-31-1: No, it is under neural (sympathetic) control,rily.
K5-tu-31-2: We are now discussing what happens in the DR period, before any neural (reflex) effects.
K5-tu-31-3: Sowhat will happ en to CC in this pe;riod?
K5-st-32-1: Cc 0.
K5-tu-33-1: Correct.
K5-tu-33-2: While we're on the subject, what other variable is underneural contro l and how will it be affected in the DR?
K5-st-34-1: SV 0.
K5-st-34-2: It will not be affected in the DR.
K5-tu-35-1: Not true.
K5-tu-35-2: SV is only partially under neural control via CC, one of its importan t determinants.
K5-tu-35-3: We'll come back to this in a moment.
K5-tu-35-4: What othervariable is un der neural control?
K5-tu-39-3: LIKE CC!.
K5-st-40-1: TPR 0.

Example 5. More interesting analogies can be found in several sessions. Keyboard-to-keyboard session number sixty-four (K64) contains an analogy proposed by the student (st) between the heart and a traffic cop. The mapping between these analogs is not correct; the tutor (tu) proposes a more suitable analogy between the heart and a traffic jam. The structure mapping theory discussed in Gentner (1983, 1998), Goldblum (2001), Holyoak and Thagard (1995), and formalizes what the tutor is doing.

K64-st-54-1: Would it be a reasonable analogy to look at the heart like a traffic cop?
K64-st-54-2: If it slows down the rate of blood flow (lets fewer cars through) then there will be a

backup behind it (a backflow of blood prior to the heart, and therefore an increase in CVP) and fewer cars coming through (less blood coming out of the heart and therefore a decrease in MAP)

K64-tu-55-1: The analogy is OK.

K64-tu-55-2: But just as traffic jam does not occur because cars back up, the increase in CVP caused by a fall in CO is not the result of blood BACKING UP.

K64-tu-55-3: Everything soes in one direction.

K64-st-56-1: well, slowing down would be a better way to put it then

K64-tu-57-1: Yes.

K64-tu-57-2: A traffic jam caused by everybody piling into the same area at once.

Analogies in Human Tutoring Sessions

In the tutoring sessions that we have studied, we observe expert tutors taking steps to avoid misconceptions. They (Holyoak & Thagard, 1995):

- Make certain that students understand the system mapping.
- Use a variety of analogies.
- Inform students when an analogy is relevant and when it is not—point out the differences, as well as the similarities, between the known knowledge and the target.
- Correct misconceptions when they occur.

The outcomes of the analogies proposed by the tutor are shown in Table 1 (as discussed in Lulis & Evens, 2003; Lulis, Evens, & Michael, 2003). We summarize the analogies that we found in human tutoring sessions described here.

Table 1: Use of observed analogies proposed by tutors

Type	No. observed in corpus
no inference requested	**5**
successful mapping	4
failed mapping	1
inference requested	**37**
successful inference	15
failed inference	
success after repair	15
failure after repair	7
enhancement only	**9**
Total:	**51**

Out of the fifty-one analogies proposed by the tutors, nine were used after correct inferences and apparently intended to enhance the student's understanding of the material discussed and not to lead to further development. In forty-two cases, the tutor used analogies after the students made incorrect inferences. In five of the forty-two cases, the tutors did not request inferences from the students. However, students did make correct inferences four out of the five times without prompting. In the remaining thirty-seven cases, an inference was requested after the analogy was proposed resulting in correct inferences being made by students fifteen times without repair to the analogy (to correct misunderstandings) and fifteen times with repair—81% success rate. In only seven of the thirty-seven cases—19% of the time—did the tutor abandon the use of analogy and opt for a different teaching strategy. In total, the use of analogy after an incorrect prediction was followed by a correct prediction in 34 out of the 42 times—81% success rate. The empirical evidence suggests that the use of analogy had positive affects on the students' ability to understand the material.

If we examine the different bases employed while tutoring using analogies—proposed by students and tutors—we find a wide range, as shown in Table 2. The analogy that was most often proposed by the tutors was another neural variable—twenty-nine times. In five of these cases, the tutors eventually gave up on the analogy and utilized a different approach to the material, but the other twenty-four were ultimately successful. There was one successful mapping without an attempt at an inference, twelve successful mappings with correct inferences, and four successful mappings with correct inferences after repairs. Other successful mappings occurred using in a wide variety of bases such as the heart as a balloon or pump, Ohm's law, airplane wings, bootstraps, a dimmer switch, traffic jams, and a black box. These bases were not observed as often,

Table 2: Bases present in the corpus

Base	No. observed in corpus
Airplane wing	1
Another algorithm	2
Another neural variable	29
Another procedure	3
Balloon	1
Balloon as a compliant structure	2
Black box	1
Bootstrap	1
Brake & accelerator	1
Compliant structure	3
Dimmer switch	1
Elastic reservoir	1
Flight or fight	1
Gravity	1
Last problem	1
Ohm's Law	2
Physician	1
Pump	1
Reflex	2
Sugar or glucose	1
Summation	1
Traffic jam	2

but made for extremely productive and interesting structural mappings resulting in correct inferences.

Gentner's (1983; Lowenstein, Thompson, & Gentner, 1999) work suggests that information from abstract and concrete bases may be processed differently. She has observed that children find it easier to understand analogies with concrete bases than with abstract ones. We hope to investigate this phenomenon using CIRCSIM-Tutor. In our data in Table 2, we see twenty-two different bases, twelve are concrete and ten are abstract (Table 3). The use of abstract bases are observed forty-four times in the corpus, while the concrete bases are used only fifteen times. Examination of the language used suggests another potentially useful classification—into analogies that remind students of earlier experience with another neural variable or another procedure and those that depend on a base from outside the immediate domain.

Table 3: Analogies with abstract and concrete bases

No. Type of base	No. of times seen in the corpus
12 different concrete	15
10 different abstract	44

Implementation

Holyoak & Thagard (1995) identified the steps of analogical reasoning: the retrieval of possible analogs from memory, the mapping of these analogs to the new knowledge being learned, inferring something from the mapping, adjusting the new knowledge if necessary, and storing the new knowledge for future use. Computational models dealing with analogy address the first two steps—retrieval based on similarity and structural mapping. There are two dominating models for the retrieval step—case based reasoning (Birnbaum & Collins, 1989; Kass, 1990, 1994; Kolodner, 1984, 1993, 1994; Schank, 1982) and a model that emulates a document retrieval system, retrieving both relevant analogs and irrelevant ones. There are also two approaches to the mapping step. One makes inferences before the mappings—projection first—the other makes the mappings before the predictions—alignment first.

It is our goal to implement an analogy generating function in CIRCSIM-Tutor (Michael, Rovick, Glass, Zhou, & Evens, 2003). It has been decided that a document retrieval model coupled with an alignment-first mapping—MAC/FAC—(Gentner, 1998; Gentner & Markman, 1997; Forbus, Gentner, Everett, & Wu, 1997) was best suited for use when simulating human tutoring in CIRCSIM-Tutor System. MAC/FAC was chosen because we believe that it simulates how people process analogies and it the implementation is very successful.

MAC/FAC

MAC/FAC (Many Are Called/Few Are Chosen) models Gentner's (1983) theory of structure mapping and simulates the human propensity to favor relationships between bases and targets when comparisons are made and to favor superficial similarities and not retrieve the more profound analogical similarities while still, on occasion, retrieving relevant structural comparisons (Forbus, Gentner, & Law, 1995). Working memory consists of content vectors constructed from the structural representations of the bases. The MAC stage functions like a document retrieval system, searching working memory in a parallel manner seeking content vectors that are similar to the target. The dot product between each of the bases and the target is computed to determine the best and those within 10% of the best matches. Stage two, the FAC stage, utilizes the output from the MAC phase to do Gentner's (1983) structure mappings. The structure mapping engine (SME) selects the best mapping and all those within 10% of it.

Conclusion

Analogies are used by our human tutors infrequently; on the average, less than once a session. However, the human sessions have demonstrated that the use of analogies is extremely effective. We have observed tutors using analogy to tutor the topic at hand and to enhance existing knowledge. Misunderstandings were corrected and inappropriate analogies replaced with more suitable ones. The structure mappings between the analogs underlie what the tutor was doing.

Future research includes simulating the schemas observed in the corpus in our expert system CIRCSIM-Tutor (Michael et al., 2003). Many of the analogies observed can be implemented using structure mapping (Gentner, 1983, 1998; Goldblum, 2001; Holyoak & Thagard, 1995) to connect new knowledge to existing knowledge. We will attempt to simulate mutual alignment (Gentner, Loewenstein, & Thompson, 2003; Loewenstein, Thompson, & Gentner, 1999) for the most commonly found analogy in the corpus—another neurally controlled variable. The recommendations of Goldblum (2001), and Holyoak & Thagard (1995)—use more than one analog, detect and fix incorrect mappings, identify the analogical scope, and refine analogies—will also be attempted.

Social and cultural influences on causal models of illness

Elizabeth B. Lynch (bethlynch@northwestern.edu)
Department of Psychology, 2029 Sheridan Road
Evanston, IL 60208 USA

Abstract

Causal models of illness vary extensively across socio-cultural groups. The current paper describes two studies that were designed to explore the role of universal domain-specific causal knowledge in causal models of illness. The first study compares illness causal models in three American groups: registered nurses, energy healers, and college undergraduates. The second study examines illness causal models in a group of Maya in Guatemala. In all groups illness models are composed of systematic combinations of domain-specific causes. It is argued that analysis of causal models in terms of domain-specific causal types reveals similarities in illness models that would be obscured by comparison of specific, detailed causes. The analysis of illness models as patterns of domain-specific causes suggests that American energy healers have models of illness that are more similar to those of the Maya than to illness models of American undergraduates and RNs.

Introduction

An issue of interest to both anthropologists and psychologists is the extent to which conceptual representations are affected by socio-cultural factors and the mechanisms by which this influence occurs. The extent to which thinking varies across cultures depends in large part on the content of the domain. For example, the domain of folkbiology is characterized by striking similarities across cultures, while less consistency has been observed in social attribution (Choi, Nisbett & Norenzayan, 1999) moral reasoning (Miller, Bersoff, & Harwood, 1990, Haidt, Koller, & Dias, 1993), and reasoning about illness (Murdock, 1980; Kleinman, 1978). In general, theories of cultural knowledge transmission that explain diversity of knowledge are distinct from ones that explain uniformity.

Explanations for cultural diversity often assume that the mind is a "blank slate," open to any form of knowledge (Atran, 2001; Pinker, 2000; Sperber & Hirschfeld, 2004). In contrast, explanations of uniformity in knowledge across cultures appeal to a view of the mind as a highly structured, modular information-processing device. As Pinker (2000), Atran (2001), and Sperber & Hirschfeld (2004) argue, the view of the mind as a blank slate is almost certainly wrong. There is plenty of evidence that the mind is not a blank slate, but is structured in a modular way such that qualitatively distinct reasoning processes are utilized for different kinds of phenomena (Carey & Gelman, 1991; Hirschfeld & Gelman, 1994, Pinker, 2004).

The mind, like other parts of the natural world, evolved in an environment with a particular structure. The modular nature of the mind is the result of evolutionary adaptations to the objective structure of the world. The mind evolved different cognitive processes in order to effectively predict the behavior of ontologically distinct objects. This view predicts and explains cross-cultural universals in human thinking. Sperber and Hirschfeld (2004) argue that stability of cultural knowledge results from the universal structure of the human mind, in particular the fact that all minds process information in similar, highly constrained ways. For example, there is striking cross-cultural uniformity in folkbiological knowledge. Medin and Atran (in press) argue that cross-cultural uniformity in thinking and behavior with regard to plants and animals is due to the existence of a universal cognitive module, the folkbiology module, that evolved specifically to process information about plants and animals. Despite differences in experience or environmental input, minds are universally constrained to construct a particular kind of representation of plants and animals – hence, cultural uniformity and stability.

The current paper presents two descriptive studies that demonstrate how universal domain-specific knowledge is expressed in causal models of illness, which are characterized by cross-cultural diversity rather than uniformity. Domain-specificity theory implies that, just as there are different ontological kinds of objects in the world (e.g. mental and physical objects), there are also different kinds of causal mechanisms. For example, there are psychological causal mechanisms, like intentionality, which explain behavior of animate objects, and there are physical causal mechanisms which explain the behavior of inanimate objects. One role of cognitive modules is to constrain the search for causal explanations by delimiting the range of possible causes for a particular phenomenon. Thus, causes can be divided into types based on the module with which they are associated. For example, *blocked arteries* and *chemical imbalance* are physical causes of illness. *Low self-esteem* and *problems in love relationships* are psychological causes. These causes differ in specific detail but are of the same type. Causal models of illness can be analyzed in terms of the kinds of causes of which they are composed.

One important dimension of variation among cultural belief systems about illness is whether illness is attributed to psychological causes – human or spiritual agents – or to natural causes (Murdock, 1980, Foster, 1976). In a world survey of illness theories, Murdock (1980) found that every cultural group in his sample (which did not include industrialized societies) explained (at least some) illness in terms of spirit aggression. Spirit aggression is a psychological cause. In contrast, biomedical theories of illness (used by medical doctors) explain illness using physical causes. One explanation for this difference is that

different cultural groups use different cognitive modules to process information about illness. That is, some cultural groups think about illness as a psychological phenomenon, and generate psycho-social attributions, while others construe illness as a physical phenomenon, and generate physical explanations. On this account, cultural environment influences the domain in which individuals search for causes of illness. Perhaps, some cultural groups use the domain of folk psychology to explain illness where other groups use the domain of folk physics (or folk biology). An alternative possibility is that multiple domains are used to process information about illness. Sperber & Hirschfeld (2004) suggest that some belief systems, like religion, maintain stability by being "anchored" in several cognitive domains at once. Thus, different cultural groups may combine different kinds of causes in different ways in their causal models of illness (Ahn, 1998).

The current paper will look at use of psycho-social causes and physical causes in the causal models of illness of three groups of participants. The groups were chosen precisely because they have different beliefs systems of illness. The first group consisted of registered nurses (RNs) who work as medical practitioners in professional medical settings and practice standard scientific biomedicine. The second group of participants consisted of energy healers. These individuals believe that illness is caused by a disruption or imbalance of "energy" in the body and that illness can be treated by balancing that energy. Energy healers often explain illness as the result of psychological problems (Eden, 1999). RNs and energy healers were chosen because they practice healing within belief systems that vary in the kinds of causes to which illness is attributed. Variation along the dimension of psychological versus physical attribution is cross-culturally salient, as mentioned above. While findings from these groups cannot be automatically generalized to other cultural groups, current findings can generate hypotheses about the causal models of other cultural groups which can then be tested. Study Two in the current paper demonstrates that this framework can be usefully extended to very different cultural settings.

Experiment One

The question of interest is how domain-specific causes are invoked in illness causal models of different groups. To measure causal models, causal chains leading to depression and heart attack were elicited from each participant in an open-ended format. The key feature of this study is the elicitation of causal chains rather than lists of causes. Elicitation of causal chains will provide evidence for distinguishing between three possible patterns of use of domain-specific causal information. The three possible patterns are:

1. Different groups use different domains of knowledge to construct causal models of illness. This hypothesis predicts that the causal chains of energy healers will consist of psychological causes while the causal chains of RNs will consist of physical causes.

2. Illness models are anchored in several domains. Causal models of illness are composed of both psychological and physical causes which are patterned systematically within groups.

3. A third possibility is that there is no systematicity in use of domain knowledge in illness models. That is, mental and physical causes may be distributed in different ways across different individuals and/or across different illnesses.

It is expected that energy healers will cite psycho-social causes of both illnesses more often than RNs. The question that will distinguish between the first and second alternatives above is whether illness models consist of a single kind of cause or multiple kinds of cause. The question that will distinguish between the second and third alternatives is whether different kinds of causes pattern systematically within groups.

In addition to the two practitioner groups, a group of undergraduates was also interviewed. Because the nurses may have had more experience with illness than the energy healers, undergraduates were included as an independent measure of the effect of experience on concepts of illness.

Method

Participants This study included three groups of participants. The first group consisted of 13 registered nurses (RNs) with an average age of 41 and an average of 13 years of nursing experience. The second group consisted of 14 energy healers with an average age of 48 and an average of 8 years of energy healing experience. Practitioners had an average of four years of college education and there was no difference in level of education across groups. The final group consisted of 23 undergraduates (UGs) with an average age of 18 and no energy or medical experience. Some undergraduates did only a single illness and others did both (5 did both illnesses, 10 only heart attack, 8 only depression). No differences were observed among those who did one versus both illnesses.

Procedure All participants were asked about heart attack, a physiological illness, and clinical depression, a psychological illness. The order of the illnesses was counterbalanced across participants. For each illness, participants were first asked to list all the causes of the illness and then, for each cause, were asked for causal chains linking each elicited cause to the target illness. To elicit the causal chain linking cause X to the illness, the experimenter asked, for example, "How does X cause illness A" (e.g. How does high blood pressure cause a heart attack?). The participant responded with an intermediary cause, Y. The experimenter then repeated the probe with

cause Y: "How does Y cause a heart attack?" This process was continued until the participant said the causal chain was complete. All interviews were recorded and transcribed.

Results

Across illnesses causes were collapsed into four types: physiological, psycho-social (henceforth called mental), behavioral, and energy. Depression models included an additional cause type, external environmental.

Depression Table 1 lists the average proportion of each type of cause in the models of participants from each group. Anovas were used to compare the proportion of each type of cause across groups. Because these measures are not independent a Bonferroni adjustment set the p-value for significance to 0.01. With this adjustment, only the difference in proportion of energy causes was reliably different across groups [$F(2,40)=17.77$, $p<.001$]. Proportion of physical causes [$F(2,40)=.925$, $p=.41$], mental causes [[$F(2,40)=4.12$, $p=.024$], and environmental causes [$F(2,40)=2.15$, $p<.13$] did not differ across groups. Proportion of behavioral causes [$F(2,40)=5.24$, $p=.01$] was marginally different across groups. Tukey post hoc tests showed that the Energy group cited slightly more behavioral causes than the UG group.

Table 1. Proportion of depression cause types by group.

CAUSE	UG	RN	EN
Physical	0.33	0.43	0.32
Mental	0.66	0.53	0.43
Behavioral	0.00	0.02	0.11
Environmental	0.01	0.02	0.10
Energy	0.00	0.00	0.19

The next set of analyses measured the types of causal relations in the conceptual models of each group. Systematic differences in the types of causal relations across groups indicates the extent to which groups represent different patterns of causal types within their models of illness. The majority of causal relations within the depression models of all groups consist of physical and mental factors (UG=99%, RN=96%, EN=75%) so analysis of causal relations focused on physical and mental causes only. Table 2 shows the proportion of each type of causal interaction among physical and mental causes across groups.

Table 2. Proportion of relations in depression models.

Causal Relation	UG	RN	EN
Physical-Physical	0.10	0.28	0.16
Mental-Mental	0.80	0.47	0.43
Physical-Mental	0.03	0.12	0.02
Mental-Physical	0.07	0.14	0.40

These measures are not independent so with a Bonferroni adjustment the p-value for significance was adjusted to 0.013. There were no differences between groups in the proportion of causal interactions among physical causes [$F(2,40)=1.4$, $p=.257$], nor in the proportion of physical-mental causal interactions [$F(2,40)=2.1$, $p=.13$], which were quite low across groups. The key difference between groups was that energy participants were more likely than other groups to cite mental-physical interactions [$F(2,40)=5.26$, $p=.01$]. Tukey post hoc tests showed that Energy healers cited more mental-physical interactions than RNs and UGs, who did not differ from one another. Undergraduates were more likely than RNs and Energy healers to cite interactions among mental causes [$F(2,40)=5.28$, $p=.01$]. Interactions among mental causes made up the bulk of undergraduate depression concepts.

The most important finding in depression models is that all groups included equal proportions of mental and physical causes in their conceptual models of depression but showed systematic differences in the patterns of causal interaction among them. Specifically, the RNs and UGs placed mental and physical causes on separate causal chains but Energy healers included both types of causes on a single causal chain.

Heart attack Table 3 shows proportions of causes in heart attack models across groups. Energy participants cited proportionately fewer physical causes of heart attack than RNs or Undergraduates [$F(2, 42 = 14.9$, $p<.0001$]. Post hoc tests indicated that the RNs and UGs cited equal proportions of physiological causes and EN participants cited fewer than both groups. Energy participants cited a greater number of psychological causes of heart attack than did either of the other groups, who were equivalent [$F(2, 42 = 34.9$, $p<.0001$]. These differences were reliable with a Bonferroni adjustment. Not surprisingly Energy participants cited a greater proportion of energy causes.

Table 3. Proportion of causes in heart attack models.

Relation	UG	RN	EN
PHYSICAL	0.70	0.77	0.45
PSYCHOLOGICAL	0.08	0.08	0.27
BEHAVIORAL	0.16	0.15	0.17
ENERGY	0.00	0.00	0.10

The next set of analyses explores patterns of causal relations in models of each group. A majority of the causes in heart attack models of all groups were ones with physical effects (RN=0.98, UG=0.99, DUAL=0.88, ENERGY=0.77), so the following set of analyses compares the proportion of physical effects that have either physical, mental, behavioral, or energy causes. Table 4 shows the distribution of these types of relations in individual models of participants in each group.

Table 4. Proportion of causal relations across groups.

Causal Interaction	UG	RN	EN
Physical-Physical	0.54	0.61	0.21
Physical-Mental	0.11	0.11	0.42
Behavioral-Physical	0.35	0.27	0.27
Energy-Physical	0.00	0.00	0.09

These measures are not independent but all effects are reliable with a Bonferroni adjustment. An ANOVA showed that Energy participants cited proportionately fewer physical – physical causal interactions (PP relations) than RNs and UGs [$F(2,42)=20.31$, $p<.0001$]. ENERGY participants mentioned the greatest number of mental-physical causal interactions in their heart attack models [$F(2,42)=23.73$, $p<.0001$]. There were no differences across groups in the frequency of behavioral-physical relations [$F(2,42)=.68$, $p=.51$]. Finally, Energy participants mentioned a greater number of energy-physical relations [$F(2,42)=9.79$, $p<.0001$]. In all causal relation analyses, Tukey post hoc tests showed that RNs and UGs were equivalent and both were different from Energy participants.

As in models of depression, energy healers and RNs and UGs showed different patterns of causal relations among the causes in their conceptual models of heart attack. Like in depression models, Energy healers cite causal interactions among mental and physical causes whereas RNs and UGs do not.

Summary Experiment 1 provides compelling evidence for Alternative two cited above – that illness models are anchored in several domains. Alternative One predicted that illness models would consist of a single kind of cause. This was not supported by current findings. All groups used both psycho-social and physical causes in illness models. Alternative Three was also ruled out, because mental and physical causes patterned systematically, rather than randomly, across participants within a group. Causes also patterned similarly across illnesses for each group. Across both illnesses energy healers frequently cited causal relations in which mental (psycho-social) causes led to physical effects. RNs and UGs rarely mentioned causal interactions between mental and physical features. For depression, mental and physical causes were conceived as distinct causal chains. For heart attack, these participants rarely mentioned mental causes at all. While energy healers combined mental and physical causes within a single causal chain, RNs and UGs kept mental and physical causes on separate causal chains. Further, they did not conceive of heart attack as psychologically caused.

Experiment Two

Whereas Experiment One included groups from a single cultural environment, the current experiment uses the same method to measure concepts of illness in individuals from a very different cultural environment, Peten, Guatemala. The question of interest is whether Maya have systematic patterns in their conceptual models of illness, and if so, whether their concepts correspond to either of the American groups.

Method

Participants Participants were 13 illiterate Itza' Maya adults living in Peten, Guatemala. All participants spoke Spanish as their primary language. Peten is a very different cultural environment from Chicago, IL where participants from Experiment 1 reside. None of the Itza' participants was trained in medicine.

Procedure Causal models were elicited in Spanish for the Itza' illnesses which most closely resemble depression and heart attack. The illnesses were *tukul* (meaning "thought" and glossed "pensiveness" in Itza', a wasting illness) and *derrame* (glossed as the verb "to spill" in Spanish; derrame cerebral is the Spanish gloss for "stroke").

Results

Itza' explain *tukul* as the result of separation from a family member which leads to dilution of the blood and rashes on the skin. 100% of Itza' participants attributed *tukul* to social causes (85% to separation from a family member), and 77% stated that social causes led to a change in the state of the blood (62% said the blood thinned, or was diluted, by too much thinking). 85% specified physical effects that result from the thinning of the blood, usually skin rashes (69%). Every Itza' participant explained *tukul* as the result of psycho-social factors leading to physical changes in the body.

Derrame is also seen as the result of an interaction of mental and physical causes. Itza' explain *derrame* as resulting from anger, which slows the blood, causing it to "spill" into the brain or nerves. 100% of Itza' participants attributed *derrame* to strong emotions (85% to anger), and 70% claimed that strong emotions cause the blood to change state in some way (e.g. blood stops circulating or gets cold), which causes it to mix inappropriately with some other substance of the body (85%), usually the brain or nerves (70%). Every Itza' participant explained *derrame* as the result of the deleterious effect of strong emotions on the state of the blood in the body.

Summary Itza concepts of tukul and derrame were structurally similar to energy healer concepts of depression and heart attack. Specifically, their conceptual representations of both illnesses included causal interactions in which psycho-social factors led to physical ones.

General Discussion

The current experiments show that, rather than being processed from within a single domain, illness knowledge is anchored in multiple domains. Illness models can be explained as specific combinations of domain knowledge. In Experiment 1 illness concepts of energy healers, RNs and Undergraduates showed systematically different causal patterns among mental and physical features. Specifically,

RNs and undergraduates rarely mentioned causal interaction between mental and physical causes. Energy healers, on the other hand, saw both illnesses as resulting from psycho-social causes which result in physical changes. Experiment 2 showed that the Itza' also view these illnesses as resulting from the physical effects of psycho-social factors.

Results from both studies clearly distinguish between the three alternatives presented above. Alternative Three, which was that mental and physical causes would be distributed in unsystematic ways in illness models, was ruled out. Evidence from RNs and undergraduates was also inconsistent with the first alternative, which proposed that illness models would be composed of causes from a single domain. RNs and undergraduates used psycho-social causes in explanations of depression, and physical causes in explanations of heart attack and depression. Thus, these participants utilized causes from distinct domains. However, for these participants a single causal chain consisted of only one type of cause. Data suggest that depression is construed both psychologically and physically for RNs and undergraduates, and heart attack is construed physically. Stress was the only psychological cause utilized in heart attack models of RNs and undergraduates. Stress may be a cause that is flexible, and can function as either psychological or physical. When RNs and undergraduates mentioned stress in the context of heart attack, they usually discussed physiological aspects of stress, such as increased adrenalin. However, because the nature of stress was ambiguous in the current study, it was coded as a psychological cause. For RNs and undergraduates, some illness models are constructed from within the cognitive domain of folk psychology, and others are constructed from within the domain of folk physics. For these participants, cultural factors influence whether an illness should be construed in psychological or physical terms. In this sense, Alternative Two is correct. Knowledge about illness is anchored in both domains.

Energy healer models are also consistent with Alternative Two. But in the case of energy healer models, single causal chains were composed of knowledge from different domains. For these participants causal chains are composed of psycho-social and physical causes. Further, when causal chains contain both kinds of causes, psycho-social causes are the distal causes and physical causes are proximate. The fact that domain boundaries are not preserved in causal chains of energy healers might be taken to suggest that domain knowledge does not constrain models of illness for energy healers. However, the systematicity in the models of energy healers is reflected in the uniformity with which individual participants combined psycho-social and physical causes. That is, the coherence of illness models across participants and across illnesses is precisely in their systematic use of causes from different domains. Participants cited different specific causal factors for heart attack and depression, but all participants were committed to the belief that some kind of psycho-social factor was the initial, distal cause of both illnesses and that physical, mechanical factors were the proximate cause. Analysis at the level of causal types reveals more agreement across individuals and illnesses than analysis at the level of specific, detailed causes.

Similarity in the causal models of energy healers and Maya is also revealed by analysis of patterns of causal types rather than analysis of overlap in specific causes. There was virtually no overlap in the specific causes cited by energy healers and Maya. In fact, it is not even clear that the illnesses being explained were conceptualized as precisely the same (biomedically defined) conditions across groups. But when analyzed as patterns of domain-specific causal types, it is clear that Maya and energy healers have similar causal models of illness. For both groups illnesses are caused by psycho-social factors which lead to proximate causes which are physical in nature. It would be unreasonable to expect that Maya, who have little or no formal education, would independently derive the same specific causes of illness as energy healers or undergraduates who live in a completely different cultural context. Analysis of illness models as patterns of domain-specific causal types reveals uniformities in thinking across cultures that are obscured by exclusive focus on specific, detailed causes.

In sum, cultural knowledge about illness may take the form of learning the culturally appropriate heuristics for combining domain specific knowledge to construct causal models of illness. Diversity among illness models reflects differences in the ways that different cultural groups combine information from different domains. For RNs and undergraduates, illness explanations are constructed from single causal types and culture specifies which type of cause is relevant to which illness. For energy healers and Maya, all illnesses are presumed to be caused by psycho-social factors which lead to physical changes. Thus, diversity in models of illness across cultures may be analogous to diversity in language across cultures where an overlapping set of categories, for example nouns and verbs, are combined in different ways.

Acknowledgments

The work in this paper would not have been possible without the generosity of the research participants, all of whom volunteered their time and wisdom. Thanks also to Douglas Medin, Lance Rips, Scott Atran, Michael Bailey, the Medin lab, and three anonymous reviewers for comments on earlier drafts. Abstract

This paper addresses the issue of how to compute the intensity of surprise in an artificial agent. Resolution of this issue is important for the further specification of the computational model of surprise proposed by Macedo and Cardoso (2001) that was implemented in artificial agents "living" in a multi-agent environment. This model of surprise is mainly rooted in the cognitive-psychoevolutionary model of surprise proposed by the research group of the University of Bielefeld (Meyer, Reisenzein, & Schützwohl, 1997) and in proposals by Ortony and Partridge. We propose several possible functions to compute the intensity of surprise. To assess their accuracy, they were evaluated in an experimental test that focused on the comparison of surprise intensity values generated by artificial agents with ratings by humans under similar circumstances.

Introduction

Considered by many authors a biologically fundamental emotion (e.g.: Ekman, 1992; Izard, 1991), surprise may play an important role in the cognitive activities of intelligent agents, especially in attention focusing (Izard, 1991; Meyer et al., 1997; Ortony & Partridge, 1987; Reisenzein, 2000b), learning (Schank, 1986) and creativity (Boden, 1995; Williams, 1996). Psychological experiments conducted by Meyer, Reisenzein and Schützwohl provide evidence that surprising-eliciting events initiate a series of mental processes that (a) begin with the appraisal of a cognized event as exceeding some threshold value of unexpectedness or schema discrepancy, (b) continue with the interruption of ongoing information processing and the reallocation of processing resources to the surprise-eliciting event, and (c) culminate in the analysis and evaluation of that event plus immediate reactions to it and/or schema (belief) updating/revision. According to these authors, surprise has two main functions, the one informational and the other motivational: it informs the individual about the occurrence of a schema-discrepancy, and it provides an initial impetus for the exploration of the unexpected event. Thereby, surprise promotes both immediate adaptive actions to the unexpected event and the prediction, control and effective dealings with future occurrences of the event.

Ortony and Partridge's (1987) model of surprise shares several aspects with the one proposed by Meyer, Reisenzein and Schützwohl (1997), especially in that both models assume that surprise is elicited by unexpected events. The same is also true for Peters' (1998) computational model of surprise, implemented in a computer vision system, that focuses on the detection of unexpected movements. Finally, models of surprise have also been proposed in the fields of knowledge discovery and data mining (e.g. Suzuki & Kodratoff, 1998).

Macedo and Cardoso (e.g., Macedo & Cardoso, 2001)) developed a computational model of surprise that is an adaptation (although with several simplifications) of the models proposed by Meyer, Reisenzein and Schützwohl (1997) and by Ortony and Partridge (1987). In the present article, we elaborate and evaluate this model further by discussing different possible functions for the computation of surprise and by evaluating these functions in an empirical study.

The following section describes Macedo and Cardoso's surprise model in more detail, including an overview of its theoretical background models. Subsequently, we discuss several possible functions for computing the intensity of surprise. Finally, we describe an experimental test that was carried out to evaluate the accuracy of these surprise functions.

Surprise Model

As mentioned, the surprise model developed by Macedo and Cardoso (2001) is mainly based on Ortony and Partridge's (1987) proposals and on those of Meyer, Reisenzein and Schützwohl (1997). Therefore, we first give an overview of these background theories and then explain the computational model proposed by Macedo and Cardoso, by comparing it with these two models.

Background Models

Although Ortony and Partridge agree with Meyer, Reisenzein and Schützwohl and other authors that surprise is caused by events that are commonsensically called unexpected, they proposed that unexpectedness covers two cases. First, surprise results when prior expectations regarding an event are disconfirmed. Second, however, surprise can also be caused by events for which expectations were never computed. That is, according to Ortony and Partridge, there are situations in which one is surprised although one had no explicit expectations (either conscious or unconscious) regarding the surprising event. Ortony and Partridge also proposed that surprisingness is an important variable in artificial intelligence systems, particularly in attention and learning.

In more detail, Ortony and Partridge's model of surprise assumes a system (or agent) with an episodic and semantic propositional memory whose elements may be immutable (propositions that are believed to be always true) or typical (propositions that are believed to be usually but not always true). Furthermore, they distinguish between practically deducible propositions and practically non-deducible propositions. *Practically deducible propositions* comprise all propositions that are explicitly represented in memory, as well as those that can be inferred from these by few and simple deductions. Hence, practically deducible propositions are that subset of formally deducible propositions that don't require many and complex inferences. Furthermore, practically deducible propositions may be either actively or passively deduced. In the former case, their content corresponds to *actively expected* or *predicted* events; in the latter case, to *passively expected* (*assumed*) events.

Based on these assumptions, Ortony and Partridge proposed that surprise results when the system encounters a conflict or inconsistency between an input proposition and preexisting representations or representations computed "after the fact". More precisely, surprise results in three situations (Table 1 presents the corresponding range of values): (i) *active expectation failure*: here, surprise results from a conflict or inconsistency between the input proposition and an *active prediction* or *expectation*; (ii) *passive expectation failure* (or *assumption failure*): here, surprise results from a conflict or inconsistency between the input proposition and what the agent implicitly knows or believes (*passive expectations* or *assumptions*); and (iii) *unanticipated incongruities* or deviations from norms: here, surprise results from a conflict or inconsistency between the input proposition (which in this case is a practically non-deducible proposition) and what, after the fact, is judged as normal or usual (Kahneman & Miller, 1986), that is, between the input proposition and practically deducible propositions (immutable or typical) that are suggested by the unexpected fact. Note that, in this case, prior to the unexpected event there are no explicit expectations (passive or active) with which the input proposition could conflict.

In their cognitive-psychoevolutionary model, Meyer, Reisenzein and Schützwohl also assume that surprise (considered by them as an emotion) is elicited by the appraisal of unexpectedness.

Table 1: Three different sources of surprise and corresponding value ranges (adapted from (Ortony & Partridge, 1987)).

Confronted proposition	Related Cognition	
	Active	Passive
Immutable	[1]; $S_A=1$; *Prediction*	[2]; $S_P=1$; *Assumption*
Typical	[3]; $0< S_A<1$; *Prediction*	[4]; $S_P<S_A$; *Assumption*
Immutable	[5]; ∅	[6]; $S_P=1$; *none*
Typical	[7]; ∅	[8]; $0< S_P<1$; *none*

More precisely, it is proposed that surprise-eliciting events give rise to the following series of mental processes: (i) the appraisal of a cognized event as exceeding some threshold value of unexpectedness (schema-discrepancy) - according to Reisenzein (2001), this is achieved by a specialized comparator mechanism, the unexpectedness function, that computes the degree of discrepancy between "new" and "old" beliefs or schemas; (ii) interruption of ongoing information processing and reallocation of processing resources to the investigation of the unexpected event; (iii) analysis/evaluation of that event; and (iv) possibly, immediate reactions to that event and/or updating or revision of the "old" schemas or beliefs.

Overview of the Computational Model of Surprise

Macedo and Cardoso (e.g., Macedo & Cardoso, 2001) developed a multi-agent environment in which, in addition to inanimate agents (objects such as buildings), there are two main kinds of animate, interacting agents: the "author-agents" or creators, whose main function is to create things (objects, events), and the "jury-agents" or explorers whose goal is to explore the environment by analyzing, studying and evaluating it. An agent can also show both of these activities (creation and exploration).

The computational model of surprise is integrated into the *motivations* module of the architecture of the artificial agents (see Figure 1). The other modules of this architecture are: *sensors/ perception*; *memory*; *goals/desires*; and *reasoning/decision-making*. This last module and the module *motivations* are provided with information from the world obtained through *sensors/perception*, as well as with information recorded in *memory*. The *reasoning/decision-making* module then computes the current state of the world. Afterwards, probability theory is applied to predict possible future states of the world for the available actions, and a utility function (which makes use of the intensity of the generated emotions) is applied to each of these world states. Finally, the action that maximizes the utility function is selected.

The computational model of surprise incorporated in this agent system is an adaptation (although with some simplifications) of the surprise model proposed by Meyer, Reisenzein and Schützwohl in which the above-mentioned four mental processes elicited by surprising events are

present. The suggestions by Ortony and Partridge are mainly concerned with the first of these steps, and are compatible with the Meyer, Reisenzein and Schützwohl model. Accordingly, in our model, we drew on the assumptions of Ortony and Partridge for the implementation of the appraisal of unexpectedness and the computation of the intensity of surprise, as well as for the selection of knowledge structures.

In Macedo and Cardoso's model, knowledge is exclusively of an episodic kind (for an example, see Figure 2), rather than being both semantic and episodic in nature (although this will be considered in future work), as in Ortony and Partridge's model. In this respect, the knowledge structure of our model also differs from the schema-theoretic framework of the Meyer, Reisenzein and Schützwohl model that also assumes both episodic and semantic knowledge. In our model, an input proposition (or new belief) is therefore always compared with episodic representations of objects or events (or their properties) (for instance an object with squared windows, rectangular door, etc.). Besides, the agent has in its episodic memory explicit representations of similar objects. Following Ortony and Partridge, we also distinguish between *deducible* and *non-deducible*, *active* and *passive*, *immutable* and *typical* propositions as well as between different possible sources of surprise (see Table 1). The immutability of a proposition can be extracted from the absolute frequency values associated with the cases stored in episodic memory (see Figure 2). For instance, in the example shown in Figure 2, the proposition "houses have square facades" is immutable (since all the houses in memory have squared facades), whereas "houses have square windows" is a typical proposition with a probability (immutability) value of 0.50 (as implied by Ortony and Partridge's model, in our model immutability is a continuous variable).

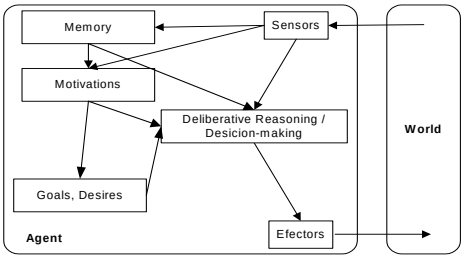

Figure 1: Architecture of an agent.

Field \ Case	C_1	C_2	C_3	C_4
Structure				
Function	House	House	Church	Hotel
Behavior	Static	Static	Static	Static
Abs. Freq.	50	40	5	5

Figure 2: Example of an episodic memory in the domain of buildings.

The usual activity of the agents consists of moving through the environment hoping to find interesting things (objects or events) that deserve to be investigated. We assume that this exploratory behavior is ultimately in the service of other (e.g., hedonic) motives, although this issue is not explicitly addressed in the present model. When one or more objects/events are perceived, the agent computes expectations for the missing information (e.g., "it is a house with 67% of probability", "it is a hotel with 45% of probability", etc.; note that the *function* of a building becomes available to the agent only when its position and that of the building are the same). On the basis of the available information (e.g., the visible *structure* of an object) and the computed expectations (e.g., predictions for the *function* of an object), the agent then determines the intensity of surprise that may be caused by the object/event (these computations, which correspond to the "appraisal of unexpectedness" in the Meyer, Reisenzein and Schützwohl model, are described in more detail below). Subsequently, the object/event with the maximum estimated surprise is selected to be visited and investigated. This corresponds to the "interruption of ongoing activity" and the "reallocation of processing resources" assumed in the Meyer, Reisenzein and Schützwohl model. The previously estimated value of surprise may subsequently be updated on the basis of the additional information acquired about the object/event. The object/event is then stored in memory and the absolute frequencies of the affected objects/events in memory are updated. This is a simplification of the fourth step of the Meyer, Reisenzein and Schützwohl model (for alternative approaches to belief revision, see, for instance, (Gärdenfors, 1988)).

The different surprise-eliciting situations distinguished by Ortony and Partridge are dealt with in our model in the following way. As said above, when an agent perceives an object, it first computes expectations (*deducible*, *active expectations*) for missing information (e.g., "it is a hotel with 45% of probability"). If, after having visited that object, the agent detects that the object is different from what was expected (e.g., if it is a post office), the agent is surprised because its *active expectations* conflict with the input proposition (note that, in our model, belief conflicts may be partial as well as total). This is thus an example of the first source of surprise distinguished by Ortony and Partridge. In contrast, when an agent perceives an aspect or part of an object with particular properties (e.g., a building with a window of a circular shape) that were not actively predicted, it may still be able to infer that it expected something (e.g., a rectangular-shaped window with, 45% probability, a square-shaped window with 67%, etc.). This is an example of a *deducible*, *passive expectation*: although the expectation was not present before the agent perceived the object, it was inferred after the object had been perceived. This case is therefore an example of the second source of surprise distinguished by Ortony and Partridge, where an input proposition conflicts with an agent's *passive expectations*. Finally, when an agent perceives an object with a completely new part (e.g., a building with no facade), it has neither an active nor a passive expectation available.

The reason is that, because there are no objects of this kind (e.g., buildings with no facade) stored in the agent's memory, the agent cannot predict that such objects might be encountered. The perception of an object with a completely new part is thus an example of a *non-deducible proposition*. This is an example of the third source of surprise distinguished by Ortony and Partridge: there is a conflict between the input proposition (e.g., "the house has no facade") and what *after the fact* is judged to be normal or usual (e.g., "buildings have a facade").

The Computation of Surprise Intensity

We now address the question of how the intensity of surprise should be computed in the model. In humans, this problem has already been successfully solved by evolution; therefore, a reasonable approach is to model the agent's surprise function according to that of humans. Experimental evidence from human participants summarized in (Reisenzein, 2000b) suggests that the intensity of felt surprise increases monotonically, and is closely correlated with, the degree of unexpectedness. On the basis of this evidence, we propose that the surprise "felt" by an agent elicited by an object/event X is proportional to the degree of unexpectedness of X (which in the model is based on the frequencies of objects/events present in the memory of the agent). According to probability theory, the degree of expecting an event X to occur is its subjective probability P(X). Accordingly, the improbability of X, denoted by 1-P(X), defines the degree of not expecting X, or for short its unexpectedness. The intensity of surprise elicited by X should therefore be an (at least weakly) monotonically increasing function of 1-P(X). As a first approach, this function (S1) could simply be taken to be the identity function, that is, the intensity of surprise could simply be equated with the degree of unexpectedness:

$$S1(Agt, X) = 1 - P(X)$$

However, on second thought, S1 does not seem to faithfully capture the relation between unexpectedness and surprise. For example, consider a political election with three candidates A, B and C, where the probability of being elected is P(A) = P(B) = P(C) = 0.333. In this case, one would not be surprised if either A, B or C is elected. Therefore, in this situation at least, S1 fails.

To arrive at a more adequate surprise function, consider the case where there are only two mutually exclusive and exhaustive alternative events, X and Y (i.e., not X). Here, intuition suggests that X is not surprising as long as P(X) ≥ 0.5, whereas X is surprising for P(X) < 0.5, and increasingly more so the more P(X) approaches 0. This intuition is captured by the following surprise function (S2):

$$S2(Agt, X) = \begin{cases} 1 - P(X) \Leftarrow P(X) < 0.5 \\ 0 \Leftarrow P(X) \geq 0.5 \end{cases}$$

To deal with sets of more than two mutually exclusive events, S2 could be generalized as follows (S3, where *n* denotes the number of events in the set):

$$S3(Agt, X) = \begin{cases} 1 - P(X) \Leftarrow P(X) < \frac{1}{n} \\ 0 \Leftarrow P(X) \geq \frac{1}{n} \end{cases}$$

However, it may be more adequate to set the upper limit of surprise not to 1, but to $\frac{1}{n}$ (see S4):

$$S4(Agt, X) = \begin{cases} \frac{1}{n} - P(X) \Leftarrow P(X) < \frac{1}{n} \\ 0 \Leftarrow P(X) \geq \frac{1}{n} \end{cases}$$

Yet another possible surprise function, suggested by further reflection on the above election example, is the following (S5):

$$S5(Agt, X) = P(Y) - P(X)$$

In this formula, Y is the event with the *highest* probability of a set of mutually exclusive events. S5 implies that, within each set of mutually exclusive events, there is always one (Y) whose occurrence is entirely unsurprising, namely the event with the maximum probability in the set (P(Y)). For the other events X in the set, the surprise intensity caused by their occurrence is the difference between P(Y) and their probability P(X). This difference can be interpreted as the amount by which P(X) has to be increased for X to become unsurprising. For instance, in the election example considered earlier, where P(A) = P(B)= P(C) = 0.333, S5 correctly predicts that one would not be surprised if either A, B or C is elected. By contrast, if P(A) = 0.55, P(B) = 0.40 and P(C) = 0.05, S5 predicts that the surprise caused by B is 0.15 and for C is 0.50, whereas for A it is 0. S5 also implies that maximum surprise, that is, S(X) = 1, occurs only if P(Y) = 1 and hence, by implication, P(X) = 0. (In the Ortony and Partridge model, this corresponds to situations [1], [2], [5] and [6], where the disconfirmed event Y is immutable, i.e., its probability is 1). Therefore, S5 seems to correctly describe surprise in the election example. Confirming this impression, S5 also acknowledges the intuition behind S2: if there are only two alternative events X and Y (= not X), S5 predicts, like S2, that X should be unsurprising for P(X) ≥ 0.5, for in this case X is also the event with the highest probability in the set. By contrast, for P(X) < 0.5, S5 predicts that X should be surprising and increasingly so the more P(X) approaches 0, with maximum possible surprise (S(X) = 1) being experienced for P(X) = 0.

Yet another possible surprise function (S6) is suggested by Information Theory (Shannon, 1948):

$$S6(Agt, X) = \log_2 \frac{1}{P(X)}$$

According to S6, surprise about X is 0 when P(X) = 1 and increases monotonically with decreasing P(X). In these respects, then, S6 is similar to S1. However, in contrast to S1, S6 is a nonlinear function of P(X), and it is not normalized. For instance, for P(X) = 0.3, *S6(X)* = 1.7 (bits), for P(X) = 0.01, *S6(X)* = 6.6, and for P(X) = 0.001, *S6(X)* = 9.9. In fact, there is no upper limit of S(X): for P(X)=0, *S6(X)* = $+\infty$. To overcome this problem, we propose the following normalized function S7 (stipulating the upper limit to be 10):

$$S7(Agt, X) = \frac{\log_2 \frac{1}{P(X)}}{10}$$

Finally, yet another surprise function (S8), a nonlinear modification of S5, is suggested by the results of the experiment, reported below, performed with humans in the domain of elections and sport games:

$$S8(Agt, X) = \log_2 (1 + P(Y) - P(X))$$

This function retains the essential features of S5: when X is the most expected event (X = Y), then S8(X) = 0; when X is different from Y, S8(X) > 0 and increases monotonically with the difference between P(Y) and P(X); and S8(X) is maximal (= 1) if P(Y) = 1 and P(X) = 0. In addition, however, S8 also captures the nonlinearity of the surprise function suggested by the experiments with humans reported below.

Experiment

To test the validity of the proposed surprise functions, we conducted an experiment that involved two steps. In step 1, we collected ratings of probability and surprise intensity from humans in two domains, political elections and sports games. In step 2, artificial agents that implemented the different surprise functions were provided with the probability judgments obtained from the humans and, on this basis, computed surprise intensity values. These predicted surprise values were then compared with the actual surprise ratings provided by the human participants.

Step 1 was conducted with ten participants (mean age, 29 years). They were presented with 20 brief scenarios, 10 of which described political elections with 2-4 candidates (see Figure 3), whereas the other 10 scenarios described sports games with 2-4 teams or players (see (Reisenzein, 2000a) for a conceptually similar experiment using knowledge questions). Political elections and sports games were chosen because we thought that these domains are familiar to most people and that the participants would have no problems to state their probabilities and their surprise about outcomes. In addition, in contrast to the domain of buildings used in a previous study reported in (Macedo & Cardoso, 2001), elections and sport games allow for an easier matching of the knowledge of artificial agents with that of humans. Part of the scenarios did not include information about the actual outcome of the election or game, whereas the remaining scenarios included this information. For scenarios without outcome information, the participants were asked to first state their expectations for all possible outcomes and to rate their probability on a 1-100 scale. Subsequently, they were informed about the outcome of the election or game and rated their surprise about the outcome first on a qualitative intensity scale and then again on a quantitative intensity scale within the chosen qualitative level. By contrast, for the scenarios that included outcome information, participants first rated the intensity of surprise about the outcome and subsequently their (passive) expectations regarding the outcome. An example of a scenario is shown in Figure 3.

> Given the following prognosis for the election of candidate A, B and C for a political position:
>
> Victory of A=45%; Victory of B=45%; Victory of C=10%
>
> a) What are your personal expectations regarding the victory of candidates A, B and C?
> b) Assume that candidate A won the election and rate the intensity of surprise that you would feel.

Figure 3: Example of a test item.

In step 2 of the study, the probability ratings obtained from each participant in step 1 were delivered to eight artificial agents, each of which implemented one of the eight surprise functions S1-S8 described earlier. Using these functions, the agents computed surprise intensity values from the probabilities. These predicted surprise values were then compared with the surprise ratings of the humans obtained in step 1.

The data obtained in the first step of the experiment suggested two qualitative conclusions. First, the occurrence of the most expected event of the set of mutually exclusive and exhaustive events did not elicit surprise in humans. For example, when the expectations for the election of three political candidates A, B and C were P(A) = 0.55, P(B) = 0.40, and P(C) = 0.05, the participants felt no surprise about the election of candidate A. This was also true when two or more candidates had equal maximal probabilities. For example, when P(A) = 0.40, P(B) = 0.40 and P(C) = 0.20, participants were not surprised when either A or B was elected. Second, beyond the point of zero surprise, the surprise function appeared to be nonlinear. For example, relatively high surprise was indicated when candidate C won the elections in both of the above situations, although it was still higher for P(C) = 0.05 than for P(C) = 0.20.

To compare the surprise values generated by the artificial agents and the surprise ratings provided by the human judges, the following fit indices were used: the root mean squared difference, the mean absolute difference, and the Pearson correlation. The results of these comparisons are shown in Table 2, separately for the 10 participants (H1, …, H10) and for six of the eight artificial agents (A1,…,A8) (the surprise functions S6 and S7 were not included because

they have a different range than the human ratings and therefore computation of the absolute and squared differences is not meaningful). It can be seen from Table 2 that, regardless of which fit index is used, agent A8 (which implemented surprise function S8) was the one with the best fit to the human ratings: it had on average, the lowest root mean squared differences (*Ms*= 0.10), the lowest absolute differences (*Md*= 0.06), and the highest correlation to these ratings (*Mr*= 0.98). A8 was closely followed by A5 (*Ms* = 0.21; *Md* = 0.08; *Mr* = 0.97), whereas agents A1 and A2 had the comparatively worst fit values (for instance, A1 had *Ms* = 0.35; *Md* = 0.26; *Mr* = 0.81). A main reason for the bad performance of A1 was apparently that it failed in the case of the occurrence of the most expected event of the set: A1 still predicts a positive surprise value (1-P(X)) for this case, whereas humans do not feel surprised by the occurrence of this event. However, in other situations, A1 performed well.

Table 2: Statistical comparison of the surprise values computed by the artificial agents and those provided by the humans (*s* = root mean squared difference, *d* = mean absolute difference, and *r* = Pearson correlation).

Conclusions

The empirical study of the surprise functions suggests S8(X) = $\log_2(1+P(Y)-P(X))$ as the most appropriate surprise function for the domains of political elections and sport games, although S5 (the linear counterpart of S8) is a very close contender. However, before more definitive conclusions can be drawn, additional tests need to be performed in other domains, as well as with yet other possible surprise functions (e.g., Shackle, 1969).

Abstract

The concept of *manipulative abduction* is devoted to capturing the role of action in many interesting situations: action provides otherwise unavailable information that enables the agent to solve problems by starting and performing a suitable abductive process of generation or selection of hypotheses. Many *external representations*, even if in some cases inert from an epistemological point of view, can be transformed into what is called *epistemic mediators*, active in creative abductive reasoning. An often neglected side of human creativity is related to emotional, artistic, and ethical aspects, and concerns the active shaping of values in an esthetical and ethical world. I will present some aspects of this kind of reasoning in the case of scientific and ethical thinking; moreover, I will illustrate some aspects of what I call "ethical mediators" in their activity of shaping and reshaping ethical worth of human beings and collectives.

The Inexplicability of Creativity

Creativity is certainly an important aspect of our definition of "intelligence" but the literature associates many different notions to creativity. This ambiguity has brought to a lack of consensus in the research community. The common views associate to creativity unusual and mysterious qualities that drive the concept of creativity to a confused verbosity. Statements like "to break the rules", "to think different", "to destroy one *Gestalt* in favor of a better one", and "to arrange old elements into a new form", present in the field of psychological research on creativity since 1950s, certainly do not clarify the topic, and seem to lead to the Freudian conclusion that creativity cannot be understood. This conclusion has also been supported by many philosophers who studied conceptual change in science during the second half of the last century. They distinguished between a logic of discovery and a logic of justification (i.e. between the psychological side of creation and the logic argument of proving new discovered ideas by facts). The consequent conclusion was that a logic of discovery (and a *rational* model of discovery) could not exist: scientific conceptual change is cataclysmic and irrational, dramatic, incomprehensible and discontinuous. Many other studies already argued that creativity can be understood (Boden, 1991, Sternberg, Kaufman, and Pretz, 2002), but paid attention mainly to the psychological and experimental aspects, disregarding the philosophical, logical, and computation ones.

In AI research, however, since Simon, two characteristics seem to be associated to creativity: the *novelty* of the product and the *unconventionality* of the process that leads to the new product. Hence, in a strictly *pragmatic* sense, when we can clarify what behavior we are looking for, we could implement it in a machine: a methodological criterion enables us to define and consider just those practical effects we conceive to be associated with novelty and unconventionality (cf. Buchanan, 2001).

I maintain we can overcome many of the difficulties of creativity studies developing a theory of abduction, in the light of Charles Sanders Peirce's first insights.

Abduction and Epistemic Mediators

If we decide to adopt this kind of methodology it is necessary to develop a cognitive model of creativity able to represent not only "novelty" and "unconventionality", but also some features commonly referred to as the entire creative process, such as the expert use of background knowledge and ontology (defining new concepts and searching heuristically among the old ones) and the modeling activity developed in the so called "incubation time" (generating and testing, transformations in the space of the hypotheses). The philosophical concept of *abduction* may be a candidate to solve this problem, and offers an approach to model creative processes of hypotheses generation in a completely explicit and formal way, which can fruitfully integrate the narrowness proper of a merely psychological approach, too experimentally human-oriented.

Theoretical and Manipulative Abduction

A hundred years ago, C. S. Peirce (*CP*, 1931-1958) coined the concept of abduction in order to illustrate that the process of scientific discovery is not irrational and that a methodology of discovery is possible. Peirce interpreted abduction essentially as an "inferential" *creative process* of generating a new hypothesis. Abduction has a logical form (fallacious, if we model abduction by using classical logic) distinct from deduction and induction. Reasoning which starts from reasons and looks for consequences is called *deduction*; that which starts from consequences and looks for reasons is called *abduction*.

Abduction is the process of *inferring* certain facts and/or laws and hypotheses that render some sentences plausible, that *explain* or *discover* some (eventually new) phenomenon or observation; it is the process of reasoning in which explanatory hypotheses are formed and evaluated. There are two main epistemological meanings of the word abduction (Magnani, 2001): 1) abduction that only generates "plausible" hypotheses ("selective" or "creative") and 2) abduction considered as inference "to the best explanation", which

also evaluates hypotheses. To illustrate from the field of medical knowledge, the discovery of a new disease and the manifestations it causes can be considered as the result of a creative abductive inference. Therefore, "creative" abduction deals with the whole field of the growth of scientific knowledge. This is irrelevant in medical *diagnosis* where instead the task is to "select" from an encyclopedia of prestored diagnostic entities. We can call both inferences ampliative, selective and creative, because in both cases the reasoning involved amplifies, or goes beyond, the information incorporated in the premises.

Theoretical abduction[1] certainly illustrates much of what is important in creative abductive reasoning, in humans and in computational programs, but fails to account for many cases of explanations occurring in science when the exploitation of environment is crucial. It fails to account for those cases in which there is a kind of "discovering through doing", cases in which new and still unexpressed information is codified by means of manipulations of some external objects (*epistemic mediators*). The concept of *manipulative abduction*[2] captures a large part of scientists' and physicians' thinking where the role of action is central, and where the features of this action are implicit and hard to be elicited

Peirce uses the terms "inference" and "inferential process" to refer to abduction. It is useful to try to clarify the meaning of the term "inference" as considered by Peirce's thought. Peirce stated that all thinking is in signs, and signs can be icons, indices or symbols. Moreover, all *inference* is a form of sign activity, where the word sign includes "feeling, image, conception and other representation" (*CP* 5.283), and, in Kantian words, all synthetic forms of cognition. Feelings, images, simulations, etc., are currently characterized as forms of model-based reasoning (Magnani & Nersessian, 2002). Consequently, following Peirce, we can say that a considerable part of thinking activity is *model-based* (cf. footnote 1), that most of the forms of constitution of phenomena are characterized in a model-based way. I use the term "model-based reasoning" following Nersessian (1995), that is, to indicate the construction and manipulation of various kinds of representations, not necessarily sentential and/or formal. Scientific concept formation, scientific discovery, and – as we will see – diagnostic reasoning are often related to *heuristic* procedures that resort to mental/internal but also to external "models" and representations.

Peirce gives an interesting example of model-based abduction related to sense activity: "A man can distinguish different textures of cloth by feeling: but not immediately, for he requires to move fingers over the cloth, which shows that he is obliged to compare sensations of one instant with those of another" (*CP* 5.221); this idea surely suggests that abductive movements also have interesting extra-theoretical characteristics and that there is a role in abductive reasoning for various kinds of manipulations of external objects (cf. below, the problem of "action-based, manipulative abduction"). One more example is given by the fact that the perception of tone arises from the activity of the mind only after having noted the rapidity of the vibrations of the sound waves, but the possibility of individuating a tone happens only after having heard several of the sound impulses and after having judged their frequency. Consequently the sensation of pitch is made possible by previous experiences and cognitions stored in memory, so that one oscillation of the air would not produce a tone.

Model-based thinking activity also exploits *external models*. We have seen that the concept of manipulative abduction is devoted to capturing the role of action on external models in hypothetical and creative reasoning. This kind of manipulation provides otherwise unavailable information that enables the agent to solve a problem by performing abductive processes of generation or selection of hypotheses. An expert manipulation of objects directed by abductive movements that implicates the strategic application of old and new *templates* of behavior mainly connected with extra-theoretical components also esthetical, ethical, and emotional.

Manipulative abduction happens when we are thinking *through* doing and not only, in a pragmatic sense, about doing. It refers to an extra-theoretical behavior that aims at creating communicable accounts of new experiences to integrate them into previously existing systems of experimental and linguistic (theoretical) practices. Gooding (1990) refers to this kind of concrete manipulative reasoning when he illustrates the role in science of the so-called "construals" that embody tacit inferences in procedures that are often apparatus and machine based. The embodiment is of course an expert manipulation of objects in a highly constrained experimental environment, and is directed by abductive movements that imply the strategic application of old and new *templates* of behavior mainly connected with extra-theoretical components, for instance emotional, esthetical, ethical, and economic.

Epistemic Mediators

Recent research, taking an ecological approach to the analysis and design of human-machine systems, has shown how expert performers use action in everyday life to create an "external" model of task dynamics that can be used in lieu of an internal model (Kirlik, 1998). Not only a way for moving the world to desirable states, action performs an *epistemic* and not merely performatory role that is very relevant to abductive reasoning.

The whole activity of manipulation is devoted to build various external *epistemic mediators* that function as an enormous new source of information and knowledge. I derive this expression from the cognitive anthropologist Hutchins (1995), that coins the expression "mediating structure" to refer to various external tools that can be built to cognitively help the activity of navigating in modern but also in "primitive" settings. Any written procedure is a simple example of a cognitive "mediating structure" with possible cognitive aims: "Language, cultural knowledge, mental

[1] Magnani (2001) introduces the concept of theoretical abduction. He maintains that there are two kinds of theoretical abduction, "sentential", related to logic and to verbal/symbolic inferences, and "model-based", related to the exploitation of internalized models of diagrams, pictures, etc., cf. below in this paper.

[2] Manipulative abduction and epistemic mediators are introduced and illustrated in Magnani (2001).

models, arithmetic procedures, and rules of logic are all mediating structures too. So are traffic lights, supermarkets layouts, and the contexts we arrange for one another's behavior. Mediating structures can be embodied in artifacts, in ideas, in systems of social interactions […]" (pp. 290-291).

In this light manipulative abduction in science represents a kind of redistribution of the epistemic and cognitive effort to manage objects and information that cannot be immediately represented or found internally (for example exploiting the resources of visual imagery).[3]

The *hypothetical* character of manipulations in creativity is clear: they are a sort of test, they can be developed to examine further chances, they are a provisional creative organization of experience and some of them become in their turn hypothetical "interpretations" of experience, suggesting new worldviews. Step by step the new interpretation – that at the beginning is completely "practice-laden" – relates to more "theoretical" modes of understanding (narrative, visual, diagrammatic, symbolic, conceptual, simulative).

A Cognitive Theory of the Abductive Modeling Activity

We can say abduction is a complex *process* that works through *imagination*: it suggests a new direction in reasoning by *shaping* new possible ways for explaining object and hypotheses (cf. the templates mentioned above). In this sense imagination should not be confused with an act of intuition. Peirce describes abduction as a dynamic modeling process that fluctuates between states of doubt and states of belief. To solve the doubt, and some eventually linked anomalies, the agent implements a process of information gathering which at the same time relates to the "problem", to the agent's evolving understanding of the situation and to its changing requirements. By imagination here I mean this process of knowledge gathering and shaping. A process, that Kant considered "blind", that leads to *see* things *as* we would not otherwise have seen them: "a blind but indispensable function of the soul, without which we should not have no knowledge whatsoever" (Kant, 1929, A78-B103, p. 112). Scientific creativity, it is pretty obvious, involves seeing the world in a particular new way: scientific understanding permits us to see some aspects of reality in a particular way and creativity relates to this capacity to shed new light. Suggestions which make us able to further analyze this process come from a theory developed in the area of computer vision: the *active perception* approach (see Thomas, 1999).

This approach aims at understanding cognitive systems in terms of their environmental *situatedness*: instead of being used to build a comprehensive inner model of its surroundings, the agent's perceptual capacities are seen as simply used to obtain "whatever" specific pieces of information are necessary for its behavior in the world. The agent constantly "adjusts" its vantage point, updating and refining its procedures, in order to uncover a piece of information. This resorts to the need of specifying how to efficiently examine and explore and to the need of "interpreting" an object of a certain type. It is a process of attentive and controlled perceptual exploration through which the agent is able to collect the necessary information: a purposefully moving through what is being examined, actively picking up information rather than passively transducing (cf. Gibson, 1979).

As suggested for instance by Lederman and Klatzky (1990), this view of perception may be applied to all sense modes: for example, it can be easily extended to the haptic mode**.** Mere passive touch, in fact, tells us little, but by actively exploring an object with our hands we can find out a great deal. Our hands incorporate not only sensory transducers, but musculature which, under central control, moves them in appropriate ways: lifting something tells about its weight, running fingers around the contours provides shape information, rubbing it reveals texture. As already stressed by Peirce in the quotation I already reported above, when dealing with the hypothesizing activity of what I call manipulative abduction, "A man can distinguish different textures of cloth by feeling: but not immediately, for he requires to move fingers over the cloth, which shows that he is obliged to compare sensations of one instant with those of another" (*CP* 5.221).

Thomas (1999) suggests we can think of the fingers together with the neural structures that control, for example, running them so that we can consider the afferent signals that they generate as a sort of (perceptual) *instrument* to gather knowledge: a complex of physiological structures capable of active testing for some environmental property. The study of manipulative abduction that I outlined above, can gain from this approach. To give an example, the role of particular epistemic mediators (*optical diagrams*) in non-standard analysis has been studied, and so their function in grasping and teaching abstract and difficult mathematical concepts (see Magnani and Dossena, 2002). In this case the external models (mathematical diagrams) do not give full available knowledge, but, on the contrary, compel the agent to engage a continuous epistemic dialogue between the diagrams and its internal knowledge to the aim of understanding an already existing information or at "creating" a new one (cf. also the geometrical example in the following section).

It is clear that humans and other animals make a great use of perceptual reasoning and kinesthetic abilities. We can catch a thrown ball, cross a busy street, read a musical score, go through a passage by imaging if we can contort out bodies to the way required, evaluate shape by touch, recognize that an obscurely seen face belongs to a friend of ours, etc. Usually the "computations" required to achieve these tasks are not accessible to a conscious description. Mathematical reasoning uses language explanations, but also non-linguistic notational devices and models. Geometrical constructions represent a relatively simple example of this kind of extra-linguistic machinery we know as characterized in a model-based and manipulative - abductive - way.

Creativity and Ethical Mediators

The active process of information gathering through *mediators*, to shape knowledge, should not be restricted to the

[3] For example it is difficult to preserve precise spatial relationships using mental imagery, especially when one set of them has to be moved relative to another.

scientific activity and so to the "epistemic" side of them. An often neglected side of human creativity is, in fact, related to emotional, artistic, and ethical aspects, and concerns the active shaping of values in an esthetic or in an ethical world. In the case of morality the role of hypotheses and manipulation of the world is clear in Kant's moral doctrine. When Kant considers pure moral rules, in fact, he says that they could be applied to the concrete experience through a kind of "typification", a figurative envisioning of a non existing world, based on a metaphoric mapping, as a means for judging a given moral situation (Johnson, 1993).

As already outlined above, for Peirce all knowing is *inferring* and inferring is not instantaneous, it happens in a process that needs an activity of comparisons involving many kinds of models (signs) in a more or less considerable lapse of time. All sensations or perceptions participate in the nature of a unifying hypothesis, in the case of "emotions" too. In Peircian sense *emotions* too express a kind of model-based reasoning and have and "inferential" character. In decision making emotions play a distinguished role: they make the velocity of the decision process, surely related to what we care about, and lead directly to actions. But they are also usually considered irrational because of the serious disadvantages they present: failure to consider other options, lack of consideration of accurate and relevant information, not sharability in group situation, when the decisions have be adopted collectively. It is important to understand that emotions are not inherently irrational, for example they can be usefully intertwined with cultural aspects.

In general we can say that moral deliberations relate to a sort of selection or creation of principles (rules, prototypes) and to their application to concrete cases. We can both just select (or create, if we do not have any) moral principles (rules, prototypes) and apply them to concrete cases or looking for the best ones among them according to some ethical meta-criteria. When we create new ethics, we provide new knowledge and new rules about problems and situations not yet clearly covered from the moral point of view. In this last case we certainly are in front of a particular case, but the problem is not only the one of ethically solving the case at hand by applying already available ethical concerns – indeed we lack a satisfactory moral knowledge to handle the puzzling situation. Instead we need to create something new, for example new good reasons first which can provide an acceptable intelligibility of the problem. Once created, it will be possible to see the new principle and the new moral knowledge as a crystallization of the various insights emerging from peoples' and/or experts' experience and thinking.

The role of cognitive delegations to external objects and structures has to be extended to the case of human actions and organizations, so viewed as cognitive "mediating" mechanisms endowed with moral aspects. In this light it is possible to introduce the concept of *ethical* (or *moral*) *mediator*. Moral mediators play an important role in reshaping ethical worth of human beings and collectives. They especially involve a continuous reconfiguration of social orders aimed at rebuilding new moral perspectives and chances. These mediators represent a kind of redistribution of the moral effort through managing objects and information in such a way that we can overcome the poverty and the unsatisfactory character of the moral options immediately represented or found internally. *Moral mediators* are also used to exploit latent constraints in the human-environment system. These new constraints grant additional and precious ethical information. When we spontaneously act in a way so that we spend more quality time with our partner to save our marriage, for example, then our actions automatically can cause variables relating to "unexpected" and "positive" contents of the relationship to covary with perceptible new released informative, sentimental, sexual, and in general bodily variables. Prior to the adoption of the new reconfigured "social" order of the couple, there is no active constraint between these hidden and overt variables causing them to carry information about each other. It is also well-known that also "trained" emotions[4] play an important creative role in moral deliberations.

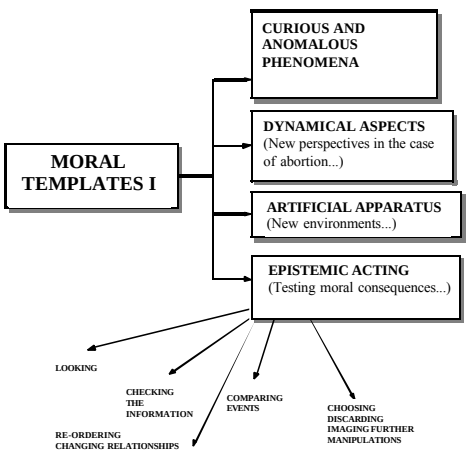

Figure 1. Conjectural moral templates I.

Templates of Moral Doing

It is difficult to establish a list of invariant behaviors that are able to illustrate manipulative reasoning in ethics. As illustrated above, certainly the expert manipulation of non-human objects in real or artificial environments implies the application of old and new *templates* of behavior that exhibit some regularities. As I have said it is important to remember they are embodied and implicit, as tacit forms of acting: I are not referring here to the moral actions and manipulations that simply follow previous explicit and devised plans. Anyway, this moral activity is still conjectural: these templates are embedded hypotheses of moral behavior (creative or already cognitively present in the people's mind-body system, and ordinarily applied) that enable a kind of moral "doing". Hence, some templates of action and manipulation can be *selected* in the set of those available and pre-stored, others have to be *created* for the first time to

[4] That is not just shaped by biological evolution but also by cultural aspects.

perform the most interesting accomplishments of manipulative moral inference.

Some common features of these "tacit" templates that enable us to manipulate external human and non-human things and structures to achieve moral effects are related to (Figure 1): 1. sensibility to the aspects of the moral situation which can be regarded as *curious* or *anomalous*; manipulations can also be performed to be able to introduce potential inconsistencies in the received knowledge (we suddenly adopt a different attitude with respect to our wife/husband to get some reactions we can regard as interesting – or "unexpected" – to confirm or discard hypotheses about her/feelings or to develop further hypotheses about them; in an investigation about a crime we spontaneously engage further manipulations of the evidence to get more interesting data to morally shape the suspect); 2. preliminary sensibility to the *dynamical* character of the situation at hands, and not only to entities and their properties, common aim of manipulations is to practically reorder the dynamic sequence of the events correlated to the main problem to promote the subsequent possibility of new possibilities and options for action (a women in front of decision in favor of abortion spontaneously tries to modify the dynamical aspects of her behavior and the structure of her human relationships to try to establish new perspectives able to make her able to envisage a possible decision different from the first one first envisaged); 3. referral to manipulations that exploit *artificial* created feelings and environments to free new possibly stable and repeatable sources of information about hidden moral knowledge and constraints (when dealing with the moral problem of capital punishment we can spontaneously handle people, for example with statistics, interviews, scientific research, associations, to artificially reconfigure social orders in a way suitable to get real and not hypocritical information, for example about the real relief generated in the victim's relatives by killing the criminal); 4. various contingent ways of spontaneous moral acting: *looking* from different perspectives, *checking* the different information available, *comparing* subsequent events, *choosing*, *discarding*, *imaging* further manipulations, *re-ordering* and *changing relationships* in the world by implicitly *evaluating* the usefulness of a new order (for instance, to help memory) (in the ethical case they certainly are all useful ways for getting suitable evidence and for stimulating the derivation of further consequences to test our previously established moral judgments; analogous of all these manipulative templates are active in epistemic settings, as illustrated in Magnani, 2001).

More features of our tacit templates and ethical mediators are related to the following additional issues (Figure 2): 5) moral spontaneous action that can be useful in presence of *incomplete* or *inconsistent* information – not only from the "perceptual" point of view – or of a diminished capacity to morally act upon the world: it is used to get more data to restore coherence and/or to improve deficient knowledge; 6) action as a *control of sense data* illustrates how we can change the position of our body (and/or of the external objects) to reconfigure social orders, collective relationships, and how to exploit various kinds of artificially created events to get various new kinds of stimulation: action provides some tactile, visual, kinesthetic, sentimental, emotional, and bodily information (e.g, in taking care of people, cf. below in the following subsection), otherwise unavailable; 7) action enables us to build new *external artifactual models* of ethical mechanisms and structures (for example through "institutions") instead of the corresponding "real" and "natural" ones.[5] For instance, we can substitute to the "natural" structure "family" an environment more adequate to agent's moral needs. In this case we aim at reconfiguring relationships for instance when we exploit the social reshaping role of the "houses" were children molested inside family are recovered, to rebuild in a whole artificial framework their moral perception for example of the sexual molestation received and of the related bad feelings. Something similar occurs in the case of the addicted people. We also establish structures to implicitly favor good manners, for example fences, barriers in the lines, etc.

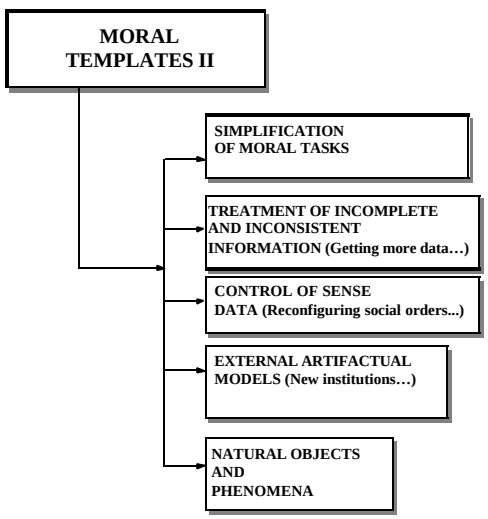

Figure 2. Conjectural moral templates II.

Moral Mediators

The whole activity of manipulation is also devoted to build various external *moral mediators*[6] that function as an enormous new source of information and knowledge. Therefore, these mediators represent a kind of redistribution of the moral effort through managing objects and information in such a way that we can overcome the poverty and the unsatisfactory character of the moral options immediately represented or found internally (for example exploiting the resources in terms of merely internal/mental moral principles, utilitarian envisaging, and model-based moral reasoning).

[5] Of course these "real" and "natural" structures are also artificial, because we can think of a "family" as a kind of not merely natural institution.

[6] I derive this expression from the one "epistemic mediators" I introduced in Magnani (2001, chapter 3): these consist of external representations, objects, and artifacts that are relevant in scientific discovery and reasoning processes.

Not only a way for moving the world to desirable states, action performs a moral and not just merely performatory role: people structure their worlds to simplify and solve moral tasks when they are in presence of incomplete information or possess a diminished capacity to morally act upon the world when they have insufficient opportunities to know. *Moral mediators* are also used to exploit latent constraints in the human-environment system. These elicited new constraints grant us additional and precious ethical information: when we spontaneously act in a way in which we spend more quality time with our partner to save our marriage, then our actions automatically cause variables relating to "unexpected" and "positive" contents of the relationship to covary with perceptible new released informative, sentimental, sexual, and, in general, bodily variables. Prior to the adoption of the new reconfigured "social" order of the couple, there is no active constraint between these hidden and overt variables causing them of carry information about each other

Conclusion

What I call *theoretical abduction* (sentential and manipulative) certainly illustrates much of what is important in creative abductive reasoning both in humans and computational programs, especially the objective of selecting and creating a set of hypotheses that are able to dispense good (preferred) explanations of data, but fails to account for many cases of explanations occurring in science or in everyday reasoning when the exploitation of the environment is crucial. The concept of *manipulative abduction* is devoted to capture the role of action in many interesting situations: action provides otherwise unavailable information that enables the agent to solve problems by starting and performing a suitable abductive process of generation or selection of hypotheses. Many external things, even if usually inert from the epistemological point of view, can be transformed into what is called *epistemic mediators*, which are illustrated in the second part of this paper, together with an analysis of the related notion of "external representation steps in a way that discharges the "internal" mind of a computational load. To define a cognitive system it seems we can no longer identify it only with internal processing devices.

By exploiting the concept of "thinking through doing" and of manipulative abduction I have tried to shed new light on some of the most interesting cognitive aspects of creative ethical reasoning of what I call "ethical mediators". Indeed, I contend that the whole activity of manipulation can be seen as an activity for building various external "ethical mediators" that function as an enormous new source of information and knowledge. Furthermore, while describing morality "through doing" a list of "moral templates" as forms of invariant behaviors that are able to illustrate manipulative ethical reasoning is furnished. These templates are forms of behavior which are inclined towards providing ethical outcomes. The application of old and new (creative) moral templates of behavior exhibits some regularities and expresses expert manipulation of human and non-human objects in real or artificial environments. These templates are embodied and implicit as tacit forms of acting. They are embedded hypotheses of moral behavior (creative or already cognitively present in the people's mind-body system, and ordinarily applied) that enable a kind of moral "doing". Hence, some templates of action and manipulation can be selected in the set of those available and pre-stored, while others have to be created for the first time in order to perform the most interesting accomplishments of manipulative moral inferences. These "tacit" templates enable us to manipulate external human and non-human things and structures to achieve moral effects.

Abstract

Many studies in cognitive science address how people categorize objects, but there has been comparatively little research on event categorization. This study investigated the categorization of events involving material destruction, such as "cutting" and "breaking". Speakers of 28 typologically, genetically, and areally diverse languages described events shown in a set of video-clips. There was considerable cross-linguistic agreement in the dimensions along which the events were distinguished, but there was variation in the number of categories and the placement of their boundaries.

Introduction

Categorization research in cognitive science has focused overwhelmingly on the mental representation of **objects**. Behavioral studies with adults, neuropsychological studies with patient populations, cross-cultural comparisons, and acquisition evidence provide converging evidence about how objects are represented. For example, objects are stored according to semantic domains, with natural kinds represented distinctly from artifacts. Within these categories there are subdivisions: animals are stored separately from fruits, while musical instruments are stored separately from furniture (Shallice, 1988). Objects are organized not only by semantic domain but also hierarchically, with categories at the superordinate, basic, and subordinate levels (Rosch, 1978). Basic level categories are cognitively privileged, in the sense that they are labeled with shorter words, they constitute the preferred level of naming, they can be verified faster than superordinate and subordinate categories in judgment tasks, and they are acquired earlier by children (Brown, 1958; Rosch et al., 1976). There also appears to be considerable cross-cultural consensus in the organization of object representations (Berlin, 1992; Malt, 1995).

In contrast to all the work on objects, relatively little has been done on the mental representation of **events**. One line of research, with roots in social psychology, has investigated how people segment events (Newtson & Engquist, 1976; Newtson, Engquist, & Bois, 1977; Zacks et al., 2001). Another important line of work on event representation, originating in cognitive psychology and artificial intelligence, has examined the organization of event knowledge in scripts, frames, and schemas (Minsky, 1975; Schank & Abelson, 1977).

Neither of these approaches to event representation has examined how everyday activity types are categorized. Studies of event segmentation do not ask which event segments are regarded as being "of the same kind". Script and frame research concentrates on scenarios like "going to the movies", "going to a restaurant", "sports", or "housework" (Morris & Murphy, 1990; Rifkin, 1985). These scenarios are often culture-specific, and so do not lend themselves to cross-cultural research. They are also complex, consisting of sequences of finer-grained events such as "walking into the restaurant", "sitting down", "ordering", "eating", and "paying the bill". Little is known about how uniformly people categorize such finer-grained units, but it has been widely assumed – certainly by developmentalists – that there is a universal core set of everyday event types and that children learn basic verbs such as *have, hit, move, put*, and *give* by linking them directly to these concepts (Gleitman, 1990; Pinker, 1989).

In the present study, we focus on the linguistic categorization of a set of everyday events of "cutting and breaking" – more formally known as events involving a "separation in the material integrity" of objects (Hale & Keyser, 1987).[1] This domain was chosen because such events are universal and do not rely on specialized knowledge; they are accessible to everyone. The manufacture and use of tools for purposes of cutting and breaking has been dated back to at least 2.5 million years ago in the East African Rift area. Modern humans (*homo sapiens sapiens*) appear to be distinctive for making and using particular tools for "cutting", such as pressure-flaked knives (Toth & Schick, 1993). "Cutting" and "breaking" can, then, be taken as human activities that are central to human language and cognition.

We examine the categorization of "cutting and breaking" events by looking at how speakers of

[1] The terms "cutting" and "breaking", with quotes, designate actions of the type that speakers of English typically label with verbs like *cut* and *break*; other languages may or may not have words with closely similar meanings. Throughout this paper, words in quotation marks point to actions of a certain general type, and words in italics designate linguistic forms.

genetically, typologically, and areally diverse languages describe a set of actions shown in video-clips. Do speakers of all languages make the same distinctions when they are talking about such events?

The verbs c*ut* and *break* have been widely discussed in the linguistics literature. One influential approach has suggested that "cutting"-type verbs and "breaking"-type verbs can be universally distinguished on the basis of their semantic and syntactic behavior (Guerssel et al., 1985). This suggests that speakers of different languages should recognize similar distinctions.

Other work, however, suggests that there may be significant differences in the way languages categorize "cutting" and "breaking" events; for example, English speakers use *break* for actions on a wide range of objects (e.g., a plate, a stick, a rope), while speakers of K'iche' Maya must choose from among a set of "breaking" verbs on the basis of properties of the object; e.g., *-paxi:j* 'break a rock, glass, or clay thing' (e.g., a plate); *-q'upi:j* 'break (other kinds of) hard thing' (e.g., a stick); *-tóqopi'j* 'break a long flexible thing' (e.g., a rope) (Pye, 1996; Pye, Loeb, & Pao, 1995). Differences in the categorization of "cutting and breaking" events might also be expected due to variation in cultural tools and techniques; for example, Americans and Europeans chop vegetables by holding them still and bringing a knife down on them from above, whereas Punjabi speakers in rural Pakistan and India often move the vegetables against a stationary curved knife.

In studying the categorization of "cutting and breaking" events, it is not obvious a priori what the domain of investigation should be taken to encompass. Whereas speakers of English do not use *cut* and *break* for actions like peeling a banana or pulling paper cups apart, and they do not use *open* for events like breaking the stem off an apple, perhaps such categorizations occur in other languages. Children learning English in fact make such overextensions (Bowerman, in press; Schaefer, 1979), which suggests that the boundaries of the "cutting and breaking" domain may not be cognitively obvious, and therefore not universally shared. One important goal for the present study, then, is not only to examine the categorization of "cutting and breaking" events by speakers of different languages, but also to discover the extent to which "cutting and breaking" events hang together in the first place as a relatively coherent semantic domain, as distinct from events involving other kinds of separations.

Method

Participants

Event descriptions were collected from speakers of 28 typologically, genetically and areally diverse languages. For each language there were between one and seven consultants. Twenty researchers collaborated in this effort, all of them experts on the language they worked on – a critical point for the validity of the coding of the data (see Results section). Data collection was carried out in the language being studied, not a contact language. Details of the languages, language affiliations, and researchers responsible for the collection and coding of the data are given in Table 1.

Materials

The data were collected using a set of 61 video-clips that depicted a wide range of events (Bohnemeyer, Bowerman, & Brown 2001). The majority of these clips showed an event in which an actor brought about a change of state in an object – specifically, some kind of destruction of the object's material integrity. Some clips depicted state-change events that involved separation but not material destruction, such as opening a pot or pulling paper cups apart. Still others depicted "peeling" events, which share properties with events of both material destruction and simple separation. Stimuli were constructed by varying the agent, the instrument used, the object acted upon, the manner of the destruction, and the prototypicality of the event (see Figure 1).

Figure 1: Example stills from video clips

Procedure

Consultants saw one video-clip at a time on a laptop. The clips were presented in a fixed order. The consultants' task was to describe what the agent did. After free description they were asked what other descriptions could be applied felicitously to each clip. They were also asked whether other descriptions would be infelicitous.

Results

Coding

We defined the target event we were interested in as the change in an object from a state of integrity to a state of separation or material destruction. For each of the languages, the researcher who collected the data identified those constituent(s) of a speaker's description which

encoded the event. For example, the event of "a boy cutting a carrot", at the top left of Figure 1, can be expressed in English as *The boy cut the carrot*. Here the caused state-change event is expressed solely by the transitive verb *cut*.

Languages differ in whether information about the state change is typically located in a single verb or is spread out across a number of constituents, such as additional verbs or particles. For example, speakers of Mandarin use verb compounds to describe many of the events; e.g., *qie1-duan4* 'cut-break.long.thin.object' for the scene of someone karate-chopping a carrot shown in the lower left corner of Figure 1. For purposes of the present study, we concentrated on how the stimuli were categorized by the **verbs** of a language. Every verb in the data that described the target event was input to the analysis.

Analysis

Speakers' event descriptions can be treated as analogous to the data obtained in sorting tasks designed to study categorization. In a typical sorting task, a subject might receive a set of cards, each depicting a different stimulus, and be asked to sort them into piles of objects that are similar. Speakers in the present study received no metalinguistic instructions; they were simply asked to describe what they saw in the video-clips. But each different verb they applied to the target events was taken to define a category ("pile"). Across languages (and of course also within individuals or across individuals within the same language), stimuli that are often described with the same verb ("are sorted into the same pile") can be taken to be more similar to each other than stimuli that typically fall under different verbs (Bowerman, 1996). Multivariate statistics can then be used to explore the similarity structure of the data set as a whole.

To extract the most important dimensions organizing the similarity space of our stimuli, we used correspondence analysis (Greenacre, 1984). Correspondence analysis provides a dual factoring of a rectangular matrix in which the column scores and row scores are projected into the same low dimensional space. To perform the correspondence analysis, we first transformed the linguistic data for each language into a similarity matrix. This was done by determining, for all scenes taken pairwise, whether each member of the pair was ever described by the same verb. If so, the pair was assigned a similarity score of one; if not, zero.[2]

[2] This technique was adopted rather than a more graded approach to similarity based on the number of speakers within each language who used the same description, so as not to bias the results toward the categorizations favored by languages for which we happened to have more speakers.

The similarity matrices from all the languages were then stacked one on top of another to build a matrix with 61 columns (the stimuli) and 28*61 (language*stimuli) rows. This matrix was submitted to correspondence analysis to find the dimensions that are cross-linguistically the most important in structuring the similarity space of the stimulus set. The analysis extracts first the dimension that accounts for the most variance, then the dimension that accounts for the next most variance, and so on. Each stimulus scene is positioned in this multidimensional space in such a way that the distance between any two scenes reflects the degree to which, across languages, people described them with the same verbs. Scenes often described with the same verb are positioned close together, while scenes that are rarely or never described with the same verb are positioned far apart.

The major dimensions

The first and most important dimensions extracted in our analysis distinguished between events of material destruction and other events involving separation. There was widespread consensus across languages that events of "taking apart" (e.g., separating paper cups), "opening" (e.g., opening a box) and "peeling" (fruit) should be described with different verbs than events of "cutting and breaking". "Cutting and breaking" events are distinguished as a group from other kinds of separation, and so form a coherent semantic domain.

Leaving aside the events of "taking apart", "opening", and "peeling", we next focused specifically on the similarity structure of the remaining 46 events. These stimuli were analyzed with the same procedure outlined in the previous section.

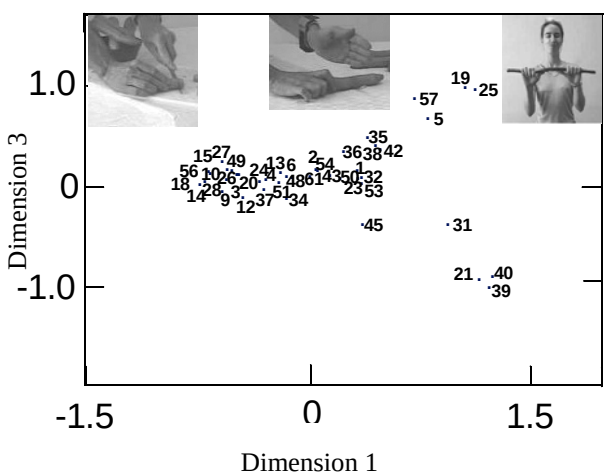

Figure 1: Plot of scenes, based on all languages, along Dimensions 1 and 3. Dimension 1 distinguishes events with precise control over the locus of separation (cutting a carrot with a knife) from scenes with intermediate control (karate-chopping a carrot) and imprecise control (breaking a stick with the hands).

The first and most important dimension of this analysis distinguishes among events on the basis of how precisely the agent controls the locus of the separation in the object. The events are distributed continuously on this dimension. (See Figure 1 for the placement of the scenes along Dimension 1. Each scene is represented by a number.) Events involving relatively precise control (e.g., cutting a carrot with a knife, scene 10) is positioned to the left, events with imprecise control (e.g., breaking a stick with the hands, scene 19) to the right, and events with intermediate degrees of control (e.g., karate-chopping a carrot, scene 32) in between. Events intermediate on this dimension are treated variably across languages, with some languages grouping them with the "precise control" events positioned to the left, others with the "imprecise control" events positioned to the right, and still others assigning them to categories of their own.

Dimension 2 distinguishes just two scenes from the rest – those showing an agent tearing a piece of cloth (a two-dimensional flexible object) partially (scene 36) or completely (scene 1) with the hands. These events were labeled *tear* in English, as distinct from *cut* and *break*. Nineteen out of the 28 languages have a verb that was used to categorise these and only these scenes. The remaining 9 languages did not distinguish these scenes, but grouped them in various ways with other scenes.

Within the group of scenes pulled out on Dimension 1 as lacking precise control over the locus of separation, Dimension 3 makes a further distinction between "snapping" and "smashing" events (see Figure 2a). The "snapping" cluster comprises events in which a one-dimensional rigid object is separated into two pieces by applying pressure to both ends (scenes 25, 19, 57, 5), while the "smashing" cluster is made up of events in which a rigid object is fragmented into many pieces by applying a blow, e.g., with a hammer (40, 39, 21, 31). The Dimension 3 distinction between "snapping" and "smashing", like the Dimension 2 distinction between "tearing" and separations of other kinds, is respected by speakers of many languages – cf. the distinction in Likpe between events described with *f3s3* (the snapping scenes) and those described with *ba* (the smashing scenes) (see Figure 2b). But this distinction is not made in all languages; colloquial Tamil, for example, collapses these two categories (along with a few additional scenes) into a single event type, denoted by the verb *oDai* (see Figure 2c).

Discussion

Speakers of a variety of typologically, genetically and areally diverse languages agree to a surprising extent in their linguistic categorization of events of material destruction of objects ("cutting and breaking" events). First, they agree on treating such events as a relatively coherent semantic domain. A priori, it is not obvious that languages will distinguish "cutting and breaking" events as a group from events involving other kinds of separations of objects or object parts, such as "taking apart", "opening", and "peeling"; after all, learners of English make a number of errors suggesting that the

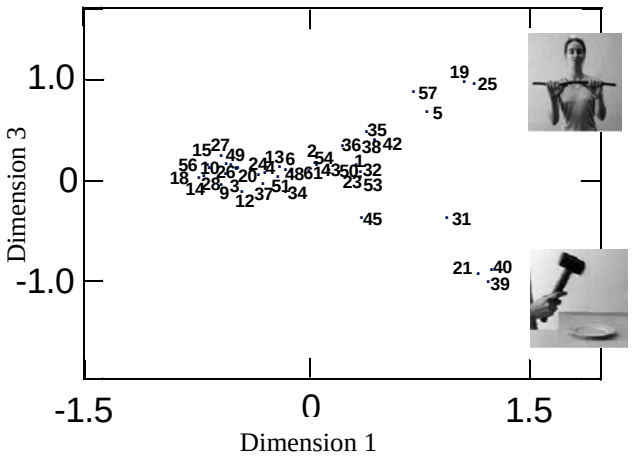

Figure 2a: Plot of scenes, based on all languages, along Dimensions 1 and 3, showing the distinction between "snapping" and "smashing" events.

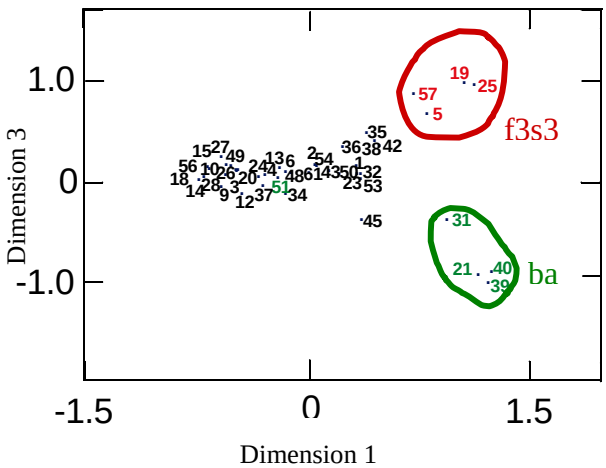

Figure 2b: Likpe is a good example of a language which distinguishes "snapping" from "smashing" events.

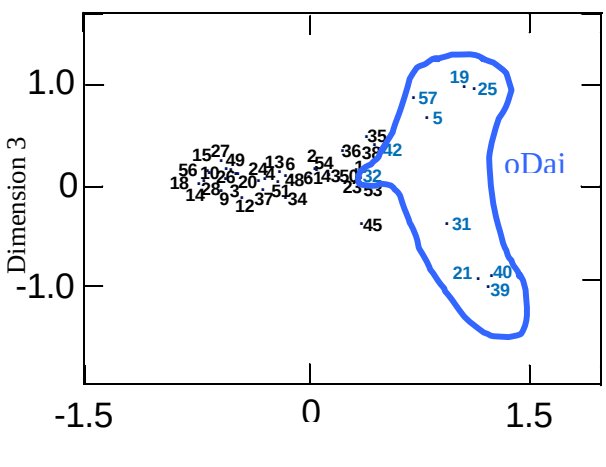

Figure 2c: Tamil collapses the "snap-smash" distinction.

boundaries of these event types are not obvious. For this reason our set of events to be described included not only scenes of "cutting and breaking", but also of various other kinds of separations. But these other separations were rarely described with the same verbs that were applied to the core set of "cutting and breaking" events. The "cutting and breaking" events were treated as far more similar to each other than they were to the other kinds of separations, in the sense that they were much more often described by the same verbs.

Second, speakers of different languages also showed considerable agreement in the kinds of distinctions they drew **within** the domain of "cutting and breaking" events. Although their societies ranged from industrial urban-dwelling to rainforest-dwelling swidden agriculturist, and they varied in their tools and techniques for cutting and breaking things in their daily lives, they converged on a shared similarity space for events of "cutting and breaking". The most important dimension for the set of 28 languages taken as a group distinguishes events featuring precise control over the locus of separation from those with imprecise control (roughly, "cutting" events vs. "breaking" events). Further, "tearing" events are very often distinguished from among other events with an intermediate degree of control (Dimension 2), while "snapping" and "smashing" events are often distinguished among the events involving imprecise control (Dimension 3).

Despite this cross-linguistic agreement there were also many differences – language-learners clearly have something to learn. Speakers of different languages varied in the number of categories of "cutting and breaking" they recognized and in where they placed the category boundaries. For example, speakers of most of the languages respected the distinction between "tearing" and other actions of material destruction, but some did not; speakers of many languages rigorously distinguished between actions of "snapping" and "smashing", but some did not (see Figures 2a-c); and languages differed in where they placed the boundary between "precisely" and "imprecisely" controlled acts of separation. These differences respected the overall structure of the semantic space; for example, no speakers described events at the far left of Dimension 1 with the same verb(s) as events at the far right, while describing the events falling between them with different verbs.

One topic we have not yet mentioned is how a language's semantic categories of "cutting and breaking" are related to one another. For instance, English clearly organizes its "cutting and breaking" terms hierarchically, with the high-frequency verbs *break* and *cut* each encompassing a number of more specific subtypes, such as *snapping* and *smashing* for *break*, and *slicing* and *chopping* for *cut*. This kind of organization is less apparent in many of the other languages in our sample. For example, Dutch has no verbs for "cutting and breaking" with as wide an application as English *cut* and *break*. "Cutting" events are obligatorily subdivided according to whether they involve a single-bladed tool like a knife or a double-bladed tool like scissors (*snijden* vs. *knippen*), and there is also no cover term for a wide range of "breaking" events; e.g., *breken* – cognate with English *break* – is used only for "snapping" events. It is unclear, then, whether the hierarchical organization found

across languages in words for **objects** will also be characteristic of words for **events**.

A final topic that we also leave to future work is the intriguing question of how the categorization of events imposed by language is related to categorization as studied with nonlinguistic techniques such as similarity ratings. For the object domain of "containers", speakers of different languages classified nonlinguistically more similarly than they classified linguistically (Malt et al., 1999). Whether the same will be true for event categories remains to be seen.

Acknowledgments

This study of "cutting and breaking" took place in the Event Representation project at the Max Planck Institute for Psycholinguistics. We thank all our colleagues who contributed their insights, data, and analysis to the study. The research was supported by the Max Planck Gesellschaft, as well as by a European Union Marie Curie Fellowship awarded to the first author, and a NWO grant to the second author. Mapping Written Input onto Orthographic Representations: The Case of Bilinguals With Partially Overlapping Orthographies

Abstract

Mapping of written input onto orthographic representations was examined in bilingual speakers whose two languages have partially overlapping orthographies. Russian-English bilinguals and English monolinguals were tested with a modified version of the picture-word interference paradigm, adapted for use with eye-tracking. Compared to English monolinguals, Russian-English bilinguals (tested in English) made more eye movements to written stimuli that, if mapped onto two orthographic systems simultaneously, constituted Russian words. Results suggest parallel activation of both languages during visual processing of written input, even when the orthography is associated with different phonological representations in the two languages. We suggest that decoding of written input in languages with partial orthographic overlap is not limited to one language only, but that the mapping of visual stimuli takes place onto the orthographic systems of both languages and that lexical representations in the non-target language become activated.

Introduction

Recent studies of bilingual language processing challenge earlier accounts of the language switch hypothesis (e.g., MacNamara & Kushnir, 1971), according to which bilinguals are able to selectively activate and deactivate their two languages. Instead, data support interactive parallel processing accounts, according to which linguistic input activates both languages simultaneously. For *spoken* word recognition, evidence supporting activation of both lexicons comes from research investigating spoken language processing in bilinguals using eye-tracking (Marian & Spivey, 2003a,b; Spivey & Marian, 1999). In the eye-tracking paradigm, participants are given spoken instructions to move objects on a table while their eye movements are recorded. Although participants rarely pick up incorrect objects, it is often observed that they fixate objects that have similar phonology to the spoken word (e.g., Allopenna, Magnuson, & Tanenhaus, 1998; Tanenhaus, Spivey-Knowlton, Eberhard, & Sedivy, 1995). The eye-tracking technique, merging input from both the visual and auditory modalities, was adapted for use with bilinguals to index activation of a second language non-linguistically. For example, when Russian-English bilinguals were presented with a visual display containing four objects (actual objects or toy replicas, as applicable), such as a shark, a balloon (*sharik* in Russian), a horse, and a napkin, and were instructed in English to "pick up the shark," they frequently made eye movements to the cross-linguistic phonological competitor *sharik*. In this case, the Russian word *sharik* was a cross-linguistic cohort (cf. Marslen-Wilson, 1987; see also Cutler, 1995; Marslen-Wilson & Welsch, 1978) of the English target word *shark*, i.e., the beginning portion of the name of the target object carried phonetic similarity to the name of one of the other objects in the other language. Eye movements to the cross-linguistic cohort, even when the other language is not being used overtly, supports the hypothesis that phonemic input initially activates both languages during bilingual spoken language processing.

For *written* word recognition, studies examining whether or not both languages are activated in parallel used code switching (e.g., Doctor & Klein, 1992; Grainger, 1993; Grainger & Dijkstra, 1992; Li, 1996; Nas, 1983; Soares & Grosjean, 1984), phoneme monitoring (e.g., Colome, 2001), lexical decision (e.g., Brysbaert, Van Dyck, & Van de Poel, 1999; DeGroot, Delmaar, & Lupker, 2000; Dijkstra, Grainger, & van Heuven, 1999), and priming tasks (e.g., Beauvillain & Grainger, 1987). Results indicate that orthographic input simultaneously activates lexical items across the two lexicons in the very early stages of processing, that bilingual visual word recognition is based on a stimulus-driven analysis indifferent to language, and that lexical representation in bilingual visual word recognition is governed by orthography rather than by language. For example, Bijeljac-Babic, Biardeau, and Grainger (1997) investigated activation of orthographic representations in bilingual visual word recognition by using a masked priming paradigm. Orthographic priming was observed in both monolingual and bilingual conditions, suggesting that printed strings of letters can simultaneously activate lexical representations in both languages, insofar as these share the same alphabet.

In another study on visual word recognition, Van Heuven, Dijkstra, and Grainger (1998) used the interlingual neighbors paradigm (an orthographic neighbor is any word differing by a single letter from the target word). Cross-

language interference on target word recognition was examined with a comprehensive corpus of Dutch and English words by varying the number of orthographic neighbors of the target word in the non-target language. The results showed that words in the non-target language with a greater number of orthographic neighbors in the target language had slower response times than words that had fewer orthographic neighbors in the target language. An increase in orthographic neighbors within the same language consistently produced inhibitory effects for the non-target language and facilitatory effects for the target language.

Because this work is based on bilinguals whose languages share orthography and where orthography-to-phonology mappings largely overlap across the two languages, the extent of parallel activation for languages that do not share orthography, or share it only partially, remains unclear. Studies with bilinguals that speak languages that do not overlap orthographically are limited (e.g., Tzelgov, Henik, Sneg, & Baruch, 1996). Languages that do not share visual representation make it possible to examine phonological and semantic activation of the non-target language during bilingual reading (Besner & Hildebrandt, 1987; Bowers, Mimouni, & Arguin, 2000; Brown, Sharma, & Kirsner, 1984; Chen & Tsoi, 1990; Smith & Kirsner, 1982), but not activation of the written form of both languages. Testing Russian-English bilinguals whose two languages share some, but not all, orthographic and phonological forms, provides precisely this advantage--it becomes possible to dissociate the activation of phonology and orthography during language processing by manipulating stimulus make-up.

The two languages of a Russian-English bilingual include some graphemes that share both visual and auditory form (e.g., *K*), other graphemes that share visual, but not auditory form (e.g., *P*, which in Russian reads *R*), yet others that share auditory, but not visual form (letters specific to the Latin vs. Cyrillic alphabets). Of particular interest in designing the present study are the 12 letters that overlap orthographically across English and Russian. Of these, 6 share both orthography and phonology—A, E, K, M, O, T. The remaining six, although identical orthographically, carry no phonological overlap—B, C, H, P, Y, X (the corresponding phonological representations in Russian are, following the Library of Congress Transliteration Schemes for Non-Roman Scripts (1991): B-v, C-s, H-n, P-r, Y-u, X-h). Testing Russian-English bilinguals makes it possible to examine the mapping of the visual stimulus onto orthographic and phonological representations in the two languages during bilingual lexical access in circumstances where phonemic overlap across two languages is possible without orthographic overlap and where orthographic overlap between the two languages is possible without phonemic overlap. By manipulating orthographic form and the associated phonological representations, the present experiment tests activation of the other language when the written input shares orthographic, but does not share phonological, representation across languages. The stated relationship between Russian and English in terms of phonological and orthographic structure of the two languages can provide valuable insights into orthographic and phonological processing and contribute to understanding the extent to which constraints imposed by language structure modulate cross-language interactions.

The only other similar work exploring processing of Latin and Cyrillic alphabets comes from studies of monolingual speakers of Serbo-Croatian (e.g., Feldman & Turvey, 1983; Lukatela, Savic, Gligorijevic, Ognjenovic, & Turvey, 1978). Serbo-Croatian as a language is unique in that it uses two alphabets, Latin and Cyrillic. Serbo-Croatian speakers are slower in lexical decision tasks when two phonological interpretations could be assigned to the same letter string, an effect sensitive to the number and distribution of ambiguous characters. The major difference between studying Russian-English bilinguals and studying Serbo-Croatian speakers is that Serbo-Croatian speakers are monolingual and therefore, by definition, have an integrated lexicon.

In the present experiment, a modified version of the Picture-Word Interference (PWI) paradigm, adapted for use with an eye-tracker, was used. The PWI paradigm consists of presenting participants with a picture that also contains a written word. Participants have to name the picture while ignoring the word; reaction times are recorded. Multiple studies suggest that picture naming latencies vary as a function of the relation between a picture and a distracter word (e.g., Caramazza & Costa, 2000, 2001; Deschneiak & Schriefers, 2001; LaHeij & van den Hof, 1995; Rayner & Springer, 1986; Schriefers & Meyer, 1990). For example, semantically related words interfere more than semantically unrelated words (e.g., Levelt, Schriefers, Vorberg, Meyer, Pechmann, & Havinga, 1991; Starreveld & LaHeij, 1996, 1995). The surface form of the distractor word also influences picture naming (e.g., Meyer & Schriefers, 1991), with phonological similarities facilitating picture naming (e.g., Descheniak & Schriefers, 2001). Performance on the bilingual PWI task has been examined both for semantically and phonologically related items (e.g., Costa & Caramazza, 1999; Costa, Miozzo, & Caramazza, 1999) and was found to be vulnerable to semantic interference from a non-target language (e.g., Ehri & Buchard-Ryan, 1980; Hermans, Bongaerts, de Bot, & Schreuder, 1998), but the effect was mediated by degree of proficiency (e.g., Goodman, Haith, Guttentag, & Rao, 1985), by similarity of the two languages, and by response language (for a review, see Smith, 1997). The modification of the PWI task for use with eye-tracking consists of presenting the written word in a different quadrant of the visual display (as opposed to within the picture). The technique was piloted with monolingual English and bilingual Russian-English speakers and confirmed that interference effects persisted.

In sum, the present experiment examined parallel activation of both languages during bilingual written word recognition in monolingual settings and extended the study of parallel activation during bilingual written word recognition to languages with partial overlap in orthography

and orthography-to-phonology mappings. We predicted that, compared to English monolinguals, Russian-English bilinguals naming pictures in English would make more eye movements to written stimuli that are semantically unrelated to the picture in English, but are related to it in Russian, thus suggesting that processing of written input is not limited to the target language, but that the visual stimulus is also mapped onto non-target language orthography, even when orthographic representations are associated with different phonological forms in the two languages.

Methods

Design

The study followed a 2 x 2 mixed factorial design, with group (bilingual vs. monolingual) as the between-subject factor and condition (control vs. Russian words) as the within-subject factor. All participants were tested in English only. In the first condition, the picture and the distracter word were semantically unrelated if the written stimulus was mapped onto either language (e.g., picture of a *palmtree*, written stimulus HOCTA). In the second condition, the picture and the distracter were unrelated if the written word was mapped onto English orthography only, but semantically related if it was also mapped onto Russian orthography (e.g., picture of a palmtree, word stimulus is COCHA. In English COCHA is a non-word, while in Russian it is the orthographic representation of the word *pinetree* and is pronounced *sasna*.) In the second condition, semantic interference is present if the written stimulus is mapped in parallel not only onto English orthography, but also onto Russian orthography, therefore activating the other language in a bottom-up manner. Proportion of eye movements to distracter words and reaction times for picture naming were measured.

Participants

Fifteen Russian-English bilinguals (mean age=25 years) and 15 English monolinguals (mean age=21 years) were tested. Russian-English bilinguals and monolingual English speakers were recruited among undergraduate and graduate students at Northwestern University and via personal contacts. All participants were paid for their participation.

In addition to picture naming, all participants were administered the Language Experience and Bilingual Status (LEABS) Questionnaire (Marian, Blumenfeld, & Kaushanskaya, 2003) for self–reported measures of language preference, proficiency, acquisition history, and current exposure. All bilinguals were fluent in both languages and were not enrolled in ESL classes. Measures of language experience collected via self-reports were included in analyses of covariance.

Stimuli

Twenty-four stimulus sets were generated for the two conditions. Across conditions, stimuli were controlled for length and bigram frequency. For English frequencies, the CELEX database was used (Baayen, Piepenbrock, & Van Rijn, 1993). For Russian frequencies, the new Frequency Dictionary at the Russian Research Institute of Artificial Intelligence (www.artint.ru/projects/frqlist/frqlist-en.asp; Sharoff, 2002) was used. Stimuli consisted of black line drawings and were generated using the IMSI Masterclips database and original artwork, and were altered in Adobe Photoshop. In order to meaningfully monitor eye movements, the locations of the target picture and the written word on the display were varied across four possible quadrants (top left, top right, bottom left, bottom right).

Procedure

All participants were tested in English. The bilingual speakers were tested in one language only so as to prevent overt activation of the other language during the experiment. Participants were asked to label pictures presented on a Mac computer display (G4 dual-processor computer) using Superlab software. Their verbal responses were recorded using a microphone. Eye movements during the experiment were recorded using an ISCAN head-mounted eye-tracker. The head-mounted eye-tracker consisted of a baseball-like cap, with two small cameras attached to the visor. One camera recorded the participant's field of view, and the other camera recorded the participant's eye movements; the outputs from the two cameras were superimposed and recorded using a digital recorder and were later analyzed using FinalCutPro software with frame-by-frame audio/video playback.

Results

The proportions of eye movements to distracter words during picture naming were analyzed with a 2 x 2 Analysis of Covariance, with group (monolingual or bilingual) and condition (control or Russian word) as the two independent variables and language preference when reading as covariate. Results revealed a main effect of group, $F(1, 27)=5.06$, $p<0.05$ and a significant interaction between condition and group, $F(1, 27)=4.78$, $p<0.05$. Overall, bilinguals made more eye movements to distracter words than monolinguals, 56% vs 34%. However, post-hoc analyses suggest that this difference was larger in the Russian words condition (61% for bilinguals vs 32% for monolinguals), where the two groups were significantly different from each other ($F(1,27)=7.77$, $p<0.01$), than in the control condition (50% for bilinguals vs 37% for monolinguals), where the two groups did not differ significantly ($F(1,27)=1.92$, $p>0.1$). A similar 2x2 Ancova on reaction time data did not reveal any significant effect of condition ($F=1.16$, $p>0.1$), group ($F=1.33$, $p>0.1$), or interaction between the two ($F=0.21$, $p>0.1$).

Based on self-reports collected with the LEABS Questionnaire, Russian-English bilinguals were grouped into 2 types, one consisting of bilinguals who preferred to read in English and one consisting of bilinguals who preferred to read in Russian. The proportion of looks made

by the two types of bilinguals to Russian competitor words and to control stimuli were compared in two ways. First, we examined whether or not the two types of bilinguals looked at the written stimuli at all (individual trials were coded with a 0 if participants did not look at the written stimulus and with a 1 if they did). Next, we examined the number of times the participants looked at a written stimulus (individual trials were coded with a 0 if participants did not look at the written stimulus, with a 1 if they looked at it once, with a 2 if they looked at it twice, with a 3 if they looked at it three times, and so on). Results of the first comparison did not reveal any significant differences, suggesting that the two types of bilinguals were just as likely to fixate distracter Russian words. Results of the second comparison revealed a marginally significant interaction between condition and type of bilinguals, $F(1, 13)=4.43$, $p<0.06$. Bilinguals who preferred to read in English (N=9) looked at Russian words more often (60%) than at control stimuli (48%); this pattern was not observed for bilinguals (N=6) who preferred to read in Russian (47% to Russian words and 52% to control stimuli).

Discussion

The present experiment examined mapping of visual input onto orthographic representations and lexical forms in bilinguals whose two languages share partial orthographic overlap. Results suggest that Russian-English bilinguals, when presented with written language input in a monolingual English setting, map the visual stimulus onto orthographic representations in both languages. As a result, lexical representations in the non-target language become activated, as evidenced by more eye movements to Russian distracter words relative to bigram-matched control stimuli in bilinguals, but not in monolinguals. These findings contribute to the existing body of literature suggesting simultaneous activation of a bilingual's two languages during written language processing and extend them to speakers whose two languages overlap orthographically only partially.

Absence of differences in picture-naming reaction times suggests that the simultaneous activation of non-target language orthography and lexicon (as demonstrated by eye movement data) did not minimize the efficiency with which bilinguals accomplished a language production task in the target language. This finding is consistent with recent accounts of optimal speed/accuracy outcomes achieved by parallel interactive models of language processing.

The finding that preferred reading language influenced the degree of activation of a bilingual's other language (as indicated by number of times bilinguals looked at Russian words) points to the importance of carefully assessing bilinguals' experience and proficiency in the two languages. Proficiency understanding, speaking, reading, and writing in the two languages, as well as factors pertaining to acquisition and current use of the two languages are just some of the variables to be taken into account when testing language processing in bilinguals (Marian, to appear). In our study, bilinguals who preferred reading in their second language (English) were just as likely to fixate Russian words as their peers who preferred reading in Russian, but once a written stimulus drew their eye movements, bilinguals who preferred to read in English were more likely to look at the Russian word again, fixating it repeatedly. These results suggest that, while the non-target language was activated in both types of bilinguals, processing the written input and possibly accessing its lexical representation was more effortful for those bilinguals whose preferred reading language was English.

It is notable that activation of the non-target language occurred in spite of the differential orthography-to-phonology mappings associated with the two languages. Although these results suggest simultaneous mapping onto the orthography and lexicon of the non-target language, they do not provide information about activation of the non-target language phonology, since lexical activation of the non-target language during orthographic processing may or may not have included phonological activation (i.e., mapping to the lexicon may have been directly from orthographic representations, bypassing phonology). To examine activation of non-target language phonology during written language processing, a mirror image of the present experiment is required. Namely, while the present experiment tested activation of non-target language *orthography* by examining processing of input that overlapped *orthographically, but not phonologically*, a separate experiment tested activation of non-target language *phonology* by examining processing of input that overlapped *phonologically, but not orthographically* (Kaushanskaya & Marian, 2004).

Moreover, for a more comprehensive understanding of parallel activation of both languages in Russian-English bilinguals during written language processing, a closer look at semantic processing is necessary. In the present study, stimuli consisted of English non-words, so as to avoid word frequency confounds across languages. Future work needs to expand this paradigm to processing written stimuli that constitute words in both languages. Whether the written stimuli are English words or nonsense strings is likely to influence the strength of competition from Russian semantically-related words. Furthermore, when the written stimulus is a word in each language, word frequencies in the two languages are likely to influence the effect, with higher-frequency mappings resulting in faster activation. Finally, future efforts will also focus on examining input properties that are likely to influence the relative activation of the non-target language during written word recognition, such as amount of orthographic and phonemic overlap across the two languages.

The proposed project has implications for understanding language development and processing in bilinguals, and reading and acquisition of literacy in bilinguals, with potential implications for bilingual education and for assessment of bilinguals. For instance, understanding written word recognition in bilinguals who are in

monolingual contexts may have implications for bilingual children entering mainstream (not ESOL) classrooms. The results of the 2000 Census indicate that 18% of American households speak a language other than English at home and that this proportion is increasing. Understanding how bilingual status influences cognitive and linguistic functioning may have direct implications for this linguistically diverse and severely under-served segment of the population. Beyond bilingual language processing, this research will contribute to advancing the understanding of language processing in general, including written word recognition and spoken word production.

Acknowledgments

This study was supported by Northwestern University junior faculty start-up funds to the first author and by a Graduate Research Grant to the second author. We thank Karla McGregor, Doris Johnson, Henrike Blumenfeld, Caitlin Fausey, and the members of the Bilingualism and Psycholinguistics Research lab for helpful discussions during the course of this work.

An ACT-R Modeling Framework for Interleaving Templates of Human Behavior

Michael Matessa (mmatessa@arc.nasa.gov)
NASA Ames Research Center, Mail Stop 262-4
Moffett Field, CA 94035 USA

Abstract

Performance modeling has been made easier by architectures which package psychological theory for reuse at different levels. Both CPM-GOMS, which packages theory at the task level, and ACT-R, which packages theory at the lower level of rules for perceptual-motor interaction, have been shown to be useful. This paper describes ACT-Stitch, a framework for translating CPM-GOMS templates and interleaving theory into ACT-R. The research involved in producing ACT-Stitch will benefit reusable template research by showing how to implement templates and interleaving in a new architecture that processes resource information. ACT-R research will benefit from re-usable productions packaged at a higher task level and from the multi-tasking control structure used that allows ACT-R to interleave productions from different templates. The zero-parameter predictions of ACT-Stitch are empirically validated.

Introduction

Predicting well-practiced human performance in human-computer interaction (HCI) domains by means of computer modeling is a valuable but difficult process. For example, modeling has been used to predict the outcome of a test of new computer workstations, saving a telephone company millions of dollars per year (Gray, John & Atwood, 1993), but much of the modeling was done by hand.

For accurate predictions, a large amount of psychological theory needs to be applied. Several modeling architectures have been developed to make modeling easier by packaging this theory for reuse. CPM-GOMS (John, 1988; 1990) uses templates of behavior to package at a task level (e.g., mouse move-click, typing) predictions of lower-level cognitive, perceptual, and motor resource use. These templates are interleaved to reflect the ability of skilled people to perform parts of one task in parallel with another. For example, an eye-movement study has demonstrated interleaving in a hand-washing task -- while people perform the subtask of first getting their hands wet they interleave a look to the soap dispenser before performing the motor actions in the subtask of soaping their hands (Pelz & Canosa, 2001). The CPM-GOMS theory has been automated (John, et al., 2002) in a computational architecture that schedules blocks of abstract resource use (Freed et al., 2003). ACT-R (Anderson & Lebiere, 1998; Anderson et al., submitted) uses a computational production system architecture for packaging knowledge at the lower level of rules for working with cognitive and perceptual information and motor actions. In contrast with CPM-GOMS, the ACT-R system can interact with an environment to perceive objects and manipulate them. However, ACT-R does not have a built-in theory of multi-tasking which would interleave tasks, although some work has been done in modeling multi-tasking in the ACT-R architecture (Byrne & Anderson, 2001; Lee & Taatgen, 2002; Salvucci, 2002).

This paper presents a new framework, ACT-Stitch, which combines the usefulness of modeling at the task level with the process theory of a lower-level cognitive architecture. It uses a process of macro-compilation similar to that used by Salvucci and Lee (2003) to translate CPM-GOMS templates into ACT-R productions. Their system will be compared to the current system in the discussion section, but one difference is that their system models at the level of KLM-GOMS, which does not interleave cognitive operators (John & Kieras, 1996). The control structure used by ACT-Stitch to achieve the interleaving of cognitive operators from different templates is one of the major contributions of this paper. The research involved in producing ACT-Stitch will benefit reusable template research by showing what aspects of template and interleaving theory are important in a new architecture that processes resource information. ACT-R research will benefit from re-usable productions packaged at a higher task level and from the multi-tasking control structure used that allows ACT-R to interleave productions from different templates.

Templates

Templates are building blocks of human behavior containing a detailed theory of cognitive, perceptual, and motor behaviors. They are beneficial for modelers because they package this theory at the task level and can be reused in different applications (Matessa et al., 2002). Even behavior as simple as a mouse move and click requires coordination of the use of cognitive, perceptual, and motor resources, as Figure 1 shows in PERT chart form with boxes representing resource use and lines indicating dependencies. The template was developed for the simple task of clicking on lit circles by Gray and Boehm-Davis (2000), but has been successfully reused for clicking to operate a simulated automated teller machine (John, et al., 2002).

Templates require a theory of interleaving to reflect the ability of skilled people to perform operations from different tasks in parallel. When CPM-GOMS was first developed, this interleaving was done by hand, with modelers applying their knowledge of the psychology involved. John et al. (2002) codified this knowledge and implemented automated interleaving in a system that scheduled blocks of abstract resource use. Results from this work were used in the construction of ACT-Stitch templates that produce productions which ACT-R can interleave.

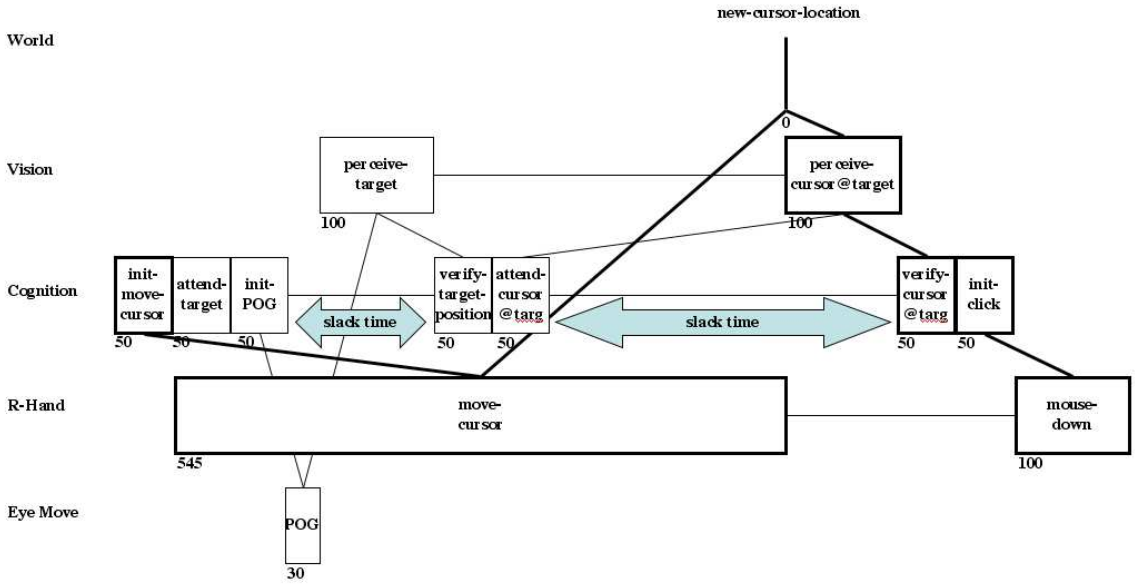

Figure 1: A template of carefully moving the cursor to a target and clicking the mouse (adapted from Gray and Boehm-Davis, 2000).

Macro-Compilation

ACT-Stitch uses a process of macro-compilation to translate CPM-GOMS templates of human behavior into ACT-R productions. More specifically, cognitive operators are translated into productions with ACT-R perceptual-motor commands that represent CPM-GOMS perceptual-motor operators. Productions also contain a control structure that allows ACT-R to implement CPM-GOMS interleaving and have productions from one template execute during the execution of productions from another template. This differs from the ACT-Simple system (Salvucci & Lee, 2003) that compiled a sequence of KLM-GOMS tasks into a series of productions which were controlled by an incrementing state counter.

Macro-compilation should not to be confused with ACT-R production compilation in which two productions are translated into another more efficient production. Salvucci and Lee (2003) argue that macro-compilation facilitates theoretical consistency, inheritance of architectural features, model integration, and model refinement. Theoretical consistency is maintained by having the higher task-level template share a consistent representation with the lower-level ACT-R architecture. The macro-compiled template inherits parameters and limitations that increase psychological plausibility as well as a framework for learning, showing individual differences, and making errors. Model integration is helped by providing a common language where models from different domains can interact.

ACT-Stitch Framework

To understand how ACT-Stitch works, this section will first explain the process of how a modeler uses ACT-Stitch, then describe the ACT-R architecture, then go into more detail about macro-compilation and production execution, and finally give an example of macro-compiled productions.

ACT-Stitch modeling

ACT-Stitch currently has two templates implemented, Slow-Move-Click and Fast-Move-Click, based on templates from Gray and Boehm-Davis (2000). For Gray and Boehm-Davis, Slow-Move-Click represented the selection of a target when there is uncertainty about where the target appears in each trial. Fast-Move-Click represented the selection of a target at a known location. and skipped the verification of the cursor being at the target. These templates were reused by John et al. (2002) in modeling interactions with a simulated automated teller machine. There, Slow-Move-Click represented the selection of difficult targets at far distances, requiring more careful verification of target and cursor location before clicking than the selection of easier targets, which are represented with Fast-Move-Click.

To use ACT-Stitch, the modeler creates two lists, one for target objects and one for a task sequence. The target object list contains target names, positions, and sizes. The task sequence list contains template/target pairs. The system then creates an environment including target objects and macro-compiles templates into productions. The ACT-R system is then run, and information about resource use and

dependencies is automatically stored. This information can be exported to a PERT chart viewing program.

ACT-R

ACT-R (Anderson & Lebiere, 1998; Anderson et al., submitted) is a computational theory of human cognition incorporating both declarative knowledge (e.g., addition facts) and procedural knowledge (e.g., the process of solving a multi-column addition problem) into a production system where procedural rules act on declarative chunks. Chunks are made up of slots containing information, and production rules which match the information in chunk slots are able to execute. The goal chunk represents the current intentions. The ACT-R system includes the capability for modelers to create simulated environments, such as screen interfaces. Production rules have the ability to interact with this environment by perceiving objects and making motor movements through perceptual and motor buffers. With this interaction, ACT-R can make use of Fitts' Law to make predictions of movement time based on distance to target and target size.

ACT-Stitch production creation

CPM-GOMS templates contain predictions of cognitive, perceptual, and motor behavior. When translating a template into ACT-R productions, each cognitive operator in a template corresponds to a production in ACT-R. Cognitive operators and productions are both predicted to take 50 ms to perform by each theory. Both theories predict parallel execution of cognitive, perceptual, and motor processes. In CPM-GOMS, each perceptual and motor operator requires an initiation by a cognitive operator. This corresponds to the ACT-R requirement of productions to initiate vision and motor processes. To move visual attention to a new location and perceive an object, CPM-GOMS predicts that it takes 30 ms to move attention plus some time for perception, while ACT-R predicts that is takes 85 ms to move attention with no additional time for perception. For mouse movement, CPM-GOMS predicts an execution time calculated by Fitts' Law, while ACT-R predicts a 200 ms preparation time plus a time calculated by Fitts' Law plus a 50 ms finish time. For mouse clicks, CPM-GOMS predicts a 100 ms mouse down time plus a 100 ms mouse up time, while ACT-R predicts a 150 ms preparation time plus a 60 ms execution time plus a 90 ms finish time. ACT-R can perform motor preparations in parallel with the motor executions and finishes of previous motor commands, and ACT-Stitch creates productions that take advantage of this capability.

ACT-Stitch creates a set of productions for each template/target pair in the task list, and the productions created from macro-compilation must insure proper sequencing of motor actions, insure the ability to allow the correct productions in future templates to interleave during the execution of productions in the current template, and insure the ability to block the incorrect productions in future templates from interleaving with productions in the current template.

These three requirements are accomplished in productions by using information in the current goal as well as perceptual-motor buffers. Slots in the goal are created for the vision and hand resources for both the intended action and target making use of the resource. This makes four slots in the goal: vision action, vision target, hand action, and hand target. To insure proper sequencing, the action slots in productions of the current template are filled with an intended action appended with the unique number of the current template. Also, the target slots are filled with an intended target. The intended action cannot be used alone since without the template number no sequence information would be stored. The template number cannot be used alone since there may be multiple actions in the same template using the same resource (e.g., mouse move and click). The intended target cannot be used alone since sequence information would be lost if a target appears twice in a sequence (e.g., clicking the same number twice). The intended target cannot be ignored since the same action could be used in a template for two targets (e.g., verify target and verify cursor).

To insure the ability to interleave productions, separate action slots are used for each resource (vision and hand). This allows, for example, a procedure to initiate a vision action from a future template before a procedure initiates a hand action from the current template. To insure the ability to block productions from future templates, the action slots are filled with intended actions appended with the current template number. This prevents, for example, moving to the next target while the hand resource is free between moving to the current target and clicking on the current target. The template number cannot be contained in a separate goal slot because that would not allow productions from the next template to execute before the productions of the current template have finished.

Perceptual-motor buffers are also used in sequencing. Productions that interact with the perceptual-motor buffers check to make sure the buffers are free before using them. Also, the task logic of perception and action makes use of buffers to order productions. For example, the process of verifying a target position before clicking requires filling the visual location buffer with the location of the intended target, then filling the visual object buffer with the object found at that location, and then making a mouse click through the motor buffer.

These goal slots and buffers could be extended to include resources such as a left hand and buffers such as memory retrieval in future template development.

ACT-Stitch production execution

The ACT-R system is initialized with the goal containing the actions and targets of the first template. ACT-R selects productions to execute based on the state of the goal and perceptual-motor buffers. Productions make calls to the perceptual-motor system which has assumptions for how long the resources are used. Slack time corresponds to the time a resource is available during procedure execution. A production that is created from the next template can execute (even if all the productions made from the current

template are not finished executing) when it matches values in the action and target goal slots. Action slots contain intended actions appended with unique template numbers, and target slots contain intended targets. When a resource is no longer needed by a template, a production in the template will fill the action slot with the next intended action appended with the next template number, and the target slot will be filled with the next intended target.

Within-template dependencies are implemented by productions waiting for action and target slots to be filled in the goal and for resources to be available. Template productions are created so that a production will change the contents of action and target slots appropriately. A production (A) from a future template that is waiting for another production (B) in that template to change the contents of action and target slots cannot execute during the execution of productions in the current template until production B is executed.

Relationships across templates are established the same way as within templates, using action and target slots in the goal. Values in these slots allow the blocking of productions that would use resources even if the resource is free.

Example ACT-Stitch productions

To get an idea of what a template looks like after being macro-compiled into ACT-R productions, the following shows pseudo-code for the Fast-Move-Click template. Each instance of a template in the task sequence list would have its own set of productions labeled by the position of the template in the list (x).

```
Tx-Init-Move-Cursor
IF
        right hand action goal is to move in this template
        right hand target goal is this template's object
        motor preparations have completed
THEN
        move cursor
        empty right hand target goal
        set right hand action goal to click in this template

Tx-Attend-Targ
IF
        vision action goal is to attend target in this template
        vision target goal is this template's object
        visual location and object buffers are empty
        vision is available
THEN
        fill visual location buffer with location where
           this template's object should be

Tx-Init-Eye-Move
IF
        vision action goal is to attend target in this template
        vision target goal is this template's object
        visual object buffer is empty
        visual location buffer holds object location
 THEN
        fill visual object buffer with object at location
        empty visual location buffer

Tx-Verify-Targ-Pos
IF
        vision action goal is to attend target in this template
        vision target goal is this template's object
        right hand target goal is empty
        visual object buffer holds object at location y
        location y is the expected location of this template's object
THEN
        empty visual object buffer
        set visual action goal to attend in the next template
        set visual target goal to next template's object
        set right hand target goal to this template's object

Tx-Init-Click
IF
        right hand action goal is to click in this template
        right hand target goal is this template's object
        motor preparations have completed
THEN
        click mouse
        set right hand action goal to move in next template
        set right hand target goal to next template's object
```

Productions that initiate motor movements (Init-Move-Cursor and Init-Click) first check that the motor preparations from previous motor movements have completed Since motor preparations can happen in parallel with motor executions and finishes in ACT-R, this means that preparations can start during previous executions and finishes. Productions could be written to wait for the previous executions and finishes to complete before starting preparations, but they would not be as efficient.

Empirical Validation

ACT-Stitch was applied to the ATM task used by John et al. (2002) to test their automation of CPM-GOMS. The task was to make an $80 withdraw from a checking account on a simulation of an automated teller machine. Users interacted with the ATM by using a mouse to click on simulated keys or slots. The users were instructed to follow the following steps:

Insert card (click on the card slot)
Enter PIN (click on the 4, 9, 0, and 1 keys in turn)
Press OK (click on the OK button)
Select transaction type (click on the withdraw button)
Select account (click on the checking button)
Enter amount (click on the 8 and 0 keys)
Select correct/not correct (click on the correct button)
Take cash (click on the cash slot)
Select another transaction (click on the No button)
Take card (click on the card slot)
Take receipt (click on the cash slot)

This task was repeated 200 times by the users, and results were analyzed using the means of trials 51-100. This level of practice is comparable to that used by both Card, Moran, and Newell (1983) in a text editing task and Baskin and John (1998) in a CAD drawing task when they explored the effects of extensive practice on match to various GOMS models. As in John et al. (2002), Slow-Move-Click templates were used for targets that were difficult to select because of size and distance (e.g. the thin card slot) and Fast-Move-Click templates were used for easier targets (e.g. keypad keys).

Figure 2 compares ACT-Stitch predictions of mouse click times to average subject mouse click times of trials 51-100. The results are highly correlated (r=.96) with a low average absolute difference of 62 ms.

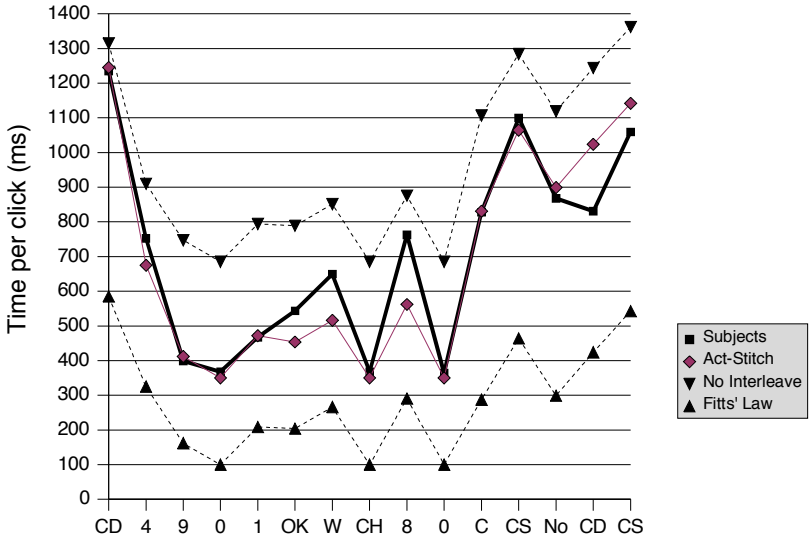

Figure 2: Average subject performance compared to ACT-Stitch predictions, ACT-Stitch predictions with no interleaving, and Fitts' Law predictions.

Figure 2 also shows the value of cognitive modeling over a Fitts' Law only prediction and the value of ACT-Stitch interleaving. A Fitts' Law prediction has a high correlation with subject performance (r=.97) but predicts faster performance, with an average absolute difference of 416 ms. A version of ACT-Stitch was created that did not interleave template productions, and while the correlation with subject performance was still high (r=.95), the predictions are too slow (average absolute distance = 257 ms).

The effect of interleaving on resource use is shown in PERT chart form in Figure 3. This output is from the Sherpa visualization tool developed by John et al. (2002) in their work to automate CPM-GOMS. The top row shows vision resource use, the second shows cognition, the third shows motor preparation, and the bottom shows motor execution and finishing. Resource use is indicated with shaded boxes, and instances of resource use in the same template are shown with the same shade of gray. The figure shows how cognitive, perceptual, and motor resources are interleaved between templates.

General Discussion

ACT-Stitch appears to be a useful framework for modeling the cognitive, perceptual, and motor processes involved in HCI tasks. With a simple description of an environment and task sequence, it is able to produce detailed, zero-parameter predictions that match well to human data.

ACT-Stitch has some similarities and differences with the ACT-Simple framework created by Salvucci and Lee (2003). They both use a process of macro-compilation to translate task-level descriptions of behavior into ACT-R productions, which give a detailed account of the cognitive, perceptual, and motor processes involved in the task. ACT-Stitch adds the ability to easily simulate simple environments, the ability for templates to interleave cognitive operators, and the ability to view resource use of the model with PERT chart tools. With the environment, models can take advantage of Fitts' Law to make detailed predictions of movement times. With a theory of interleaving that is based on fixed resources instead of spontaneous task demands, ACT-R modelers have the ability to start moving away from control theory based on simple chained productions. With PERT chart output, complex interactions of resource use in models can be understood easier.

CPM-GOMS is assumed to model skilled performance, and a CPM-GOMS model translated into ACT-R can be thought of as a state of performance after learning. With the ACT-R compilation process of learning more efficient productions, the whole learning curve from slow reading and remembering instructions to quick interleaving of resources can be studied. There has already been some start on this by Lee and Taatgen (2002), where they describe a model of performance on an air traffic controller task that at first has slow performance to due interpreting instructions, then speeds up due to production compilation creating more efficient productions, and eventually interleaves an optional step to look at wind conditions during multiple keystrokes.

In the ATM task, ACT-Stitch accounts for the data as well as CPM-GOMS automated in another system (see John et al., 2002), but it differs from that system in that it predicts a 200 ms motor preparation that occurs between the movement of attention and motor execution (see Figure 3). ACT-Stitch predicts that during this motor preparation time previous motor operations are taking place. This prediction could be tested with eye-tracking experiments.

This paper offers only a first step of a template and interleaving theory in ACT-R. Many more templates are needed to test the robustness of the representations used for the interleaving theory.

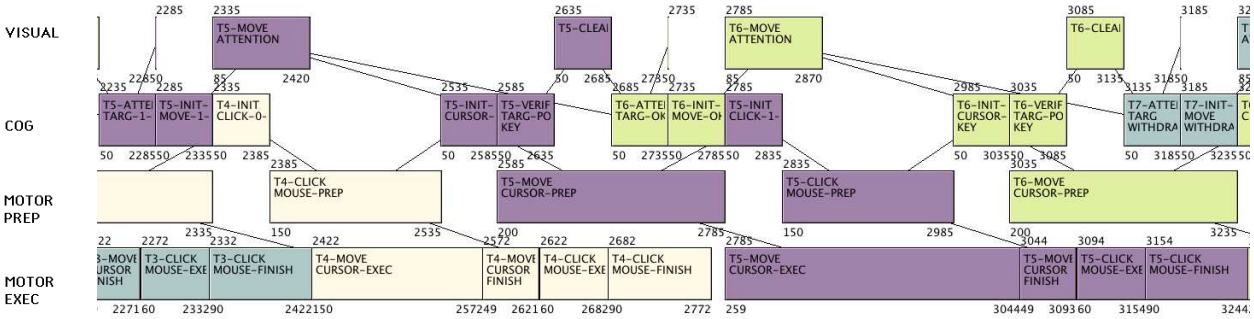

Figure 3: PERT chart of ACT-Stitch interleaving perceptual, cognitive, motor preparation, and motor execution and finishing resources

There are some interleaving abilities that the current framework cannot accomplish, for example, hovering a hand over a key for a key press that occurs in a template that is more than one template away in the future, or blocking an arbitrary combination of resources (such as both hands during typing) from interleaving. But this work is a first step to easier modeling and multi-tasking in ACT-R.

Do eye movements go with fictive motion?

Teenie Matlock (tmatlock@psych.stanford.edu)

Abstract

Cognitive scientists interested in the link between language and visual experience have shown that linguistic input influences eye movements. Research in this area, however, tends to focus on literal language alone. In the current study, we investigate whether *figurative* language influences eye movements. In our experiment, participants viewed two-dimensional depictions of static spatial scenes while they heard either fictive motion sentences, such as *The palm trees run along the highway,* or non-fictive motion sentences, such as *The palm trees are next to the highway*. Overall, sentence type influenced participants' eye movements. Specifically, gaze duration on the figure (e.g., palm trees) was longer with fictive motion sentences than with non-fictive motion sentences. Our results demonstrate that figurative language influences visual experience. They provide further evidence that fictive motion processing includes mentally simulated motion.

Introduction

Imagine that you and a friend are sitting in a courtyard chatting. During the course of the conversation, you occasionally glance over at a long, thin stationary object on the ground. You assume the object is a tree branch or a walking stick until your friend says, "Oh! Look what slithered onto the courtyard." At that point, your perceptions and conceptions of the object dramatically change. The object goes from a piece of wood to a snake.

Situations like these—in which language influences the interpretation of objects and actions—are ubiquitous. The question addressed here is whether this influence is limited to *literal* language, or whether it also includes *figurative* language. We are especially interested in whether sentences such as *The road goes through the desert* or *The fence follows the coastline* (figurative because they include a motion verb but express no motion) affect eye movements. Our results suggest they do.

What We Know about Fictive Motion

Everyday language is replete with sentences such as (1a) and (1b). These are literal descriptions of static scenes.

(1a) *The road is in the desert*
(1b) *The fence is on the coastline*

Language is also full of sentences such as (2a) and (2b).

(2a) *The road goes through the desert*
(2b) *The fence follows the coastline*

These sentences are figurative because they contain a motion verb (e.g., *goes*, *follows*) but express no actual motion (Matlock, 2001).[1] They contrast with literal sentences with motion verbs, such as *The bus goes through the desert*, or *The herd of sheep follows the coastline*, which feature mobile agents that move from one point in space and time to another (Talmy, 1975; Miller & Johnson-Laird, 1976).

Despite the absence of actual movement with sentences such as (2a) and (2b), they have been claimed to involve *fictive motion*, an implicit mental simulation of "movement" through a construed scene (Talmy, 1983, 1996, 2000). On this view, the conceptualizer subjectively "scans" from one part of the scene to another, most notably, along the figure (i.e., prominent entity, subject noun phrase referent). For (2a), this means "moving" along the road, and for (2b), it means "moving" along the fence. According to the argument, fictive motion is a way to impose motion on what is otherwise a static scene. It enables the language user to compute information about the layout of a scene, for instance, a road in a desert in (2a), or a fence aligned with a coastline in (2b). Importantly, Talmy (1996) and other cognitive linguists do *not* maintain that fictive motion involves vivid imagery whereby the conceptualizer "sees" himself or herself (or any other animate entity) moving point by point along the figure in the scene being described. Instead, they take the motion to be relatively fleeting and tacit. (See also Langacker's *abstract motion*, 1986, 2000, and Matsumoto's *subjective motion*, 1996).[2]

At first, the claim that people simulate motion while processing descriptions of static scenes seems bizarre. Why would motion be processed, for instance, with sentences such as (2a) and (2b) when neither the road nor the fence is

[1] Like Rumelhart (1979) and Gibbs (1994), we do not maintain a hard and fast distinction between "literal" and "figurative". We simply use these terms here to operationalize two types of motion verb constructions: those that express motion and those that do not.
[2] Our study looks at just one type of fictive motion, Talmy's (2000) *co-extension path* fictive motion. There are many others.

capable of movement? Perhaps it is more reasonable to assume that such sentences are yoked to a purely static representation, as proposed by Jackendoff (2002). On this view, the representation underlying sentences such as (2a) and (2b) is static and atemporal. It is not unlike the representation underlying the literal sentences shown in (1a) and (1b), in which all points along the figure are activated simultaneously rather than incrementally.

Recent experimental work suggests that mental simulation, a fundamental part of cognition (e.g., Schwartz & Black, 1999; Freyd, 1983; Barsalou, 1999) generalizes to fictive motion. In several reading studies, Matlock (in press) investigated whether thinking about motion would affect fictive motion processing. In one study, participants read vignettes about fast or slow travel through a large-scale spatial region (e.g., driving in a desert), and then a fictive motion critical sentence, such as *The road goes through the desert*. Participants were quicker to read the critical sentences after reading about fast motion than they were after reading about slow motion. The same effects were also observed with easy versus difficult terrains, and with short versus long distances. Critically, the effect was *not* obtained with non-fictive motion test sentences at the end of the same stories, such as *The road is in the desert*. In sum, the results show that thinking about motion influences the processing of fictive motion sentences, but not the processing of comparable non-fictive motion sentences. They provide evidence that simulating motion is part of fictive motion understanding.

Matlock, Ramscar, and Boroditsky (2003a, 2003b) investigated whether engaging in thought about fictive motion would influence metaphoric construal of time in the way that engaging in thought about real motion has been shown to do (see Boroditsky, 2000; Boroditsky & Ramscar, 2002). In one experiment, participants were primed with fictive motion sentences or non-fictive motion sentences (e.g., *The tattoo runs along his spine* versus *The tattoo is next to his spine*) before reading this ambiguous question: "Next Wednesday's meeting has been moved forward two days. When is the meeting now that it has been rescheduled?"[3] When primed with fictive motion (congruent with an *ego-moving* construal), people were more likely to say, "Friday", suggesting they viewed themselves "moving" forward in time. When primed with non-fictive motion (congruent with a *time-moving* construal), people were more likely to say, "Monday", suggesting they viewed time as "moving" toward them. Another experiment issued this same question with one of two primes: *The road goes all the way to New York* (fictive motion away from conceptualizer), *The road comes all the way to New York* (fictive motion toward conceptualizer). The results indicated that people were more likely to respond "Friday" after the *away* prime and more likely to respond "Monday" with the *toward* prime. They suggest that people take a perspective and simulate motion when thinking about fictive motion, and that that in turn affects the way they perform abstract reasoning, such as reasoning about temporal movement.

Hence, people simulate motion when processing figurative sentences such as *The road runs along the coast*, and this naturally affects conceptual representation. Given this, we would like to know whether fictive motion also influences perceptual processing.

What Eye Movements Can Tell Us

Eye movements have been measured during a range of cognitive and perceptual activities (for review, see Richardson & Spivey, 2004). Scene perception has been studied in terms of the "bottom up" statistical properties of the image that attracts eye fixations, and in terms of the "top down" knowledge, beliefs or expertise that might affect how one person inspects a scene differently from another (for review, see Henderson, 2003). In a separate research tradition, eye tracking has been used to investigate reading, which engages both linguistic and perceptual processing (Rayner, 1998; Tinker, 1946).

Until recently the intersection between language and visual perception—looking at a scene and listening to a voice—had not been studied. The advent of head-mounted and remote eye tracking devices has allowed researchers to place participants in relatively rich, natural visual contexts and record how the eyes respond to spoken instructions and descriptions. Such experiments have yielded a surprisingly close integration between incremental linguistic processing and visual perception, demonstrating that eye movements to possible referents in the world are used to resolve temporary ambiguities in word recognition and syntactic structure (Tanenhaus, Spivey-Knowlton, Eberhard, & Sedivy, 1995), and to predict upcoming agents based on thematic role information (Altmann & Kamide, 2004).

Language has also been shown to modulate eye movements even when there is nothing to look at. In studies by Spivey and colleagues (Spivey & Geng, 2001; Spivey, Tyler, Richardson, & Young, 2000), people stared at a blank screen or closed their eyes and listened to a story that was spatially extended along an axis, for example, a story about a train going past, or a sequence of activities occurring on successive floors of a tall apartment block. While listening, participants' saccades tended to be extended along the horizontal or vertical axes that were consistent with those communicated in the story.

Whether it is in the presence of temporary ambiguity, or in the absence of visual input, linguistic input has been shown to influence eye movements. However, with the current surge of interest in language and vision (e.g., Henderson & Ferreira, 2004) one question has been left behind. What about figurative language? Does it influence eye movements? If so, how? This is an important question, for figurative language is not restricted to poetic or literary works. It is at least as pervasive in every day talk as literal

[3] The question is ambiguous because people are just as apt to answer Friday as they are Monday when the question is posed without any prime. (See Boroditsky, 2000; Boroditsky & Ramscar, 2002 for discussion.)

language, if not more pervasive (see Gibbs, 1994; Katz, Cacciari, Gibbs, & Turner, 1998; Lakoff, 1987).

Experiment

In the current study, participants viewed static depictions of scenes while they heard fictive motion and non-fictive motion sentences. Of interest was whether there would be differences between the eye movements that accompanied fictive motion sentences, such as *The palm trees run along the highway,* and those that accompanied non-fictive motion sentences, such as *The palm trees are next to the highway*. On the surface, the sentences convey similar information: Both include a linearly extended subject noun phrase reference (e.g., *palm trees*) and both describe a static spatial scene. However, the former has been argued to involve mentally simulated motion or scanning along the figure, but the latter has not. Would participants spend more time inspecting figures with fictive motion sentences than figures with non-fictive motion sentences? Longer gaze durations on regions of interest with fictive motion sentences would suggest mentally simulated motion or scanning.

Method

Participants

A total of 24 Stanford University psychology students participated for course credit. All had normal or corrected-to-normal vision.

Design

Gaze durations were recorded along the axis referred to by the subject of the sentence (the compatible region) and along the axis not referred to by the subject of the sentence (the incompatible region). Half the sentences included fictive motion language and half did not. Therefore, the experiment was a 2 x 2 design, with compatibility as one factor and sentence type as the other.

Stimuli

Sixteen pictures served as the primary visual stimuli. Each depicted a simple spatial scene and featured both a horizontally extended figure and a vertically extended figure, for example, a river extending from top to bottom, and a fence extending left to right. A further 16 pictures were used as filler items. All pictures were matched on level of color luminance.

Sixteen blocks of recorded English sentences served as primary stimuli. Each block contained two sentence pairs. Each pair included a FM-sentence (fictive motion sentence) and a comparable NFM-sentence (non-fictive motion sentence), for example, *The cord runs along the wall*, and *The cord is on the wall*. One sentence pair referred to the vertical object in a picture and the other referred to the horizontal object in that same picture. Figure 1 displays an example picture and its block of sentences. Sixteen sentences that described the filler pictures were also recorded.

We conducted three norming studies on our sentences and pictures. In the first, 57 Stanford undergraduates judged all FM- and NFM-sentences on a scale of 1 to 7, in which 1 indicated "makes no sense at all" and 7 indicated "makes good sense". The mean for all FM-sentences was 5.85 and the mean for all NFM-sentences was 6.02. A t-test showed no reliable difference between the two, $t(31) = 1.16$, $p > .1$. In the second norming study, 28 undergraduates rated pairs of FM- and NFM-sentences on how similar they were in meaning. They used a scale of 1 to 7, in which 1 indicated "not at all similar" and 7 indicated "very similar". The mean for all sentence pairs across all subjects was 6.04, with the highest average at 7 and the lowest average at 5.25. In a third norming study, 12 undergraduates judged our pictures and sentences on how well they went together. Overall, the sentence-picture combinations were judged as well-matched. The means were 6.63 FM-horizontal, 6.58 FM-horizontal, 6.53 NFM-horizontal, and 6.34 NFM-vertical. A one-way ANOVA yielded no difference, $F(3, 63) = .04$, $p > .1$, showing that they were equally good descriptions.

Together, the norming studies indicate that (a) all FM- and NFM-sentences were equally sensible in meaning, (b) all FM- and NFM-sentences described comparable information, and (c) all FM- and NFM-sentences were equally good descriptions of the pictures.

Horizontal landmark

FM *The books run along the wall*
NFM *The books are on the wall*

Vertical landmark

FM *The cord runs along the wall*
NFM *The cord is on the wall*

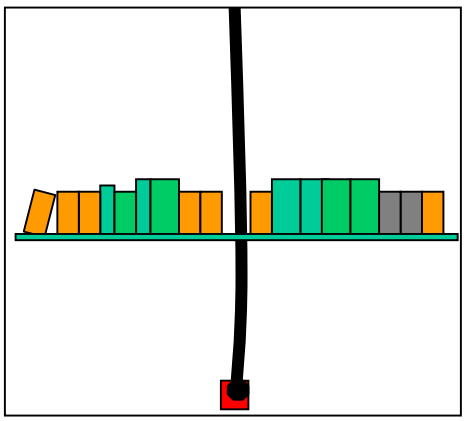

Figure 1. Example of picture with vertical and horizontal fictive motion and non-fictive motion sentences.

Apparatus

An ASL 504 remote eye tracking camera was positioned at the base of a 17" LCD stimulus display. Participants were unrestrained, and sat approximately 30" from the screen. The camera detected pupil and corneal reflection position from the right eye, and the eye tracking PC calculated point-of-gaze in terms of coordinates on the stimulus display. This information was passed every 33ms to a PowerMac G4 which controlled the stimulus presentation and collected gaze duration data. Prior to the experimental session, participants went through a 9 point calibration routine, which typically took between 2 and 5 minutes.

Procedure

Once a successful eye track was established, participants were told to "Look at the pictures and listen to the sentences." On each trial, a picture appeared 1000ms before the sentence began, and then remained in view for 2000ms after the sentence finished. There was a 2000ms inter-stimulus interval, during which participants saw a gray screen, roughly isoluminant with the pictures.

Following 4 practice trials, each participant was presented with a random sequence of 16 experimental and 16 filler trials. Each experimental picture was accompanied by one of four sentences that described the picture (e.g., vertical FM-sentence). Sentence presentation varied such that each participant heard 4 vertical FM-sentences, 4 horizontal FM-sentences, 4 vertical NFM-sentences, and 4 horizontal NFM-sentences.

Coding

The screen was partitioned into 17 non-overlapping regions of interest, corresponding to a central square, six squares spanning the horizontal axis, six squares spanning the vertical axis, and four squares in each corner (see Figure 2). During the period that the experimental picture was onscreen, total gaze durations in each region were recorded.

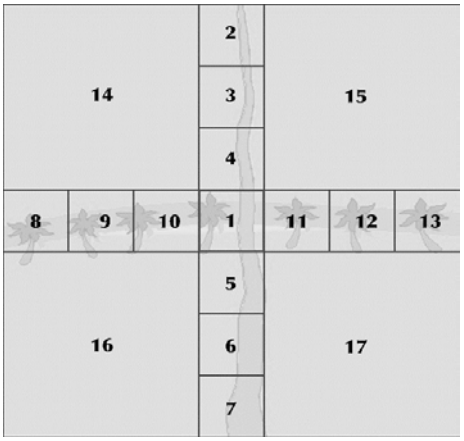

Figure 2. Grid defining relevant regions superimposed on grayed example picture.

Results and Discussion

For a quantitative analysis, we compared total gaze durations to the vertical region of the picture (regions 2 to 7) and the horizontal region of the picture (regions 8 to 13). Each accompanying sentence described either the horizontal or vertical element in the picture. Thus our data could be expressed in terms of gaze durations to the compatible and the incompatible regions. [4]

We conducted a 2 (compatibility) x 2 (sentence) ANOVA. There was a main effect of compatibility, indicating that our participants spent more time inspecting the compatible portion of the grid containing the figure described in the sentences, $F(1,23) = 5.51$, $p < .03$. There was also a main effect of sentence, revealing a reliable difference between inspection time for FM-sentences (M= 995) and inspection time for NFM-sentences (M=827), $F(1,23) = 10.18$, $p < .001$. Most importantly, there was a reliable interaction between these factors, $F(1,23) = 6.00$, $p < .03$, shown in Figure 3. Tukey's HSD revealed that the only cell that differed from all others was gaze duration to the compatible region with fictive motion sentences ($p < .01$).

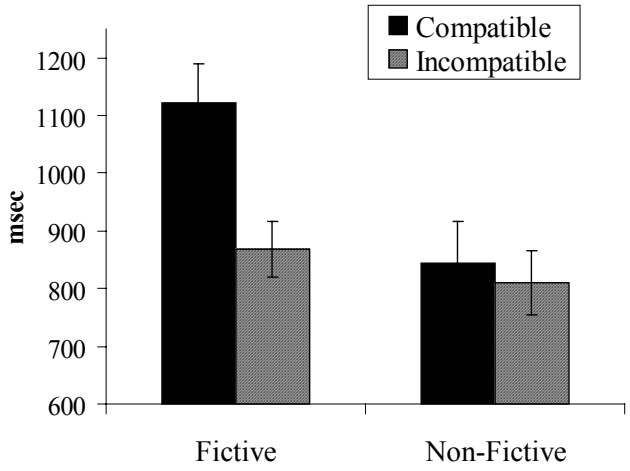

Figure 3. Gaze durations to compatible and incompatible picture regions only differed when the sentence employed fictive motion.

As predicted, people spent more time gazing at the region of a picture associated with the figure in fictive motion input than with the figure in non-fictive motion input, especially when the figure in the picture was compatible with the

[4] Example recordings of eye tracks can be seen at http://psychology.stanford.edu/~richardson/ficmot.

figure in the sentence. Taken together, our results show that fictive motion sentences had a consistent and dramatic effect on eye movements, most notably on the compatible region of interest.

General Discussion

Participants in our preliminary study spent more time inspecting the compatible region of interest in spatial scenes when they heard fictive motion sentences than when they heard non-fictive sentences. The results demonstrate that *figurative* language influences eye movements in consistent and predictable ways. The results are in line with other work on fictive motion (Matlock, in press; Matlock, Ramscar, & Boroditsky, 2003a, 2003b), and they suggest a dynamic mental representation that mirrors perception or enactment of motion (e.g., Barsalou, 1999, Glenberg, 1999).

One explanation for the results obtained here is that when our participants were presented with fictive motion input, they mentally simulated motion along the figure, and then their eye movements mirrored that internal simulation. For example, on hearing the sentence *The road runs through the desert*, participants conceptually "moved" along a road and then their eye movements enacted a congruent simulation. Another not incompatible explanation assigns a more active role to eye movements. It might be that participants' eye movements were central to simulation and building an appropriate representation of the figure. For example, on hearing the sentence *The road runs through the desert* and seeing a depiction of that scene, participants' eye movements allowed them to incrementally construct an appropriate model of the road. If this is the case, then perhaps eye movements allowed participants to simulate and compute some information about the scene externally (for related views, see Spivey, Richardson, & Fitneva, in press; Spivey, et al 2000).

Are there other explanations for longer gaze durations with fictive motion sentences? For instance, could it be that people activated the literal meaning of the motion verb in fictive motion sentences, and that that literal interpretation led to longer inspection times? Based on the results reported here, we cannot rule out this possibility entirely. But we would argue that our compatibility results suggest that this is not likely. Namely, if the verb alone – independent of the figurative meaning of the fictive motion sentence – brought on longer gaze durations, we would not have seen selective differences in the axis of orientation (vertical versus horizontal). After all, the motion verb alone provided no information about direction.

Our data show that figurative language, like literal language, influences eye movements. We argue that this is because fictive language evokes a dynamic mental simulation, and that this simulation determines how the visual system interprets and inspects the world. Further research will reveal how these simulations occur and the extent to which they mirror perception or enactment of physical motion in the world.

Biased stochastic learning in computational model of category learning

Toshihiko Matsuka (matsuka@psychology.rutgers.edu)
RUMBA, Rutgers University – Newark
101 Warren St., Smith Hall 327, Newark, NJ 07102 USA

Abstract

Matsuka and Corter (2003b) presented evidence that people tend to utilize only the minimally necessary information for classification tasks. This approach for categorization was efficient and valid for the stimulus set used in the experiment, but might be considered a statistically or mathematically non-normative approach. In the present paper, I hypothesized human category learning processes are biased toward simpler representation and/or conception rather than complex but normative ones. In particular, a few variants of "biased" learning algorithms are introduced and applied to Matsuka and Corter's stochastic learning algorithm (2003a, 2004). The result of a simulation study showed that the biased learning models account for empirical results successfully.

Introduction

In their recent work, Matsuka and Corter (2003b & 2004) investigated the possibility of using stochastic learning rather than gradient-based methods in neural network models of human category learning. They introduced stochastic learning models to more accurately account for human category learning. The gradient based learning algorithm used in many neural network models may be considered to have a normative justification (i.e., it models how people "should" learn or process information), but may not be descriptively valid at the individual level. Models utilizing a gradient method for learning seem to require a high degree of mental effort and assume that optimal adjustments are made to the vector of parameters on each trial. In contrast, Matsuka & Corter's stochastic learning model (2003a, 2004) does not assume that learning is associated with monotonic increases in accuracy (and attention) or continuous search for better categorization processes by humans. Rather, it models random fluctuations or "errors" in people's memory and learning processes, and how people utilize and "misutilize" such errors.

In their simulation studies (Matsuka & Corter 2004a), the effectiveness of stochastic learning methods applied to an ALCOVE-like model (Kruschke, 1992) was evaluated in several settings. The modified models were shown to be satisfactory in replicating two phenomena observed in empirical studies on categorization; namely, rapid change in attention processes (Macho 1997; Rehder and Hoffman 2003), and individual differences in distribution of attention (Matsuka & Corter 2003b).

Although the stochastic learning model reproduced more realistic individual differences than models with a gradient type learning algorithm, it did not replicate one tendency observed in the empirical study of Matsuka and Corter (2003b). They found that for four dimensional stimulus sets with two diagnostic but perfectly correlated dimensions, the proportion of human participants who paid attention primarily to only one of the two correlated dimensions was higher than that of those who paid attention to both of the two correlated dimensions approximately equally (see Figure 2, top row, third column). In other words, many participants utilized only the minimal necessary information for this task. In contrast, the stochastic learning model inadequately predicted that a higher proportion of participants would pay attention to the two correlated dimensions approximately equally.

The strategy of using minimal information may be a very natural and efficient usage of limited mental resources for humans. This would be particularly true for real world categorization tasks, where the number of feature dimensions could easily exceed a manageable number, in which many are not necessary or crucial (e.g., irrelevant and or highly correlated) for successful categorization. There are several ways that could lead people to use a lesser amount of information, resulting in simple conception of categories. One possible explanation is that there may be an implicit or explicit penalizing mechanism in human cognition that encourages less complete but simpler concepts than more complete but more complex concepts. Another possible explanation is that there may be a mechanism in human cognition that leads to a more thorough search for simple concepts.

In the present research, based on these remarks, I hypothesize and model human category learning as being biased toward simpler and heuristic concepts [1] (or representation) than complex and complete ones.

Biased Stochastic Learning

The proposed algorithm is based on a simulated annealing algorithm (Kirkpatrick, Gelatt, & Vecchi, 1983; Metropolis, Rosenbluth, Rosenbluth, Teller, & Teller, 1958) and somewhat resembles Boltzmann Machine (Hinton & Sejnowski, 1986). In the present algorithm, initial association weights are randomly selected from a uniform distribution centered at 0, and initial dimension attention weights are equally distributed across all dimensions. This equal attention allocation in the early stages of learning is motivated by the results of empirical studies (Matsuka, 2002; Rehder & Hoffman, 2003) that showed many participants initially tended to evenly allocate attention to the feature dimensions. In the present algorithm, at the beginning of each training epoch, a hypothetical "move" in

[1] In the present paper, the concepts of categories correspond to the configurations of the association weights and dimensional attention attractiveness.

the parameter space is computed by adjusting each parameter by an independently sampled term. These adjustment terms are drawn from a prespecified distribution. The move (i.e., the set of new parameter values) is then accepted or rejected, based on the computed relative fit or utility (defined below) of the new values. Specifically, if the new parameter values result in a better fit/utility, they are accepted. If they result in a poorer fit/utility, they are accepted with some probability *P*. This probability is a function of a parameter called the "temperature", which decreases across blocks according to the annealing schedule.

Because of the human's biased cognitive processes, possibly as a consequence of our implicit or explicit biased processes and/or preference toward simpler but less complete concept (these processes are discussed in detail in the model section), the learned concepts of categories, thus the configuration of the association weights and attention strengths, are inclined toward simpler ones. Note that in the present algorithm the notion of simplicity (or complexity) is directly related to the number of effective (non-zero, or non-subzero) association weights and attention strengths.

The proposed models would not require computation intensive (back) propagations of classification errors. Rather, in the present biased stochastic learning model framework, a very simple operation (e.g., comparison of two values) along with the operation of stochastic processes are assumed to be the key mechanisms in category learning. These learning algorithms can be applied to virtually any feed-forward NN model of human category learning

General Algorithm for Stochastic Learning

A general framework for the stochastic learning algorithm is discussed in this section. Here, the stochastic learning algorithm is embedded into ALCOVE, which is one of the most studied and applied computational models of category learning incorporating a selective attention mechanism (Kruschke, 1992). Again, it should be noted that this learning algorithm is very general and can be applied to virtually any NN model of category learning.

STEP 0: Initialization:

Problem specific parameters: (T^0,υ)

T^0 : initial temperature.

υ : temperature decreasing rate

Association weights w_{kj},, Attention strengths α_i,, Exemplar ψ_{ji}

STEP 1: Calculate ALCOVE output activations:

$$O_k = \sum_J w_{kj} \exp\left[-c\left(\sum_I \alpha_i \mid \psi_{ji} - x_i \mid\right)\right] \quad \text{(SL-1)}$$

STEP 2: Calculate fit index for the current parameter set:

$$F(w^t, \alpha^t) = \sum_{n=1}^{N}\sum_{k=1}^{K}(d_k - O_k^t)^2 \quad \text{(SL-2)}$$

where K = # categories, N = # input in one block, d_k is a desired output for category node k. Here, the superscript t indicates time.

STEP 3: Accept or reject of parameter set, $\boldsymbol{\alpha}$ & $\boldsymbol{w}$:

Accept all weight and attention parameters at the probability of:

$$P(w^t, \alpha^t \mid w^s, \alpha^s, T^t) = \left\{1 + \exp\left(\frac{F(w^t, \alpha^t) - F(w^s, \alpha^s)}{T^t}\right)\right\}^{-1} \quad \text{(SL-3)}$$

if $F(w^t, \alpha^t) > F(w^s, \alpha^s)$, or 1 otherwise, where $F(w^s, \alpha^s)$ is the fit index for the previously accepted parameter set, and T^t is temperature at time t.

STEP 4: Reduce temperature:

$$T^t = T^o \delta(\upsilon, t) \quad \text{(SL-4)}$$

where δ is the temperature decreasing function that take temperature decreasing rate, υ, and time t as inputs.

STEP 5: Generate new w_{kj} and α_i.

$$w_{kj}^t = w_{kj}^s + r^w,\ r^w \sim \Phi^w(\cdot) \quad \text{(SL-5)}$$

$$\alpha_i^t = \alpha_i^s + r^\alpha,\ r^\alpha \sim \Phi^\alpha(\cdot) \quad \text{(SL-6)}$$

where r^w and r^α are random numbers generated from prespecified distributions Φ^w and Φ^α.

REPEAT STEPS 1~5 until stopping criterion is met.

Biased Stochastic Learning Models

There are several approaches to model biased learning processes using stochastic learning model. Here, two simple approaches are introduced. The first biased learning model is based on the parameter regularization in which complex parameter configurations are penalized. The second model based on asymmetric random distributions, searches simpler parameter configurations more thoroughly.

Model 1: Bias via penalizing fitness function

In the present algorithm the utility index rather than the fit index is used for the decision on acceptance and rejection of the current parameter set. The utility of a particular parameter configuration is defined as a weighted sum of the accuracy in classification and the mental effort required by the parameter configuration. Thus, the utility index consists of two independent indices, namely "classification accuracy", *L* and "mental effort", *Q*, both dependent on learnable parameters $\boldsymbol{w}$ and $\boldsymbol{\alpha}$ at time *t*.

$$U(w^t, \alpha^t) = L(w^t, \alpha^t) + Q(w^t, \alpha^t) \quad \text{(M1-1)}$$

The *L* function can be the same function for the fitness index (i.e., Eq. SL-2). Here, the *Q* function may be considered as a penalty function, penalizing "complex" parameter configurations that are believed to require more mental effort. The general form of *Q* function is given as follows:

$$Q(w^t, \alpha^t) = \gamma_w \phi^w(w_m^t) + \gamma_\alpha \phi^\alpha(a_m^t) \quad \text{(M1-2)}$$

where ϕ^w and ϕ^α are functions calculating mental effort required for specific parameter configurations at time *t* (i.e., $\boldsymbol{w}^t$ and $\boldsymbol{\alpha}^t$), and γ_w and γ_α are coefficients weighting these mental efforts. Note that γ_w and γ_α also control relative importance of *L* and *Q* functions (i.e., accuracy vs. simplicity). That is the hypothetical coefficient, γ_Q, weighting importance of *Q* function relative to *L* function is

included in γ_w and γ_α. I.e., $\gamma_w = \gamma_Q \gamma_w^*$ and $\gamma_\alpha = \gamma_Q \gamma_\alpha^*$. Thus Equations M1-1 and M1-2 may be rewritten as:

$$U(w^t, \alpha^t) = L(w^t, \alpha^t) + \gamma_Q Q^*(w^t, \alpha^t) \quad \text{(M1-1R)}$$

$$\gamma_Q Q^*(w^t, \alpha^t) = \gamma_Q \gamma_w^* \phi^w(w_m^t) + \gamma_Q \gamma_\alpha^* \phi^\alpha(a_m^t) \quad \text{(M1-2R)}$$

There are several functions applicable for ϕ:

$$\phi^w = \sum_j \sum_k w_{kj}^2 \quad \text{(M1-3a)}; \qquad \phi^\alpha = \sum_i \alpha_i^2 \quad \text{(M1-3b)}$$

$$\phi^w = \sum_j \sum_k I(|w_{kj}| > \zeta^w) \quad \text{(M1-4a)}$$

$$\phi^\alpha = \sum_i I(\alpha_i > \zeta^\alpha) \quad \text{(M1-4b)}$$

where ζ^w and ζ^α are threshold values, and $I(expression)$ is the indicator function that returns 1 if the *expression* is satisfied. Equations M1-3a and M1-3b, often referred to as ridge penalty function or weight decay, encourage parameter settings that have small parameter values, whereas Equations M1-4a and M1-4b encourage parameter settings that have large number of parameters with less than the threshold values ζs. More general ϕ function is given as follows:

$$\phi^w = \sum_j \sum_k \frac{\left(w_{kj}/q\right)^2}{1+\left(w_{kj}/q\right)^2}, \qquad \phi^\alpha = \sum_i \frac{\left(\alpha_i/q\right)^2}{1+\left(\alpha_i/q\right)^2} \quad \text{(M1-5)}$$

where q, which can be either time dependent or independent, controls types of penalization or encouragement. That is, Equations M1-5 approach Equations M1-3s as $q \to \infty$, and approach Equations M1-4s as $q \to 0$ (Cherkassky & Mulier, 1997).

In many simulation studies, relative, but not absolute predicted attention allocation strengths are analyzed and compared (e.g. Matsuka, 2002). In such cases, the relative attention strengths $a_i = \alpha_i / \Sigma(\alpha_m)$ should be used as inputs for the penalty function. In addition, the penalization functions do not have to be in the same form for association weights and attention strengths. For example, in order to pay attention to a smaller number of feature dimensions it seems more sensible to use M1-4b or M1-5 with small q values for the attention parameters, because the relative but not absolute attention strength values are usually considered. In contrast, either choice seems appropriate for the association weight parameters where raw values are usually used.

Model 2: Bias via asymmetric distribution.

In the present model, random numbers are drawn from an asymmetric distribution with its mode equal to zero. Thus, as in the previous model, the probability of drawing a random number r from the vicinity of current values (i.e., vicinity of zero) is still the highest

$$P(0-\varepsilon < r < 0+\varepsilon) > P(M-\varepsilon < r < M+\varepsilon) \quad \text{(M2-1)}$$

for all $M \neq 0$.

However, unlike the previous model, for a particular parameter value, the probability of drawing a random number which will lead its updated value toward zero is higher than that of a random number that leads to the opposite direction. In other words, when the association weight value, w_{kj} is negative, then the probability of drawing a positive number is greater than a negative number; when the weight is positive, then the opposite is true, or

$$P(r^w > 0 \mid w_{kj} > 0) < P(r^w < 0 \mid w_{kj} > 0)$$
$$P(r^w > 0 \mid w_{kj} < 0) > P(r^w < 0 \mid w_{kj} < 0) \quad \text{(M2-2)}$$

For the attention strength parameter α_i the probability of drawing a negative random move is larger than for a positive move, assuming that α_i is constrained to be positive, thus,

$$P(r^\alpha > 0) < P(r^\alpha < 0). \quad \text{(M2-3)}$$

Parameter updates are accomplished by the following functions:

$$w_{kj}^{t+1} = w_{kj}^t + r_{kj}^w \quad \text{(M2-4)}$$

$$\alpha_i^{t+1} = \alpha_i^t + r_i^\alpha \quad \text{(M2-5)}$$

where $r_{kj}^w \sim \text{sgn}(w_{kj}^t) \cdot \Phi^w(\cdot)$ and $r_i^\alpha \sim \Phi^\alpha(\cdot)$

The random movement r_m is drawn from the negatively skewed distributions for α_i and w_{kj} if w_{kj} is positive, and from the positively skewed distributions for negative w_{kj}. Thus, the expected value of the distance of the random movement leading the learnable parameters to zero is greater than that of the opposite direction. This makes the model to decrease values of "irrelevant" parameters quickly.

There are several asymmetric distributions, and the χ^2 (Eq. M2-6, Figure 1, left panel) and Rayleigh (M2-7 & Figure 1, right panel) distributions are examples of asymmetrical distributions.

$$f(x \mid v) = \frac{1}{\Gamma(v/2)} \left(\frac{1}{2}\right)^{v/2} x^{\frac{v}{2}-1} \exp\left(\frac{-x}{2}\right) \quad \text{(M2-6)}$$

where $\Gamma(\cdot)$ is a gamma function, v is the degree of freedom.

$$f(x \mid b) = \frac{x}{b^2} \exp\left(\frac{-x^2}{2b^2}\right) \quad \text{(M2-7)}$$

where b is the Rayleigh distribution parameter.

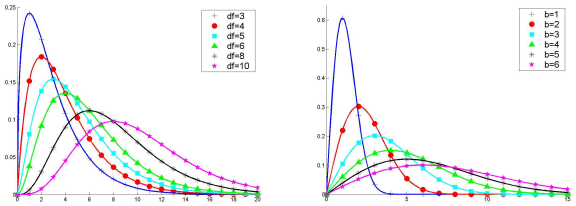

Figure 1. Example asymmetric distributions. Left panel: χ^2 distributions with several different distribution parameters. Right panel: Rayleigh distributions with several different distribution parameters.

Since the modes of these asymmetric non-negative distributions are not zero, and the distribution parameters affect both central tendencies and spreads of the distributions, the random numbers should be transformed as:

$$r = -s^t(f(x) - MODE(f(x))) \quad \text{(M2-8)}$$

where s^t is a time-dependent scalar controlling the width of the search areas. This ensures that the mode of the transformed random variable is zero and thus satisfies M2-1. Note that the distribution parameter v or b may be selected a priori and held constant throughout the training, or they can be time dependent so that the model starts with a highly skewed distribution and terminates with a near normal distribution, or vice versa.

While the present biased learning model (bias via thorough searches around zero) may be interpreted as active bias, actively trying to reduce the effective number of parameters or simplifying concepts, the bias via regularization (Model 1) may be interpreted as passive bias, involuntary resulting in simpler concept because of the limitation of mental capacity.

Simulations

Here, I examined how the two new biased stochastic learning models account for individual differences in attention learning. To do this, I simulated the results of an empirical study on classification learning, Study 2 of Matsuka (2002). In this study, there were two perfectly redundant feature dimensions, Dimension 1 & Dimension 2 (see Table 1), and those two dimensions are also perfectly correlated with category membership. Thus, information from only one of the two correlated dimensions was necessary and sufficient for perfect categorization performance. Besides classification accuracy, data on the amount of attention allocated to each feature dimension were collected in the empirical study. The measures of attention used were based on feature viewing time, as measured in a MouseLab-type interface (Bettman, Johnson, Luce, & Payne, 1993).

The empirical results that I am trying to simulate indicated that 13 out of 14 subjects were able to categorize the stimuli almost perfectly (Figure 2, top left panel). The aggregated results suggest that on average subjects paid attention to both of the correlated dimensions approximately equally (Figure 3, top middle panel). However, more interestingly when the attention data were analyzed per individual, it was found that many subjects tended to pay attention primarily to only one of the two correlated dimensions, particularly in the late learning blocks as shown in Figure 2, top row third column (Matsuka & Corter, 2003). This suggests that subjects used only the minimal necessary information for this task.

Simulation method: There were three ALCOVE-type models in the present simulation study, namely ALCOVE with stochastic learning (ASL; Matsuka & Corter, 2003a, 2004); ALCOVE with a regularized stochastic learning (ARSL); and ALCOVE with the Rayleigh distribution-based stochastic learning (ARAY). The standard ALCOVE will not be evaluated in the present simulation study, because its standard gradient learning method was shown to be unsuccessful in replicating individual difference when attention allocation is initialized equally (Matsuka & Corter, 2003a, 2004).

All three models were run in a simulated training procedure to learn the correct classification responses for the stimuli of the experiment. ARAY was run for 300 blocks of training, where each block consisted of a complete set of the training instances, while ASL and ARSL were run for 500 training blocks. For each model, the final results are based on 50 replications.

The model configurations (e.g., type of distribution, temperature decreasing rate & function, search ranges) for ASL and ARSL were the same except for the additional parameter-penalization functions incorporated in RSL to model biased processes in category learning. The random numbers for these two models were drawn from the Cauchy distribution, and its random number generation algorithm was based on Ingber (1989). For ARSL, the ridge penalty (Equation M1-3a) was imposed on the association weights, and a subset selection method (M1-4b with $\zeta = 0.1$) was used for the *relative* attention strengths.

For ARAY, a (pseudo) random number generator function from MATLAB Statistical Toolbox (MathWorks, 2001) was used to generate random numbers, and its transforming scalar s (see Eq. M2-8) was exponentially decreased during the learning. For all models, an exponential function was used as the temperature decreasing function. Models' user-definable parameters (e.g., initial temperature, temperature decreasing rate, ζ, and etc…) were selected arbitrarily.

Table 1: Stimulus structure used in Study 2 of Matsuka

Category	Dim1	Dim2	Dim3	Dim4
A	1*	1*	3	4
A	1*	1*	4	1
A	1*	1*	1	2
B	2*	2*	2	1
B	2*	2*	3	2
B	2*	2*	4	3
C	3*	3*	1	3
C	3*	3*	2	4
C	3*	3*	3	1
D	4*	4*	4	2
D	4*	4*	2	3
D	4*	4*	1	4

*Diagnostic feature

Results: All three models correctly replicated aggregated or averaged relative attention allocations to the four feature dimensions (Figure 2, second column). However, there are some minor differences in their predictions; ARAY paid less attention to non-diagnostic dimensions than ASL, which in turn paid less attention to those dimensions as compared with ARSL. Qualitatively, ARSL appears to be the most successful in replicating not paying attention to both Dimension 1 and 2 equally, while ASL appears to be least successful in this regard. ARAY was similarly unsuccessful, overestimating the proportion of people who would attend to both of the correlated dimensions equally. A noticeable difference between ARAY and other two

models is that ARAY virtually ignored non-diagnostic feature dimensions and paid attention exclusively to either or both Dimensions 1 and 2.

Among all three models, the proportion of sub-zero association weights for ARAY was the largest (Figure 2, fourth column), indicating it yielded simpler category conceptions than the other two models. Here, the notion of simplicity (or complexity) is directly related to numbers of effective (i.e., non-zero, or non-subzero) association weights and attention parameters. When compared with the distribution of the association weights of ASL, the proportion of sub-zero weights for ARSL was larger, indicating penalizing processes incorporated in ARSL resulted in simpler configuration. Note that the model configurations and settings for ASL and ARSL were the same expect for the regularization process incorporated in ARSL. Thus, the straightforward comparison of ASL and ARSL seems reasonable. However, because ARAY and ARSL had different parameter settings, interpreting the comparisons of distributions of the weights for ARAY and ARSL or ASL should be done with care.

In sum, the stochastic learning model with the regularizing processes penalizing mentally-expensive complex category conceptions (i.e. ARSL) appears to be the most successful model capturing human category learning trends that appeared biased, heuristic, and/or less optimal.

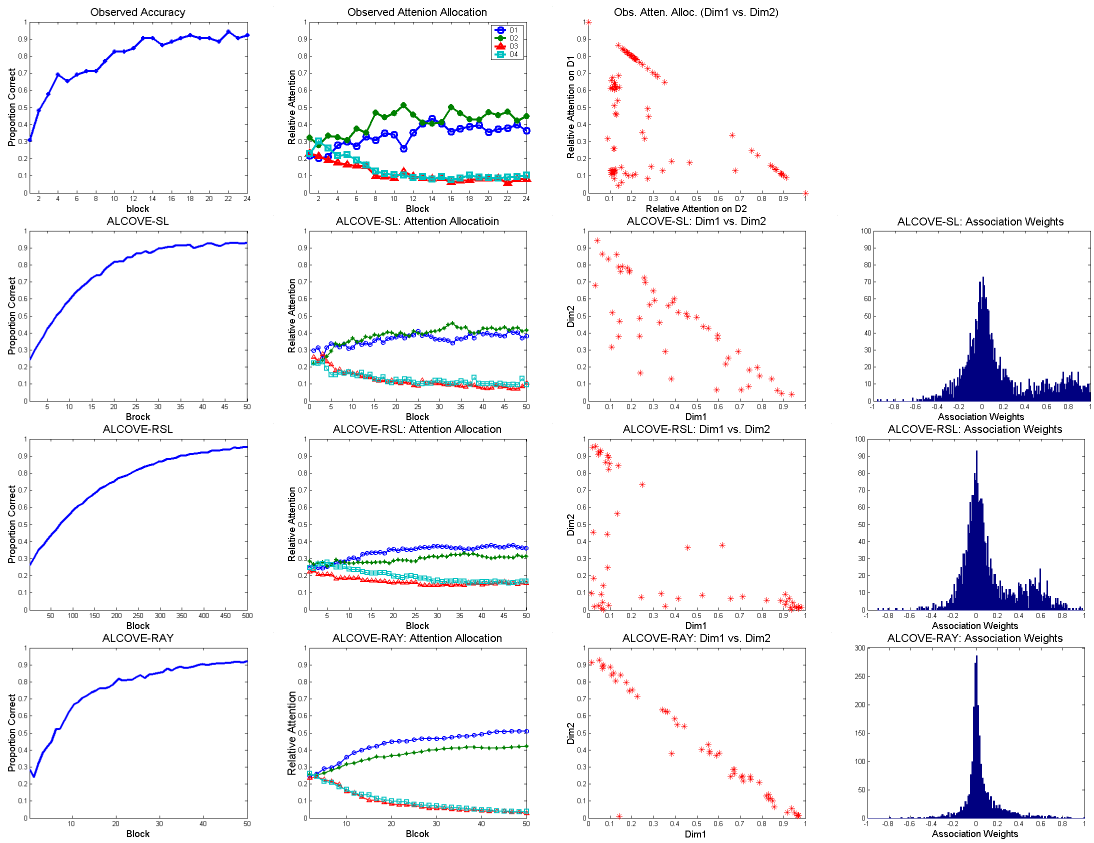

Figure 2. Results of the simulation study. Top row: Observed empirical results of Matsuka & Corter (2003b). The graphs on the first column show observed and predicted classification accuracy, second column shows relative attention allocation for the four feature dimensions; third column compares relative attention allocated to Dimensions 1 and 2 for the last four blocks, where each dot represents an observation. Fourth column shows histograms for the final association weights. Second row shows results of ALCOVE-SL; Third row, ALCOVE-RSL; Fourth Row, ALCOVE-RAY.

Discussion: Although there are 12 unique exemplars in the stimulus set, there are only four exemplars (one from each category) needed for a perfect categorization. Then, one might wonder if people would utilize all the exemplars or not. The distribution of ARAY's association weights may suggest that there are several "dead" or inactive exemplars whose association weights are all zero or near-zero, not being utilized for categorization. This characteristic along with not paying attention to irrelevant feature dimensions may suggest that ARAY replicates learning of an efficient learner, who utilizes a lesser amount of information. In contrast, ARSL predicts that people would utilize more than necessary information. In terms of attention allocation, the empirical results indicate that some people do try utilizing irrelevant information, suggesting that ARSL is more descriptive than other models. This suggests that people may not actively being biased, searching for simpler concepts (i.e., Model 2). Rather it suggests that biases may be caused by the limited mental capacity, involuntarily resulting in simpler concepts.

Discussion

RULEX vs. Stochastic Learning: The stochastic learning's take-all-or–none parameter updating strategy may be considered as a type of hypothesis testing learning model, which makes it similar to the RULEX model (Nosofsky, Palmeri, & McKinley, 1994). However, its random search method, interpreted as unstructured hypothesis generation and search, is very distinct from RULEX whose hypothesis generation algorithm is very strategic and well-structured. Thus, for Matsuka's (2002) stimuli set, RULEX would predict that everyone would allocate his/her attention exclusively to the one of the two diagnostic dimensions. Whereas the stochastic learning would predict some paying attention to either one of the two dimensions, another paying attention to both, and others distributing attention in some other combinations, since, as an exemplar-based model, it can minimize classification error with several different attention allocation patterns (i.e., it can learn to classify stimuli without "optimal" or "rational" attention distribution). In other words, when there are several minima, which is probably true for real world category learning task, stochastic learning can result in several different learning trajectories and parameter (i.e., association weight & attention allocation) configurations, corresponding to possible individual differences. In contrast, RULEX would always predict that people pay attention to the least number of dimensions, which may be a too normative prediction.

Gradient-type vs. Stochastic Learning: For two perfectly redundant feature dimensions, a gradient-type learning algorithm in general would allocate the same amounts of attention to the two dimensions, or its attention learning curves for the two dimensions would be parallel. In contrast, (biased) stochastic learning could result in asymmetric attention allocation to the two dimensions, and its attention learning curves are not necessarily parallel. In these regards, stochastic learning's predictions appear more realistic than those of gradient-type learning. However, this point alone does not necessarily indicate stochastic learning is what people would do. Perhaps, a gradient-type learning with some stochastic elements or errors might, as well, result in more "realistic" predictions.

Conclusion

Biased stochastic learning is a descriptive model of heuristic learning that prefers a simpler conception of categories in which less mental effort seems to be needed. Although the present two stochastic learning algorithms are intended to model such bias, the algorithms appear to be modeling two different types of learners, namely "ordinary people" and "proficients". The simulation study indicates that modeling biased learning via parameter-configuration regularization was the most successful in replicating the empirical results (i.e., ordinary people). In contrast, biased learning via asymmetric distributions appears to be more optimal or rational model, paying attention to only diagnostic feature dimensions and having smaller numbers of effective association weights (proficient-like concepts).

Although the present study supports biased stochastic learning's descriptive validity, more comprehensive simulation studies would be useful in evaluating the present learning models.

Comparisons of prototype- and exemplar-based neural network models of categorization using the GECLE framework

Toshihiko Matsuka (matsuka@psychology.rutgsers.edu)
RUMBA, Rutgers University – Newark
101 Warren St., Smith Hall 327, Newark, NJ 07102 USA

Abstract

In the present study, GECLE (Matsuka, 2003) was used as a general modeling framework to systematically compare the plausibility of two prominent assumptions about internal representations of neural network (NN) models of human category learning. In particular, exemplar-model friendly Medin and Schaffer's 5/4 stimulus set (1978) was used for comparing prototype- and exemplar-based NN models. The results indicate that some prototype-based models performed as good as or better than an exemplar-based model in replicating the empirical classification profile. In addition, a phenomenon called A2 advantage (i.e., people tend to categorize the less "prototypical" stimulus A2 more accurately than more "prototypical" stimulus A1) reported in empirical studies (e.g., Medin & Schaffer 1978) was also successfully reproduced by these prototype-based NN models.

Introduction

There have been an increasing number of studies debating how stimuli are internally represented in human cognition during the last few decades (e.g., Minda & Smith 2002; Nosofsky & Zaki 2002). Most of these debates have been based on quantitative models of categorization, and only a few have considered representational aspects of adaptive, network, or learning models of categorization. Several studies (Matsuka, 2002; Matsuka, Corter, & Markman, 2003) have compared exemplar-based (EB) and prototype-based (PB) adaptive network models of categorization, but there has been no systematic comparison of specific assumptions in EB and PB modeling. Although these comparative studies provided information on the models' capabilities for reproducing human-like categorization learning, they did not necessarily provide information that can lead to specific understanding of the nature of human category learning. That is because model-to-model comparisons are not informative for testing the plausibility of each specific assumption, rather such model comparisons are essentially omnibus tests collectively comparing all variations in assumptions at once. In other words, it has been difficult to use the results of these previous comparative studies to understand which specific assumptions are supported by the empirical data. Therefore, it seems desirable to make systematic comparisons between competing model assumptions using a general modeling framework that allows us to manipulate and test one or a limited number of model assumptions at a time.

In the present study, a generalized exploratory modeling approach for human category learning is introduced. Then, using this general framework two assumptions about how categories are internally represented, namely prototypes and exemplars, are compared in a systematic fashion.

GECLE

GECLE (for Generalized Exploratory models of Category LEarning) is a general and flexible exploratory approach for modeling human category learning, that is capable of modeling human category learning with many variants using different model assumptions (Matsuka, 2003). This general modeling framework allows model assumptions to be manipulated separately and independently. For example, one can manipulate assumptions about how stimuli are internally represented (e.g. exemplars vs. prototypes), or about how people selectively pay attention to input feature dimensions (e.g., paying attention to dimensions independently or not).

The GECLE model uses the Mahalanobis distances (in the quadratic form) between the internally represented reference points (RP: corresponding to either exemplars or prototypes) and the input stimuli as the measure of similarity between them. Thus, unlike other neural network models of category learning, GECLE does not necessarily assume that attention is allocated independently dimension-by-dimension. Rather, it assumes that humans in some cases might pay attention to correlations among feature dimensions. This allows GECLE to model processes interpretable as dimensionality reduction or mental rotation in the perception and learning of stimuli. Such processes may increase the interpretability of stimuli in categorization tasks. Another motivation for using the Mahalanobis distance is that the capability for paying attention to correlations among feature dimensions may be necessary for classification tasks defined on integral stimuli.

In the GECLE framework, the attention parameters (which are the diagonal and off-diagonal elements of the covariance matrices) can be considered as *shape* and *orientation* parameters for receptive fields or attention coverage areas of the reference points. It should be noted, however, that one can constrain GECLE to incorporate the "dimensional attention processes" assumption (i.e., attention is allocated independently on a dimension-by-dimension basis) by forcing the off-diagonal entries in the covariance matrices to be equal to zero.

Another unique feature of GECLE's attention mechanism is that it allows each reference point to have uniquely shaped and oriented attention coverage area, which is referred to as "local attention coverage structure" (Matsuka 2003). Again, one can impose a restriction on the model's attention mechanism by fixing all covariance matrices to be the same, which may be called "global attention coverage structure". Many NN models of category learning, ALCOVE (Kruschke, 1992) for example, incorporate the global attention coverage structure.

The local attention coverage structure model is complex, but may plausibly model attention processes in human category learning. For example, it allows models to be sensitive to one particular feature dimension when the input stimulus is compared with a particular reference point that is highly associated with category X, while the same feature dimension receives little or no attention when compared with another reference point associated with category Y. Thus the local attention coverage structure causes models to learn and be sensitive to within-cluster or within-category feature configurations, while the global attention coverage structure essentially stretches or shrinks input feature dimensions in a consistent manner for all RP receptive fields and all categories.

Another way of interpreting GECLE's capabilities for paying attention to correlations among feature dimensions and having local attention coverage structures is that the model learns to define what the feature dimensions are for each RP and to allocate attention to those dimensions independently. In contrast, for almost all previous adaptive models of category learning, the definition of the feature dimensions is static and supplied by individuals who use the models.

Some studies showed that humans learn much better in "filtration" tasks, in which information from only one dimension is required for (perfect) categorization, than in "condensation" tasks, in which information from two dimensions is required (e.g., Gottwald & Garner, 1975). This finding has been used as evidence that people pay attention to each dimension independently, rather than dependently (i.e., paying attention to correlations). Thus, a model paying attention to correlations or having diagonal attention coverage, as GECLE does, may not replicate filtration advantage. However, Matsuka (2003, 2004) successfully replicated the filtration advantage using a prototype based correlation-attentive GECLE with local attention coverage structure. He suggested that for a prototype based GECLE, the condensation stimuli require a stricter correspondence or synchronization between prototype search (i.e., shifting centroids of prototypes) and psychological scaling of the two feature dimensions (i.e., attention processes) as compared with the filtration stimuli. This is because the "correct" prototypes and "correct" scaling are defined by two dimensions in the condensation stimuli as compared to one dimension in the filtration stimuli.

In its natural form, the GECLE may be considered as a model using prototype internal representation, because it tries to learn to locate its reference points at the centers of each category cluster. However, with proper user-defined parameter settings, it can behave like a model with an exemplar-based internal representation.

Quantitative Descriptions (Algorithm)

The feedforward and learning algorithms of the GECLE are typical for implementation of the Generalized Radial Basis Function (Haykin, 1999; Poggio & Girosi, 1989, 1990). GECLE uses the following function to calculate the distances or similarity between internally represented reference points and input stimuli:

$$D_j^n\left(x^n, r_j\right) = \left(x^n - r_j\right)^T \Sigma_j^{-1}\left(x^n - r_j\right) \quad (1)$$

where x^n is an I-ruple vector representing an input stimulus consisted of I feature dimensions presented at time n, r_j, also an I-ruple vector, that corresponds to the centroids of reference point j, expressing its characteristics, and Σ_j^{-1} is the inverse of the covariance matrix, which defines the shape and orientation of the attention coverage area of reference point j. For a model with global attention coverage structure, there is only one global Σ^{-1} for all reference points.

The psychological similarity measures $D_j(x,r)$ cause some activations in internal "hidden" units or reference points (i.e., exemplars or prototypes). The activation of "hidden" basis unit j, or h_j, is obtained by any differentiable nonlinear activation transfer function (ATF), or

$$h_j = G\left(D_j(x,r)\right) \quad (2)$$

given that its first derivative $G'(\cdot)$ exists. An exponential function, $\exp(-cD_j(x,r))$, is an example of an ATF. The ATF must be a differentiable function, because GECLE uses a gradient method for learning, where the partial derivatives are used for updating the learnable parameters. However, it is possible to eliminate this restriction by incorporating a form of derivative-free learning algorithm such as stochastic learning (Matsuka & Corter 2004).

The activations of hidden units are then fed forward to output nodes. The activation of the kth output node, O_k, is calculated by summing the weighted activations of all hidden units connected to the output node, or

$$O_k = \sum_{j=1}^{J} w_{kj} h_j \quad (3)$$

where w_{kj} is the association weight between output node k and reference point j. The probability that a particular stimulus is classified as category C_k, denoted as P(C), is assumed equal to the activity of category k relative to the summed activations of all categories, where the activations are first transformed by the exponential function (Kruschke, 1992)

$$P(C) = \frac{\exp(\phi O_c)}{\sum_k \exp(\phi O_k)}. \quad (4)$$

ϕ is a real-value mapping constant that controls the "decisiveness" of classification responses.

GECLE uses the gradient method to update parameters. The error function is defined as the sum of squared differences between targeted and predicted output values (i.e., L_2 norm), or

$$E(w, r, \Sigma^{-1}) = \frac{1}{2}\sum_{k=1}^{K} e_k^2 = \frac{1}{2}\sum_{k=1}^{K}\left(d_k - O_k\right)^2 \quad (5)$$

Then the following functions are used to update parameters.

$$\Delta w_{jk} = \frac{\partial E}{\partial w_{jk}} = -\eta^w e_k h_j \quad (6)$$

where η^w is the learning rate for the association weights.

$$\Delta r_j = \frac{\partial E}{\partial r_j} = -\eta^r \sum_{k=1}^{K} e_k w_{jk} G'\left(D_j(x,r)\right)\Sigma_j^{-1}\left(x - r_j\right) \quad (7)$$

where $G'(\cdot)$ is a derivative of $G(\cdot)$. Equation 7 can be considered as a function that locates or defines prototypes of

stimuli. For the exemplar-based modeling η^r must be set to zero to maintain the static nature of reference points.

$$\Delta\Sigma_j^{-1} = \frac{\partial E}{\partial \Sigma_j^{-1}} = \eta^{\Sigma} \sum_{k=1}^{K} e_k w_{jk} G'\left(D_j(x,r)\right)\left(x - r_j\right)\left(x - r_j\right)^T \quad (8)$$

For models with global attention coverage structure, Equation 8 should be summed over both k and j.

Hierarchy of Constraints on Attention Parameters

There is a hierarchy of constraints that one can impose on the attention parameters Σ^1 to manipulate GECLE's attention mechanisms. There are two levels of uniqueness of Σ^1 (global and local attention coverage structure), in each of which there are three levels of constraints on entries in Σ. The following is a list of six possible levels of restriction. Note that regardless of the types of restriction, the entries (s_{im}) in Σ_j are assumed and constrained to satisfy the following conditions: $s_{ii} \geq 0$ & $|s_{im}| \leq$ MIN(s_{ii}, s_{mm}).

Global Attention Coverage Structures

A. Global Pure Radial (GPR): Constraints on Σ_j: $s_{ii} = s$, for all i: $s_{im} = 0$, for all $i \neq m$; $\Sigma_j = \Sigma$, for all reference points j.

B. Global Uncorrelated Non-radial (GUN): Constraints on Σ_j: $s_{im} = 0$, for all $i \neq m$; $\Sigma_j = \Sigma$, for all reference points j.

C. Global Correlated Non-radial (GCN): Constraints on Σ_j: $\Sigma_j = \Sigma$, for all reference points j.

Local Attention Coverage Structures

D. Local Pure Radial (LPR): Constraints on Σ_j: $s_{ii} = s$, for all i; $s_{im} = 0$, for all $i \neq m$.

E. Local Uncorrelated Non-radial (LUN): Constraints on Σ_j: $s_{im} = 0$, for all $i \neq m$.

F. Local Correlated Non-radial (LCN): Constraints on Σ_j: none.

Simulations

In this section, three simulation studies were conducted to compare adaptive network models of category learning utilizing prototypes or exemplar internal representations using the GECLE framework. Here, a classical category learning study (Medin & Schaffer 1978) was replicated with several variants of GECLE. Simulation 1 reports the predictions by several GECLE models based on "optimal" parameter values. In Simulation 2, the general tendencies in some key aspects associated with the stimulus set were investigated with the same GECLE models used in Simulation 1. The plausibility of prototype models was further investigated using two variants of prototype-based GECLE in Simulation 3.

Simulation 1

In Simulation 1, I simulated category learning using the well-known Medin and Schaffer's 5/4 stimulus set (1978). Table 1 shows the schematic representation of the stimulus set. Eight different GECLE-based models were involved in the present simulation study. Among them there were seven prototype-based models (PB) with 2,3,4,5,6,7, or 8 prototypes and one exemplar-based model (EB) with all 9 unique exemplars. The global attention structure with dimensional attentional processes (i.e., GUN) was used for all eight models. They were run in a simulated training procedure to learn the correct classification responses for the training set. The models were run for 100 blocks of training, where each block consisted of a complete set of the training instances. The final parameter values used for each model were chosen by a simulated annealing method to minimize the objective function (i.e., sum of squared error: SSE) in reproducing the classification profile reported in the original Medin & Schaffer's work (1978). There are a total of 50 simulated subjects in each condition.

The following one-parameter exponential activation transfer function was used for the models:

$$h_j = \exp\left(-c \cdot D_j(x,r)\right)$$

One of the main interests of the present simulation study was how well the eight models could reproduce observed classification profile reported in Medin & Schaffer (1978). The other related interest was how well each model performs on stimuli A1 and A2 (see Table 1). These two stimuli have been considered to be very important and diagnostic, because PB and EB tend to give different predictions for these particular stimuli (e.g., Nosofsky & Zaki, 2002). Specifically, EB models are used to explain empirical results that show that humans are better able to categorize less "prototypical" A2 than more "prototypical" A1 (e.g., Medin & Schaffer 1978). Moreover, simulation studies (e.g., Nosofsky & Zaki 2002) indicate that EB gives a better fit for differential performance on these particular stimuli.

Table 1. Stimulus set used in Simulation 1

	Training Set					Transfer Set			
	Cat	D1	D2	D3	D4	D1	D2	D3	D4
A1	A	1	1	1	0	1	0	0	1
A2	A	1	0	1	0	1	1	1	1
A3	A	1	0	1	1	0	1	0	1
A4	A	1	1	0	1	0	0	1	1
A5	A	0	1	1	1	1	0	0	0
B1	B	1	1	0	0	0	0	1	0
B2	B	0	1	1	0	0	1	0	0
B3	B	0	0	0	1				
B4	B	0	0	0	0				

Results: Table 2 shows two fit indices for the eight models, namely SSE as an absolute fit index, and SSE multiplied by

the number of learnable parameters (NLP) as a (crude) relative fit index that may account for the model complexity. A pure prototype model (here a pure prototype is defined as a model that has as many RPs as the number of categories) performed worst before and after controlling for the model complexities. In addition, it failed to show the A2 advantage. Rather as in many previous studies, it predicted that A1 was easier than A2. However, other PB models performed well; PB8 resulted in the best absolute fit, and PB5 resulted in the best relative fit.

When the PB models are compared with the EB model, some PBs fit the observed profile better than EB, particularly after controlling for the model complexities. More interestingly, as the EB model, almost all PBs were able to predict the A2 advantage (Table 2, last column).

Although, this Medin and Schaffer 5/4 stimulus set has been used as evidence supporting exemplar-based models and undermining prototype-based models, the results of the present simulation study appear to show no competitive advantage of the exemplar-based model. Instead, some PB models were able to reproduce the observed classification profile and the A2 advantage equally successfully with smaller numbers of learnable parameters.

Table 2. Results of simulation 1

Model	NLP	NRP	SSE	SSE x NLP	A2-A1
PB2	16	2	0.1438	2.301	-5.633
PB3	22	3	0.0694	1.527	3.643
PB4	28	4	0.0361	1.011	5.444
PB5	34	5	0.0250	0.850	9.046
PB6	40	6	0.0215	0.860	2.663
PB7	46	7	0.0193	0.888	4.314
PB8	52	8	0.0182	0.946	3.273
EB9	58*	9	0.0201	1.166	8.011

NLP: Number of Learnable Parameters
NRP: Number of Reference Points (e.g. prototype or exemplar)
* Location parameters for exemplar were static & not subject for learning, but assumed that optimized locations were learned when the exemplars were created.

Discussion of Simulation 1: All GECLE models that were capable of learning to locate the reference points were interpreted as prototype-based models in the present simulation study. However, it might not have been a sensible interpretation for some of those models, particularly for models with larger numbers of prototypes (e.g., PB5 ~ PB8). That is, it does not seem logical to create eight prototypes from only nine unique stimuli. Rather, there may be better interpretations for these models. Two possible alternative interpretations are discussed below.

First, it might be more sensible to interpret PB GECLE with larger numbers of prototype as models utilizing "fuzzy" or modular prototypes (or simply modules) as the reference points (RP) in a combinatorial fashion: it tries to create and memorize modules (defined by or being prototypes of subsets of stimuli belonging to a particular category) that summarize characteristics of particular feature dimensions more correctly than the other feature dimensions for a particular category, and uses combinations of the module activations triggered by similarities between the modules and input stimuli for categorizing. This combinatorial coding seems to be a very efficient use of limited mental resources for categorizing virtually unlimited number of unique instances.

Alternatively, those models that were interpreted as prototype-based GECLE with many prototypes might have been utilizing RPs that were more sensible to be interpreted as probabilistic, partial, or erroneous exemplars, instead. That is, although the models might have tried to store correct exemplars in their memory, the process was not fully completed because of the limited mental resources, resulting in imprecise exemplars memorization, in which a particular feature of a particular exemplar was more correctly memorized than other features. Then, these imprecise exemplars were utilized for categorizing the stimuli.

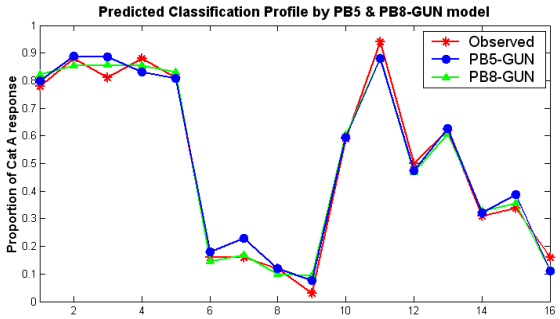

Figure 2. Predicted classification profiles by two best prototype based GECLE models (i.e., PB8-GUN: lowest absolute fit; PB5-GUN: lowest relative fit).

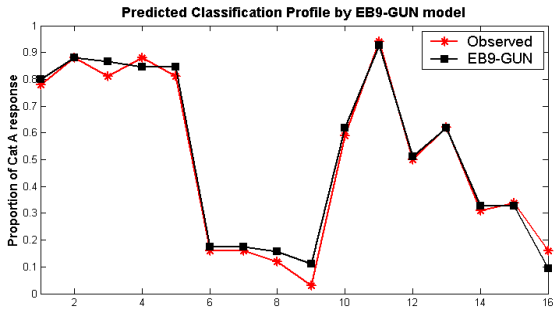

Figure 3. Predicted classification profiles by exemplar based GECLE model (i.e., EB9-GUN).

Simulation 2

Simulation 2 is a replication of Simulation 1 with 10,000 randomly chosen parameter configurations to investigate general tendencies in the A2 advantage by the same eight models used in Simulation 1. Here, the 10,000 simulated subjects with randomly assigned parameter values were trained to classify the 5/4 stimulus set. The ranges of parameters were [0.1 10] for c and ϕ, [0.001 1] for the three learning rates.

Results & discussion: Table 4 summarizes the results of Stimulation 2. In short, the A2 advantage was observed in almost all PB and EB models, indicating that the results of Simulation 1 are reasonably generalizable in this regard.

More interestingly, the EB model showed lesser magnitude of the A2 advantage than several PBs. This was mainly because EB9 learned to produce network output activations correctly with many parameter configurations (i.e., minimizing the error defined as Equation 5 perfectly) since the model was supplied the correct locations of all unique stimulus exemplars from the beginning of the training. This in turn, resulted in very small differences in classification responses for Stimuli A1 and A2, because the activations triggered by Stimulus A1 and A2 for the output nodes were almost identical (i.e., L_2 was minimized). This implies that any EB-based GECLE or any EB-based model such as ALCOVE would find this learning task (here, learning task does not correspond to categorization, but L_2 minimization, i.e., Eq. 5) easy because it can satisfactorily complete the task with virtually any parameter settings inasmuch as the locations of exemplars were well defined. Although this may be true if the condition of correctly memorizing exemplars is met, there is no guarantee for satisfying the condition in real human cognition. But, more likely, the condition would not be tenable for some people (i.e., some memorize exemplars more correctly and/or faster than other individuals). This difference in memorization ability may be one of the factors creating individual differences in category learning. This aspect of exemplar type modeling alone does not invalidate the assumption of exemplar-type internal representation, but it does suggest that exemplar-based (computational) models of categorization could be benefited from integrating an algorithm or quantitative explanation of how people learn and memorize exemplars.

On the contrary, exemplar theorists may argue that the upper limits of the randomly selected learning rate parameters (or the number of training epochs) were set unrealistically high. Although this argument is likely valid and thus the interpretation of the results may require some caution, it is still true that exemplar model may need to have learning algorithm for exemplar initialization, maintenance, and memorization.

Table 4. Results of Simulation study 2: Differences in classification accuracies for A2 and A1. (numbers of observed cases shown in parentheses).

Model	Overall	Classification Accuracy (CA) in training	
		100≥ CA >90%	90≥ CA >80%
PB2	1.011	-8.725(117)	-8.178(162)
PB3	2.184	0.056(250)	0.539(295)
PB4	2.521	0.331(556)	1.261(369)
PB5	3.071	0.885(905)	3.007(342)
PB6	2.711	0.661(1212)	3.816(365)
PB7	2.962	0.342(1690)	4.029(367)
PB8	2.446	0.330(2037)	2.885(393)
EB9	0.050	0.014(7660)	0.087(837)

Note: Observed classification accuracy for the training set is 0.85

Simulation 3

Simulations 1 and 2 showed that the pure prototype model, PB-2, accounted poorly for phenomena associated with the Medin and Schaffer's stimuli. However, these results might have resulted from incorrect assumptions about the prototype modeling. For example, I assumed that the locations of prototypes were continuously updated throughout the training, but in reality, people may quickly identify prototypes which may be less likely to be updated unless absolutely necessary. Another possible explanation is that people may have a uniquely shaped activation area for each prototype and/or pay attention to correlation among feature dimensions. For example, Matsuka (2003 & 2004) showed that there may be an interaction between types of internal mental representation and types of attention mechanism: the prototype-based model performed better when it incorporated unique attention structure with the capability of paying attention to dimensional correlations; whereas the exemplar-based model performed better with global attention structure with independent dimensional attention processes (i.e., no attention to correlations).

In the present simulation study, pure prototype modeling was reinvestigated using two variants of the original PB2 GECLE. The first one, SPB-2 is a static version of PB-2. That is SPB-2 is identical to PB2 appeared in Simulations 1 and 2, but the locations of prototypes were supplied from the beginning of the training and the learning rate for RPs was set to zero. Thus, this model resembles EB-based GECLE (except that RPs were prototypes) in that the locations of RPs were static. The second one, CPB2, is PB2-GECLE with the most complex attention mechanism, namely LCN (see Figure 1, lower right panel), having a unique receptive field for each prototype and the capability of paying attention to correlation.

For SPB2, the prototype for each category was created by averaging the feature values of each dimension of every object in a particular category, thus [0.8 0.6 0.8 0.6] for Category A and [0.25 0.5 0.25 0.25] for Category B. The rest of the procedures of the present simulation study follow those of Simulations 1 and 2.

Table 5a. Simulation 3: Results based on optimal parameters

Model	NLP	NRP	SSE	SSE x NLP	A2-A1
SPB2	16	2	0.1972	3.155	-9.208
CPB2	32	2	0.0377	1.206	11.130

Table 5b. Simulation 3: A2 advantage based on randomly drawn parameters.

Model	Overall	Classification Accuracy (CA) in training	
		100≥ CA >90%	90≥ CA >80%
SPB2	-2.346	-3.740 (2263)	-4.535(1920)
CPB2	2.931	-0.814(2215)	5.964(1505)

Results & discussion: A great decrease in SSE was obtained for CPB2 as compared with the original PB2, and after controlling for the model complexity by the simple linear adjustment (i.e., SSE x NLP) it performed nearly as good as EB9 (1.206 vs.1.166). In addition, unlike PB2, CPB2 was able to replicate the A2 advantage, and it was

shown to be generalizable to some extent in the second part of the present simulation study using the randomly drawn parameters (Table 5b). In contrast SPB2 performed worse than PB2 for replicating the observed classification profile. Moreover, SPB2 consistently failed to replicate the A2 advantage in the randomized simulation study.

Discussion on Simulations

Medin and Schaffer's 5/4 stimulus (1978) has been used as a benchmarking stimulus set for computational models of categorization and category learning, usually favoring exemplar models (e.g. Matsuka et al. 2003; Minda & Smith 2002; Nosofsky & Zaki, 2003). However, the results of the present simulation studies showed that several GECLE models with prototype internal representation performed as good as or better than the exemplar-based GELCLE. One type of those successful prototype-based GECLE was the model that created and utilized multiple *modular* prototypes for categorization. The modular prototype is a prototype defined by subsets of stimuli belonging to a particular category that summarize characteristics of particular feature dimensions more correctly than the other feature dimensions for the particular category (however, the modular prototypes may be interpreted as imprecise exemplars). The other type of the successful prototype-based GECLE was the one with uniquely shaped and oriented attention coverage areas and with the capability of paying attention to correlations among feature dimensions.

There are at least few concerns associated with the present simulation studies. First one, as discussed in Simulation 1, is that as the number of GECLE's reference points (RP) increases, it become philosophically difficult within the cognitive science paradigm to interpret what these RP are representing (e.g., modular prototypes vs. imprecise exemplars). The other concern is the way the numbers of learnable parameters were counted for the exemplar-based GECLE (see notes on Table 2). That is, in the present simulation studies, the location parameters of the exemplars were counted as learnable parameters. On one hand, the locations of exemplars may be learnable, because they are initialized at the "optimal" location without error. On the other hand, they may not be learnable, because they reside in static locations.

Conclusions

Generalized Exploratory model of human Category LEarning (GECLE) is a flexible and general framework for modeling human category learning that is capable of manipulating a limited number of assumptions independently and systematically. In the present study, the plausibility of two different assumptions about internal representation was investigated with GECLE using exemplar-model-friendly Medin & Schaffer 5/4 stimulus set (1978). The results of simulations showed no competitive advantage of previously favored exemplar-based modeling. Rather, they appeared to suggest some prototype models performed better than an exemplar model. In addition, the exploratory nature of GECLE yielded new plausible prototype-based adaptive models of category learning with different structures and model assumptions.

Although, several models were examined in some depth in the present research, the results were based only on a simulation of one empirical study. More simulation studies with several other stimulus sets should help identify models or assumptions with descriptive validities more accurately. In addition, measurements of several different cognitive processes associated with category learning, such as, attention allocation should be collected in empirical studies, in order to restrict model parameters and to better differentiate among models.

Abstract

In eye-movement experiments using gaze-contingent windows, the stimulus display is continuously updated in response to the participant's current gaze position. Usually, a window is centered at the participant's gaze position and follows it wherever the participant looks. Within the window, all stimulus information is visible, while outside of the window at least part of the information is masked. In the present paper, we apply this technique to a face recognition task. By varying the size of the window, we gain insight into face recognition processes in humans and characterize the visual information on which face recognition relies. The results also motivate the use of gaze-contingent windows to study visual perception.

Introduction

Face recognition is a very important function of the human visual system and is fundamental to our complex social behavior. Therefore, it is not surprising that face recognition in humans has been extensively studied. Many studies concluded that face recognition relies more strongly on holistic information than does object recognition in general (see Maurer, Le Grand & Mondloch, 2002, for a review). In other words, ideally, the recognition process uses the entire visual information available from a face.

What makes faces so special in this regard? An important reason seems to be our everyday-life expertise in identifying people by their faces. It was found that people can be trained to recognize individual non-face objects, and thereby develop analysis patterns that are similar to those used in face recognition (e.g., Diamond & Carey, 1986; Gauthier, Williams, Tarr & Tanaka, 1998).

Other researchers presented participants with face images filtered by different spatial frequencies and found that only a rather narrow band of spatial frequencies (about 6 to 12 cycles per face width) contributes significantly to the recognition of a face (e.g., Näsänen, 1999). Again, this finding does not apply to non-face objects, even if individual objects of the same class are to be distinguished (Biederman & Kolacsai, 1997).

Moreover, face recognition has received considerable attention in machine vision research (e.g., Phillips, Moon, Rizvi & Rauss, 2000; Senior, Hsu, Mottaleb & Jain, 2002; Zhou., Krueger & Chellappa, 2003). Despite these immense efforts, however, even the currently best vision algorithms achieve face recognition rates that are far below the ones of a human observer.

We believe that a better understanding of the mechanisms underlying human face recognition will be beneficial to both the fields of medicine and machine vision. In the present study, we applied the sophisticated method of gaze-contingent windows to a psychophysical eye-movement study of a face recognition task in order to broaden our understanding of the underlying perceptual and attentional processes. The gaze-contingent window technique provides powerful experimental control and has been used extensively in reading, scene perception, and more recently in visual search studies (e.g. Bertera & Rayner, 2000; McConkie & Rayner, 1975; Pomplun, Reingold & Shen, 2001; Saida & Ikeda, 1979; see Rayner, 1998, for a review).

In most of its applications, this technique obscures all objects from view except those within a certain window that is continually centered on the participant's current gaze position. The window position changes across fixations to follow the gaze position. For example, in a study by McConkie and Rayner (1975), participants read text that was masked outside a visual window that included the fixated character and a number of characters to the left and to the right. Only the text within the window was legible. The visual span in reading was assessed by varying the window size across trials and determining the smallest window size that allowed participants to read with normal speed.

In the present study, participants were presented with images of famous and non-famous faces and had to indicate whether they recognized the displayed person or not. While viewing the images, a gaze-contingent window was administered with its size varying across trials. This allowed us to address the following questions: First, to what extent does face recognition rely on the simultaneous availability of the entire face features? Second, from which positions in the image and in what manner do participants acquire information about a face when their peripheral vision is restricted? It is well known that saccades during unrestricted face viewing tend to be aimed at the region formed by the eyes, nose, and mouth (e.g., Yarbus, 1967). However, where and how do participants gather information if they have to do it sequentially and be as efficient as possible? Third, how can the moment of recognition be characterized? Is it possible to determine this moment based on psychophysical data?

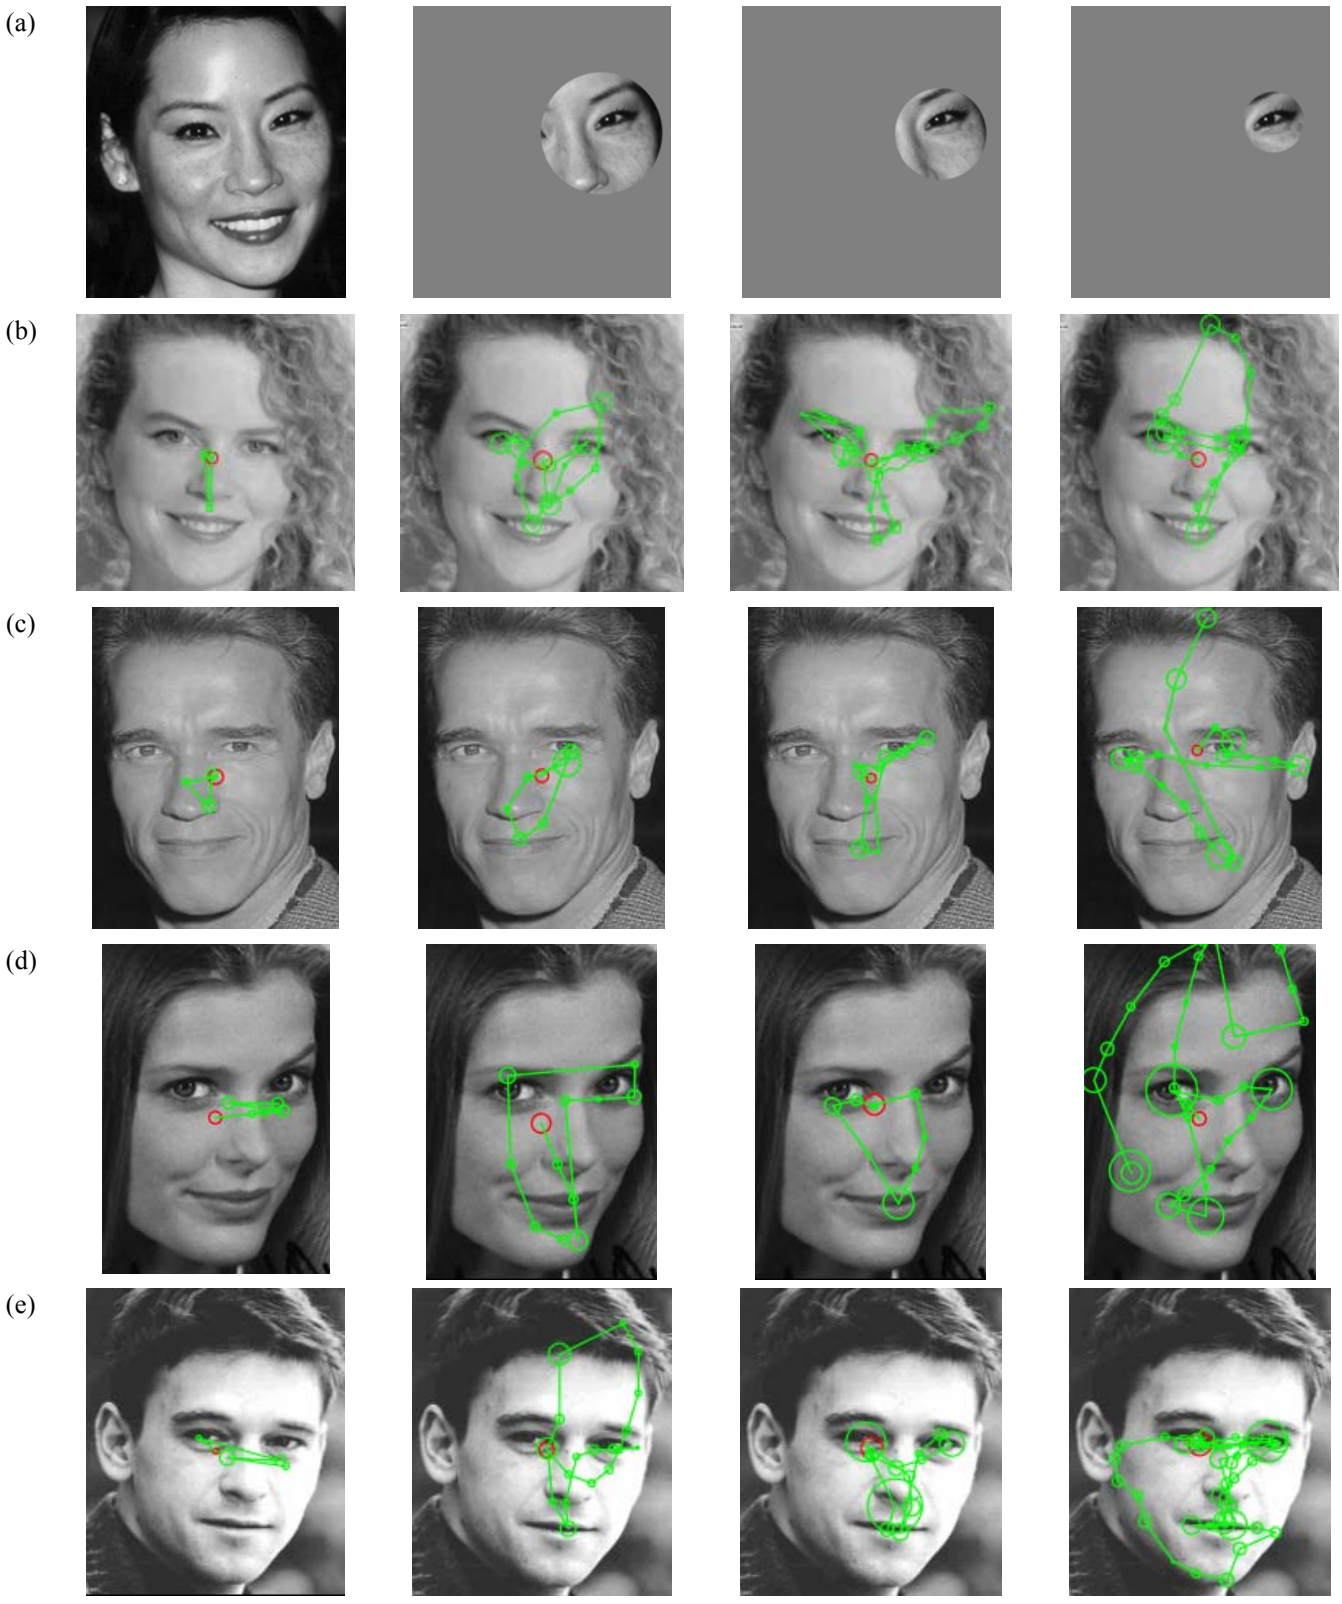

Figure 1: Sample stimuli used in the present study – each column represents one of the viewing conditions. From left to right column: unrestricted, large window, medium window, and small window. (a) Illustration of the different window sizes. (b) - (e) Sample gaze trajectories for each of the four stimulus categories (from top to bottom row): famous females, famous males, non-famous females, and non-famous males. Fixations are shown as circles with their size indicating fixation duration; the initial fixation is displayed in red color.

Method

Participants. Twenty students of the University of Massachusetts at Boston (ten females and ten males) participated in the present study. All of them had normal or corrected-to-normal vision. They were naïve with respect to the purpose of the study and were paid $10 for their participation.

Materials. We prepared 80 face images to serve as stimuli – 20 in each of the following four categories: famous females, famous males, non-famous females, and non-famous males. We chose the most popular American actresses and actors for the "famous" categories, while foreign actresses and actors, who had never appeared in international movies, were chosen for the "non-famous" categories. These grayscale images subtended an area of about 18° horizontally and 24° vertically on the screen of a 21-inch monitor. In the gaze-contingent window trials, the display area outside a circular, gaze-centered window was replaced with plain gray color. Four different viewing conditions were included in the experiment: unrestricted, large window (diameter of 8.2°), medium window (diameter of 5.5°), and small window (4.1°). These window sizes are illustrated in Figure 1a.

Apparatus. Eye movements were measured with an SR Research Ltd. EyeLink-II system. After a calibration procedure that was typically completed in less than a minute, gaze-position error was below or equal to 0.5 degrees of visual angle. The temporal resolution of the system was 2 ms. The gaze-contingent window followed the participant's gaze position with an average delay of 12 ms.

Procedure. Prior to each trial, participants were asked to fixate a marker in the center of the display. Following a button press, a face display was presented. As soon as participants had decided whether the depicted person was famous or non-famous, they terminated the trial by pressing one out of two buttons indicating their decision. Each participant was presented with each of the 80 stimuli exactly once, resulting in 80 trials per participant. The trials were administered in eight blocks of ten successive trials. Each of the four viewing conditions was applied in two of these blocks. The order of blocks and stimuli as well as the combination of stimuli with viewing conditions was systematically varied across participants.

Results and Discussion

Figures 1b to 1e show sample gaze trajectories for different stimuli across the four viewing conditions. Notice that the four trajectories for the same stimulus were generated by different participants, because each participant saw each stimulus only once. Two things can clearly be observed: First, in the unrestricted viewing condition, only a few central fixations were performed; the parafoveal and peripheral information of most of the face seems to be sufficient for successful face recognition. Second, when the gaze-contingent window was implemented, participants produced more fixations and directed them also at features that would normally not require foveal inspection, such as the hair or the ears, but obviously hold important information for the face recognition process. This effect of the gaze-contingent window on the eye-movement patterns generally increased with decreasing window size.

The quantitative analysis of the empirical data included the "standard" variables response time, proportion of correct responses, fixation duration, and saccade amplitude, but also the variables area coverage per trial and relative pupil size (see below). Interestingly, four-way analyses of variance (ANOVAs) for each of these variables (factors: viewing condition, stimulus recognizability, stimulus gender, and participant gender) revealed no significant effect by the factors stimulus gender or participant gender or their interaction. In other words, the gender of the participants or the people shown in the stimuli had no significant influence on any of the obtained variables. Therefore, in the following analyses, data were collapsed over these factors and only two-way ANOVAs (factors: viewing condition and stimulus recognizability) were conducted.

Response time was found to significantly depend on the viewing condition, $F(3; 57) = 80.93$, $p < 0.001$ as well as on recognizability (famous faces vs. non-famous faces), $F(1; 19) = 8.80$, $p < 0.01$. The interaction between the two factors also reached significance, $F(3; 57) = 2.77$, $p = 0.05$. As can be seen in Figure 2a, response time increased with smaller window size for both famous faces (no window: 1.90 s; large window: 4.57 s; medium window: 6.57 s; small window: 9.34 s) and non-famous faces (1.82 s, 5.69 s, 7.60 s, and 11.33 s). With more severe viewing restriction, response time became increasingly longer for non-famous faces as compared to famous ones. The pattern of these findings was expected, because restricting the participants' parafoveal and peripheral vision obviously makes their task more difficult. Detecting a familiar face should on average be faster than deciding that a face is unfamiliar, because before a negative decision can be made, all reasonable possibilities for a match have to be considered. With a smaller field of view, this effect increases, because more information needs to be obtained for a negative decision. The only unexpected finding is the pure magnitude of the response time difference imposed by the window manipulation.

The *proportion of correct responses* was also significantly influenced by the viewing condition, $F(3; 57) = 21.92$, $p < 0.001$, while there was neither an effect by recognizability, $F < 1$, or an interaction between the factors, $F < 1$. As shown in Figure 2b, there was no tradeoff between participants' response time and accuracy, but actually the opposite effect was found: The proportion of correct responses strongly decreased with more severe viewing restriction (91.3%, 78.0%, 67.8%, and 68.7%). Given that a participant who just gives random responses would reach an average of 50% correct responses, this result indicates a dramatic decrease in performance accuracy. The fact that there was no significant difference between famous and non-famous faces demonstrates that participants were not biased towards giving positive responses or towards giving negative responses. The latter would have been found if participants had just clicked the "non-famous" button

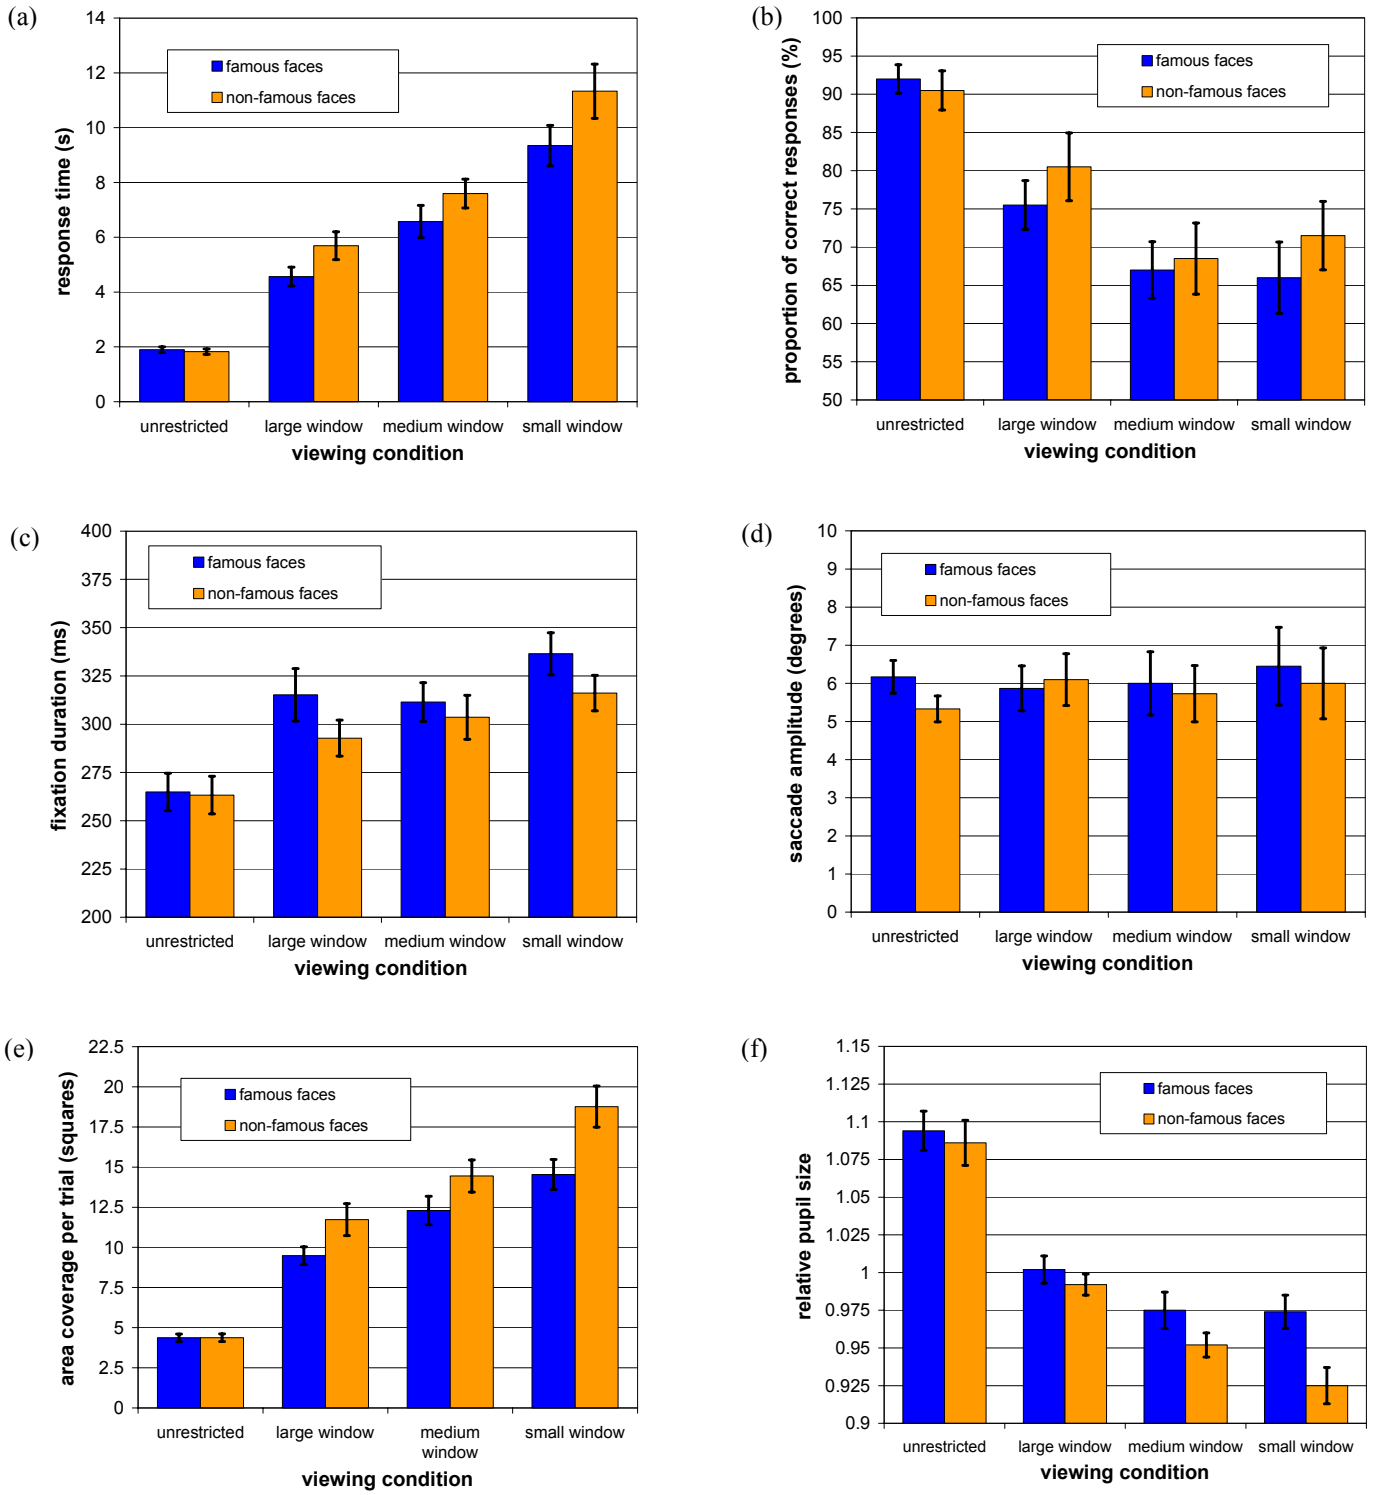

Figure 2: Psychophysical measurements obtained in the present study: (a) response time, (b) proportion of correct answers, (c) fixation duration, (d) saccade amplitude, (e) area coverage per trial, and (f) relative pupil size. Notice that the depicted interval of the variable values does not always start at 0.

whenever they did not recognize a face immediately, instead of making an effort to verify their first impression. Therefore, the analysis of the proportion of correct responses provides evidence for the participants of the present study to perform their task according to the instructions.

A variable that is analyzed in almost all eye-movement experiments is *fixation duration*. The duration of a fixation indicates how long the local information in a display was processed, which includes the duration necessary to program the subsequent saccade. In the present experiment, we found a significant effect by the viewing condition on fixation duration, $F(3; 57) = 23.15$, $p < 0.001$. The factor recognizability also exerted a significant effect, $F(1; 19) = 7.84$, $p < 0.05$, while there was no interaction between the two factors, $F(3; 57) = 1.33$, $p > 0.2$. In Figure 2c, fixation duration can be seen to increase with smaller windows for both famous faces (266 ms, 315 ms, 312 ms, and 336 ms) and non-famous faces (263 ms, 293 ms, 304 ms, 316 ms). Since smaller gaze-contingent windows reduce the amount of information that is available near the fixation point, there are two likely factors that determine this pattern of results: First, the smaller the window, the more effort is required to merge the available visual information with the current representation of the face in visual working memory. Second, for efficient task performance, a smaller window increases the necessity to aim saccades at locations where the most useful information is assumed to be located; consequently, the programming of these saccades requires more time. The finding of longer fixations for famous than for non-famous faces (see Figure 2c) is more puzzling; one possible explanation is that the recognition process itself causes one or more prolonged fixations – such fixations do not occur in non-famous faces. We conducted another analysis, reported later in this section, to test this hypothesis.

Another variable is routinely analyzed in eye-movement studies, namely *saccade amplitude*, measuring the length of saccades in degrees of visual angle. Short saccades can indicate fine-grained processing of local information, whereas long saccades often signify low information content or superficial scanning of local visual input. In the present context, we might expect saccades to become shorter with decreasing window size in order to uncover contiguous patches of an image. However, no influence by the viewing condition on saccade amplitude was found, $F < 1$, and recognizability showed no effect either, $F(1; 19) = 2.83$, $p > 0.1$. There was no interaction between the factors, $F(3; 57) = 1.74$, $p > 0.1$. As shown in Figure 2d, saccade amplitude (famous faces: 6.17°, 5.87°, 6.00°, and 6.45°; non-famous faces: 5.33°, 6.10°, 5.73°, and 6.00°) is unaffected by the recognizability of faces or the viewing condition. This result suggests that saccadic endpoints are not chosen to completely inspect local areas of the image by patching together adjacent pieces of visual information. Instead, saccades are aimed at positions that are assumed to contain the most significant information for the famous versus non-famous decision. This interpretation is in line with the view that fixations become longer with decreasing window size because of increased effort in the programming of saccades.

If it is true that the additional saccades induced by smaller gaze-contingent windows are aimed at "foraging" for useful information wherever in the image it is suspected, rather than inspect focused areas more thoroughly, then this behavior should be quantitatively reflected in the eye-movement data. In order to investigate this, we analyzed the eye-movement variable *area coverage per trial*. To compute this variable, we divided the stimulus area into 9 (horizontally) by 12 (vertically) squares. For each trial, we calculated the area coverage as the number of different squares that contained at least one fixation. This number should increase with the amount of "information foraging" (as opposed to focused examination) performed by participants. We found the area coverage per trial to be significantly influenced by the viewing condition, $F(3; 57) = 96.42$, $p < 0.001$, and by recognizability, $F(1; 19) = 13.50$, $p < 0.01$. The interaction between these factors was also significant, $F(3; 57) = 5.78$, $p < 0.01$. As shown in Figure 2e, the pattern of results for area coverage per trial is very similar to the one for response times (Figure 2a): Area coverage per trial increases strongly with decreasing window size, both for famous faces (4.37, 9.49, 12.30, and 14.54 squares) and for non-famous ones (4.38, 11.73, 14.45, and 18.77 squares). Area coverage is also smaller for famous faces than for non-famous ones, with this difference being more pronounced for smaller windows. This finding supports our assumption that peripheral restriction of information induces an exploration strategy that guides saccades towards the most promising new locations in the stimulus.

Finally, a variable that usually receives less attention, although it is a "by-product" of video-based eye tracking, is *pupil size*. Pupil size is known to depend on factors such as the luminance in the visual field or the cognitive activation of a person (e.g. Kahneman, 1973; Pomplun & Sunkara, 2003). Since we were only interested in relative changes in pupil size, we divided all measurements by the participants' initial pupil size after the eye tracker setup. Consequently, values above 1 indicate a dilated pupil, while values below 1 signify a contracted pupil. We found a significant influence of the viewing condition on pupil size, $F(3; 57) = 42.58$, $p < 0.001$, and also a significant influence by recognizability, $F(1; 19) = 8.37$, $p < 0.01$. There was no interaction, $F(3; 57) = 1.81$, $p > 0.1$. Figure 2f illustrates that pupil size clearly decreases with smaller window size for both famous faces (1.094, 1.002, 0.975, and 0.974) and non-famous faces (1.086, 0.992, 0.952, 0.925). This could be explained by the smaller amount of information that is available for processing at any given time during the trial. However, why was the pupil larger for famous than for non-famous faces?
A possible explanation is that the *moment of recognizing* a famous face has an impact on the eye-movement data. In an earlier, unpublished study on a face search experiment, we observed that the moment of recognizing the presence of a face tended to coincide with a prolonged fixation and temporarily dilated pupils. If such a reaction also occurs at the moment of recognizing a known face, then in the present study this would not only explain the greater in pupil size, but also the longer fixations measured for famous as compared to non-famous faces. To test this hypothesis, we

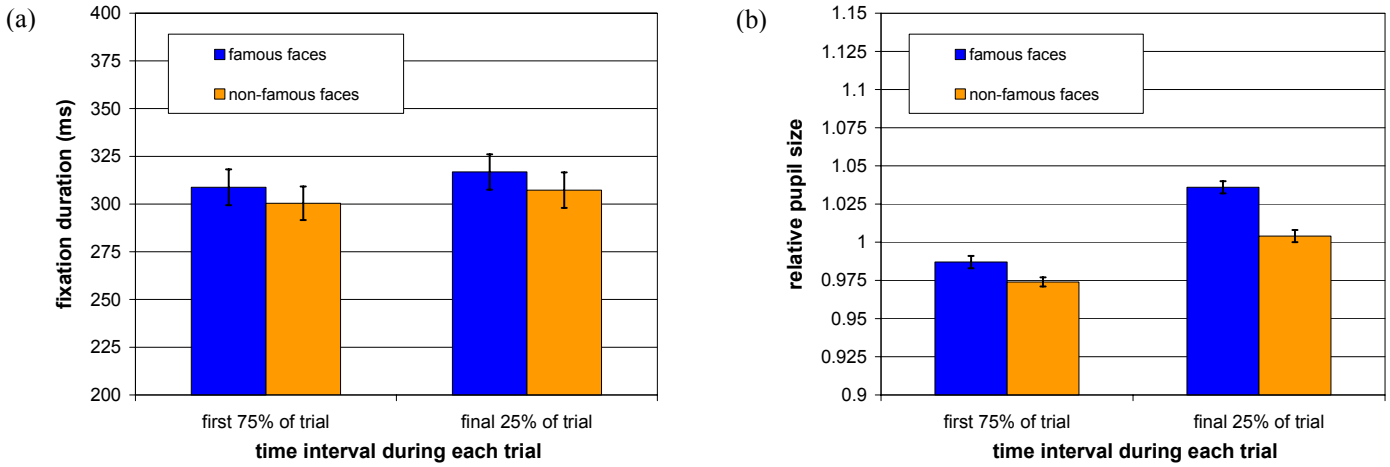

Figure 3: (a) Fixation duration and (b) pupil size analyzed separately during the first 75% and the last 25% of each trial.

separated the data for the first 75% of the duration of each trial from the final 25%. The moment of recognition is most likely to occur during the last 25% of a trial, so if we found the recognizability effects on fixation duration and pupil size to only occur during the last phase, as indicated by an interaction of the factors recognizability and time interval, it would support the moment of recognition interpretation.

For each of the two variables, we therefore conducted a two-way (recognizability and time interval) ANOVA. While there was no significant interaction for fixation duration (Figure 3a), $F < 1$, it was found for pupil size, $F(1; 19) = 6.92$, $p < 0.05$. Figure 3b shows that the difference in pupil size between famous and non-famous faces clearly increases during the final 25% of the trials. This finding suggests that the moment of recognizing a face may be associated with pupil dilation.

All in all, the present study has shown that the simultaneous availability of the entire face information is crucial for efficient face recognition, which supports the view that face recognition is a holistic process that heavily relies on parafoveal and peripheral input. Restricting this input has provided us with insight into which essential information was eliminated and needed to be foveally processed instead. Finally, we have found that the moment of recognizing a face may be indicated by a dilated pupil. This line of research is only at its beginning, and we hope to inspire other researchers to consider the technique of gaze-contingent windows for their face recognition and other perceptual studies.

Abstract

Two experiments examine the use of the recognition heuristic which states that, in the absence of other information, individuals make judgments on the basis on recognition alone. This has been shown to be adaptive (Borges, Goldstein, Ortmann & Gigerenzer, 1999) and in Experiment 1 we demonstrate that the heuristic is reliably employed when participants are placed under time pressure. Experiment 2 considers a possible confound of the adaptive recognition heuristic with a less-adaptive recognition-preference strategy and shows that both may be employed but that the recognition-preference strategy is not sufficient to account for the recognition heuristic. We discuss the implications of our results for the recognition heuristic and the rest of the adaptive toolbox (Gigerenzer & Todd, 1999).

Introduction

A recent approach to human judgment and rationality put forward by Gigerenzer and colleagues (Gigerenzer, 2000; Gigerenzer & Todd, 1999) emphasizes the real-time constraints of many decision-making and reasoning tasks. In doing so they have suggested that many so-called "biases" in human judgment are actually adaptive within real-world situations. The approach uses "fast and frugal" heuristics that have been shown to be highly effective in a number of situations (Goldstein & Gigerenzer, 1999; Borges et al., 1999) even when compared to more sophisticated methods that take into account multiple sources of information.

The recognition heuristic is one such strategy and is, furthermore, the first step in a number of fast and frugal strategies within what has been termed the adaptive toolbox (Gigerenzer & Goldstein, 1996). Simply stated, the recognition heuristic provides the following rule of thumb: "*If one of two objects is recognized and the other is not, then infer that the recognized object has the higher value"* (Goldstein & Gigerenzer, 1999, p. 41). So, for example, if an experimental participant is asked to judge which of two cities has the larger population, the participant will be following the recognition heuristic if they choose the city which they recognize. This leads to the less-is-more effect whereby participants using the recognition heuristic outperform other participants who recognize both cities and should, therefore, have more information available upon which to base their decision. The reason for this is that recognition of city correlates with the size of the city and hence may be a more effective cue than those used by more knowledgeable participants.

Having demonstrated the usefulness of the heuristic, Goldstein & Gigerenzer (2002) examined whether the heuristic was actually employed in practice. Data from 22 participants showed that all of them produced choice behavior consistent with use of the recognition heuristic. These data were, however, disputed by Oppenheimer (2003) who noted that the American participants tested by Goldstein & Gigerenzer may have accessed information other than mere recognition in making their choices. Goldstein & Gigerenzer required their participants to select the larger of the two in pairs of German cities. Oppenheimer suggested that the stimuli employed conflated recognition with knowledge that the recognized city was one of the largest cities in Germany.

In his study, Oppenheimer presented participants with towns or cities that were local to them and that were known to be small. In doing so, Oppenheimer demonstrated that the recognition heuristic is not an inevitable strategy when faced with forced-choice tasks where only one of the choices is recognized. Oppenheimer's participants proved smarter than the recognition heuristic by choosing the recognized city significantly less often than would be expected by chance. However, the differences between the studies by Goldstein & Gigerenzer (2002) and by Oppenheimer (2003) go beyond the choice of stimuli. One aim of the current paper is to consider how differences in procedure may have contributed to the reported contradictions in choice behavior between the two studies. In doing so we will provide a more balanced view of the place of the recognition heuristic in decision-making generally and in the adaptive toolbox in particular.

The key methodological difference between the two studies was the time pressure that participants experienced. In the Oppenheimer study (Experiment 1), participants made 10 choices over a five-minute period, an average of 30 seconds for each choice. In Oppenheimer's Experiment 2, participants were given a week to return the booklet containing their answers. In contrast, in the Goldstein & Gigerenzer study (Experiment 1), participants made between 300 and 435 choices during a single experimental session. Although Goldstein and Gigerenzer did not specify how long their participants had to complete the task, it is likely that their participants had substantially less time per

choice than the 30 seconds for each choice taken by participants in the first Oppenheimer study (as, if this were the case, participants who had 435 choices to make would have taken over 3 ½ hours). We suggest that participants will be much more likely to use so-called "fast and frugal" strategies when tasks put them under time pressure. This situation basically reinstates the constraints under which boundedly rational approaches such as the use of fast and frugal heuristics are presumed to operate (Simon, 1956). It alos provides an alternative explanation, besides the difference in stimuli, of why participants were much more likely to use the recognition heuristic in the Goldstein and Gigerenzer study than in Oppenheimer's experiment.

In the two experiments that we report we therefore replicated the general procedure of Oppenheimer (2003) but gave participants a strict time limit for the experimental session. In order to address the issue of the confound in the stimuli identified by Oppenheimer we chose English towns or cities whose soccer teams played in the UK First Division, not in the Premier League, as the recognizable stimuli. The town or city names would thus have been familiar to the participants without being considered a large or major city as large cities in the UK (e.g., London, Liverpool, Manchester) tend to have soccer teams in the Premier League. The city names used as the (hopefully) unrecognizable stimuli were the fictional cities invented by Oppenheimer, all of which had made-up but (to UK participants) foreign-sounding names.

The general situation experienced by the participants therefore is one where the recognition heuristic is applicable (only one of the names is recognized) and there is no other information upon which to base a choice. The recognized name is not known to be a particularly large city (unlike the Goldstein & Gigerenzer study). Equally, the participant has little time with which to consider what they know of the recognized town or city or attempt to infer anything regarding the unrecognized city (unlike the Oppenheimer study). Under these circumstances the recognition heuristic is the only tool available in the adaptive toolbox. In Experiment 1 we consider whether, with these potential confounds identified and controlled for, participants will make use of the recognition heuristic. Failure to observe the use of the single simplest heuristic in the toolbox under such circumstances would be a severe setback to the fast and frugal heuristics research agenda.

Experiment 1

Participants and Procedure

The participants were 50 adult volunteers. The 30 men and 20 women who took part had an average age of 28 years (range 17-62; standard deviation 11.2). Each participant was presented with a four-page experimental booklet. The instructions told them that they would be presented with pairs of names of towns, and that their task was to circle the town with the largest population in each pair. Participants were given one minute to complete the task, timed with the stopwatch. In order to encourage them to work quickly, participants were given updates on the time at 15-second intervals. On completion of the first part of the task participants were then given a list of all of the towns used in the experiment (both real and fictional) and were asked to circle those out of the list that they recognized.

Materials and Design

The materials used in this experiment were based on those used by Oppenheimer (2003). We created a group of stimuli where participants could show the recognition heuristic by pairing the names of 10 real English towns with the names of 10 fictional towns (taken from Oppenheimer; see Appendix). The English towns were selected from the list of towns with First Division soccer teams, and each was paired with three different fictional towns, giving 30 recognition heuristic items in all. In addition, we created two groups of filler items. The first group consisted of pairs of real towns and cities taken from a list of 8, which contained four international towns/cities (e.g., Limerick) and four English towns (e.g., Bradford). Each participant received 10 pairs of this type. The second type of filler item consisted of pairs of the fictional towns. Participants each received 9 pairs of this type[1]. Therefore, each participant received 49 choice pairs in total, of which 30 were of the critical recognition heuristic type. The order of presentation of these pairs was randomized across participants.

Results

Coding Some participants did not complete all 49 choices in the allotted time. In addition, some participants either failed to recognize a real place name, or erroneously recognized a fictional place name. Therefore, on the basis of the number of items that they had completed, and their responses to the recognition task, we calculated for each participant: (a) the number of times that they could have used the recognition heuristic, (b) the number of times that they did use the recognition heuristic. The second figure divided by the first gave us a figure for the proportion of responses that conformed to the recognition heuristic.

Analysis One sample t-test showed that, by participant, the proportion of responses attributed to the recognition heuristic was significantly greater than would be expected by chance, $t = 3.55$, $df = 49$, $p = .001$ (2-tailed). These data are shown in Figure 1 (overleaf).

[1] There should have been 10 pairs of this type, but, due to a printing error with the materials, participants only received 9 pairs.

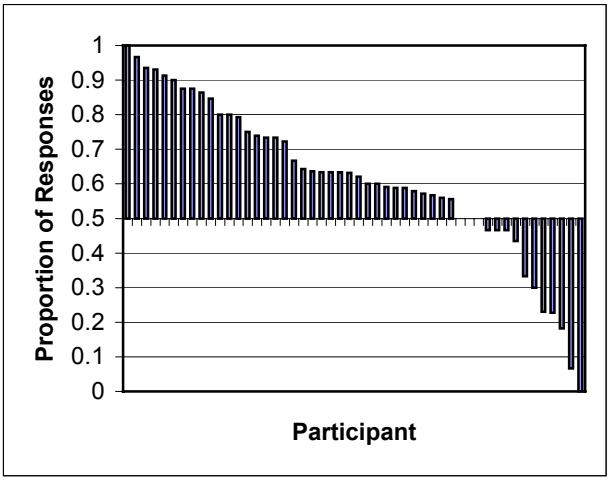

Figure 1: Proportion of Recognized Items Chosen by Participant (Experiment 1).

Further analysis of the choices made by individual participants shows that 23 out of the 50 participants showed evidence of use of the recognition heuristic at levels greater than chance, binomial $z > 1.28$, $p < .05$. Interestingly, a further 6 participants showed the reverse pattern, using the recognition heuristic significantly less often than chance, binomial $z > 1.66$, $p < .05$.

Discussion

These data confirm Goldstein & Gigerenzer's contention that participants use recognition in choice behavior when no other information is available. Use of this recognition heuristic may, however, be limited to situations when the participant is under time or other pressure. We should note that our participants did not use the recognition heuristic as frequently as those of Goldstein and Gigerenzer. This may have been due to the materials we used, and hence may provide some support for Oppenheimer's position. Additionally, not all the participants used the recognition heuristic consistently in their responses in our experiment and a significant subgroup of participants appeared to be using quite the opposite strategy. This was confirmed by the spontaneous self-reports of some participants. There are drawbacks to analyzing individual participants' data in this manner, for example, if participants were responding at random we might expect some individual participants to appear to use the recognition heuristic purely by chance. However, we are following a precedent in the literature (Goldstein & Gigerenzer, 2002; Rieskamp & Hoffrage, 1999) in attempting to identify individual strategies rather than averaging over potentially very different strategies. To answer some of these questions, we therefore ran a further experiment to examine whether altering the form of the question for the same choice stimuli would influence use of the recognition heuristic.

One possible explanation of our data is that participants, rather than using the recognition heuristic in the manner suggested by Goldstein & Gigerenzer (1999), were using recognition in a different way. For example, one participant reported deliberately choosing city names he did not recognize on the assumption that these foreign-sounding cities must be larger than the local towns that he knew. This use of recognition could explain the pattern of choice displayed by those participants who showed significantly less choice of recognized towns than would be expected by chance. This explanation is consistent with the data reported by Oppenheimer (Experiment 1).

If participants are capable of using recognition in a strategic and less rigid way than suggested in the formulation of the recognition heuristic, we would expect to see recognition effects not only in judgments of which of two cities is the larger but also in judgments of which of two cities is the smaller. According to the formal account of the recognition heuristic asking which of two cities is the smaller is equivalent to asking which is the larger. So participants would, paradoxically, be expected to use the recognition heuristic to choose the unrecognized city (since it is inferred that the unrecognized city is smaller of the two). However, if participants merely choose the recognized city because of some learned preference (e.g., Zajonc, 1968) or strategy we might expect them to continue to choose the recognized city. This hypothesis is tested in Experiment 2.

Experiment 2

Method

The participants were 42 adult volunteers. The 24 men and 18 women who took part had an average age of 21 years (range 18-48; standard deviation 4.5). The procedure and materials for this experiment were the same as that of Experiment 1. The only difference being that instead of making judgments of which of two towns was the larger, participants made judgments of which of two towns was the smaller.

Results

Coding We once again assessed participants' usage of the recognition heuristic taking into account the number of items completed and the participants responses to the recognition task in calculating a proportion of choices of the recognized item.

Analysis In this experiment, one sample t-test by participant failed to show that choice of recognized item varied significantly from chance, $t = 1.0$, $df = 41$, $p > .05$. These data are shown in Figure 2. Examination of Figure 2 also suggests, however, that some individual participants did use the recognition heuristic reliably in their responses.

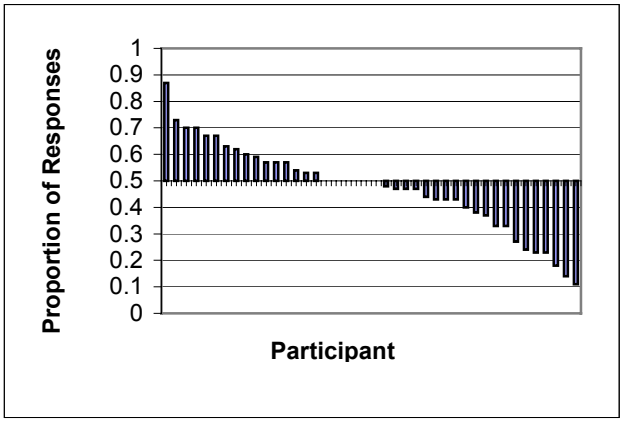

Figure 2: Proportion of Recognized Items Chosen by Participant (Experiment 2).

Further analysis of the choices made by individual participants shows that 10 out of the 42 participants showed evidence of use of the recognition heuristic at levels greater than chance, binomial $z > 1.28$, $p < .05$. A further 7 participants showed the reverse pattern, using the recognition heuristic significantly less often than chance, binomial $z > 1.28$, $p < .05$.

Discussion

The results of this experiment are intriguing because exactly the same stimuli and presentation conditions were used as in Experiment 1 yet we find a different pattern of results. The choice that participants needed to make was also identical to the previous experiment - judging the relative sizes of two towns or cities. The only thing that changed was the framing of the question, from asking which of the two was larger, to asking which was smaller. Some participants ($n = 10$) used a recognition heuristic to judge the smaller of the two towns, however, others ($n = 7$) used a diametrically opposed strategy. Consequently, the sample as a whole did not significantly differ from chance in their choice behavior. In this experiment, therefore, although all the preconditions for using a recognition heuristic were met, only a minority of participants did so.

Analysis of individuals' data showed that some participants *did* reliably use the recognition heuristic in their choices. It also showed that, as in the previous experiment, some participants used the even simpler strategy of always picking a town they recognized, regardless of the framing of the question. However, only a small group of participants appear to use this strategy, which, in the previous experiment, would have been indistinguishable from the recognition heuristic.

General Discussion

The recognition heuristic is an adaptive strategy in decision-making because of the correlation between recognition and magnitude. When a choice is made between the larger, or the more numerous, of two items it is frequently the case that the recognized item is, in fact, the larger or more numerous of the two. This is formalized within the recognition heuristic by stating that "when an individual only recognizes one of two items, the individual will judge the recognized item to be greater in whatever dimensions are positively correlated with recognition" (Oppenheimer, 2003, p. B2; see also Goldstein & Gigerenzer, 1999; 2002). Oppenheimer questioned the unthinking use of the recognition heuristic in his study. However, both Oppenheimer's study and the earlier reports by Goldstein & Gigerenzer confound choosing the recognized object because of the inferred correlation between recognition and magnitude and choosing the recognized object on some other basis, for example preference due to mere exposure (Zajonc, 1968).

In our studies, the two possible strategies of use of the recognition heuristic as a means of inferring relative magnitude and simple choice of the recognized item regardless of the question were examined in Experiment 2. We found that some participants do indeed choose the recognized item regardless of the framing of the question, a strategy indistinguishable from the recognition heuristic in standard formulations of the problem. However, the number of participants who use this strategy is small and although it might exaggerate the effect ascribed to recognition heuristic elsewhere, it cannot account for it.

The recognition heuristic was demonstrated in our Experiment 1 using similar materials to Oppenheimer (2003) and a similar procedure to that of Goldstein & Gigerenzer (2002). The majority of our participants did use the recognition heuristic as a "fast and frugal" means of decision-making when placed under time pressure, a constraint that was absent in the Oppenheimer (2003) study. However, the heuristic is not automatically applied as the number of participants showing it was reduced in our Experiment 2. This was despite the fact that the choice to be made was identical and the heuristic would therefore have equivalent adaptive value in both situations. The recognition heuristic is the single simplest heuristic in the adaptive toolbox and makes up the first principle in more complex decision-making algorithms such a take-the-best (Gigerenzer & Goldstein, 1996). Establishing the situations when the recognition heuristic is employed is a necessary prerequisite for evaluating the applicability of the fast and frugal tools within the adaptive toolbox. There have been very few experiments on this. The current study goes some way towards addressing this issue. We suggest that our results also throw up some interesting avenues for future research. For example, a future study could vary the degree of time, or other, pressure on participants and examine the effects of this on the frequency with which a recognition strategy is used.

Acknowledgments

Thanks to Alexandra Marshall for collecting and scoring the data for Experiments 1 and 2.

Don't teach me 2 + 2 equals 4: Knowledge of arithmetic operations hinders equation learning

Nicole M. McNeil (nmmcneil@wisc.edu)
University of Wisconsin-Madison
Department of Psychology, 1202 W. Johnson Street
Madison, WI 53706 USA

Abstract

This study investigated whether children's knowledge of arithmetic operations hinders their ability to solve novel equations after instruction. Second- and third-grade children completed a timed arithmetic pretest as a means for assessing their proficiency with arithmetic operations. Next, they received lessons on the principle of mathematical equivalence either in a context designed to activate their knowledge of arithmetic operations (e.g., 15 + 13 = 28), or in a context designed to not activate their knowledge of arithmetic operations (e.g., 28 = 28). Then, children completed an equation-solving posttest (e.g., 3 + 9 + 5 = 6 + __). After the posttest, children switched lesson contexts and completed the posttest again. Children solved more equations incorrectly after receiving lessons in the operational context. Additionally, the operational context led children who were most proficient with arithmetic operations to solve more equations using the typical addition strategy of adding up all the numbers. Results highlight that the activation of existing knowledge can interfere with the acquisition of new information.

Some domains of knowledge are particularly difficult for people to learn, even after significant amounts of training or instruction. There are many examples of this in our formal education system, including reading, mathematics, science, and foreign language. Over the past several years, a number of scientists (e.g., Flege, Yeni Komshian, & Liu, 1999; Kuhl, 2000; McNeil & Alibali, 2002; Schauble, 1990; Zevin & Seidenberg, 2002) have begun to consider how existing knowledge may contribute to these difficulties. The general theoretical view is that later learning is strongly constrained by early learning (cf. Tolman, 1948). If this is true, it obviously has implications in domains, like second language learning, where people learn one thing for many years (native language) before switching gears and learning something new, but closely related (second language).

The domain of mathematics is another domain in which people learn one topic for many years before switching gears and learning a new, but closely related, topic. Specifically, in most American mathematics classrooms, children learn arithmetic operations for many years (i.e., grades K-6) before eventually reaching algebra and being introduced formally to equations and the principle of mathematical equivalence. Mathematical equivalence is the principle that the two sides of an equation represent the same quantity.

Elementary school children (ages 7-11) have significant difficulties with equations and the principle of mathematical equivalence (Carpenter & Levi, 2000; Kieran, 1981; Baroody & Ginsburg, 1983). Their difficulties are most apparent when they are presented with equations that have operations on both sides of the equal sign (e.g., 3 + 4 + 5 = 3 + __). In the absence of instruction, approximately 80% of second- through fifth-grade children solve these types of equations incorrectly (Alibali & Goldin-Meadow, 1993; Alibali, 1999; McNeil & Alibali, 2000; NCISLA, 2000; Perry, Church, & Goldin-Meadow, 1988; Rittle-Johnson & Alibali, 1999).

Although there are many possible accounts of children's difficulties, including immature working memory function (Adams & Hitch, 1997; Gathercole & Pickering, 2000) or insufficient knowledge of necessary prerequisite skills (Haverty, 1999), the *change-resistance account* suggests that children's equation-learning difficulties are due, at least in part, to children's existing knowledge (McNeil, 2004). More specifically, the account posits that children construct knowledge on the basis of their early experiences with arithmetic operations and that this knowledge contributes to children's difficulties with more complex equations.

There are at least three knowledge structures that children learn from their early experiences with arithmetic operations that may ultimately hinder the ability to learn complex equations (see McNeil & Alibali, 2002). First, children may learn an operational strategy for solving math problems—perform all the given operations on all the given numbers. For example, in a typical addition problem like 3 + 4 + 5 + 3 = __, a problem solver simply needs to add up all the numbers and put the total in the blank. Second, children may learn an operational perceptual pattern related to the structure of math problems—the traditional "operations = answer" problem structure. For example, in the typical addition problem above, all of the numbers and operations are on the left hand side of the equation, and the answer blank is on the right side of the equation (directly following the equal sign). Third, children may learn an operational concept of the equal sign—the equal sign means "the total." Although these three operational patterns facilitate fast and accurate

performance on typical addition problems, they do not map onto more complex equations. For example, when presented with the equation "3 + 4 + 5 = 3 + _", a problem solver cannot just add up all the numbers. He or she cannot assume that the equation will conform to the traditional "operations = answer" problem structure. And, he or she needs to understand that the equal sign denotes an equivalence relationship between the two sides of the equation in order to generate a correct solution.

According to the change-resistance account, children learn these operational patterns from their experience with arithmetic operations. They store these operational patterns in memory. Then, when they are presented with a novel equation, their representations of the operational patterns are activated. Once activated, the representations guide attention and can hinder the ability to encode and interpret novel equations that do not directly map onto the patterns (cf. Bruner, 1957; Luchins, 1942; Knoblich, Ohlsson, & Raney, 2001).

In accordance with the change-resistance account, studies have shown that children do, indeed, rely on their knowledge of arithmetic operations when presented with complex equations. For example, when asked to solve the equation "3 + 4 + 5 = 3 + __", most students use their knowledge of the "perform all given operations on all given numbers" strategy and just add up all the numbers and put 15 in the blank (McNeil & Alibali, 2000, 2002, in press b). When asked to reconstruct the equation "3 + 4 + 5 = 3 + __" after viewing it briefly, many students use their knowledge of the traditional "operations = answer" problem structure and write "3 + 4 + 5 + 3 = __" (McNeil & Alibali, 2002, in press b). When asked to define the equal sign, many students use their knowledge of operational symbols (e.g., +) and say that it means, "the total" (McNeil & Alibali, in press a). Thus, children rely on their knowledge of the operational patterns when presented with complex equations.

McNeil and Alibali (2002) provided additional evidence for the change-resistance account by showing that children's reliance on the operational patterns can hinder the ability to learn about equations. In the study, they documented a significant negative linear relationship between children's reliance on the operational patterns on a pretest and the generation of correct equation-solving strategies after a brief lesson on equations. Children who were most reliant on the operational patterns at pretest were the least likely to generate correct equation-solving strategies following a lesson, and children who did not rely on the operational patterns at pretest were the most likely to generate correct equation-solving strategies following a lesson.

Although the results of McNeil and Alibali (2002) support the change-resistance account, they provide only correlational evidence about the relationship between children's knowledge of arithmetic operations and equation-learning difficulties. The change-resistance account argues that the activation of children's knowledge of arithmetic operations *causes* equation-learning difficulties. Thus, in the present study, the activation of children's knowledge of arithmetic operations is manipulated. Children are given lessons about the principle of math equivalence either in a context designed to activate their knowledge of arithmetic operations (operational context), or in a context designed to *not* activate their knowledge of arithmetic operations (non-operational context). If the activation of knowledge of arithmetic operations contributes to difficulties with equations, then the operational lesson context should be inferior to the non-operational lesson context. That is, after receiving lessons in the operational context, children should solve more equations incorrectly, and they should solve more equations with the strategy that is the most often used in the absence of instruction (i.e., they should rely on their knowledge of the operational strategy and just add up all the numbers in the equations).

Additionally, if knowledge of arithmetic operations contributes to difficulties with equation learning, then children who are most proficient with arithmetic operations should be least likely to benefit from the lessons. This, of course, is assuming that children who are most proficient with arithmetic operations have the strongest representations of the operational patterns. Children who are proficient with arithmetic operations should solve more equations incorrectly, and they should solve more equations by just adding up all the numbers in the equations.

Continuing this rationale, the combination of the operational lesson context and proficiency with arithmetic operations should be a "double whammy." That is, proficient children who have just received lessons in the operational context should solve more equations incorrectly, and they should solve more equations by just adding up all the numbers in the equations.

Method

Participants

Ninety-three second- and third-grade children from a public elementary school in Youngsville, North Carolina participated. Eleven children were excluded from the analysis because they were absent on one or more days of the study. Two additional children were excluded because their performance on the equations was three standard deviations away from the mean. The final sample contained eighty children (38 boys and 42 girls).

Measures

Timed Arithmetic Pretest The timed arithmetic pretest was used to assess children's proficiency with arithmetic operations. Participants were given 30 seconds to solve as many arithmetic problems (out of 20) as possible. The problems involved only addition and subtraction (no multiplication or division).

Equation-solving Posttest Participants were given unlimited time to solve twelve equations with operations on both sides of the equal sign (e.g., 5 + 4 + 7 = 5 + __, 6 + 4 + 8 = __ + 3).

Procedure

The study was conducted over a two-week period in children's regular mathematics classrooms. Children's mathematics teachers collected the measures and administered the lessons in the classroom setting. Children first completed the timed arithmetic pretest. Then, teachers taught a set of lessons about the principle of mathematical equivalence. The following is an excerpt from the spoken lesson script: "The correct answer is 28! That's because whatever is on one side of the equal sign has to be **the same amount as** [teachers were told to stress words in bold] whatever is on the other side of the equal sign."

Because the lessons were scripted, all children received the same *spoken* lessons. Children were randomly assigned to lesson contexts through the use of individual booklets. The booklets enabled children to follow along with the spoken lessons. Children received lessons in one of two contexts. In the operational context, booklets contained problems designed to activate children's knowledge of arithmetic operations (e.g., 15 + 13 = 28). In the non-operational context, booklets contained problems designed to *not* activate children's knowledge of arithmetic operations (e.g., 28 = 28). Children received two days of lessons (approximately 15 minutes per day) before they completed the first equation-solving posttest. After the first posttest, children received lessons in the other context (e.g., children who had already received lessons in the operational context now received lessons in the non-operational context). Finally, children once again completed the equation-solving posttest.

Coding

Proficiency with Arithmetic Operations Children were categorized as proficient on the timed arithmetic test if they both solved three (median) or more arithmetic problems correctly, *and* solved one (median) or fewer arithmetic problems incorrectly. This coding system led to approximately equal numbers in the proficient (N = 37) and not proficient (N = 43) groups.

Equation-solving Performance Children's strategies were coded using a system developed by Perry, Church and Goldin-Meadow (1988). Strategies were assigned based on the solutions that children wrote in the answer blank. Examples are presented in Table 1. Solutions were coded as reflecting a particular strategy as long as they were within ±1 of the solution that would be achieved with that particular strategy. Again, we were especially interested in children's use of the add-all strategy (see Table 1) because it is the most commonly used strategy in the absence of instruction.

Table 1: Example solutions and corresponding strategy codes for the given equation.

5 + 4 + 7 = 5 + __	
Solution	Strategy
11	Correct
21	Add all
16	Add to equal sign
4	Carry
1	Idiosyncratic

Results

Number of Incorrect Solutions

Overall, performance on the equation-solving posttest was abysmal. Children solved 11.27 (SD = 0.98) equations incorrectly (out of 12). We performed a 2 (proficiency with arithmetic operations: proficient or not proficient) x 2 (lesson context: operational context or non-operational context) ANOVA with repeated measures on lesson context and number incorrect on the equation-solving posttest (out of 12) as the dependent measure. As expected, the analysis revealed a significant main effect of lesson context, $F(1, 78) = 5.24$, $p = .025$. Children solved more equations incorrectly after receiving lessons in the operational context (M = 11.44, SD = 0.90) than after receiving lessons in the non-operational context (M = 11.11, SD = 1.03). Neither the main effect of proficiency nor the interaction of proficiency and lesson context was significant. Although, as mentioned, children's performance was very poor overall, so there was not a great deal of variability on the dependent measure to predict.

Number of Add-all Solutions

Consistent with prior work, the add-all strategy was the most popular strategy. On average, children solved 5.29 (SD = 3.67) equations (out of 12) by just adding up all the numbers in the equations. We performed a 2

(proficiency with arithmetic operations: proficient or not proficient) x 2 (lesson context: operational context or non-operational context) ANOVA with repeated measures on lesson context and number of equations solved with the add-all strategy (out of 12) as the dependent measure. As expected, the analysis revealed a significant interaction of proficiency and lesson context, $F(1, 78) = 4.90$, $p = .03$. As shown in Figure 1, the children who solved the most equations using the add-all strategy were the ones who were proficient with arithmetic operations and had just received lessons in the operational context ($M = 6.11$, $SD = 3.60$).

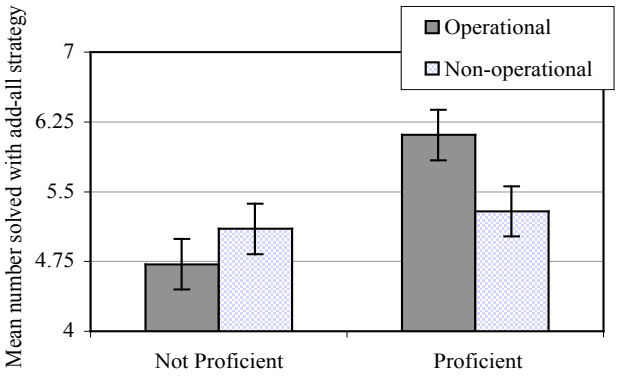

Figure 1: Mean number of equations solved with the add-all strategy (out of 12) as a function of arithmetic proficiency and lesson context. Error bars represent the pooled standard error.

Discussion

Consistent with the change-resistance account of children's equation-learning difficulties, results of the present study suggest that children's knowledge of arithmetic operations hinders their ability to learn about more complex equations. Children solved the fewest equations correctly after receiving lessons in contexts designed to activate their knowledge of arithmetic operations. Moreover, children who were most proficient with arithmetic operations and had just received lessons in the operational context solved the most problems by just adding up all the numbers, which is the most common strategy used by children who have not received any instruction at all.

Results suggest that it is vital to consider the state of children's existing knowledge when theorizing about children's learning difficulties. Thus, prevailing theories that focus on children's immature working memory system or their lack of prerequisite knowledge are missing a layer of complexity. More generally, results contribute to a growing body of work that suggests that knowledge can be detrimental to learning in some cases (Adelson, 1984; Flege et al., 1999; Kuhl, 2000; Schauble, 1990). Because knowledge typically facilitates learning, cases like these in which knowledge hinders learning can provide a unique window onto how the mind works (cf. Luchins, 1942).

Although the present study suggests that knowledge of arithmetic operations hinders equation learning. The results are not definitive. Performance on the equations with operations on both sides of the equal sign was abysmal, even after four, fifteen-minute classroom-based lessons. Thus, most children in the study had difficulties learning from the lessons on the principle of math equivalence. However, this is not surprising when viewed from the perspective of the change-resistance account. Children in the study are learning math on a day-to-day basis from a traditional, skills-based mathematics curricula. Thus, they are deeply entrenched in the operational patterns that are predicted to hinder learning. It is not that surprising that the brief lessons in the present study were not able to override this deeply entrenched way of thinking.

In terms of educational implications, results conflict with both intuition, and traditional mathematics practices. Intuition suggests that the children who are best at one topic in math should be best at another topic in math. And indeed, most schools assign, or track, children to algebra based on their performance in elementary school with arithmetic operations. This policy certainly makes sense if children need to be highly proficient with arithmetic operations before they are able to learn algebraic equations. However, it makes less sense if arithmetic proficiency hinders equation learning. Thus, our schools may be holding back children who would thrive in an early algebra course.

Equally important, American schools often implement spiral curricula in which old information is reintroduced year after year. The idea is that old information provides a framework within which new material can be introduced. In relation to mathematics instruction, this means that basic arithmetic operations are reintroduced year after year. Indeed, data from the Third International Mathematics and Science Study (Beaton et al., 1996) show that, unlike students from higher-achieving countries, students in American mathematics classrooms spend substantial amounts of class time practicing and reviewing basic arithmetic skills throughout the elementary and middle school years, when they should be concentrating on more advanced topics.

This type of spiral, review-based instruction has received some support from the scientific community. For example, Nathan et al. (2004) argue that the most effective instructions are the ones that "bridge" from children's existing knowledge to the new material. However, results of the present study suggest that teachers need to be careful about what they are trying to build bridges between. In some case, to-be-learned information does not map well onto existing knowledge, and in these cases, bridging might not be the most effective instructional strategy.

Instead of reintroducing basic arithmetic facts year after year, mathematics educators may wish to develop creative ways to integrate more algebraic ways of thinking into the math curricula as early as possible. One recommended strategy for integrating algebraic thinking into the earlier grades is to focus on equality and the equal sign (e.g., Carpenter, Franke, & Levi, 2003). For example, instead of simply reviewing and practicing basic arithmetic "facts" such as "3 + 4 = 7" year after year, young students can learn "3 + 4 = 7," "7 = 3 + 4," "3 + 4 = 5 + 2," and "7 = 7." Instructional strategies such as this may prevent the entrenchment of operational patterns and facilitate the notoriously difficult transition from arithmetic to algebra.

Acknowledgments

This research was supported by a Research Award from the University of Wisconsin Department of Psychology to N. M. McNeil. I thank members of the Cognitive Development Research Group at the University of Wisconsin for helpful discussions about the study and Jerry Haeffel for comments on a previous version of this paper. I also thank the students, teachers, and administrators at Youngsville Elementary School in North Carolina. Special thanks go to third-grade teacher Heather Shipley for her organization and enthusiasm.

Processing Ambiguous Words: Are Blends Necessary for Lexical Decision?

Abstract

A previous computational model (Joordens & Besner, 1994) has suggested that during lexical access, ambiguous words tend toward a blend state; that is, network activations settle into an incorrect state that is a mixture of the multiple representations of the ambiguous item. It has been suggested that this blend state actually aids lexical decision (LD) for ambiguous items as the blend state creates a larger "feeling of familiarity" which lexical decision may exploit. This theory, however, is based on the results of a computational model (a simple Hopfield network) in which multiple representations cannot be learned. Here we use a Symmetric Diffusion Network (SDN) to effectively learn and retrieve multiple mappings for a single input (i.e., ambiguous items). The model consists of three main processing regions–orthographics, phonology, and semantics–and is trained on a corpus of unambiguous items and ambiguous items that range in their degree of balance (probability distribution) between the multiple meanings. Following training, the SDN is able to reproduce the correct probability distributions for the ambiguous items; that is, it does not produce blend states. Furthermore, the model qualitatively captures the processing advantage for ambiguous items. Consequently, the notion of a blend state being used for LD is re-evaluated, and further assumptions about semantic processing are explored.

Introduction

From a computational perspective, we can break basic language processing into three main components: the semantic representation (what a word means), a phonological representation (the sound of a word), and an orthographic representation (the written form of a word) (e.g., Seidenberg & McClelland, 1989; Plaut, McClelland, Seidenberg, & Patterson, 1996; Harm & Seidenberg, 1999). The relationship between the phonological and semantic representations is initially established in early childhood, and then the mapping between the orthographic representation and the phonological representation (spelling-to-sound conversion) along with the mapping between the orthographic representation and the semantic representation (spelling-to-meaning conversion) is learned later in life (e.g.,Harm & Seidenberg, *in press*).

Ideally, there would be a one-to-one mapping between any of the representations, such that one spelling would correspond to one pronunciation, which would correspond to one meaning. Unfortunately, one-to-one mappings are far from the norm in English. That is, words that sound the same (homophones) can have different semantic representations (/flaI/: fly [insect]; fly [zipper]), different orthographic representations (/laIt/; light [fewer calories]; lite [fewer calories]), or different semantic and orthographic representations (/beɚ/: bear[furry animal]; bare[naked]). Similarly, words that are spelled the same (have the same orthographic representation) can have different phonological representations (either: /ˈaI.Dɚ/ [one or the other], /ˈIːDɚ/ [one or the other]), or phonological and semantic representations (wind: /waInd/ [twist]; /wInd/ [moving air]).

In fact, many words in English have polysemous or ambiguous semantics. For example, WordNet® (Fellbaum, 1998) lists a total of 146,350 noun, verbs, adjectives, and adverbs. Table 1 shows the percentage of unique and ambiguous words, as well as sense data. Whereas ambiguity is often defined as a word having multiple meanings across semantic categories or word classes, a word's sense is defined as it's meaning within a semantic category and can vary dramatically from the prior definition of ambiguity. For example, although Borowsky & Masson (1996) consider "deep" to be an unambiguous word, WordNet® lists "deep" with 3 noun senses, 15 adjective senses, and 3 adverb senses. It is clear that ambiguity is prevalent in English, and there is evidence that it has an effect on how we process words.

Table 1. Percentage of words having unique, ambiguous, and multisense meanings.

Word Class	Unique	Ambiguous	Senses
Noun	86.7	13.3	29.7
Verb	53.4	46.6	75.4
Adjective	74.5	25.5	48.7
Adverb	82.9	17.1	33.1

For example, the behavioral data from word ambiguity studies produces a paradox. In a lexical decision (LD) paradigm, ambiguity aids in word identification; that is, ambiguous words are identified as words more quickly and more accurately than unambiguous words (Gernsbacher,

1984; Borowsky & Masson, 1996). In contrast, in connected text studies (Rayner & Duffy, 1986; Rayner & Duffy, 1987; Duffy, Morris, & Rayner, 1988), ambiguous words are processed more slowly than unambiguous words. In other words, when semantic decisions (SD) (decisions on word meaning) are required, words with multiple meanings pose more difficulty than words with single meanings. This ambiguity paradox was illustrated in a single experiment in which participants first made a lexical decision, and then had to make a relatedness judgement on a subsequently presented word (Piercey & Joordens, 2000). In this study, participants showed an ambiguity advantage for lexical decision, and an ambiguity disadvantage on the subsequent relatedness decision. The importance of the ambiguity paradox lies in the fact that it leads directly to the question of how words are represented in the brain, and how we get access to these words. Any model of language will have to account for the ambiguity paradox if it is to be successful.

Previous models of the ambiguity advantage in LD, however, have shown mixed results. For example, Joordens & Besner (1994) trained a two layer Hopfield network consisting of 125 binary nodes (75 perceptual nodes and 50 conceptual nodes; activations of either +1 or -1). The perceptual nodes represented perceptual features and were never updated during retrieval (that is, they were clamped to a specific pattern). The conceptual nodes represented semantics, and the network was effectively fully connected. Learning was via a Hebbian learning algorithm.

They had two criteria for deciding if a PDP model could successfully account for the ambiguity effect; (a) the network had to retrieve one of the semantic patterns associated with the ambiguous words, and (b) the network had to retrieve ambiguous words faster than unambiguous words. Joordens and Besner (1994) were able to produce an ambiguity advantage within the *conceptual* nodes of their network when it into a stable pattern. This only occurred, however, when the network was relatively small and when the ambiguous meanings had equal probability. Most of the time (over 50% of the trials), their networks failed to settle into a correct pattern and formed a "blend" of the two learned meanings of the words over the conceptual units. Their initial conclusion from these simulations was that distributed models trained with Hebbian learning rule may not be suitable for capturing ambiguity effect.

In a different computational model, Kawamoto, Farrar & Kello (1994) trained a recurrent neural network with the Least Mean Square learning algorithm. Their model contained both "spelling" nodes and "meaning" nodes using a distributed representational coding scheme. During recall, the "spelling" nodes were given environmental activation, and the network was allowed to settle into a stable state. They found that they could produce an ambiguity advantage within the units representing "spelling", but showed the opposite effect in units representing "meaning" (an ambiguity disadvantage in semantics?). It has been suggested, however, that Kawamoto et al.'s (1994) network also settled into blend states in the meaning units (Kello, 2003, *Personal Communication*).

Although both of these models produced an ambiguity advantage (albeit in different processing regions), the networks failed to differentiate between the ambiguous items and produced blended representations. However, in later commentaries (Masson & Borowsky, 1995; Rueckl, 1995; Besner & Joordens, 1995), it was concluded that it may be possible for lexical decisions to be made prior to the network settling into these blend states. In other words, correct lexical decisions could be based on the "blend" states for ambiguous words resulting in a greater feeling of familiarity which could then be used to produce LD.

Using the model of Joordens and Besner (1994) as a basis for their theory, Piercey and Joordens (2000) developed the "efficient then inefficient" hypothesis for the processing of ambiguous words. They concluded that a lexical decision is made based on early processing and that a blend state (i.e., when all meanings of a word are simultaneously activated) produces an advantage for lexical decision but a disadvantage for the relatedness decision. That is, lexical decisions are made based on a feeling of familiarity that occurs during the early stages of processing, before a complete representation of the current item forms (i.e., efficient processing). Therefore, these decisions could be made regardless of an eventual blend state. However, when the participants need to determine which meaning of the word is appropriate to a particular context, processing slows down. The participant continues to process the ambiguous word and each of the word's meanings compete with each other. That is, the participant needs to leave the blend state and choose a meaning for the item so that further semantic processing can occur. This disambiguation of the blend state is an inefficient process that unambiguous words do not share. It should be noted that this theory is based specifically on the fact that the model of Joordens and Besner (1994) produced blended states for ambiguous words.

In this paper, we readdress the ambiguity advantage for lexical decision using a computational model that is able to learn multiple mappings for a single input. These models do not produce blend states; therefore, if the ambiguity advantage can be reproduced, then the notion of blend states existing should be questioned.

Symmetric Diffusion Networks

Symmetric Diffusion Networks (SDNs) are a class of computational models based upon the principles of continuous, stochastic, adaptive, and interactive processing (Movellan & McClelland, 1993). From a computational perspective, SDNs can be viewed as a continuous version of the Boltzmann machine; that is, time is intrinsic to the dynamics of the network. Furthermore, SDNs embody Bayesian principles in that they develop internal representations based upon the statistics of the environment. One of the main advantages of SDNs is that they are able to

learn multiple mappings for a single concept, something previous models often have difficulties with. In other words, SDNs are able to learn ambiguous mappings.

Recent work (Medler & McClelland, 2001) has shown that when biologically inspired constraints (i.e, activations within the range [0,1], positive between layer projections, lateral inhibition) are applied to SDN's, their effective performance is increased substantially in terms of the number of patterns they can be trained on, the rate at which patterns are learned, and their ability to separate out independent sources in an unsupervised manner.

Network Dynamics and Learning

Network dynamics are based upon continuous activations that develop over time, and are governed by the following equation:

$$\Delta a_i(t) = \Delta t[net_i(t) - n\hat{e}t_i(t)] + \sigma \cdot \sqrt{\Delta t} Z_i(t) \quad \textbf{Eq. } 1$$

where,
is the summed activation of all the activities coming into the unit–including its bias–passed through a squashing function

$$net_i = h(\sum_{j=1}^{n} a_j w_{ij})$$

such as the logistic, $h(u)$ = 1-exp(-u), and

$$n\hat{e}t_i = 1/g_i \cdot f(a_i)$$
$$= 1/g_i \cdot \log[(a_i - \min)/(\max - a_i)]$$

represents the net input required to maintain an activation value of a_i. Here we use the inverse logistic, where min and max are the minimum and maximum activation bounds respectively. g_i is a gain function, and $Z_i(t)$ is the standard Gaussian variable with zero mean and unit variance. The last term in the equation adds stochasticity to the network, which allows it to learn multiple meanings for a single input.

SDNs are trained with the *Contrastive Hebbian Learning* (CHL) algorithm, which performs both supervised and unsupervised learning depending on the environmental inputs to the network. Basically, learning occurs by presenting a pattern to the network and letting it settle for a set number of cycles. During this positive phase, co-occurrence statistics are computed for all the units. A negative phase then follows where the pattern is removed, the network is allowed to re-settle, and co-occurrence statistics are collected once again. Weights are then adjusted using the difference between the negative phase statistics and the positive phase statistics.

$$\Delta w_{ij} = \varepsilon\left[\sum\left(a_i^+ a_j^+\right) - \sum\left(a_i^- a_j^-\right)\right] \quad \textbf{Eq. } 2$$

In essence, the CHL algorithm makes weight adjustments based upon subtracting out the statistics of the base activity of the network (negative phase) from the statistics of the environment plus base activity (positive phase). Weight adjustments in this model were computed after each pattern presentation, as opposed to batch learning which adjusts weights only after all patterns have been presented (Movellan & McClelland, 1993).

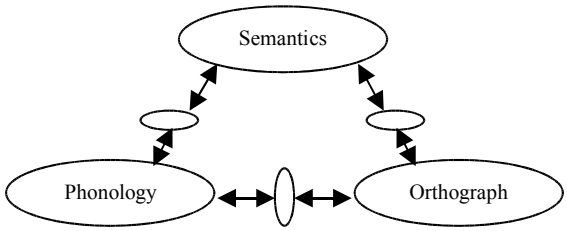

Figure 1. Network architecture showing the three main processing layers and connecting hidden layers.

Network Architecture, Stimuli, & Training

In keeping with previous models of language (e.g., Harm & Seidenberg, 1999), the network consisted of three main processing layers: an "orthographic", a "phonological", and a "semantic processing" layer. To capture the gross relationship between semantics and the orthographic and phonology representation of words, there were twice as many units (10) in the semantic layer as in the orthographic and the phonology layers (5 units each). Each layer was connected to the other via a set of hidden layers (5 units). Between layer connections were excitatory, while within layer connections were inhibitory (Medler & McClelland, 2001).

Stimuli were arbitrary, distributed binary patterns [0,1] that encoded the orthography, phonology, and semantics of a given "word". It is recognized that the abstract, distributed codes used in this simulation are not true representations of semantics, phonology, and orthography; however, future simulations using the same architecture will use more systematic encodings for these representations. Half of the training patterns (20) were unambiguous words, and half (20) were ambiguous words. In this model, only semantics had ambiguous patterns (as opposed to ambiguous orthography or phonology). Hence, ambiguous words had two possible meanings, and were selected with either a 70/30 distribution or a 50/50 distribution. Two representational training patterns are shown in Table 2; the presentation probability is the likelihood of that specific pattern being selected during the positive phase. Nonwords were simply random patterns across the orthographic and phonology units that had not been previously trained[1].

During training, the orthography and phonology units were clamped on, and the semantic and hidden units were modified during the positive and negative phases. Following training, the network was able to correctly produce the probability structure of the training stimuli. That is, the network was able to successfully recall the semantic patterns with the same probabilities that it was trained on. The

[1] As previous results have suggested that non-word foils need to be word-like for the ambiguity advantage to be stable (Borowsky & Masson, 1996), and we are assessing LD over the semantic units, we clamped both the orthographic and phonology units for the non-words.

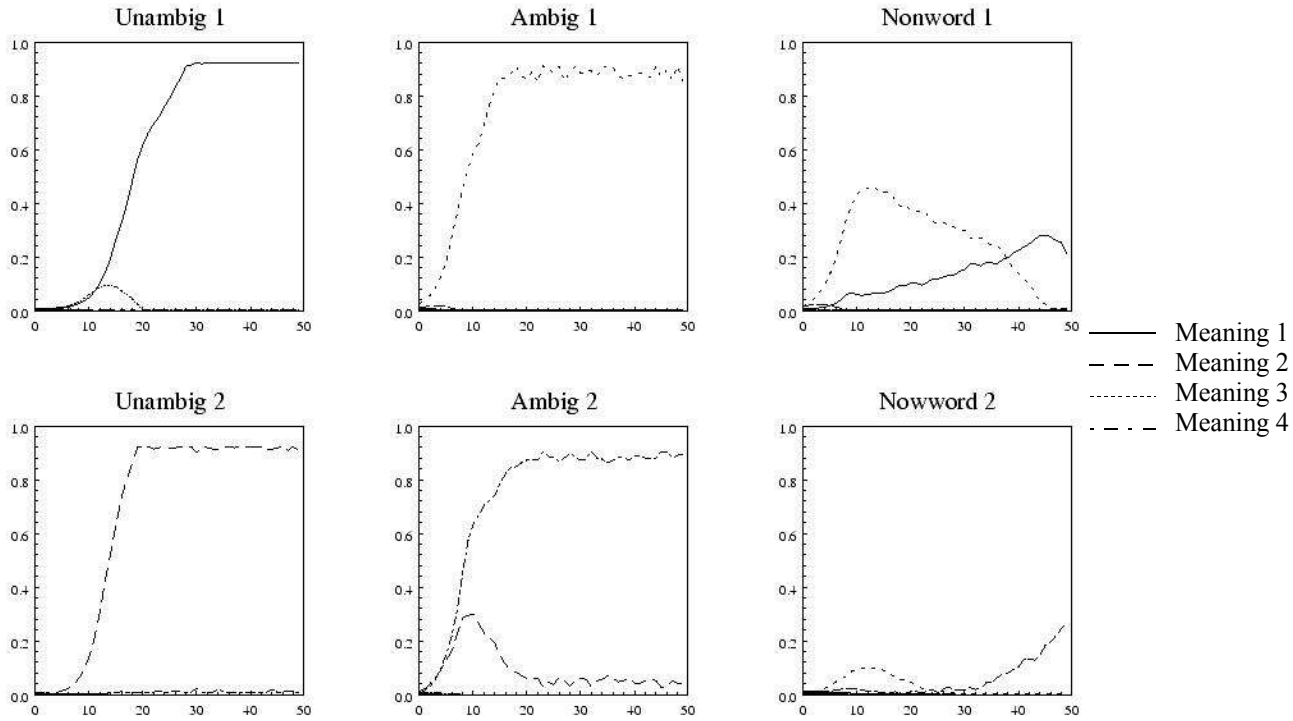

Figure 2. Sample differentiation scores for a subset of unambiguous, ambiguous, and non-words. Note that the first non-word is mistaken for a word at a criterion of 0.25.

network did not produce blend states for the ambiguous items.

Table 2. Sample Patterns Showing Positive and Negative Training Phases for Unambiguous and Ambiguous Words

Present.	Unambiguous		
Prob.	Orthography	Phonology	Semantics
+1.0	1 0 0 1 1	0 1 1 0 1	1 0 1 0 1 1 1 0 1 0
-1.0	1 0 0 1 1	0 1 1 0 1	* * * * * * * * * *
	Ambiguous		
	Orthography	Phonology	Semantics
+0.7	0 1 1 1 0	1 1 0 0 0	0 1 1 0 0 1 1 0 0 1
+0.3	0 1 1 1 0	1 1 0 0 0	1 0 1 1 0 0 0 0 1 0
-1.0	0 1 1 1 0	1 1 0 0 0	* * * * * * * * * *

During testing, the orthography and phonology units were clamped on, and the semantic units were allowed to settle. Previous models waited for the networks to settle into a stable state, and took this measure as a reaction time. In our model, we assume a speeded decision based on a differentiation measure (McClelland & Chappell, 1998) computed over the known words, *k*:

$$diff_k = \prod_{i=1}^{n} |1 - \mathrm{P}(T_i) - \mathrm{P}(G_i)|$$

where G_i is the generated pattern, and T_i is a target. If a generated pattern does not match a target pattern, then the differentiated score should approach zero. A matched pattern, on the other hand, should produce a score that approaches one. If multiple patterns are partially activated (i.e., a blend), then several words should show a differentiation score that approaches a middle value.

When $diff_k$ exceeds a threshold (in this case, an arbitrary value of 0.25), a decision of "word" is made. If a word (or non-word) fails to reach the threshold within a certain time limit (an arbitrary point such as 20 time steps plus or minus some random time to introduce stochasticity in the response times), then a nonword decision is made. This nonword time limit can be adjusted to reflect task instructions (e.g., "respond as quickly as possible" vs. "respond as quickly and accurately as possible"). Consequently, we can produce both accuracy and reaction time measurements from our model.

Results

Figure 2 shows some representative differentiation scores for a sub-sample of the testing stimuli. As can be seen, no blends were formed (a single score tended towards one, whereas all other scores tended towards zero). Furthermore, the figure shows how using a threshold criterion of 0.25 for a speeded decision leads to the first non-word being misclassified as a word. Finally, it should also be noted that although the second ambiguous word looks like it is initially activating two word meanings (heading towards a blend

perhaps?), the second word meaning (i.e., the dashed line) is actually associated with the second unambiguous word.

In terms of reaction times, the network showed an ambiguity advantage. The network made a lexical decision for unambiguous items in an average of 13.0 time steps, whereas ambiguous items took 11.5 time steps. In contrast to previous empirical work (Piercey & Joordens, 2000), however, there was not a clear advantage of ambiguous items in terms of accuracy. Lexical decision for unambiguous items was approximately 97% correct, while ambiguous items were only 95% correct within the speeded decision.

One last note to make is that the final differentiation score for ambiguous items was often lower and more variable than for unambiguous words. The differentiation score averaged over the last ten time steps for the unambiguous items was 0.92 (var = 3.7×10^{-4}) whereas ambiguous items had an average differentiation score of 0.87 (var = 5.1×10^{-4}). This suggests that, for ambiguous items, the final settled state for the networks was more unstable than unambiguous items, and that if speeded decisions were not made, then the ambiguity advantage in reaction times may disappear.

Discussion

We have shown how a network trained with the *CHL* produces the ambiguity advantage over the semantic nodes based on speeded decision. Furthermore, the model was able to produce the approximate correct probability distributions of the training corpus, thereby avoiding "blend" states. Consequently, the theory of blend states having to exist to aid in LD for ambiguous items may have to be re-evaluated. Furthermore, the efficient-then-inefficient hypothesis of Piercy and Joordens (2000) may have to be recast.

The results from this network stimulation suggest an alternative theory as to why ambiguous items show an advantage for lexical decision. Given that there are multiple distinct attractor states in semantics for ambiguous items, and given a random start state, then the probability of starting near an attractor is greater for ambiguous items than unambiguous items. Consequently, if a decision is based on traveling toward an attractor basin, then ambiguous items should—on average—reach a basin sooner than unambiguous items. This is similar to the attractor basin theory proposed by Plaut and Booth (2000). Consequently, lexical decisions are efficient for ambiguous items because they have a higher probability of starting near an attractor basin.

Note that this theory would require lexical decisions to be made at the semantic level. That is, if LD could be completed at the orthographic level or at the phonological level (say by having non-words that either violated the orthographic rules or the phonological rules of English), then the ambiguity advantage would disappear (cf., Borowsky & Masson, 1996).

Interestingly, this theory would also explain the disadvantage seen for ambiguous items during semantic decisions. If we assume that the network has settled into a stable state following the lexical decision (processing is automatic and continues even after the decision process), then both the unambiguous and ambiguous items will have activated a meaning in semantics. For unambiguous items, the semantic comparison would be relatively easy as there would only be one meaning to compare. For ambiguous items, however, the comparison becomes more unsettling. On some trials, the semantic decision would be relatively quick[2] as the network would be in the correct semantic attractor. On other trials, however, the network would be in an incorrect attractor, and would have to switch attractor states. Therefore, when trials are averaged, ambiguous items should show a disadvantage for semantic decisions. Consequently, semantic decisions are inefficient for ambiguous items because of the need to visit multiple attractor basins. Hence, this theory predicts that if we prime an ambiguous item towards one meaning or another, then the disadvantage should be lessened. Indeed, preliminary behavioral results show this to be the case (Piercey, Medler, & Hebert, 2003).

One area of potential criticism for the current model is that although it showed an ambiguity advantage for reaction times, it did not show an ambiguity advantage for accuracy. This discrepancy may be due to the choice of the differentiation score to evaluate network performance. This scoring mechanism assumes that the currently presented pattern is simultaneously compared to all learned words (thus, assuming that the learned patterns are stored somewhere exterior to the current model). Consequently, as unambiguous and ambiguous words are learned to criteria in the model, a decision based on the learned representations should show equal performance (where failure to recognize a word is based on a combination of the threshold criterion and the nonword decision time limit). One possible solution to this would be to use a different type of LD process, such as the harmony/referent model (Piercey, 2002; Joordens, Piercey, & Azarbehi, 2003) of lexical decision.

Future models will focus on training all processing levels (orthographic, phonological, and semantic) to address the theory of non-word background driving the ambiguity advantage in LD. As well, we will explicitly address the semantic relatedness decision issue to evaluate the theory predicted by the current simulations.

Abstract

The goal of the current paper is to investigate the behavior of gesture when the information conveyed by speech and the information conveyed by the image being described conflict as a result of perspective taking. To construct a corpus of speech-image mismatches, we designed a picture description elicitation procedure using path-like networks of colored circles. The results of our analysis demonstrate that gestures can be mismatched to both speech, as has been previously observed, and to the image, which has not been previously reported. The results provide insights into the nature of the representations that give rise to gestures.

The Origin of Gesture

This paper investigates the underlying cognitive processes involved in relating spatial information from a visual input to two separate output modalities, namely speech and gesture. Three theoretical possibilities have been proposed for how these three modalities of representation, visual-spatial, verbal and gestural, are related: The Lexical Semantic Hypothesis (Butterworth & Hadar, 1989; Schegloff, 1984), the Free Imagery Hypothesis (Krauss, Chen, & Chawla, 1996; Krauss, Chen, & Gottesman, 2000; but see de Ruiter, 1998, 2000 for another version of this hypothesis), and the Interface Hypothesis (Kita & Özyürek, 2003).

The Lexical Semantic Hypothesis (Butterworth & Hadar, 1989; Schegloff, 1984) proposes that gestures are generated from the semantics of the lexical items chosen to express the desired message. It predicts that gestures should always correspond to the meaning expressed by specific lexical items. In contrast, the Free Imagery Hypothesis (Krauss et al., 1996, 2000) claims that gestures are generated on the basis of pre-linguistic non-propositional representations; the strong reading of this proposal implies that the information conveyed by gesture should be unaffected by the specific lexical items selected during formulation and by the 'thinking for speaking' (Slobin, 1987, 1996) processes that convert the imagistic representation into propositional content (however, see below for alternative readings of this proposal). The Interface Hypothesis (Kita & Özyürek, 2003) claims that gestures originate from a mediating representation connecting spatio-motoric representations in memory and linguistic representations. According to this view, gestures are generated from the imagistic representation, but they can also be influenced by 'thinking for speaking' operations on this representation.

Discriminating between these theoretical alternatives is difficult because there is usually a close isomorphism between the semantic content of speech and the imagistic content of the representation speech is describing.

Bearing on this discussion are recent studies demonstrating that gestures can convey complementary information to what is expressed in speech. For example, when describing their solutions to the Tower of Hanoi problem, speakers' gestures sometimes corresponded to possible strategies that were not mentioned in the concurrent speech rather than to the strategy that was mentioned in speech. (Garber & Goldin-Meadow, 2002). The non-isomorphism between the content of speech and gesture has been referred to as *speech-gesture mismatches*. High rates of speech-gesture mismatches have also been reported for children who are in the transitional stage of acquiring the ability to correctly respond to the Piagetian conservation task (Church & Goldin-Meadow, 1986).

Speech-gesture mismatches appear to contradict the claims of the Lexical Semantic Hypothesis in that they express information not included in speech. However, the information expressed by gesture in the speech-gesture mismatches does not actually conflict with either the linguistic or the imagistic representation; instead they provide complementary information. Thus, they do not provide a strong test of the competing theories. In this paper we employed perspective taking to create situations in which what was said *conflicted* with what was seen. Examining the behavior of gesture in these cases should discriminate between the competing hypotheses regarding gesture generation. The Lexical Semantics Hypothesis predicts that gestures will always align with the speech. The Free Imagery Hypothesis predicts that the gestures will always align with the image. The Interface Hypothesis predicts that gesture alignment will be influenced by 'thinking for speaking' processes and therefore the alignment of gesture could be to either or both representations, depending on the specific situation.

Perspective Taking

Perspective taking is a critical step required to express spatial relations in speech (cf. Miller & Johnson-Laird,

1976). Spatial representations, which are inherently relative, must be grounded to some referent in a scene. The choice of the grounding referent impacts the linguistic terms that can be selected to express the relationship. Thus, perspective taking necessarily precedes linguistic formulation. It forms part of the 'thinking for speaking' conceptualizing process (cf. Levelt, Roelofs & Meyer, 1999) that abstracts away from the visual imagery and maps the relations onto propositional representations. Choice of perspective can be influenced by, among other things, language/culture specific resources (Levinson, 2003), the specific task at hand (Tversky, 1991) and/or pragmatic concerns (Levelt, 1996).

Consider the image in Figure 1. In describing the relationship between the ball and the car, the speaker can select himself as the grounding referent, describing the relationship from his own personal orientation, as in (1). This perspective will be referred to as the *deictic* perspective. Alternatively, he can select one of the objects in the scene as the grounding referent, such as the car, and describe the relation with respect to the car's inherent orientation, producing the *intrinsic* description in (2).

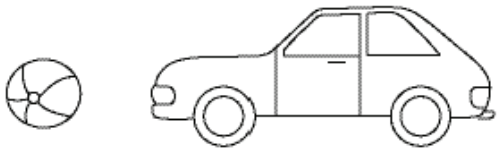

Figure 1

(1) The ball is to the left of the car.
(2) The ball is in front of the car.

When speakers choose to describe the relationship between the ball and car as in (2), a special situation arises; namely, the characteristics of the visual input, pre-abstraction, do not match the linguistic terms used to describe them. On the two dimensional representation of the image, nothing is *in front* of the car; the notion of *front* used in (2) is only relevant with respect to the orientation of the car — only within the perspectivized mental representation of the image. This contrast between the pre-abstraction visual input and the perspectivized mental representation provides the gesture researcher with the opportunity to contrast the content of the image with the content of speech in a unique way. Specifically, the content of the input imagistic representation and the output linguistic representation can be pitted against each other. How gesture behaves when the input and output representations conflict will reveal the underlying representation from which gesture was generated, thus discriminating between the three hypotheses.

Mismatch Corpus

To compile a corpus of speech-image-gesture mismatches, we presented speakers with networks of colored circles arrayed along a path. The images were very similar to networks used previously by Levelt (1996) to investigate perspective taking in speech production. As with other spatial relations, adopting different linguistic perspectives to describe an image, such as in Figure 2, results in the use of different linguistic terms to express the same spatial relations, as seen in examples (3a) and (3b).

Deictic Sample descriptions:
(3a) You begin with a yellow circle. *Above* that you see a blue circle. To the *right* you see a red circle and *above* the red circle you see another red circle. *Right* of the second red circle is the yellow circle and *right* of that is a blue circle.

Intrinsic Sample descriptions:
(3b) You begin with a yellow circle. You go *straight ahead* to a blue circle. Then you go to the *right* to a red circle and then *left* to another red circle. From the second red circle, go to the *right* again to a yellow circle and then *straight ahead* to a blue circle.

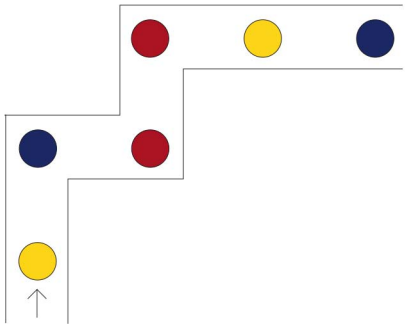

Figure 2

Notice that the term *straight ahead* in description (3b) is used to refer to two different directions of transition. First, it is used for the vertical transition from the first (yellow) circle to the second (blue) circle. Later, it is used again to refer to the lateral transition from the second from the last (yellow) circle to the last (blue) circle. In contrast, the terms used in description (3a) hold a constant relationship to a particular axis on the paper. For the deictic description, there is perfect isomorphism between the input image and the output description. In contrast, for the intrinsic descriptions, there is non-isomorphism, which allows for a further investigation of how gesture is related to the two representations.

If gesture is generated on a faithful memory representation of the image, as proposed by the strong version of the Free Imagery Hypothesis, then, in cases of speech-image mismatch, gesture should align to the image and conflict with speech. If gesture is generated from the lexical semantics of the words used to encode the message,

as suggested by the Lexical Semantics Hypothesis, then gesture should always match the speech and conflict with the image. If gesture is generated from an interface representation that results from 'thinking for speaking' processes, as suggested by the Interface Hypothesis, then gestures may match preferentially either the image or the speech, depending on the needs of the speaker at any given moment. In this case, characteristics of the image, the lexical item, or the situation could affect to which representation the gesture is aligned.

Constructing the Corpus

Speakers. Sixteen native speakers of Dutch from the Max Planck Institute for Psycholinguistics' subject pool were paid for their participation.

Pictures. Sixteen path-like images depicting networks of colored circles were constructed. Each image consisted of an explicit start point as well as red, yellow, and blue circles arrayed along a path. Half of the pictures had branching paths while the other half did not. All speakers saw all pictures in the same presentation order. In sum, 256 picture descriptions were collected.

Procedure. Speakers were seated across from their interlocutor separated by a visual block. Their task was to describe the pictures to the interlocutor, who was, in fact, a confederate.

Speakers were given approximately 15 seconds to study the image, which was placed on the table by the experimenter. After this memorization period, the picture was removed and the speaker began to describe the image. Speakers were free to describe the routes in any way that was natural to them; they were not given any linguistic examples to bias their description strategy. The listener was instructed not to ask any specific questions that might bias the content of the descriptions. She was free, however, to ask the speaker to repeat portions or even the entire description of an image. All sessions were video recorded.

Coding system. A native Dutch speaker familiar with gesture transcription systems but blind to the hypotheses under investigation used the videotapes to create a transcription of the speech as well as a record of all gestures. Several types of linguistic information were identified, including directional information (e.g., *right*, *left*, *straight ahead*), destination information (e.g., *a red circle*, *a blue circle*), landmark information (e.g., *you arrive at an intersection*), and shape information (e.g., *you will travel in a big circle*). In this paper, we will focus exclusively on directional information and accompanying directional gestures.

Gestures were either produced with the head or hands. Both were coded for several features, most crucially for the direction of the stroke but also for handedness. Once speech and gesture were fully transcribed, they were coded for three binary features: Speech matches image, gesture matches speech, and gesture matches image. These codes, together with codes for which directional term was produced and unperspectivized direction of transition, form the bases of the mismatch analysis.

Speech-image mismatches were identified as any transition in the network for which the verbal description provided in the intrinsic perspective did not match the actual direction of the transition in the network. For example, any transition labeled *right* that did not progress rightward on the page was a mismatch. Likewise, any use of *straight ahead* that did not correspond to an upward transition was coded as a mismatch. (Note that as the image was placed on the table in front of the speaker, the upward transition in the image was in the forward direction for the speaker, for which *straight ahead* is felicitous.)

Every picture provided multiple mismatch opportunities. For example, 11 networks included an upwards transition, similar to the transition from circle 3 to 4 in Figure 2, which intrinsic speakers described as *right* or *left*. Eight networks included lateral transitions, similar to the final movement in Figure 2, linguistically described as *straight ahead.* Four networks included downward transitions, linguistically described as *right* and three networks including lateral transitions that followed downward transitions. These transitions leftwards or rightwards were described with the opposite directional term, namely, rightward turns were described as *left* and vise versa.

Corpus Analysis

In this section we first give some descriptive details of the corpus before we turn to the crucial questions under investigation.

Characteristics of speech and gesture varied greatly between speakers. Six speakers produced almost no gestures at all. Of the ten gesturers, three produced predominantly deictic descriptions and seven produced predominantly intrinsic descriptions. While the deictic speakers are generally orthogonal to the issue of speech-image mismatch, two produced some mixed perspective descriptions, producing mismatch opportunities. Only speakers who adopted the intrinsic frame of reference AND who gestured are of relevance to our investigation.

In total, the corpus of directional terms consisted of 1440 directional tokens, 389 of which were produced with a co-expressive gesture. Table 1 presents lexical, gesture, and mismatch frequencies for each of the directional terms found in our corpus.[1]

[1] We will present English translations for the Dutch directional terms found in our corpus. With respect to the description of our images, there are no critical differences in how directions and spatial relations are lexicalized.

Table 1. For each directional term, the total number of tokens, the percentage of tokens produced with a gesture, and the number of speech-image mismatches.

Lexemes	Total Tokens	% With Gesture	Speech- Image Mismatches
Right	494	27%	100
Left	317	26%	79
Straight ahead	321	15%	62
Up	120	8%	--
Down	19	10%	--
Back	106	37%	--
Further	63	13%	--

The three directional terms that are relevant for mismatches are *right, left,* and *straight ahead*. In 241 instances, these words did not match the direction in the image. 58 of these speech-image mismatches were produced with a gesture that could either align with the linguistic term or the direction in the image. The terms *up* and *down* were only used by deictic speakers and therefore always matched the input image. The terms *back* and *further* can only be interpreted in the context of prior movements, and therefore the question of whether they match the picture is not applicable

The term *back* received the highest proportion of co-expressive gestures. The terms *left* and *right* were each produced with co-expressive gestures over 25% of the time, *further* and *straight* were produced with intermediate gesture rates and *up* and *down* had the lowest gesture rates.

We now turn to the central question of the paper. The crucial data from the corpus are gestures produced when speech and image are mismatched. The critical question is whether these gestures reflect the direction represented in the image, in speech, or both. The number of gestures that matched the image or the speech for each directional term is presented in Table 2.

Table 2. Number of speech-image mismatches for which the gesture matches either the speech or the image, for the three relevant directional terms.

Lexeme	Gesture = Image	Gesture = Speech
Right	8	15
Left	9	10
Straight ahead	13	3

The distribution of cases where the gesture matches the image compared to when it matches speech is different for the three directional terms, *right, left,* and *straight ahead*, χ^2 (2) = 7.13, $p < .05$. Two by-speakers comparisons were also carried out to assess this relationship. First, for the cases in which gesture aligned with speech, the proportion of speech-image mismatches for each of the three lexemes was calculated for each speaker by dividing the number of speech-image mismatches for the lexeme divided by the total speech-image mismatches for all three lexemes. The proportions differed significantly between the lexemes, Friedman's χ^2 (2) = 7.3, N=8, $p < .05$. Second, for the cases in which gesture aligned with image, the proportion of speech-image mismatches for each of the three lexemes was calculated for each speaker in the analogous way to the previous analysis. There is no evidence that proportions differed between the lexemes, Friedman's χ^2 (2) = 0.9, N=8, $p > .1$.

Table 2 shows that gesture alignment patterned differently for different lexemes. Table 3 further breaks down the information for different directions of transition within the network.

Table 3. Number of speech-image mismatches in descriptions of either upwards, downwards or lateral transition in which gesture aligned to either the image or to speech.

Transition Direction	Lexeme	Gesture = Image	Gesture = Speech
Up	Right or left	5	12
Down	Right or left	5	11
Laterally	Right or left	7	2
Laterally	Straight ahead	13	3

The alignment pattern for vertical (up and down) transitions was significantly different compared to lateral transitions, χ^2 (1) = 12.15, $p < .001$. Speakers preferred to align with the image when the transition was lateral but preferred to align with speech when the transition was vertical. One possible interpretation of this pattern is that speakers generally prefer to gesture laterally.

In speech-image mismatch cases, gestures sometimes aligned with the image and sometimes with the speech. This split was quite even for gestures produced for the lexemes *left* and *right* but not for *straight ahead*. In the latter case, speakers preferred to align their gestures with the image. The different alignment patterns to different lexical items may also be interpreted in terms of a general preference to gesture laterally rather than vertically.

What the data from the corpus clearly indicate, however, is that there is no strong tendency to align gestures to the image at the expense of speech or vise versa. When the information conveyed in speech conflicts with the information presented in the visual input, gesture can align with either. The decision as to whether a gesture aligns with the con-current speech is mediated by a spatial factor (lateral vs. vertical transitions). This result was not predicted by the Free Imagery Hypothesis or the Lexical Semantic Hypothesis, as we will discuss in more details in the next section. The result is, however, compatible with the Interface Hypothesis.

Discussion

By using images consisting of path-like networks of circles, we succeeded in constructing a corpus of picture descriptions in which the content of speech and the content of the to-be-described image often conflicted. Our aim was

to see whether gestures produced in these instances would be co-expressive with the lexical affiliate, as predicted by the Lexical Semantics Hypothesis (Butterworth & Hadar, 1989; Schegloff, 1984), with the characteristics of the image, as predicted by the strong reading of the Free Imagery Hypothesis (Krauss et al., 1996, 2000), or whether the alignment to one representation or another would be influenced by 'thinking for speaking' processes, as proposed by the Interface Hypothesis (Kita & Özyürek, 2003).

What our corpus analysis reveals is that gesture alignment behavior in speech-image mismatches was not driven solely by either the characteristics of the input image or the characteristics of speech. Rather, the gestural content seemed to be co-determined by the lexeme choice and the type of spatial representation. Specifically, when the lexemes *left* and *right* were used to express the spatial representations *upwards* and *downward*, gesture tended to align with speech rather than with the spatial representation. When the lexeme *straight ahead* was used to express the spatial concepts *leftwards* and *rightwards*, gestures tended to align with the spatial representation of the image. When the lexemes *left* and *right* were used to express the spatial representations *rightwards* and *leftwards*, respectively, gesture again tended to align with the spatial representation.

The fact that the gestural content was determined by the interplay between both lexical and spatial representations makes it difficult to maintain either the Lexical Semantics Hypothesis, which holds that gestures are generated from the semantic representations of lexical items that have been selected for speaking, or the strong version of the Free Imagery Hypothesis, which holds that gestures are generated from pre-linguistically generated imagery.

However, we need to recognize that there are different versions of the Free Imagery Hypothesis, which make different assumptions. In de Ruiter's (2000) version of the Free Imagery Hypothesis, gestures are generated in the Conceptualizer in Levelt's (1989) sense, which generates the (pre-linguistic) proposition to be linguistically formulated in the next utterance. According to de Ruiter, both gestural and linguistic perspectives are determined in the Conceptualizer. Similarly to the strong version of the Free Imagery Hypothesis, "the shape of the gesture [iconic gesture] will be largely determined by the content of the imagery" (de Ruiter, 2000: 293). As such, the results from the present study are problematic not only to the strong version of the Free Imagery Hypothesis, but also to de Ruiter's version. However, because in de Ruiter's model the shape of a gesture is determined in the Conceptualizer, which in principle has access to (pre-linguistic) propositions to be linguistically formulated, it might be possible to modify the model to account for the present results.

The gestural content is determined by the interplay between lexical choice and directions of the transition in the image. This result could be accounted for by the Interface Hypothesis (Kita & Özyürek, 2003), which proposes that gestures are generated from an interface representation, namely, a spatio-motoric representation that is in the process of being prepared for speech. According to this hypothesis, there is a general tendency for an interface representation to converge with the linguistic representation in the utterance being planned. The degree of convergence is determined by various contextual factors (Kita, 2000). In the case of this study, when the spatial representation of the transition is confusable, that is, when the transition is lateral (i.e., *leftwards* or *rightwards*), the convergence to the linguistic representation is weak, and thus gesture tends to match the spatial representation of the transition, rather than the linguistic representation. When the spatial representation of the transition is not confusable, that is, when the transition is vertical (i.e., *upwards* or *downwards*), the interface representation converges strongly to the linguistic representation. Note further that the idea that gestures help distinguish confusable spatial representations is compatible with theories of self-oriented functions, in particular, the theory that gestures help organize spatio-motoric information for speaking (Kita, 2000; Alibali, Kita, Yong, 2000; Kita, 2003).

The data also rule out the possibility that gestures can be randomly generated from either the input imagistic representation or the output lexical representations, alternating randomly between these two sources. This possibility, previously discussed in Kita and Özyürek (2003) predicts that speech-gesture mismatches should randomly align to the input or to speech, without a discernable pattern. This is not the observed pattern, as seen in Table 3.

One could object to our definition of speech-image mismatch. Consider for example the possibility that speakers mentally rotate the image in memory in order to calculate the correct directional term for the intrinsic perspective. In this case, apparent speech-image mismatches would in fact be matches. However, if this were true we would not have expected gesture alignment to ever conflict with speech, since speech would always match the perspectivized internal memory representation of the image for the speaker at that moment. This is not consistent with the observe data pattern, as seen in Table 1.

The gesture-speech mismatches reported in this study are of a different type from what have been attested in previous research. Gesture-speech mismatch has been observed in children's explanations for Piagetian conservation tasks (Church & Goldin-Meadow, 1986) and children's explanations for equivalence of an equation (Perry, Church, & Goldin-Meadow, 1988), and adult and children's description of the solution to the Tower of Hanoi puzzle (Garber & Goldin-Meadow, 2002). In these studies, gesture and speech refer to two distinct referents that are both relevant to the current goal of discourse, or two alternative strategies or solutions that might apply to the problem at hand. For example, in the explanation for a Piagetian conservation task, speech may indicate the height of a glass, *this one is tall*, and gesture may indicate the width of the same glass. By contrast, mismatches that result from perspective taking can be called same-referent mismatches. Speech and gesture have the same referent, namely a motion

vector, but they map the vector to a gestural body movement under different perspectives. Using these same-referent mismatches allows the predictions of the competing theories to be properly tested.

To conclude, we have introduced a new source of evidence into the field of gesture research, namely *speech-image* mismatches with concomitant gestures. These speech-image mismatches allow the content of the linguistic and the imagistic representations to be separated and contrasted. An analysis of the behavior of these gestures revealed that gestures cannot be generated from a purely linguistic or purely imagistic representation. Rather, gestural content was determined by the interplay between the lexical items used in the description and the type of directional information in spatial representation of the transitions. Many issues in gesture research have had difficulty in finding clear evidence for or against specific proposals exactly because it is generally difficult to disentangle the independent contributions of linguistic and imagistic representations. The present paper uses perspective taking to avoid this problem. The present study is also significant in that the methodology affords reliable elicitation of same-referent mismatches from normal adult speakers.

Acknowledgments

We acknowledge useful comments from the members of the Gesture Project at the Max Plank Institute for Psycholinguistics. We greatly appreciated comments on an earlier version of this paper from Joana Cholin, Asifa Majid and Andrea Weber. We also benefited greatly from insightful comments by anonymous reviewers. Special thanks also go to Anne-Marie van Hoof and Esther Vrinzen for acting convincingly as our confederate and for transcribing the descriptions.

Abstract

This research investigates thinking processes of duos of jazz improvisers in performance. Of particular interest are cognitive processes related to creativity and to reasoning about time, since both activities are fundamental to improvisation. Data sources are the group members' retrospective verbal protocols, collected after the performance of each tune. One result of this work is that cognition related to reasoning about time and creativity varied little either within or across groups, regardless of the type of tune being played. This result is further investigated by examining some of the statements from the protocols themselves.

Introduction

This research examines the thinking processes of duos of jazz improvisers in performance. Of particular interest are cognitive processes related to creativity and to reasoning about time, since both activities are fundamental to improvisation. To produce the data used in this study, each member of the duo watched and listened to a tape of the duo's performance and recalled out loud what he had been thinking during it. The study addresses a gap in prior research by presenting an analysis of cognition during improvisation as reflected in verbal protocol data. Since this study is thought to be the first of its kind, an exploratory approach is taken.

A brief review of related work is followed by a presentation of exploratory questions concerning how performers reason about time and how they produce ideas for performance. The results of the study are then presented, followed by an analysis of the contents of selected statements in the protocols. The paper concludes with a discussion of implications for current theory and directions for future work.

Related Prior Research

Improvisation in jazz is said to involve "reworking precomposed material and design in relation to unanticipated ideas conceived, shaped, and transformed under the special conditions of performance, thereby adding unique features to every creation" (Berliner, 1994). While improvising has been compared to "real-time composing" (Kernfeld, 1988), the two differ in salient ways (Nettl, 1974). Composition refers to "the discontinuous process of creation and iteration (usually through notation) of musical ideas" (Sarath, 1996). Improvisation, by contrast, is a continuous and serial process. Composing involves distributing musical elements (such as notes) over a score that is to be played serially: the composer may add to, delete or edit any part of the composition at any time before its performance. Performance of a composition involves interpreting and articulating a written or memorized score. Performance of an improvisation involves *conceiving, articulating* and *remembering* an unwritten, evolving score (Berliner, 1994). While a misplaced note in a composition can be erased and rewritten; a misplayed note in improvisation cannot. Errors in improvisation therefore "must be accepted as part of the irrevocable chain of acoustical events, and contextually justified after the fact by reinforcement or development" (Pressing, 1984). As stated by Pressing (1984), "If erasing, painting over, or non-real-time editing exist, improvisation does not."

Temporal Cognitive Processes

Following Berliner's (1994) comments, improvisers must reason about time in order to *conceptualize* what is to be *articulated* in light of what they *remember* has been played (see Sarath, 1996 for further discussion). In comparison with a tune that is being composed as it is being played (i.e., a free tune), the performance of a well-learned tune (such as a jazz standard) may place fewer demands on remembering, since much of what needs to be recalled (e.g., chord changes) is easily accessible from long-term memory (Johnson-Laird, 2002). Similarly, conceptualization may also be easier for a jazz standard, since the path in front of the improviser is better known. A tentative hypothesis, then, is that players will spend more cognitive effort on remembering and planning ahead for a free tune than on a standard.

Creative Cognitive Processes

Creativity—the production of new ideas—is fundamental to improvisation, since it is not enough for improvisers to produce music that has already been composed: they must produce something that, to them at least, is new. There have been numerous proposed models of the cognitive processes involved in creative thinking (Sternberg, 1999) and on the factors that influence creative thinking (Welsh, 1973). These

theories typically include convergent and divergent processes, along with some mechanism that governs switching between them (Newell, 1962). The Geneplore model (Finke, Ward, & Smith, 1992) describes creative thinking as entailing divergent processes of generation and subsequent exploration of ideas (see Ward, Smith, & Finke, 1999 for a discussion). Evaluation (a convergent process) is discussed in Geneplore in terms of constraint satisfaction.

A jazz standard may afford more opportunities for divergent thinking than a free improvisation. Jazz standards are tunes with familiar structures and a long history of performance which players routinely draw upon. Their performance may enable the improviser to spend less time trying to recall the tune or, in the case of free improvisation, trying to determine the structure and content of the tune. Similarly, evaluation may be easier to accomplish for a jazz standard, since the player can easily recall what has been played and speculate reliably what is to be played.

Analytic Framework

The analytic framework for this study is used to define a set of temporal and creative processes. A scheme for classifying the contents of the protocols based on these definitions was developed so that independent coders could identify these processes in the protocols. This section provides the definitions of the processes; the method of their application is discussed in the subsequent section on "Study Design."

An improviser in performance must reason about past, present and likely or possible future events, resulting in three different processes related to *temporal* cognition. *Orientation* is the process of considering a current performance event. An example of orientation is the statement "The time is in 4," since the speaker is referring to the present moment. *Retrospection* is the process of recalling a previous performance event. The statement "He had just played in three so I did too" is an example of retrospection. *Prospection* (a term coined for this research) is the process of looking ahead; that is, of predicting or speculating about a future event in the performance. An example of prospection is the statement "I knew I was coming to the end of my solo so I looked up."

Three different types of *creative* cognition are considered here. Idea *generation* is said to occur when a musical idea (i.e., one that pertains to the performance) is recalled or created. An example is the statement "I was thinking about playing an open figure there." Idea *development* is said to occur when a player further develops a musical idea which has already been generated, either by the speaker or the other member of the group. An example is the statement "I was thinking of inverting the figure I played previously." Both idea generation and development are regarded as divergent processes. Finally, idea *evaluation* is said to occur when the speaker makes a statement about the value or worth of a musical idea. An example is the statement, "I remember liking what I played there." Idea evaluation is a process that leads to decisions about whether or not to pursue ideas, and is therefore convergent.

Research Questions The research questions concern the frequencies of occurrence of temporal and creative cognition within and among groups during the performances of various jazz tunes. Although some tentative hypotheses have been discussed, a broad range of questions are addressed. This decision is due to the exploratory nature of the study, one goal of which is to provide suggestions for further lines of research. The research questions explore (i) the defensibility of the assumption of between-group homogeneity; they also examine possible differences in creative and temporal cognition (ii) within a group for a particular tune and (iii) across tunes by the same group. Data from performances of a jazz standard and a free improvisation are used. An example of question (i) is, do the proportions of occurrence of the various types of temporal processes differ across the groups for the performance of a jazz standard? An example of question (ii) is, do the proportions of occurrence of the various types of temporal processes differ between the trumpet and bass player in the performance of a jazz standard? An example of question (iii) is, do the proportions of occurrence of the various types of temporal processes differ between the performance of a jazz standard and of a free improvisation for a particular group?

Study Design

The study employs the preceding three research questions to investigate the impact of different types of tunes on how members of professional jazz duos reason about time and think creatively.

Tune Choice The tunes which the duos were asked to perform were intended to vary in difficulty and familiarity. The first tune played, "I Got Rhythm," has been extensively recorded and is the origin of the so-called "Rhythm Changes," a set of widely-used chord changes in jazz (Berliner, 1994; Kernfeld, 1988). All participants were expected to be very familiar with this tune and comfortable in improvising on it. The second tune, "Willow Weep for Me," was chosen since it is not as familiar as "I Got Rhythm" and because it is typically played as a blues ballad. In case a duo did not know this tune well enough to play it without sheet music, a backup tune— "Blue Train"—was used. The third tune, "Giant Steps," is known for being a difficult tune, since the chord progressions are highly idiosyncratic and the tempo is fast. The backup tune for "Giant Steps" was "Cherokee," which is in part challenging because it is also typically played at a quick tempo. The fourth tune was a free improvisation. A free improvisation has no pre-determined structure other than the one which performers create.

Solicitation of Participants Groups of two players each were solicited through word-of-mouth contact with professional musicians working in the Albany, New York area. (Though the duo is a common configuration in jazz, the use of duos was also due to practical concerns of cost

and the availability of appropriate recording space.) The player of the lead instrument—a trumpet player in all cases—was first secured. The lead player then suggested the second member of the duo, someone with whom he played often. The groups were intended to be reasonably homogeneous in terms of musical experience and experience improvising. Accordingly, all participants were asked to describe their backgrounds. Because they would be asked to verbalize their thoughts, only players who had experience in teaching—and therefore talking about—improvisation were asked to take part in the study. Finally, they were then told that, during the study, they would be given three or four tunes to play, videotaped during the performance of each tune and then asked to recall their thinking while watching the videotape.

Procedure

The study was conducted at a local professional recording studio. Once a duo arrived, study personnel reviewed the study protocol with them. The duo's members next signed consent and contract forms, tuned their instruments and performed a sound check.

Each member of the duo then entered a vocal (i.e., isolation) booth to practice giving concurrent and retrospective verbal protocols, using two tasks from the literature (Ericsson & Simon, 1993). In the third task they whistled or sang a short tune then recalled their thinking during the performance of the tune. Once these practice tasks had been completed to the player's and the experimenter's satisfaction, the players practiced operating the VCR that would assist them in giving the retrospective verbal protocol. The main part of the study then began.

The group first played "I Got Rhythm." They were asked to keep the performance to less than ten minutes and to take one solo each. A maximum length of ten minutes was chosen since that is the maximum length recommended in guidelines for conducting a retrospective verbal protocol (Ericsson & Simon, 1993). Once any questions had been answered, all personnel except two video camera operators left the main studio and the duo performed the tune. The videotape recorded the images and sound of the two performers, along with a display of the duration of the performance.

After the performance, each participant went to a vocal booth in order to watch and listen to a videotape of the performance and to deliver the protocol. (About two to three minutes usually elapsed between the end of the performance and the beginning of the protocol.) As is commonly done in verbal protocol-based studies, one experimenter remained with the participant in order to reiterate the instructions and to ask the participant to "keep talking" whenever there was silence for more than about ten seconds (Ericsson & Simon, 1993). While giving a protocol, each participant could control the videotape as necessary. All protocols were audio- and video-taped, so that it would be possible to hear and see what was on the videotape while the participant was speaking.

Once the protocol had been delivered, the participants returned to the performance area and prepared for the next performance. The above procedure was repeated for the tunes "Willow Weep for Me" and "Giant Steps." If the participants decided not to play a tune, the backup tune was played. For the fourth and final tune, participants were asked "to work out the composition of the tune as you play it." Again they were asked to keep the total length of the performance to less than 10 minutes. They were not asked to take solos, since doing so would have helped determine the structure of the performance.

Once the think-aloud protocol for the final tune had been given, participants were asked a series of questions about their background and their participation in the study. They were then paid and invited to discuss the study further in a relaxed atmosphere without being recorded. The total duration of each session was approximately two hours.

Results

Data are taken from the verbal protocols associated with the performances of "I Got Rhythm" (IGR) and a free improvisation (Free). Performances of these two tunes were chosen for initial analysis since they represent opposite ends of the spectrum of jazz performance. All the groups played IGR first and Free fourth.

Participants' protocols were first transcribed and segmented (Ericsson & Simon, 1993). All references to study participants in the protocols were masked so that it would not be possible for a reader to determine which protocol corresponded to which session or player. Segments pertaining to cognition during the actual performance of the tune were coded using the definitions for the types of temporal and creative cognition that are given above in the "Analytic Framework" section. Coders were provided with (i) the segmented and masked protocols and (ii) instructions on how to use the above definitions to code the protocols. Coding was done by two independent coders unfamiliar with the objectives of the research. The coders were trained first to identify creative processes, then applied the instructions to the protocols. The same procedure was then followed for temporal processes. A second coder coded approximately 10% of the data, and reliability as measured by Cohen's kappa (Cohen, 1960) was approximately 87%.

Counts of the various types of temporal and creative processes were then entered into contingency tables. For creative cognition, it was immediately obvious that there were too few instances of idea development to justify the use of the appropriate statistical test, the Chi-squared test for differences in proportions (Conover, 1999). All instances of idea development were therefore recoded as instances of idea generation, since, as discussed previously, both are processes of divergent thinking. All statistical tests were then performed on the tables at a 0.05 significance level. The observed significance level of a test is denoted p. Some of the contingency tables are shown below, with the following symbols used: for temporal cognition, O=orientation, P=prospection and R=retrospection; for

creative cognition, *G*=idea generation and *E*=idea evaluation.

Between-group Differences

A reasonable degree of homogeneity was desired among the groups in order to minimize the possibility of between-group confounding effects. Information on participants' backgrounds was collected, as discussed previously. Also, differences in groups' temporal and creative thinking processes for each tune were investigated using question (i), with the following results. For temporal thinking, no significant between-group differences were found among the groups for either IGR or Free.

For creative cognition, no significant differences were found among the groups for IGR, but a significant difference (p=0.0045) was found for Free. This result may be stated by saying that at least two of the proportions in some column were not equal to each other. Table 1 shows the data associated with Free.

Table 1: Creative Cognition, by Group for *Free*.

Group	G	E
One	33	37
Two	13	9
Three	68	26

The assumption of homogeneity may therefore be seen as reasonable for IGR but not for Free. Accordingly, the analysis will consider individual groups rather than pooling data across groups.

Description of Performances

I Got Rhythm All groups structured their performances of IGR in approximately the same way, with the head (i.e., the introduction and first AABA chorus) and ending (i.e., the last AABA chorus) played more or less as discussed by Kernfeld (1995). In Groups One and Two, solos were two choruses long; in Group Three they were four choruses long. All performances were less than ten minutes long.

Free Improvisation For the free improvisation, participants were asked to "work out the composition of the tune as you play it." Groups in sessions one and two asked for some additional guidance but were given nothing more than a key and/or time signature. All performances were less than ten minutes long and had a stable time signature. It should be noted that, although all free tunes were spontaneously composed, all were clearly in the idiom of bebop jazz.

Temporal Processes

For question (ii), no significant differences in temporal cognition were evident between the participants in each group for IGR or Free. Table 2 shows the question (ii) data associated with Group One for IGR.

Table 2: Temporal Cognition for IGR, by Player in Group One.

Player	O	P	R
Trumpet	25	13	11
Bass	17	10	4

Similarly, for question (iii), no significant differences were evident across the two tunes as performed by each group. Table 3 shows the question (iii) data associated with Group One.

Table 3: Temporal Cognition for Group One, by Tune.

Tune	O	P	R
IGR	42	23	15
Free	30	21	21

Creative Processes

No significant differences were evident in creative cognition between the participants in each group for IGR or Free. So, in Group One, the proportion of segments from the trumpet player reflecting idea generation is not significantly different from the corresponding figure for the bass player. Table 4 shows the question (ii) data associated with Group One for IGR.

Table 4: Creative Cognition for IGR, by Player in Group One.

Player	G	E
Trumpet	18	16
Bass	8	6

No significant differences were evident across the two tunes as performed by each group. Table 5 shows the question (iii) data associated with Group One.

Table 5: Creative Cognition for Group One, by Tune.

Tune	G	E
IGR	26	22
Free	37	33

For both temporal and creative processes, the results suggest that—contrary to expectation—the same proportion of segments reflected each type of temporal or creative process. The same was true for differences within the same group across the two tunes. This result is particularly surprising, since groups were expected to approach IGR and Free quite differently; indeed, the recorded performances of the tunes by any given group, while sharing certain elements (e.g., stable key signature

and meter within each performance) nonetheless sound quite different, particularly in Group Three and to a lesser extent in Group One.

Content Analysis

The contents of the protocols from the performance of IGR by Group One are now analyzed in order to provide further insight into individual- and group-level creative and temporal cognition. These protocols were chosen because they are richer in content than those of the other groups and because it is appropriate to begin with an analysis of a simpler tune before moving to more complex ones. The statements examined here were those thought to provide the most insight into processes of collaboration, temporal reasoning and creativity. To aid the discussion, statements are labeled with their segment number from the protocols.

Collaboration Statements by one player about himself, the other player in the group and the group itself suggest how the duo collaborated. In IGR, the trumpet player (JH) explicitly mentioned trying to fit the melody and rhythm of his playing with that of the bass player (PT), as follows:

19. I'm just ah, I'm hearing melodies, I'm trying to play them, that I know will fit with what PT is playing.
24. I'm trying to keep, trying to keep a steady rhythm with PT, trying to make my eighth notes very steady.

JH also engaged in active listening following the completion of his own solo and the onset of PT's solo:

32. I'm kind of ah thinking after the thought and reacting to what he's playing.

Segments 19, 24 and 32 reflect JH trying to solve two types of problems related to collaboration. The first type, as in S24, is reasonably well-posed and technical. In this case, it involves keeping the rhythm of the tune. In contrast, the second requires the generation of new melodies: here, ones that "fit with" PT's playing. Segment 19 (S19) suggests that generation of the melodies occurred closely in time to their evaluation and performance. The use of the phrase "hearing melodies" would seem to indicate that the process is more one of retrieval rather than on-the-spot composition. Computational approaches to this type of thinking in jazz improvisation have sometimes involved retrieval and use of fragments or motifs (e.g., Ramalho, Rolland, & Ganascia, 1999) S32 is similar in spirit to S19, the distinction being that JH was not actually playing anything at that moment. The statements show that JH was actively listening to PT, analyzing PT's playing and attempting to use the results of this analysis to guide his own playing.

Temporal Processes A number of statements by both players reflect reasoning about time, particularly about the group's movement through the structure of the tune. Once they were asked to play IGR, one of the things they discussed was whether or not to play the tag (an optional ending to the melody). JH decided that they would play the tag at the very end of the tune. As they neared the end of the tune (i.e., the last A section), JH recalled thinking

47. I'm, I'm thinking about how we're going to resolve the tune, how we're going to end it here.
48. I know we're going to put the tag on, which is what we're doing right now.

Similarly, at about the same point PT recalled thinking

41. Ah, we're coming up on the last eight, eight bars.
42. And we had talked about putting the the tag at the end, so I'm actually thinking, yeah we're going to put that tag on the end.

Successful completion of the tune was therefore in part dependent on both players recalling the need to play the tag at the end of the tune. Additionally, JH was thinking about how to resolve the tune, given the need to include the tag.

At numerous points in the performance, JH and PT each speculated about what might be played by the other person. For example, after the first chorus of JH's solo, PT thought

22. Now I'm, right now I tell you I'm thinking, is he taking another chorus?
23. There, so, he's taking two choruses.

These segments suggest that the *de facto* structure of the tune was in part determined during performance, thus requiring the performers to think explicitly about past, present and future events. For example, because JH had taken two choruses in his solo, PT did the same.

Creative Processes An interesting exchange occurred at the very end of the group's performance of IGR. As shown in S47-48 and S41-S42 (above), JH and PT recalled the agreement to play the tag and planned for it. JH made the following statements immediately after S48:

49. Now, I didn't, I also extended the tag.
50. I could have made that, I could have made that tag a few bars, uh one or two bars shorter. By not extending it, I I kind of doubled the time.
52. Ok, as I said I I I doubled the length here, just to see what PT would do, how he'd react.
53. And I held that note out because that gave PT an opportunity to decide for both of us how exactly that was going to end.
54. Um and then I just threw that little tag of those couple notes on the end uh expecting he might react off of that,...

JH therefore elaborated upon the tag by doubling the time, holding out a note and adding a couple of notes to the tag. Each generated idea was intended to result in PT generating an idea in reaction to it, which would of course require evaluation. PT's reaction was as follows:

43. And right there I'm thinking, should I put a tag after his little ending there, but I decided to just let him have the final word.

S54 (above) concludes with JH saying "and he chose not to. And that was his choice." This example therefore shows cycle of idea generation (by JH), evaluation of those ideas by (PT), and finally JH's evaluation of PT's evaluation.

Discussion and Conclusions

The statistical analysis suggests a great degree of stability in creative and temporal cognition across the various conditions. Groups may therefore have applied similar cognitive strategies, regardless of the conditions of performance. The analysis of the "I Got Rhythm" protocols for Group One provides additional insight into how improvisers collaborate while simultaneously abiding by constraints of an evolving musical structure and generating, evaluating and executing new ideas.

Temporal cognition is necessary when a tune's structure evolves in real time. A theory of improvisation, even for the performance of standard tunes, should therefore include explicit modeling of temporal reasoning (see Johnson-Laird, 2002 and Ramalho et al., 1999 for discussions on both sides of this issue). A key consideration is range of planning (Palmer, 1997), since the current study and others (Sarath, 1996) have suggested that improvisers engage in contingency-based reasoning during performance. This study used prompted retrospective verbal protocols as primary data sources. Data on physical movements (Palmer, 1997) and cues and communications (Brinner, 1995) of performers may be useful in triangulating the results.

Further work is needed in understanding the role of knowledge and experience in the production of new musical ideas. A large body of work (see Pressing, 1984) shows that skilled improvisers draw upon and adapt highly resilient motifs during performance. Some evidence (Berliner, 1994) suggests that the use of these motifs can be conscious, though this claim has not been rigorously tested.

The results show that some creative and temporal processes may themselves be highly collaborative. Indeed, as suggested by Pressing (1984), the nature of improvised performance demands that the all "acoustical events" must be folded into the performance. The protocols contained evidence of both routine and non-routine problems arising out of collaboration between duos.

Finally, as discussed by Johnson-Laird (1991, 2002), additional work is needed in expressing theories of improvisation as computer programs. The current study has provided some evidence that such programs should include mechanisms for reasoning about (i) evolving conceptions of musical structure (and therefore time), (ii) processes of creativity and (iii) how dependencies among group members are negotiated (e.g., Bongers, 1999; Walker, 1997) in order to deal with temporal constraints while thinking creatively (Ramalho et al., 1999). Such an approach ought to result in a theory of improvisation that seeks to explain how it occurs in a wide variety of domains.

Help-seeking with a computer coach in problem-based learning : Its interaction with the knowledge structure of the learning domain and the tasks' cognitive demands

The Problem and its Context

Research on tutoring has shown that the student's interaction with the tutor heavily determines the learning outcomes. In human tutoring, the responsibility of the interaction is shared between the tutor and the student (Chi, 2001). In the case of a computer coach such as the McGill Statistics Tutor, the control of the interaction is put entirely in the hands of the learners. Learners' ability to interact with the system productively therefore represents a critical aspect affecting the learning outcomes. This ability of help seeking (Nelson-LeGall, 1981) has not been well researched from a cognitive science point of view in the context of computer-supported learning (Aleven et al., 2003).

The aims of the present work are to elaborate a cognitive model of help seeking and to examine its interaction with critical aspects of the learning situation. Two studies using discourse analysis methodology are conducted using a formal model of the learning domain.

Methodology

First-level Participants are 20 graduate students from a faculty of Education of a Canadian university. The seven-hour experiment involves working in pairs to solve a very challenging statistics problem (a two-way analysis of variance) for which students don't have sufficient background. A computer coach based on human tutoring, the McGill Statistics Tutor, is available to provide help with every aspect of the task.

Data consist of three complementary sources. The dialogue between the pair of participants as they work on the statistics problem using the computer coach. The interaction with the computer coach is also recorded, in two forms. First, the display of the computer is recorded using a special device. Second, the computer coach keeps a log of some characteristics of every help request made by the students. The students solutions to the problem are also integrated in the database.

Data analysis consists of complementary strategies. Trace analyses of the task performance and the help seeking process were elaborated. Statistical analyses were also performed..

Results and Discussion

Results show that a help seeking model based on information processing theory is reflected in the data. The components of the model are (1) recognize an impasse, (2) diagnose the impasse, (3) establish a specific need for help, (4) find appropriate help, (5) comprehend help, and (6) evaluate help.

Help seeking interacts with the performance of the task and with the structure of the domain knowledge. Help seeking is intertwined with problem solving ; help is sought to fill gaps in students' knowledge in order to solve the problem. However, student's use of the computer coach is not optimal since they tend to select help at higher levels in the hierarchical knowledge structure while they tend to problem solve at lower levels.

Conclusion

These results have implications for the design of computer coaches and instructional situations. These results help characterize the contribution of the learners to the emergence of more or less contingent tutorial interactions. In addition, identifying key skills that students use in problem-based learning situations is a first step in training and assessing those skills.

What distributional information is useful and usable for language acquisition?

Padraic Monaghan (pjm21@york.ac.uk)

Abstract

Numerous theories of language acquisition have indicated that distributional information is extremely valuable for assisting the child to learn syntactic categories, yet these theories differ over the type of information that is proposed as useful in acquisition. Mintz (2003) has proposed that children utilize the previous word and the following word (AxB frames) for acquiring categories, whereas Monaghan, Chater, and Christiansen (submitted) have suggested that information about the previous word alone provides a rich source of data for categorization. In three modeling experiments we found that bigrams were better than fixed AxB frames for learning syntactic categories in a corpus of child-directed speech. However, presentation of the preceding and succeeding words when these can be processed separately resulted in better learning than presenting the preceding word alone, and also improved performance over presenting the previous two words.

Introduction

What sort of information does the child use to develop an understanding of their language? The rational analysis approach answers this question by assessing what sort of information is *useful* for learning the language. If a particular source of information proves to be rich and reliable then a computational system (of which the child is a very special case) will exploit it. The child learns a sense of syntactic categories early in language development. In order to understand speech and relate it to the world, the child must know which part of speech refers to an action, and which to objects, and which words modify relations between objects. "Look at the cow mooing" elicits many possibilities for relations between words and the world, for example, whether the animal in question is referred to by the word "cow", "look", or "mooing". Constraints *within* the language, restricting which words in the sentence can refer to objects, for example, greatly limit the number of possibilities for relating words to the world.

But what sort of information is useful for constructing syntactic categories? A variety of different types of information have been proposed as useful for categorization, including gestural, semantic, phonological, and distributional information. Combining more than one type of information has indicated improvements in categorization (Reali, Christiansen, & Monaghan, 2003), and it may indeed be the case that combining multiple sources is necessary for categorization to take place (Braine, 1987).

This paper focuses on distributional information as a cue for syntactic categorization, and questions what type of information is most useful and thus usable by the child. Theories of the use of distributional information in language acquisition have suggested different analyses of the context in which a word (category) occurs, but no empirical comparisons of these competing accounts have been made. We present a series of computational models that compare the extent to which accurate syntactic categorization of language directed to the child can be made on the basis of different sources of distributional information.

Sources of distributional information

Theories of distributional information in language acquisition have tended to focus on demonstrating that such information can contribute significantly toward categorization, rather than proposing that the particular implementation is psychologically realistic. Redington, Chater, and Finch (1998) produced context vectors based on the two preceding words and the two words following the target word from the CHILDES (MacWhinney, 2000) database of child-directed speech. The resulting vectors for the most frequent 1000 words in the database clustered together with a high correspondence to syntactic categories. Redington et al. (1998) also assessed vectors resulting from using different context words. They found that good results were also obtained for the one preceding and one following word, and also for the two preceding words, and for the two succeeding words (with better performance for preceding words than succeeding words). Yet, using only the immediately preceding word also resulted in good performance, though addition of richer contextual information improved performance.

An alternative approach is the proposal that particular sequences of words are useful for determining syntactic category. Fries (1952) produced a set of "frames" in which only words of a certain category could appear. For example, only a noun could appear in "The __ is/was/are good". Similarly, Maratsos and Chalkley (1980) proposed that there were local constraints on the occurrence of particular word categories, such as that only a verb can occur before the inflection *–ed*.

Mintz (2003) provided an empirical test of this local source of information, by analyzing corpora of child-directed speech for the occurrence of frames of the preceding and the succeeding words. We refer to these as AxB frames, where A and B are fixed, and x indicates the intervening word. For example, for the frame "you __ to", "go" and "have" both occur as "x" words in the frame.

Mintz selected the 45 most frequent frames involving the preceding and succeeding word, and then grouped the words that occurred within each of these frames. In the above example, "go" and "have" would be grouped together in the analysis. Accuracy was assessed by counting the number of times that words of the same category were grouped together, and dividing this by the number of pairings of all words within the groups. Completeness was determined by counting the number of pairings of words of the same category within the group, and dividing this by the number of pairings of words of the same category occurring in any of the groupings.

The 45 most frequent frames resulted in high accuracy but low completeness, indicating that these frequent AxB frames grouped together words of the same category, but that many words of the same category tended to occur in different groups. Relatedly, Mintz (2002) found that people categorized words together when they occurred in AxB frames in an artificial language learning task, and consequently claimed that such AxB frames were a source of distributional information that children used to acquire syntactic categories.

An alternative proposal is that a frame involving only the preceding word – an Ax frame – is required in order to produce effective categorization (e.g., Valian & Coulson, 1988). Monaghan, Chater, and Christiansen (submitted) found that categorizations of child-directed speech based on the association between the 20 most frequent preceding words and the target word resulted in accurate classification of words of different categories, but critically, also resulted in a large proportion of words being classified. Additionally, Monaghan et al. showed that, in an artificial language learning task, participants could group words on the basis of Ax frame information alone.

Both AxB and Ax frames can therefore be exploited in learning artificial languages, but which source of information is most useful to the child learning their language? AxB frames result in high accuracy, but low completeness, whereas Ax frames produce high completeness at the expense of some accuracy. Should a learning system select accuracy over completeness, or vice versa?

A comparison of different sources of distributional information requires that alternative methods are subjected to the same analyses. In addition, an empirical test of whether accuracy or completeness is a priority in acquisition is necessary. We now present a series of modeling experiments that test the extent to which different types of distributional information lead to successful categorization of words in child-directed language. Experiment 1 replicated Mintz's (2003) analysis of AxB frames in child-directed speech, and directly compared the resulting classification to an Ax analysis. Experiment 2 assessed whether a neural network model learned to categorise words more accurately on the basis of AxB information or Ax information alone. Finally, Experiment 3 tested a neural network model learning from AxB information when the relationship between A and x and B and x can also contribute separately towards categorization, and compared performance to a model with information about the two preceding words.

Experiment 1

Method

Corpus preparation From the CHILDES database, we selected a corpus of speech directed towards a child of age 0-2;6 years (anne01a-anne23b, Theakston, Lieven, Pine, & Rowland, 2001). This was one of the corpora used by Mintz (2003). We replaced all pauses and turn-taking with utterance boundary markers, and the resulting corpus contained 93,269 word tokens in 30,365 utterances (mean utterance length = 3.072 words). There were 2,760 word types, and the syntactic category for these words was taken from the CELEX database (Baayen, Pipenbrock, & Gulikers, 1995), according to the most frequent category usage for each word. Some interjections, alternative spellings, and proper nouns were hand-coded. There were 12 syntactic categories: noun, adjective, numeral, verb, article, pronoun, adverb, conjunction, preposition, interjection, wh-words (e.g., *why*, *who*), and proper noun.

Analysis In accordance with Mintz (2003), we selected the 45 most frequent AxB frames from the corpus, and determined the words that occurred in the x position within each frame. Each AxB frame thus resulted in a cluster of words. Accuracy and completeness were assessed in the same way as for Mintz (2003), described above. An additional method for assessing completeness was taken as the total number of word types that were classified in (at least) one frame.

For the Ax analysis, the 45 most frequent words were selected from the corpus, and co-occurrence with these frequent words formed the clusters in the bigram analysis. Accuracy and completeness were assessed in the same way as for the AxB co-occurrence analysis.

Results

As an example of the resulting classification, Table 1 shows a summary of the words that were classified into the 5 most frequent AxB and Ax frames. For these most frequent AxB frames, two frames clustered verbs together, and two clustered only pronouns. For the Ax classifications, the results are noisier, but have far higher numbers of words classified. The most frequent Ax frame – "the x" – classifies 623 nouns, and very few verbs, whereas the next most frequent Ax frame – "you x" – classifies 210 verbs, and only 26 nouns. The accuracy and completeness results are shown in Table 2, together with those from Mintz (2003)[1]. In parentheses are the random baseline values. We closely replicated Mintz's (2003) results indicating the high accuracy of the AxB frames, though, as noted in the

[1] Data are shown from Mintz's analysis of the anne corpus, with standard labeling and word-type analyses.

Table 1. Classifications based on the 5 most frequent Ax and AxB frames.

Ax						
Ax	noun	verb	pronoun	adjective	preposition	other
a	335	33	2	56	0	11
it	37	69	12	29	13	43
to	76	107	16	6	1	9
you	26	210	15	27	8	39
the	623	23	9	38	5	14
AxB						
Ax**B**	noun	verb	pronoun	adjective	preposition	other
do_think	0	0	1	0	0	0
do_want	0	0	6	0	0	0
are_going	0	0	5	0	0	0
what_you	0	10	0	0	1	0
you_to	0	19	2	1	1	1

Table 2. Completeness and accuracy of classifications for the Ax and the AxB co-occurrence models.

	CO-OCCURRENCE MODEL		
	MINTZ	**AX**	**AXB**
Accuracy	0.94 (0.41)	0.57 (0.22)	0.88 (0.26)
Completeness	0.09 (0.04)	0.07 (0.04)	0.06 (0.03)
Words classified	405, 14.7%	1930, 69.9%	394, 14.3%

Introduction, there was very low completeness for this classification. The Ax analysis also resulted in high accuracy, and slightly higher completeness according to Mintz's definition. However, a striking difference between the AxB and the Ax analyses is the overall number of words from the corpus that were categorized. Clustering based on bigrams resulted in a classification of almost 5 times as many words as the trigram analysis. The small differences in completeness between the two analyses is therefore misleading, as this only considered words that were clustered – in the AxB case, completeness was assessed over only a fraction of the corpus considered in the Ax analysis.

Discussion

We successfully replicated Mintz's (2003) demonstration that classifications of syntactic category based on occurrence within the most frequent AxB frames resulted in impressively high accuracy. However, our prediction that high accuracy could also be achieved by the smaller, less specific Ax frame was supported. The Ax analysis had the additional advantage of enabling a classification of far more words from the child's environment than was possible using AxB frames. There is a pay-off between accuracy and completeness: a specific context will result in high accuracy, but low completeness, whereas a general context will result in lower accuracy but high completeness.

This raises the question as to whether categorization is best based on information that renders highly reliable classifications of only a few words, or whether learning would benefit from using information that classifies a larger proportion of the words in the environment, but with the possibility that such classifications may contain more errors.

One way to test this issue is to train a neural network to base predictions of the syntactic category of words based on either AxB frames, or Ax frames. After training, the neural network model's error on the predicted classifications reflects the extent to which the given source of information is beneficial for learning the syntactic categories of the language. If the model trained on AxB frames has lower error then learning is more effective when based on high accuracy but low completeness, whereas if the model trained on the Ax frames has lower error then high completeness at the expense of high accuracy is a better source of information for learning.

We were concerned with how effective the frame is in predicting the category of the x word, so we trained the models to predict the category of x without entering the identity of the x word at the input. In addition, we did not preselect the frames that were input into the model: the entire corpus was used for training and not just the 45 most frequent frames, as we were interested in whether the model would be able to pick up which frames were useful for categorisation. From Mintz's (2003) analysis, it is not clear whether the AxB frames are to be interpreted as non-compositional, or whether the relationship between A and x and between x and B may also contribute to categorization. Experiment 2 tests the non-compositional interpretation, whereas Experiment 3 assesses the compositional version of the AxB frames.

Experiment 2

We trained two neural network models to learn to predict the category of the target (x) word using the same corpus of child-directed speech as in Experiment 1. We compared the learning of models that were given either Ax or AxB information. The AxB model was designed to test whether the AxB frame was useful for learning when the frame is interpreted as a whole, i.e., the "A" and the "B" do not contribute separately toward classification.

Architecture

Ax model The model was a feed-forward network with a set of input units fully-connected to a hidden layer, which was fully-connected to an output layer. The model is shown in Figure 1. Each unit in the input layer represented one word type in the child-directed speech corpus (so there were 2,760 input units), and there was also a unit representing the utterance boundary, in accordance with other connectionist models of syntax learning (e.g., Elman, 1990) that provide this additional information to the simulated child learner. There were 10 units in the hidden layer. The output layer contained units representing the syntactic category of the next word in the corpus. The model was trained on all Ax bigrams in the corpus, with the first word in the bigram occurring in the input layer, and the category of the second word in the bigram as the target at the output layer.

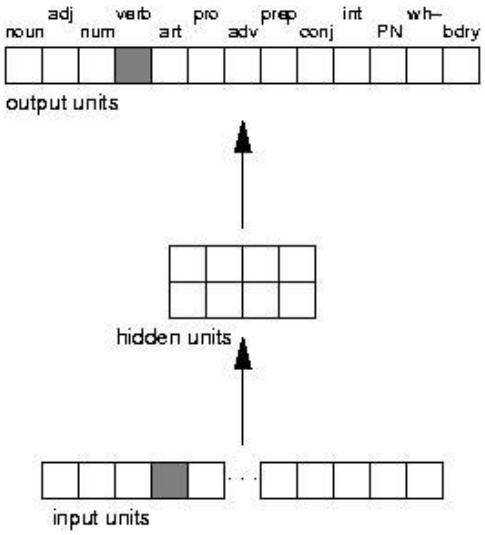

Figure 1. The feedforward neural network model of syntactic categorization. The active input unit represents either the A-word in the Ax model, or the AxB frame in the AxB model. The active output unit is the category of the x word, or the utterance boundary if x represents the end of the utterance. In the Figure, the output verb unit is active.

AxB model The AxB model was identical to that of the Ax model, except that in the input layer each unit represented one of the possible AxB frames. There were 36,607 such AxB frames, and so there were 36,607 input units in the model. The model was trained on all AxB frames in the corpus, with the A_B frame activating the appropriate unit in the input layer, and the syntactic category of the x word as the output layer target.

Training and testing

The models were trained using backpropagation with gradient descent with learning rate 0.01, and momentum 0.95. Before training, the weights between connections were randomized with mean 0 and standard deviation 0.1. We imposed a 0.1 error tolerance on the output units to prevent the development of very large weights on the connections. The models were trained on all Ax or AxB frames in the corpus, with each epoch being one pass through the corpus, and training was halted after 5 epochs, which was over 600,000 training events. As a baseline, we trained and tested the Ax model and the AxB model on a corpus where the frequency of words was maintained, but word-order was randomized. In the AxB randomized control model, there were 44,786 AxB frames and thus 44,786 input units in the model.

The models were tested after each epoch on the whole corpus, with the mean square error (MSE) across the output units taken as a measure of the ability of the model to learn to categorize words in the corpus on the basis of either the Ax or the AxB information. As an additional measure, we assessed whether the target unit – that is, the appropriate category of the x word – was the most highly activated for each pattern presentation.

Table 3. Percent correctly classified and MSE for the Ax and AxB models for each syntactic category in the corpus, with number of tokens (n) and *t*-test on MSE (all $p < 0.001$).

		% CORRECT		MSE		
CATEGORY	N	AX	AXB	AX	AXB	*t*
Nouns	12458	66.3	0	0.533	1.000	-116.316
Adjectives	4125	1.9	0	1.116	1.035	21.373
Numerals	1087	0	0	1.128	1.040	20.304
Verbs	23182	83.9	0	0.511	0.851	-145.602
Articles	7996	31.0	0	0.848	1.025	-52.371
Pronouns	18932	47.6	0	0.675	0.869	-71.369
Adverbs	5456	0	0	1.150	1.040	46.221
Prepositions	9491	31.3	0	0.865	1.016	-34.894
Conjunctions	1955	0	0	1.147	1.032	29.448
Interjections	3762	0	0	0.984	1.026	-24.608
Proper nouns	2104	0	0	1.149	1.032	28.642
Wh-words	3500	0	0	1.041	1.024	7.510
Boundary	30365	79.6	100	0.446	0.793	-147.391
TOTAL	**123634**	**52.4**	**22.9**	**0.680**	**0.911**	**-205.957**

Results

The Ax model performed better than the random baseline, MSE was 0.680 compared to 0.920, $t(247266) = -189.808$, $p < 0.001$. The model also classified more words correctly than the random baseline: 52.4% compared to 22.9%, $\chi^2 = 75{,}014.859$, $p < 0.001$.

The AxB model performed at a level similar to the random baseline. MSE was 0.911 which was slightly higher than the randomized version of 0.910, $t(247264) = 4.418$, $p < 0.001$. Classification was poor, with the model classifying all words as the utterance boundary, which was the single most frequent token in the input, This behavior was identical to the performance of the AxB model on the randomized corpus.

Table 3 shows the comparison between the Ax and the AxB models, for all words, and for each syntactic category. In terms of MSE, performance was better for the Ax model than the AxB model on all categories apart from adjectives, numerals, adverbs, conjunctions, proper nouns, and wh-words. However, performance was better for the large closed-class categories – pronouns and articles – and for nouns and verbs. Overall, the Ax model classified more words correctly than the AxB model, $\chi^2 = 75{,}014.011$, $p < 0.001$.

Discussion

The Ax model performed significantly better than chance in predicting the category of the x word from the preceding word. The AxB model performed at a chance level, and did not discriminate any word category. The better performance of the AxB model in terms of MSE on adjectives, numerals, adverbs, conjunctions, proper nouns and wh-words may have been due to a broader context serving these categories better: adverbs often occur after nouns in positions normally taken by verbs, and adjectives intervene between determiners and nouns. An enriched context would undoubtedly assist the categorization of these types. However, the better performance may merely have been due

to a lack of discrimination between any of the word types in the AxB model.

These simulations demonstrated that categorization of a large, entire corpus of child-directed speech was best achieved using information about the preceding word, rather than information about set frames comprised of the preceding and the following word. Greater coverage of the set of words, rather than greater accuracy in categorization, resulted in better performance.

The next experiment assessed whether a compositional treatment of the AxB frame may provide better information about the syntactic category of the target x word than the Ax frame alone, and compared it to a model with information about the two preceding words.

Experiment 3

We trained neural network models to learn to predict the category of the next word from the same corpus of child-directed speech as used in Experiments 1 and 2. We compared the learning of a model that was given information about the preceding and the following word in order to predict the category of the intervening word, but could operate on this information separately and combined. We call this the AxB-compositional (AxB-c) model. We also tested a model where information was given about the two preceding words: the ABx model. Note that these models embed the bigram information from the Ax model in the input. We predicted that both models would perform better than both the Ax model and the non-compositional AxB model from Experiment 2. We also predicted that the AxB-c model would outperform the ABx model, as proximity to the target word is most informative.

Architecture and training

The AxB-c model had the same architecture as the Ax model in Experiment 2, except that it had two banks of input units. In the first bank of units the unit corresponding to the A-word was activated, and in the second bank of units the B-word unit was activated. At the output layer, the model had to learn to predict the category of the x word. The same architecture was used for the ABx model, but it had as input the two words preceding the target word.

Training and testing was identical to that for the models in Experiment 2. Baselines for learning were determined by training and testing the models on the randomized corpus.

Results

For both models, performance was better than the random baseline in terms of accurate classifications and MSE. For the AxB-c model, accuracy was 69.4% (baseline 22.9%), χ^2 = 82422.148, $p < 0.001$, and MSE was 0.480 (baseline 0.920), $t(247266) = -329.487$, $p < 0.001$. For the ABx model, accuracy was 56.3% (22.9%), χ^2 = 60841.166, $p < 0.001$, and MSE was 0.628 (0.920), $t(247266) = -221.728$, $p < 0.001$.

As predicted, both the AxB-c and the ABx model performed with greater accuracy than the non-compositional AxB model from Experiment 2 for all syntactic categories: overall, $t(123633) < -300$, $p < 0.001$, for each individual syntactic category, all $t < -50$, all $p < 0.001$.

Table 4. Percent correctly classified and MSE for the AxB-c and ABx models. *T*-tests are computed on MSE (all $p < 0.001$, except † $p < 0.1$).

	% CORRECT		MSE

TOTAL	**69.4**	**56.3**	**0.480**	**0.628**	**-147.470**

Compared to the Ax model in Experiment 2, the additional word information in the AxB-c and ABx models resulted in an increase in accurate classifications. For both models, classification was more accurate ($p < 0.001$), and resulted in lower error, both $t < -300$, $p < 0.001$. For the individual syntactic categories, the AxB-c and the ABx model performed better for all syntactic categories apart from numerals, all $t < -50$, all $p < 0.001$, though the difference for conjunctions was non-significant.

Table 4 compares the AxB-c model to the ABx model, indicating that accuracy was lower and MSE higher in the ABx model. The AxB-c model performed better on all syntactic categories apart from numerals and proper nouns.

Discussion

Providing decomposable information about the preceding and following word resulted in increased accuracy of performance in the model. The AxB-c model classified words of all syntactic categories better than the non-compositional AxB and the Ax models of Experiment 2. Accuracy across all the categories was high, though classifications of adjectives and adverbs was still inaccurate – these tended to be classified as nouns/pronouns and verbs, respectively. Adding information about the two preceding words also assisted in increasingly accurate classifications, though not to the same degree as providing the preceding and succeeding word.

General Discussion

Experiment 1 demonstrated, as predicted, that AxB information provides high accuracy at the expense of completeness, whereas Ax information results in slightly lower accuracy but much higher coverage of the language.

Experiment 2 tested the extent to which a computational model could utilize AxB frame information in categorizing the intervening word. The model trained on AxB frames performed at slightly below chance level, and well below the accuracy that could be achieved from categorizing on the basis of Ax information alone. The high completeness of Ax frames resulted in significantly better learning than the high accuracy but low-coverage of AxB information.

However, when the model is able to learn on the basis of AxB information when this information is compositional, i.e., the relationship between the preceding word and the target word and between the succeeding word and the target word can be computed separately, then a different picture emerges. The AxB-c model of Experiment 3 was more accurate than the Ax model of Experiment 2. Furthermore, this provided better classification results than the two preceding words (the ABx model), though this latter model also improved performance over a non-compositional AxB frame or just the single preceding word.

The simulations presented here suggest that learning is most effective when information about the preceding word and the succeeding word is available. However, this is only the case when the AxB frame is not computed as a whole. Learning must also be based in part on the relationship between A and x and between x and B. In the experiments presented in Mintz (2002), such a distinction is not made – the learning situation resembles that of the AxB-c model, where the participant has access not only to the AxB frame, but also to the Ax and the xB bigrams. Therefore, it is not yet possible to distinguish the contribution of bigram and trigram information in adult learning situations (though see Onnis et al., 2003).

The possibility remains that the requirement for category learning depends on establishing distinctions and similarities between only a few words in the language: it is not realistic or feasible to attempt to learn the whole language simultaneously. However, performance for the most frequent 100 words was poorer in the non-compositional AxB model than the Ax model, and even taking only those words that occurred in the most frequent 45 AxB frames resulted in poorer performance than for the 45 most frequent Ax frames.

The experiments presented in this paper require the models to learn pre-ordained syntactic categories. The task facing the child is more difficult: the child must also construct the categories. Yet, both tasks concern learning about which words co-occur. When the relationship between the occurrence of certain categories in particular distributional contexts is easy to learn then this demonstrates that the category itself is more clearly defined.

We have shown that AxB frames provide poor information about categorization unless this information is componential, such that Ax information is also available. We suggest that the distributional information that a neural network model finds most useful is more likely to be used by the child in acquiring syntactic categories.

Abstract

In order to investigate how analogs are retrieved from everyday experience, we conducted an experiment in which subjects were not presented with analogies by an experimenter, but presented with only one story as a retrieval cue. In our experiment, subjects were divided into four groups varying the cue stories, which were manipulated by their surface and structural features. In all the groups, the subjects were asked to report the cases that came to mind when they read the cue story. After retrieving, the subjects rated the inferential soundness (goodness as analogy) of each retrieved case. We computed similarities between each retrieved case and the cue stories, using a computational model MAC/FAC ("many are called but few are chosen"), which was developed for simulating two stages of analogy making (Forbus, Gentner, & Law, 1995). The results showed that (1) the retrieved cases were similar to the presented story in the surface features rather than in the structural features and (2) the structural similarity between the retrieved cases and the presented story increased with the rated scores of inferential soundness. These results confirmed that, as the results of prior controlled experiments suggested, the surface similarity guides the retrieval of cases and the structural similarity guides the evaluation of the cases.

Introduction

Analogy making is a core component of higher-order cognition, such as problem solving (Gick and Holyoak, 1980), decision-making (Markman and Moreau, 2001), and creative generation (Smith, Word, and Schumacher, 1993). In the past two decades, many researchers have conducted controlled experiments and gained reliable findings on analogy making. However, there have been only a few studies to verify the findings in less controlled environments. Our goal here is to replicate previous findings on analogy making in extended laboratory settings.

Prior to presenting our experiment, we briefly review a framework developed in the area of analogy research. First, in analogy research, a representation of a novel situation is called a target, and a past case that is similar to the target is called a base. The process of analogy making is comprised of two main components: the retrieval of the base and the mapping from the base to the target.

It has been pointed out that the analogy process is guided by similarities between the base and the target. Using propositional representations (predicate-argument formalism), Gentner (1983) distinguished three types of correspondence between the base and the target.

- Correspondence of *attributes*: e.g., The sun is round and yellow → The orange is round and yellow [sun (round) sun (yellow) → orange (round) orange (yellow)]
- Correspondence of *first-order relations*: e.g., The planets revolve around the sun. → The electrons revolve around the atom [revolve-around (planet, solar) → revolve-around (electron, atom)]
- Correspondence of *higher-order relations*: e.g., Because the sun attracts the planets, the planets revolve around the sun. → Because the atom attracts the electrons, the electrons revolve around the atom [cause (attract (solar, planet), revolve-around (planet, solar)) → cause (attract (atom, electron), revolve-around (electron, atom))]

The above discrimination was based on the types of predicates. The attribute is a predicate type that takes only a single argument. On the other hand, the first-order and higher-order relations are predicate types that take multiple arguments. There is no depth in the former, but there is in the later. Based on this discrimination, in analogy research, further discrimination of similarity has been proposed: i.e., surface similarity and structural similarity. The degree of surface similarity is roughly defined as the number of attributes shared between the base and the target. Contrary to the surface similarity, the degree of structural similarity is defined as the depth of structural mapping from the base to the target; so correspondence of higher-order relations is deeper than that of first-order relations (Gentner, 1983).

It has been demonstrated that two types of similarities take different roles in the analogy process (Holyoak, & Koh, 1987; Gentner, Rattermann, & Forbus, 1993; Wharton, Holyoak, Downing, Lange, Wickens, & Melz, 1994). For example, Gentner, Rattermann, & Forbus (1993) conducted experiments in which subjects learned several stories and then retrieved the learned stories when they read new cue stories. The cue stories were manipulated by two factors: surface and structural similarities to the learned stories. As a result, the subjects retrieved more often the surface similar stories than the structurally similar stories. However, once the subjects were presented with the learned stories with the cue stories, they rated the inferential soundness (goodness as analogy) of the structurally similar stories higher than that of the surface similar stories.

To explain these results, Forbus, Gentner, & Law (1995) proposed a computational model, called MAC/FAC ("many are called but few are chosen"), which simulates two stages of the analogy process. In the first stage of MAC/FAC, several potential bases are retrieved from a memory pool, computing the dot product of the target's content vector (CVector), which is a simple list of the predicates contained in the propositional representation, with the CVector of each case in the memory pool. In the next stage, the cases retrieved at the initial stage are further evaluated by using the Structure-mapping Engine (SME), which computes structural alignment and evaluation of the match between each set of cases and the target (Falkenhainer, Forbus, & Gentner, 1989). Finally, MAC/FAC selects the cases that have high structural evaluation scores (SES), which indicate the degree of depth and breadth of the common structure. In brief, MAC/FAC can discriminate the initial stage of retrieval that is guided by surface similarity from the evaluation stage that is guided by structural similarity. In the past, similar discrimination has been employed in many other models of analogy (Thagard, Holyoak, Nelson, & Gochfeld, 1990; Hummel & Holyoak, 1997).

Recently, however, limitations on the above finding have been pointed out. The limitations are derived from the fact that many analogy researchers have only dealt with cases created by the researchers themselves. In other words, the experiments have been conducted in closed laboratories, where the subjects retrieved cases created by researchers in advance. In real-world situations, it is impossible to predict the cases that will be retrieved or used. In real-world situations, the analogy is made from individuals' everyday experience. Therefore to extend the findings to realistic problems, it is necessary to investigate analogy making using cases that the subjects learn in their own everyday life.

From this viewpoint, Blanchette & Dunbar (2000) conducted experiments that examined analogy making in situations where the subjects were not provided analogies guided by an experimenter. In their experiments, the subjects were asked to generate analogies to the zero-deficit problem - the deficit that Canadian governments had to cut. The results showed that the subjects generated few analogies that have surface features in common with the target (the zero-deficit problem), but generated many analogies that shared deep structures with the target. Further, being asked to select the best analogy from the generated analogies, the subjects selected analogies that had deeper structural correspondence than the others.

These results indicate the strong effect of structural similarity on both the retrieval and the evaluation stages, contradicting the previous studies that showed different similarities involved in the two stages. Based on the results, Blanchette & Dunbar claimed that surface similarity has little effect on analogy making in situations where subjects use their own analogies.

Although we agree on the importance of their approach, which aims to combine naturalistic settings and controlled experiments (Dunbar & Blanchette, 2001), we think that further investigation is needed for their claim. Thus, we reexamined the similarity effects on the analogy process in a situation where the subjects retrieved cases that were learned in their own everyday life. The method of our experiment is similar to that of Blanchette & Dunbar, but there are three important differences, as follows.

First, we modified the instruction in which the subjects were asked to "generate analogies". Because many researchers argued that the term "analogy" commonly implies "the cases that have low surface similarity and high structural similarity" (e.g., Gentner, 1983), there exists a possible other account for Blanchette & Dunbar's results: The subjects might actually be reminded of surface similar cases, but would not report those cases. In order to test this possibility, we did not include the term "analogy" in our instruction.

Second, we constructed several controlled experimental conditions. Blanchette & Dunbar conducted the experiments without clear manipulations using surface or structural similarities. In such an experiment, it is difficult to exclude possible conjectured factors, such as the types of cases that subjects hold, or the frequency of using these cases in their everyday life. To control these factors, we divided subjects into several experimental groups and presented the targets whose surface and structural features were systematically changed.

Third, we analyzed the data quantitatively. In Blanchette & Dunbar's study, the generated analogies were analyzed by categorizing their surface/structural features and comparing frequencies of categories. However, they did not show how much the generated analogies shared surface/structural features with the target. For quantitative analysis, we computed similarity scores for each retrieved case based on the algorithm assumed in the MAC/FAC (Forbus, Gentner, & Law, 1995).

Method

Materials

The experiment was conducted to investigate the effects of similarities on the analogy process in a situation where subjects retrieved cases that were learned in their own everyday life. In our experiment, the subjects were presented with a cue story and then were asked to report the cases that came to mind while they read the cue story. The cue story consisted of about 600 Japanese characters. In this paper, we call these stories the target stories.

The texts of the target stories were manipulated with their surface and structural features. The subjects were divided into four experimental groups varying target stories (the between-subjects factor). As the surface features, a set of attributes related to *animals* (A) and a set of attributes related to *countries* (C) were chosen. As the structural features, a story whose plot is a transition from *peace to war* (PW) and a story whose plot is a transition from *war to peace* (WP) were created. Combining the surface and structural features, four types of

PW	28.8	12.2
WP		27.9

Figure 1: Propositions contained in the target stories.

target stories were prepared (A/PW, A/WP, C/PW, and C/WP).

Figure 1 shows the propositions converted from the texts in the target stories. Each of them was included in either set A or set C. Two complements $[(A \cap \bar{C})$ and $(\bar{A} \cap C)]$ contain attributes of objects and an intersection $(A \cap C)$ includes first-order relations between two objects. Each of the first-order relations was connected by two types of higher-order relations (PW/WP) represented by two types of arrows (solid/dotted).

Figure 1 also shows similarity scores calculated based on the algorithms of the MAC/FAC. The CVector, indicating surface similarity, was computed as a dot product of each pair of surface features (A vs. A, A vs. C, and C vs. C). In our study, the CVector was represented as a list of attributes, not containing first-order and higher-order relations. The SES, indicating structural similarity, was computed by inputting each pair of relational structures (PW vs. PW, PW vs. WP, and WP vs. WP) into the SME model. From the several matching rules of the SME package, we chose analogy rules that do not compute the match of attributes.[1]

In order to verify the above manipulation, we conducted a preliminary experiment. The subjects (n = 8) were presented with four target stories and then rated the inferential soundness of each pair of the target stories on a 1 ("low") – 5 ("high") scale. Similar to Gentner, Rattermann, & Forbus (1993), soundness was explained as "the degree to which inferences from one story would hold for the other".

[1]Our way of computing similarity was slightly modified from Forbus's method. Forbus treated the CVector as a list of all types of predicates including relations, and computed the SES using the literal-similarity rules that mapped all types of predicates including attributes (Forbus, Gentner, & Law, 1995). In our study, for clear discrimination between surface (attributes) and structural similarity (relations), we chose the above method.

The results showed that the manipulation is consistent with human feelings of soundness. Seven of eight subjects judged the structurally similar pairs (A/PW vs. C/PW and A/WP vs. C/WP) as having higher inferential soundness than the other pairs (A/PW vs. A/WP, CPW vs. C/WP, A/PW vs. C/WP, and A/WP vs. CPW).

Participants

Thirty-three undergraduate and graduate students participated in the experiment. They were divided into four groups: a group presented with A/PW (n = 8), a group with A/WP (n = 9), a group with C/PW (n = 8), and a group with C/WP (n = 8).

Procedure

The subjects participated in the experiment individually or in groups of two to four. The experiment was divided into the following three phases.

Retrieval phase In the first phase, the subjects reported the cases of which the target story reminded them. In explaining the task, we avoided using terms like "analogy" or "analogous". The subjects were simply told that "while reading the presented story, you should write out any cases that come to mind". After the instruction, the subjects were presented with one of the four targets and then they wrote down any reminded cases. This phase continued for twenty minutes.

Evaluation phase Following completion of the retrieval phase, the subjects were given a soundness rating task. The subjects rated the soundness of the match between each retrieved case and the presented target on a 1 – 5 scale.

Figure 2: Examples of subjects' descriptions and propositions.

Explanation phase Finally, the subjects were asked to explain the retrieved cases in as much detail as possible.

Coding

The retrieved cases were coded using propositional representations. The subjects' descriptions were segmented by the appearance of a predicate. Then a coder judged whether each segmented sentence could be represented as a proposition by using predicates contained in the targets (the predicates in Figure 1). If possible, a proposition would be constructed by complementing for proper arguments. Examples of the coding are shown in Figure 2.

Results and Discussion

The total number of cases retrieved by the subjects was 266. There was no significant difference on the number of cases among the four experimental groups [$\chi^2(3) = 6.15, ns.$]. Thus, we treated each retrieved case as an individual datum for statistical tests.

In order to examine the relationship between the surface/structural similarities and the retrieval/evaluation stages of analogy making, we tested (1) whether the retrieved cases were similar to the presented target in the surface/structural features, and (2) whether the surface/structural similarity between the retrieved cases and the presented target increased with the degree of soundness rating.

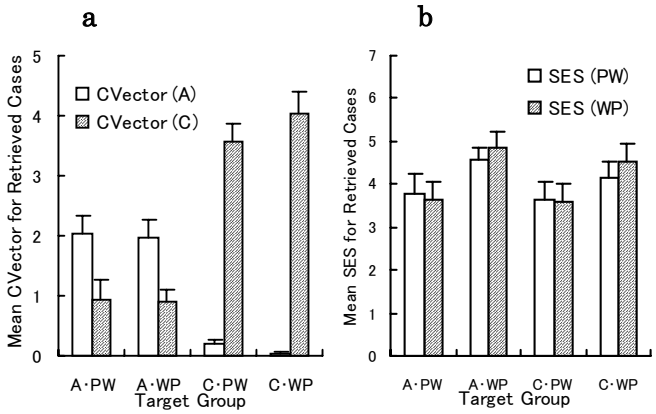

Figure 3: (a) Mean CVector for four groups. (b) Mean SES for four groups. *Note.* Error bars represent one standard error of mean.

1. Effects of Similarities on Retrieval

For investigation of the effects of similarities on retrieval, four types of similarity scores were computed based on the algorithm assumed in the MAC/FAC.

- *CVector (A)* was computed as the dot product between each retrieved case and the surface feature A ($A \cap \bar{C}$ in Figure 1).
- *CVector (C)* was computed as the dot product between each retrieved case and the surface feature C ($\bar{A} \cap C$) in Figure 1).
- *SES (PW)* was computed by inputting each retrieved case and the structural feature PW (the solid lines in Figure 1) into the SME model.
- *SES (WP)* was computed by inputting each retrieved case and the structural feature WP (the dotted lines in Figure 1) into the SME model.

We conducted two ANOVAs to investigate interaction between the above similarity scores and the experimental groups. If the surface/structure features affected the case retrieval, the retrieved cases would be similar to the presented target rather than the targets that were not presented for each group.

Effects of Surface Similarity on Retrieval Figure 3a shows the mean CVector for each group. A 2 × 2 × 2 surface features of targets (between) × structural features of targets (between) × types of CVector (within) ANOVA revealed significant interaction between the surface features of targets and the types of CVectors [$F(1, 262) = 118.21, p < .05$], indicating CVector (A) was higher than CVector (C) in the group A [$F(1, 262) = 14.22, p < .05$], and CVector (C) was higher than CVector (A) in the group C [$F(1, 262) = 134.67, p < .05$].

Both in group A and group C, the retrieved cases were more similar to the target that was presented for each group than the targets that were not presented. A strong effect of surface similarity on retrieval contradicts the results of Blanchette & Dunbar (2000), but is consistent with the findings of the previous controlled experiments (Holyoak, & Koh, 1987; Gentner, Rattermann, & Forbus, 1993; Wharton et. al, 1994).

Effects of Structure Similarity on Retrieval Figure 3b shows the mean SES for each group. A 2 × 2 × 2 surface features of targets (between) × structural features of targets (between) × types of SES (within) ANOVA revealed significant interaction between the structural features of the target and the types of SES $[F(1, 262) = 8.01, p < .05]$. However, simple main effects were significant only in group WP $[F(1, 262) = 7.50, p < .05]$. There was no significant difference of types of SES in group PW $[F(1, 262) = 1.60, ns.]$.

These results suggest that structural similarity has more restricted effects on retrieval than surface similarity. Again, this result contradicts the study by Blanchette & Dunbar, but is consistent with the findings of the previous controlled experiments (Holyoak, & Koh, 1987; Gentner, Rattermann, & Forbus, 1993; Wharton et. al, 1994).

2. Effects of Similarities on Evaluation

In order to investigate the effects of structural similarity on the evaluation stage, we treated the subject groups as counterbalance conditions, and reduced the number of factors for the ANOVA. Therefore, we investigated four types of similarity scores as follows:

- *CVector (presented)* was computed by combining CVector (A) in group A and CVector (C) in group C. This score indicates the degree of surface similarity, meaning how many attributes were shared between each retrieved case and the target that was presented for the subjects.

- *CVector (not presented)* was computed by combining CVector (A) in group C and CVector (C) in group A. This score indicates how many attributes were shared between each retrieved case and the target that was not presented for the subjects. Because two types of surface features (A and C) share no attributes, this score indicates surface dissimilarity.

- *SES (presented)* was computed by combining SES (PW) in group PW and SES (WP) in group WP. This score indicates the depth of structural mapping from each retrieved case to the presented target. Thus, this score indicates structural similarity that reflects higher-order relations.

- *SES (not presented)* was computed by combining SES (PW) in group WP and SES (WP) in group PW. This score indicates the depth of structural mapping from each retrieved case to the target that was not presented for the subjects. Since two structural features (PW and WP) share no higher-order relations but only first-order relations, this score indicates the degree of overlap of the first-order relations.

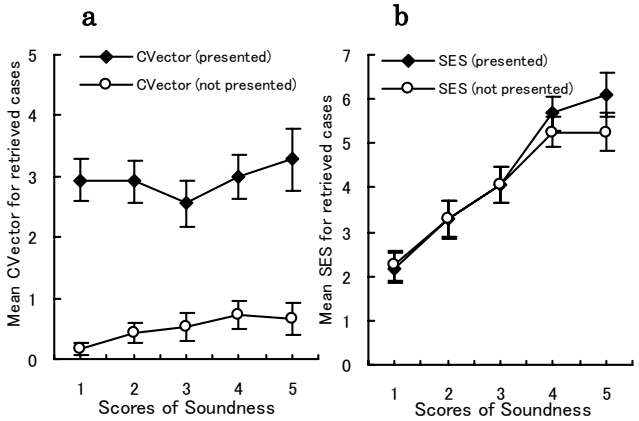

Figure 4: (a) Mean CVector for rating scores of soundness. (b) Mean SES for rating scores of soundness. *Note.* Error bars represent one standard error of mean.

We computed two ANOVAs for the retrieved cases by using the above similarity scores. Each ANOVA tested whether the similarity scores increased with the rated scores of soundness (1 – 5). If the structural similarity had a strong effect and the surface similarity had only a little effect in the evaluation stage, as suggested by the previous studies (Gentner, Rattermann, & Forbus, 1993; Blanchette & Dunbar, 2000), the CVector (presented/not presented) would not increase with the soundness rating, but the SES (presented/not presented) would increase with the soundness rating. Further, the SES (presented), which reflects the higher-order relations, would be related to the soundness ratings more than the SES (not presented), which reflects only the first-order relations.

Effects of Surface Similarities on Evaluation Figure 4a shows the mean CVector for each score of soundness (1 – 5). A 5 × 2 soundness scores (between) × CVector types (within) ANOVA detected a significant main effect of CVector types $[F(1, 261) = 121.17, p < .05.]$. However, a main effect of soundness $[F(4, 261) = 1.91, ns.]$ and an interaction between CVector types and soundness scores $[F(4, 261) = 0.40, ns.])$ were not significant. These results indicate an advantage of surface similarity over surface dissimilarity regardless of soundness ratings. Thus, as the previous studies indicated, the results suggest that there is no effect of surface similarity or dissimilarity on the evaluation stage.

Effects of Structural Similarity on Evaluation Figure 4b shows the mean SES for each score of soundness (1 – 5). A 5 × 2 soundness scores (between) × SES types (within) ANOVA revealed a significant interaction between soundness scores and SES types

$[F(4, 261) = 7.52, p < .05]$. Simple main effects of soundness scores were significant for both SES (presented) $[F(4, 261) = 15.46, p < .05]$ and SES (not presented) $[F(4, 261) = 11.09, p < .05]$. Further it was confirmed that SES (presented) was higher than SES (not presented) at the soundness scores 4 $[F(1, 261) = 8.76, p < .05]$, and 5 $[F(1, 261) = 35.73, p < .05]$.

Significant main effects of soundness on both the SES (presented) and the SES (not presented) indicate that the subjects' evaluation was positively correlated to the degree of commonalities in the first-order relations. The fact that the SES (presented) was higher than the SES (not presented) in the cases in which the subjects rated high soundness (rate scores 4 and 5) implies that commonalities in the higher-order relations are more strongly related to soundness than mere first-order relations. In summary, these results are consistent with prior studies (Gentner, Rattermann, & Forbus, 1993; Blanchette & Dunbar, 2000) showing the strong effects of structural similarity on evaluation.

General Discussion

Influence of Similarities on Analogy Process

In this study, we investigated types of similarities influencing the analogy process, conducting an experiment in which the subjects retrieved cases that they had learned in their own everyday life. As with the results of previous controlled experiments, our results also suggest that different types of similarities are responsible for the retrieval and evaluation stages of the analogy process. The results were different from those of Blanchette & Dunbar (2000), which showed little effect of surface similarity on the retrieval phase. The difference between our results and Blanchette & Dunbar's results could be explained by differences in the instructions. The subjects who participated in the experiments of Blanchette & Dunbar may have filtered out the surface similar cases because they were instructed to "generate analogies". Since there exist other differences between our experiment and Blanchette & Dunbar's experiments, such as the reality of the tasks used and the method of analysis, we must conduct further experiments controlling for these factors.

In addtion, our study obtained results indicating a strong effects of structural similarity on the evaluation stage. The results were clearer than Blanchette & Dunbar's results. Blanchette & Dunbar's analysis was based on counting elements shared with the base and the target, without any consideration of relational structures. In contrast, our analysis was based on a computational model that computes structural alignment and structural evaluation. Our analysis showed that the degree of shared attributes did not increase with the soundness rating, whereas the degree of shared relations increased with the soundness rating. Further, sharing higher-order relations made the relation to the soundness rating stronger. These results are important for the extension of the systematicity principle, proposed by Gentner (1983), which predicted that deeper structural mapping would be preferred in an analogical inference.

Investigation based on a Computational Model

The above results imply the benefit of using a computational model for analysis of psychological data. In the past, few studies have used a computational model to analyze data obtained from psychological experiments. However, without a sufficient computational model, it would be impossible to investigate complex cognitive conceptual products such as structural similarity.

Recently, in the community of cognitive science, the connection between theory and experimental data has been stressed. Usage of a computational model for analysis, demonstrated in this paper, could open a new way of directly licensing these two entities that play the most important role in cognitive scientific studies.

Abstract

Students learning facts such as foreign language vocabulary often rely on a self-testing procedure in which they cue themselves with the English word and try to recall the foreign language target, instead of simply memorizing cue-target pairs. The value of this strategy has been empirically verified by a long history of research, yet existing computational models of human learning do not address the enhancing-learning-through-testing phenomenon. Using a simple, well studied model—a feedforward neural net with no hidden units—we propose two different hypotheses for characterizing the phenomenon. Hypothesis 1 is that self-testing generates a target which is used for additional training. Hypothesis 2 is that self-testing produces a more reliable error signal for training than rote memorization. Through simulation studies, we find that hypothesis 2 readily explains the phenomenon whereas hypothesis 1 does not. Further, hypothesis 2 makes predictions worthy of further empirical study, and can be viewed as a natural consequence of temporal difference learning.

When learning foreign language vocabulary and other facts, students often study using index cards that have an English vocabulary word (or *cue*) on one side and a foreign language vocabulary word (or *target*) on the other. The intuition is that by testing oneself, the associations are better learned and retained.

This intuition has been supported by a long history of empirical demonstrations (e.g., Izawa, 1966; Young, 1971). For example, Bartlett and Tulving (1974) asked participants to learn a list of paired associates (the *study phase*), and later tested retention of the pairs using free recall or recognition (the *final test*). Before the final test, subjects were given a cued-recall test (a *self test*) of some of the paired associates. Retention was better on the final test for those items that received the self test.

In this paradigm, it is unclear whether the benefit of the self test is attributable to attempting retrieval per se, or to the fact that successful retrieval of an associate also results in a re-presentation of the pair—an additional training trial.

An obvious strategy for examining the effect of retrieval is to conduct and experiment with, in addition to the initial study phase and the final test, an intervening phase in which participants are given either a self test or an experiment-provided re-presentation of the paired associate (which we'll refer to as *study only*). In this paradigm, the outcome is ambiguous (Carrier & Pashler, 1992): self testing outperforms study in some experiments (e.g. Hogan & Kintsch, 1971), but not others (e.g., McDaniel & Masson, 1985). One explanation for the inconsistency is that the rate of retrieval success on self test trials varies among experiments, and the mechanisms of learning are likely to be dependent on retrieval success. The experiments have other problems, including different amounts of time for study-only and self-test conditions, and failure to control the time spent on individual items (Carrier & Pashler, 1992).

To overcome these metholological difficulties, Carrier and Pashler (1992) compared a *study-only* or *SO* condition in which each cue-target pair was presented for ten seconds to a *test/study* or *TS* condition in which the cue was presented alone for five seconds and then the target appeared for the final five seconds. In TS trials, participants were supposed to use the cue to retrieve the target, but even if retrieval failed, the trial still had value due to the presentation of cue and target together for five seconds. Consequently, the dependence on retrieval success rate is minimized. Also, the paradigm matches the total time per item in SO and TS conditions. If anything, self testing is at a disadvantage because the total viewing time for cue plus target was lower.

In Experiments 1 and 2 of Carrier and Pashler, 40 cue-target pairs were used, half each assigned to the SO and TS conditions. The experiment began with a study only phase in which participants viewed each of the 40 pairs once for ten seconds. Then two more passes were made through the pairs, presented in the manner designated for that pair—SO or TS. For both conditions, participants were instructed to say aloud the target. In the TS condition, this instruction required that participants recall the target, or if they failed to recall, to wait until the target appeared. Following the three presentations of each pair, a final test phase evaluated performance in the two conditions via cued recall.

In Experiment 1, the cues were consonant-vowel-consonant trigrams and the targets were two digit numbers. For the sake of ecological validity, Experiment 2 used a language learning task with English language word cues and the corresponding Siberian Eskimo Yupik language translation targets. Table 1 shows the percentage of error responses. In both Experiments 1 and 2, performance was better in the TS condition than

TABLE 1. Performance in Enhancing-Learning-Through-Testing Experiments

	Human Data (% Error)		Simulation (Mean Squared Error)	
	Study Only	**Test Then Study**	**Study Only**	**Test Then Study**
Carrier & Pashler, Expt. 1	42.0%	36.0%	.389	.321
Carrier & Pashler, Expt. 2	43.0%	36.0%		
Carrier & Pashler, Expt. 3	40.0%	32.7%	.356	.258

~~the SO~~ condition. These results indicate roughly 10% fewer errors with testing, therefore, having to retrieve the target is more effective than simply studying the target, when all else is controlled for.

Carrier and Pashler conducted a further experiment to rule out an alternative explanation of their results. In Experiments 1 and 2, participants may have used the first retrieval attempt in the TS condition to determine which items were difficult, and then increased their encoding effort for the difficult items on the second retrieval attempt, thereby learning the items better. Experiment 3 ruled out this explanation by giving participants only a single pass through the items in either the TS or SO conditions, following two passes through the items as study-only trials. The total number of items was reduced to 30. The results were similar to Experiments 1 and 2 (see Table 1), suggesting that the effect of attempting retrieval on later retention does not depend on strategic allocation of encoding effort.

Mechanism Underlying Enhanced Learning Through Testing

Why does testing oneself—i.e., attempting to retrieve a target from memory—have beneficial effects for later retention, above and beyond the effects due to mere study? A variety of explanations have been proposed for the self-testing benefit.

- Landauer and Bjork (1978) considered that retrieval attempts provide a general sort of practice or context that boosts performance at a future time. However, this account predicts that the benefits would not be item specific, i.e., SO and TS items would benefit equally in an experiment where the item types were mixed within subject.
- Mandler (1979) suggested that cued recall might strengthen the structural, integrative information about a cue-target pair. Cooper and Monk (1976) proposed that retrieval requires neural activity that consolidates the representation of the target in memory. However, both of these accounts do not provide a strong explanation for why TS should be better than SO, because both conditions involve simultaneous activation of cue and target.
- Bjork (1975) hypothesized that the act of retrieval may strengthen existing retrieval routes to the target representation, or may create new routes. Although interesting and consistent with the data, it is unclear what this hypothesis corresponds to in computational terms, and seems as if it might require novel, custom learning mechanisms.

This paper explores two alternative hypotheses concerning the enhancement of learning through testing, and we evaluate their plausibility via simulation studies. In proposing hypotheses, our aim was to determine whether an existing, well-accepted model could explain the basic phenomenon without requiring additional assumptions. A model is not convincing if two novel assumptions are needed to explain two data points. Further, an existing model is already constrained and therefore has the power to make strong predictions, which can guide the design of behavioral experiments.

Our hypotheses lie within the framework of neural network models. We explore the simplest architecture that might be capable of explaining the phenomenon: an associative network consisting of a pool of n_I input units fully connected to a pool of n_O output units. The activity of output unit j, y_j, is simply a weighted sum of the inputs, x_i, passed through a sigmoid squashing function that limits the output in the range [–1, +1]:

$$y_j = \tanh\left(\sum_{i=1}^{n_I} w_{ji} x_i\right).$$

A training set consists of n_L paired associates to be learned, $\{(\boldsymbol{x}^1, \boldsymbol{d}^1), \ldots, (\boldsymbol{x}^{n_L}, \boldsymbol{d}^{n_L})\}$, where the superscript is the index over pairs in the training set, and $\boldsymbol{x}$ and $\boldsymbol{d}$ are the activity vectors of the cue and target of the pair, respectively. To reflect the fact that items to be learned in the behavioral studies are arbitrary, make little contact with existing knowledge, and have no systematic similarity to one another, we assume that the cue and target activity vectors are random. (Further details in the methodology section that follows.)

In neural net models of cognition, the training of the model is often viewed as an abstract procedure for loading knowledge into a network, and as having no direct correspondence to the sequence of episodes a human learner experiences. In contrast, we commit to a one-to-one correspondence: An SO trial in a behavioral experiment is modeled as one weight update in the neural network. For many neural net architectures and learning procedures, this correspondence is implausible; training the network requires dozens if not hundreds of passes through the training examples, and training on one example can result in catastrophic interference with other examples. We avoid these problems in two ways. First, our architecture has direct connections from input

units to output units, in contrast to strictly layered architectures with hidden units. Second, we endow our architecture with as many inputs as training examples, i.e., $n_L = n_I$; consequently, cues are approximately orthogonal to one another, and interference among examples is minimal. Due to the architecture, the model can learn associations with roughly the same number of exposures as a human participant in a paired-associate experiment.

We use the standard supervised learning procedure for associative networks, a generalization of the Widrow-Hoff or LMS learning algorithm (Widrow & Hoff, 1960) to nonlinear outputs. Following presentation of a cue $\boldsymbol{x}$ to be paired with target $\boldsymbol{d}$, a weight update is performed:

$$\Delta w_{ji} = \varepsilon(d_j - y_j)x_i(1 + y_j)(1 - y_j)$$

where ε is a step size (learning rate).

Having described the general class of models we consider, we turn to two specific hypotheses concerning the nature of learning via self testing.

Hypothesis 1: Self-generated training

One hypothesis is based on the notion of Guthrie (1952) that one learns what one does. That is, when individuals test themselves, they generate a candidate response, and then learn the association between the cue and the candidate response, whether it is correct or incorrect. If the candidate is correct, existing connections are strengthened and are therefore more resilient to decay or interference; if the candidate is incorrect, the wrong association is reinforced, making it more difficult to unlearn.

This interpretation of self testing suggests that testing should benefit an individual only if the material is already somewhat familiar. Some evidence indeed suggests that testing on novel paired associates—when individuals cannot possibly know the correct response—is detrimental to learning (Cunningham & Anderson, 1965).

By this hypothesis, a TS trial involves the following steps: (1) The cue is presented and a candidate response is generated. (2) The LMS weight update is computed for the candidate response. (3) When the target is eventually presented, the LMS weight update is computed for the experiment-provided target. In contrast, an SO trial involves only the third step. In a TS trial, two weight updates are generated; the weight updates are added together and performed at the end of the trial.

How does the model generate a candidate response? It might produce an output and then deterministically select the nearest *well formed state*, defined as a state which has a meaning in the domain (e.g., the set of all targets used for training, plus some distractor alternatives, plus a null or "no response" state). However, individuals are essentially guessing at early stages of learning, and the deterministic rule implies an ability to find the best response among a set of barely-known alternatives. Instead, one might wish to introduce a stochastic selection rule. A standard stochastic procedure for reading out from a neural network is to use a Luce choice or Boltzmann rule (Luce, 1959). By this rule, the distance between each possible response, $\boldsymbol{r}^i$, and the network output, $\boldsymbol{y}$, is computed, $v_i = \|\boldsymbol{r}^i - \boldsymbol{y}\|^2$, and the probability of choosing response i is

$$p_i = \exp(-\beta v_i) / \sum_j \exp(-\beta v_j),$$

where large β achieves a more deterministic selection.

Rather than treating β as a free parameter, we chose β such that the mean correct-response probability is 0.95 if the network produces the correct response on each trial. The model has other free parameters, though, including learning rates for supervised and self-generated targets, the number of distractor vectors considered as candidates for response selection, and the possibility of memory (weight) decay that introduces forgetting.

Hypothesis 2: Complete processing of cue

Carrier and Pashler (1992) speculated on an intriguing basis for the self-testing benefit. They reasoned that in neural net models that learn by error correction, which includes the LMS algorithm, learning requires a comparison between the desired output and the *actual* output—the output that the network produces given its current state of knowledge. If presentation of the target simultaneously with the cue "contaminates" (to use their term) production of the actual output, learning would be less efficient. Essentially, presentation of the target terminates ongoing processing and interferes with the estimation of error needed for learning.

An elegant instantiation of this hypothesis in the context of neural net models is via the incorporation of time into the neural net, specifically, the notion that units in a neural net are slow integrators of information and therefore require many time steps for information to propagate from the input layer to the output layer (McClelland, 1979). We can do this in the network by indexing its output by the (discrete) time step t, i.e., $y_i(t)$, and adding a time constant to the activation dynamics:

$$y_j(t) = (1 - \tau)y_j(t - 1) + \tau\tanh(\sum w_{ji}x_i),$$

where $y_i(0) = 0$ Asymptotically, the output is independent of the time constant τ, for $0 < \tau \leq 1$, but τ determines the rate at which convergence is achieved, i.e., how rapidly information is transmitted from the input to the output.

If we assume that activation dynamics freeze—equivalent to setting $\tau = 0$—when the target is presented, the model will produce a more accurate estimate of its output in the TS condition than in the SO condition, and the learning procedure will have a better estimate of the error. From another perspective, note that if activation dynamics freeze at $t = 1$, the actual output y will be zero, and the training procedure reduces to a form of Hebbian learning; at the other extreme, if the activation dynamics do not freeze and the asymptotic

value $\boldsymbol{y}(\infty)$ is used for training, the learning procedure is exactly the LMS gradient descent step. Because LMS is a more powerful procedure than Hebb, it should yield better performance.

For our simulations, we established a relatively coarse-grained correspondence between time steps in the neural net and real-world time by designating the duration of each time step to be 250 msec. Rather than leaving the time constant τ as a free parameter, we chose τ in advance such activation would reach halfway to asymptote by 2000 msec. To match the TS condition in the behavioral studies, 20 time steps (= 5 seconds) of processing was allowed before the onset of the target. For the SO condition, we had some freedom to determine the time step at which activation dynamics freeze. Although the cue and target appeared simultaneously in the behavioral experiments, participants may nonetheless have done some amount of processing of the cue before the target is processed. We experimented with 0, 1, and 2 time steps of processing in the SO condition, and all yielded similar results; we chose 1 time step in modeling Carrier and Pashler, because that was a sufficient amount of processing to ensure that with enough practice, the model could learn the items in the SO condition. For evaluation of the model during the final test, the activity at time step 80 was used.

Simulation Studies

General Methodology

In all simulations, we used networks with $n_L = n_I = n_O$. Cue and targets were random binary vectors in $\{-1, 1\}^{n_I}$. To model Experiments 1-3 of Carrier and Pashler, we used the same number of items as in their experiment, $n_L = 40$ for Experiments 1 and 2, and $n_L = 30$ for Experiment 3. Because Experiment 2 is essentially a replication of Experiment 1 with different stimulus materials, and the materials in both experiments were intended to be unfamiliar to participants, we capture both experiments with one simulation. Half of the items were assigned to the SO condition and half to the TS condition.

Weights in the neural network were initialized to zero. We also conducted stimulations in which the initial weights were chosen from a normal distribution with mean zero and standard deviation 0.001. However, because the variability of the weights had no systematic effect on the results, we simplified by eliminating this source of noise from the simulation.

The experiments of Carrier and Pashler each involved three *epochs* of training, followed by a final test. An epoch is a presentation of all items in the training set. Within an epoch, order of presentation was randomized, with the constraints that Carrier and Pashler imposed to ensure an intermixing of SO and TS items.

Epochs were of two sorts: in a *pure study* epoch, all items were studied without testing, regardless of whether they were SO or TS items; in an *experimental* epoch, presentation of an item depended on whether it was assigned to the SO or TS condition. In Experiments 1 and 2, the first epoch was pure study (denoted *S*), and epochs 2 and 3 were experimental (denoted *E*); we use the shorthand notation *SEE* for this design. In Experiment 3, the first two epochs were pure study and the third was experimental, i.e., an *SSE* design.

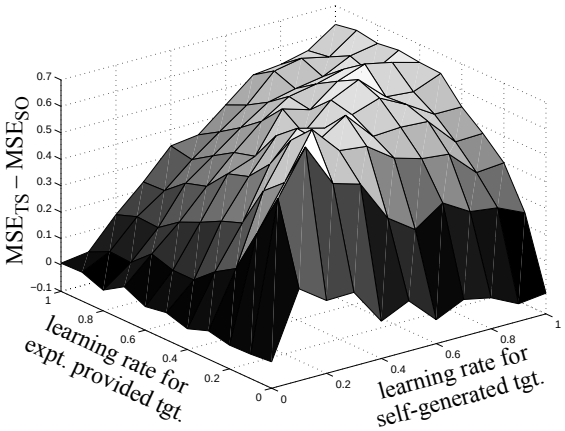

FIGURE 1. Testing error for TS minus SO as a function of the learning rates for self-generated and experiment-provided targets. The difference is nonnegative everywhere, indicating no enhancement through testing. For this simulation, no additional distractor states or weight decay are included.

All results reported are a mean computed from 1,000 independent simulations, where the simulations differ from one another in the choice of random training vectors and the randomization of items within an epoch.

We use mean squared-error (MSE) as a measure of performance of the model. With additional assumptions, we could classify a response as correct or incorrect (e.g., using the stochastic read out procedure that is built into Hypothesis 1), but there is little value in transforming a qualitative fit to a quantitative fit if several new assumptions are required. Consequently, we focus on obtaining qualitative measures of recall, and determining how manipulations of the model affect relative recall.

Hypothesis 1: Self-generated training

After a systematic exploration of the model parameter space, we failed to find any parameter settings that yielded an enhancement of learning by testing. Error was consistently higher in the TS condition than in the SO condition. The two conditions converge as the learning rate for the self-generated target approaches zero, where at the limit SO and TS become identical. Figure 1 illustrates one exploration of the parameter space.

In retrospect, the negative result should not have been surprising. After one or two epochs, the model—like people—is about as likely to make an error as to guess correctly. Consequently, the model will receive as much training from self-generated targets that steers it away from veridical recall as training that steers it toward veridical recall.

Hypothesis 2: Complete processing of cue

Fortunately, our second hypothesis yields more encouraging results. Consistent with Carrier and Pashler, the model produces an enhancement of learning by testing—a lower error for TS than SO—in simulations of Experiment 1/2 (one simulation for both experiments, since they are identical except for the stimulus materials) and Experiment 3 (right side of Table 1). In these simulations, we chose a learning rate that yielded the best possible performance, averaged over TS and SO items. However, the testing benefit was robust over the choice of learning rate.

Figure 2 facilitates a better understanding of the phenomenon in terms of the model. The Figure shows mean-squared error for TS and SO items for four different experimental designs. All designs involve three epochs of training, but they differ in how many epochs of pure study (*S*) precede the experimental (*E*) epochs. The designs range from all study (*SSS*) to all experimental (*EEE*). *SEE* and *SSE* correspond to Experiment 1/2 and Experiment 3, respectively.

The Figure shows that two testing trials helps more than one (*SEE* versus *SSE*). Interestingly, three testing trials shows little benefit over two (*EEE* versus *SEE*). This latter result was at first surprising to us, because it would seem that the more accurate error estimate that is obtained via testing would benefit epoch 1 as well as epochs 2 and 3. However, with an untrained net whose weights are all zero or close to zero, the initial output of the net is close to zero regardless of the number of time steps of activation dynamics.

Comparing SO items in *SSS* versus *EEE* designs, it appears that the SO items benefit from being in a context where testing is occurring; this is a bit surprising considering that the training of these items is identical and learning rates are identical across designs.The result also cannot be explained by virtue of generalization from the better-learned TS items to the SO items, because the items were generated with no systematic similarity structure. Instead, we suggest that the transfer from TS to SO is due to the TS items generating a more meaningful error signal—an error signal that reflects the sort of outputs the network is likely to produce if it is allowed to run to asymptote. Although the precise outputs will differ from one cue to another, the TS items provide information about the distribution of activity values for each output unit across items. This information can certainly be used to determine characteristics of the weight vector (e.g., its overall magnitude, and the sign of biases).

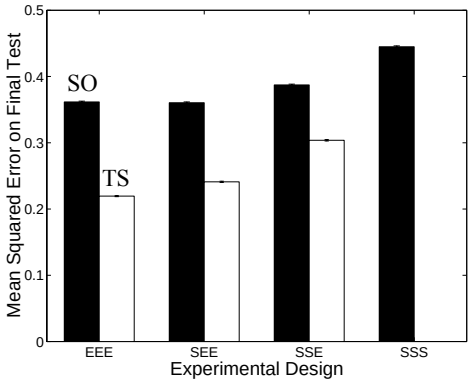

FIGURE 2. Mean-squared error in TS (white bar) and SO (black bar) conditions for experimental designs with three training epochs. +/–1 standard error of the mean is indicated.

We discuss the implication of these results next.

Discussion

In simulations of two models, we found that one hypothesis for the enhancement-of-learning-through testing effect—the hypothesis that self-generated responses are used as targets for further training—is not supported. Another hypothesis—that presentation of the target terminates processing of the cue—is consistent with the experimental data. In the remainder of the paper, we discuss predictions, extensions, and implications of the second hypothesis.

Predictions

- Our model predicts little difference between an *EEE* design and the *SEE* design used in Experiment 1/2. That there is no cost to testing on the first epoch runs against at least one experimental study (Cunningham & Anderson, 1965), but that study used a quite different methodology, and the finding of an initial-epoch-testing cost has not been widely reported in the literature.
- Our model predicts that an SO item should benefit from being embedded among TS items. If it is observed experimentally, a natural interpretation of this effect is that the greater effort on TS items spills over to the SO items. However, the model achieves this spillover without any notion of generalized "effort."
- Our model predicts the relative magnitude of the testing enhancement as a function of the cue-target asymmetry (CTA), i.e., the difference in time between the onset of the cue and the onset of the target. The Carrier and Pashler experiment used a CTA of 5 seconds (20 time steps in the model). One could conduct an experiment in which the CTA was longer or shorter. (Because the time scale of retrieval in the model was set arbitrarily, there is a degree of indeterminacy in the model's predictions. Nonetheless, with one free parameter tied down, the model can characterize the effect of shorter or longer CTAs) Figure 3 shows the model's performance as the CTA is varied. For small CTAs, there is little difference between SO and TS conditions; for large CTAs, the conditions are similar to those studied in the present simulations. Clearly, increasing the CTA has diminishing returns.

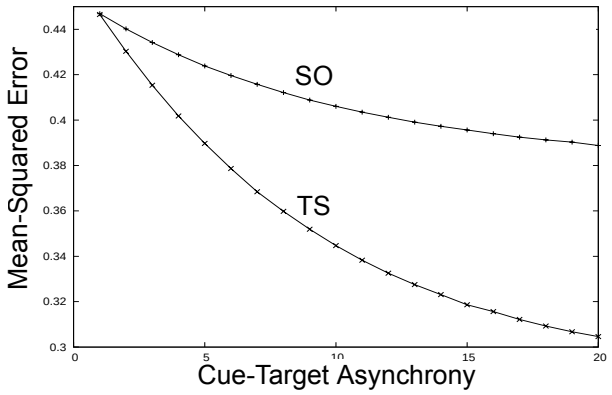

FIGURE 3. Test performance as the cue-target asynchrony in training is varied in the TS condition.

Extensions to the Model

In both SO and TS conditions, each simulation trial began by presenting the cue for T time steps—T being different for SO and TS conditions—at which point a weight update was performed to reduce the difference between the actual response, $\boldsymbol{y}(T)$, and the target. An alternative procedure involves updating the weights to reduce the difference between *each* of $\boldsymbol{y}(1)$, $\boldsymbol{y}(2)$, ..., $\boldsymbol{y}(T)$ and the target. This alternative procedure encourages the net to produce the target as rapidly as possible, and is equivalent to a form of *temporal difference* (TD) learning known as TD(1) (Sutton, 1988). Temporal difference learning is concerned with learning to predict the future given successively better information over time—exactly the situation experienced by the network with time constants, because the propagation of information occurs gradually. However, TD(1) is often not useful in practice because the earliest predictions, e.g., $\boldsymbol{y}(1)$, are treated as important as later, better predictions, e.g., $\boldsymbol{y}(T)$. To remedy this problem, Sutton proposed a family of algorithms, denoted TD(λ), for $0 \le \lambda \le 1$, where λ is roughly the emphasis on achieving correct early predictions. The λ that yields optimal performance depends on the domain. Although it would be interesting to discover how the self-testing benefit depends on λ, the deeper contribution of casting the learning procedure in the TD framework is that it offers a rationale for the termination of processing when the target is presented.

The TD framework is based on the notion that learning mechanisms are fundamentally concerned with predicting eventual outcomes at the earliest possible moment. The adaptive value of prediction is clear; accurate prediction can avoid danger and missteps. Considering the associative learning task in this manner, the cue is a predictor of the target, and TD learning aims to get from the cue to the target as rapidly as possible. However, once a target has been presented, nothing remains to be predicted. The TD framework has been valuable for explaining a broad range of data, from the animal conditioning literature (Sutton & Barto, 1981) to the neural basis of reward (Schultz, Dayan, & Montague, 1997). It seems a natural extension to the mechanisms of associative learning, although one must confront the finding that associative learning appears symmetric (Kahana, 2002).

Abstract

In most cognitive and motor tasks, speed-accuracy trade offs are observed: Individuals can respond slowly and accurately, or quickly yet be prone to errors. Control mechanisms governing the initiation of behavioral responses are sensitive not only to task instructions and the stimulus being processed, but also to the recent stimulus history: when stimuli can be characterized on an easy-hard dimension (e.g., word frequency in a naming task), an easy item is responded to more slowly when intermixed with hard items than when presented among other easy items; likewise, hard items are responded to more quickly when intermixed with easy items. We propose a mathematical theory with three components: a model of temporal dynamics of information processing, a decision criterion specifying when a response should be initiated, and a mechanism of adaptation to the stimulus history. Performance during the course of an experimental trial is cast in terms of a utility function that increases with accuracy and decreases with response time. We assume a decision criterion that initiates a response at the point in time that maximizes expected utility. We posit that the effect of the stimulus history arises because information concerning recent trial difficulty is incorporated into the utility estimate. We present further behavioral studies to validate predictions of the theory.

Consider a simple task in which you are asked to name the sum of two numbers, such as 14+8. Given sufficient time, you presumably produce the correct result; however, under speed pressure, mistakes can occur. In most all cognitive and motor tasks, such empirical *speed-accuracy trade offs* are observed: Individuals can respond slowly yet accurately, or quickly and be prone to errors. Speed-accuracy trade offs are due to the fact that evidence accumulates gradually in response systems over time (Rabbitt & Vyas, 1970). Responses initiated earlier in time will be based on lower quality information, and hence more likely to be incorrect. This paper addresses a simple yet fundamental form of cognitive control—the mechanism that governs the initiation of a behavioral response, and therefore, where an individual operates on the speed-versus-accuracy continuum. In the following section, we describe data that place constraints on the nature of control mechanisms. We describe shortcomings of existing theoretical frameworks that have tried to account for these data. We then present a framework that successfully explains key phenomena and makes further predictions which we have verified through additional behavioral studies.

The Blocking Effect

To understand the control mechanism that initiates responses, consider the variables that affect its operation. The mechanism is influenced by task instructions: individuals can choose to emphasize speed or accuracy. The mechanism is also influenced by recent performance: participants often slow down after producing an error (Rabbit & Vyas, 1970). Finally, even in the absence of errors, the mechanism is sensitive to the recent stimulus environment (Kiger & Glass, 1981): when items are presented in a sequence or *block*, reaction time (*RT*) and error rate to an item depends on the immediately preceding items.

This *blocking effect* is generally studied by manipulating item difficulty. Some items are intrinsically easier than others, e.g., 10+3 is easier than 5+8, whether due to practice or the number of cognitive operations required to determine the sum. By definition, individuals have faster RTs *and* lower error rates to easy problems. However, the RTs and error rates are modulated by the composition of a block. Consider an experimental paradigm consisting of three trial blocks: just easy items (*pure easy*), just hard items (*pure hard*), and a mixture of both in random order (*mixed*). When presented in a mixed block, easy items slow down relative to a pure block and hard items speed up. Thus, the control mechanism that initiates responses uses information not only from the current stimulus, but also adapts to the stimulus environment in which it is operating. Table shows a typical blocking result for a word reading task, where word frequency is used to manipulate difficulty. Based on our review of the blocking-effect literature (e.g., Lupker, Brown & Columbo, 1997; Lupker, Kinoshita, Coltheart, & Taylor, 2000; Taylor & Lupker, 2001), we summarize the central, robust phenomena as follows.

TABLE 1. RTs and Error Rates for Blocking study of Lupker, Brown, & Columbo (1997, Experiment 3)

	Pure Block	Mixed Block	Difference
Easy Item	488 ms (3.6%)	513 ms (1.8%)	+25 ms (–1.8%)
Hard Item	583 ms (12.0%)	559 ms (12.2%)	–24 ms (+0.2%)

(1) Easy items are faster *and* less error prone than hard.

(2) When intermixed, easy items slow down and hard items speed up. However, the convergence of RTs for easy and hard items in a mixed block is not complete. Thus, RT depends both on the stimulus type and the composition of the block.

(3) Speed-accuracy trade offs are observed: a drop in error rate accompanies easy-item slow down; a rise in error rate accompanies hard-item speed up.

(4) Blocking effects occur across diverse paradigms, including naming, arithmetic verification and calculation, target search, and lexical decision. They are obtained when stimulus or response characteristics alternate from trial to trial (Lupker et al., 2000). Thus, the blocking effect is not associated with a specific stimulus or response pathway, but rather is a general phenomenon of response initiation.

(5) Overt responses are necessary for obtaining blocking effects, but overt errors are not.

(6) A signature of the effect concerns the relative magnitudes of easy-item slow down and hard-item speed up. Significantly more speed up than slow down is never observed. The trend is that speed up is less than slow down—indeed, some studies show no reliable speed up—although equal magnitude effects are observed.

(7) The effects of stimulus history are local, i.e., the variance in RT on trial n due to trial $n–k$ decreases rapidly with k. Dependencies for $k>2$ are not reliable (Taylor & Lupker, 2001).

Explanations for the Blocking Effect

The blocking effect demonstrates that the response time depends not only on information accruing from the current stimulus, but also on recent stimuli in the trial history. Therefore, any explanation of the blocking effect must specify how control processes, which determine the point in time at which a response is initiated, are sensitive to the composition of a block. Various mechanisms of control adaptation have been proposed.

Domain specific mechanisms. Most of the proposed mechanisms are domain specific. For example, Rastle and Coltheart (1999) describe a model with two routes to naming, one lexical and one nonlexical, and claim that the composition of a block affects the emphasis that is placed on the output of one route or the other. Meyer, Roelofs, and Levelt (2003) manipulate word length and explain blocking effects in terms of a control process, sensitive to block composition, that decides when to initiate a naming response—either after the motor program for the first syllable has been generated, or after the motor program for the entire word has been generated. Because of the ubiquity of blocking effects across tasks, domain-specific accounts are not compelling. Parsimony is achieved only if the adaptation mechanism is localized to a stage of response initiation common across stimulus-response tasks.

Rate of processing. Kello and Plaut (2003) have proposed a *rate-of-processing* explanation, according to which control processes adjust a gain parameter on units in a dynamical connectionist model. The parameter determines the steepness of the sigmoid curve. Technically, the gain does not affect rate of processing, i.e., it does not simply rescale time. Increasing the gain does result in more rapid convergence, but it also yields a higher error rate; thus the account should more appropriately be framed in terms of adapting the *rate of convergence.* Simulations of this model have explained the basic blocking effect, but not the complete set of phenomena we listed previously. Of greater concern is the fact that the model predicts that naming *duration* decreases with increased speed pressure, which doesn't appear to be true (Damian, 2003; Kinoshita, unpublished).

Evidence criterion. A candidate mechanism with intuitive appeal is the trial-to-trial adjustment of an *evidence criterion*, which specifies the level of evidence that must accumulate in support of a decision before the response is initiated. Random walk and diffusion models have such a parameter, often called the response criterion (Ratcliff, 1978). According to this account, the evidence criterion is determined by recent trial history: if previous trials were easy, the criterion is set low, if previous trials were hard, the criterion is set high. Thus, the criterion would be lowest in a pure-easy block, intermediate in a mixed block, and highest in a pure-hard block. When the criterion is high, RTs are slower but error rates are lower, resulting in slow down of easy items and speed up of hard items in a mixed block.

Taylor and Lupker (2001) illustrate that adaptation of an evidence criterion can—at least in some models—yield incorrect predictions concerning the blocking effect. Strayer and Kramer (1994) attempted to model the blocking effect with an adaptive response criterion in the diffusion model. They managed to fit their blocking data but the account had two fatal shortcomings. First, they allowed different criteria for easy and hard items in a mixed block, which makes no sense because the trial type was not known in advance, and setting differential criteria depends on knowing the trial type. Second, they used a nonstandard blocking paradigm in which the trial difficulty depended on whether an item was presented in a pure or mixed block, easy items being more difficult and hard items being less difficult in a mixed block.

In spite of these problems, we were also convinced an evidence-criterion-adjustment explanation should be feasible. We used a somewhat different model of temporal dynamics and response initiation than Strayer and Kramer (to be described shortly), but like Strayer and Kramer, the model had an adaptive parameter that determined the trade off between speed and accuracy. After six frustrating months of exploration, we admitted defeat: The model was unable to obtain the right qualitative pattern of results; either the blocking effect was an order of magnitude smaller than that observed in experi-

ments, or went in the wrong direction. Several variants of the model came close, but were not robust; tiny changes to parameter values yielded qualitative effects on the pattern of results.

The failure of an evidence-criterion-adjustment account is not surprising from another perspective. On logical grounds, the relative importance of speed versus accuracy should be determined by task instructions and pay offs. Item difficulty is independent and unrelated factor. Consistent with this logical argument is the finding that manipulating instructions to emphasize speed versus accuracy does not produce the same pattern of effects as altering the composition of a block (Dorfman & Glanzer, 1988).

Adaptation to the statistics of the environment. Having ruled out three possible explanations, we sketch a fourth alternative, which is based on the premise that the goal of cognition is optimal and flexible performance across a variety of tasks and environments. In service of this goal, control mechanisms must be sensitive to the statistical structure of the environment, e.g., stimulus characteristics and configurations, response contingencies, etc. Previous models of control have exploited this assumption. For example, Treisman and Williams (1984) and Mozer, Colagrosso, and Huber (2002) considered a sequential choice task involving two response alternatives, and proposed that control mechanisms estimate prior probabilities of the two responses. If one response is more frequent, the larger prior induces a bias toward that response, which typically boosts performance.

Blocking effects can be explained via a related hypothesis. Because RTs depend on whether a trial is easy or hard, the control mechanisms responsible for response initiation must utilize an estimate of the item difficulty, or the quality of information available to response processes. If this estimate is unreliable (noisy), and if control mechanisms make the ecological assumption that the current trial is similar to recent trials, the estimate can be made more reliable by incorporating estimates from recent past trials. We elaborate this idea in a mathematical model of response initiation, and show that it can explain the key blocking phenomena listed earlier as well as other puzzling phenomena.

The ASE Model

We refer to our model as ASE, which stands for *Adaptation to the Statistics of the Environment*. Although the key claim of the model concerns the *mechanism of control adaptation* based on recent experience, we must make two additional sets of assumptions, one set concerning the *temporal dynamics* of information processing, and another set concerning the *decision criterion* for response initiation Although the specific assumptions we make are not critical, they must be made explicitly to fully flesh out the model.

Temporal dynamics. We need a way to characterize the temporal dynamics of information processing in tasks such as naming. The particular model of temporal dynamics is not critical, as long as it has the property that the quality of information available for responding increases gradually and monotonically over time.

We chose the probabilistic information transmission (PIT) model of Mozer, Colagrosso, and Huber (2002, 2003). To summarize the key properties relevant for the current work, the model consists of a cascaded series of processing *pathways* whose details are determined by the task being modeled. For example, to model a word naming task, we use a perceptual pathway that maps visual word forms to an internal semantic/lexical representation, and a response pathway that maps the internal representation to a distinct verbal naming response. Each pathway is a dynamic Bayesian network, and the conditional probability distributions in the model are specified by the nature of the mapping, the state of expertise being modeled, and the similarity structure among elements of representation. Given a stimulus presentation, the output of the model is a probability distribution over response alternatives as a function of time (Figure 1a). The response chosen at a particular time is a sample from the distribution (the model cannot choose the most probable response). The time course of processing depends on information transmission probabilities in the model. Easy, high frequency, and well practiced items have higher transmission probabilities, and hence are conveyed more rapidly.

This model is a generalization of random walk models and has several advantages. It provides a mathematically principled means of handling multiple alternative responses (necessary for naming) and similarity structure among elements of representation, and characterizes perceptual processing, not just decision making. The counter model (Ratcliff & McKoon, 1997) or connectionist integrator models (e.g., Usher & McClelland, 2001) could also serve us, although the PIT framework has an advantage in that it operates using a currency of probabilities—versus more arbitrary units of *count* or

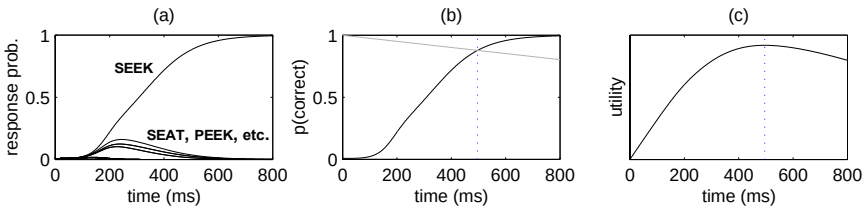

FIGURE 1. (a) Output of the probabilistic information-transmission model for presentation of the stimulus, e.g., SEEK, on a word naming task. (b) Treating the most probable output is an estimate of accuracy (light line is the time threshold). (c) Utility function based on most probable output (dashed line = time of maximum utility)

activation—which leads to explicit, interpretable decision criteria and adaptation mechanisms, and requires fewer additional assumptions to translate model output to predictions of experimental outcomes.

Decision criterion. To model blocking effects, we must make an explicit assumption concerning the decision criterion used for response initiation. A simple speed criterion (i.e., respond at α milliseconds following stimulus onset) or accuracy criterion (i.e., respond when the error rate is below α) is inadequate, because easy items are both faster and more accurate than hard items in pure blocks. Ratcliff's (1978) diffusion model uses an evidence threshold, which effectively yields an accuracy criterion that declines over time. We adopt this notion, as illustrated by the gray line in Figure 1b. The line is characterized by one free parameter, the slope κ. This criterion can be recast in an optimization framework: A response is initiated at the point in time that maximizes *utility*, where utility increases with expected accuracy and decreases with time (Figure 1c). Previous psychological theory has suggested that individuals can choose the optimal point at which to respond (Mozer et al., 2002; Rabbitt & Vyas, 1970; Triesman & Williams, 1984).

To summarize, we propose a theory premised on five key assumptions. (1) Transmission of stimulus information to response systems is gradual and accumulates over time. (2) Control mechanisms respond at the point in time that maximizes a utility measure that depends on both expected accuracy and time. (3) During ongoing processing, the system is able to compute an estimate of its response accuracy for the current stimulus. (4) This estimate is unreliable. (5) If control systems make the ecological assumption that the current trial is similar in difficulty to recent trials, the accuracy estimate can be made more reliable by incorporating estimates from recent trials.

An accuracy estimate can be obtained from the PIT dynamics by assuming that the most probable output at a point in time is correct (Figure 1b); we refer to this as curve as the *current accuracy trace (CAT)*. Given the response criterion (grey line, Figure 1b), a response initiation time can be determined (dashed line).

If the model's transmission probabilities are noisy, the CAT is a high-variance estimate of accuracy, because the assumption that the most probable response state is correct may be wrong. The suggestion of noise is not arbitrary, but rather is a central claim of the diffusion model, and has been key to explaining a variety of RT data. To overcome this noise source, it is sensible for control mechanisms to rely not solely on the CAT, but on accuracy traces from recent trials. We claim that the model maintains a *historical accuracy trace (HAT)*, and the trace used for estimating utility—the *mean accuracy trace (MAT)*—is a weighted average of CAT and HAT, i.e., $\mathrm{HAT}(n) = \lambda\mathrm{CAT}(n-1) + (1-\lambda)\mathrm{HAT}(n-1)$, where n is an index over trials, and $\mathrm{MAT}(n) = \theta\mathrm{CAT}(n) + (1-\theta)\mathrm{HAT}(n)$; λ and θ are averaging weights. Figure 2a depicts the CAT, HAT, and MAT. The two solid curves represent CATs for easy and hard trials, as well as the MATs for pure blocks. The dotted curve represents the expected HAT in a mixed block—an average of easy and hard CATs. The dashed curves represent the MATs for easy and hard trials in a mixed block, formed by averaging the HAT and corresponding CAT. Because the CAT and HAT are time-varying functions, the notion of averaging is ambiguous; possibilities include averaging the accuracy of points with the same time value and times of points with the same accuracy value. It turns out that the choice has no qualitative impact on the simulation results we present. The essential requirement is that the computation to determine response-initiation time can be performed in real time, including identification of the utility maximum.

Modeling Blocking Effects

Figure 2b provides an intuition concerning the model's ability to replicate the basic blocking effect. The mean RT for easy and hard items in a pure block is indicated by the point of intersection of the CAT with the time threshold. The mean RT for easy and hard items in a mixed block is indicated by the point of intersection of the MAT with the time threshold. The easy item slows down, the hard item speeds up. Because the rate of processing is not affected by the blocking manipulation, the error rate will necessarily drop for easy items and rise for hard items. Although the RTs for easy and hard items come together, the convergence is not complete as long as $\theta > 0$. The theory thus explains the first three phenomena of Section 1. The fourth phenomenon, that the effects occur across diverse paradigms, is consistent with the theory: the theory concerns the response curves, but not the stimulus or response modalities or domains that underlie the curves. Consequently, cross-task blocking effects are implied by the theory. The theory is consistent with the observation that blocking effects occur even in the absence of overt errors, because the theory is neutral with regard to error production, and only if response mechanisms are engaged (phenomenon 5). If responses are not produced, the

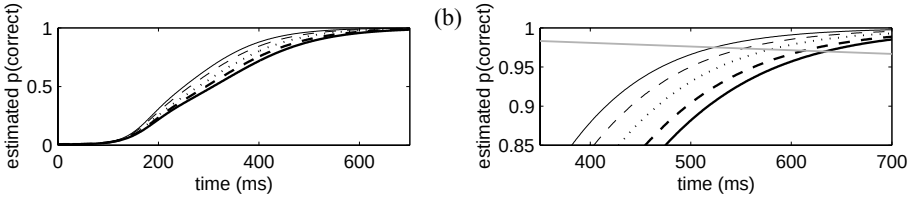

FIGURE 2. (a) easy and hard CAT (solid), mixed block HAT (dotted), and easy and hard MAT (dashed); (b) close up of the traces, along with the decision threshold

Hard	514 ms	467 ms	–47 ms	514 ms	470 ms	–44 ms

response-accuracy curves need not be generated, and the averaging process that underlies the effect cannot occur.

The fact that hard-item speed up is never greater than easy-item slow down (phenomenon 6) turns out to be a key diagnostic. Our initial candidate models tended to yield more speed up than slow down because the magnitude of RT change was proportional to the RT, and hard RTs are larger than easy RTs. Empirically, the error-averaging model we propose never yields more speed up than slow down. As shown in Figure 2b, the mixed-block MAT (dashed) hugs the pure-block MAT (solid) more tightly for hard than easy items. The asymmetry is due to the fact that the easy CAT reaches asymptote before the hard CAT. The model produces more symmetric blocking effects when responses are initiated at a point where both easy and hard CATs are ascending at the same rate (leading to high error rates, unlike the behavioral data). However, we were unable to find model parameters that produced the invalid pattern of more speed up than slow down.

Beyond providing qualitative explanations for key phenomena, the model fits specific experimental data. Taylor and Lupker (2001, Expt. 1) instructed participants to name high frequency words (easy items) and nonwords (hard items). Table 2 compares mean RTs and error rates for human participants and the simulation. One should not be concerned with the error-rate fit, because measuring errors in a naming task is difficult and subjective. (Over many experiments, error rates show a speed-accuracy trade off.) Taylor and Lupker further analyzed RTs in the mixed block conditional on the context—the 0, 1, and 2 preceding items. Figure 3 shows the RTs conditional on context. The model's fit is excellent. Trial *n* is most influenced by trial *n–1*, but trial *n–2* modulates behavior as well; this is well modeled by the exponentially decaying HAT.

Simulation details. Parameters of the PIT model were chosen to obtain pure-block mean RTs comparable to those obtained in the experiment and asymptotic accuracy of 100% for both easy and hard items. We added noise to the transmission rates to model item-to-item and trial-to-trial variability, but found that this did not affect the expected RTs and error rates. We fixed the HAT and MAT averaging terms, λ and θ, at 0.5, and picked κ to obtain error rates in the pure block of the right order. Thus, the degrees of freedom at our disposal were used for fitting pure block performance; the mixed block performance (Figure 3) emerged from the model.

Asymptotic Effect of Context

In the standard blocking paradigm, the target item is preceded by a context in which roughly half the items are of a different difficulty level. We conducted a behavioral study in which the context was maximally different from the target. Each target was preceded by a context of ten items of homogeneous difficulty, either the *same* or *different* difficulty as the target. This study allows us to examine the asymptotic effect of context switching. We performed this study for two reasons. First, Taylor and Lupker (2001) obtained results suggesting that a trial was influenced by only the previous two trials; our model predicts a cumulative effect of all context, but diminishing exponentially with lag. Second, several candidate models we explored predict that with a strong context, speed up of hard is significantly larger than slow down of easy; the model we've described does not.

The results are presented in Table 3. The model provides an excellent fit to the data. Significantly larger context effects are obtained than in the previous simulation (~50 ms in contrast to ~25 ms), and—given the strong context—the easy items become slower than the

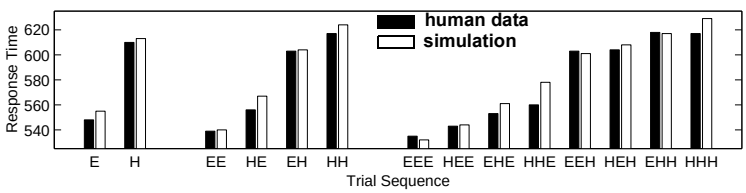

FIGURE 3. RTs from human subjects (black) and simulation (white) for easy and hard items in mixed block, conditional on 0, 1, and 2 previous item types. Last letter in a string indicates the current trial and first letters indicate context. Thus, "EHH" means a hard item preceded by another hard item preceded by an easy item.

TABLE 4. Simulation of validity-modulating masked priming effect

	Repetition-Prime Trial	Unrelated-Prime Trial	Priming Effect
20% valid	560 ms	585 ms	25 ms
80% valid	515 ms	580 ms	65 ms

hard (although this effect is not statistically reliable in the experimental data). Further, both data and model show more slow down that speed up, a result that allowed us to eliminate several competing models. For this simulation, we fit parameters of the PIT model to the same-context results. We also treated the MAT averaging constant, θ, as a free parameter on the rational argument that this parameter can be tuned to optimize performance: if there is not much variability among items in a block, there should be more benefit to suppressing noise in the CAT using the HAT, and hence θ should be smaller. We used 0.35 for this simulation, in contrast to 0.5 for the first simulation.

Reinterpreting Other Experimental Findings

In many studies, contrasts are made between experimental blocks whose composition varies in terms of the proportion of easy and hard items. In such cases, our model may provide an alternative interpretation of experimental results. Consider a subliminal priming study in which participants are asked to perform lexical decision on a target string preceded by a masked prime (Bodner & Masson, 2001). The prime and target could be identical or unrelated. Although the prime was subliminal—not accessible for report—a repetition priming effect is observed: lexical decision RT to a target is faster if the prime is identical to the target. Subliminal repetition priming effects are common in the literature, but what is surprising in this study is that *prime validity* influences priming: The priming effect is larger when the prime and target are identical on 80% of trials (high validity) than when they are identical on 20% of trials (low validity). Bodner and Masson suggest that "recruitment of the prime resource to assist target processing should be more likely when the...prime validity...is higher." (p. 618). This counterintuitive explanation implies that the prime is analyzed deeply: its match to the target is determined, prime validity is estimated, and the estimate is available for strategic control.

Our model offers an alternative account. The repetition prime makes a trial easy because the prime activation supports the target, and the unrelated prime makes a trial relatively hard. Low and high validity conditions are thus mixed blocks containing 20% and 80% easy trials, respectively. We ran a simulation to show that these mixtures yield a blocking effect consistent with the reduction of priming in the low validity condition (Table 4). In the model, the prime influences the time course of information transmission, which modulates the model's response-initiation criterion on future trials—a simpler, more elegant account than Bodner and Masson's.

Conclusions

Theories in cognitive science occasionally hand the problem of control to a homunculus. More commonly, control processes are left unspecified. And when implemented, control generally involves explicit, active, and sophisticated mechanisms. We have described a model that achieves an interesting sort of control—sequential adaptation of the speed-accuracy trade off. However, the mechanism that gives rise to this adaptation is passive and in a sense dumb; it essentially reestimates the statistical structure of the environment by updating an expectation of task difficulty. Our hope and belief is that many aspects of cognitive control can be explained away by such simple, passive mechanisms, eventually eliminating the homunculus from cognitive science.

Abstract

What is the current U.S. immigration rate? Policy-makers, voters, and consumers should have a sense of quantities of this kind in order to help shape effective policies, and schools must prepare students for such roles. We examine the Numerically-Driven Inferencing paradigm (NDI), using a method in which participants: *Estimate* policy-relevant quantities, state *Preferences* for these, receive actual quantities as feedback to *Incorporate*, and offer preferences again to exhibit any policy *Changes* (EPIC). Past work has generally suggested rather poor estimation of such base rates, but there is potential for improvement as one carries out many estimates over various issues, and perhaps a benefit for taking a more analytic approach to estimation. Here we consider whether one can improve estimation skills broadly by using multiple perspectives in estimation problems, and by working out of conflicts that arise among multiple, locally coherent, numerical understandings. Using an NDI curriculum that emphasized disconfirmation, we found that estimation improved across a wide variety of questions.

What is the current annual U.S. immigration rate (including both legal and illegal immigration)? Please take a moment to estimate this quantity, and reflect on the kinds of skills you used to generate your estimate. One might assume that those who know about immigration issues are good at estimating immigration rates, while those who know about environmental issues are good at estimating per capita garbage production, but that there is no general skill for estimating across content domains. Research on estimation suggests that people can improve the accuracy of estimates in a variety of ways, including using category information (e.g., Huttenlocher, Hedges, & Prohaska, 1988), or learning relevant "seed" numbers (e.g., Brown & Siegler, 2001), but there is no indication that such benefits transfer broadly to estimation over a wide variety of quantities, to say nothing of problem solving skills more generally. However, we suggest that in domains ranging from estimation to physics problem-solving, it is important to learn to seek alternatives to initial conceptions of problems, which brings the possibility of disconfirming hypotheses. The potential value of such a strategy is illustrated Johnson-Laird and Hasson (2003), who have found that when some premises are consistent with an invalid conclusion, counterexamples are useful in rejecting the conclusion. The focus of the present paper is on the extent to which analytic estimation skills can transfer broadly, so that people might improve their estimates for quantities across a broad range of issues without specific instruction on those issues.

Theoretical Framework

This project builds on the Numerically-Driven Inferencing paradigm (NDI; Ranney, Cheng, Nelson, & Garcia de Osuna, 2001), which examines how understandings of relevant base rate information (e.g., the present U.S. immigration rate) affects people's attitudes on public policy issues (e.g., given the immigration rate, what would you *prefer* that rate to be?). With NDI's methods, people need not be asked whether they are for or against a particular issue, but rather what they would prefer the *numbers* to be. Indeed, it is not uncommon that those who consider themselves to be in favor of reducing immigration (e.g., believing the current base rate of a policy-relevant quantity to be 10%, one might prefer 5%) have more in common than they realize with those who claim to favor an increase (e.g., believing the rate to be 1%, but sharing a preference for 5%). However, if such people were only asked the extent to which they favor or oppose an issue, they would appear to be at odds. In contrast, NDI asserts that qualitative attitudes have some—albeit not necessarily direct—relationships with relevant quantities, and aims to explore the nature of the relationships. By focusing on numerical concepts, NDI can shed light on how these concepts interact with people's initial attitudes, and the extent to which learning actual values shapes subsequent attitudes: Do we maintain preferences for the same *absolute* rates, or for the same *proportions* relative to actual rates? To what extent do we shift our policy stances after surprising feedback (Munnich, Ranney, Nelson, Garcia de Osuna, & Brazil, 2003)?

NDI builds on research in many fields, such as attitude, conceptual change, mental models, and judgment and decision-making (although NDI deals directly with base rates—not through Bayesian analyses). In particular, NDI has drawn on work in scientific conceptual change including the Theory of Explanatory Coherence (TEC; Ranney & Thagard, 1988; Thagard, 1989), which describes change as spawned by incoherence and conflicts among ideas, such that people try to revise their beliefs to increase global coherence. In an illustration of this, Ranney, Schank, Mosmann, and Montoya (1993; based on a misconception noted by Keysar, 1990) found that most participants initially believed that Berlin lay *on* the East/West German border, but revised their beliefs as they incrementally received

information that could be used to disconfirm "on-border" hypotheses (e.g., they were told/reminded of the Berlin airlift, the Western Allies' agreement to halt their troops far west of Berlin, Berlin's location within united Germany, and northern and southern ends of the border). With each successive piece of evidence, participants moved toward a more accurate view of Berlin's location relative to the border, suggesting that they modified their belief networks to maintain coherence in the face of the new information.

According to TEC, evidence that is critical, germane, and credible carries considerable weight in our belief systems. Within NDI, we seek to understand when and how a particular kind of evidence that meets these criteria—numerical propositions—can catalyze knowledge-transforming effects. NDI asserts that estimates and numerical preferences are outputs of our belief systems—the tips of a "reasoning iceberg." One's understanding of an issue may be thought of as a network of ideas connected by personal experiences, media, religion, etc. When asked to estimate an immigration rate, few can simply recall it. Instead one activates various understandings about immigration that shape the estimate. Likewise, numerical preference is an output from an extensive belief network that lies below the surface of overt response. For example, one might believe the assumed immigration rate to be acceptable and simply reiterate one's estimate as one's preference (a status quo policy). However, if later surprised by the actual immigration rate, one's sense of reality is challenged, and one might come to the conclusion that prior reasoning was incorrect or incomplete.

In this conception, the iceberg's "bulk"—the belief network from which estimates and numerical preferences emerge—may be transformed by the impact of feedback. As such, NDI can offer rich, quantitative findings to cognitive scientists concerned with the dynamics of belief networks. In this paper, we consider *curricula* based on NDI, designed to facilitate the recruitment of multiple, locally coherent understandings that can mutually constrain one another. Just as feedback that conflicts with one's numerical understanding might lead to a transformation, when one spontaneously seeks to disconfirm one's own numerical hypotheses by bringing alternative numerical notions to bear, it may lead to revisions that bring one's belief network into closer alignment with facts of the world. Such a transition would be evidenced by improved estimation across a wide range of issues.

NDI Findings That Frame the Issues

To address NDI, Ranney and colleagues developed a variety of methods, including EPIC (Estimate-Prefer-Incorporate-Change), which is used in this paper: (1) Participants *estimate* a quantity that is relevant to an issue, as you did for the U.S. immigration rate at the beginning of this paper. (2) Participants indicate what they *prefer* the quantity to be; to familiarize yourself, please write down what you would prefer the U.S. immigration rate to be (including both legal and illegal immigration). (3) Participants receive correct base rate feedback to *incorporate*; now, please look at the actual immigration rate in the footnote below.[1] Finally, (4) participants indicate again what they prefer the quantity to be; has your preference *changed* now that you know the actual number? We have found that, to the extent feedback is surprising, it generally leads to nontrivial belief revision. So far, research on estimates within NDI has focused on a rather short period of time, but an obvious extension of this work is to consider (a) whether estimation skills can *improve* with targeted interventions, and (b) the extent to which there may be broad transfer.

Illustrations of the kinds of alternative conceptions that people can have comes from Munnich et al. (2003), who reported differential patterns of estimation for the same underlying question: One group was asked to estimate the number of abortions in the U.S. *per million live births,* while a second group drawn from the same undergraduate class estimated the number of abortions in the U.S. *per million fertile women* each year. The results showed a striking contrast in numerical understanding, depending on how the question was framed: For the *per-women* question the median response (10,000) was *half* the correct answer at that time, but for the *per births* question, the median estimate (10,000 as well, coincidentally) was *33.5 times* too low at the time the study was conducted.[2] Could people perhaps improve their estimates of abortions per live births by considering how many abortions there are per fertile women? More broadly, what might happen when people bring together alternative conceptions and resolve conflicts on their own, without external feedback? To address this issue, McGlothlen (2003) interviewed high school students as they produced estimates and numerical preferences for a variety of issues, and reported on their online reasoning processes. She coded responses as analytic—containing relevant numerical information and constraints—or holistic—based on a feeling or general sense of the issue. McGlothlen found that estimates reached through an analytic process were significantly more accurate than those reached through a holistic process. This leads us to the following hypothesis:

> An analytic approach invokes multiple locally coherent numerical representations that provide mutual constraints among themselves, leading to more refined, more globally coherent, and hence more accurate estimates than would be observed if only one representation were invoked.

To discover whether there is a causal relationship between invoking multiple representations and accuracy, we might manipulate the degree to which people take an analytic approach. Below, we discuss an experiment in which the analytic process is explicitly emphasized in the instruction given to one group of students, and the accuracy of this group's estimates, pre- and post-instruction, is compared to

[1] The U.S. Census Bureau reports that the annual U.S. immigration rate, including legal and illegal immigrants, is 0.4%.

[2] Garcia de Osuna, Ranney, and Nelson (2004) observed a median of 5,000, sixty-seven times too low.

a parallel group who received no such instruction. If those taught analytic strategies show greater estimation accuracy, it would provide causal evidence for the benefit of an analytic approach.

Previous Curricular Interventions

In several recent studies, our group has observed estimation accuracy benefits, arising from practice with forming estimates and generating preferences. These activities are unusual for math or science classes, for which problems are generally solvable in straightforward ways by applying formulas and principles. Our curricula illustrate the utility of mathematical and scientific reasoning through our use of problems about issues that students find interesting. We ask students for societally-relevant opinions, which is virtually unheard of in math classes. These factors motivate students in ways that standard curricula may not, and shows benefits for estimation ability with relatively little practice.

In one such intervention, Curley (2003) and Howard (2003) gave fifth-grade science camp students standard physics labs about the stopping distances of vehicles. An Experimental class received NDI problems to frame the labs, while a Control class did not. Both classes took a pretest with estimation and preference problems, then a posttest with a different set of items three days later.[3] In this between-subjects design, Curley and Howard observed improvement in estimation accuracy for *both* classes on items about U.S. household income and the number of alcohol-related automobile crashes. Notably, the only NDI experience that the Control class received was during the pretest, suggesting that exposure to such items alone might be sufficient to improve estimation abilities.

In a later study, Juan (2003) found similar effects among eighth-grade Algebra students. Her Experimental class received one NDI problem per day for three days, followed by graphing activities and class discussions on estimates and preferences. In contrast, the Control class received standard algebra instruction. All students took a pretest and a posttest, in which they estimated twelve quantities (six per test). Questions dealt with issues such as California's population and teachers' salaries. On each test, students estimated and offered preferences before and after feedback for two items, and simply estimated for the remaining four items. Experimental students showed a significant overall gain between pre- and posttest estimates, while the Control class showed only a marginally significant improvement. However, an additional sign test between groups showed no advantage for the Experimental class.

The studies discussed up to this point showed minimal benefit for the curricula themselves—while both Experimental classes improved, the Control classes may have also benefited just from their pretest experience with NDI. This raised the possibility that one may improve estimation merely by working on NDI problems. Before drawing this conclusion, we carried out the following experiment, which lasted much longer than past interventions, and focused not on content areas like physics or college costs, but on analytic techniques aimed at improving students' general estimation abilities.

[3] When we ask for preferences, the objective is to assess how students' numerical understandings affect their preferences, not to make a normative assessment.

A Focal Experiment

Method

Two high school geometry classes participated, each with 27 students. Both classes received a normal geometry curriculum, but the Experimental class spent 12% of their time over a ten-week period on activities centered on six NDI questions. Activities included discussions and written reflection aimed at promoting the analytic responses that McGlothlen (2003) found to correlate with successful estimation. In addition, explicit connections were made between logical argumentation about issue-relevant quantities and the argumentation required in geometric proof. Due to limited space, we omit discussions of possible benefits regarding student motivation and the transfer of argumentation skills from NDI to geometric problems.

Table 1: Pretest, Intervention, and Posttest Questions
(Group B received the pre- and posttest in reversed order)

Pretest (Group A)	**Intervention**	**Posttest** (Group A)
Average US age	CA population	Cars per driver
Athlete salary	College vs. H.S. grad earnings	College degrees (%)
College cost	H.S. dropout rate	Homes-with-computers
Miles driven/Year	Athlete salaries by gender	% Female teachers
Commute time	Poverty line	Garbage per person
Incarceration rate	US oil imports	Hours of sleep
Soda calories		Inflation
Homes-with-TVs		Voting percentage
US population		Teacher salary
		Car price

On Thursday of each week, students generated estimates and preferences for a given quantity as homework (see Munnich et al., 2003, for examples of how such items are worded). In class on Friday, they discussed their estimates in groups and generated a group estimate, in which they: (a) provided a consensus estimate, (b) explained their rationale for that number, (c) provided rationales for a number considerably higher than their estimate, and for a number considerably lower than their estimate. This was followed by a short class discussion to acquaint students with alternative approaches that their classmates had taken. Between hearing classmates' arguments and generating rationales for estimates and preferences other than their own, students were encouraged to engage in problems analytically, considering the strengths and weaknesses of various constraints that might be placed on the estimate.

The following Monday, students' original estimates and preferences were returned, along with the actual number as feedback. From Monday to Tuesday, they generated final

preferences, based on the feedback and any insights they gleaned from group discussions. Finally, on Tuesday, students discussed their preferences in groups and generated arguments that might be used by one who preferred (a) decreasing the quantity, (b) maintaining the status quo, and (c) increasing the quantity. As with estimation discussions, this was followed by a whole class discussion on preferences.

To measure the intervention's effects, both Experimental and Control classes were given ten NDI items as a pretest, and then, ten weeks later, ten different NDI questions as a posttest (an immigration rate item was excluded when it became clear that responses were bizarrely high in many cases; students also reported numerous misinterpretations). Questions were counterbalanced so that the items that half of each class saw on the pretest (Group A in Table 1) appeared on the posttest for the other half of each class, and vice versa. Students were asked to generate estimates and preferences, and were then handed a separate sheet of paper with the actual quantity, which also elicited a Likert surprise rating and their final preferences. Students received two items per day for five days (as past studies indicated that fatigue sets in when students receive many items on a single day). Each of the ten problems was presented in the same order to all students, minimizing any benefit for discussing items with classmates in unintended ways.

Results and Discussion

All estimates (for both classes, pre- and posttest) were ranked by proximity to the actual value for each item, in order to put data from questions with different scales onto one common scale (i.e., accuracy rankings). Between-group analyses on the rankings assessed whether there were differences between the classes, and whether each class improved from pre- to posttest. Mann-Whitney tests showed no reliable pretest difference between Experimental and Control classes (z=1.04, n.s.). On the posttest, however, the Experimental class estimated reliably more accurately than Controls (z=3.29, p<.001). Further, while there was no difference among Controls on pre- and posttests (z=0.41, n.s.), Experimentals showed a significant improvement (z=2.74, p=.003). These effects indicate that the intervention led to improved estimation of novel quantities (i.e., transfer).

To explore the effect's loci for the Experimental class, planned Mann-Whitney comparisons were performed separately on each item. Participants improved significantly on three items (U.S. population, z=2.49; cars per driver, z=1.97; hours of sleep, z=1.96; ps<.05), and marginally on three other items (college cost, z=1.48; teacher salary, z=1.36; miles driven/year, z=1.19; ps<.10). Among these items, we see patterns of both near and relatively far transfer from the intervention. The only one of these items that was directly related to one of the intervention questions was that on U.S. population (i.e., related to an question on California's population in the intervention). The other items range from those that seem to have only an indirect relationship with intervention items (e.g., "teacher's salary" may be related to "H.S. vs. college grad earnings," although teachers' incomes are closer to the incomes of high school graduates than to those of other college graduates), to items that have no obvious relationship with the intervention problems (e.g., hours of sleep the average person gets).

The results point to benefits from an intervention focused on analytic approaches to estimation. Looking more closely, we found both transfer among highly similar questions, as well as the relatively far transfer of general estimation skills to seemingly unrelated quantities. These findings are in line with the hypothesis that multiple numerical representations provide constraints on one another and can lead to more globally coherent estimates. The difference between the classes was that, although both had experience with estimation and giving preferences on the pretest, the Experimental class received a curriculum that engaged them in discussions of multiple perspectives in estimation and numerical preference. These results are rather surprising if one believes that estimation ability is not a broadly transferable skill. Given the variety of topics covered by items on the pre- and posttests, it is unlikely that the Experimental class could have learned the vast array of new facts about the world necessary to drive observed improvements. Rather, they appeared to use their extant numerical knowledge about the world more constructively than before.

Why did students improve broadly in estimation? McGlothlen (2003) found that those who invoked a richer repertoire of analytic tools estimated better than those who used a more holistic/feeling approach. With this in mind, one explanation for the Experimental students' improvement is that the intervention moved them towards a more comprehensive approach to estimation. Our lab is conducting ongoing research to examine other possible causes for students' improved performance. One such possibility is that Experimental students enjoyed the curriculum and were simply more motivated than Controls to complete the posttest exercises. If this were the source of improvement, we would expect Experimental students to spend more time on solutions, and report more interest in the task, but we would not expect to see greater richness in the strategies they employ. Another possibility is that Experimental students benefited from the recency of their practice with estimation during the intervention. If this caused the difference between the groups, then, again, although Experimentals gave more accurate estimates, we would not expect subsequent analyses to show that they used richer strategies than Controls. We cannot reject this possibility at present, but we find it highly unlikely, as estimation curricula are generally quite taxing for students: Our prior results indicate that without a particularly engaging curriculum, more recent practice leads to a performance decrement, presumably due to fatigue.

General Discussion

Many propositions inform our social preferences (e.g., Ranney & Schank, 1998), but to illustrate the role played by numbers, consider whether your immigration preference would change if you made an estimate that was highly inaccurate. What sort of numerical feedback might call your assumptions into question, leading you to a different preference? Preferences are central to human cognition, and *numerical* preferences provide useful sources of evidence regarding conceptual change. Numerical preference represents a concrete way in which mathematics is relevant to our lives, and contributes to discussions of quantitative literacy in math education. By ignoring base rates, voters or political candidates may take stands that conflict with what they would otherwise prefer. Of course, some people take *absolute stances* on particular issues, such as completely eliminating abortion; as such, they imply that the numbers are irrelevant to their beliefs on the issue, and we would not expect them to change their preferences after feedback very often (Ranney et al., 2001). For those who indicated nonzero preferences, Munnich et al. (2003) found two main patterns: First, those who were less surprised by base rates generally *proportionately rescaled* their preferences—those who preferred halving the abortion rate initially, still preferred halving the actual rate when it was revealed. This suggests the base rate was belief-relevant, but that it did not inspire dramatic revisions of belief networks. Second, those who were more surprised by feedback showed *policy shifs*—accommodative belief revisions—for instance, those who preferred halving the abortion rate initially, but were surprised by the actual rate, indicated final preferences notably more or less than half of that rate (see Garcia de Osuna, Ranney, & Nelson, 2004, for more discussion of the qualitative nature of such shifts).

Even when considering the same issue, people can arrive at markedly different estimates and policies, depending on how the issue is framed (cf. Schwarz, 1999). As noted earlier, when Munnich et al. (2003) asked for the number of abortions per live births, the median response was 33.5 times too high. With their estimates so far off, what happened with these people's preferences? After feedback, they showed a policy shift—a 64% more reductive policy than they had initially indicated. By contrast, when participants estimated the number of abortions per fertile women, the median estimate was much closer—half the actual number. Rather than shift policies, for the fertile-women variant, participants merely rescaled their preferences to adjust to their new understanding of the number. In other words, when a quantity (e.g., the number of abortions performed each year) is framed in different ways, people show vastly different abilities in estimating the quantity, and this strongly affects their preferences after they learn the actual numbers.

Our hypothesis in this paper focused on the estimation side of NDI, but there are also implications for preference. When an intervention successfully fosters estimation ability, what might we predict, regarding people's preferences? One possibility is that as estimates improve, feedback-driven surprise will abate, and policies will stabilize, producing *less* subsequent policy shift. However, it is also possible that when estimates improve, people might become more sensitive to numbers, and attach more importance to small errors, yielding *more* policy shift**.** Note that while some of our past studies showed framing effects, they did not focus on people who recruited relevant facts to frame issues in different ways for *themselves*. When an individual integrates multiple constraints without prompting, the effects may be quite different than what we see with more passive participants. In analyses of the preference data gathered along with the estimation data reported above, we find support for both possibilities—while some participants appear to shift policies less after intervention, others seem to be more sensitive to small changes in numbers, and thus shift less. In aggregate these effects largely cancel each other out. A more in-depth analysis of individuals' changes in estimation ability, surprise levels, and preferences is being conducted to determine how each phenomenon contributes to the overall pattern of results. One possible benefit of this research may be in teaching people to construct policies that are less susceptible to rhetoric. That is, as people adopt more analytic strategies (assuming this is why estimates improve in our curricula), when they hear a quantity in advertisements or on the news, they might think of the issue several different ways and generate a preference that is constrained by other numbers they have considered.

Beyond transfer to tasks involving numerical understanding, what other forms of transfer might exist? NDI problems can be considered examples of "Fermi Problems," after the physicist who famously posed queries such as "How many piano tuners are there in Chicago?" Few, if any, can simply *recall* answers to Fermi questions, but through successive approximations and drawing on other known quantities, one can approach the correct answer. When Fermi questions are posed—often by potential employers or as classroom exercises—the implicit assumption is that one's answers are indicative of general analytic ability and creativity in problem solving. It is not difficult to imagine that NDI-type interventions might benefit reasoning about the location of Berlin relative to the former East-West border: With analytic techniques, one could do for oneself what Ranney et al. (1993) did for their participants—foster the integration of multiple, mutually constraining, perspectives into a solution.

More broadly, was Fermi's physics problem-solving ability related to his ability to estimate the number of piano tuners in Chicago? Much of the problem solving literature indicates little *general* transfer of problem solving skill across divergent domains (Singley & Anderson, 1989), so this may initially seem unlikely. However, we note that one of Ranney and Thagard's (1988) participants ("Pat") reached a more sophisticated understanding of projectile motion through the same kinds of processes that we have argued to underlie strong numerical reasoning. Pat initially believed that a ball dropped by a walking person would fall

straight to the ground. Later on in her verbal protocol, she contemplated the motion of a ball thrown obliquely upwards, and decided that it would follow an arc-shaped trajectory. Upon realizing this, it occurred to her that, from the zenith of its trajectory to the ground, the ball would descend analogously to a ball dropped while walking. Accordingly, she concluded that the two trajectories must have a similar arc-shape. Pat thus revised her view of the path of the dropped ball to a (more accurate) curved trajectory. This example illustrates the potential generality of the analytic skills that are useful in numerical reasoning: In both physics and estimation, we seem to benefit from using alternative representations, and then resolving conflicts among them. The degree to which one skill transfers to another is a worthy topic for future research.

Summary

It is critical that citizens and consumers be able to make decisions on numerically laden issues. We found that people can improve their numerical understandings through activities emphasizing the consideration of multiple perspectives and the integration of mutual constraints, and we discussed possible implications of such findings for individuals' policy stances. We propose that improvements in estimation abilities arose from an analytic approach that this intervention cultivated, leading students to seek evidence that might disconfirm their initial hunches. Such an approach might have value beyond the numerical and policy realms, with respect to more general reasoning and problem solving skills. In these ways, classroom interventions that test aspects of the emerging theory around the Numerically-Driven Inferencing paradigm have the potential to answer questions of fundamental interest to both cognitive science and society.

Workload is Bad, Except when it's Not: The Case of Avoiding Attractive Distractors

Abstract

Increased cognitive workload is typically considered to hinder task performance. The current study presents an example where increased workload *aided* a visual search task. Increased workload, via a secondary task, provided participants extra time to avoid distracting stimulus configurations. Furthermore, initial fixations on distracting densities occurred at higher frequencies when initial saccades lasted less–than 400 milliseconds. We conclude that the combination of the primary visual search task and the secondary task create an environment where the secondary task was *beneficial* to the visual search task.

Introduction

There is a rich literature demonstrating how visual stimuli affect visual search patterns (Findlay, 1982, 1997; He & Kowler, 1991; McCarley, Kramer, & Peterson, 2002; Pomplun, Reingold, & Shen, 2003; Rayner, Liversedge, White, & Vergilino-Perez, 2003; Wolfe, Cave, & Franzel, 1989; Zelinsky, 1996). However, few studies have focused on how *stimulus configurations* influence eye movements. An example of a stimulus configuration is differences in inter-stimulus distance, or *density*. Stimulus density can be easily manipulated. Increasing the inter-stimulus distance decreases density, and vice-versa. There is also little research describing the effects of increased workload on visual search. Do visual search strategies change as a function of workload? In this paper, we address workload and stimulus configuration effects on visual search.

Previous research suggests that saccades are programmed and targeted in an automatic, data-driven fashion. Data-driven processes shape overt behavior via environmental factors, and are typically considered unconscious processes. There are two striking examples that suggest data-driven processes determine saccadic endpoints. The first example is the *global effect* (Findlay, 1982, 1997). The global effect occurs when saccadic endpoints land at intermediate target positions during abrupt onset tasks containing at least two stimuli. That is, when two stimuli appear to the right or left of an initial fixation point, saccadic endpoints tend to be located between the stimuli. The global effect provides evidence that global target configurations influence saccadic amplitude. It appears that saccadic processes use stimulus attributes such as spatial properties in determining endpoints.

The second example is the *center–of–gravity effect* (He & Kowler, 1991). The center–of–gravity effect indicates that saccades directed toward a shape land at consistent locations near the center of the shape, and that the shape's contour information is all that is necessary for consistent saccades. The two effects taken together suggest that the saccadic mechanism relies on spatial properties of stimuli when determining saccadic endpoints.

The amount of influence deliberate, top-down strategies have on saccadic endpoint location is still unclear. However, it is unlikely that humans solely rely on purposeful, top-down strategies when determining saccadic endpoints. He and Kowler (1991) propose a serial, two-stage process for determining saccadic endpoints that incorporates both automatic processes and intentional strategies. The two-stage process involves an initial intentional target selection, followed by an automatic weighted averaging of the shape or stimuli to determine the saccadic endpoint.

Shen, Reingold, and Pomplun (2000) demonstrated that in a conjunctive search task visual search is also affected by the cost structure of the search environment. When few same-color distractors were present, saccadic selectivity was biased towards color. However, as the number of same-color distractors increased, saccadic selectivity shifted from same-color to same-shape stimuli. This suggests that visual search may be sensitive to the soft constraints of the search space. Hard constraints arise from the types of stimuli built into the search environment, and the types of interactive behavior permitted (such as searching by color or shape). Hence, hard constraints determine which microstrategies are possible (Gray & Boehm-Davis, 2000). In contrast, soft constraints determine which of the possible microstrategies are *most likely* to be selected (Gray & Fu, 2004). When selection is non-deliberate or automatic the least effort microstrategy is chosen. Searching same-color targets when they are the majority distractor leads to higher movement latencies, higher manual response times, and more fixations than searching the minority, same-shape distractors (Shen et al., 2000).

Our research has focused on where a participant is likely to initially fixate. Initial fixations are the dwells located at the endpoint of the initial saccade. This work has uncovered an effect of stimuli density on initial fixation locations, or the *pro-density effect* (Myers, Gray, & Schoelles, 2003, 2004). As the density of stimuli increases (inter-stimulus distances become smaller), the probability of initially fixating the dense group also increases. Our work in conjunction with Shen et al. (2000) makes it apparent that stimulus features are not the only aspects of the search space considered. Rather, we have found that stimulus configurations are also important. It is likely that the results of Shen et al. (2000) and Myers et al. (2003; 2004), are solely attributable to neither data–driven nor purposeful,

top–down search strategies, but are attributable to a combination of both processes.

If the determination of saccadic endpoints and initial fixation locations are not the exclusive result of top-down, purposeful processes, then taxing top-down processes in order to eliminate any purposeful search strategy will allow automatic, data-driven processes greater influence in overt behavior. Our research has demonstrated that the pro-density effect is heightened with increased workload. The pro–density effect *doubled* with an added auditory task (Myers et al., 2004). This result suggests a data–driven component when determining where to initially fixate or saccade.

In the studies conducted by Myers et al. (2003; 2004), target and density locations were completely orthogonal; as a result, dense clusters of stimuli provided no useful information of the target's whereabouts. Therefore, there was no incentive to *avoid* dense clusters of stimuli.

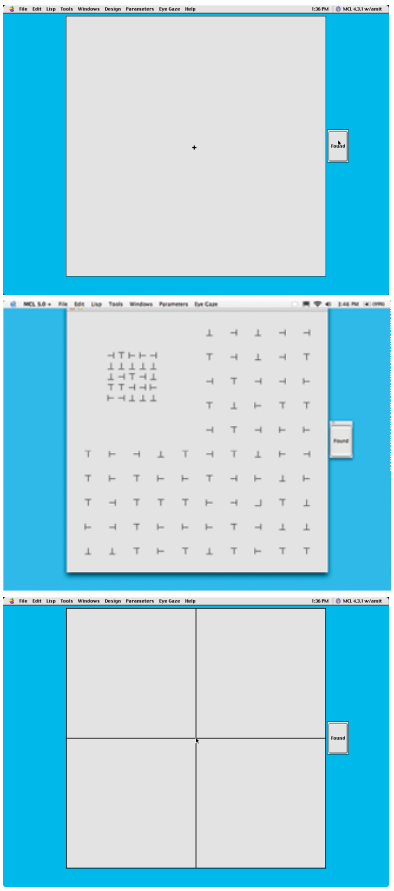
Having found a pro-density effect in previous work, the current study attempted to determine the robustness of this effect by establishing a negative correlation between dense clusters and the probability of a target being located in a dense cluster. If initial fixations still land on the dense cluster, this would suggest that the effect is determined by low–level, bottom–up process that are drawn to certain configural properties. On the other hand, if initial saccades resist the dense cluster or show an *aversion* to the dense cluster, this "anti-density" effect would suggest target location information provided by dense clusters might be incorporated into a conscious, top–down strategy such as deliberately avoiding the dense cluster. However, Myers et al. (2003; 2004) demonstrate that dense clusters are initially fixated more than chance and the number of initial fixations increases with the degree of density and added workload. Therefore, a dense cluster of stimuli is an *attractive distractor* in the current study. Workload was manipulated between participants as a dual task condition and a single task condition. Participants in the dual task condition performed two tasks simultaneously, thereby increasing cognitive workload. The single task group performed one task.

If participants were able to resist initially fixating a dense cluster, the pro-density effect would drop to at most chance levels in the single task group. This would suggest that deliberate processes are overriding the influence of unintentional, data-driven processes on overt behavior in the task environment. We also predicted no effect of degree of density (moderate vs. strong) in the single task group. For the dual task group, we predicted an increase in the pro-density effect as demonstrated in Myers et al. (2004). This would suggest that data–driven processes begin to peer through deliberate strategies in dual task, high load situations. We did not predict the pro-density effect to increase two–fold, rather that it would increase to levels significantly greater than chance. Finally, we predicted that there would be a significant effect of degree of density in the dual task condition, specifically that strong densities would be initially fixated more often than moderate densities.

Method

Participants

A total of thirty-three undergraduate students volunteered to participate. All participants had normal, or corrected–to–normal vision. Participants were randomly assigned to one of two groups. The single task group performed a visual search task, and the dual task group simultaneously performed the same visual search task and an auditory letter classification task. There were 16 participants in the single task condition and 17 participants in the dual task condition. The study lasted approximately 1 hour, and participants were run individually.



1. Fixation
2. Stimulus
3. Test

Figure 1. One visual search task trial, presented in order of from top to bottom.

Apparatus

The data collection apparatus consisted of a PowerMac G4 Apple computer running MacOS Jaguar, a 17-inch flat panel display with the resolution set to 1024 x 768, a chinrest, and an Eyegaze eye-tracking system developed by LC Technologies that measured gazepoint at a 60Hz rate.

Visual Search Task

The visual search task was composed of three different displays, each presented sequentially and in a fixed order. Each display was composed of a window and a *Found* button. An example of the task is depicted in Figure 1. The initial display was composed of a single cross hair located in the middle of the window. The cross hair was used as an initial fixation point for each trial (top, Figure 1). Once the eye tracking system determined cross hair fixation, the stimulus display appeared. The stimulus display (middle, Figure 1) contained a target (e.g., L) and distractors (e.g., T) that were randomly rotated about their axes on each trial. The stimulus display consisted of a 10x10 stimuli matrix, enabling the display to be divided into four equal quadrants of stimuli. The L was placed at the center of a randomly chosen quadrant that did not contain a dense cluster of stimuli.

The within-subject independent variable, stimuli density, varied on 3 levels: strong, moderate, and weak with an inter-stimulus distance of 0.54°, 0.97°, & 1.94° of visual angle, respectively. Each density level occurred on 33% of all trials, with quadrant location randomized for each trial. Quadrants not containing a dense cluster had an inter-stimulus distance equal to weak. (Hence, on weak density trials, all four quadrants were of equivalent density.) The L was *never* located in a dense cluster of stimuli.

Participants were instructed to find the target as quickly as possible and were aware there were only four possible target locations. On target discovery, participants clicked the 'found' button. After clicking 'found', the test display appeared (bottom, Figure 1). The test display was divided into four visible quadrants with the mouse pointer located at the quadrants' intersection. Participants were instructed to click on the quadrant where the target was discovered. Once the participant clicked on a quadrant, the pointer was automatically relocated to the 'found' button and the fixation display reappeared, beginning a new trial. Each participant performed 4 blocks of 48 trials.

Auditory Letter Classification Task

Participants in the dual task condition were acoustically presented random letters of the alphabet in four-second intervals via the speaking software *Victoria*, developed by Apple™. For each letter presented, the participant pressed X if the current letter came before the previous letter or C if it came after. For example, if the subject heard 'A' followed by 'G' she would press C signifying 'G' occurs *after* 'A' in the alphabet. If after four more seconds 'B' was presented, she would press X signifying 'B' occurs *before* 'G'. Letter presentation occurred every four seconds throughout each block of 48 trials. Participants were instructed to simultaneously perform both the visual search task and the letter classification task to the best of their ability. Each dual task participant received accuracy feedback on the letter classification task at the end of each block. No subject scored below 85% accuracy in the last three blocks. Single task participants did not participate in the letter classification task.

Dependent Measures

Our dependent measure was the initial fixation location for each trial, where the initial fixation is the second dwell on the stimuli display. The first dwell was a *residual fixation* resulting from fixating the cross hair on the fixation display. Fixations were determined using the eye tracking software's default fixation analysis. Initial saccades were defined as the eye movement from the residual fixation to the initial fixation.

Results

Comparisons are between the *actual* number of initial fixations on a dense cluster and the number expected by chance. Since there were four possible quadrants to fixate within, there is a 25% chance that an initial fixation would occur on the dense cluster. All t-tests reported are two-tailed and measured at a 0.05 significance level. The first block was removed to reduce any variance attributable to task familiarization. Trials in which all four quadrants were of equivalent density (weak density trials) were excluded from the analyses.

Single Task Condition

The dense cluster was initially fixated on 23.63% of the trials when a dense cluster was present. This rate of initial fixation does not differ from chance [$t(15) = -0.71$; $p = 0.485$]. The planned comparison of degree of density (moderate vs. strong) was not significant ($p = 0.95$). This supports our hypothesis that for the single task there would be no pro-density effect.

Dual Task Condition

The dense cluster was initially fixated on 17.44% of all trials. The rate of initial fixation significantly differs from chance [$t(16) = -2.88$; $p = 0.01$]. There was a marginally significant effect between degrees of density [$t(16) = 1.962$; $p = 0.067$] when comparing moderately dense clusters ($M = 15.14$, $SE = 2.51$) to strongly dense clusters ($M = 19.86$, $SE = 2.72$).

In the dual task condition, we predicted a positive effect of density on initial fixation locations. Instead, we found a negative effect. Initial fixations on dense clusters of stimuli, under dual task conditions, were less than would be expected by chance. We term this the *anti-density effect* and explore it in the following sections. We also found the strong density was initially fixated more often than the moderate density.

Initial Saccade Latencies (ISLs)

Initial Saccade Latencies were defined as the amount of time the participant continued to fixate the cross hair location *after* the stimuli display appeared. The eye tracker used in the study sampled the eye position every 16.67

milliseconds. Each sample in the residual fixation was counted and multiplied by 16.67 in order to determine each subject's ISL for each trial.

ISL Analyses

Before analyzing the ISL data we removed outliers from the data set. Outliers were identified for each group by calculating the mean and standard deviation for each group and removing any data point that exceeded the mean by +/– 3 standard deviations. This procedure resulted in removing 27 data points from the single task group and 41 data points from the dual task group. All blocks were included.

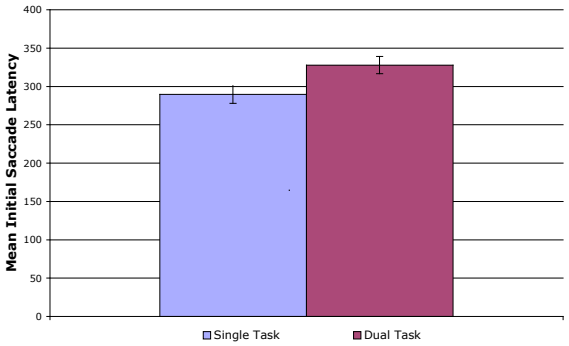


Figure 2. Comparison between dual and single task ISLs. The error bars represent standard error.

An independent groups t-test was performed between the dual and single task conditions on mean ISL. The dual task group had longer ISLs on average (M = 327.79, SE = 11.5) when compared to the single task group (M = 289.53, SE = 11.3), and this difference was significant, $t(31) = 2.37$; p = 0.024 (see Figure 2). This result signifies that there was a difference between the groups average ISL.

Discussion of Results

The single-task manipulation worked as predicted: the density effect occurred at chance levels. However, our dual-task manipulation exhibited an anti-density effect. This result is quite startling in the face of previous research that consistently demonstrated dense clusters *attracting* initial fixations (Myers et al., 2003, 2004). We also found a marginally significant effect of degree of density in the dual task condition.

When unintentional processes associated with dense clusters are not producing an effect, dense clusters should only be initially fixated at chance levels. However, if participants were using implicit information provided by the dense cluster (that the target was not located there), then participants should avoid dense clusters. However, 23.63% of initial fixations are located on a dense cluster of stimuli. The results do not support dense cluster avoidance for the single task. In the single task condition it is apparent that the unintentional attraction of dense clusters has been overridden by a different, possibly deliberate, strategy.

Perhaps participants learned to avoid the dense cluster in the single task condition, but were unable to reduce the effect below chance levels. However, in the dual task condition, the pro-density effect is reduced to below chance levels (17.44%, depicted in Figure 3). This was a significant reduction from chance, and suggested the dense cluster was avoided. It is apparent that something was aiding participants to avoid dense clusters in the dual task group. Initial saccade latencies provided a clue. Due to longer ISLs, participants might have more time to implement a conscious, deliberate strategy. We explore this possibility in the upcoming sections.

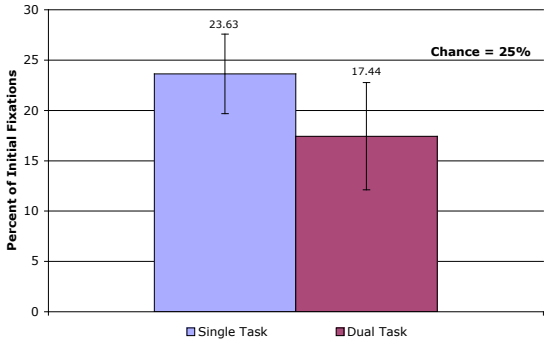

Figure 3. Effects of density by task compared to chance, error bars indicate 95% confidence interval.

Post-Hoc Analyses

Our initial analyses suggested the letter classification task aided dual task participants. Extra time might allow participants to avoid dense clusters. Added time could result from performing some aspect of the letter classification task at stimuli display onset, such as making a comparison, pressing a keyboard key, or even retrieving a memory of the previous letter presented. Extra time was apparent in participants' initial saccade latencies (ISLs). Specifically, dual task participants had significantly longer ISLs compared to single task participants. Further analyses were performed to determine if short ISLs led to a stronger pro-density effect and longer ISLs led to a weaker pro-density effect (anti-density effect). All four blocks were included in the analyses.

To determine if the pro-density and anti-density effects occurred at different rates for different ISLs, we divided our data into 5 bins. Each bin spanned 150 ms, and ranged from 100 ms to 550+ ms. The number of pro-density initial fixations was derived for each bin and divided by the total number of initial fixations for the same bin, creating a percent of pro-density fixations (see Figure 4).

Figure 4 shows a reduction in the pro-density effect as ISLs increase in duration. Figure 4 also shows that single task participants followed the same general trend. The separation between the single task curve and the dual task curve is a result of the single task having a greater number of pro-density fixations.

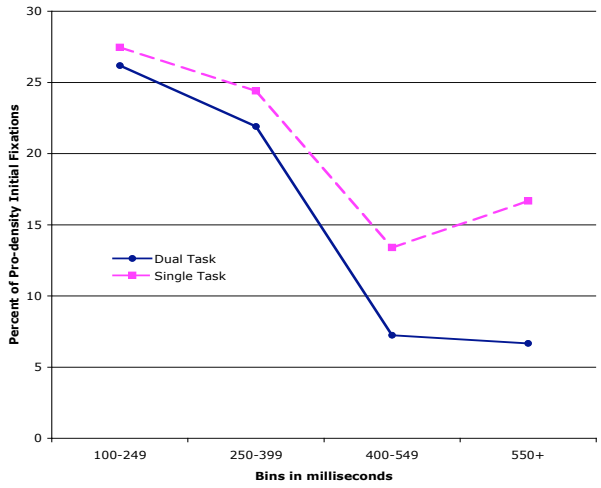

Figure 4. Pro-density effect as a function of initial saccade latency, by task.

It is important to note that the 550+ bin does not contain much data, especially for the single task condition. In fact these data points may be considered aberrant for the single task condition, however they fell within the outlier cutoff. Very few single task participants had ISLs that were 550 ms or greater, as demonstrated in Figure 5.

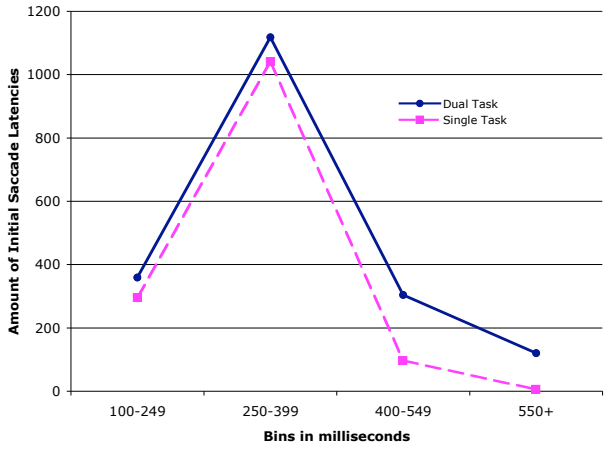

Figure 5. Frequency of initial saccade latencies for each bin, by task

Figures 2 and 4 provide evidence that there was a difference in mean ISLs between the dual and single task conditions. Figure 4 demonstrates that as ISLs increased, the likelihood of initially fixating a dense cluster reduced dramatically. In order to test for significance, a 2 (single task, dual task) x 3 (bins 100–249, 250–399, & 400–549) repeated measures ANOVA was performed. The 550+ bin was removed from the analysis due to insufficient data in the single task group, as demonstrated in Figure 5. Results indicate that there is a significant interaction [$F(1,2) = 3.292$; $p = 0.045$)] between the presence of the letter classification task and ISLs (see Figure 6). There was also a main effect of ISL on the percent of initial fixations on a dense cluster [$F(1,2) = 31.275$; $p < 0.0001$)].

Summary and Discussion

The results of our post-hoc analyses revealed a surprising effect. Participants were *aided* in the dual task condition via the auditory task. Generally, aid came in the form of not initially fixating distracting dense clusters. As a result of increased ISLs, the visio-cognitive system gained the opportunity to acquire and use information relevant to the task at hand. This analysis suggests that low-level strategies are chosen based on the soft constraints inherent in the task environment (Gray & Fu, 2004).

In previous research (Myers et al., 2003, 2004) dense clusters were *uninformative* and we found that dual task situations increased the pro-density effect. In the current study, dense clusters were made *informative* and the information was somehow used in a beneficial manner. When dense clusters are uninformative, they should always be considered as a possible target location. However, when a dense cluster provides target location information, then it becomes possible to reduce your search costs, and is akin to differences in saccadic selectivity as a function of distractor ratios discussed by Shen et al. (2000). Costs attributable to the current experiment's search space begin at very low levels. However, when the opportunity arose to reduce cost, providing benefit by reducing the search space, both dual *and* single task participants seized the opportunity. This occurred at greater rates as ISLs increased. It appears that the visio-cognitive system is extremely sensitive to cost-benefit tradeoffs, even when the cost is an average of one extra fixation. Our data suggests a limit: enough time must be provided in order to achieve a reduction.

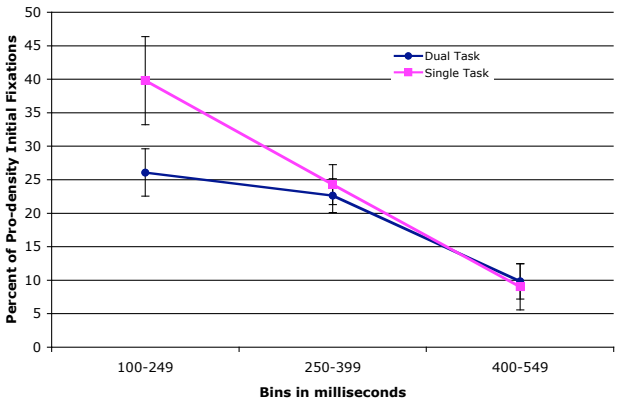

Figure 6. Interaction of initial saccade latency and task condition. Error bars represent standard error.

The reasons for and ways in which purposeful, top-down strategies interact with automatic, data-driven processes are unclear; however our analyses do shed some light. The data

suggest that the pro-density effect is an automatic, data–driven process. This is attributable to short ISLs leading to high percentages of initial fixations on dense clusters. This was observed in both task conditions when ISLs were relatively short (see Figure 6). Dense clusters were avoided on roughly 90% of all trials in both task conditions when ISLs were ≥ 400 ms. This suggests more time is necessary to impose deliberate, top–down strategies. In addition, dense clusters were initially fixated more than chance levels for short ISLs. This indicates that automatic, data–driven processes have more influence in overt behavior when ISLs were relatively short, and as ISLs increased the ability to impose top–down strategies on the search task increased. Soft constraints theory suggests that after initially adopting a least-cost strategy, such as avoiding the dense cluster, the number of initial fixations on dense clusters should be reduced as the new microstrategy gains in success over time. It is likely that participants do reduce initial fixations from block 1 to block 4 for all ISL bins, and this reduction would be an example of a learned, unconscious, data-driven strategy.

Further support comes from the planned comparisons between moderate and strong densities in the dual task condition. When top-down processes are sapped by added workload, there are differences between strong and moderate densities. However, there was no difference in the single task condition. When deliberate top–down strategies are taxed, it is likely that bottom-up processes have an opportunity to exert more control on overt behavior.

Pomplun, Reingold, & Shen (2003) have developed a computational model (Area Activation Model) that predicts where saccadic endpoints will be located. These locations are based on information in the search space such as color and shape. The current study points to areas in the model where more work is needed; namely, that stimuli configuration and cognitive workload are important aspects of visual search that must be considered when developing models of saccadic selectivity.

Although the experiment revealed surprising effects, we did not design the experiment with these effects in mind. We see this as a possible limitation in our study and feel that more studies such as the one presented here need to be completed to understand the true nature of the effects that stimuli configurations and high levels of cognitive workload have on visual search.

Abstract

Two experiments are reported which examine how manipulations of visual attention affect adult speakers' linguistic choices regarding word order and verb use when describing simple visual scenes. Participants in Experiment 1 were presented with scenes designed to elicit the use of one of two perspective verbs (e.g., "A dog is chasing a man"/"A man is running from a dog"). Speakers' visual attention was manipulated by preceding the display with a crosshair positioned on one or the other character. Cross-hair position affected word order and verb choice in the expected direction. Experiment 2 replicated this effect with a subliminal attention-capture cue, and results were further extended to the order within conjoined noun phrases in sentential subjects ("A cat and dog are growling…"). The findings have important implications for incremental theories of sentence planning and suggest some specifics for how joint-attention might serve as a useful cue to children learning verbs.

Introduction

What makes people say what they say? This is a complex question, which has been the source of much investigation and dispute over the past several decades. Early on in the generative linguistic tradition, the emphasis on the productive and creative power of structural expression led many researchers to assume that properties of a visual stimulus can be related to a speaker's linguistic choices in only vague and theoretically uninteresting ways (e.g., Chomsky, 1957). Currently, though not disputing that one can say – or not say – many different things under the same environmental conditions, investigators doing experimental research on word order and structural choices in sentence production have concluded that some combination of perceptual, conceptual and linguistic accessibility contribute in a dynamic way to utterance planning. In particular, questions of word order have received much attention, and prompted much debate, as this issue must be richly intertwined with the planning of both an utterance's overarching message and the syntactic structure carrying that message. In advance of speaking, one must somehow decide where the upcoming utterance is to start, and much of how it is to proceed. A number of factors seem to contribute to this process.

First, studies have found a crucial role for preferred (i.e. primed or otherwise accessible) syntactic structures in the form a message ultimately takes (e.g. Bock & Loebell, 1990). Additionally, lexical/conceptual factors (e.g. accessibility, animacy) have been shown to affect word order materially, even at the expense of a preferred syntactic structure (Tversky, 1977; Bock, 1986; MacDonald, Bock & Kelly, 1993).

The role perceptual prominence plays in word and/or constituent order, however, seems a bit more nebulous. Within the literature on visual attention, it is quite clear that perceptual cues are involved in the interpretation of visual stimuli; research on perception of ambiguous figures (e.g. duck/rabbit, wife/mother-in-law) has shown that the perception of such stimuli can be driven by localizing eye gaze on critical features of a given interpretation (Georgiades & Harris, 1997). And perceptual factors (e.g. size, color) are clearly involved in ordering within simple conjoined noun phrases (e.g. *A bear and a dog*) (Osgood & Bock, 1977; Gleitman, Gleitman, Miller & Ostrin, 1996), but the role of perceptual prominence in constituent order remains unclear. Some find no relationship between initially fixated stimuli and subject role assignment (Griffin & Bock, 2000), while others find evidence supporting a role for attention (perceptual prominence) in constituent order (Tomlin, 1997; Forrest, 1996).

Some have interpreted these latter results as evidence for an incremental account of language production, in which a speaker builds an utterance as it is produced, and is apt to begin with whichever sentential elements are most salient at the time of speech onset. This account contrasts with more structuralist version of sentence planning, in which the underlying message of an utterance must be wholly planned prior to the onset of speech, and which accounts for the robust and reliable effects of syntactic priming (see Bock, in press, for discussion).

A troubling issue with all prior investigations into perceptual prominence and word ordering arises, however, if one examines the methodology. Manipulations have all been overt attention-getting devices (raising demand characteristic concerns), and have often had rigid task demands allowing for minimal generalization.

The current research investigates the question of perceptual contributions to word and constituent order, drawing on the attention and perception literature for more suitable methods. In two experiments, subjects' attention was directed subtly (Experiment 1) and then subliminally (Experiment 2) to scene participants, to determine whether perceptual cues under these covert conditions have any effect on the linguistic choices speakers must make. If such perceptual factors lead subjects to differing descriptions of identical scenes, a clear role can be established for attentional factors in sentence planning and constituent order. Such results may also provide evidence for an incremental approach to production, or perhaps, rather, to message planning. Finally, as we describe later, these effects may rebound on aspects of word learning.

Experiment 1

In the spirit of the afore-mentioned perceptual attention research on ambiguous figure resolution, our first investigation of attentional effects on event interpretation used a simple crosshair fixation point – prior to stimulus presentation – to direct a subject's eye gaze to a scene participant (analogous to directing gaze to a set of critical features in the ambiguous figure literature). Stimuli were designed to elicit one of two word order and verb choices on the part of the speaker, thereby making one or the other character in a scene the subject of the sentence. If initial visual attention subtly alters a speaker's perspective on the scene, we should expect that the speaker's choice of sentential subject and verb would be influenced by our attentional manipulation.

Methods

Norming and Stimuli Prior to initiating data collection on an attention-manipulating task, the specific stimuli to be used were normed, to identify baseline rates of verb selection for these particular items. Twenty-one monolingual English-speaking University of Pennsylvania Intro Psychology students participated for course credit. Subjects were presented with the 52 pictures to be used in experiment one, and asked to describe the event that was taking place in the scene using a simple sentence. No other manipulations or cues were introduced. Of these 52 pictures, twelve depicted pairs of so-called Perspective Verbs (e.g. chase/flee, see Figure 1), and these were the critical items (PVs).

Rates of verb use for these twelve items varied (see Table 1), but for each verb pair, subjects showed some degree of bias towards one interpretation and/or verb choice; there was a preferred verb and a dispreferred verb, and hence a corresponding preferred subject and dispreferred subject (passives were rare, occurring only 6 times across all 252 items). Overall, preferred subjects and verbs were used 69% of the time, dipsreferred subjects and verbs were used 27% of the time.

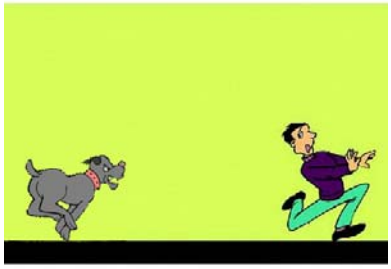

Figure 1: Sample Perspective Verb item from Experiment 1.

Table 1: Norming study baseline rates of verb usage in PV stimuli in Experiment 1. Percentage of total usage across all utterances in parentheses.

Item	Preferred Verb	Dispreferred Verb
Buy/sell	Sell (62)	Buy (38)
Chase/flee (dog/man)	Flee (57)	Chase (43)
Chase/flee (rabbit/elephant)	Chase (71)	Flee (29)
Eat/feed (puppies/dog)	Feed (76)	Eat (24)
Eat/feed (child/mother)	Feed (95)	Eat (5)
Give/receive	Give (71)	Receive (29)
Listen/talk (office)	Talk (76)	Listen (24)
Listen/talk (phone)	Talk (19)	Listen (29)
Perform/watch (singer)	Perform (67)	Watch (33)
Perform/watch (speaker)	Perform (86)	Watch (14)
Win/lose (boxing match)	Win (95)	Lose (5)
Win/lose (race)	Win (48)	Lose (24)

Participants and Design Eighteen monolingual English-speaking Introductory Psychology students at the University of Pennsylvania participated in this study for course credit. There were three conditions, defined by the location of the crosshair fixation point prior to scene presentation: Dispreferred (where the dispreferred subject would appear), Preferred (where the preferred subject would appear), and Middle (a neutral middle region, as a control). Manipulations were within-subjects, with each subject's gaze directed to the dispreferred subject on four of the twelve critical items, to the preferred subject on four of the

twelve critical items, and to a neutral middle region on the remaining four items.

Procedure Subjects in this experiment were presented with 52 scenes depicting participants engaged in a given activity (e.g. a picture of a boy swimming), including the twelve critical items, depicting perspective verb pairs. Subjects were instructed to describe each picture using one simple sentence, and subjects' utterances throughout the task were recorded.

A crosshair fixation point preceded presentation of each of the 52 scenes. This fixation point was presented on-screen for approximately 500 msec, then immediately followed by presentation of the scene (either filler or trial). (Earlier pilot work with an eyetracker confirmed that subjects followed directions and routinely fixated the cross prior to stimulus presentation.) Subjects in the current study were misled to believe that position of the crosshair was random and irrelevant to their task, so as to prevent their eyes from inspecting scenes in the same fashion on each trial. Position of the crosshair in fact corresponded directly to position of an upcoming scene participant. Although some subjects noted that the fixation marker frequently had been where an object appeared, no subject reported noticing the correlation between the location of scene participants and the crosshair. And in post-experimental interviews, most subjects who bothered to posit a guess as to the experiment's purpose speculated that it pertained to color brightness and/or interpersonal relationships of scene elements.

Results and Discussion

Rate of preferred verb usage was highly influenced by cue location in the expected direction (see Figure 2). In particular, when the preferred subject (e.g., the dog) was visually cued, speakers uttered on 77% of the trials sentences like "A dog is chasing a man." When the dispreferred subject was cued, however, speakers produced such utterances only 61% of the time (and showed a corresponding increase in utterances like "The man is running from the dog"). Analyses of Variance (ANOVAs) on participant and item means revealed that the effect of cue location was significant (both p's<.05).

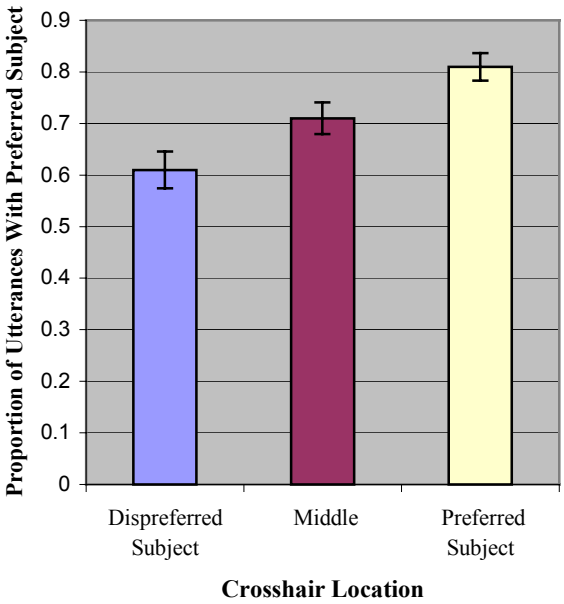

Figure 2: Proportion of utterances beginning with the preferred subject and verb, by condition, in Experiment 1.

Experiment 2

Following the results of Experiment 1, a couple of questions arose. First were concerns regarding demand characteristics of the crosshair fixation point manipulation. Although subjects did not seem to sense the specific purpose of the experiment (namely, subject and verb selection), many noticed that the crosshair's position frequently corresponded to an object in the upcoming scene. We worried that this knowledge alone might have subtly influenced their linguistic choices. To this end, we developed an attention-capture cue (see Jonides & Yantis, 1988), as discussed below, which successfully directed subjects' attention to a particular region of the scenes, without being consciously perceptible.

Secondly, as discussed previously, much prior research on sentence production and linguistic choice has compared the role of many different factors, from animacy to size of entities, on differing constructions. Specifically, different variables seem to contribute differently to linguistic choice in simple conjoined noun phrases (e.g. *the dog and the man* vs. *the man and the dog*) than to linguistic choices involving thematic role assignment (e.g. *the dog chased the man* vs. *the man fled the dog*). In Experiment 2, we wanted not just to replicate our prior result, but also to compare the influence of our covert attention-capture manipulation on these sorts of different constructions. To this end, twelve additional items were added in Experiment 2, depicting events in which two scene participants were engaging in an activity together (see Figure 3, designed to elicit "The cat/dog and the dog/cat are growling at each other"). These Conjoined Noun Phrase (CNP) items were aimed at eliciting descriptions containing a conjoined noun phrase in the sentential subject position (e.g. A dog and a cat are growling), so as to investigate the effect of our covert manipulation on word order in a simple conjoined noun phrase.

Figure 3: Sample Conjoined Noun Phrase item from Experiment 2.

Methods

Norming and Stimuli CNP pictures were first normed for baseline preferences. Twenty-one monolingual English-speaking University of Pennsylvania Intro Psychology students described 64 scenes (52 fillers, and the 12 CNP items), absent any manipulations or cues. In an effort to avoid utterances beginning with uninformative sentential subjects (e.g. "Two people are…"), CNP stimuli consisted of scenes with animal, rather than human, participants (e.g. a dog and a cat growling, see Figure 3).

Baseline rates of first-mentioned scene participants varied less than with the PV stimuli in Experiment 1 (See Table 2). Most items were relatively unbiased, but scene participants with even a slight advantage were dubbed *Preferred First-Mentioned*, and referred to as such from this point onward, for the sake of simplification. Overall, preferred first-mentioned participants were mentioned first 56% of the time, dispreferred first-mentioned only 44%.

Table 2: Norming study baseline rates of first-mentioned participants in CNP stimuli in Experiment 2. Percentage of total usage across all utterances in parentheses.

Item	Preferred First-mentioned	Dispreferred First-mentioned
Biking	Turtle (61.9)	Dog (38.1)
Dancing	Fish (57.1)	Bear (42.9)
Eating	Koala (52.4)	Panda (47.6)
Growling	Cat (52.4)	Dog (47.6)
Juggling	Elephant (52.4)	Seal (47.6)
Jumping	Frog (57.1)	Cat (42.9)
Playing cards	Pig (57.1)	Dog (42.9)
Playing horns	Rhino (52.4)	Snail (47.6)
Rowing	Bear (52.4)	Snowman (47.6)
Skating	Monkey (57.1)	Rabbit (42.9)
Swinging	Elephant (61.9)	Monkey (38.1)
Waiting	Penguin (52.4)	Deer (47.6)

An additional consideration that arises when adding the CNP stimuli is orientation. As previously mentioned, one factor driving word order in conjoined noun phrases is the left-to-right bias, with leftmost participants more likely to be first mentioned. This prediction bore out in the current norming study as well, with leftmost participants mentioned first 78.2% of the time for CNP items (as compared to only 52.8% of the time for PV items in prior norming study).

Participants and Design Forty monolingual English-speaking Introductory Psychology students at the University of Pennsylvania participated in this study for course credit. Both the location of the attention-capture cue and the left-to-right orientation of the scene were systematically varied, creating a 2 X 2 design (cued participant X leftmost participant) and four stimulus lists. Manipulations were within-subjects, with each subject assigned randomly to one of these four lists.

Procedure Subjects in this experiment were presented with 64 scenes: the same 40 fillers and 12 PV scenes used in Experiment 1 and the 12 normed CNP scenes. Subjects were instructed to describe each picture using one simple sentence, and subjects' utterances and eye movements were recorded throughout the task.

Prior to stimulus presentation, subjects fixated a crosshair fixation point (equidistant from the two scene participants) for 500 msec. Subjects were misled to believe that position of the crosshair was randomized, to assist the experimenters in maintaining eyetracker calibration accuracy (no subject reported suspecting anything otherwise). The fixation point was then followed by a brief, covert attention-capture manipulation. This manipulation consisted of a small black target area (subtending an area of approximately 0.5X0.5 degrees of visual angle) against a white background, with a duration of 60-80 msec, followed immediately by the stimulus. Although no subject reported noticing the subliminal cue, it was highly effective in capturing attention. Subjects looked first to the cued location a median of 76% of the time.

Results

Table 3 shows rates of mentioning the Preferred First-Mentioned participant first for the CNP stimuli, and Table 4 shows rates of using the Preferred Subject for the PV stimuli for all four conditions in the 2X2 design. Collapsing across sentence types, significant effects of Left-Right Position and Attention-Capture were observed; leftmost and cued entities were more likely to be first-mentioned (p's<0.01). Further analyses showed that Left-Right orientation was significant only for word order in CNP stimuli ($p<0.01$), not for subject selection in PV items. Both sentence types, however, showed significant, stable effects of Priming, with primed characters more likely to appear first in CNPs ($p<0.05$) and to be the subject of a perspective verb ($p<0.01$).

Table 3: For all four conditions of Conjoined Noun Phrase stimuli, proportion of utterances in which subjects mentioned Preferred First-Mentioned participant first

	Preferred First-Mentioned Primed	**Dispreferred First-Mentioned Primed**	Average
Preferred First-Mentioned on Left	79.3%	63.8%	**71.6%**
Dispreferred First-Mentioned on Left	58.1%	41.4%	**49.7%**
Average	**68.7%**	**52.6%**	

Table 4: For all four conditions of Perspective Verb stimuli, proportion of utterances in which subjects mentioned used Preferred Subject

	Preferred Subject Primed	**Dispreferred Subject Primed**	Average
Preferred Subject on Left	87.4%	66.4%	**76.9%**
Dispreferred Subject on Left	77.3%	60.1%	**68.7%**
Average	**82.3%**	**63.2%**	

General Discussion

Language Production Overall, our results show a role for perceptual prominence in constituent ordering, and may be taken as support for a more incremental approach to sentence production.

It is important, however, to keep these results in the context of the current literature on the subject of speech production. Although Griffin and Bock (2000) found no correlation between first-fixated scene participants and first-mentioned participants, in an extensive investigation into the time course of message extraction from a visual scene, they *did* show tightly linked eye movement and speech patterns once an utterance was to begin; subjects looked reliably to an object less than a second before producing the corresponding word. This, and other research in this vein (Bock, Irwin, Davidson & Levelt, 2003), implies a system that begins with an initial, message-planning stage, followed by a more incremental process of retrieving the necessary lexical elements to construct an utterance (see Bock, in press, for discussion).

Our result is in no way inconsistent with this model of speech production. It is quite possible that subjects in our studies, rather than beginning to incrementally code their final utterance at the onset of the stimulus, begin with an information-extracting, message-planning stage, and that the perceptual priming effects we see take effect in this early stage. In the analogous ambiguous-figure literature, such attentional manipulations seem to affect the way subjects *perceive*, or interpret a stimulus. This may well be what's resulting from our similar attention-driving tools: a different perception, or interpretation of the stimulus. Ongoing research will investigate the effects of the same perceptual prime on both transitive verbs – where subjects must shift to an infrequent, passive structure to alter subject role assignment – and symmetrical predicates – where prominent information tends to appear in the object role/position (e.g. "I met Meryl Streep" vs. "Meryl Streep met me") (Gleitman et al., 1996). These explorations into the underlying nature of the perceptual prime should begin to determine where and how it is having its effect.

Language Acquisition These results have interesting implications for word learning studies as well. It has been noted that perspective verb pairs should be specifically very difficult for children acquiring a language to learn, as in many cases both members of these pairs necessarily co-occur under the same situational circumstances (Gleitman, 1990; Fisher, Hall, Rakowitz & Gleitman, 1994); for instance, a child is not apt to be presented with a situation that involves chasing but, at the same time, does *not* involve fleeing, and vice versa. How can the young learner figure out, then, whether the mother was saying "chase" or "run away?" These studies showed that syntactic information can inform the listener/learner as to the speaker's intended meaning. By varying the syntactic frame in which a novel verb appeared while referring to a perspective verb stimulus (e.g. "The man is glorping the dog" vs. "The dog is glorping the man," with regard to Figure 1) Fisher et al. showed that young listeners are quite adept at using this syntactic input, or "zoom lens," to arrive at the same interpretation intended by the speaker.

Another "zoom lens" that is more closely related to the present studies, is joint visual attention of speaker and listener. Infants as young as 2-months-old engage in such gaze-following activities (Bruner, 1998), looking where an adult is looking, during conversation. Moreover, by 12 to 18 months of age, the infant can successfully use this gaze-

direction information as a cues for how to label new objects (Baldwin, 1993). Contributions of attentional cues to word learning have not been as broadly or rigorously investigated for the case of verb learning. Given our current result on the relationship between attention-direction and variation between subject and verb choice, we suggest that similar attentional cues are available to the young language learner in successfully parsing and interpreting speech as well, even in the especially difficult case of perspective verbs.

Conclusion

Taken together, the results of these two experiments as they interface with relevant prior investigations clearly demonstrate a relationship between attention and language production. Further investigation will be necessary to delve into the detailed nature of this relationship, and explore the way it fits into a model of language production. These results, though, and the implications they have for attentionally-aware young language learners trying to interpret the speech stream, open exciting new investigative doors in both language production and acquisition.

Abstract

Building new information tools to support cognitive work requires research at a level that, within the constraints of time and resources, will reveal higher-order cognition among practitioners. Practitioners develop cognitive artifacts in order to perform technical work. As densely encoded representations of work domains, their artifacts embody the most meaningful information in the task setting. The study of cognitive artifact development and use makes it possible to study individual and team cognition. This approach reveals what information is important, and how practitioners capture and use it. As replicas of physical artifacts, digital cognitive artifacts often amount to only meager representations of what matters in the work environment. This clumsy automation imposes a burden on practitioners by forcing them to cope with its shortcomings. In this setting, user-centered automation must support reasoning through time. The study of physical artifacts indicates ways that digital artifacts might better support temporal reasoning.

Use of Cognitive Artifacts to Understand Technical Work

The coordination of anesthesia assignments at a major urban teaching hospital spans 50 to 80 cases a day and requires the orchestration of multiple departments including anesthesia, surgery, nuclear medicine, obstetrics and gynecology, gastrointestinal endoscopy, diagnostic and interventional radiology, and psychiatry. This activity involves a distributed cognition (Hutchins, 1995), that is comprised of the shared awareness of goals, plans, and details that no single individual grasps. Through socially distributed cognition (Perry, 1999), individuals cultivate the mutual awareness and understanding that is needed to collectively accomplish shared goals.

Surgeons, anesthesiologists and the others at the hospital work to a Standard of Medical Expertise (SME). Resources among care settings, patient populations and system are constrained and must be allocated prudently in order to meet a Standard of Resource Use (SRU). (Sharpe and Faden, 1998). A few of the senior anesthesiologists serve in the role of daily coordinator, assigning staff to perform a full schedule of anesthesia, sedation or pain management procedures each weekday. To do this, the coordinator must evaluate the number and types of procedures, determine the number and types of staff available, assign staff to perform procedures, and evaluate the balance between the two. The coordinator typically manages the execution of that schedule on the following day. Management of this process involves the synchronization of complex, changing activities through time. This requires an accurate grasp of the number and nature of available staff as well as an accurate, up-to-the-minute account of procedures that have been performed so far, are underway, and have yet to be performed within work setting constraints.

Research into cognitive activity in this setting is challenging for a number of reasons. Healthcare practitioners may have little insight into how their work is organized. Information and interaction at the sharp (operator) end is dense, complex, varies widely, and changes rapidly. (Cook and Woods, 1994)

In order to understand cognition in this environment, the researcher needs to employ a number of methods. Woods and Roth's (1988) cognitive engineering approach studies behavior in actual environments in order to change behavior and to improve performance. Klein's (2000) naturalistic decision making (NDM) approach accounts for the performance of decision makers in actual settings. Hutchins' (1995) ethnomethodology describes how distributed cognition includes artifacts that make it possible for a group to accomplish shared goals.

The development and use of cognitive artifacts makes it possible to perform the otherwise impossible process of assignment coordination. Cognitive artifacts are an efficient representation of what matters here because they represent only the information that is critical in this work domain. Previous work (Nemeth 2002, 2003a) describes the use of observational studies to discover how the acute care team uses cognitive artifacts to make the plan for the day's work. It also explains how controlled study of artifact creation reveals the strategies that coordinators employ in order to create a feasible future for the next day of procedures. Two artifacts are essential to the coordinator while developing a plan. The Daily Availabilities sheet is used to account for the status of each of the members in the department who are available for assignment. The preliminary copy of the Master Schedule lists all procedures that are scheduled to be

performed the following day that will require anesthesia, sedation or pain management. These two artifacts are the tools that are used to create the Master Schedule.

An example shows how one coordinator uses the Daily Availabilities sheet and the preliminary copy of the Master Schedule to build a final version of the Master Schedule. Figure 1, from Nemeth (2003b), represents the schedule development process in three ways. The left column shows the verbatim transcript of how the coordinator describes his deliberations using Verbal Protocol Analysis (VPA). The Daily Availabilities and Preliminary Copy that he refers to are shown at center, along with indications of where he is paying attention. A diagram and comments at right show the analysis of his cognitive activity as he assigns available attending and resident anesthesiologists to cover procedures in eight outpatient clinic rooms. After scoping the supply of staff resources and evaluating the type and number of procedures, the coordinator assigns staff to particular procedures and then assesses the assignments. In eleven minutes, he has assigned attending and resident anesthesia staff to perform a day's

All names are fictitious

outpatient procedures. This planning process requires deep domain knowledge and deft diplomacy. It also requires the ability to exploit opportunities, to create trial solutions and to ȧssess their possible consequences. No two coordinators approach the process in the same way. Until recently, the coordinator would use only hard copies of the artifacts to develop the Master Schedule. During the day the coordinator would track and update case status by making marks on the Master Schedule hard copy that was posted at the Inpatient Operating Rooms (IOR) coordinator station. Team members also used the OR Board, a white marker board with magnetic plaques, as a platform to discuss assignments, negotiate trade-off decisions, plan and re-plan assignments, speculate about how to re-balance changes in demand and staff.

Digital Artifact Concerns

Hard copies of the Master Schedule have recently been replaced by a computer-based system, OpAssign. The Daily Availabilities remains a hard copy report that the coordinator refers to while composing the Master Schedule.

The OpAssign display is an alphanumeric table that is shown on a flat screen monitor. As a mimic of the physical Master Schedule, OpAssign shows surgical procedures that are organized by room and by time of day within the room. All procedures are represented by alphanumeric characters and each procedure occupies the same amount of space in the layout. Colored bars are intended to indicate case status such as called for, arrived on unit, in OR, in-progress, delayed, and concluded. Procedures appear identical on the display even though they differ as markedly in criticality and duration as a circumcision and a coronary artery bypass graft (CABG).

A number of changes have occurred as a result of the transition from physical to digital cognitive artifact.

▪ The physical artifact had previously made it possible for the coordinator to control the accuracy of information that was used to make decisions. Only the coordinator would make marks on the one original hard copy that was posted at the coordinator station. The physical artifact also allowed for the coordinator to make margin notes to keep track of unofficial, yet important information such as the name and extension of a staff member who had called with information

that pertained to a case. Now that the Master Schedule is no longer a physical artifact, neither the coordinator nor the acute care team can annotate it.

- Data field limitations force certain compromises in the information that can be shown. Many elements of information are truncated on the OpAssign display. Details can only be found by drilling down through multiple levels of the interface.

- Information on case status was traditionally written onto the Master Schedule hard copy by the coordinator as a patient was wheeled past the coordinator station toward an IOR room. Now, case status must be entered via laptop from a very busy IOR room. This means that information on the Master Schedule display can lag actual events by 30 minutes or more. The lag causes the coordinator to second guess the display and to do additional cognitive work to check on case status. It also erodes the coordinator's ability to manage decisively.

- Case location on the original hard copy remained the same. Team members could use the fixed location for each case to find and refer to it. As case status changes through the day on OpAssign, their location on the screens also changes and team members have to search to find them.

These and other shortcomings have caused team members to do additional cognitive work to cope with limitations of the digital display, impeding team performance. Figure 3 shows OpAssign in use at the coordinator station.

Figure 3: OpAssign Display at Coordinator Workstation

Opportunities to Improve Displays

Interestingly, both the hard copy of the Master Schedule and the OpAssign display list scheduled start and end times. However, neither of these two reflect the time-related demandsand complexity that are the primary drivers in this environment. Figure 4 illustrates a conceptual prototype for a digital version of the Master Schedule information that draws on the findings from research into coordinator schedule development and team schedule use. Six of the IOR rooms are shown in the figure. Information on each case is shown in a horizontal bar that is aligned next to the label of the operating room to which it is assigned. A shaded segment follows each procedure to indicate the 45 minute period that is required to clean-up and restock the room. The arrow at top of the display indicates that the time is 0800 on the day of procedures that are being conducted in the Inpatient Operating Room (IOR) unit.

IOR1 shows that a half hour is open after the first procedure and clean-up have been completed. The procedure that is scheduled for 0730 to 1330 in IOR2 has just been cancelled and the display indicates that the room is scheduled and prepared for use. IOR3 shows that cases are scheduled efficiently. IOR4 is available for any general surgery to be added on after 1215. Somehow, the second procedure scheduled for IOR6 has been slated to start before the technicians would be able to finish clean-up. The solid bar can be used to display more information on the cases by choosing it with an input device such as a mouse or touching the screen.

Certain information is crucial in order to optimize assignments. This includes knowing when procedures are likely to finish, which procedures can be moved into another room, and which opportunities (such as Medicare payment) might be exploited. Such information can be made available by polling the database of scheduled cases to see what opportunities may exist.

The example in Figure 4 is based on research into the work domain in which it would be used. Because of this, it avoids many of the shortcomings that the OpAssign display encountered. It may also improve on the OpAssign design in a number of respects.

- The visual organization of the display remains the same as it evolves. By using a graphic representation of time, the team can understand and evaluate relationships among events through time.

- Relevant variables such as age are shown within each case window, which saves the need to locate and assemble information that is related but is displayed separately.

- Cases that were performed remain on the display in sequence, making it possible to review the entire day's activities while they are still underway.

- Aspects of schedule management that were previously hidden are made evident. These include requirements that are the objects of coordinator cognitive work such as showing conflicts and gaps in timing, and constraints on schedule management such as room clean-up and restocking.

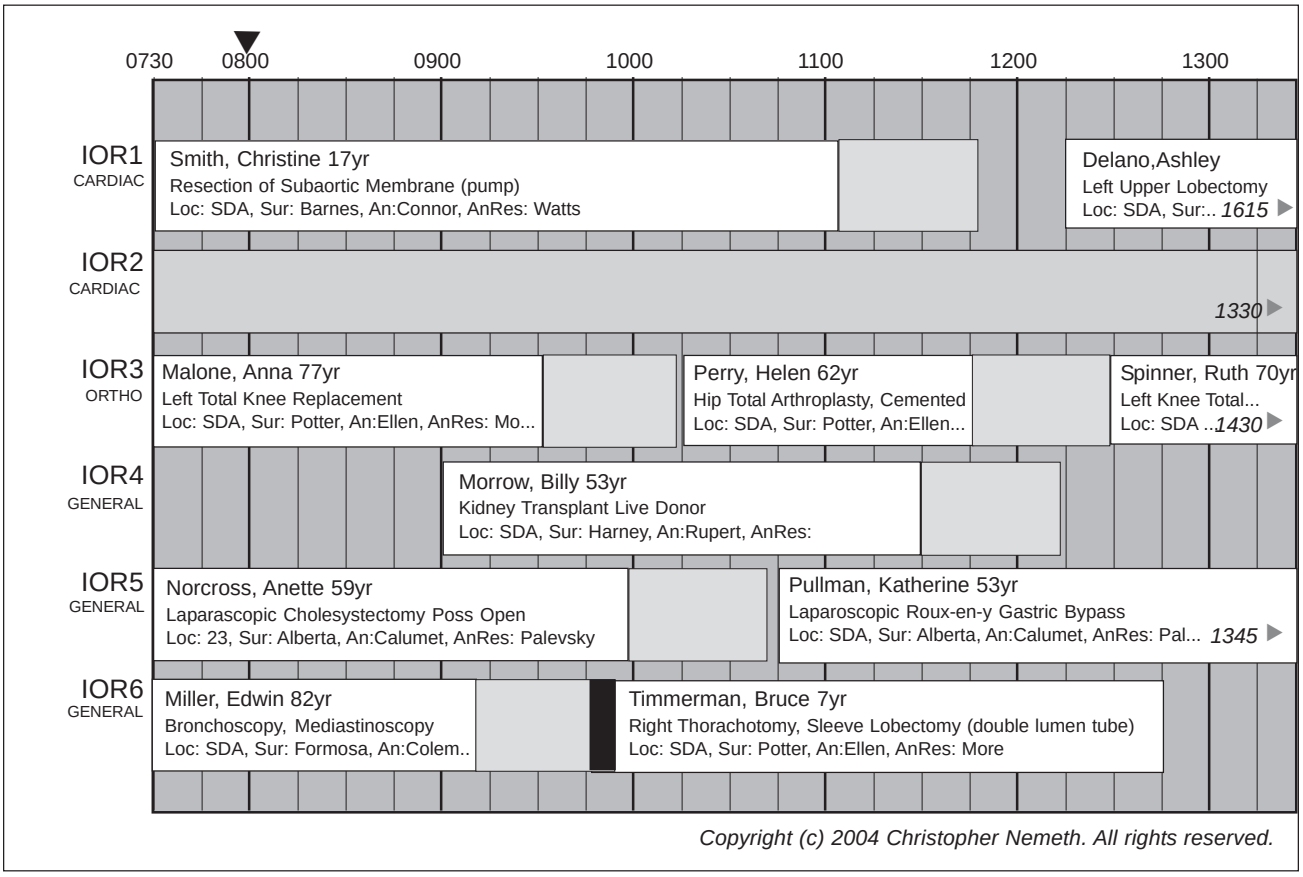

Figure 4: Prototype Digital Display of the Master Schedule
All names are fictitious

Adding Value to Cognitive Tools

Any tools that are created to assist these complex and highly sensitive interactions need to reflect the underlying complexity of the work that is to be performed. A digital version of the Master Schedule might improve team performance by supporting work in ways that the research that was described earlier in this paper demonstrated.

The flexibility that digital representation offers is powerful and can be used to support cognitive work. However, this does not happen automatically. The digital artifact's design must represent constraints and opportunities that are relevant in this domain. Because time is the key aspect here, organizing display design according to time allows users to easily track changes, to anticipate future events, and to respond to emerging situations.

Further features such displays might provide include:

Prompting—Digital artifacts might survey information in the distributed cognition for gaps and inconsistencies that go unnoticed and unaccounted for. Nominating the item(s) for consideration would enrich and improve the cognition.

Speculation—Digital artifacts can enable coordinators to speculate about and choose among possible courses of action. For example, speculation about plans for the afternoon staff is currently limited to the OR Board. Developing potential courses of action would make it possible to evaluate how desirable they might be.

Consequences—Applying evaluation criteria to potential courses of action could make it possible to display the consequences of choices. One example is to show how billing might be increased, or costs might be minimized, by opening one operating room or closing another.

Value-based decisions—Digital artifacts can be used to develop templates of schedule planning strategies. Coordinators could review and use the template that best matches their values and preferences. Such templates can capture scheduling expertise and make it available beyond a single individual. Study of template use through time might open the way to insights about coordinator training and the development of further schedule models that might ease coordinator workloads.

Conclusion

This paper has described a detailed study of the operational aspects in a complex, high hazard work setting, assessed the role and effect of physical and digital cognitive artifacts on cognitive work, and presented a display concept that embodies the task demands that workers confront. Support for the cognitive work of those who labor in this setting is the hallmark of user-centered automation. (Billings, 1997)

As a readily available source of information, cognitive artifacts make it possible to study cognition in complex environments. Because those who work in the environment have created them, artifacts are highly encoded representations of what matters most in complex settings. The creation and use of cognitive artifacts also provide the researcher with a means to understand deeper structure of behavior in the work domain.

Findings from such research can be used to identify the functions of computer-supported displays that are needed to not only support but to improve performance. Validation of those findings and related display designs will come from operator acceptance in actual use. Improving work efficiency and reliability can make it possible for work teams to be more effective, thereby improving medical safety.

Abstract

The paper reports empirical and computational research on semantic facilitation and inhibition in the picture-word interference paradigm for different values of stimulus onset asynchrony (SOA). The main claim it makes is that purely semantic facilitation effects are conditioned by the degree of picture-word semantic similarity in contrast to inhibition effects for which categorical relatedness is typically sufficient. The experimental results support this claim and a simulation with an attractor neural network attempts to provide a unified account of semantic facilitation and inhibition in this paradigm as a function of SOA.

Introduction

Semantic facilitation from context words in a picture naming task, just like semantic priming in visual word recognition, has been a somewhat controversial issue. However, in picture naming, unlike word recognition, the issue does not seem to have been settled in favor of facilitation. It is naturally to ask then why purely semantic facilitation should show up when making a lexical decision or reading words but not when naming pictures. Both methodological and theoretical grounds are examined as potentially responsible for the failure to establish such a result with a picture naming task. The claim we attempt to support is that the categorical view on semantic similarity, as opposed to a graded featural one, is mainly responsible here. However, if facilitation is shown to be possible, one has to face the challenge of accommodating it with other experimental results, notably picture-word interference, in the framework of a general theory of speech production.

Originating with the study of Rosinski, Golinkoff & Kukish (1975), the picture-word interference paradigm established a classical result in the psycholinguistic literature. To put it succinctly, it takes more time to name the picture of an object in the presence of a semantically related word than in the presence of an unrelated one. For instance, naming the picture of a DOG in the presence of the word 'cat' takes longer than in the presence of 'tree'.

The classical study of Glaser and Düngelhoff (1984) opened the way to time-course analyses of the interference effect in the picture-word paradigm by systematic manipulation of the stimulus onset asynchrony (SOA) values, i.e. the temporal difference between the onsets of the two stimuli on a trial, the target picture and the context word. Examining different SOA values ranging from –400 to 400 ms, where negative SOA values correspond to word onset preceding picture onset, the two researchers found semantic inhibition in a small time window around synchrony (SOA=0) with a maximum inhibitory effect at 100 SOA. A facilitation effect at – 400 ms SOA, on the other hand, was not found to be significant.

Semantic interference around synchrony has been replicated many times and extended to cover various modifications of stimulus properties such as modality of the prime, category of named objects, stimulus duration, SOA etc. (Alario, Segui & Ferrand, 2000; Damian & Martin, 1999; La Heij, 1988; Roelofs, 1992; Schriefers, Meyer & Levelt, 1990; Starreveld & La Heij, 1996).

Facilitation at early SOAs, on the other hand, was more of a debated possibility. While the early studies of Sperber, McCauley, Ragain and Weil (1979) and Carr, McCauley, Sperber and Parmelee (1982) reported facilitation, later research failed to obtain it (Alario, Segui & Ferrand, 2000; Glaser & Glaser, 1989; La Heij, Dirx & Kramer, 1990). The reason invoked for this difference was twofold. First, early studies used long or very long SOAs – Sperber et al. (1979), for instance, reported facilitation for an interstimulus interval of as much as one second – which opened the gate to strategies on the part of subjects. Second, they failed to separate semantic from associative relatedness. 'Dog' and 'cat', for example, are good candidates not only for cohyponims, i.e. members of the same semantic category, but also for close associates as recorded by free association norms. The nature of the facilitation could have been then associative rather than semantic as suggested by robust purely associative facilitation results at negative SOA values (Alario, Segui & Ferrand, 2000; La Heij, Dirx & Kramer, 1990; Lupker, 1988). As a result, currently the issue seems to be settled pretty much against the possibility of purely semantic facilitation at negative SOAs.

The debate on facilitation in the picture-word paradigm can be paralleled quite interestingly with the debate on automatic semantic priming in lexical decision and word reading. Does a word prime speed up, for instance, the lexical decision for a semantically related word compared to a semantically unrelated one? The examination of many studies investigating this issue cannot give us a straight answer (see Neely, 1991 for a review). Similarly to the line taken in the picture-word paradigm, it was suggested that automatic priming in such a task reflects only an associative relationship (Shelton & Martin, 1992).

McRae and Boisvert (1998) suggested that the divergence of results and the failure to elicit purely semantic priming in

a number of studies could be due to an inadequate conception of semantic relatedness. In many of the previous studies two concepts have been taken as semantically related if they belonged to the same intuitive semantic category as judged by the researcher. However, if categorical relationships do not reflect accurately the organization of our semantic memory and only approximate quite roughly the graded nature of semantic similarity, e.g. featural similarity (McRae, de Sa & Seidenberg, 1997), then our choice of semantically related prime-target pairs in the experiment should be performed accordingly. McRae and Boisvert tested their hypothesis in a series of experiments with a lexical decision task controlling the semantic similarity of stimuli. The results supported their hypothesis. Highly similar pairs, e.g. *turkey – goose*, did elicit semantic priming at –250 ms while less similar pairs, e.g. *turkey – robin*, did not. Purely semantic priming was also obtained with synonyms and near-synonyms by Perea and Gotor (1996) both in lexical decision and word reading tasks, a result which adds further support to the hypothesis mentioned above.

In picture-word experiments researchers also tend to adhere to a categorical understanding of semantic relationship. Two concepts are judged as semantically related if they relate as cohyponyms or as category – exemplar pairs. This is enough to guarantee a reliable interference effect, so facilitation is searched for by the same standards. What if facilitation is a smaller effect sensitive to the degree of similarity between picture target and context word? An average or even low degree of similarity might be enough for a large and robust interference effect around synchrony but facilitation at earlier SOAs might remain undetected.

If one could show, as we attempt below, that there is semantic facilitation and, additionally, that it is conditioned by the degree of semantic similarity, that would be a successful extension of the results from one experimental paradigm to another and additional support for a graded view of semantic relatedness. However, it would amount to more than simply importing an experimental result from one paradigm to another. In picture-word experiments, in contrast to primed lexical decision or word reading, semantic interference is the rule. Putting together semantic facilitation and inhibition as a function of SOA is the challenge one would have to face next. A simulation with an attractor neural network is our candidate for accommodating these opposite effects.

The proper way of understanding and deploying semantic relatedness, on the other hand, might not be the only problem in detecting a small facilitation effect in picture-word experiments. One particular aspect of the procedure made use of in such experiments can also be a source of worry. In most of the studies in the paradigm, subjects are allowed to familiarize themselves with the target pictures and their proposed names in a pre-experimental session. Presenting the pictures and their desired names in advance certainly offers a number of benefits like keeping low the rate of misnaming errors. Familiarization with the target pictures is also supposed, as argued by Glaser and Düngelhoff (1984), to homogenize subjects with respect to visual processing of the pictorial stimuli. All of this, however, comes at a price. Subjects are primed before the experiment with the visual stimuli. Asking them to name the pictures in a pre-experimental session extends the scope of priming to all levels of processing in speech production. Moreover, having subjects learn the names of the pictures in advance could be a way of turning a lexical task into more of a memory task. Instead of accessing semantic memory for the concept corresponding to the picture, subjects may try to recall the name used for it before the experiment. The impact of these factors on the detection of a semantic effect, especially a small one, is hard to predict. The alternative we offer is a careful control of the pictorial stimuli, in particular their name and image agreement. Optimizing the stimulus material rather than preparing subjects for the test could be a reasonable alternative.

Experiment

The experiment addresses mainly the possibility of a semantic facilitation effect at an early SOA in the picture-word interference paradigm. The hypotheses we explore ascribe the failure to find such an effect in previous studies to an inadequate view on semantic similarity and to procedural specificity.

First, the experiment aims at exploring the role of semantic similarity in this paradigm. The question we ask is whether a high degree of semantic similarity, as opposed to simple categorical relatedness, could induce such an effect at an early SOA.

Second, we attempt to improve on the experimental procedure by eliminating subjects' familiarization with the stimulus material before the experiment and replace it with careful control of the stimuli. If this familiarization is the main culprit for hiding facilitation, we would expect to detect such an effect independent of the degree of picture-context word semantic similarity as long as they qualify for categorical relatedness.

Finally, as we deploy a somewhat nonstandard procedure and as it is the first time an experiment in this paradigm is run with Bulgarian stimuli, it is desirable to seek the replication of the classical result in the paradigm, i.e. semantic inhibitory effects around synchrony.

Participants

We tested 45 undergraduate students at the New Bulgarian University in Sofia, Bulgaria. All were native Bulgarian speakers and reported normal or corrected-to-normal vision. None of them participated in the norming studies performed in advance on the stimulus material used in the experiment.

Materials and Design

Thirty-six black-and-white drawings of common objects were selected from the pool of items for which norms are available in Bulgarian as part of the crosslinguistic study of

Bates et al. (2003). The choice of items was guided mainly by the attempt to maximize their nameability or consensus, i.e. percent of subjects naming the picture with the same name (dominant name), and image agreement as rated by subjects on a 1-to-7 scale. The main properties of the materials are summarized in Table 1.

Table 1: Properties of the target picture stimuli.

	Mean	Range
Consensus (%)	92	78-100
Image agreement (1-7)	5.7	4.6-6.6
Subjective frequency (1-7)	4.7	3.5-6.2
Concreteness (1-7)	5.9	4.5-6.7

Next, 36 picture-word pairs were constructed such that each picture and its corresponding word denote concepts from the same intuitive semantic category, e.g. *spider* and *ant* as insects. Care was taken that the pairs would not be close semantic associates by the examination of free association norms for Bulgarian (Gerganov, Ivancheva, Kurlova, Nikolov & Nikolova, 1984).

The total set of pairs was split in two halves as they scored higher (M=5.03, SE=0.15) or lower (M=3.33, SE=0.1) on a semantic similarity test in which 20 subjects were asked to rate the degree of similarity of the objects denoted by the pair items on a 1-to-7 scale (1 – very dissimilar, 7 – very similar).

Each picture was additionally assigned a nonword and an unrelated word by random choice of a word from a different semantic category. Thus, our first factor was type of context: semantically related, unrelated and nonword. Context type was crossed with the SOA. Three values were chosen to cover the time-course of semantic effects in picture naming: -350, 0 and 100 ms. Negative SOA values indicate that the context item was presented before the target picture. Both factors were within-subject.

Nine different lists were constructed containing all picture-word pairs, an equal number of pairs per condition. Half of the semantically related pairs in each list fell in the higher semantic similarity group while the other half in the lower semantic similarity one.

Procedure

Subjects were randomly assigned to lists and tested individually using the PsyScope Experimental Control Shell on a Macintosh computer with a 14-in. monitor.

The pictures were scaled and centered in an imaginary square with dimensions 4.5° X 4.5° visual angle. The (non)words, displayed below the pictures, were selected for each target so as to maximize the length match with their corresponding pictures. Both stimuli on a trial, the picture and the distractor, were thus displayed within an imaginary rectangle with dimensions 4.5° X 6° centered in the middle of the screen.

The subjects were instructed to name the pictures that would appear on the screen as quickly and accurately as possible with the best name they could think of and to avoid false starts, hesitations or extraneous material.

Each experimental trial had the following structure. A fixation crosshatch appeared in the center of the imaginary rectangle containing the picture and the (non)word for 200 ms followed by a 50 ms blank interval. Depending on the SOA, next appeared the picture, the (non)word or both. The (non)word stimulus duration was set to 200 ms. The target picture remained on the screen for a maximum of 2 seconds. The picture disappeared from the screen as soon as a vocal response was registered by a voice key.

The experimental session was preceded by a 6 trial warm-up set to let subjects familiarize with the task. There was no previous presentation of the stimulus material in the experiment and once presented stimuli were not repeated later with the same subject.

Results

Responses such as productions of names different from the dominant name, verbal disfluencies or no responses were scored as errors and excluded from the analysis. Three subjects and two items were excluded from the analysis because of the large percentage of errors they produced (more than 25 %). The error percentage for the remaining trials reached a level of 6.4%. Latencies greater than 3 SDs above the mean per condition were also removed. The resulting mean naming latencies per condition averaged by subjects are presented in Table 2. Positive values for semantic effects indicate facilitation while negative values indicate inhibition.

Table 2: Mean naming latency and semantic effect per condition[1].

Context type	SOA		
	- 350	0	100
Semantically related	892	973	958
Semantically unrelated	911	941	934
Nonword	898	910	910
Semantic effect	19	-32*	-24*

An overall analysis of variance (ANOVA) was conducted on the RT data, with context type and SOA as within-subject factors. Both analyses, by subjects and by items, revealed significant main effects for distractor type[2] ($F_1(2,82)=12.99$; $F_2(2,66)=8.51$), for SOA ($F_1(2,82)=23.96$; $F_2(2,66)=13.48$) and for their interaction ($F_1(4,164)=6.52$; $F_2(4,132)=2.97$). The lexical effect between the unrelated word condition and the nonword one was also found significant in a separate analysis ($F_1(1,41)=9.11$; $F_2(1,33)=66$). Naming latencies were significantly smaller at the negative SOA compared to either of the other two conditions. More importantly, we obtained semantic facilitation at –350 ms SOA and inhibition at 0 and 100 ms. Planned comparisons run for each of the SOA values established significant inhibitory effects both at synchrony

[1] Effects significant at $p<.05$ are marked with an asterisk *.

[2] In all analyses reported, $p<.05$ unless otherwise stated.

($F_1(1,41)=6$; $F_2(1,33)=11.27$) and at 100 ms ($F_1(1,41)=4.8$; $F_2(1,33)=4.3$). However, at the negative SOA there was only a trend to semantic facilitation both by subjects and by items ($F_1(1,41)=3.48$, $p<.07$; $F_2(1,33)=3.42$, $p<.08$).

Next, planned comparisons by items between the related and unrelated conditions were run at each SOA separately for the high and low similarity sets. They both replicated the inhibition pattern found at 0 and 100 ms with all items. The only difference showed up for the negative SOA where semantic facilitation reached significance for the high similarity set ($F(1,16)=4.57$) but not for the low similarity set ($F(1,16)=0.5$, $p<.56$). An additional power analysis showed the power to detect with all items an effect of the same size as the one obtained with the high similarity set was as high as 0.84.

The error analysis did not lead to any significant results.

Discussion

The experiment tested the possibility of detecting semantic facilitation at a negative SOA along with inhibition around synchrony in the picture-word interference paradigm.

One hypothesis ascribing the failure to detect facilitation in previous experiments to potential procedural drawbacks, namely pre-experimental familiarization of subjects with the stimulus material, was not supported by the results. Without familiarization we only noticed a trend to facilitation at −350 ms SOA (Glaser & Düngelhoff, 1984). However, we were able to replicate the inhibition results they and many others reported for small positive SOAs.

A second hypothesis linked this failure to too rough a conception of semantic similarity, namely categorical relationship. A move from a categorical view to a featural similarity view on semantic similarity proved successful in obtaining semantic facilitation in the word recognition paradigm (McRae & Boisvert, 1998). Making the same move in the picture-word interference paradigm proved to be a successful strategy, too. Categorical relatedness alone was not enough to deliver a significant facilitation effect. But high semantic similarity did provide us with such an effect. Additionally, the power analysis indicated that categorical relatedness, that is, the analysis including all semantically related pairs, was very likely to detect a significant effect of the size of the one we observed with the high semantic similarity set, if such an effect existed. The absence of a graded inhibitory effect at positive SOAs, on the other hand, was not a surprising result. As categorical relatedness is able to ensure large inhibitory results, a ceiling effect seems a likely explanation for this absence.

However, one worry we still need to address is the possibility of strategy use. Facilitation alone is not at stake. One has to ensure it is automatic. We could argue against expectancy effects at least on two grounds. First, 350 ms is still a small interval. It does not depart so much from the 250 ms limit proposed by Neely and Keefe (1989) for ensuring automaticity of effects and is still far from the large SOA values used in the early studies. Second, a lower relatedness proportion is believed to diminish or eliminate expectancy effects for long SOAs, e.g. de Groot (1984). Related pairs made up only a third of the stimuli subjects were presented and they could have deployed expectancy strategies meaningfully only at –350 ms SOA, that is, on one ninth of the total number of trials. Taken together, the size of the interval and the proportion of the occasions for potential strategy use could offer reasonable support for the claim that the semantic effect we observed was automatic.

Finally, our results and interpretation need to be qualified by the remark that they were obtained in Bulgarian, a Slavic language. To what degree effects like the one we investigate are sensitive to language characteristics is an experimental question. The study of Bates et al. (2003) raised such an issue with respect to timed picture naming. One peculiarity noticed about Bulgarian in this study was that naming latencies were longer than in other languages. In our experiment we also obtained naming latencies a little longer than the ones reported in similar experiments carried out in other languages. However, we were successful in replicating semantic interference effects for this language as they have been observed in many others. That only gives further ground for the expectation that semantic effects are robust enough across language dissimilarities.

Simulation

Once experimental evidence is available, the next step would be to offer an explanation for the effect in the general framework of a speech production theory. A unified account of semantic inhibition and facilitation in a picture naming task as a function of SOA would be the main challenge here.

If we conceive of the speech production system as a series of layers (stages) one on top of the other, we might get a very general idea of the way most theories in the field go. The sequence semantic representations (semantic processing) – lemmas (syntactic processing) – lexemes (morpho-phonological processing) – phonetics is a good candidate here (Dell, 1986; Levelt, Roelofs & Meyer, 1999). The interference effect is typically explained in this framework by competition / inhibition of the lexical items at the level built on top of semantics, e.g. lemmas (Roelofs, 1992) or lexemes (Starreveld & La Heij, 1996). A semantically related word compared to an unrelated one activates more its corresponding lexical unit at the next level as it receives additional support from the semantic representation of the target to be named. Thus it makes a more powerful competitor than the lexical representation of an unrelated word and interference shows up as a result.

In order to explain the pair of facilitation - inhibition effects in single word production we set up a small 3 layer neural network simulating lexical item activation based on semantic input. The input layer hosts semantic representations distributed over a set of feature units. The output layer stands for localist representations of lexical items at some level in the speech production system, possibly lexemes. The hidden layer thus compresses the intermediate levels of processing, notably lemma (syntactic) processing. Therefore, we may view the network as a

simplified model of speech processing in three stages: concept activation, lemma retrieval and lexeme selection.

A 20 X 30 X 20 feedforward architecture was enriched with a full set of interconnections at the hidden layer (without self-connections). Continuous spread of activation and a continuous version of backpropagation through time (Pearlmutter, 1989) as a training algorithm were made use of in order to be able to simulate temporal properties and relations of the stimuli like SOA and stimulus duration as well as naming latencies (see Plaut, 1995).

The network was trained for a fixed amount of time on 20 input-output pairs. The inputs were random distributed patterns on the semantic layer while the outputs were localist lexeme representations. That is, each input pattern was supposed to activate only its corresponding lexeme node on the output layer. Semantic relatedness was simulated by featural overlap. We had 15 related input pairs sharing on average around 5 features and 3 for a minimum. Another 15 unrelated pairs had at most 2 features in common. The first item in each pair stands for the concept denoted by the context word while the second stands for the meaning evoked by the picture.

In the simulation context meanings were presented to the network by clamping the state of the semantic layer to their assigned representations for a limited amount of time. Target meanings, in contrast, were presented to the network until the network settled, that is, until no lexeme unit changed its state by more than an output tolerance value. The time needed for the network to settle provided us with an estimation of naming latencies.

The three SOAs in the experiments were simulated by presenting the context meaning before the meaning of the target, at the same time or after it. Figure 1 presents the results. Both the mean latency differences and the size of the three SOAs are given in network time units. (The absolute time scale of the network is arbitrary.)

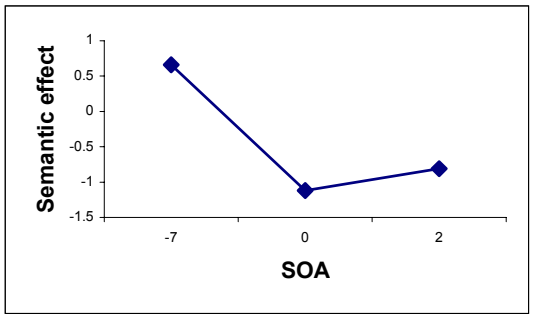

Figure 1: Mean latency differences between the related and unrelated conditions for three SOA values

The simulation replicated the experimental pattern of results: facilitation at an early SOA and inhibition for positive SOA values. Tracing the patterns of activation at both the hidden and the output layer suggested to us the following explanation of the effects. Related input patterns tend to have similar hidden layer representations or, at least, more similar than unrelated input patterns. Thus, it takes less time for a negative SOA to change the overall hidden layer configuration moving from a related context to the target than from an unrelated one. Therefore, the locus of the facilitation effect seems to be the hidden layer, that is, in our interpretation, the lemma level. Next, inhibition shows up at synchrony and at a short positive SOA as the lexeme node for a related context tends to be more active than the lexeme of an unrelated context making it a stronger competitor for the target node. On the other hand, processing of related and unrelated contexts did not seem to make much difference at the hidden layer. So, we could conclude that the locus of the inhibition effect is the lexeme level rather than the lemma level (see also Starreveld & La Heij, 1996). To conclude, the simulation offers a tentative explanation of both effects suggesting, however, that they reside at different levels and stages of processing.

The theoretical relevance of the simulation and the architecture we proposed intends to reach, however, farther than the simulation of the two opposite semantic effects we discussed. The key feature, we could say, is a distributed conception of lemma representation and the view that lemma retrieval corresponds to slipping into an attractor rather than activating above threshold a distinct lemma node. While the theoretical advantages of such a proposal are certainly in need of evaluation, we believe it could answer a major challenge put forward by Caramazza (1997): why should the speech production system be in need of lemma entities? The answer we propose is that lemmas play the role of a hidden layer in a connectionist network, namely they re-represent the semantic input (see also Dell, Schwartz, Martin, Saffran & Gagnon, 1997 for a similar suggestion). However, if lemmas continue to be conceived of as separate individual nodes as current models describe them (Dell, 1986; Levelt, Roelofs & Meyer, 1999), it is hard to see how such a re-representation could take place. Distributing lemmas across a set of features, on the other hand, can make them serve that purpose.

Conclusions

A graded featural view of semantic relatedness, as opposed to simple categorical relatedness, proves to be essential for ensuring purely semantic facilitation effects not only in word recognition but also in picture naming. Besides giving support to a featural account of semantic similarity and semantic memory organization, this also serves as a warning that categorical relations might be too rough a conception of semantic relatedness for the detection of potential semantic effects in various tasks.

Different loci for semantic facilitation and inhibition in picture-word experiments as a function of SOA are identified based on a simulation with an attractor neural network – the lemma level and the lexeme level in our interpretation. A hypothesis concerning the distributed nature of lemma representation is advanced with the more general goal of motivating the presence of lemmas in the speech production system.

Acknowledgments

The paper summarizes the main results reported in the master thesis of the first author under the supervision of the second. We thank Maurice Grinberg for his help in designing the simulation. We also thank Armina Janyan and Velina Balkanska for their help in designing and running the experiment. Finally, we are much indebted to Keith Stenning for his helpful comments and his review of the original material this paper is based on.

Abstract

To investigate people's ability to update memory in a dynamic task environment we use the experimental card game TRACS™ (Burns, 2001). In many card games card counting is a component of optimal performance. However, for TRACS, Burns (2002a) reported that players exhibited a baseline bias: rather than basing their choices on the actual number of cards remaining in the deck, they chose cards based on the initial composition of the deck. Both a task analysis and computer simulation show that a perfectly executed memory update strategy has minimal value in the original game, suggesting that a baseline strategy is a rational adaptation to the demands of the original game. We then redesign the game to maximize the difference in performance between baseline and update strategies. An empirical study with the new game shows that players perform much better than could be achieved by a baseline strategy. Hence, we conclude that people will adopt a memory update strategy when the benefits outweigh the costs.

Introduction

Optimal performance in dynamic environments requires that we base our decisions on the current state of the world, not on past states. Radar operators must act on the basis of continuously changing variables such as plane altitude and heading. Drivers constantly need to monitor the current speed limit, posted road signs and the traffic behind and in front of them. Failure to mentally update these types of information can lead to dangerous decisions and catastrophic behavior. Even our chances to win at card games like Blackjack or Bridge are closely tied to our ability to count cards and update memory.

Previous research suggests that human ability to monitor and adjust to change is limited and dependent on various factors. Yntema (1963) found that people are better at tracking a small number of variables with a large range of values each, than a large number of variables with a small set of possible values each. In addition, reducing the frequency of update can improve performance. Other manipulations, such as increased predictability of a sequence, provide little or no advantage in remembering the current state of the environment. Venturino (1997) distinguished the memory capacity for static information from that for dynamically changing information and showed that the latter is highly limited, particularly when the to-be-remembered attributes are similar. Hess, Detweiler and Ellis (1999) added that update performance is improved when spatial invariants constrain where different data values are presented on a visual display.

In general, human rational behavior is constrained by the structure of task environments and the computational capabilities of the actor (Simon, 1990). To capture functional relationships of complex tasks while abstracting away from domain specific details we advocate the use of synthetic task environments, or microworlds (Gray, 2002). If the properties of the synthetic task environments are known and manipulable, the scope and limits of human rationality can be assessed. Moreover, the effects of environmental changes are tractable.

Table 1: Baseline distribution of cards in the deck. The back of every card shows only its shape, whereas the front shows both its shape and color.

Shape:	▲	●	■	▲	●	■
Color:	red	red	red	blue	blue	blue
Initial deck:	6	4	2	2	4	6

Straight TRACS

TRACS™ is a 'Tool for Research on Adaptive Cognitive Strategies,' designed and developed by Kevin Burns (2001, 2004). Being both entertaining card game and experimental research tool, TRACS provides a microworld which promises to bridge the gap between mathematical rigor and real-world relevance. We will limit our discussion to *Straight* TRACS, which is the simplest version of an entire family of games.[1]

TRACS is played with a deck of 24 cards. The back of each card shows one of three shapes—circle, triangle, or square—filled in with black. The front of each card shows both its shape, and one of two colors (red or blue). Table 1 shows the initial deck distribution for each of the six possible card types. This baseline information is always available to the player. As hands are played the number of cards remaining in the deck decreases, and the odds for each shape change accordingly.

At the start of a game, three cards are dealt in a row. The middle card is dealt face up (showing both its shape and color), while the left and right cards are dealt face down, showing their shape not their color. The task for the player is to choose the card, either left or right, most likely to match the *color* of the middle card. The chosen card is then turned over, revealing its color. If the chosen card matches the color of the middle card, a *hit* is credited to the player's score. A mismatch is scored as a *miss*. The two face up cards (the middle and the chosen card) are then removed from the game. On

[1] Online versions are available at www.tracsgame.com.

the next turn, the unchosen card is flipped over and becomes the new middle card, and two new cards are dealt face down to the left and right. A game lasts 11 turns, at which point there are not enough cards in the deck to deal another hand. A player's objective in TRACS is to maximize the number of hits.

As a probe of the player's assessment of odds at each turn, Burns (2002a, 2002b) added a confidence meter to the task. On each turn, players were presented with a red to blue color gradient for each of the two face-down cards. Prior to choosing a card, the participants used the gradient to indicate the likelihood of each candidate card to be red or blue. In another condition, Burns used a scale of nine buttons rather than a continuous spectrum. For consistency reasons all gradient estimates were rounded to the nearest button, corresponding to the nearest 12.5%.

Burns (2002a) characterized players' likelihood estimates as exhibiting a *baseline bias*; i.e., their judgments of odds deviate systematically from the actual odds in the direction of the initial card distribution. There are six types of color–shape combinations. Burns (2002b) reports that players could only monitor 2–4 types of cards with reasonable reliability. He concludes that the dual tasks of concurrently counting and normalizing numbers 'are naturally hard' and that continuously updating odds exceeded the cognitive capacity of the 'unaided mind' (Burns, 2002a, p. 159).

In the following sections, we will challenge this claim both theoretically and empirically. To preview our conclusions, we find that subtle constraints in the task environment can have profound effects on the strategy adopted by participants. The reported baseline bias is revealed as both rational and adaptive when considered in light of a cost-benefit analysis of the environment. We then demonstrate that players will adopt a more effortful memory strategy if the cost-benefit structure of the environment rewards this.

Tracking TRACS

Given the original finding that players find it challenging to succeed at TRACS, a natural starting point for our investigation is a task analysis. What specifically makes this game so difficult to play?

Task Analysis

In describing TRACS as a game of 'confidence and consequence' Burns (2001, 2002b) distinguishes two subtasks of diagnosis and decision. On each turn, a player first provides an odds judgment for each face-down card and then chooses one on the basis of these estimates.

Extending Burns' analysis, we suggest that each turn involves a minimum of *three* distinct cognitive tasks: a memory retrieval task, an odds conversion task, and a decision task (see Figure 1). The first subtask on each turn consists in remembering how many cards of each candidate shape and color remain in the deck. As the initial card distribution is provided in terms of frequencies and players encounter card instances through a process of natural sampling, we assume that this retrieval is framed in terms of natural frequencies. Secondly, the retrieved frequencies need to be converted into odds, which is a non-trivial process involving Bayes' rule for natural frequencies (Gigerenzer, 2000). For example, to determine the likelihood of a red triangle, a player has to divide the number of red triangles currently left in the deck by the sum of red and blue triangles left in the deck. As people are notoriously bad at dealing with probability information (see Gigerenzer, 2000, and Koehler, 1996, for reviews) it is conceivable that this translation process incurs a loss of accuracy. If so, merely asking for likelihood estimates confounds memory updates with probability judgments and may underestimate players' true memory capacity. As a third subtask, a player needs to integrate all estimates and decide which candidate card is more likely to score a hit on the current trial.

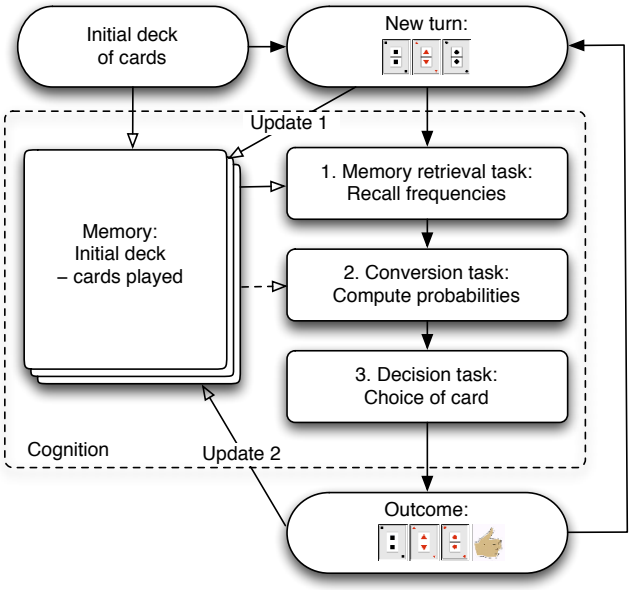

Figure 1: Subtasks and memory updates required on each turn of Straight TRACS.

In addition to these three subtasks, each turn requires two distinct updates of memory. The first update is necessary as soon as the middle card is revealed. If the middle card happens to be a red triangle, the player needs to realize that there now is one less red triangle left in the deck. The second update ought to occur at the end of a turn when the chosen card is revealed. This second update is critical, as at this point in the game, players may be distracted by focusing exclusively on the correctness of their choice and ignoring the additional information revealed.

This task analysis reveals both the complexity and simplicity of TRACS. On one hand, multiple subtasks and memory update requirements make the game quite challenging. Even if frequency information on card types was readily available, the conversions into probabilities, comparisons between odds, and selection of cards introduce potential sources of error. On the other hand, remembering and updating a list of six numbers (representing the current frequency of each card type) does not in itself seem beyond the capacity of human memory.

The Impact of Memory

At first glance, it seems that TRACS is a 'memory game' (Burns, 2001, 2002a) in which players can succeed only by remembering which cards have left the deck. However, our

experience playing TRACS casts some doubts on the importance of memory. Due to the random card selection process a typical game contains many knowledge-indeterminate turns. For example, whenever both face-down cards show the same shape, a player has no choice but to guess. Likewise, both face-down cards frequently have the same color, so that the player scores a hit or miss regardless of knowledge or choice. Even when the cards differ in shape, color, and odds, it is possible that selecting the card with higher actual odds results in a miss, whereas choosing the 'wrong' card scores a hit.

These concerns raise questions about whether memory really matters. To what extent can poor performance be blamed on failures of memory? Would better memory improve performance? The non-deterministic nature of the game makes it hard to answer these questions analytically; thus, we implemented the game as a computer simulation.

Simulation As Allen Newell and Herbert Simon famously stated, "Just as a scissors cannot cut paper without two blades, a theory of thinking and problem solving cannot predict behavior unless it encompasses both an analysis of the structure of task environments and an analysis of the limits of rational adaptation to task requirements." (1972, p. 55). In this spirit, we created a simulation in MATLAB™ in which 'pure' cognitive strategies could be formalized and implemented. By running these artificial agents for thousands of trials, we were able to determine precise performance levels, despite the dynamic and nondeterministic aspects of the game.

We compared four cognitive agents that differed in their memory resources and strategies, but did not make any errors in odds translation or judgment. A *baseline* agent has perfect knowledge of the initial deck distribution, but is amnesic with regards to the cards played during a game. In contrast, the *update* agent enjoys perfect memory of every hand played, and bases all choices on the actual odds at any given moment.

Two additional agents bracket the performance of baseline and update agents: *random* agent has neither memory nor knowledge of the initial distribution, and hence is forced to blindly guess at every turn. On the other end of the scale, *omniscient* agent effectively enjoys X-ray vision and can observe the colors of both candidate cards, allowing for optimal card selections without the need for memory or odds estimates.

The mean score for the random agent across 10,000 simulated games was 5.24 (out of 11 possible) hits per game. To our surprise, baseline and update agents performed about the same, scoring 6.57 and 6.79, respectively. Thus, the average performance difference between the baseline and update agents was roughly two tenths of one point per game. Further, both strategies achieved only marginally better scores than the random strategy.

Figure 2 shows the mean percentage of hits per turn for each agent. It is obvious that the performance of baseline and update agents are very similar, except for an increasing benefit of update strategy late in a game. The entire range between random and omniscient performance scores is only 25%, which is essentially due to 25% of all turns not allowing for a hit.

While an optimal update agent acts to maximize performance regardless of the effort involved, humans have limited cognitive resources and are required to negotiate cost–benefit tradeoffs (Anderson, 1990; Simon, 1990, 1992). Given these

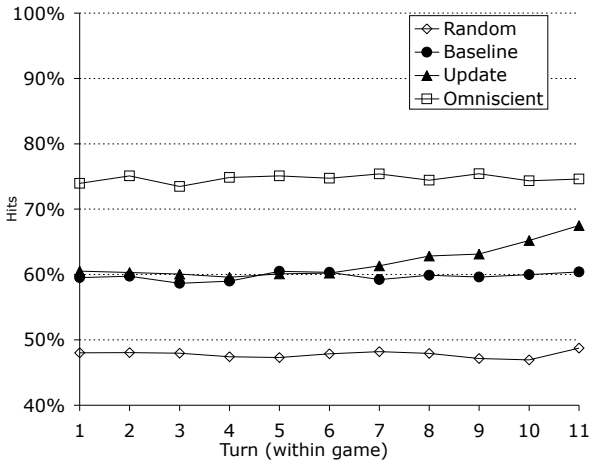

Figure 2: Simulation results for four artificial agents playing 10,000 games of original TRACS.

constraints and the minimal benefits of an update strategy, participants might well have adopted a baseline strategy for good reasons. Thus, our analysis suggests a re-interpretation of Burns' original findings: In Straight TRACS, memory update yields no performance benefit over adopting a much easier baseline strategy. Hence, adopting the baseline strategy is both adaptive and *rational*.

TRACS*

The simulation results suggest that—by not offering an incentive to a memory update strategy—Straight TRACS is inadequate for investigating people's willingness and capacity to monitor and update changing environmental circumstances. In this section we introduce TRACS*, which provides a clear benefit for adopting an update strategy, as well as introduces additional probes of memory performance.

In designing TRACS*, we sought to create a variant of the game for which a memory update strategy clearly benefits performance. We achieved this by carefully controlling the cards dealt to the players. While cards were selected randomly, they were selected from a card space constrained by two rules. First, only pairs of face-down cards that would not have equal odds of matching the target color would be dealt. By eliminating ties, this rule eliminates the need to guess. Second, pairs were not selected if the card with the lower odds resulted in a hit, or if the card with the higher odds did not. This rule aimed to reduce the influence of luck by eliminating win-win and lose-lose situations, thus driving a wedge between the baseline and update strategies.

Figure 3 illustrates the effects of these changes. The mean score for the random agent in TRACS* remained stable, at 5.49 (out of 11) hits per game across 10,000 games. However, baseline and update scores rose to 8.22 and 10.83, respectively. Hence, our game modifications were successful in introducing a substantial benefit of the update strategy over the random and baseline strategies. Given that baseline and update strategies now yield unique performance signatures, it should be possible to determine which strategy our participants actually adopt in the game.

Our second alteration in TRACS* was procedural. In addi-

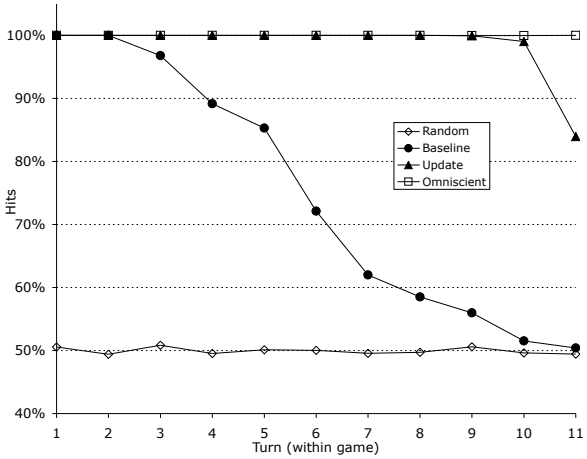

Figure 3: Simulation results for four artificial agents playing 10,000 games of modified TRACS*.

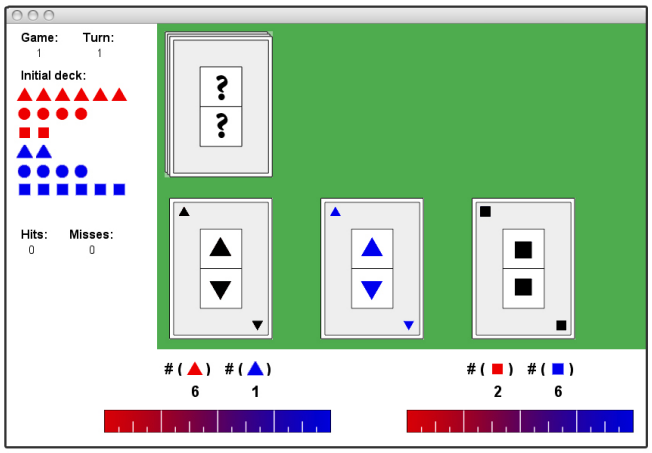

Figure 4: Screenshot of the TRACS* interface requesting odds estimates (after the completion of the recall task).

tion to using continuous color gradients to assess our participants' odds calculations, we introduced memory recall boxes to judge the accuracy of their memory. In this way we hoped to elucidate whether Burns' findings indicated an actual baseline bias, or merely just difficulty in converting accurately recalled frequencies into points along a likelihood gradient.

Experiment

Method

Twenty-five undergraduates from Rensselaer Polytechnic Institute participated in partial fulfillment of a course requirement. They ranged in age from 18 to 22 years, with an average of 19.6 years. Participants were tested individually.

The experimenter spent about ten minutes instructing each participant on the rules of original TRACS. Each participant played a total of 10 games of 11 turns each. On every turn, players had to complete the recall task, provide odds estimates, and choose a card.

On the newly added recall task participants were asked, for each face-down card, to report the number of red and blue cards of that shape which remained in the deck. Answers were typed into text boxes immediately below each face-down card. Players then estimated the odds of each face-down card being red or blue by placing a marker on a continuous color gradient. Gradients were red on the left and blue on the right, and 300 pixels wide (≈10 cm), allowing for a precision below one percent (see Figure 4 for a screenshot). Finally, participants chose a card by clicking on it. Feedback on correctness was then provided by a thumbs-up/thumbs-down image and the next turn was initiated by clicking on the feedback image.

The game was implemented in Macintosh Common Lisp 5.0 running on OS 10.2 with a 17" flat panel display set to a 1024×768 screen resolution. The initial card distribution and a hit/miss counter were shown to the left of the game window.

Results

We will assess participants' performance before turning to more detailed analyses of various error types.

Performance TRACS* allows for a straightforward correspondence between a player's awareness of the current game state and his or her outcome score. Thus, scores reliably exceeding the expected values of a simulated baseline agent would signal a memory update strategy.

On average, participants scored 9.3 hits per game with 22 out of 25 players (88%) exceeding the theoretic baseline score of 8.2 hits. This strongly suggests that memory updates contributed to task performance.

To allow for a statistical assessment of these differences, we let our simulated baseline and update agents both play the same number of games as human participants. A comparison of mean scores over the sequence of ten games per player showed that human players scored significantly more points than baseline agents [9.3>8.2, $t(26)=2.1$, $p<.001$], and significantly fewer hits than update agents [9.3<10.8, $t(25)=2.1$, $p<.001$]. Figure 5 contrasts the performance of human participants with that of simulated agents on a within-game resolution. It is obvious that human players did not perform on

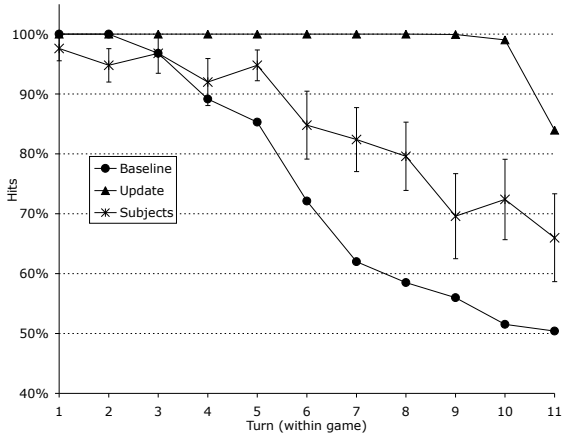

Figure 5: Participants' mean percentage of hits by turn compared to those of simulated baseline and update agents. (Error bars indicate 95% confidence intervals.)

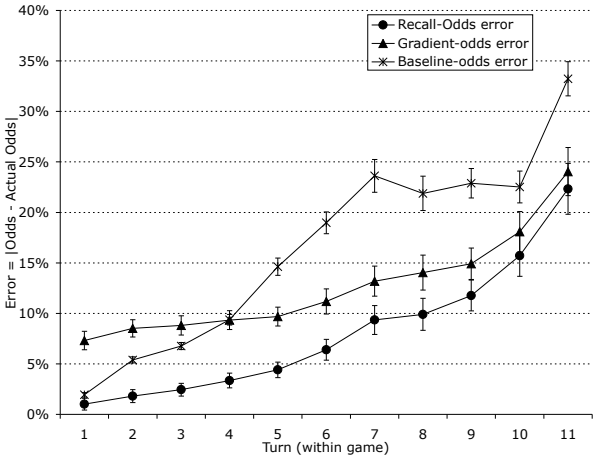

Figure 6: Average errors of odds by turn. (Error bars indicate 95% confidence intervals.)

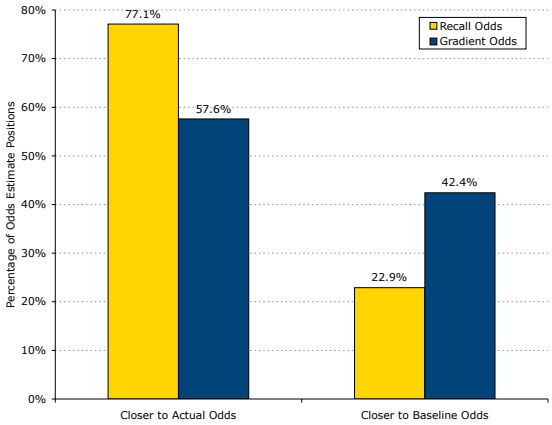

Figure 7: Percentage of odds selections closer to the baseline vs. closer to the actual value (based on n=4404 estimates).

the level of an ideal update agent, but did reliably better than a baseline agent.

To assess possible effects of learning we conducted an ANOVA with game number as a within-subjects factor. A significant main effect [$F(9,216)=3.0$, $p<.01$] indicated that players improved their scores reliably from an average of 8.8 hits in earlier to about 9.7 hits in later games. Subsequent comparisons showed that human participants outperformed a pure baseline agent in all but the initial two games.

Errors Even though human participants performed better than a baseline agent, their performance was worse than that of an ideal update agent. In this section, we examine this discrepancy by first considering erroneous frequency and likelihood estimates before assessing errors of internal consistency.

As participants estimated card frequencies as well as likelihoods we were provided with two distinct indices of memory. To allow for direct comparisons of both indices on a single scale, we converted reported frequencies into 'recall odds'. For both recall odds and likelihood estimates (as indicated on the gradient scales) we then calculated and summed up the absolute difference from the actual odds.

Figure 6 illustrates that both recall-odds and gradient-odds errors increase over the course of a game, but errors in frequency recall (with a mean of 8.0%) are significantly lower than the errors in likelihood estimates provided on gradient scales (12.6%). The third line in Figure 6 shows the mean size of the 'baseline-odds' error (16.5%) which would result if participants had adopted a baseline strategy on the given trial. Even though the mean gradient-odds error exceeded the baseline-odds error on the first three trials, the general trend indicates that participants' actual errors on both scales were lower than suggested by a baseline bias.

Taking into account the direction of deviations rather than just error magnitudes, we can also ask whether empirical recall and gradient odds are closer to the baseline or to the actual odds. Whenever the actual odds value deviates from the baseline value there are two possible attractors: Participants might specify odds closer to the baseline odds, or they might select odds closer to the actual odds. A *bias* is defined by a systematic preference. If participants—due to update failure or memory decay—were more likely to choose odds closer to the baseline than to the update value this would constitute a baseline bias. Likewise, an "update bias" could be diagnosed if participants were more likely to select odds in the vicinity of the actual value. Figure 7 shows that, in TRACS*, the evidence for an update bias clearly outweighs the evidence for a baseline bias. Participants' preference for actual values seems particularly pronounced when odds are based on recall frequencies (77.1% vs. 22.9%). In contrast, the same preference is weaker when odds estimates are measured by probability gradients (57.6% vs. 42.4%). As the baseline attractor seems to exert less gravitational pull when providing frequency estimates than when responding on a gradient scale, examining only the latter (e.g., Burns, 2002a, 2002b) might overestimate the size of a baseline bias.

All errors reported so far were deviations of empirical estimates from either true or baseline values. Our finding that participants' frequency estimates are closer to the actual values than to the initial baselines makes it implausible that participants' frequency estimates are governed by a baseline bias. At the same time, it raises questions about alternative breakdowns in performance. On the basis of our initial task analysis, the complexity of TRACS allows for a variety of non-memory related errors. In the following and final sections we consider conversion errors and errors of choice as examples of errors of internal consistency.

Due to our sequential procedure of first requiring frequency information and then asking for probability estimates, participants' responses on the likelihood gradients ought to be a direct function of recall performance. Nonetheless, people's notorious problems with probabilities can cause *conversion errors* when transforming recalled frequencies into odds on continuous scales. To assess the occurrence of such errors, we compared subjective recall odds (based on the card frequency entries of each participant and turn) with the likelihood estimates provided on the same turn. An average deviation of 6.6% indicates that this translation process was indeed non-trivial and error-prone. The magnitude of this error is striking not only as it is almost as large as the average error in fre-

quency recall (8.0%, see Figure 6), but also when considering that players reported their subjective frequencies immediately before indicating their judgment of odds and had all relevant frequencies displayed directly above the gradient scales (see Figure 4). Thus, we conclude that a large proportion of participants' error-prone responses on likelihood scales were due to errors in odds conversion.

Two curious errors of internal consistency address the relation between odds estimates and card selections. *Recall-choice errors* can be defined as instances in which the card with lower recall odds (based on the subjective card frequency estimates) is selected by the participant. Similarly, *gradient-choice errors* occur whenever the card with lower likelihood odds (based on probability estimates) is chosen.

There were 4.3% (119 out of 2750 choices) recall-choice errors, but 8.3% (229) gradient-choice errors. Given that any conflict between judgment and choice is relatively bizarre, both errors are more frequent than we would have expected. As the gradients are evaluated immediately before a choice is made, we interpret the relative size of both errors as evidence that players were more likely to base their choices on perceived frequencies than on perceived odds.

Discussion

Our first result is of a methodological nature: When creating artificial task environments to assess the scope of human rationality, the cost–benefit structure of the task must provide an incentive to display the behavior in question. Our simulation of Straight TRACS revealed that the original game provides only minimal benefits for adopting an effortful memory update strategy. This led us to re-interpret Burns' (2002a, 2002b) original finding of a 'baseline bias' as an adaptive and rational response to the properties of the task environment.

Our critique, however, does not imply that TRACS is not an interesting game and valuable research paradigm—quite to the contrary! We now believe that TRACS is both more complex and more interesting than it at first appeared. Our task analysis has suggested the need to distinguish three cognitive components: retrieving numbers of cards from memory, converting frequencies into probabilities, and mapping frequency or probability estimates to choices.

We are particularly intrigued by the errors our players made when converting natural frequency information to likelihood estimates. Players who had to provide the same information in two different formats within seconds and saw the frequencies displayed in front of them while computing probabilities still made substantial errors when coming up with simple likelihood estimates. Interestingly, our analysis of choice errors revealed that players seemed less likely to act on their inaccurate probability estimates than on their perceived frequencies even though the former just preceded their choice.

A potential caveat of our study is that by altering the cost-benefit structure of the task and assessing players' memory for card frequencies we introduced *two* changes to the original game. It is conceivable that the mere query for frequencies made the necessity to count cards more explicit, whereas it remains rather implicit in the original game. The extent to which each of our modifications contributed to the improved performance and to which a procedural task demand may have inadvertently prompted different memory strategies is an empirical question to be addressed in future studies.

Finally, the performance results of our modified version TRACS* provide a more optimistic view of the human capacity for concurrent memory updates than do previous studies. As our players were able to reliably exceed baseline performance, we conclude that the previously reported 'baseline bias' may be an artifact of the original game.

Despite our criticisms, our results agree with those of Burns (2002a, 2002b) that people are able to take baserate information into account. However, we additionally demonstrate that—when memory matters—people are also able to dynamically update their memory while being engaged in a highly demanding task.

Acknowledgments

We are grateful to Kevin Burns for allowing us to use TRACS and providing many helpful comments. In addition, we thank Christopher Myers, Bram van Heuveln and Jamie Sowder for many valuable contributions. The work reported was supported by grants from the Air Force Office of Scientific Research (AFOSR #F49620-03-1-0143), as well as the Office of Naval Research (ONR #N000140310046).

Defining New Words in Corpus Data: Productivity of English Suffixes in the British National Corpus

Eiji Nishimoto (enishimoto@gc.cuny.edu)

Abstract

The present study introduces a method of identifying potentially new words in a large corpus of texts, and assesses the morphological productivity of 12 English suffixes, based on some 78 million words of the written component (books and periodicals) of the British National Corpus (BNC). The method compares two corpus segments (created by randomly sampling at the level of documents within the BNC), and defines new words as those that are not shared across segments (segments being interpreted as randomly sampled speaker groups). The approach taken differs from others in the literature in that new words are identified irrespective of how many times a given word is used by the same speaker (author). A productivity ranking of the 12 English suffixes is obtained, and the results are shown to be intuitively satisfying and stable over different sample sizes. With a psycholinguistic interpretation of the data, implications for the nature of intuitions about productivity are considered.

Introduction

Morphological productivity is central to the study of word formation, but it continues to defy a solid, uniform description (see e.g., Aronoff, 1976; Bauer, 2001; Plag, 1999). The coinage of a "new" word is abundant in our daily use of language; for example, a person who is being gossiped about may be referred to as a *gossipee*, or a used book may be *cleanish*. Affixation in English (as in *gossip* + *-ee* → *gossipee*; *clean* + *-ish* → *cleanish*) is a productive word formation process, and there is plenty of evidence that affixes differ in their *degree of productivity* (e.g., Aronoff, 1976; Bauer, 2001); for example, words can in general be formed more easily with *-ness* than with *-ity* (and thus we may accept *cleanness* but not *cleanity*). The majority of researchers investigating the issue of productivity are interested in accounting for varying degrees of productivity, and several productivity measures have been proposed in the literature (e.g., Aronoff, 1976; Baayen, 1992, 2001; Bauer, 2001; Plag, 1999). Assessing the degree of productivity, however, has proven to be a complex task (Bauer, 2001): while the consensus seems to be that capturing the coinage of new words is essential in assessing productivity, there is an inherent difficulty in defining what a "new" word is.

Most notable among previous studies is a corpus-based approach proposed by Baayen (1992, 2001). Based on word frequency in a large corpus of texts, his productivity measure is formulated as $P = n_1/N$, where given a particular affix, n_1 is the number of word types with that affix that occur only once (the so-called *hapax legomena*, hereafter *hapaxes*), N is the sum of word tokens with that affix, and P is the productivity index.[1] P is interpreted as expressing the probability of encountering a word type with a given affix that has not been seen in the sampled corpus. Thus, new words are defined under this measure as "unseen" words in a corpus. An important characteristic of P is that it is based on token frequency—N directly refers to a count over tokens, and a word is included in the n_1 count only if it occurs just once. The measure P, with its focus on hapaxes as estimators of unseen words, is motivated by the probability estimation method of Good (1953)—or the *Good-Turing* estimation method (Church & Gale, 1991).[2]

While a dictionary provides another source of data for quantifying morphological productivity, a corpus-based approach has many advantages. A large corpus of texts contains productively formed words that are typically not listed in a dictionary (e.g., *gossipee*), and corpus data reflect how words are actually used (Baayen & Lieber, 1991; Baayen & Renouf, 1996).

The present study pursues and extends the corpus-based approach by introducing a new method of identifying new words and assessing productivity.

Type Frequency and Deleted Estimation

It has been suggested that the type frequency for an affix (the number of word types with an affix) in a corpus, represented by V, is inadequate in expressing its degree of productivity. Baayen and Lieber (1991: 804) point out that in their reference corpus of 18 million words, the type frequencies for *-ness* (497) and *-ity* (405) do not adequately express the fact that *-ness* is intuitively felt to be much more productive than *-ity*. They find that the P indices for *-ness* (0.0044) and *-ity* (0.0007) are more in line with linguists' intuitive estimates for these suffixes. There are, however, some aspects of the measure P that can be quite counter-intuitive. In Baayen and Lieber (1991), for example, the P index for verbal suffix *-ize* (0.00007) is substantially lower

[1] As is usually the case in a corpus study, the term *token* refers to each occurrence of a word, and the term *type* refers to each distinct word. For instance, if we have {*awareness*, *fairness*, *fairness*, *sharpness*, *sharpness*}, the *token frequency* for *-ness* is 5 (the sum of all occurrences of *-ness*), whereas the *type frequency* for *-ness* is 3 (the number of distinct words with *-ness*).

[2] For more detail, see Baayen (2001).

than that for *-ity* (0.0007). To correctly interpret these data, we need to take into account the fact that *P* is dependent on token frequency, and that verbs and nouns generally differ in their overall frequency in a corpus (Baayen & Lieber, 1991). Consequently, an across-the-board comparison of affixes across lexical categories is ruled out.

The view that type frequency in a corpus is problematic for assessments of degree of productivity holds only if type frequency alone is examined, for an entire corpus. A use of type frequency is suggested by Nishimoto (2003) in a productivity measure that adopts the mechanism of *deleted estimation* (Jelinek & Mercer, 1985; see also Manning & Schütze, 1999: 210–211), a probability estimation method used in Language Technology. The basic concept underlying the proposed productivity measure is the cross-comparison of corpus segments to identify word types that are not shared. The P_{DE} measure, a productivity measure based on the deleted estimation method, is formulated as:

$$(1) \quad P_{DE} = \frac{V_0^{AB} + V_0^{BA}}{V^A + V^B} = \frac{(V_0^{AB} + V_0^{BA})/2}{(V^A + V^B)/2} = \frac{V_N}{V}$$

Given a particular affix and two corpus segments *A* and *B* (both of some size *m*), V^A is the number of word types with that affix that are present in segment *A*, and V_0^{AB} is the number of word types with that affix that are present in segment *A* but are absent (unseen) in segment *B*. V^B and V_0^{BA} are defined similarly. Averaging the elements of the denominator and of the numerator separately, we obtain *V*, the total number of word types with that affix in a corpus segment of size *m*, and V_N (V-New), the number of *otherwise-unseen* word types with that affix (unseen being dependent on the relationship between segments). P_{DE} expresses the degree of productivity of an affix as the likelihood that a given word type with an affix will be unseen, hence potentially new. In addition to *V* and V_N, we also define V_{NN} (V-Non-New) as the number of word types with the relevant affix that are seen in both segments, hence non-new. What is essentially achieved by the P_{DE} measure is the division of sampled word types (*V*) into new word types (V_N) and non-new word types (V_{NN}). The relationship $V = V_N + V_{NN}$ holds in each application of the measure.

What are the grounds for associating new words with words that are not shared by two corpus segments? In the *British National Corpus* (BNC), data from unique sources are sampled in single documents, and thus each document could be considered to represent a set of words used either by one speaker (author) or by a few speakers (co-authors). Randomly distributing these documents into two corpus segments therefore gives us two groups of randomly sampled speakers (and the words that they used). Words that are not used in common by the two speaker groups are more likely to be new than words used by both groups. Cross-comparing two corpus segments offers a crude yet computationally simple method of separating words into potentially new words and potentially non-new words.[3]

Simulation Environment

We will examine the performance of the P_{DE} measure, based on the written component (books and periodicals) of the BNC, which offers some 78 million words sampled in 2,688 documents. Each sampled document is randomly assigned to one of two corpus segments, until each segment has a specified number of words in total (say, 30 million words). Documents are sampled without replacement, so no document is shared by two corpus segments. One simulation run (i.e., one application of the P_{DE} measure) consists of creating two corpus segments (as above) and obtaining values for *V*, V_N, and P_{DE}, based on formula (1).

Table 1 lists 12 English suffixes and 1 non-suffix control selected for the current study.[4] At least one suffix is included for each major lexical category.

Table 1: 12 English suffixes and 1 non-suffix control.

Suffix	Category	Prediction
-ness, *-ity*	Nominal	*-ness* > *-ity*
-er, *-ee*	Nominal	*-er* > *-ee*
-ion, *-ment*	Nominal	*-ion* > *-ment*
-th	Nominal	Unproductive
-ish, *-ous*	Adjectival	*-ish* > *-ous*
-ize, *-ify*	Verbal	*-ize* > *-ify*
-ly	Adverbial	Productive
ch#	Noun ending	Unproductive

The predicted differences in productivity in the last column of Table 1 are largely based on views expressed in the literature. We also examine *ch#*, the word ending of a noun (as in *church*), as a presumably unproductive non-suffix control that provides a baseline for determining whether suffixes are productive (or unproductive). Different semantic patterns among words formed with a suffix are ignored: for example, *amputee*, *absentee*, and *employee* exhibit different semantic patterns, but they are collectively treated as *-ee* words. We do not distinguish words with a suffix by the class of bases that the suffix attaches to: for example, *-er* includes *employer* (verb base) and *islander* (noun base). Ordinal numbers are excluded from *-th*.

A database of 17,347 word types representing the 12 suffixes and the non-suffix control was compiled, based on 100 million words occurring in the entire BNC. The database crucially relies on decisions about what constitutes a word type with a suffix. Most problematic are prefixation and compounding, which could dramatically increase the number of word types with a suffix. Removing all prefixes

[3] Nishimoto (2004) offers more detailed exploration of the mechanism of the P_{DE} measure, by increasing the number of cross-compared corpus segments (speaker groups) to 6.

[4] These are suffixes whose productivity is often discussed in the morphology literature. We focus on suffixes only, as they play a more prominent role than do prefixes in English word formation.

has some negative consequences, such as *encouragement* → **couragement* or *disagreement* → *agreement*.[5] On the other hand, allowing all prefixes does not seem plausible, since words such as *anti-institution* that appear to be cases of prefixation would count as distinct word types with a suffix. Compounding poses a similar problem, and the issue is further complicated by the variable hyphenation of words. In solving this familiar problem, we make use of entries in the *Oxford English Dictionary* (OED) and *Webster's Third New International Dictionary* (WD). All prefixed forms and compounds are checked against the OED/WD, and any preceding part of a word that cannot be spelled without a hyphen in both the OED and WD is removed. As a result, for example, *anti-institution* will be treated as *institution*, but *disagreement* will remain as *disagreement*. With the assumption that the OED and WD are conservative in accepting novel word forms, the current treatment effectively prevents novel cases of prefixation and compounding from inflating the count of word types with a suffix. Each word type in the database was inspected to exclude errors (e.g., misspelled words, words with a pseudo-suffix).[6] See Nishimoto (2004) for further detail.

Evaluation of Data

Productivity Indices

Table 2 presents mean values for V, V_N, and P_{DE}, averaged over 100 simulation runs, with 30 million words in each of the two corpus segments required by the P_{DE} measure (i.e., the total of 60 million words were sampled in each run). The suffixes in Table 2 are sorted by their P_{DE} value, to achieve a productivity ranking.

Suffixes *-ish* and *-ness* meet our expectations by being found at the more productive end of the ranking (although we might have expected *-ness* to be more productive than *-ish*), and *-th* and *ch#* fall at the less productive end. We consider the P_{DE} index for *ch#* to arise from processes other than affixation, such as the coinage of simplex words, compounding, or some sources of noise including the occurrence of rare or obsolete words.

Taking *ch#* as a baseline for determining productivity in affixation, we find that *-th* is unproductive. The finding that *-ment* is effectively non-productive matches Bauer's (2001: 8–9) observation that the productivity of *-ment* has been in decline so that new *-ment* words are synchronically rare.

Table 2: Mean values of the P_{DE} measure.

	V	V_N	P_{DE}
-ish	261.3	90.6	0.347
-ness	1354.9	431.2	0.318
-ee	88.6	26.1	0.295
-ize	437.6	114.5	0.262
-ity	1008.5	234.4	0.232
-er	2517.8	558.6	0.222
-ly	3585.0	754.3	0.210
-ify	105.8	21.1	0.199
-ous	639.1	107.1	0.168
-ion	2152.9	348.7	0.162
-ment	424.2	61.6	0.145
ch#	213.6	29.7	0.139
-th	40.9	3.5	0.085

The high productivity of *-ee* is somewhat unexpected, on its face. Based on the measure *P*, Baayen and Lieber (1991) also find *-ee* (0.0016) to be more productive than *-er* (0.0007), and they attribute the high productivity of *-ee* to the "vogue" nature of this suffix, as suggested by Marchand (1969).

In contrast to *-ee*, the productivity of *-er* is lower than we might have expected. Also lower than expected is the P_{DE} index for *-ly*. The result for *-ly* seems unsatisfactory considering the high regularity in *-ly* word formation—the suffix attaches to almost any adjective to form an adverb, with few restrictions (Aronoff, 1976: 37 fn 4; Baayen & Renouf, 1996: 82–83). The low P_{DE} indices for *-er* and *-ly* might be thought to arise from large values of V for these suffixes; however, Spearman's test shows no significant correlation between V and P_{DE}, $r_s = .203$, $p > .10$. We will return later to the data for *-er* and *-ly*.

Overall, we find that the P_{DE} measure yields results that largely accord with the productivity expected for the suffixes examined.

Sample Size Dependency

A question that naturally arises in evaluating the P_{DE} measure is to what extent the measure is dependent on sample size. Could it be the case, for example, that the productivity ranking of suffixes would differ markedly if the two corpus segments were smaller? Table 3 presents P_{DE} as a function of corpus segment size.[7] Again, each P_{DE} value is a mean over 100 simulation runs.

We find that P_{DE} values are remarkably similar across three series with different corpus-segment sizes. Friedman's test finds no significant difference in P_{DE} among the three, $\chi^2(2,13) = 2.627$, $p > .10$. Spearman's test shows that the P_{DE} indices are highly positively correlated: for 10 vs. 20 million words, $r_s = .990$, $p < .01$; for 10 vs. 30 million words, $r_s = .971$, $p < .01$; and for 20 vs. 30 million words, $r_s = .984$, $p < .01$. Thus, the P_{DE} measure offers a consistent

[5] Removing *dis-* from *disagreement* appears to be undesirable if we view *disagreement* as a nominalization of *disagree*.

[6] There are 6,797 rules defined for these corrections (mostly generated automatically, but some inevitably defined manually for cases such as "dona-a-a-ation" → *donation*). The number of rules is large, but it must be noted that some are needed to obtain correct forms for irrelevant words (so that they can be deemed irrelevant), and that a given word can be misspelled in a number of ways. Errors in a corpus cannot be overlooked. Evert and Lüdeling (2001) point out, for example, that each error in a corpus typically occurs only once and could greatly distort the number of hapaxes.

[7] As is clear from the formulation of the measure, a change in corpus segment size applies simultaneously to both corpus segments.

characterization of the productivity of these suffixes over different sample sizes.

Table 3: P_{DE} as a function of corpus segment size.

	P_{DE}		
	10 million	20 million	30 million
-ish	0.322	0.332	0.347
-ness	0.371	0.336	0.318
-ee	0.313	0.301	0.295
-ize	0.262	0.260	0.262
-ity	0.238	0.235	0.232
-er	0.260	0.236	0.222
-ly	0.226	0.215	0.210
-ify	0.179	0.191	0.199
-ous	0.164	0.165	0.168
-ion	0.169	0.163	0.162
-ment	0.153	0.148	0.145
ch#	0.164	0.153	0.139
-th	0.078	0.081	0.085

Token Frequency of New Words

One advantage of the P_{DE} measure is that new words in a corpus are identified in a way that is not solely dependent on token frequency. To ensure that advantage, it is crucial to implement the measure by creating corpus segments via random sampling at the level of documents (hereafter *RD*), rather than random sampling at the level of words (hereafter *RW*). The data presented in the preceding sections arise in implementations using RD.

If we were to follow RW, which words become identified as new would be dependent on their token frequency in the whole corpus.[8] Under the P_{DE} measure, a word is identified as new if all its tokens are distributed into only one corpus segment. If we were to randomly distribute words into two corpus segments (i.e., RW), the probability P that word *w* with token frequency *r* (in the whole corpus) will be identified as new is given by: $P(w\text{: new}) = 2(0.5^r)$. Figure 1 shows how P(*w*: new) changes as a function of *r*. We find that words that occur more than a few times in the whole corpus are highly unlikely to be identified as new. Hapaxes are exceptional in that they are guaranteed to be new, regardless of whether RD or RW is adopted. What is of interest regarding the difference between RD and RW is how many *non-hapaxes* are found to be new.

[8] The *whole corpus* here refers to the set of data used to create two corpus segments.

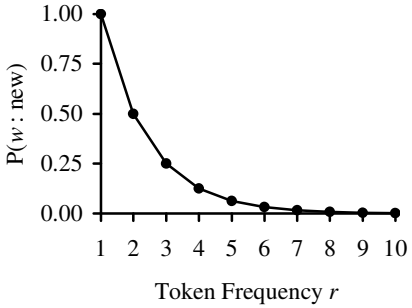

Figure 1: Probability of word *w* being identified as new.

We compare the outcome of RD and RW as follows. V_N values obtained under RD are listed in Table 2. For each of the 100 simulation runs generating these values, we sum the two corpus segments to obtain the whole corpus, and then, based on token frequencies in this whole, calculate a V_N value expected under RW, $E(V_N)$, based on the following formula:

$$(2) \quad E(V_N) = \sum_{r=1} N_r(0.5^r)$$

Here, *r* is the token frequency of a word, and N_r is the number of word types that occur *r* times. Table 4 contrasts V_N under RD and $E(V_N)$ under RW.

Table 4: Mean values for V_N (RD) and $E(V_N)$ (RW).

	V_N	$E(V_N)$
-ish	90.6	85.9
-ness	431.2	401.4
-ee	26.1	18.3
-ize	114.5	101.4
-ity	234.4	186.5
-er	558.6	463.9
-ly	754.3	707.0
-ify	21.1	18.5
-ous	107.1	89.1
-ion	348.7	270.6
-ment	61.6	49.4
ch#	29.7	23.0
-th	3.5	2.8

We find that each value of $E(V_N)$ is consistently an underestimation of the V_N. That is, more new words are captured by RD than by RW.

What kind of words are responsible for the discrepancy between RD and RW that is exhibited in Table 4? Consider *causee* (undoubtedly new to the majority of English speakers, except perhaps those who are syntacticians), which occurs 9 times in 1 document of the written component of the BNC. Under RW, the probability that all 9 tokens of *causee* will be distributed into only a single corpus segment is as low as about 0.002—in effect, *causee* is virtually guaranteed to be identified as non-new under RW.

Under RD, on the other hand, all 9 tokens of *causee* (occurring in just 1 document) will inevitably be distributed into only one corpus segment, and *causee* will thus be identified as new. The advantage of the P_{DE} measure (when implemented with RD) is that it captures as new words those words such as *causee* that are repeatedly used by the same speaker.

Implications for Linguistic Intuitions

Intuition-Based Interpretation

Although intuitions about productivity may not be reliable, they play an informal yet important role in evaluating results for a productivity measure—such results are often said to be intuitive or counter-intuitive. However, to the extent that little is known about the nature of such intuitions, determining the validity of a productivity measure on this basis may not be viable. Nevertheless, we may still ask what kind of information could be available to speakers (linguists) when they offer intuitive judgments about productivity.

We found in Table 2 that P_{DE} indices for *-er* and *-ly* are unexpectedly low, but one possibility is that the data on which P_{DE} is built are simply not in the form to be accessible to intuition. Speakers presumably cannot tell with any precision, for example, how many *-er* and *-ee* word types exist in the BNC, and thus, exact values of V, V_N, and P_{DE} may have little relevance to speakers' intuitions. On the other hand, speakers may be able to predict that "more" *-er* words than *-ee* words will occur.

What will be attempted here is a transformation of the data underlying the P_{DE} measure into a form that could be relevant to speakers' intuitions. There are two points to consider. The first is the possibility that whatever type frequency information speakers may have access to may be better represented on a logarithmic scale. Word frequency effects have been well studied in psycholinguistics (since Howes & Solomon, 1951; see Monsell, 1991, for an overview), where it has been noted that reaction time for a word in a lexical decision task is inversely proportional to the log frequency of that word. Although word frequency effects are normally discussed with respect to token frequency, the possibility that we entertain is that a similar logarithmic scaling may be also applicable to type frequency information.

The second point to consider is Baayen's (1993: 204) view that speakers' intuitive judgments on productivity are ordinal rather than interval in nature. Speakers presumably cannot tell to what extent *-ness* is more productive than *-ity*, but they may reject a productivity ranking in which *-ness* is ranked lower than *-ity*. Baayen also suggests that intuitions about productivity may simply be unavailable for some affixes.

Transforming V and V_N into $\log_{10}V$ and $\log_{10}V_N$ and taking their ratio (by analogy to V_N/V) is too simplistic a solution, and suffers a problem in that the complementary relationship between V_N and V_{NN} will be broken: the order of suffixes defined by V_N/V should be the reverse of the order defined by V_{NN}/V, but that relationship will no longer hold when values are log-transformed values. A solution to this dilemma is to shift our point of view, and to think of $\log_{10}V_N$ as the *extent* to which words are new and of $\log_{10}V_{NN}$ as the *extent* to which words are non-new. These are two conflicting factors that may simultaneously affect speakers' "impression" about a given word formation process. When $\log_{10}V_N$ (the extent to which words with a suffix are new) approaches $\log_{10}V_{NN}$ (the extent to which words with that suffix are non-new), the word formation process for that suffix may be felt to be productive, with a degree that can be calculated by the ratio of $\log_{10}V_N$ to $\log_{10}V_{NN}$.[9] Table 5 presents a productivity ranking of suffixes calculated in just this way.

Table 5: Intuition-oriented productivity ranking of suffixes.

	$\log_{10}V_N$	$\log_{10}V_{NN}$	Ratio
-ness	2.63	2.97	0.886
-ish	1.96	2.23	0.879
-er	2.75	3.29	0.836
-ly	2.88	3.45	0.835
-ize	2.06	2.51	0.821
-ity	2.37	2.89	0.820
-ee	1.42	1.80	0.789
-ion	2.54	3.26	0.779
-ous	2.03	2.73	0.744
-ment	1.79	2.56	0.699
-ify	1.32	1.93	0.684
ch#	1.47	2.26	0.650
-th	0.54	1.57	0.344

Following the view that intuitive judgments on productivity have an ordinal character, we concentrate only on the ranking of suffixes shown in Table 5. Interestingly, we seem to have gained many improvements as compared to Table 2. We particularly note the following: (a) *-ness* now counts as the most productive suffix; (b) *-er* and *-ly* move up in the ranking to be close to *-ness* and *-ish*; (c) *-ee* moves down in the ranking but is still close to *-ize*; and (d) *-ify* is now much lower in the ranking. Perhaps one unsatisfactory result is that *-ly* still does not emerge as the most productive suffix.

Although the exploration offered in this final section is based on speculation about what information could be available to speakers, the fact that the productivity ranking of suffixes in Table 5 is intuitively satisfying, by and large, suggests that the approach merits further investigation in future research.

Conclusion

The analysis of the data for the P_{DE} measure demonstrates that the deleted estimation method offers an effective means of capturing new words in corpus data and of assessing the

[9] The complementary relationship between V_N and V_{NN} is of course maintained by the ratio of $\log_{10}V_{NN}$ to $\log_{10}V_N$.

productivity of affixes. An interesting characteristic of the P_{DE} measure is that its identification of new words is not dependent on token frequency, and this may be construed as an advantage, given potential burstiness in the use of new coinages. The current measure identifies a word as new regardless of whether it is used repeatedly by the same speaker. The measure is also shown to be stable over different sample sizes.

Some findings appeared to deviate slightly from our intuitive expectations, but we proposed, (appealing to a psycholinguistic interpretation of the data), that it may be necessary to draw a distinction between raw corpus statistics and information that could be accessible to intuitions about productivity. Corpus statistics, scaled in psychologically plausible ways, may offer insights into the kind of information available to speakers when they make intuitive judgments on productivity.

A description of productivity obtained with a corpus-based productivity measure will be useful in many forms of linguistic research, not necessarily limited to the study of word formation. The success of the present study provides another indication that the corpus-based approach to the study of productivity advocated by Baayen (1992, 2001) is worthy of many future extensions.

Acknowledgments

The author wishes to thank Dianne Bradley, Harald Baayen, and the anonymous reviewers for their insightful comments on this paper. Any errors remain the responsibility of the author.

Testing Three Theories of Knowledge Transfer

Timothy J. Nokes (tnokes@uic.edu)

Abstract

Three theories of knowledge transfer -- analogy, knowledge compilation, and constraint violation -- were tested across three transfer scenarios. Each theory was shown to predict human performance in distinct and identifiable ways on a variety of transfer tasks. Results support the hypothesis that there are *multiple mechanisms* of transfer and that a general theory of transfer must incorporate each mechanism in principled ways.

Introduction

In order to understand human thinking and problem solving in complex and novel situations we need to have a general theory for how people use and adapt their prior knowledge to solve new problems. Aspirations towards such a goal have traditionally been discussed in terms of *transfer*, or how knowledge acquired from one task or situation can be applied to a different situation (Bransford & Schwartz, 1999; Detterman & Sternberg, 1993; Salomon & Perkins, 1989).

Work in cognitive science over the past thirty years has progressed towards this goal by investigating separate strands of transfer phenomena that occur in particular learning and problem solving situations. Although this research strategy has proven successful in developing local, independent explanations of knowledge transfer for particular experimental scenarios (e.g., analogical transfer and transfer appropriate processing), it has done little to bring us closer to a *general theory of transfer*. It is time to begin to weave these separate strands of investigation into a more complete theory that incorporates each strand in principled ways.

It is this charge of theoretical synthesis that motivates the two hypotheses under investigation in the current study. First, it is proposed that there is no single knowledge transfer mechanism, but multiple ones. These mechanisms include (but are not limited to) analogy, knowledge compilation, and error correction. Second, the particular transfer mechanism used depends on both (a) the knowledge actually present and how it is represented, and (b) the processing demands of the transfer task.

Below I summarize some of the prior work on transfer that is relevant to the investigation of these two hypotheses.

Mechanisms of Knowledge Transfer

The first mechanism of interest is *analogical transfer* (Gentner, Holyoak, & Kokinov, 2001). Analogical transfer is composed of three subprocesses: retrieving a prior knowledge structure, creating a mapping between it and the current problem or situation, and then using that mapping to generate new knowledge structures relevant to the application context. The transferred knowledge is typically assumed to be a declarative representation, but it can also include procedural attachments (Chen, 2002).

The empirical evidence for analogical mapping is extensive (Catrambone & Holyoak, 1989; Gentner & Toupin, 1986). However, the evidence also shows that although people are capable of mapping deep relational structures, the retrieval of an analogue is heavily dependent upon matches between the surface features of the current problem and prior problem solving experiences (Catrambone, 2002; Ross & Kilbane, 1997). Therefore, analogy is perhaps a better explanation for near transfer than for far transfer.

The second transfer mechanism of interest is *knowledge compilation* proposed by John R. Anderson and co-workers (Anderson, 1983; Neves & Anderson, 1981). Knowledge compilation was specifically proposed to explain how declarative knowledge is brought to bear on problem solving in the context of the ACT-R theory. This computational mechanism operates through the deliberate and explicit, step-by-step interpretation of a declarative statement that generates new production rules as a side effect. Those rules are then optimized via rule composition and the result is a procedural representation of the content of the declarative knowledge given a specific goal.

The knowledge compilation mechanism can be viewed as a translation device that translates or interprets declarative knowledge (e.g., advice, instructions, and strategies) into a set of procedures and actions that can be used to solve problems. Since knowledge compilation operates on declarative knowledge it can be used in a wide variety of application contexts because the knowledge has yet to be proceduralized, or tied to the goals of a particular problem solving context. This mechanism embodies a tradeoff between applicability and efficiency in that it has wide applicability across many contexts but requires a complicated and lengthy application process to translate the declarative knowledge into a set of actions. There is some empirical support for knowledge compilation but the evidence is not extensive (Anderson, Greeno, Kline, & Neves, 1981; Neves & Anderson, 1981).

The third transfer mechanism of interest is Ohlsson's (1996) *error correction* mechanism. Ohlsson and co-workers (Ohlsson, 1996; Ohlsson & Rees, 1991) have proposed that

the role of declarative knowledge is primarily to help a learner identify and correct his or her own errors. The constraint violation theory has both declarative and procedural components that operate in parallel, and the function of declarative knowledge is to constrain possible problem solutions. When incomplete or faulty procedural knowledge generates undesirable outcomes, these are recognized as violations of those constraints and the responsible rules are revised accordingly.

The power of declarative knowledge is that it can help the learner pinpoint the cause of an error, and transfer is the process by which errors are identified and remedied. This mechanism has wide applicability in that the constraints can be applied to a variety of problems that may require *different* strategies or sequences of actions to produce the correct solution. The constraint violation theory has been shown to generate power law learning curves (Ohlsson, 1996) and to support the design of successful tutoring systems (Mitrovic & Ohlsson, 1999).

In addition to each transfer mechanism using different cognitive processes, each mechanism has also been hypothesized to operate on specific types of prior *knowledge structures*. Analogy uses exemplar knowledge that consists of a declarative representation that may also have procedural attachments (Gentner, 1983). Knowledge compilation uses declarative knowledge such as instructions, advice, or tactical knowledge (Anderson, 1983). Error correction uses declarative knowledge of the constraints for a particular problem domain (Ohlsson, 1996).

In summary, researchers have proposed multiple alternative transfer processes including analogy, knowledge compilation, and error correction. Each mechanism has been associated with a particular kind of transfer scenario that specifies the conditions necessary for transfer (i.e., type of prior knowledge and application context). The purpose of the current study is to test the predictions of each transfer theory, and ask whether we can predict what transfer mechanism will be triggered for a given set of transfer scenarios.

The Present Study

In order to test these theories I implemented a between-groups training study in which subjects were given one of three training scenarios (exemplar, tactics, or constraints) and then were tested on a common set of problem solving tasks.

Each training scenario was designed to facilitate the construction of one of the three of the aforementioned knowledge structures associated with each transfer mechanism (i.e., exemplars for analogy, tactics for knowledge compilation, and constraints for error correction). In the exemplar training condition participants solve problems similar to those used in the transfer phase. In the tactical training condition participants learn instructional tactics for solving the transfer problems. In the constraints training condition participants learn the constraints associated with the problem solving task domain.

The transfer task is Thurstone's *letter extrapolation task* (Thurstone & Thurstone, 1941). In this task subjects are given a sequence of letters containing a pattern and their task is to find the pattern and continue it. Here is a simple example, A B M C D M . . . the correct continuation is E F M G H M. An important aspect of these problems for the current purposes is that prior declarative and procedural knowledge can make them easier to solve.

Although letter extrapolation is an invented task, it has several elements in common with many real world tasks including: a prior knowledge base (e.g., the alphabet), conceptual content (e.g., the pattern), materials to study (e.g., tactics), and generativity (e.g., one has to generate a sequence of coordinated actions).

Three different extrapolation problems were used in the transfer phase. Each problem was constructed with different properties or affordances, to elicit quantitative (accuracy, solution time, self-corrected errors) and qualitative (solution type) differences in performance from each training group.

The first transfer problem was designed to have a similar surface and deep pattern structure as that used in the exemplar training problems. This problem can also be solved by applying either tactical or constraint knowledge. The second transfer problem is open-ended and depending on how the given sequence is interpreted, different solution types are expected. This problem shares the same deep structure as the exemplar problems. However, the surface similar characteristics are misaligned and suggest a different interpretation. If the given sequence is interpreted as similar to the *surface sequence* one solution is expected. If it is interpreted as a *deep analogy* a second solution is expected. Tactical knowledge can also be used to solve this problem and biases one towards the second solution. Constraint knowledge can be applied as well and does not provide an a-priori bias towards any one of the correct solutions. The third transfer problem has neither surface nor deep structure similarity to the exemplar problems. The tactics are also not directly applicable. However, the constraints can be applied to find a unique solution.

In addition to comparing task performance across training groups, each training group was compared to a *no-training* control group for a measure of transfer relative to baseline performance.

Predictions

Exemplar Training. If participants in this training condition use exemplar knowledge and analogy to solve the first transfer problem they are expected to show high accuracy and fast solution times with few error-correcting behaviors as compared to the no-training group. They should show fast solution times for this problem because there is both surface and deep similarity to the training exemplars (i.e., fast memory access). They should show few error-correcting behaviors because they can transfer both declarative and procedural knowledge from the exemplars. For transfer problem 2 participants are expected to show high accuracy with slower solution times and few self-corrected errors. In

addition, they should show a bias for the surface similar problem solution. For transfer problem 3 they should show similar performance to no-training participants.

Tactical Training. If participants in this training condition use tactical knowledge and knowledge compilation to solve the first two transfer problems they should show high accuracy but similar solution times and error-correcting behaviors to that of the no-training group. In addition, for transfer problem 2 they should show a bias for the tactics relevant solution. For transfer problem 3 they should show similar performance to that of the no-training participants.

Constraints Training. If participants use constraint knowledge and error correction to solve all three transfer problems they should show high accuracy, similar solution times, and many error-correcting behaviors compared to the no-training group. In addition, they should show more variability in solution types for transfer problem 2.

Methods

Participants

One hundred and twenty-five undergraduate students from the University of Illinois at Chicago's subject pool participated in return for partial course credit.

Materials

Training Materials. The training materials for the *exemplar group* consisted of four sequence extrapolation problem isomorphs. Each problem was presented on a separate sheet of paper. All four training problems had the same deep pattern structure as each other and the first two transfer problems, but each was instantiated with different surface features. Below are two examples:

Exemplar 1: L M Z M L Y M N X . . .
Exemplar 2: E F S F E R F G Q . . .

The training materials for the *tactics group* consisted of a general tutorial, a tactic summary sheet, and several blank recall sheets. The tutorial (10 pages) provided instruction on specific kinds of pattern relations including: *forward*, *mirror-flip*, *backward*, *repeat*, and *identity*. Each pattern relation was defined and multiple examples were given. The tactics summary sheet consisted of one pattern continuing tactic and four pattern finding tactics including: (1) look for mirror flips or periods to break apart the pattern, (2) repeated letters may signal a mirror-flip order of symbols, group repeat, or period marker, (3) letters that are far apart in the alphabet may signal a mirror-flip alphabet, (4) letters close together may signal backward or forward relations. The tactics could be used to solve the first two transfer problems.

The training materials for the *constraints group* consisted of a constraints tutorial, constraint summary sheet, blank recall sheets, and letter string violation worksheet. The tutorial (5 pages) provided instruction on four letter pattern constraints: (1) all *completed* letter strings must be divisible into six groups of letters, (2) the number of letters in each similar group must be the same, (3) each letter group must be derived from either the immediately preceding letter group or the letter group two back, (4) letter operations must be repeated. The string violation worksheet provided a series of completed letter strings in which the participants' task was to identify constraint violations.

Test Materials. The test tasks were three letter extrapolation problems. See Table 1 for each transfer problem and its solution(s). The first extrapolation problem had a periodicity of three letters. It was superficially similar to the exemplar training problems and shared the same deep pattern structure. This problem could also be solved by applying either tactics or constraint knowledge. Subjects were asked to continue the solution to six positions.

The second extrapolation problem also had a periodicity of three letters. However, the correct continuation was ambiguous and was dependent on how the subject interpreted or "parsed" the given sequence. There are two primary solutions depending on the interpretation of the given sequence. If the letters are parsed into cross period relations of *forward-1* and *backward-1* comparable to surface similar relations used in the exemplar problems, one solution type will be derived (see Table 1, solution 1). However, if the given string is instead parsed as cross period relations of *mirror-flip-alphabet* and *backward-1* relations as suggested by a deep analogy or pattern finding tactic 3, a different solution will be derived. Subjects were asked to continue the solution to nine positions. In addition, there were four other possible correct solutions.

The third problem had a periodicity of two letters and had neither surface nor deep structure similarity to the exemplar problems. In addition, there was no pattern finding tactic that directly applied to this problem. However, a unique solution could be derived by constraint application. The pattern consists of pairs of letters incrementally increasing through the alphabet, each pair skipping an additional letter as the pattern progresses.

Table 1. Transfer problems and their solutions.

Problem Type	Given letter sequence & the correct extrapolation
Transfer 1	
	Given: R S F S R E S T D T S C . . .
	Solution → T U B U T A
Transfer 2	
	Given: B C P X Y O C D N . . .
	Solution 1 → Y Z M D E L Z A K
	Solution 2 → W X M D E L V W K
Transfer 3	
	Given: B A C B E D H G . . .
	Solution → L K Q P

Transfer problems were presented on a Macintosh computer with a 17'' color monitor, standard keyboard and mouse. Problems were presented in black 30 pt font in the center of the screen. The transfer portion of the experiment was designed and presented using PsyScope software.

Design

A between-subjects design was used with subjects randomly assigned to one of four training conditions: *exemplar training* (n = 31), *tactic training* (n = 31), *constraint training* (n = 33), and *no-training* (n = 30). Participants were tested individually. The procedure consisted of a training phase and a transfer phase.

Procedure

Training procedure for the exemplar group. Participants were first given general instructions for solving extrapolation problems. Next they were given three minutes to solve the first training problem. After three minutes participants received feedback on each position of their solution. If they extrapolated any position of the solution incorrectly they were given another instance of the same problem and three minutes to solve it. This cycle continued until the problem was solved correctly or the participant made four attempts to solve that problem. After the first problem this same procedure was continued for the remaining three training problems.

Training procedure for the tactics group. Participants first read the general tutorial. Next they memorized a summary sheet of the tactics for three minutes. Then they were given a simple unrelated distractor task to solve (e.g., three arithmetic problems). Participants were then asked to recall and write down all of the tactics. The experimenter assessed memory performance for recall of each tactic. If the subject omitted or incorrectly recalled any of the tactics they were given the tactic summary sheet to study again for another two minutes. After the second memorization phase they were given another distractor task followed by recall. This cycle was continued until the subject recalled all five tactics. After correct recall the subjects were asked to explain each tactic to the experimenter. If the subject gave an incorrect explanation the experimenter provided the correct explanation.

Training procedure for the constraints group. Participants first read the constraints tutorial. Next they memorized a summary sheet of the four constraints for three minutes. They were then given an unrelated distractor task to solve. Participants were then asked to recall the constraints and were given feedback on their recall performance. If they omitted or incorrectly recalled any of the constraints they were given the constraint summary sheet to memorize for another two minutes. After the second memorization phase they were given another distractor task followed by a blank recall sheet. This cycle continued until participants recalled all four constraints. After correct recall of the constraints subjects were asked to explain each constraint to the experimenter. If the subject gave an incorrect explanation the experimenter provided the correct explanation. Participants were then given the string violation worksheet.

Training procedure for the no-training group. Participants in this condition did not receive any training and served as a comparison condition of baseline performance on the transfer tasks.

Test procedure for all training groups. Subjects were seated at the computer and were told that they were to solve three extrapolation test problems. They were instructed that the given string of each transfer problem would be presented on the left side of the computer screen and that there would be an empty box for each letter position they were to extrapolate and fill in. Subjects were informed that they could re-enter new letters in any given position as many times as they would like. Subjects were told to click the mouse on the "Finished" field after all solution positions were filled and they were finished solving the problem. After the initial instructions participants were presented with each problem one at a time and given six minutes to solve each one.

Results and Discussion

Training Performance

Subjects in all three training groups were trained to criterion. The criterion measure for the exemplar group was solving at least two of the training problems completely correct. The criterion measure for the tactical and constraints groups was complete recall and correct explanation of the tactics and constraints respectively. Three subjects in the constraints training condition and one subject in both the exemplar and tactical training conditions did not pass the criterion. These subjects were excluded from further analysis leaving thirty subjects (n = 30) in each training group.

The training criterion provides evidence that each subject learned the target knowledge during the training phase (i.e., subjects in the exemplar group could solve training problems and subjects in the tactical and constraints group could recall declarative knowledge from memory). Next, I examine whether these subjects could transfer this knowledge to the problem solving tasks.

Transfer Performance

The three measures of central interest for the transfer phase were participants' accuracy scores and behavioral profiles across the three transfer problems, as well as the type of solution used to solve problem 2.

Accuracy Performance. To assess overall transfer performance participants' accuracy scores were examined for each training group. The *accuracy score* was the proportion of solution positions correctly extrapolated for a given transfer problem. The mean accuracy scores and standard deviations for each training group on the transfer problems are presented in Table 2.

Table 2. Mean proportion of solution positions correctly extrapolated for each transfer problem.

Training	Transfer1	Transfer2	Transfer3
Exemplar	.93* (.19)	.80 (.26)	.21 (.43)
Tactics	.78* (.32)	.71 (.32)	.22 (.37)
Constraints	.70* (.34)	.74 (.33)	.23 (.41)
No-training	.40 (.36)	.69 (.38)	.29 (.43)

A 4 (training) X 3 (problem type) mixed-analysis of variance (ANOVA) revealed a significant interaction of training by problem type, F (6, 232) = 6.46, $p < .05$. Follow-up comparisons showed that the interaction was best explained by the large advantage of the training groups over the no-training group on transfer problem 1, F (6, 232) = 43.14, $p < .05$, but not on problems 2 and 3, F (6, 232) = .76, *ns* and F (6, 232) = 1.41, *ns* respectively.

As predicted, all three training groups showed high accuracy in solving the first two transfer problems. Problem 1 in particular shows that the knowledge generated from each training condition facilitated transfer resulting in significantly higher accuracy performance than the no-training group. Although the constraints training group showed high accuracy on the first two transfer problems they did not show high accuracy scores on the final problem. One potential explanation for this lack of predicted transfer is that solving the first two transfer problems provided participants with partial exemplar knowledge that interfered with constraint application (this issue is further discussed in the conclusion).

Behavioral Profile. In order to assess whether a given participant used a particular transfer mechanism an ideal behavioral performance profile was created for each transfer mechanism. The use of a particular transfer mechanism can be evidenced by a constellation of scores across a set of dependent variables, what I term the *behavioral signature*.

The dependent variables used in this assessment included the accuracy score, the solution time, the number of self-corrected errors, and the checking time. The *solution time* was the total time in seconds to solve the problem. The *self-corrected error score* was the total number of times a subject re-entered a new letter into a given solution position that changed a previous response. The *checking time* was the amount of time in seconds between a subject's last extrapolation response and clicking on the finished button. This was presumably an indirect measure of error-checking behavior.

Using this set of dependent measures an ideal behavioral signature was created for each transfer mechanism (see Table 3). The qualitative indices (e.g., fast vs. slow) for a given variable are in comparison to the average no-training baseline performance.

Table 3. Ideal behavioral signatures for each transfer mechanism.

Behavior	**Transfer Mechanism**		
	Analogy	Knowledge Compilation	Error-Correction
High Accuracy	√	√	√
Fast Solution	√		
Error Checking			√

The ideal behavioral signature for analogical transfer was a high overall accuracy, a fast solution time on problem 1, and few error correcting behaviors. The ideal behavioral signature for knowledge compilation was a high overall accuracy, similar solution times and error correcting behaviors. The behavioral signature for error-correction was high accuracy, similar solution times, and a high number of error correcting behaviors.

Each subject's performance was examined as to whether it fit with a particular behavioral signature. For a subject's accuracy performance to be classified as *high* he or she had to have an overall accuracy score higher than the average (collapsed across problem) of the no-training group. For a subject's solution time to be classified as *fast* it had to be at least 1 standard deviation faster than the average solution time of the no-training group. Subjects were classified as having high error checking behavior if their performance met one of two criteria. The participant must have either scored 1 standard deviation above the average no-training group on both of the error measures (i.e., many self-corrected errors and long checking time), or have scored 2 standard deviations above on a single error measure. The number of subjects classified under each behavioral signature is shown in Table 4.

Table 4. Number of subjects classified under each behavioral signature.

Training Condition	**Behavioral Signature**			
	Analogy	Knowledge Compilation	Error-Correction	Other
Exemplar	19*	9	0	2
Tactics	2	16*	6	6
Constraints	3	7	13*	7

Chi-square tests showed that the training groups differed in the number of subjects classified for a given behavioral signature, χ^2 (6, N = 90) = 43.10, $p < .05$. Follow-up tests showed that more subjects trained on exemplars used analogy than those trained on tactics or constraints, χ^2 (2, N = 30) = 31.02, $p < .05$, more subjects trained on tactics used knowledge compilation than those trained on exemplars or constraints, χ^2 (2, N = 30) = 6.49, $p < .05$, and more subjects trained constraints used error-correction than those trained on exemplars or tactics, χ^2 (2, N = 30) = 16.94, $p < .05$.

In summary, the majority of subjects in a particular transfer condition showed the expected pattern of behavioral results as predicted by the three theories of transfer. This provides evidence that these three mechanisms are triggered under particular learning and transfer task conditions.

Solution Type. In addition to accuracy performance and behavioral profiles, further support for transfer can be assessed via the types of solutions participants used on problem 2. The number of subjects to use a given solution type is provided in Table 5.

Table 5. The number of subjects from each training group to use a given solution type.

Training Condition	Correct Solution Type		
	Solution 1	Solution 2	Others
Exemplar	19*	1	1
Tactics	5	12*	4
Constraints	12	0	4
No-training	9	0	9

Chi-square tests showed that the training groups significantly differed in the number of subjects to use a particular solution type, χ^2 (6, N = 77) = 41.68, $p < .05$. Of particular interest is that more exemplar training subjects used solution 1 than those given other forms of training, χ^2 (3, N = 77) = 20.80, $p < .05$, and that more tactics training subjects used solution 2 than subjects from the other groups, χ^2 (3, N = 77) = 29.70, $p < .05$.

In sum, these results provide further evidence that participants used training knowledge to solve the transfer problems. Subjects given exemplar training showed a preference for the surface similar solution and the tactics group showed a preference for the tactics relevant solution.

Conclusion

The results from this study provide support for the hypothesis that there are multiple mechanisms of transfer that are distinct and identifiable. Subjects in three separate transfer scenarios exhibited behavioral patterns of performance consistent with those predicted by three theories of knowledge transfer.

Several review articles have pointed out that the transfer literature exhibits a mixture of both positive and negative results (Bransford & Shwartz, 1999; Salomon & Perkins, 1989). While some studies have failed to find large transfer effects where we intuitively expect them, others have found transfer effects under particular types of study and test conditions. The complexity of the empirical results suggests that transfer is a heterogeneous phenomenon. Greater clarity might result if we assume that *different transfer processes are triggered in different types of transfer scenarios*. Results from the current study suggest that to understand transfer one must take a multifaceted approach and examine several interrelated aspects of the transfer scenario, not just one or two variables from a single theoretical perspective. Progress towards a general theory of transfer requires the synthesis and integration across current lines of research.

Future work should examine the interaction of these transfer mechanisms and investigate whether people are capable of *adaptively shifting between mechanisms* depending on their prior knowledge and the processing demands of the transfer task.

Individual differences and implicit language: personality, parts-of-speech and pervasiveness

Abstract

Dewaele and Furnham predict that in oral language Extraverts prefer to produce what they term implicit language. They use: more pronouns, adverbs and verbs; and fewer nouns, adjectives and prepositions. However, communication in a computer-mediated environment, such as e-mail, might disrupt these preferences. Also, other personality dimensions, such as Neuroticism, may be related to implicitness. The study exploited an existing corpus of e-mail texts written by native English speakers of known personality. Stratified corpus comparison used n-gram-based techniques from statistical natural language processing, to compare relative frequencies of use of (sequences of) parts-of-speech. Implicitness effects were found, and Neuroticism appeared to have a clearer impact than Extraversion.

Personality and language

Individuals differ in the way they speak and write. Some of those differences are systematic, and can be attributed to apparently deeper differences, such as personality traits, like Extraversion and Neuroticism. Extraversion is a trait strongly related to interpersonal interaction and sociability, whereas, Neuroticism, or Emotional Stability, is related to internal emotional states, rather than interaction. In the past, it has been found that both these personality traits do significantly influence an individual's language production behaviour in a variety of contexts (Pennebaker and King, 1999; Dewaele and Furnham, 1999). Recent work has investigated e-mail text, and suggested that there are characteristic sequences of words and punctuation associated with each end of both dimensions (Extravert or Neurotic) (Gill and Oberlander, 2002, 2003).

However, Mehl and Pennebaker (2003) note that linguistic style is more consistently described by its syntactic component, than by content. So, it could be that the relative use of different parts-of-speech (POSs) is a more important indicator of personality than the relative use of words or strings of words.

The work by Dewaele and Furnham suggests that, at least for Extraversion, there are real effects to be found in spoken language, at the level of POSs. In their account, implicit language involves a preference for pronouns, adverbs and verbs, whereas explicit language involves a preference for nouns, adjectives and prepositions. Heylighen and Dewaele (2002) suggest that Extraversion leads to implicitness due to greater visual-spacial capacities, and this is part of an overall preference for informal language. However, this work leaves open whether or not implicitness effects will be found for Neuroticism. Gill and Oberlander's work suggests that formality may also be a factor in Neurotic language behaviour, because the reduced resources of high Neurotics do not enable detailed language planning. But that work did not investigate implicitness in patterns of POS use. It would therefore be interesting to know whether Dewaele and Furnham's 'Implicit-Extravert hypothesis' applies in the genre of e-mail text—a genre close to spoken language—and if so, how.

To address this question, the rest of this paper is structured as follows. First, we give some background to help frame implicitness hypotheses that gives POS predictions for both Extraversion and Neuroticism. We then present the stratified corpus comparison methods used in analysing POS use in the e-mail corpus. Results were somewhat unexpected, in that implicitness predictions appear to be confirmed for Neuroticism, but not for Extraversion. We discuss possible ways of resolving the issue.

Background

Two personality traits

Extraversion and Neuroticism are traits which are common to the two major trait theories of personality: Eysenck's three factor model (Eysenck and Eysenck, 1991); and the five factor model developed by Costa and McCrae (Costa and McCrae, 1992) and others.

They are described as follows: High Extraverts are said to be sociable, easy-going, and optimistic, and to take chances. Low Extraverts (or Introverts) are said to be quiet, and reserved, and to plan ahead, and dislike excitement. High Neurotics are said to be: anxious, worrying, over-emotional, and frequently depressed. Low Neurotics are said to be: calm, even-tempered, controlled, and unworried (Eysenck and Eysenck, 1991).

Dewaele and Furnham

Furnham (1990) has proposed the following features of Extravert and Introvert language. Extravert language: is less formal; has a more restricted (rather than elaborated) code; uses vocabulary more loosely, where this is defined in terms of how correctly words are used, and how unusual they are. And it uses more verbs, adverbs and pronouns (rather than nouns, adjectives, and prepositions). This last tendency directly involves POSs. Using factor analysis of syntactic tokens produced by L2 speakers, Dewaele and Furnham (2000) describe implicit language as a preference for pronouns, adverbs and verbs, and they contrast it with explicit language, seen as a preference for nouns, modifiers and prepositions. So Extraverts prefer implicitness, and Introverts prefer explicitness. For the purposes of this paper, we shall term this the Implicit-Extravert Hypothesis. The hypothesis appears to hold in both informal and formal situations, and is consistent with previous analyses of the individual linguistic categories (Dewaele, 2001). Cope (1969) also notes a lower lexical diversity (measured as type-token ratio), for Extravert native French speakers, with this also the case for non-native speakers of English (Dewaele and Furnham, 2000).

However, although they have discussed varieties of anxiety and their effects on communication, Dewaele and Furnham have not attempted to predict which part-of-speech patterns might be characteristic of the related trait Neuroticism. What might we expect to find?

An extension: Implicit-Neuroticism

Previous work by Gill and Oberlander (2002, 2003) gathered a corpus of e-mail messages, and analysed it for characteristic words and sequences of words. The corpus comprised 210 texts produced by 105 University students or recent graduates (37 males, 68 females). Each participant composed two e-mails *to a good friend whom they hadn't seen for quite some time*, spending around 10 minutes on each message. The first e-mail concerned their activities in the past week, the second discussed their plans for the next week. The total corpus size is around 65,000 words.

Following analysis of occurrences of individual words, and sequences of words, it was reported that the corpus results on Extravert words were broadly consistent with previous findings, for instance using informal language, looser punctuation, vaguer quantification and more co-ordination. This therefore appears to fit the Implicit-Extravert hypothesis; however, no POS analysis was reported.

However, there were also results on Neurotic language use. Pennebaker and King (1999) previously argued that High Neuroticism was associated with a language factor for 'Immediacy'. Gill and Oberlander (2003) extended these results, suggesting that 'High Neurotics show a preference for forms occurring frequently in speech, for example, *I, and, that*, rather than less common words such as *abject, suspicion, tether*. This preference for common words contributes towards the very low lexical density found in highly Neurotic texts, demonstrated by the high level of repetition over ten-word sections of text.'

What is interesting about this is that it suggests that Dewaele and Furnham's ideas about formality and implicitness might be as relevant to the Neuroticism dimension as they are to the Extraversion dimension. If they are, then we would expect that—like High Extraverts—High Neurotics will use more verbs, adverbs and pronouns, while Low Neurotics will use more nouns, adjectives, and prepositions. We call this the Implicit-Neurotic Hypothesis (INH). It obviously raises the question of whether or not *both* dimensions are related to implicitness, and the relative strength of any connections.

To address this question, we here apply to the existing e-mail corpus a series of techniques to derive POS frequencies, and POS sequences.

Syntactic Analysis of the Corpus

Method

The personality corpus was acquired as described above. It was tagged using the Penn part-of-speech tagset, using the MXPOST tagger (Ratnaparkhi, 1996). Further processing removed the original words, leaving their associated POS tags. A subsequent stage of processing reduced the POS tags from the detailed Penn tagset to more general syntactic categories. The 45 Penn tags (see Marcus, Santorini, and Marcinkiewicz, 1994, for more details) were converted to 10 broader categories, as implemented in the electronic version of the Shorter Oxford English Dictionary which is incorporated into the MRC Psycholinguistic Database (Wilson, 1987). These are: Noun (NN), Adjective (ADJ), Verb (VBN), Adverb (ADV), Preposition (PRP), Conjunction (CONJ), Pronoun (PRN), Interjection (INT), Past Participle (VPP), and Other [syntactic categories] (O). In addition to these categories, we also make use of ⟨p⟩ indicating punctuation, and 'NA', which indicates that a feature does not belong to any of the above categories and generally represents the ⟨END⟩, end of text marker. Note that here we use a different set of labels to enhance intelligibility, and these do not co-incide exactly with those used in the MRC database: for instance, we use 'PRP' instead of 'R'.

The reduced-tag corpus—with the more general syntactic categories—was then divided into stratified sub-corpora. In stratifying, we isolate a 'reference corpus' of text from authors with a personality profile which is not extreme on any of the measured dimensions. We can then compare authors from each of the extreme personality groups with this 'neutral' (here termed 'mid') group. Thus, High

and Low personality group samples were created by splitting them at greater than 1 standard deviation above and below the EPQ-R score for each dimension. The additional requirement was made that authors had to be *within* 1 standard deviation on the dimensions other than the one for which they were extremely high or low. Additionally, all texts which were within 1 standard deviation across *all* personality dimensions were assigned to the personality 'neutral' Mid sub-corpus. Thus, on any dimension, we have three groups to compare (High, Mid, and Low).

The resulting sizes of the subcorpora are as follows: Around 6,000 words for the high Extraversion, and over 2,000 words for the low Extraversion groups (11 and 4 authors respectively); Over 3,000 words for the high Neurotic and around 6,000 words for the low Neurotic groups (6 and 9 authors). The Neutral group was around 10,000 words (23 authors).

To identify collocations in the tagged sub-corpora, we calculate 1–5 word n-grams, and do not use a rank or frequency cut-off during calculation, but only present features with a frequency $\geq$5. This enables an accurate log-likelihood statistic (G^2) of their occurrence between groups to be calculated (cf. Rayson, 2003). We use N-gram software (Banerjee and Pedersen, 2003) to compute G^2 for 2- and 3-grams. To identify those robust collocations which distinguish one group from another, we need to make a three-way comparison of the linguistic features across the high-mid-low corpora for each group. We calculate the relationships between the three groups, and for each feature in each corpus we identify its frequency and relative frequency, and then where relevant its relative-frequency ratio and log-likelihood between High-Low, High-Mid and Low-Mid groups. This allows us to compare the relative usage and statistical significance of the difference in the use of features between groups.

Results

We first report the results of the unigram analysis for Extraversion and Neuroticism dimensions, we then report the findings of the overall n-gram analyses (1–5 item sequences). Following this, the results for Extraversion and Neuroticism are outlined.

Unigram Syntactic Analysis

Results of the unigram analysis for the reduced set of syntactic tags can be found in Tables 1 and 2. We display the results for all tags present in our data; however G^2 values which achieve significance of $p \leq 0.05$ or $p \leq 0.01$ are noted by $*$ or $**$ respectively.

In this presentation of the results, we draw attention to features which are characteristic of the High or Low groups, compared with the usage of the feature more generally. In the tables, we distinguish whether a feature is under- or over-used by one of the three groups (High, Mid or Low), relative to the two other groups; this information is given in the final three columns of each table, with over-use indicated by + and under-use by −. However, a more concise view of the results can be gained in the following way. At least two kind of features can be associated with (say) High Neuroticism: unigrams which are over-used by High Neurotics; and unigrams which are under-used by Low Neurotics. Thus, Figure 1 lists, for each dimension and each sub-group, the features which are associated with that group *either* via their over-use of the feature, *or* an opposite group's underuse.

High Extraverts [CONJ]
Mid Extraverts –
Low Extraverts [VPP]

High Neurotics [CONJ] [PRN]
Mid Neurotics –
Low Neurotics [ADJ] [NN]

Figure 1: Summary of unigram POS analysis

For Extraversion, conjunction (CONJ) is characteristic of High Extraverts, and past participle verbs (VPP) of Low Extraverts. The Mid Extravert group shows no significant under- or over-use of the general tags. For Neuroticism, conjunction (CONJ) and pronouns (PRN) are characteristic of High Neurotics, and adjectives (ADJ) and nouns (NN) of Low Neurotics. The Mid Neurotic group shows no significant under- or over-use of the general tags.

For these results, we note the generally modest levels of significant differences we found between personality groups. We may take this to indicate that these groups generally use relatively similar proportions of the relevant parts of speech. However, the POSs may also occur in different contexts or sequences, thus indicating differences in they way they are used. We therefore turn to the results of the n-gram analysis of the syntactic tag data.

N-gram Syntactic Analysis

There is insufficient space to display the full results. A concise view is therefore given in Figure 2. Notice that for the Mid groups, we have to distinguish features labelled specifically as under-use, since this is of course relative to both the High and Low groups.

The features here reach much higher levels of significance than the unigrams, so here we only discuss those which reach the critical value of 10.83 (i.e., $p \leq 0.001$). 32 n-gram features reach this value for Neuroticism, and 25 for Extraversion. Of these, the majority in each case reach the 15.13 critical value ($p \leq 0.0001$): 23 and 17, respectively. The features reaching this higher value are predominantly bigrams, exceptions being the longer n-grams for

Note. $*p < .05$, $**p < .01$, $df = 1$.

punctuation found for Neuroticism. In interpreting this data, we seek distinctive POS collocations. Table 3 shows, for each sub-group, how many distinctive collocations involving each POS were found.

Extraversion From the unigram analysis, we are particularly interested in collocations involving conjunctions (for the High E group) and past participle verbs (for the Low E group). As far as conjunctions are concerned, High Extraverts are associated with the use of [CONJ VBN] and [CONJ ADV], while Low Extraverts are associated with the use of [CONJ VBN PRN]. The latter offers a particularly distinctive collocation, since the pronoun switches the preference from High to Low E. Turning to past participles, we find that High E prefer [VPP PRP], but there are no preferred collocations for Low Extraverts.

Given Table 3, the remaining discrepancies between the High and Low E groups are as follows. Allowing that there are substantially more distinctive collocations for the High E group overall, we find that the High E group has notably more collocations involving: punctuation, adjectives, nouns, and POSs in the Other category. The Low E group has notably more collocations involving verbs and pronouns.

Neuroticism Here, we are most interested in collocations involving pronouns and conjunctions (for the High N group) and adjectives and nouns (for the Low N group). Taking pronouns first, we find a High Neurotic preference for [ADJ PRN VBN], [ADJ PRN] and [VBN PRN O]. Turning to conjunctions, they also show a preference for [VBN ADJ CONJ]. Three of these collocations also involve adjectives, which are used overall more by Low Neurotics. However, the rest of High N preferences for collocations involving pronouns instead involve adverbs: [VBN PRN O ADV VBN], [VBN PRN O ADV], [PRN VBN PRN O ADV] and [ADV PRN VBN PRN]. While Low Neurotics have only one pronoun collocation involving an adjective—[PRN ADJ]—the other three of their preferred pronoun or conjunction collocations also involve adverbs: [PRN ADV], [ADV PRN] and [CONJ ADV].

Given Table 3, and allowing that there are rather more distinctive collocations for the High Neurotic group overall, we find that the High Ns have notably more collocations involving verbs, and POSs in the Other category. The Low Ns have notably more collocations involving: past participle verbs and adverbs.

Discussion

Dewaele and Furnham's original Implicit-Extravert Hypothesis predicted that in spontaneous speech High Extraverts will use more verbs, adverbs and pronouns, and that Low Extraverts will use more nouns, adjectives, and prepositions (see Heylighen and Dewaele, 2002, for a discussion as to why certain POSs are preferred by Extraverts). The unigram analysis did not support these predictions. It indicated that High E use more conjunctions, and that Low E use more past participle verbs. No other overall differences were found, although it is perhaps

High Extraverts [CONJ VBN] [NN NN] [ADV ⟨p⟩] [PRN NN] [⟨p⟩ O] [ADV O] [ADJ ⟨p⟩] [NN ADV] [CONJ ADV] [VPP PRP] [ADJ O] [⟨p⟩ ADJ] [PRN O ADV] [VBN O NN ⟨p⟩] [PRN O ADV VBN] [⟨p⟩ O VBN ADJ ⟨p⟩] [⟨p⟩⟨p⟩⟨p⟩]

Mid Extraverts Underuse: [⟨p⟩ ADV] [⟨p⟩ NN]

Low Extraverts [ADV PRP] [PRN ADV] [VBN PRN O] [VBN PRN ADV] [CONJ VBN PRN] [VBN ⟨p⟩ PRN]

High Neurotics [VBN PRP] [⟨p⟩ O] [⟨p⟩⟨p⟩⟨p⟩⟨p⟩⟨p⟩] [⟨p⟩⟨p⟩⟨p⟩⟨p⟩] [⟨p⟩⟨p⟩] [⟨p⟩⟨p⟩⟨p⟩] [VBN PRN O] [ADJ PRN VBN] [PRP ADJ] [VBN O VBN ADV] [PRN VBN PRN O ADV] [VBN ADJ CONJ] [ADJ PRN] [VBN PRN O ADV VBN] [VBN PRN O ADV] [ADV PRN VBN PRN]

Mid Neurotics Underuse: [PRN ⟨p⟩ ADV] [NN VBN O ADJ] [NN VBN O ADJ NN] [PRN O VBN ⟨p⟩]

Low Neurotics [⟨p⟩ ADV] [PRN ADV] [ADV ADV] [ADJ ⟨p⟩] [ADV O] [VPP ADV] [O ADV] [ADV PRN] [CONJ ADV] [ADV VPP] [PRN ADJ] [VPP PRP]

Figure 2: Summary of n-gram POS analysis

worth noting that since we have both past participles and general verbs, our categories are slightly more fine-grained, which may affect the result.

The new Implicit-Neurotic Hypothesis predicted that High Neurotics will use more verbs, adverbs and pronouns, and that Low Neurotics will use more nouns, adjectives, and prepositions. The unigram analysis partially supported these predictions. It found that High N use more pronouns (and conjunctions), and that Low N use more nouns and adjectives. However, no overall differences were found for verbs, adverbs or prepositions.

At first glance, then, it appears that the Neuroticism dimension is more closely related to implicitness than the Extraversion dimension, in this corpus

POS	Extraversion			Neuroticism			Total
	High	Mid	Low	High	Mid	Low	
⟨p⟩	7	2	1	5	2	2	19
ADJ	4	0	0	4	2	2	12
ADV	6	1	3	5	1	9	25

VBN	4	0	4	9	3	0	20
VPP	1	0	0	0	0	3	4
O	7	0	1	6	3	2	19
NA	0	0	0	0	0	0	0
Total	39	4	16	39	15	23	136

Table 3: Distinctive collocations involving a given POS.

of e-mail text. Two potential explanations emerge to explain the difference between this and Dewaele and Furnham's results: Firstly, they were studying spoken, rather than written, language; and secondly, that they were largely dealing with L2 speakers. Perhaps implicitness is more closely related to Neuroticism in written language, and for Extraversion in spoken language; likewise it may have different effects for native and non-native language users. However, before following this line of reasoning, we should also consider the results of the n-gram analysis. At least two gross patterns are interesting.

First, where a High and Low group do not differ overall in the relative frequency of use of a POS, one group may have rather more types of distinctive collocation involving that POS than the other group. If overall use does not differ, it means that one group is using the POS in many different contexts; the other may be using it in a narrower, or perhaps more stereotypical, range of contexts. Let us call the greater-range case 'pervasive' use. Secondly, where a High and Low group do differ in relative frequency of use of a POS, it is interesting to note whether higher frequency is associated with a greater set of collocations involving that POS, or a smaller set. Intuitions here are not firm; but we might expect that greater relative frequency is associated with a greater range of use—and hence, with perhaps fewer stereotypical collocations. If so, frequency may track pervasiveness.

So, consider again the original Implicit-Extravert Hypothesis: High Extraverts will use more verbs, adverbs and pronouns, and Low Extraverts will use more nouns, adjectives, and prepositions. We find that High E prefer conjunctions overall, but that it is the Low E who tend towards POS-collocations involving verbs and pronouns. So High E use of verbs and pronouns may not be not greater overall, but it is pervasive. Equally, Low E prefer past participle verbs overall, but it is the High E who tend towards POS-collocations involving nouns, adjectives, punctuation, and the Other category. Perhaps Low E use of adjectives and nouns is pervasive. And since Low Extraverts actually use proportionately more VPP, their complete lack of distinctive robust collocations suggests that they use VPP pervasively.

Now, let us turn to the new Implicit-Neurotic Hypothesis. High Neurotics will use more verbs, adverbs and pronouns, and Low Neurotics will use more nouns, adjectives, and prepositions. We find that High N prefer pronouns and conjunctions overall, but that it is the Low N who tend towards POS-collocations involving past participle verbs and adverbs. So perhaps High N use of past participle verbs and adverbs is pervasive. Equally, Low N prefer adjectives and nouns overall, but it is the High N who tend towards POS-collocations involving verbs and the Other category. And again, perhaps Low N use of verbs and Other is pervasive.

This pattern is not quite so simple as the Extravert case, and this may in part be because we have split the verb category in two, distinguishing past participle verbs from verbs in general. Putting this to one side, however, we do find High N use of adverbs to be pervasive; and this at least fits the picture of pervasiveness that seemed to be emerging with Extraversion.

Conclusion

This paper set out to establish whether Dewaele and Furnham's Implicit-Extravert Hypothesis for oral language applies in the genre of written e-mail text produced by native English speakers.

At the simple unigram level, it appears that Neuroticism rather than Extraversion fits the implicitness predictions concerning frequency of use of parts-of-speech. However, we can drill down to the collocations level, and we may assume that the pervasive use of a POS tends to reduce the likelihood of finding stereotypical collocations involving it. If we do, then Extraversion does involve implicitness after all. On this interpretation, a POS can be characteristic of some personality group not because they use it more frequently than other groups; rather, it is characteristic because they use it more pervasively.

Applications of this work include affective text categorisation, and therefore could contribute towards the rapidly expanding field of sentiment classification. In taking this work further, we need to give the idea of pervasiveness a more solid basis. But this is only worth pursuing if the idea is really needed to explain the data. And we will only know this once we have tested the hypotheses against larger corpora in other domains. The corpora could be brand new; but it would certainly be possible to apply the analytic techniques presented here to other previously gathered personality corpora.

Abstract

Scenes are composed of numerous objects, textures and colors which are arranged in a variety of spatial layouts. This presents the question of how visual complexity is represented by a cognitive system. In this paper, we aim to study the representation of visual complexity for real-world scene images. Is visual complexity a perceptual property simple enough so that it can be compressed along a unique perceptual dimension? Or is visual complexity better represented by a multi-dimensional space? Thirty-four participants performed a hierarchical grouping task in which they divided scenes into successive groups of decreasing complexity, describing the criteria they used at each stage. Half of the participants were told that complexity was related to the structure of the image whereas the instructions in the other half were unspecified. Results are consistent with a multi-dimensional representation of visual complexity (quantity of objects, clutter, openness, symmetry, organization, variety of colors) with task constraints modulating the shape of the complexity space (e.g. the weight of a specific dimension).

Introduction

Real-world scenes are composed of numerous objects, textures and colored regions, which are arranged in a variety of spatial layouts. Although natural images are visually complex, we are able to form a coherent percept amid numerous regions, and identify a complex scene at a glance (Potter, 1976), even in the face of visually degraded conditions (Schyns & Oliva, 1994). This presents the question of how a cognitive system may represent the level of complexity of a scene. Specifically, the following question motivated the experiment presented in this paper: can visual complexity be conceptualized along a single dimension? Or is visual complexity better represented as a multi-dimensional space where the axes might correspond to meaningful perceptual dimensions?

Visual complexity

The perception of visual complexity has been studied with natural texture images (e.g. Heaps & Handel, 1999; Rao & Lohse, 1993) and simple patterns (see Palmer, 1999 for a review). Heaps and Handel had participants rank texture images along several perceptual dimensions including complexity, connectedness, depth, orientation, repetitiveness, and structure. The authors defined complexity as "the degree of difficulty in providing a verbal description of an image". They observed that the complexity of a texture could be estimated along a one dimensional axis representing the degree of perceivable structure: textures with repetitive and uniform oriented patterns were judged less complex than disorganized patterns. This finding correlates with results in the domain of perceptual grouping by acknowledging that the presence of regularities (e.g., symmetry, repetition, similarity) simplifies a visual pattern (Feldman, 1997; Palmer, 1999; Van der Helm, 2000).

How can we represent the complexity of a stimulus like a scene, which has a high variability of parts and spatial layout organization? According to Heylighen (1997), the perception of complexity is correlated with the *variety* in the visual stimulus. Figure 1 illustrates two instances of *variety.* First, the perceived visual complexity can increase as a function of the quantity and range of objects. Second, the perceived visual complexity can increase as a function of the variety of materials and surface styles while the number of objects and surfaces remain constant. The representation of a real-world scene is likely to combine both levels of varieties (parts and surface styles). Intuitively, complex scenes should contain a larger variety of parts and surfaces styles, as well as more relationships between these regions than do simpler scenes.

A visual pattern is also seen complex if its parts are difficult to identify and separate from each other. Yet, paradoxically, when the parts are separated or conceptualized as a whole,

the valence of the complexity changes and the pattern becomes simpler (Heylighen, 1997). This suggests that the perceived complexity of an image also depends on the amount of perceptual grouping, a characteristic independent of the quantity of parts, an observer perceives in the scene. Additionally, the perception of visual complexity is likely to be dependent on the scale of observation (e.g. looking at a bookshelf or the books level), preexisting schemas and familiarity with the scene.

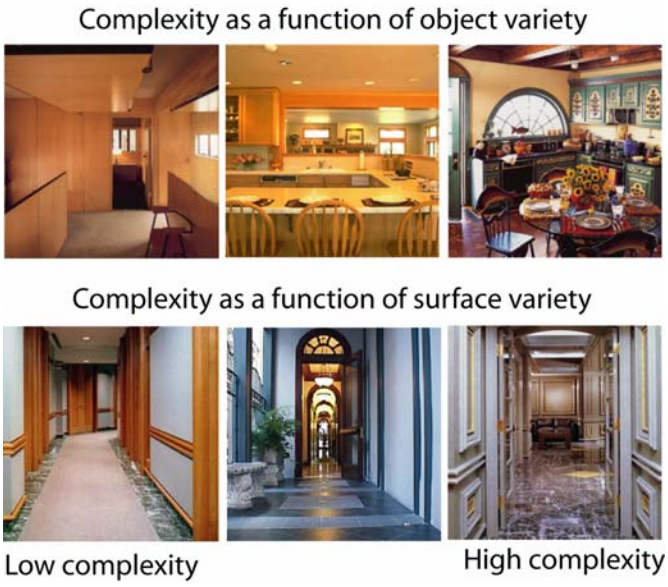

Figure 1: Illustration of how visual complexity evolves as a function of object variety (top) and surface variety (bottom).

If the perception of visual complexity is an interaction between the information in the image and task constraints, can we still identify a set of perceptual properties that participants consistently use to characterize visual complexity of real world scenes? The shape of the visual complexity representation could take three forms:
(1) Unique Perceptual Dimension: the properties of complexity are combined into one principal dimension, robust to subjectivity and task constraints. This is the case of the *naturalness* dimension in real world scenes (e.g. judging if a scene image is a natural or a man-made environment, Oliva & Torralba, 2001).
(2) Multi-dimensional Space Representation: most of visual complexity variability is explained by an identifiable number of perceptual dimensions. The weight of each dimension may vary with task constraints, but the principal dimensional vocabulary remains the same (Gardenfors, 2000). This seems to be the case of the representation of basic-level scene categories (e.g., beach, street, Oliva & Torralba, 2001).
(3) Flexible Space Representation: the properties that human observers use to represent the visual complexity of a particular scene vary with image characteristics (e.g., structure, clusters), tasks constraints, and attentional mechanisms. There is no specific vocabulary that is used for representing visual complexity.
These three levels of representation are not incompatible: for a particular task, the visual complexity space could be skewed towards a line (e.g. one perceptual property is dominant), but for a different task, the space of visual complexity might take into account multiple dimensions. The experiment presented below evaluates the format and content of the representation of visual complexity with the aim to tease apart the three levels of representation suggested above.

Experiment

The goal of the experiment is to study the representation of visual complexity while two groups of participants are told different definitions of visual complexity. Both groups performed a hierarchical grouping task with images of various levels of visual complexity. A hierarchical grouping task allows for identifying the explicit criteria participants used to perform a grouping task (see Oliva & Torralba, 2001) and helps to give a psychological interpretation of the axes provided by a multi-dimensional scaling algorithm (see Results section).

Method

Subjects Thirty-four students from an introduction to psychology course at Michigan State University participated in the study for course credits. Half were in the *control* group and the other half in the *structure* group.

Materials The present study used 100 pictures of indoor scenes. This subset was selected at random from a database of 1000 scenes previously ranked on their subjective visual complexity. The subset had the constraints to represent all levels of complexity along a scale from 1 to 100. The general scene database was originally composed from sources such as the web, magazines and various image databases. Since the volume of the space that a scene image represents is correlated with a given range of clutter (Torralba & Oliva, 2002), only scenes of a small volume range (indoors) were kept for this present study. Moreover, indoor scenes contain a greater variety of colors and objects in a variety of layouts compared to larger scaled environments (e.g. natural space, Oliva & Schyns, 2000).

Procedure The hierarchical grouping task was performed as follows (see Figure 2): starting with 100 pictures shown in a grid on a 23" Apple monitor, participants were asked to separate images into two groups on the screen, corresponding respectively to the most complex vs. the simplest scenes. In a second step, they were asked to split each group into two more subdivisions, and in a third step, split the four groups into two groups each, leading to a total of eight groups. For each subdivision, they were asked to follow a criterion corresponding to visual complexity

(simplicity) and give a verbal description of it. Participants could move each picture across boundaries at any stage, and see an enlarged version of the image by double clicking on it. Similarly to Heaps and Handel (1999), our *Control* group was told the following instruction: "Visual simplicity is related to how easy it will be to remember the image after seeing it for a short time. Visual complexity is related to how difficult it will be to give a verbal description of the image and how difficult it will be to remember the scene after seeing it for a short time." For the *Structure* group, the following instructions were given in addition to the control instructions: "Visual complexity is related to the structure of the scene and therefore, is not merely related to color or brightness. Simplicity is related to how you see that objects and regions are going well together. Complexity is related to how difficult it is to make sense of the structure of the scene". Both groups were forbidden to use a criterion related to the semantic class of the scene (e.g. kitchen) or the presence of a specific object or color.

Results

Table 1 summarizes a taxonomy corresponding to the most common criteria from the descriptions given by participants at the primary and secondary divisions. Each verbal description was recoded as a class of concepts. Some descriptions were a composition of concepts (e.g. pictures on the left seemed more *cluttered* whereas the ones on the right seemed more *open in space*), others were unique (e.g. *quantity* of objects). The percentage in Table 1 should be seen as an indicator of the strength of a perceptual property (most of the time used, often used or almost never used) and not as a fixed value, as variability among individual descriptions was high.

Table 1: Criteria of visual complexity used for the primary and secondary divisions and their % for both groups.

Criteria	Group:Structure	Group:control
Quantity of:		
object	*19*	*32*
detail	*8*	*8*
color	*2*	*19*
Quantity total	29	**59**
Clutter	**18**	5
Symmetry	**15**	2.5
Open Space	**18**	10
Organization	**13**	7
Contrast	<1	8

For the control group, where complexity was defined as a difficulty of verbal and visual recording, the criteria corresponding to *variety* and *quantity* of objects and color dominated the representation of complexity. In the second group where complexity was defined as relating to the structure of the scene, participants evenly used a set of criteria that the control group mentioned less frequently. The primary criterion of the structure group still concerns the quantity and variety of parts, participants referring either to the quantity of objects per se (19%), or the relationship between quantity of objects and spatial arrangement (18%, *clutter*). The other criteria were mostly concerned with spatial layout (symmetry, open space and organization {e.g. grid, centralized, cluster}).

For each condition, we investigated the consistency of the complexity ratings for the 100 images across subjects by computing a Spearman's rank-order correlation for each possible pairing of subjects (images within each subgroup were given the same complexity value, from 1 to 8). If participants were consistent, correlations among participants' rankings should be high. In both groups, Spearman's correlations were all statistically significant ($p < .01$) and were moderate to large in magnitude. Mean correlations of all the pair-wise comparisons were the same in the control and structure group, respectively, $r = 0.62$ and $r=0.61$; (stdev = 0.15 and 0.14).

Next, we applied a nonlinear dimensional reduction method (*Isomap*, Tenenbaum, de Silva, & Langford, 2000) onto a dissimilarity matrix constructed from participants' grouping for each condition (control and structure). To do so, a symmetric 100 x 100 matrix was constructed for each participant. Pairs of images placed in the same group versus in a different group were given respectively a score of 0 or a score of 1. Dissimilarity matrices from all participants from each condition were summed to create two pooled dissimilarity matrices. The Isomap analysis uses the dissimilarities of judgments given by human observers and provides a low dimensional visual representation of the mapping of proximities (i.e., distances) existing between images of various levels of complexity.

Figure 3 shows a two dimensional projection of the 100 images given by Isomap for the *Structure* group. The representation corresponds to the number of independent ways in which visual scenes can be perceived to resemble or differ in visual complexity. Although the dimensions per se are difficult to interpret and further experiments will be needed to assess more accurately the underlying dimensions of the space shown in Figure 3, it shows indeed a first principal direction corresponding to increasing "clutter" and quantity of objects. The second axis, illustrated in Figure 4, suggests an ordering along mirror symmetry and layout organization.

Albeit the correlation between the two first axes given by the Isomap representation for the structure and control group is nearly identical (0.98), the correlation between the ranks of images along the two second axes drops to 0.33 (see Figure 4), suggesting that participants used a different combination of criteria beside quantity while ranking the visual complexity of scenes. In the control group, participants were told that complexity was related to the difficulty of verbally describing an image. Consequently,

they estimated complexity almost exclusively based on the quantity and variety of objects and colors. In the structure group, participants were sensitive to spatial layout criteria, such as symmetry and open space.

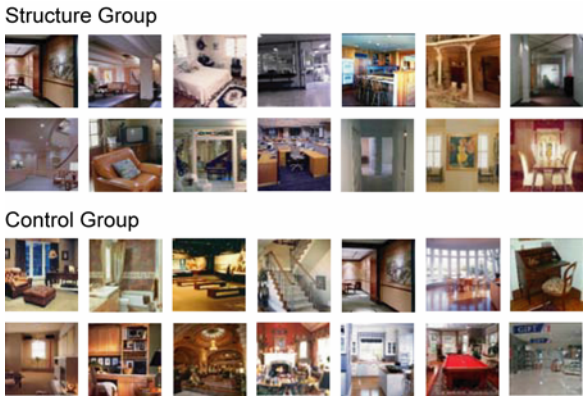

Figure 4: Sample of images projected onto the second principal dimension of *Isomap* for the structure group (top) and the control group (bottom). For the structure group, the images are organized from the top-left to the bottom-right following a property that resembles mirror symmetry. For the control group, the images are organized following a different combination of properties. These projections illustrate the differences in the criteria used between the two groups.

Discussion

The high correlations across participants for both groups (average of 0.61) suggest that participants used a same (or similar) set of holistic perceptual dimensions to represent complexity. The dimensions of visual complexity listed in Table 1 are not exhaustive: one can imagine that the perceived complexity of scenes of a larger volume of space (e.g., urban environments) might require new dimensions better suited to representing these spaces (e.g., perspective). However, the fact that there exists a set of defined properties that most people are sensitive to is appealing for modeling the visual complexity, where each dimension would be represented as a combination of low-level (e.g. contours, junctions) and medium-level features (e.g. connectedness, symmetry, Mack & Oliva, 2004). Furthermore, finding the true meaningful axes in the space generated by a multi-dimensional scaling algorithm, as well as the status of these dimensions (separable, integral, Garner, 1974; Gardenfors, 2000; Maddox, 1992) will be the subject of a follow-up study.

Conclusion

The goal of this study was to characterize the representation of visual complexity and its modulation by task constraints. The complexity ratings provided by observers on 100 pictures of (indoor) real-world scenes are consistent with a multi-dimensional representation of visual complexity. While the contribution of the dimensions are modulated by task constraints, visual complexity is principally represented by the perceptual dimensions of quantity of objects, clutter, openness, symmetry, organization, and variety of colors.

Abstract

An important aspect of language acquisition involves learning the syntactic nonadjacent dependencies that hold between words in sentences, such as subject/verb agreement or tense marking in English. Despite successes in statistical learning of adjacent dependencies, the evidence is not conclusive for learning nonadjacent items. We provide evidence that discovering nonadjacent dependencies is possible through statistical learning, provided it is modulated by the variability of the intervening material between items. We show that generalization to novel syntactic-like categories embedded in nonadjacent dependencies occurs with either zero or large variability. In addition, it can be supported even in more complex learning tasks such as continuous speech, despite earlier failures.

Introduction

Statistical learning – the discovery of structural dependencies through the probabilistic relationships inherent in the raw input – has long been proposed as a potentially important mechanism in language development (e.g. Harris, 1955). Efforts to employ associative mechanisms for language learning withered during following decades in the face of theoretical arguments suggesting that the highly abstract structures of language could not be learned from surface level statistical relationships (Chomsky, 1957). Recently, interest in statistical learning as a contributor to language development has reappeared as researchers have begun to investigate how infants might identify aspects of linguistic units such as words, and to label them with the correct linguistic abstract category such as VERB. Much of this research has focused on tracking dependencies between *adjacent* elements. However, certain key relationships between words and constituents are conveyed in nonadjacent (or remotely connected) structure. In English, linguistic material may intervene between auxiliaries and inflectional morphemes (e.g., *is cooking*, *has traveled*) or between subject nouns and verbs in number agreement (*the books on the shelf are dusty*). The presence of embedding and nonadjacent relationships in language was a point of serious difficulty for early associationist approaches. It is easy to see that a distributional mechanism computing solely neighbouring information would parse the above sentence as …**the shelf is dusty*. Despite the importance of detecting remote dependencies, we know relatively little about the conditions under which this skill may be acquired by statistical means.

In this paper, we present results using the Artificial Language Learning (ALL) paradigm designed to test learning of nonadjacent dependencies in adult participants. We suggest that a single statistical mechanism might underpin two language learning abilities: detection of nonadjacencies and abstraction of syntactic-like categories from nonadjacent distributional information.

Despite the fact that both infants and adults are able to track transitional probabilities among adjacent syllables (Saffran, Aslin, & Newport, 1996), tracking nonadjacent probabilities, at least in uncued streams of syllables, has proven elusive in a number of experiments and the evidence is not conclusive (Newport & Aslin, 2004; Onnis, Monaghan, Chater, & Richmond, submitted; Peña, Bonatti, Nespor, & Mehler, 2002). Thus, a serious empirical challenge for statistical accounts of language learning is to show that a distributional learner can learn dependencies at a distance. Previous work using artificial languages (Gómez, 2002) has shown that the variability of the material intervening between dependent elements plays a central role in determining how easy it is to detect a particular dependency. Learning improves as the variability of elements that occur between two dependent items increases. When the set of items that participate in the dependency is small relative to the set of elements intervening, the nonadjacent dependencies stand out as invariant structure against the changing background of more varied material. This effect also holds when there is no variability of intervening material shared by different nonadjacent items, perhaps because the intervening material becomes invariant with respect to the variable dependencies (Onnis,

Christiansen, Chater, & Gómez, 2003). In natural language, different structural long-distance relationships such as singular and plural agreement between noun and verb may in fact be separated by the same material (e.g. *the books on the shelf are dusty* versus *the book on the shelf is dusty*). We call the combined effects of zero and large variability the *variability hypothesis*.

Very similar ALL experiments tested have failed to show generalization from statistical information unless additional perceptual cues such as pauses between words were inserted, suggesting that a distributional mechanism alone is too weak to support abstraction of syntactic-like categories. On these grounds Peña et al. (2002) have argued that generalization necessitates a rule-based computational mechanism, whereas speech segmentation relies on lower-level statistical computations. However, these experiments tested nonadjacency learning and embedding generalization with low variability of embedded items, which we contend is consistent with the variability hypothesis that learning should be hard. Our aim is to show that at the end-points of the variability continuum, i.e. with either no or large variability, generalization becomes possible. In Experiment 1, we present results suggesting that both detection of nonadjacent frames and generalization to the embedded items are simultaneously achieved when either one or a large number of different type items are shared by a small number of highly frequent and invariant frames. In Experiment 2 we also investigate whether tracking nonadjacent dependencies can assist speech segmentation and generalization simultaneously, given the documented bias for segmenting speech at points of lowest transitional probability (Saffran et al. 1996a,b).

We conclude that adult learners are able to track both adjacent and nonadjacent structure, and the success is modulated by variability. This is consistent with the hypothesis that a learning mechanism uses statistical information by capitalizing on stable structure for both pattern detection and generalization (Gómez, 2002, Gibson, 1991).

Generalising under variability

The words of natural languages are organized into categories such as ARTICLE, PREPOSITION, NOUN, VERB, etc., that form the building blocks for constructing sentences. Hence, a fundamental part of a language knowledge is the ability to identify the category to which a specific word, say *apple*, belongs and the syntactic relationships it holds with adjacent as well as nonadjacent words. Two properties of word class distribution appear relevant for a statistical learner. First, closed class words like articles and prepositions typically involve highly frequent items belonging to a relatively small set (*am*, *the*, *-ing*, *-s*, *are*) whereas open class words contain items belonging to a very large set (e.g. nouns, verbs, adjectives). Secondly, Gómez (2002) noted that sequences in natural languages involve members of the two broad categories being interspersed. Crucially, this asymmetry translates into patterns of highly invariant *nonadjacent* items, or frames, separated by highly variable material (*am cooking*, *am working*, *am going*, etc.). Such sequential asymmetrical properties of natural language may help learners solve two complex tasks: a) building syntactic constructions that sequentially span one or several words; b) building relevant abstract syntactic categories for a broad range of words in the lexicon that are distributionally embedded in such nonadjacent relationships. Frequent nonadjacent dependencies are fundamental to the process of progressively building syntactic knowledge of, for instance, tense marking, singular and plural markings, etc. For instance, Childers & Tomasello (2001) tested the ability of 2-year-old children to produce a verb-general transitive utterance with a nonce verb. They found that children were best at generalizing if they had been mainly trained on the consistent pronoun frame *He`s VERB-ing it* (e.g., *He`s kicking it*, *He`s eating it*) rather than on several utterances containing unsystematic correlations between the agent and the patient slots (*Mary`s kicking the ball*, *John`s pushing the chair*, etc.).

Gómez (2002) found that the structure of sentences of the form $A_iX_jB_i$, where there were three different $A_i\_B_i$ pairs, could in fact be learned provided there was sufficient variability of X_j words. The structure was learned when 24 different Xs were presented, but participants failed to learn when Xs varied from sets of 2, 4, 6, or 12, i.e. with low variability. Onnis et al. (2003) replicated this finding and also found that learning occurred with only one X being shared, suggesting the nonadjacent structure would stand out again, this time as variant against the invariant X.

While Gómez interpreted her results as a learning bias towards what changes versus what stays invariant, thus leading to "discard" the common embeddings in some way, we argue here that there may be a reversal effect in noting that common elements all share the same contextual frames. If several words – whose syntactic properties and category assignment are *a priori* unknown – are shared by a number of contexts, then they will be more likely to be grouped under the same syntactic label, e.g. VERB. For instance, consider a child faced with discovering the class of words such as *break*, *drink*, *build*. As the words share the same contexts below, s/he may be driven to start extracting a representation of the VERB class (Mintz, 2002):

I am-X-ing
dont-X-it
Lets-X-now!

Mintz (2002) argued that most importantly, in hearing a new word in the same familiar contexts, for instance *eat* in *am-eat-ing*, the learner may be drawn to infer that the new word is a VERB. Ultimately, having categorized in such a way, the learner may extend the usage of *eat* as a VERB to new syntactic constructions in which instances of the category VERB typically occur. For instance s/he may produce a novel sentence *Lets-eat-now!* Applying a category label to an word (e.g. *eat* belongs to VERB) greatly enhances the generative power of the linguist system, because the labeled item can now be used in new syntactic contexts where the category applies. In Experiment 1 we tested whether

generalization to new X items in the *A_X_B* artificial grammar used by Gómez (2002) and Onnis et al. (2003) is supported under the same conditions of no or large variability that affords the detection of invariant structure. Hence, if frames are acquired under the variability hypothesis, generalization will be supported when there is either zero or large variability of embeddings. Likewise, because invariant structure detection is poor in conditions of middle variability, generalization is expected to be equally poor in those conditions too.

Experiment 1

Method

Subjects

Thirty-six undergraduate and postgraduate students at the University of Warwick participated and were paid £3 each.

Materials

In the training phase participants listened to auditory strings generated by one of two artificial languages (L1 or L2) of the type $A_iX_jB_i$. Strings in L1 had the form $A_1X_jB_1$, $A_2X_jB_2$, and $A_3X_jB_3$. L2 strings had the form $A_1X_jB_2$, $A_2X_jB_3$, $A_3X_jB_1$. Variability was manipulated in 3 conditions – zero, small, and large– by drawing X from a pool of either 1, 2 or 24 elements. The strings, recorded from a female voice, were the same that Gómez used in her study and were originally chosen as tokens among several recorded sample strings in order to eliminate talker-induced differences in individual strings.

The elements A_1, A_2, and A_3 were instantiated as *pel*, *vot*, and *dak*; B_1, B_2, and B_3, were instantiated as *rud*, *jic*, *tood*. The 24 middle items were *wadim*, *kicey*, *puser*, *fengle*, *coomo*, *loga*, *gople*, *taspu*, *hiftam*, *deecha*, *vamey*, *skiger*, *benez*, *gensim*, *feenam*, *laeljeen*, *chla*, *roosa*, *plizet*, *balip*, *malsig*, *suleb*, *nilbo*, and *wiffle*. The middle items were stressed on the first syllable. Words were separated by 250-ms pauses and strings by 750-ms pauses. Three strings in each language were common to all two groups and they were used as test stimuli. The three L2 items served as foils for the L1 condition and vice versa. The test stimuli consisted of 12 strings randomized: six strings were grammatical and six were ungrammatical. The ungrammatical strings were constructed by breaking the correct nonadjacent dependencies and associating a head to an incorrectly associated tail, i.e. $*A_iXB_j$.. Six strings (three grammatical and three ungrammatical) contained a previously heard embedding, while 6 strings (again three grammatical and three ungrammatical) contained a new, unheard embedding. Note that correct identification could only be achieved by looking at nonadjacent dependencies, as adjacent transitional probabilities were the same for grammatical and ungrammatical items.

Procedure

Six participants were recruited in each of 3 Variability conditions (1, 2 and 24) and for each of two Language conditions (L1, L2) resulting in 12 participants per Variability condition. Learners were asked to listen and pay close attention to sentences of an invented language and they were told that there would be a series of simple questions relating to the sentences after the listening phase. During training, participants in the two conditions listened to the same overall number of strings, a total of 432 token strings. This way, frequency of exposure to the nonadjacent dependencies was held constant across conditions. Participants in set-size 24 heard six iterations of each of 72 type strings (3 dependencies x 24 middle items), participants, in set-size 2 encountered each string 12 times as often as those exposed to set size 24, and so forth. Hence, whereas nonadjacent dependencies where held constant, transitional probabilities of adjacent items decreased as set size increased.

Training lasted about 18 minutes. Before the test, participants were told that the sentences they had heard were generated according to a set of rules involving word order, and they would now hear 12 strings, 6 of which would violate the rules. They were asked to give a "Yes/No" answer. They were also told that the strings they were going to hear may contain new words and they should base their judgment on whether the sentence was grammatical or not on the basis of their knowledge of the grammar. This is to guarantee that participants did not select as ungrammatical all the sentences with novel words simply because they contained novel words.

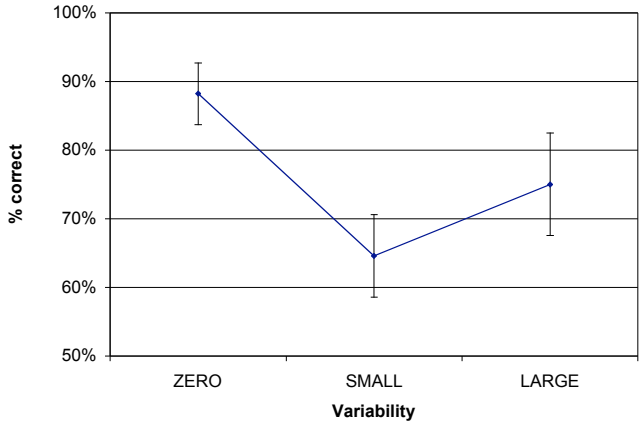

Figure 1. Generalisation under variability - Exp.1

Results and discussion

An analysis of variance with Variability (1 vs. 2 vs. 24) and Language (L1 vs. L2) as between-subjects and Grammaticality (Trained vs. Untrained strings) as a within-subjects variable resulted in a main Variability effect, $F(2,30)= 3.41$, $p< .05$, and no other interaction. Performance across the different variability conditions resulted in a U-shaped function: a polynomial trend analysis showed a significant quadratic effect, $F(1, 35) =7.407$, $p <.01$. Figure 1 presents the percentage of endorsements for total accuracy in each of the three variability conditions. These results add considerable power to the variability hypothesis: not only can nonadjacencies be detected, but generalization too can occur distributionally, and *both* processes seem to be modulated by the same conditions of variability. In addition, generalization with zero variability allows us to disambiguate previous results, in that the high performance obtained by Onnis et al. (2003) could have been due to a simple memorization of the 3 strings repeated over and over

again during training. However, in Experiment 1 correct classification of new strings as grammatical can only be done on the basis of the correct nonadjacencies. Thus, it seems that learning on zero or large variability conditions is supported by a similar mechanism. Finally, we note that A and B words are monosyllabic and X words are bysillabic, participants could simply learn a pattern S-SS-S (where S=syllable). However, because all sentences display such pattern across conditions this cannot explain the U-shape of the learning curve.

Experiment 2

In Experiment 1 the items of the grammar are clearly demarcated by pauses. It can be argued that this makes the task somewhat simplified with respect to real spoken language, which does not contain for instance such apparent cues at every word boundary. In addition, the embedded item *X* was instantiated in bisyllabic words (as opposed to monosyllabic *A* and *B* words), providing an extra cue for category abstraction. In this context, Peña et al. (2002) have argued that generalization and speech segmentation are separate processes underpinned by separate computational mechanisms: statistical computations are used in a segmentation task but this is not performed simultaneously with algebraic computations that would permit generalizations of the structure. Once the segmentation task was solved by introducing small pauses in the speech signal, their underlying structure was learned. Hence it is important to test these claims in the light of the variability hypothesis, which we argue might provide the key to learning nonadjacencies and generalizing altogether, even in connected speech, without invoking two separate mechanisms.

Recent attempts to show statistical computations of a higher order at work in connected speech with a similar AXB language have met with some difficulty: Newport & Aslin (2004), for instance, exposed adults to a continuous speech stream, created by randomly concatenating *AXB* words with 3 *A_B* syllable dependencies and with 2 different middle *X* syllables. A sample of the speech stream obtained would be …$A_1X_3B_1A_2X_2B_2A_3X_1B_3$…. In this case participants were unable to learn the nonadjacent dependencies. Concatenating words seamlessly adds considerable complexity to the task of tracking statistical information in the input for two main reasons: first, transitional probabilities between words of a language containing, say 3 dependencies and 3 Xs, p($B|A$)= 0.5 are higher than within words, p($X|A$) and p($B|X$)= 0.33, and this pressures for segmentation within words (Saffran, Aslin, & Newport, 1996ab). Secondly, assuming the statistical mechanism is sensitive to nonadjacent dependencies as seems the case in Experiment 1, concatenating items entails the additional burden of tracking nonadjacent transitional probabilities across word boundaries, e.g. $X_3\_A_2$, $B_1\_X_2$, and dependencies spanning *n* words away can in principle also be attended to, e.g. two items away ($B_2\_\ \_A_3$…,etc.). One can readily see that if all transitional probabilities of different order were to be computed this scenario would soon create a computational impasse. The insight from Gómez (2002) and Experiment 1 is that variability plays a key role, in that it allows adjacent dependencies to be overcome in favour of nonadjacent ones, but it remains to be seen whether this can be done in connected speech too.

Peña et al. (2002) tested participants on whether they learned to generalize from the rules of an *AXB* language very similar to Newport & Aslin (2004) in unsegmented speech. Again *AXB* items were instantiated in syllables and formed words concatenated one to the other seamlessly. At test, participants demonstrated no preference for so-called "rule-words", new trigram sequences that maintained the $A_i\_B_i$ nonadjacent dependencies but contained a different *A* or *B* in the intervening position (e.g., $A_1B_3B_1$), compared to part-words, i.e., sequences that spanned word boundaries (e.g., $X_2B_1A_3$, or $B_3A_1X_2$). In a further manipulation, 25-ms gaps were introduced between words during the training phase of the experiment, and now participants generalized as indicated by a preference for rule-words over part-words. Peña et al. claimed that altering the speech signal resulted in a change in the computations performed by their participants. Statistical computations were used in a (previously successful) segmentation task but this was not performed simultaneously with algebraic computations that would permit generalizations of the structure. They argued that once the segmentation task was solved by introducing small gaps in the speech signal, the underlying structure would be learned. However, using the same stimuli and experimental conditions as Peña et al. Onnis, Monaghan, Chater & Richmond (submitted) found that rule-words were preferred over part-words in both segmentation and generalization tasks even when the nonadjacent structure was eliminated: participants reliably preferred incorrect rule-words $*A_1B_3B_2$ to part-words B_1A_2X, due to preference for plosive sounds in word-initial position. Hence such preference did not reflect learning of nonadjacent dependencies. Although discouraging at first sight, all these negative results are not inconsistent with the variability hypothesis. In fact, they are all cases structurally similar to the low-variability condition in Gómez (2002) and Experiment 1. Thus, in Experiment 2 we tested whether with sufficiently large variability:

a) tracking higher-order dependencies can be used to segment speech. This is a difficult task because it implies overriding even lower transitional probabilities p($X|A$) than previously tested and this pressures for segmentation within word boundaries (Saffran et al. 1996);

b) generalization of the embeddings can occur *simultaneously* to speech segmentation, i.e. on-line in running speech, and can be done by statistical analysis of the input alone, i.e. without additional perceptual cues such as pauses. We tested this using the same material and training conditions as Peña et al. for their unsuccessful pause-free generalization task, but increasing the variability of the *X* syllables to 24 items as in Experiment 1.

Method

Subjects

20 undergraduate and postgraduate students at the University of Warwick participated for £1. All participants spoke English as a first language and had normal hearing.

Materials

We used the same nine word types from Peña et al.'s Experiment 2 to construct the training speech stream in our Experiment 2. The set of nine words was composed of three groups ($A_i\_B_i$), where the first and the third syllable were paired, with an intervening syllable (X) selected from one of either three syllables (low variability condition) or 24 syllables (high variability condition). The syllables were randomly generated from the following set of consonants: /p/,/b/,/g/,/k/,/d/,/t/,/l/,/r/,/f/,/tʃ/,/dʒ/,/n/, /s/,/v/,w/,/m/,/θ/,/ʃ/,/z/and the following vowels: /ɛi/,/uw/,/a/,/iy/,/au/,/oi/,/ai/,/æ/,/œ/.

Consonants and vowels were permuted, then joined together. No syllables occurred more than once in the set of 33 generated. Each participant listened to a different permutation of consonant-vowel pairings. Notice that the language structure in the two conditions match very closely those of small and large variability in Experiment 1. Unlike Experiment 1 all items were monosyllabic and equally stressed.

Words were produced in a seamless speech stream, with no two words from the same set occurring adjacently, and no same middle item occurring in adjacent words. Hence, adjacent transitional probabilities were as follows: for the small variability condition, and within words, $p(\underline{X}|\underline{A})$ and $p(\underline{B}|\underline{X})= 0.33$; between adjacent words $p(\underline{B_i}|\underline{A_i})= 0.5$. Nonadjacent transitional probabilities were $p(B_i|A_i)= 1$, $p(A_i|X_{previous})= 0.33$, $p(X_j|B_{previous})= 0.33$. For the large variability condition all probabilities were the same except within word adjacent probabilities $p(X|A) = 0.041$.

Therefore, the predicition is that if learners computed adjacent statistical probabilities they should prefer part-words and perhaps significantly more in the large variability condition. Conversely, if they computed nonadjacent dependencies they would rely on the most statistically reliable ones, namely $p(B_i|A_i)= 1$, i.e. they would segment correctly at word boundary.

We used the Festival speech synthesizer using a voice based on British-English diphones at a pitch of 120 Hz, to generate a continuous speech stream lasting approximately 10 minutes. All syllables were of equal duration, and were produced at a rate of 4.5 syllables/second. Words were selected randomly, except that no $A_i\_B_i$ pair occurred twice in succession. The speech stream was constructed from 900 words, in which each word occurred approximately 100 times. The speech stream faded in for the first 5 seconds, and faded out for the last 5 seconds, so there was no abrupt start or end to the stream. In addition, and crucially, for each participant, we randomly assigned the 9 syllables from the first experiment to the A_i, B_i and X_j positions. Thus, each participant listened to speech with the same structure containing the nonadjacent dependencies, but with syllables assigned to different positions. This was to avoid any bias towards choosing a rule-word because of a preference for plosive sounds, as Onnis et al. (submitted) demonstrated. Part-words were formed from the last syllable of one word and two syllables from the following word (B_iA_jX), or from the last two syllables of one word and the first syllable from the following word (XB_iA_j).

Procedure

In the training phase, participants were instructed to listen to continuous speech and try and work out the "words" that it contained. They then listened to the training speech. At test part-words were compared to "rule-words", which were composed of $A_i\_\_B_i$ pairs with an intervening item that was either an A_j or a B_j from another $A_j\_B_j$ pair. Participants were requested to respond which of two sounds was a "word" in the language they had listened to. They were then played a "rule-word" and a part-word separated by 500 ms, and responded by pressing either "1" on a computer keyboard for the first sound a word, or "2" for the second sound a word. After 2 seconds, the next rule-word and part-word pair were played. In half of the test trials, the "rule-words" occurred first. Five participants heard a set of test trials with one set of words first, and the other 5 participants heard the other set of words first.

Results

The results are shown in Figure 2. In line with the original Peña et al.'s experiment, we found no evidence for participants learning to generalize from the nonadjacent structure of the stimuli in the low-variability condition. Participants responded with a preference for rule-words over part-words 41.9% of the times, which was significantly lower than chance, $t(9) = -2.73$, $p < .05$. Conversely, in the high-variability condition participants preferred rule-words 63.3% of the times, significantly higher than chance, $t(9)= -3.80$, $p = .0042$. In addition, there was a significant difference between the low variability and the high variability condition, $t(18) = -4.68$, $p < .001$.

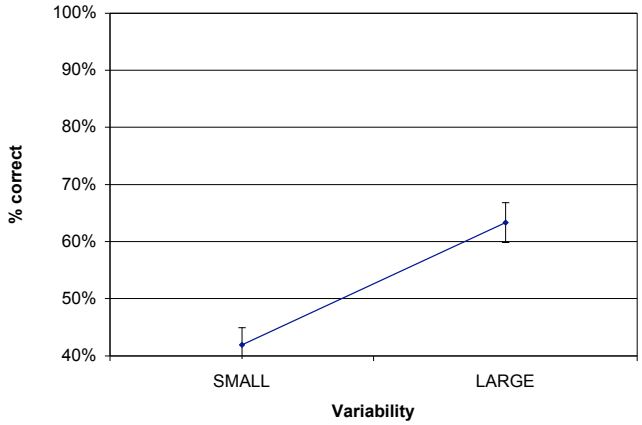

Figure 2. Generalisation in unsegmented speech - Exp. 2

General Discussion

Statistical learning of dependencies between adjacent elements in a sequence is fast, robust, automatic and general in nature. In contrast, although the ability to track remote dependencies is a crucial linguistic ability, relatively little research has been directed toward this problem. Nonadjacent structure in sequential information seems harder to learn, possibly because learners have to overcome the bias toward adjacent transitional probabilities. In fact, a statistical learning mechanism that kept track of all possible adjacent and nonadjacent regularities in the input, including syllables one, two, three away, etc., would quickly

encounter a computationally intractable problem of exponential growth. It would seem that either statistical learning is limited to sensitivity to adjacent items, or there may be statistical conditions in which adjacencies become less relevant in favour of nonadjacencies. It has been suggested that this applies under conditions of large variability of the intervening material (Gómez, 2002) or zero variability (Onnis et al., 2003). This paper contributes some steps forward: first, Experiment 1 shows that variability is the key not only for detection of remote dependencies but also for generalization of embedded material, fostering the creation of abstract syntactic-like classes, which is often assumed to require higher-level algebraic computation. Secondly, in Experiment 2 segmentation and generalization are achieved simultaneously, without the assist of pauses (a difference in signal) as Pena et al. claimed. Consequently, rather than supporting a statistical/algebraic distinction our results suggest specific selectivities in learning patterned sequences. The specific characterization of such selectivities may not be simple to identify: Newport & Aslin (2004) found that nonadjacent segments (consonants and vowels) could be learned but not nonadjacent syllables, and proposed that this accounts for why natural languages display nonadjacent regularities of the former kind but not of the latter. Experiment 2, however, shows that with large variability nonadjacent syllabic patterns can in fact be learned. The key factor for success is again variability. Experiment 2 also shows that learners are indeed able to track nonadjacent dependencies in running speech, despite the well documented bias for adjacent associations and the preference for segmenting continuous speech at points of lowest transitional probabilities.

Overall, the results suggest that the learning mechanism entertains several statistical computations and implicitly "tunes in" to statistical relations that yield the most reliable source of information. This hypothesis was initiated by Gómez (2002) and is consistent with several theoretical formulations such as reduction of uncertainty (Gibson, 1991) and the simplicity principle (Chater, 1996) that the cognitive system attempts to seek the simplest hypothesis about the data available. In the face of performance constraints and way too many statistical computations, the cognitive system may be biased to focus on data that will be likely to reduce uncertainty. Specifically, whether the system focuses on transitional probabilities or nonadjacent dependencies may depend on the statistical properties of the environment that is being sampled.

Our work ties in with recent acquisition literature that has emphasized the constructive role of syntactic frames as the first step for building more abstract syntactic representations (Tomasello, 2003 for an overview). Children's syntactic development would build upon several consecutive stages from holophrases such as *I-wanna-see-it* (at around 12 months), to pivot-schemas (*throw-ball*, *throw-can*, *throw-pillow*, at about 18 months), through item-based constructions (*John hugs Mary*, *Mary hugs John*, at about 24 months), to full abstract syntactic constructions (*a X*, *the Xs*, *Eat a X*).

Statistical learning seems, at least in adults, powerful enough to allow the discovery of complex nonadjacent structure, but simply not any condition will do: we have suggested that variability such as that emerging from the asymmetry between open and closed class words may be a crucial ingredient for understanding the building of language.

Self-Explanation Reading Training: Effects for Low-Knowledge Readers

Tenaha O'Reilly (t.oreilly@mail.psyc.memphis.edu)

Abstract

This study examined the effects of self-explanation reading strategy training (SERT) and Preview training on high-school students' comprehension of a science text. The students (n=136) were from a middle to lower SES, inner-city Virginia high school. They were assessed in terms of their science knowledge and reading skill. Nine biology classes were then randomly assigned to SERT, Preview, or Control conditions. Science comprehension was assessed both immediately after training and after a one-week interval. The results indicated that after the one-week retention interval, SERT participants outperformed both Preview and Control participants on passage comprehension. This comprehension advantage was particularly enhanced for low-knowledge readers. This result replicates with high-school student findings reported by McNamara (in press) with college students.

Introduction

Many high-school students encounter difficulties comprehending their textbooks, particularly those covering scientific material (Bowen, 1999; Snow, 2002). Problems with comprehension can occur for a variety of reasons. One source of difficulty occurs from text specific factors, such as text cohesion (Beck, McKeown & Gromoll, 1989; McNamara, Kintsch, Songer, & Kintsch, 1996). Another source of problems stems from the reader's aptitudes. Of course, efficient decoding abilities are necessary for the reader to understand the words in the sentences (e.g., Perfetti, 1985). However, comprehension difficulties also occur even for readers who understand the words. These comprehension problems can emerge from the inability to draw inferences (e.g., Long, Oppy, & Seely, 1994) and the failure to apply other higher-level reading skills, such as meta-cognitive reading strategies (Cornoldi & Oakhill, 1996).

The recent RAND report on *Reading for Understanding* (Snow, 2002) documents the pressing need to improve reading comprehension. The RAND report also provides a useful heuristic for conceptualizing reading comprehension, which includes four interactive components: Characteristics of the text, the reader, the comprehension activities, and the socio-cultural context. Accordingly, these factors rarely operate in isolation, and as such, potential interactions between attributes associated with these factors need to be considered in order to develop a more complete understanding of reading comprehension processes.

In terms of text characteristics, research has shown that the structure of the text plays a major role in comprehension. For example, in an analysis of the cohesion of social studies texts, Beck et al. (1989) found that many texts have structures that are far from optimal in terms of promoting deep comprehension. Texts often present too much information with too little detail, contain loose unconnected statements, and have poor integration with previous sections. Overall, the manner in which many informational texts are written present challenges for comprehension.

The knowledge and skills readers bring into the reading situation play an important role in the comprehension of informational texts (McNamara & Kintsch, 1996; Voss & Silfies, 1996). For example, Voss and Silfies found that prior knowledge helps the reader spell out causal links between concepts, whereas reading skill contributes to a better textbase understanding. Indeed, other research has shown that conceptual gaps in text are most easily repaired with domain knowledge (McNamara et al, 1996; cf. McNamara, in press).

Comprehension activities, or the use of higher level reading strategies, also have a major impact on learning (Pressley, Wood, Woloshyn, Martin, King, & Menke, 1992). For example, Chi, De Leeuw, Chiu, and LaVancher (1994) have found positive learning gains for a technique called self-explanation. Students who were asked to explain what they learned from a biology text made more inferences, integrated more information across topics, and developed a deeper understanding of the text than did Control students.

Similarly, McNamara (in press; McNamara & Scott, 1999) developed a comprehensive reading strategy intervention called self-explanation reading strategy training (SERT). SERT helps improve comprehension by encouraging students to make use of various reading

strategies to build connections between the reader's knowledge and the text. It teaches students to use active reading techniques including comprehension monitoring, logic and common sense, elaboration, paraphrasing, bridging inferences, and prediction to improve their ability to explain a text and understand it at a deeper level. McNamara (in press) found that college students who were trained to use SERT outperformed controls on measures of text comprehension. This improvement was especially enhanced for low-knowledge readers on text-based questions (assessing knowledge of information explicitly stated in the text).

While the effects of SERT have been beneficial in improving comprehension with college students, the effects of SERT training on high-school students has not been tested. Examining the influence of learning strategies is especially important in high-school populations because there is a dearth of strategic reading interventions being taught and used in classrooms (Cox, 1997, Garner, 1990). Moreover, in comparison to other countries, students in the United States are falling behind students in other countries on measures of reading comprehension (Snow, 2002).

The purpose of this study was to examine the effect of SERT training on high-school students' ability to comprehend science texts. We compared students' comprehension of science texts after they had received either SERT training, Preview training, or a reading Control condition. Previewing is a reading strategy designed to help students better comprehend texts by encouraging them to preview various subsections of the text before they read. This strategy training is based on, and includes the K-W-L instructional technique developed by Ogle (1986). The use of preview techniques is relatively common and has been associated with comprehension gains (Johnston & Allington, 1991).

Our goal was to examine whether SERT or Preview training helped students to better understand the science passages in comparison to the Control condition. First, we predicted that students trained with SERT and Previewing would outperform students in the reading Control group who did not receive reading strategy training. We expected both types of interventions to facilitate students' science text comprehension. However, we expected the benefits of SERT and Previewing to depend on the students' level of prior knowledge. This prediction arises from the way in which each technique encourages the use of prior knowledge. Previewing focuses on the activation of relevant prior knowledge before reading the text to provide a mental schema of the contents. While prior research has clearly shown the benefits of schemas to improve comprehension, we doubt that they will be particularly useful if the student has little prior knowledge about the topic. As such, we expect the benefits of previewing to depend largely on the amount of prior knowledge the student has about the text topic, primarily benefiting relatively high-knowledge students. In contrast, SERT encourages students to actively process texts (e.g., elaborate and link information contained in the text). The student learns to use whatever knowledge available, including logic and general knowledge, to make sense of the text. Our previous research demonstrated that SERT was primarily beneficial to low-knowledge students (McNamara, in press). We expect similar results here.

Method

Nine biology classrooms within an inner-city school were randomly assigned to one of three conditions: SERT, Preview, or Control. Students in the three SERT classrooms were provided training on how to self-explain text using five reading sub-strategies. Preview participants were taught how to preview the text before they read it. Control classrooms were simply asked to read the text. After reading, they were asked to focus on any strategies they used to help them better remember the text. Comprehension was assessed using two science passages taken from school science texts. The passages differed in topic and length, which allowed us to examine whether the strategies were used across different science texts. We used both text-based and bridging-inference questions to assess students' comprehension of the science passages.

Participants

The sample consisted of 136 ninth and tenth-grade biology classes. Students were of mixed gender and ethnicity. The high school was located in an inner city region of Norfolk, Virginia.

Materials

Student aptitudes were measured with two tests; a modified version of the Gates-MacGinitie Reading Skill Test and a Prior Knowledge Test. The Gates-MacGinitie test is a standardized reading comprehension test, designed for grades 10-12. The test consisted of 40 multiple-choice questions designed to assess student comprehension on several short text passages (Cronbach's Alpha α=.91). Due to time constraints, the vocabulary section of the test was not administered, and the time limit for the comprehension question section was reduced to 15 minutes. The prior knowledge test consisted of 35 multiple-choice items which tap knowledge of different science domains including biology, scientific methods, mathematics, earth science, physics, mathematics, and chemistry (Cronbach's Alpha α=.74).

To examine immediate and long-term retention, there were two comprehension testing sessions; one immediately following training, and again one week after training. A text on viruses, describing the structure, and reproduction of viruses as well as some examples of viruses and how they relate to disease, was used during the immediate test. The passage was 1216 words in length with a Flesch Reading Ease of 45.1 and Flesch-Kincaid Grade level of 10.6. One week later, we administered a text about earthquakes, which described the causes of earthquakes and the conditions under which they occur. The earthquake text was 749 words in length with a Flesch Reading Ease of 65.1 and Flesch-Kincaid Grade level of 7.5. In an ideal laboratory setting, the order of the texts would be counterbalanced between testing sessions. However, this was not possible due to logistical constraints (e.g., high rates of absenteeism and movement of students between classes).

Reading comprehension was assessed with a set of 8 open-ended and 8 multiple-choice questions; half were text-based and half were bridging-inference questions. For each comprehension assessment, students were asked to indicate whether they had finished reading and, if not, how far they had read.

Self-Explanation Reading Training (SERT) was delivered in three main phases; introduction, demonstration, and practice (see McNamara, in press). During the introduction phase, participants were provided with a description and examples of self-explanation. The instructor defined and provided examples for five reading strategies: comprehension monitoring, paraphrasing, elaboration/logic and common sense, prediction, and bridging.

During the demonstration phase, participants watched a video depicting a student reading and self-explaining a text about forest fires. Participants could refer to the accompanying video transcript during viewing. The video was paused at various points, and participants identified and discussed the strategies being used by the student in the video. In the practice phase, the participants worked in pairs to practice self-explanation while reading a chapter from their science textbook. The participants took turns self-explaining, alternating after each paragraph. At the end of each paragraph, the partner who was listening (and not self-explaining) summarized the paragraph.

Preview training was also delivered in the form of three phases. During the introduction, participants were given a description of the basic Preview strategy; a review of subsections in a text that can be previewed (Title, introduction, objectives bold italics, pictures/figures, conclusion and chapter review questions) and strategies for note-taking during reading (questions such as, What I know, What I need to know. What I found out). During demonstration, the instructor demonstrated the Preview strategies to the class with a text on forest fires. Finally, during practice, the students practiced using the preview techniques on a chapter taken from their textbook.

In the Control condition, participants read the science texts to which trained groups were exposed during training. Participants wrote down strategies they used while reading, but did not discuss the strategies.

Design and Procedure

Each class was randomly assigned to one of the three conditions; SERT, Preview, or Control (three classes were assigned to each condition). Experimental sessions were conducted during students' regular classroom time by two experimenters. Prior to training, students completed the prior knowledge and Gates-McGinitie Reading test. A 15-minute time limit was given for each test. The prior knowledge test was administered first.

SERT and Preview training were conducted during two class periods conducted on consecutive days. Participants were told that the purpose of the study was to learn strategies that would help them to better understand and remember what they read. The total amount of time spent learning the experimental interventions during the two days was approximately the same. The Control condition required one class period. Students in the Control condition were told that the purpose of the training was to find out about the strategies they use when reading their textbooks.

Immediately after training and after a one-week interval, participants were given 30 minutes to read the science passage and answer comprehension questions. In the experimental conditions, the experimenter briefly reviewed the strategies for either SERT or Preview before beginning the comprehension test. For both the virus and earthquakes texts, the students did not have the text available when they answered the questions.

Results

Pre-test Scores

Scores on the pretest measures of prior knowledge and reading skill were examined as a function of condition to ensure that the groups were comparable on these measures. To do this, we conducted two univariate ANOVAs, with condition as the between-subjects factor (SERT, Preview, and Control) and student aptitude scores (either prior knowledge or reading Gates-MacGinitie). There were no reliable differences in prior knowledge scores ($F(2,135)=0.74$, $MSE=0.017$, $p>0.05$) or Gates-MacGinitie scores ($F(2,134)=0.77$, $MSE=41.192$, $p>0.05$) as a function of condition.

To examine the effects of individual differences, we used a median split to divide students into high and low-knowledge groups, or high and low reading comprehension skill groups.

Effects of Training Condition

To assess the effectiveness of SERT training on students' comprehension of the virus and earthquake texts, we conducted two sets of mixed model ANOVAs. The within-subjects factors were question type (text-based or bridging-inference), question format (multiple-choice or open-ended) and the between-subjects factors condition (SERT, Preview, or Control) and either reading skill (high or low) or prior knowledge (high or low). A combined analysis of reading skill and prior knowledge could not be performed because there were too few participants. To avoid conflating effects of reading skill with prior knowledge, the participants' scores on the prior knowledge measure were entered as covariates in the reading skill analysis, and vice versa, the participants' scores on the reading skill measure were entered as covariates in the prior knowledge analysis.

There were no reliable main or interaction effects of condition on the immediate comprehension test (virus text). In contrast, the earthquake text administered one week later revealed reliable effects of training condition. Therefore, the present analysis focuses on the latter results.

Reading Skill Analysis

In the first analysis, reading skill was treated as a between-subjects variable, while prior knowledge was included as a covariate. There was a main effect of condition ($F(2,124)=3.72$, $MSE=0.268$, $p<0.05$), indicating that SERT participants ($M=0.43$, $SD=0.15$) outperformed Control ($M=0.36$, $SD=0.16$) and Preview ($M=0.36$, $SD=0.12$) participants (see Figure 1). A post-hoc analysis using Least Significant Difference confirmed this trend showing that SERT participants performed better than Preview ($p<0.05$) and Control participants ($p<0.05$); however, Control and Preview did not differ ($p<0.05$). There was also a main effect of reading skill ($F(1,124)=11.08$, $MSE=0.798$, $p<0.05$), indicating that high reading skill students ($M=0.43$, $SD=0.15$) better understood the earthquake passage than did low reading skill students ($M=0.34$, $SD=0.13$).

Our analysis also showed effects for question format and question type, which were independent of training condition. There was a significant effect for question format ($F(1,124)=16.86$, $MSE=0.664$, $p<0.05$) indicating that more multiple-choice questions ($M=0.48$, $SD=0.19$) were answered correctly than open-ended questions ($M=0.29$, $SD=0.15$). There was also a significant main effect for question type ($F(1,124)=6.63$, $MSE=0.286$ $p<0.05$), indicating that students answered more questions based on the text correctly ($M=0.46$, $SD=0.18$) than questions requiring bridging-inferences ($M=0.31$, $SD=0.17$). No other effects were significant.

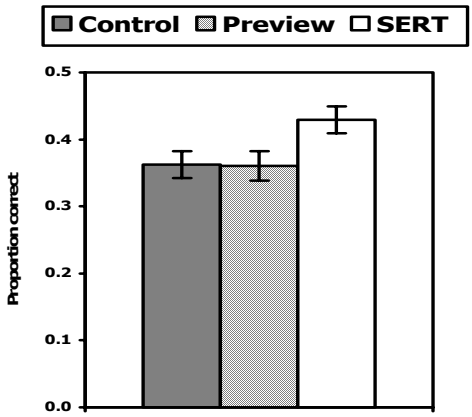

Figure 1. Proportion correct on Earthquakes comprehension test as a function of condition

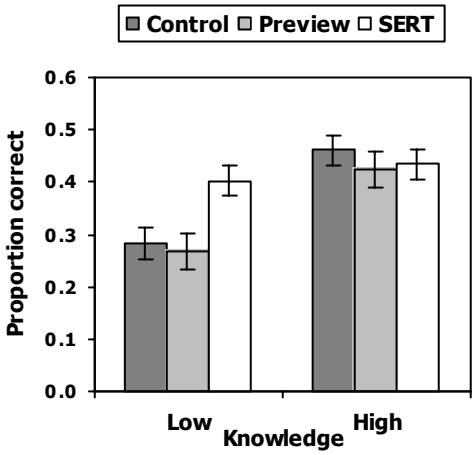

Figure 2. Proportion correct on Earthquakes comprehension test as a function of condition and prior knowledge

Prior Knowledge Analysis

This section examines how the effects of condition depended on students' prior knowledge by including prior knowledge as a between-subjects variable, and reading skill as a covariate. As reported above, the main effects of condition, question format, and question type were reliable There was also a main effect of prior knowledge ($F(1,124)=11.10$, $MSE=0.783$, $p<0.05$), indicating that high-knowledge ($M=0.43$, $SD=0.14$) students better understood the passage than did low-knowledge students ($M=0.34$, $SD=0.13$). This main effect was qualified by a significant interaction between knowledge and condition ($F(2,124)=3.84$, $MSE=0.271$, $p<0.05$). A Post hoc Least Significant Difference

analysis indicated for low-knowledge students, SERT participants (M=0.43, SD=0.15) outperformed Control ($p<0.05$) (M=0.30, SD=0.16) and Preview ($p<0.05$) participants (M=0.30, SD=0.12) (see Figure 2). There was no difference between Control and Preview participants ($p<0.05$). In contrast, the effect of condition was not evident for high-knowledge participants ($F(2,67)=0.41$, MSE=0.036, $p>0.05$).

Discussion

Our findings indicate that SERT training helps students comprehend science texts. Specifically, SERT students performed better on the earthquake comprehension assessment than did Preview or Control students. Moreover, our findings also suggest that SERT training is particularly beneficial to facilitating comprehension among low-knowledge students, as evidenced by the finding that low-knowledge students trained with SERT performed better on the earthquake comprehension test than did low-knowledge students in the Preview and Control conditions.

The finding that the effect of SERT training emerged one week after training is encouraging because it suggests that students remember and use the strategies beyond the time of training. We expect that the lack of training effects on the immediate comprehension test is likely due to a fatigue effect following training.

Overall, our findings replicate those of McNamara (in press), which showed that SERT training facilitated readers' comprehension of scientific texts. Most importantly, both McNamara's study and the present results show that low-knowledge students tend to benefit most from SERT training in terms of comprehension gains. This is a very important finding because it suggests that the SERT method may be an effective technique for supporting comprehension among low-knowledge students most at risk from comprehension problems while reading difficult textbooks.

We predicted that SERT and Previewing would have differential effects on comprehension. We predicted that Preview technique would be less effective for low-knowledge students because using the Preview technique requires students to activate their prior knowledge before reading (i.e., when previewing the titles and subtitles). Thus, we expected Previewing to help high-knowledge students and SERT to benefit low knowledge students. Although we confirmed the latter prediction, we did not find benefits for previewing. This result may be because the students were relatively low knowledge overall. Perhaps the benefits of Previewing depend on a greater availability of prior knowledge than possessed by these inner-city high-school students. Indeed, a majority of students may not have sufficient knowledge to make use of previewing (Snow, 2002).

We expected the use of the SERT method to facilitate comprehension because of the manner in which the student engages with the material during the application of the SERT techniques. Specifically, the reader engages in on-line comprehension monitoring, while at the same time applying techniques known to aid comprehension, such as elaboration and bridging (Chi et al, 1994). This on-line method allows the student to process information effectively, which, in turn, supports comprehension. SERT strategies may provide a scaffold by which the student can integrate new information into their existing knowledge schemas, even in the absence of domain knowledge. Conversely, when using the Previewing method, students do not necessarily engage in on-line comprehension monitoring and reading strategy techniques. Rather, the Preview method encourages readers' to use comprehension monitoring prior to reading. A potential problem with this method is that it does not engage the reader as effectively with the text and the information they are reading.

In terms of understanding the reading process, our study supports the view that the comprehension activities used by the reader play a critical role in reading comprehension (e.g., Pressley et al, 1992). That is, students who have better comprehension skills, as reflected in their use of comprehension monitoring practices and utilization of active reading strategies, are likely to make comprehension gains (Chi et al, 1994).

Of course, to understand the links between reading strategy use (e.g., self-explanations) and comprehension, it is necessary to investigate the associations between strategy use and comprehension. For example, McNamara (in press) investigated the links between styles of self-explanation and performance on a science comprehension test. She found a reliable positive correlation between college students' comprehension scores and their use of logic and common sense self-explanations. In a similar vein, O'Reilly, Sinclair, and McNamara (in press) also found correlations between self reported use of individual SERT strategies and comprehension. However, more research is needed in this area to understand more fully the ways in which students use strategies to facilitate comprehension actually support learning gains.

In conclusion, our findings suggest that SERT training is a useful method of reading strategy training, which can be used to enhance comprehension at the high-school level. Indeed, McNamara and colleagues are currently working on integrating the SERT method of teaching into the high-school classroom. McNamara, Levinstein, and Boonthum (in press) have developed an interactive, automated version of SERT training, designed to be integrated into classrooms. The long-term aim is to develop a SERT intervention which is tailored to the needs and level of the student. In its

current form, the automated trainer, iSTART (Interactive Strategy Trainer for Active Reading and Thinking) teaches students the SERT strategies. The program comprises the three basic components used in the tutor delivered training: introduction, demonstration, and practice. During the practice section, in which students practice using the strategies, the iSTART system assesses the quality of the self-explanations and provides feedback to the student to encourage deep processing of the text (McNamara et al., in press).

Several preliminary examinations of the iSTART system have indicated that the computerized version of SERT training is as effective as live SERT training (O'Reilly, Sinclair, & McNamara, in press). Overall, the present findings and those collected from the iSTART studies indicate that SERT is an effective reading strategy intervention, which can be used in the classroom to help students comprehend difficult textbooks.

Abstract

This study examined the effectiveness of Self-Explanation Reading Training (SERT) and an automated version of this intervention called Interactive Strategy Training for Active Reading and Thinking (iSTART) in improving science text comprehension. College students (N=297) were assigned to one of three conditions: SERT (trained by a human instructor), iSTART (trained by a computer), or no treatment control. Participants read a text on cell mitosis and answered text-based and bridging inference questions. There was a significant overall effect of condition indicating that both iSTART and SERT out performed controls on comprehension. However, this effect was modulated by question type: both SERT and iSTART significantly enhanced comprehension for text-based questions, but the effect was not reliable for bridging inference questions.

Introduction

Many students have difficulty understanding what they read; in particular, many students have trouble comprehending science texts (Bowen, 1999; Snow, 2002). Problems associated with comprehension are augmented by the lack of strategic reading interventions in classrooms: students seldom use high-level comprehension strategies that promote deep comprehension (Cox, 1997; Garner, 1990).

One way to improve comprehension is to teach reading strategies that encourage deeper processing of the text. Interventions that promote deeper processing such as self-explanation and elaborative interrogation have been successful in improving student comprehension (e.g., Chi, De Leeuw, Chiu, & LaVancher, 1994; Pressley, Wood, Woloshyn, Martin, King, & Menke, 1992). For example, McNamara (in press) has reported positive learning gains for her Self–Explanation Reading Training (SERT). SERT is a modified version of the self-explanation learning strategy (e.g., Chi et al., 1994). The SERT training program helps improve comprehension by encouraging students to utilize various sub-strategies to build strong connections between the reader's knowledge and the text. SERT teaches students various reading strategies, including comprehension monitoring, logic and common sense/elaboration, paraphrasing, bridging inferences, and prediction to improve their ability to explain text and understand it at a deeper level.

McNamara (in press) examined the effectiveness of SERT with college students who varied in prior knowledge of science. Half of the participants learned to self-explain and use reading strategies while reading four science texts. The other half of the participants read aloud the texts and answered questions concerning them. After the training phase, the two groups' ability to self-explain was compared. They also answered text-based and bridging-inference questions about the text that they had all self-explained. The results indicated that low-knowledge readers who were trained to use SERT outperformed control participants on measures of text comprehension. However, this advantage only occurred for text-based questions. In addition, protocol analyses of the readers' self-explanation indicated that the low-knowledge readers improved in terms of their ability to paraphrase the text, and more importantly, in their ability to use domain-general knowledge (or logic and common sense) to make sense of the text. Not having the requisite knowledge, they were not able to make inferences requiring domain specific knowledge while reading. Nonetheless, they showed the same level of comprehension on the text-based measures as did the high-knowledge readers, and substantially greater performance than their low-knowledge counterparts. These findings are particularly encouraging because it demonstrates improvement for the students who need the training the most: the low-knowledge students.

The present study compares the effectiveness of SERT and a similar, but automated version of the training, called Interactive Strategy Training for Active Reading and Thinking (iSTART; McNamara, Levinstein, & Boonthum, in press). Automating the core aspects of SERT training has several advantages including self-paced learning and standardized training. iSTART is a computer program that uses automated agents to provide SERT-based training to students. The program, like SERT, has three sections, introduction,

demonstration, and practice. The program has both vicarious and interactive components to enhance learning. The students learn vicariously by watching "agent students" interact and learn strategies taught by a "teacher agent." Later the student interacts with the program, and the system provides feedback on the student's performance.

While automating the SERT intervention has several advantages, one potential problem is that automation may influence the effectiveness of SERT. For example, during live SERT training, students practice with a partner while self-explaining. In iSTART, human peer interaction does not occur. In light of the work on reciprocal teaching (e.g. Palincar & Brown, 1984), removing human peer interaction may diminish the effectiveness of the training. The goal of this study was to examine whether the automated iSTART was as effective at improving comprehension as the live SERT training. Participants were assigned to one of three conditions: live SERT (trained by a human instructor), iSTART (trained by the computer program) and a control condition which had no training (and instead read a text and answered questions concerning it). One week after the training phase, participants read a passage on cell mitosis (see McNamara, 2001; McNamara, in press). The dependent measure was the total proportion of correct answers (both text-based and bridging-inference questions) based on the passage. It was expected that SERT would out perform controls because previous research showed a facilitative effect of SERT on comprehension (McNamara, in press). It was expected that iSTART training would also improve comprehension compared to controls. This prediction was made based on research that has shown the benefits of automated agents on learning (e.g., Anderson, Corbett, Koedinger, & Pelletier, 1995; Du Boulay, 2000; Graesser & Person, 1994).

Finally, we were also interested in uncovering any spontaneous strategies used by control students in our study. Prior research has indicated that the average student is not particularly strategic when learning from text (Cox, 1997; Garner, 1990). After reading the passage on mitosis, participants in all three conditions were asked to indicate what strategies they used to help them understand what they read. We predicted that both the SERT and iSTART conditions would indicate strategies such as those taught in the training session. A higher reported use of SERT strategies in the training condition serves as a manipulation check for whether the trained participants actually used the strategies to comprehend the text. Moreover, our secondary goal was to examine what, if any, strategies would be reported by the untrained participants.

Method

Participants

The sample consisted of 297 biology college students from Old Dominion University. There were 87 males and 210 females and the average age was 21 years old (SD=4.58). The students participated during the laboratory sessions of their Introductory Biology Course. Each lab was randomly assigned to one of the three conditions. The students received extra credit in the course for participation.

Materials

Two sets of individual difference measures were used to gauge students' cognitive ability: reading skill and prior knowledge. Reading skill was measured by Nelson-Denny Reading Skills Test. The test consisted of 38 multiple-choice questions designed to assess comprehension on several short text passages. Prior knowledge was measured by a 54-item multiple-choice test on general science knowledge and the humanities. The test consisted of questions drawn from biology, art, literature, history, geology, political science, and psychology.

Participants in the SERT condition were given a short list of five reading strategies (i.e., comprehension monitoring, paraphrasing, elaboration, prediction, and bridging), a video transcript and note sheet (used during the video segment of training), and a booklet with more detailed descriptions of the strategies and examples of their use in self-explanations. Participants in the iSTART condition were given written instructions on how to use the iSTART system, and a short list of the reading strategies.

A passage on cell mitosis described the sequential stages involved in cell division, and included all the information required to subsequently answer a set of comprehension questions. The text was 650 words in length and had a Flesch Reading Ease 52 and a Flesch-Kincaid Grade Level 9.1. Comprehension was assessed using a set of 12 open-ended questions: six text-based and six bridging-inference questions. The answers to the text-based questions could be found in a single sentence within the passage, while the bridging-inference questions required the reader to integrate information from two or more sentences within the passage. Participants were also given a sheet of paper which asked if they had finished reading the text and which, if any, strategies they used to help them understand the text. Finally, participants were given a 260 word text on thunderstorms with a Flesch Kincaid Grade level of 8.6 and a Flesch Reading Ease 56. For control participants the text was accompanied by 8 open-ended questions.

Design and Procedure

The experiment had three phases: pre-testing, training and post-testing. All participants were given the individual difference measures during the pre-test phase. Participants first took the prior knowledge test (20 minutes) followed by the Nelson-Denny reading skill test (15 minutes). The following day the experimental training and control phases were conducted in a 2-hour session. The post-test phase occurred after a one-week retention period, during which all participants read and answered questions for the mitosis passage. Participants were given 30 minutes to read the passage and answer the questions. Students did not have the text available to help them once they began answering the questions.

Training

SERT: The SERT training session was conducted in a 2-hour session. SERT participants were told that the purpose of the study was to teach them strategies that would help them to better understand and remember what they read. Participants were first provided with a description and examples of self-explanation. The instructor then defined and provided examples for five reading strategies: comprehension monitoring, paraphrasing, elaboration, prediction, and bridging.

Participants then watched a video depicting a student reading and self-explaining a text about forest fires. Participants could refer to the accompanying video transcript during viewing. The video was paused at various points, and participants identified and discussed the strategies being used by the reader in the video.

Finally, the participants worked in pairs to practice self-explanation while reading the thunderstorms text. The participants took turns self-explaining, alternating after each paragraph. At the end of each paragraph, the partner who was listening (and not self-explaining) summarized the student's self-explanation.

iSTART: The iSTART training session was conducted in a 2-hour session. Participants in the iSTART condition were told that the purpose of the study was to teach them strategies that would help them to better understand and remember what they read. Participants were then given instructions on how to use the iSTART system, and they proceeded to go through the three sections of the program: introduction, demonstration, and practice. The practice section involved reading and self-explaining a text about thunderstorms one sentence at a time. Participants typed their self-explanations into the computer.

Control: Participants were told that the purpose of the study was to determine the types of strategies students use when they read. Participants read the thunderstorms text and indicated the strategies they used while reading. The participants answered corresponding questions to assess comprehension.

Testing

One week following training, all three groups of participants were asked to read the science text about cell mitosis (i.e., the low-coherence version used in McNamara, 2001). The participants were asked to use the strategies that they had learned or talked about the previous week. After reading the text, participants were asked to indicate what strategies they used to help them understand the text. They were then given the 12 open-ended questions to assess comprehension. Participants were given 30 minutes to read the text and answer the questions. The text was not available to the students once they began answering the questions.

Results

The effect of training on reported strategy use.

Our first question was whether training condition affected students' reported use of strategies one week after training when reading the cell mitosis text. Table 1 lists the percent of participants who indicated using SERT strategies, while Table 2 indicates the percent of participants who reported using non-SERT strategies. Students' self-reports of strategy use during reading were tabulated into 17 categories. The categories were devised based on a combination of a priori strategies reported in the literature, and strategies that were frequently mentioned in the students' responses. It is important to note that category membership is not mutually exclusive. That is, a participant could have listed more than one strategy, and therefore the percentages per condition will not sum to 100%.

Strategy	Control	iSTART	SERT
Bridging	0%	39.8%	38.5%
Prior Knowledge	7.3%	15.1%	17.7%
Elaboration	0%	17.2%	21.9%
Prediction	0%	14%	13.5%
Self-explanation	0.9%	23.7%	19.8%
Paraphrase	0%	46.2%	46.9%

Table 1 Percent of self-reported SERT/iSTART strategies by condition

Further calculations revealed that 77.2% of iSTART and 72.9% SERT participants reported using at least one of the reading strategies taught by the iSTART/SERT, whereas only 8.3% of control participants reported using these strategies ($\chi(2,297)=123.30$, $p<0.05$). A chi-square also revealed that more control participants (58.9%) indicated using more non-SERT strategies (i.e., 10 strategies listed in table 1 other than the six SERT strategies) than iSTART (10.9%) or SERT (30.25%) participants ($\chi(2,297)=60.79$, $p<0.05$). Although this measure does

not indicate whether they actually *used* these strategies (nor whether their self reports were all inclusive, i.e., they may not have reported some strategies) it does reveal that iSTART and SERT participants become sensitive to the notion of active reading strategies through training, and that this was retained one week later.

Strategy	Control	iSTART	SERT
Imagery	7.3%	0%	4.2%
Re-Read to understand	11.9%	1.1%	1.0%
Summarize	1.8%	0%	2.1%
Mnemonics	6.4%	1.1%	4.2%
Skim text	4.6%	2.2%	2,1%
Note taking	5.5%	0%	1.0%
Memorization	3.7%	0%	2.1%
Repetition	30.3%	8.6%	25%
Focus	9.2%	0%	2.1%
Key points	14.7%	1.1%	7.3%
No Strategy	16.5%	4.3%	1.0%

Table 2 Percent of self-reported non-SERT/iSTART strategies by condition.

The effect of strategy training on comprehension.

Our second question was whether SERT and iSTART training successfully improved comprehension for those students who reported using the strategies. All control participants (N=109) were included in this analysis. However, in the iSTART and SERT conditions, only participants who explicitly stated that they used one or more of the SERT strategies (comprehension monitoring, self-explanation, paraphrasing, prediction, bridging, elaboration, and prior knowledge use) were included in the analysis. We restricted this analysis to training participants who reported using the strategies after training because our question regarded the effects of training for those participants who attempted to use the SERT strategies to read and understand the cell mitosis text. Therefore, this manipulation check reduced the number of participants in the iSTART condition from N=92 to N=71, and reduced the number of participants in the SERT condition from N=96 to N=70. While it is interesting in itself that about 25% of the training participants did not attempt to use the reading strategies after training, there are many reasons why they might not (e.g., lack of motivation in the laboratory setting, lack of sufficient learning of the strategies, preference for other strategies). However, we cannot identify these reasons and those participants are not the focus of this particular analysis. The exclusion of participants who did not report any SERT strategies is a conservative effort. The self-report measure includes both participants who actually used the SERT strategies and those who said they used them, but did not use them in practice. In a similar vein, by retaining all the control participants, the control condition has an advantage because the analysis includes the participants who may use higher-level strategies and who may, therefore, be expected to score as well as the trained participants. A similar set of analyses which also excluded control participants who did not report any strategies produced a similar pattern of results as the analysis used here that did not exclude any control participants. Hence, the analyses reported below included all control participants

Differences in pre-test abilities

A one-way between-participants ANOVA was conducted on the student's pre-test level of prior knowledge to determine whether the groups differed as a function of pre-treatment knowledge. The results indicated that there were no differences between conditions, $F(2,233)= 1.47$, $MSE= 72.25$, $p>.05$, indicating that any difference between the conditions are unlikely due to pre-treatment levels of knowledge. Likewise, a between-participants analysis was conducted on the students' reading skill scores to determine whether the pre-treatment reading skill differed as a function of condition. The analysis revealed that there was no significant effect of pre-test reading skill, $F(2,233)= 2.05$, $MSE= 71.31$, $p>.05$, and thus, differences among the conditions are unlikely due to pre-treatment differences in reading skill.

Effects of condition

A repeated measures analysis of variance was conducted on comprehension scores including the within-participants variable of question type (text-based, bridging inference) and the between-participants variables of training condition and knowledge with reading skill as a covariate. There was a significant effect of question type, $F(1,229)= 23.57$, $MSE= 0.602$, $p<.05$, indicating that more text-based questions ($M=0.52$, $SD=0.26$) were answered correctly than bridging questions ($M=0.22$, $SD=0.17$). There was also an effect of knowledge, $F(1,229)= 35.14$, $MSE= 1.85$, $p<.05$) indicating that high-knowledge students ($M=0.28$, $SD=0.15$) scored higher than low-knowledge students ($M=0.45$, $SD=0.17$). The analyses revealed a significant effect for training condition, $F(2,229)= 3.94$, $MSE= 0.207$, $p<.05$) indicating that both iSTART ($M=0.39$, $SD=0.21$) and SERT ($M=0.39$, $SD=0.19$) participants scored higher than controls ($M=0.33$, $SD=0.22$). This effect was qualified by a significant interaction of question type and condition, $F(2,229)= 2.98$, $MSE= 0.076$, $p<.05$). Post hoc Least Significant difference tests revealed that SERT ($M=0.55$, $SD=0.23$, $p<.05$) and iSTART ($M=0.54$, $SD=0.24$, $p<.05$) participants scored higher than controls ($M=0.45$, $SD=0.27$) on text-base questions, but not bridging

questions (see Figure 1). No other effects were significant.

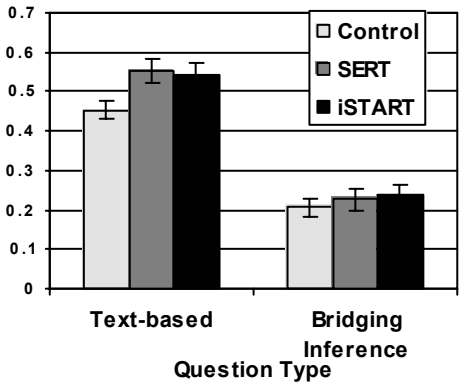

Figure 1. Proportion correct on the mitosis passage score as a function of condition and question type

To examine effects of reading skill, a second repeated measures analysis of variance was conducted on comprehension including the within-participants variable of question type (text-based, bridging-inference) and the between-participants variables of training condition and reading skill, with knowledge as a covariate. The analysis revealed a significant effect for question type, $F(1,229)=5.07$, $MSE=0.147$ $p<.05$, indicating that more text-based questions ($M=0.52$, $SD=0.26$) were answered correctly than bridging questions ($M=0.23$, $SD=0.17$). The main effect of training condition was reliable, $F(2,229)=4.69$, $MSE=0.239$ $p<.05$, indicting that iSTART ($M=0.39$, $SD=0.21$) and SERT ($M=0.41$, $SD=0.19$) participants scored higher than control participants ($M=0.33$, $SD=0.22$). This main effect was qualified by a significant interaction with question type, $F(2,229)=2.98$, $MSE=0.076$ $p<.05$. Post hoc Least Significant Difference tests revealed that iSTART ($M=0.54$, $SD=0.24$, $p<.05$) and SERT ($M=0.58$, $SD=0.23$, $p<.05$) participants scored higher on text-based questions compared to control participants ($M=0.46$, $SD=0.27$). But this effect was not found for bridging-inference questions. In sum, both SERT and iSTART improved students' comprehension compared to controls, particularly at the textbase level of understanding.

Finally, correlations between each of the 18 self-reported strategies and the total proportion correct on the mitosis passage. Six strategies were significantly correlated to comprehension. Five of the strategies were taught by the SERT/iSTART technique bridging, $r=.25$, self-explanation, $r=.19$, elaboration, $r= .14$, paraphrasing, $r=. .25$, predictions, $r=.12$, and one non-SERT/iSTART strategy, reread to understand, $r=.15$.

Discussion

The results of the present study are congruent with research demonstrating beneficial effects of reading-strategy training on understanding and learning (Chi et al., 1994; Pressley et al., 1992). First, the majority of SERT and iSTART participants reported the use of SERT strategies such as elaboration, using prior knowledge and making bridging inferences. Research has shown that high-level strategies such as prior knowledge use (Spilich, Vesonder, Chiesi, & Voss, 1979) and elaboration (Pressley et al., 1992) are much more effective than low-level strategies such as repetition. The current results suggest that both SERT and iSTART training encourage the use of higher-level strategies during reading, and that the self reported use of these strategies correlates with comprehension. The present findings also seem to support the views of Cox (1997) and Garner (1990): average untrained students are spontaneously unlikely to use higher-level strategies to help them better understand what they read.

In a related study, Best, Ozuru, and McNamara (2004) analyzed the content of students' self-explanations while interacting with iSTART. The researchers found that several of the participants indicated the use of high quality elaborations including logic/common sense and scientific reasoning. Many of these elaborations were knowledge building, which helps the reader more effectively explain the current sentence. However, the quality of the elaborations depended upon both the sentence difficulty and individual differences. In short, iSTART seems to promote the use of both high-level and high-quality comprehension strategies.

Second, and more importantly, the self-report data is bolstered by the findings from the comprehension data. Participants in both the SERT and iSTART conditions answered more text-based questions correctly than did control participants. Hence, the current study suggests that SERT and iSTART training encouraged many of the learners to use higher-level strategies, and when they did, comprehension for text-based information was facilitated. These findings are congruent with results reported by McNamara (in press) showing positive learning gains for students who were given SERT training. In that study, McNamara (in press) found evidence that SERT helped participants by encouraging them to use logic, common sense and general world knowledge. Moreover, the beneficial effects of training were most prominent for low-knowledge readers; that is, for the readers who need the training the most.

As in McNamara (in press), the facilitative effect of training in the current study did not extend to bridging-inference questions. One possible explanation is that participants did not have the specific domain knowledge required to make effective bridging inferences (cf., McNamara, in press). This interpretation is in accordance with the finding that

prior knowledge is important in generating inferences (e.g., Singer & Ritchot, 1996), particularly when text cohesion (the degree to which relations are made explicit) is low (McNamara, 2001). The mitosis text used here was taken from McNamara (2001), who manipulated text cohesion as an independent variable. The current study utilized the low-cohesion version of the mitosis text. Because text cohesion was low, readers require a greater degree of specific domain knowledge to generate the necessary inferences.

As found in previous studies (e.g., Anderson et al., 1995; Du Boulay, 2000; Graesser & Person, 1994), this research also confirms the effectiveness of computerized training, particularly those using automated agents as tutors. The benefits of automated tutors include self-paced learning, standardized training, and feedback tailored to the individual's progress. The results of the present work support the effectiveness of an automated tutoring system by showing that a computerized presentation of the SERT strategies (iSTART) was as effective as a presentation of the strategies by a human instructor. Given the current trend towards increasing classroom size and cutbacks in educational funding, this result suggests that automated trainers may provide a means for reducing the load on resource-strained educators.

In sum, this study adds to the literature by demonstrating that SERT and iSTART training increase the reported use of higher-level strategies during reading, and when used, the SERT and iSTART strategies enhance comprehension, at least for text-based information. More encouraging is the finding that the self-paced computer version of the training is as effective as the human delivered training.

Abstract

Scientific reasoning involves the use of scientific skills, practices, and domain knowledge to solve science problems. A little emphasized tool that experts use to help them reason is to refer back to previous problem solving experiences, interpreting and applying those experiences as they solve problems. Results from a pilot study conducted Fall Semester 2002 suggest that improvement in interpreting and applying expert cases to solve a problem may also lead to improvement in certain scientific reasoning skills. In this paper, we seek to explore the connection between case application and scientific reasoning skills, namely, using evidence to justify a claim, generating hypotheses, making predictions, and explaining scientific phenomena.

Introduction

Scientific reasoning involves the use of scientific skills, practices and domain knowledge to solve science problems. Much research has been done to understand how students can develop more expert-like scientific reasoning skills (e.g. Kuhn, 1993; Schauble et. al., 1995), and much research has been done to promote more expert use of scientific reasoning skills in educational settings (e.g. Bell & Davis, 2000; Reiser, et. al., 2000). However, little attention has been given to the role case interpretation and application might play in learning to reason scientifically. There is evidence that scientists use cases extensively in their reasoning. For example, when trying to analyze a series of unexpected results, scientists will refer to cases that may seem unrelated but that have similar in order to explain why those unexpected results may have occurred (Blanchette & Dunbar, 2001).

In educational settings, it is often difficult to support students as they attempt to acquire and carry out expert-reasoning processes. In many cases, the expert-reasoning process may be too complex to pare down in such a way that students can engage in it without getting lost in all of the complexity (Reiser, 2000). In other cases, because the expert-reasoning process is not fully understood, it becomes difficult to assess where students may experience difficulty, and when they do, it is difficult to know what kind of help to provide.

We have sought to address these difficulties for one complex skill: case application. Fall semester 2002, we conducted a study to understand the effectiveness of the Case Application Suite (CAS) (Owensby & Kolodner, 2004), a set of tools designed to support middle-school students in project-based inquiry classrooms as they interpret and apply the experiences of experts to solve design problems. In particular, we were interested in understanding how effective our system of scaffolds was at supporting students as they interpreted and applied expert cases, whether the distribution of scaffolding responsibilities across teacher and software was effective, how well students were able to use case application skills in the absence of the scaffolding, and whether the distribution of scaffolding responsibilities could be articulated in a cognitive apprenticeship (Collins, Brown & Newman, 1989) framework.

Analysis of the data showed that CAS was effective at supporting students in case application, showing significant differences for interpretation and trends for application. In addition, the trends in the data suggested an unexpected finding—that case application supports the learning of scientific reasoning skills. Our analysis of this phenomenon suggests that this is because case application and scientific reasoning share foundational skills, namely using evidence to support a claim, generating hypotheses, making predictions, and explaining phenomena scientifically. This paper seeks to explore the connection between case application and scientific reasoning skills to suggest that improvement of certain case application skills will promote improvement in these aspects of scientific reasoning. As part of our exploration, we will show how we've used software-realized scaffolding (Guzdial, 1994) to support the acquisition of case application skills among middle-school students in project-based inquiry science (Blumenfeld, et al., 1991).

Case Application and Scientific Reasoning

Case application is the process of interpreting, analyzing, and applying experiences to address challenges or solve problems (Owensby & Kolodner, 2003; the CBR literature, e.g., Kolodner, 1993). It involves three high-level steps: interpretation, application, and assessment. Interpretation involves, at the time of encountering the case, it, focusing on extracting the connections between its criteria and constraints and the solution chosen to address its challenge, making connections between the solution chosen and the outcomes that happened, and identifying what can be learned from the experience, and at the time of working toward applying it, making connections between the case (acting as a source case) and the new situation (target). Application involves applying those lessons to the new situation or target case, either directly or via adaptation. Assessment involves analyzing the applicability and quality of the proposed solution either by making predictions about the target case's solution or by testing the target case's solution and analyzing the outcomes that result.

Case application is integral to the practices of experts. Medical experts use cases to diagnose as well as to refine treatments for patients. Architects keep file cabinets of cases to go back to when working on new projects. Lawyers refer to previous cases and decisions when constructing a strategy to prosecute someone or to defend a client.

Analogical reasoning has long been recognized as an important aspect of scientific reasoning (e.g. Gentner, 1999; Anderson, 2000, Blanchette & Dunbar, 2001). Case application extends standard analogical reasoning. In addition to mapping the solution for one problem onto the solution for another problem, we include in case application the analysis and interpretation of a case at the time it is encountered that allows its application. We also include in case application the identification of those nuggets of an encountered case that might apply in a new situation. When the cases being used are those of others, this interpretation process involves significant reading for understanding. While reading is taught in schools, rarely does science class focus on helping learners read. Yet real science practice is impossible without the skills involved in reading a scientific case for understanding and reasoning through its application.

Understanding requires identifying claims, the evidence used to support its claims, and the quality of explanations put forth, while applying what is in a science case requires making predictions based on those claims and finding particularly useful information in a big document.

In order to use evidence to support a claim, one must interpret the experience from which the claim arose in such a way that he/she recognizes that the evidence applies. Then, one must interpret the evidence in such a way that the aspects that apply to the claim can be identified. Next, one must be able to articulate how the relevant aspects of the evidence support the claim and make predictions for future use of the concept, skill, or claim. Understanding the experience from which the claim and evidence put forth involves interpreting the experience and drawing out the lessons that can be learned from the experience. Articulating how the evidence supports the claim involves articulating the lessons learned from the evidence and the experience that the claim rises from and then applying those lessons to explain how the evidence supports the claim and then making predictions about how the claim might be useful in the future. It does make sense, then, that supporting students as they learn how to interpret and apply cases illustrating the evidence of scientific phenomena and the application of scientific principles could help those same students become better scientific reasoners.

Our approach to supporting the development of case application skills

To help middle schoolers interpret cases and apply them in new situations, we have designed a suite of software tools called the Case Application Suite (CAS) to play the role of coach within a cognitive apprenticeship framework (Collins, Newman & Brown, 1989). In a cognitive apprenticeship approach to learning complex skills, the teacher models the skills and explains his/her reasoning to the students and then coaches and hints as students begin to carry out parts of that reasoning. As students become more capable, they, in turn, model for their peers and coach them to their next levels of capability. But when students work in small groups, there may not always be a group member expert enough to be able to apply that coaching to the rest of the group. CAS supports students as they work in small groups by asking the kinds of questions and making the kinds of suggestions that a teacher or more able student might make if he/she were available.

The design of CAS was informed by suggestions made by the skills acquisition, case-based reasoning, transfer, and cognitive apprenticeship literatures (Anderson, et. al, 1981; Anderson, 2000; Kolodner 1993; Branford, Brown & Cocking, 1999; Collins, Brown & Newman, 1989, respectively). CAS contains three tools. The Case Interpretation Tool helps students identify problems the experts encountered in achieving their goals, solutions they attempted and why they chose those, criteria and constraints that informed those solutions, results they accomplished and explanations of those, and any lessons learned, or rules of thumb, that can be extracted from the experience. The Case Application Tool guides students through attempting to apply the rules of thumb gleaned from the case, prompting them to consider whether a rule of thumb is applicable and then helping them explore ways they can apply it to their solution. The Solution Assessment Tool helps students make predictions about the success of their solution, analyzing the impacts they expect their solution to make as well as where they expect their solution to fall short.

The system of scaffolds in CAS includes five different types of scaffolds: (1) the structure of the suite serves as a scaffold as each tool corresponds to a major step in the case application process; (2) the prompts in each tool's center frame focus students' attention on important aspects of the case; (3) hints are provided with each prompt to give more specific help; (4) examples are provided with each prompt to help students see what they need to be accomplishing; and (5) charts and templates serve as organizers to help students with creating an analyzing the applicability of the rules of thumb they have gleaned.

Each tool is divided into three frames (Owensby & Kolodner, 2003; Owensby & Kolodner, 2004). In the left frame is the expert case and interpretations that have already been done of it. The middle-frame shows the prompts for the tool the group is currently working on. The right frame shows hints and examples (Figure 1).

Use of CAS in the Classroom

We've tried CAS out in classrooms engaging in the Learning by Design (LBD; Kolodner et al., 2003) project-based inquiry unit called *Tunneling Through Georgia*. In this challenge, student teams serve as consultants for the design of several tunnels needed for a transportation system that will run across the state of Georgia. Four tunnels need to be designed, each for a different geological area of the state—mountainous, sandy, and so on. Students need to address several issues—at what depth to dig the tunnel, what methods to use for the digging, and what support systems are needed in the tunnel's infrastructure. Cases are used extensively in the unit to suggest which geological characteristics of the tunnel location they need to learn more about to address the challenge, to

introduce students to different kinds of tunneling technologies, and to give them an appreciation of the complexity of tunnel design. For example, the story about the design and construction of the Lotchberg Tunnel in Switzerland, shows

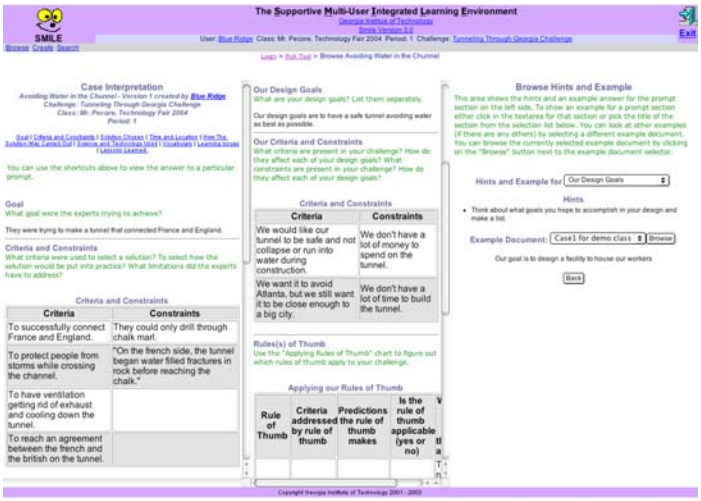

Figure 1: Case Application Tool

some of the problems the experts faced trying to tunnel through the summit of a mountain that has two peaks separated by a river and suggests understanding the composition of a mountain by using test shafts and core sampling can help to identify and possibly avoid problems like crumbling rock, flooding, and cave-ins.

The Tunneling unit is preceded by another unit that requires case application. In that unit, students learn about earth's surface processes as they engage in the challenge of designing and constructing (in a stream table) a way of managing erosion around a basketball court. They read two cases during this unit, one about the dustbowl and another about landslides on the U.S.'s West Coast. The teacher helps them read and understand the cases together as a class and moves around the room coaching them as they work in small groups to apply what they've learned to their challenge. In addition, students use a template to keep track of important aspects of the cases they are reading about. The template, created by the teacher and based on the My Case Summary Design Diary page (Puntambekar & Kolodner, 1998), organizes a page into columns representing *Case Summary, Problems, Ideas, Learning Issues, and Questions*.

As they get started with the Tunneling unit, the teacher again models case application for students as they analyze the Lotschberg Case together as a class. After analyzing the Lotschberg Case, student groups are assigned one of four tunnel cases to interpret and present to the rest of the class. They are introduced to CAS's Case Interpretation Tool to support them as they interpret the case on their own in small groups. This is followed by presentation of their interpretations of their cases to the class and discussion of the lessons that can be pulled from them. When it is time to apply what's been learned from the cases to their own tunnel challenge, students use the Case Application Tool to create a solution. This sequence is repeated a second time as groups read another set of four cases. Later, they sometimes use the Solution Assessment Tool to make predictions about how well their proposed designs might work, what they might have overlooked, and what they would do differently if given another chance

Our Study

We were interested in learning how to help students learn to interpret and apply cases to project challenges and in understanding the effects of adding software designed to augment the teacher's modeling and coaching to a cognitive apprenticeship. Our study collected data to answer three questions: (1) How are students' abilities to interpret and apply cases to their project challenge affected by such scaffolding? (2) To what extent would students' ability to apply cases in the absence of the suite be influenced by its use during a project? (3) To what extent does the suite enable students to articulate the processes involved in case application? When we noticed that some students' scientific reasoning capabilities were improved, we also analyzed to answer a fourth question: To what extent does case application capability predict scientific reasoning capability?

Methods

Procedures

We report here on a study where we used CAS in the classrooms of an 8th grade teacher (Mrs. K) (Owensby & Kolodner, 2003) who had only 4 computers available for her class. Because of this, only a subset of the students were able to use the software; the rest engaged in all of the same activities but had available only the template as scaffolding as they were interpreting and applying cases. All students in the study engaged together in solving the erosion challenge and in doing *Tunneling Through Georgia* activities, and all were exposed to the same teacher modeling. Overall, students engaged in case interpretation and application activities five times – twice during the erosion challenge, once with the teacher at the beginning of the Tunneling unit (the Lotchberg Case), and twice more in small groups. Each time, groups work together to interpret a case and draw out the lessons it teaches; they present their case interpretations to the class, and they lead discussion about their case. Comparison students (n=33 students; 9 groups) used the template to scaffold their case interpretation and application as they interpreted and applied cases after the Lotschberg Case, while experimental students used CAS (n=14 students; 4 groups). We compared the capabilities of students who had the software available to those who did not as students engaged in the unit and after its completion.

Software groups were videotaped as they used the software, and software and non-software groups were videotaped as they presented their interpretations to the class. In addition, templates and logs of CAS use were collected for analysis.

At the end of the unit, a performance assessment was given. Called the Bald Head Island Challenge, students worked in their *Tunneling Through Georgia* groups to make recommendations about the design of two subdivisions on an island off the coast of Georgia. They read a case about Bald

Head Island and used it to give advice. They were asked to identify the risks involved with the project, identify possible management methods, create rules of thumb (Part 1), design a plan for designing and constructing the subdivisions, and make final recommendations about whether the project should move forward with the given time and budget constraints (Part 2). Groups were videotaped as they discussed their ideas. All groups had only template scaffolding available as they engaged in this activity, organized into columns representing *Risk, Why Is This A Risk, Ways To Manage The Risk, Pros, and Cons*.

Analysis

Video data was analyzed using a coding scheme that described the data for specific interpretation and application dimensions. Two coders analyzed video-recorded group performance for interpretation on dimensions shown in Table 1 and for application and assessment on dimensions shown in Table 2, treating each of the two parts of the performance assessment as an episode. A five-point Likert scale was used for each, with one representing no evidence of presence of the quality being rated and 5 representing that the group fully displayed the quality being rated. Differences in ratings were negotiated by discussion, and inter-rater reliability was calculated.

Results

The results that follow provide evidence that case application can be supported in educational settings despite its difficulties, that distribution of scaffolding responsibilities across teacher and software in a cognitive apprenticeship framework seems to be a viable approach for promoting case application, and that particular scientific reasoning skills among students who used the software tools seem to be more sophisticated. We first discuss the differences between students who used the software and those who did not as they were engaging in classroom activities of the Tunneling challenge. We then discuss student capabilities while engaging in the performance assessment, completed by all students after the Tunneling unit was completed and without software scaffolding. The results are discussed with respect to using evidence to justify a claim, generating hypotheses, making predictions, and explaining scientific phenomena.

Case Application During Class Activities

Examination of student artifacts and presentations of case interpretations for groups using CAS vs. the case study template showed three major differences. First, the software groups better identified the reasons for positive and negative outcomes. For example, in learning about the Queens Midtown Tunnel, one software group told us: "They wanted to build [the tunnel] straight [through the city] but couldn't, so they continued it further underground in an S-shape under First Avenue and they took different core samples". This group was specific about the goals of the experts, the constraints that kept them from achieving those goals if they tried the obvious solution, what they did instead, and the activities they had to engage in to do that successfully. The typical non-software group, on the other hand, provided general descriptions about the experts' goals, neither mentioning the constraints' impact on the outcomes nor alternatives. For example, one non-software group told us: "The Manhattan side [was] on a large bluff higher than Queens[, so they] continued tunnels underground in a slope under First [Avenue]."

Second, the groups who used the software included more sophisticated causality in their rules of thumb. For example, the non-software groups' rules of thumb are in the form of simple imperative statements (e.g., "Control water problem", "Take core samples"), while the software groups' rules of thumb explain why (e.g., "Take core samples—they can save your life because if you hit the wrong kind of rock, you can get hurt", "You should always have an oxygen pass so the toxic fumes can get out."

Case Application at Completion of the Unit

In the performance assessment, groups discussed their answers in preparation for writing individual recommendations. We analyzed the video for interpretation and application capabilities.

Table 1 shows results for case interpretation (reliability 89%). Software groups tended to be better at all case interpretation capabilities and significantly better at specifying expert problems, identifying relevant aspects of the case to apply, and using the case to understand the context in which the risks/problems arose.

Table 1. Performance Assessment Results for Part 1 - Interpretation

Coding Characteristic (**bold** denotes significant difference, $p<0.05$)	Software group	Standard Dev. (software group	Non-Software group	Standard Dev. (non-software group)
Recognizes that the case should be used to solve the challenge	**3.88**	**0.25**	**2.66**	**0.71**
Makes direct reference to the case to justify an argument or position	3.135	0.25	2.33	0.82
Able to identify expert problems	**3.00**	**0.00**	**2.42**	**0.61**
Able to identify expert "mistakes"	2.63	0.75	2.00	1.17
Able to identify relevant aspects of the case that can be applied to the challenge	**3.88**	**0.25**	**1.83**	**0.98**
Identifies risks based on prior experience with another LBD/software case	1.88	1.44	1.33	0.41
Able to identify criteria and constraints	3.38	1.11	1.58	0.66
Uses the case to understand the context of the risks	**2.88**	**0.25**	**1.67**	**0.61**
Identifies rules of thumb	1.00	0.00	1.00	0.00

Software groups tended to describe expert problems on a finer-grained level than non-software groups

(3.00 vs. 2.42, $p<0.05$). For example, non-software groups identified "sand" as a risk, while software groups identified the "incompatibility of the old sand and the beach with the new sand dug when the channel was deepened" as a risk, or expert problem. In the case, there are a number of risks or problems that involve sand, so being able to distinguish between those problems is important.

Software groups tended to discuss whether a management method made sense for their challenge, analyzing how the management method would play out in their challenge and questioning each other about the feasibility of a proposed management method (3.88 vs. 1.83). Non-software groups tended to discuss management methods only if they were different from what they expected.

Software groups tended to use the case not only to identify the problems the experts encountered, but also to understand the context in which those problems arose (2.88 vs. 1.67, $p<0.05$). They sought to understand what was happening in the environment that caused the problems to occur or to grow worse. Non-software groups tended to look for keywords that they were familiar with when identifying problems and management methods. For example, while flipping through the case, one non-software student declared , "Oh!! I see erosion here—erosion is a problem." In a similar incident in which one software group member stated that erosion was a problem, another member of that group declared, "but it says here that the problem is the shoreline eroding." This discussion resulted in the software group providing more detail about the erosion problem. In addition, for interpretation, we looked specifically at how well software students used evidence (the case) to justify a claim, and found that software students tended to do a better job than non-software students.

Table 2. Performance Assessment Results for Part 2 – Application and Assessment

Coding Characteristic (**bold** denotes significant difference, $p<0.05$)	Software group	Stadard Dev. (software group)	Non-Software group	Standard Dev. (non-software group)
Identifies issues or problems not explicitly stated in the case	2.88	0.25	2.00	1.02
Able to identify relevant aspects that can be applied to the challenge	2.50	1.08	1.67	1.03
Suggests incorporating a solution found in the case	2.50	0.58	1.92	0.92
Notices that a management method used by the experts cannot be applied as is but must be adapted	1.63	0.58	2.08	0.88
Notices that a solution used by the experts cannot be applied as is but must be adapted	2.38	0.95	2.33	0.68
Justifies use, modification, or abandonment of an expert solution based on criteria and constraints of group's challenge	2.75	0.25	2.25	0.76
Applies a solution used by the experts directly to their challenge	1.75	1.03	1.33	0.82
Suggests that an expert solution should be abandoned	1.25	0.50	1.25	0.61
Applies the case to the challenge using rules of thumb	1.00	0.00	1.00	0.00

For the video-recorded data for Part 2, application and assessment, reliability was 86% and results show trends toward better performance by software groups on several dimensions. First, software groups tended to suggest that a solution from the case would be good to incorporate into their challenge solution (2.50 vs. 1.92). This seems to result from the fact that software groups tended to refer back to the risks and solutions they identified in the expert case in Part 1. They would discuss those solutions to figure out whether they made sense to use in their challenge solution.

Second, software groups tended to justify the use, modification, or abandonment of an expert solution based on the criteria and constraints of the group's challenge (2.75 vs. 2.25). For example, one software group member suggested that the group build a sea wall out of an expensive material. His fellow group member pointed out that that particular material would be very expensive and given that they only had 2 million dollars to work with, they should consider another material. Few non-software groups even mentioned criteria and constraints when deciding whether an expert solution or management method should be used. Again, justification of a claim using evidence was analyzed directly and software groups showed better performance than non-software groups.

Discussion

The goals of this paper are two-fold: (1) to show that through repeated use of scaffolding that supports case interpretation and application students do indeed become better users of cases and (2) to point out the connection between interpretation and application of expert cases and scientific reasoning. The first is shown in the data that has been reported. The second can be seen by connecting what students did while interpreting and applying cases to scientific reasoning.

It seems that using evidence to support a claim and explaining scientific phenomena is important in both case application and scientific reasoning, while

analysis of the data suggests that certain case application skills (i.e. understanding the context of problems, understanding criteria/ constraints, identifying relevant aspects of the case to apply) may be important in generating hypotheses and making predictions. For example, understanding the connection between addressing criteria/constraints and the outcomes that result seems to involve the same reasoning as generating a hypothesis and analyzing the results to determine whether the hypothesis is supported or rejected. This seems to suggest several things:

1. Understanding how to better support case application may lead to understanding how to better support certain scientific reasoning skills.
2. Students can be supported in case application despite its complexity, and students can improve case application skills. As such, support that leads to improvement in case application skills may also lead to improvement in certain scientific reasoning skills.
3. Using a cognitive apprenticeship framework and distributing scaffolding responsibilities across teacher and software seems to be effective at supporting case application skills that seem to be connected to certain scientific reasoning skills. As such, this same approach may be useful in supporting other scientific reasoning skills.

To make these suggestions stronger or to make stronger claims about the connection between case application and certain scientific reasoning skills, the data would need to be coded using dimensions to describe more specifically what is happening with students' scientific reasoning skills as their case application skills are improving. Though this was not the focus of this study, the trends that emerged and the suggestions that arose certainly suggest that this connection between case application and scientific reasoning is worthy of further exploration.

Abstract

Our study investigated the importance of reader aptitudes (prior knowledge and reading skill) in the processing of an expository text. We analyzed self-explanations produced by 42 high-school students while reading an expository text about thunderstorms. Specifically, we focused on students attempts to paraphrase information (i.e., restate sentences in their own words) and elaborate on the sentence content (e.g., connect information in different sentences to build a global representation of the text). Our findings suggest that reading skill is important for the active processing of expository texts. Skilled readers produced more elaborations than less skilled readers, and also a more diverse range of strategies, which may be crucial for supporting learning. Implications for learning from text are discussed.

Introduction

Successful reading comprehension requires the efficient co-ordination and integration of a number of underlying processes (Vellutino, 2003). These processes may include identification of words, decoding of word meanings, integrating the meaning of individual words into a coherent sentence level meaning using sentence syntax, and finally building a more global level representation of the text by continuously integrating the individual sentences into meaningful discourse level representation.

Our focus is on the higher level processes involved in reading comprehension, in particular, on how readers construct global mental representations of situations, and/or topics described by written material (van Dijk & Kintsch, 1983). Further, we focus on the impact of two reader-related factors on reading comprehension at this higher level of processing.

The first of these factors concerns the readers' knowledge of the topic of the text. As readers comprehension processes move from lower levels (e.g., word meaning) to higher levels (e.g., sentence/discourse processing), comprehension becomes increasingly influenced by the reader's knowledge about the topic of the text (Kintsch, 1988). General knowledge clearly influences the comprehension of narrative text (e.g., McNamara & McDaniel, 2004). Moreover, general and domain-specific knowledge is particularly critical for successful comprehension of expository texts (e.g., chemistry, biology). A great deal of research has shown that readers' knowledge facilitates comprehension and learning from expository texts (e.g., Chiesi, Spilich, & Voss, 1979; McNamara & Kintsch, 1996).

However, there are reasons to believe that other individual difference factors influence higher level processing of texts. In particular, factors associated with general reading skill, such as working memory capacity (Just & Carpenter, 1992), reading strategy knowledge (Guthrie, Anderson, Alao, & Rinehart, 1999), and meta-cognition (Baker, 2002) appear to be important. For example, McNamara and colleagues (McNamara, in press; O'Reilly, Best, & McNamara, in press; O'Reilly, Sinclair, & McNamara, in press) have shown that meta-cognitive reading strategy training improves science text comprehension, particularly for low-knowledge readers. Thus, active, strategic processing of text is particularly important to the comprehension of expository texts.

We explore here how reading skill is beneficial to comprehension of expository texts beyond the impact of prior knowledge found in various past research (e.g., Chiesi, Spilich, & Voss, 1979) A possibility explored here is the notion that general reading ability is associated with a set of skills that facilitate active processing of expository texts.

We hypothesized that knowledge level and reading ability would be associated with different aspects of the reading comprehension of expository texts. Specifically, whereas "knowledge" should be important for how easily one can comprehend the material, "reading ability" or "skill" should influence active, deep level processing of the material. Thus, our goal in this paper is to examine how reading ability as well as prior knowledge contributes to the "process of learning" from expository texts. We use the phrase "process of learning" here to refer to the processes engaged by students to acquire new

information from a text and integrate it into their own knowledge structures.

According to constructivist framework, learning occurs as a function of constructive activity one engages at the time of processing the materials (Cobb, 1994). We hypothesized that reading ability is associated with a set of skills that help readers engage in constructive activities such as elaborative inferences during reading, hence contributing to learning from the materials.

To tap into the effect of reading ability on "the process of learning," we analyzed self-explanations students produced when reading an expository text. Think aloud protocols are known to be useful for obtaining an insight into thought processes associated with problem solving (e.g., Chi, Bassok, Lewis, Reimann, & Glaser, 1989; Ericsson & Simon, 1993) and reading (Chi, 2000). Evidence further indicates that eliciting self-explanations during reading leads some readers to engage in active reading strategies that improve text comprehension (Chi, de Leeuw, Chiu, & Lavancher, 1994). Finally, there is evidence showing that the number of self-explanations (e.g., elaborative inferences) is correlated with learning (Chi, 2000). These studies reveal strong relations between self-explanation and the "process of learning." Thus, the analysis of self-explanations should afford an effective method of gaining insight into the "process of learning" that occur while students are reading expository texts.

Assuming skilled and less skilled readers possess different degrees of reading related aptitudes (e.g., motivation, working memory, effort, strategies) to deal with the reading comprehension situation, we expect variations to emerge in the type of reading strategies observed in the self-explanations generated while reading an expository text. In particular we hypothesize that reading ability will be associated with high frequency of constructive activities such as elaborative inferences.

The self-explanation protocols analyzed in this paper were collected during computerized reading strategy training, in which students typed their self-explanations to expository texts (see also, Best, Ozuru, & McNamara, 2004). The computerized trainer, called iSTART (Interactive Strategy Trainer for Active Reading and Thinking), is an automated reading strategy training program developed by McNamara, Levinstein, and Boonthum (in press). iSTART has been shown to be as effective in training reading strategies as its parallel, live version, called SERT (McNamara, in press; O'Reilly et al., in press).

Method

Participants

The sample consisted of 42 eighth and ninth grade children from an east coast suburban school. The students were enrolled in a learning program, called Learning Bridge, designed to provide summer school to students from under-privileged backgrounds.

Design and Materials

Individual differences were measured with two tests; a modified version of the Gates-MacGinitie Reading Skill Test and a Prior Knowledge Test. The Gates-MacGinite test is a standardized reading comprehension test, designed for grades 10-12. The test consisted of 40 multiple-choice questions that assess students' comprehension on several short text passages (Cronbach's Alpha α=.91). Due to time constraints we omitted the vocabulary comprehension section. The prior knowledge test had 35 multiple-choice items, which tap knowledge of different science domains, including biology, scientific methods, mathematics, earth science, physics, and chemistry (Cronbach's Alpha α=.81).

The iSTART system (McNamara et al., in press), in which the self-explanations were collected, consists of three phases: Introduction (introduces concept of self-explanation and reading strategies), Demonstration (shows users examples of self-explanation) and Practice (requires students to generate self-explanations).

In the practice section, students are presented with science texts one sentence at a time on the computer screen. For each sentence, they are asked to type a self-explanation. iSTART assesses the quality of the self-explanation and provides the feedback to students via the pedagogical agent, Merlin. The feedback is largely based on the degree of argument overlap between the students' self-explanation and the target sentence. The system is designed such that it encourages students to use information that is not in the target sentence (e.g., elaboration based on commonsense and previous sections of the text.). For example, Merlin might respond with "Try adding some more information that explains what the sentence means" when the self-explanation is too similar to the target sentence. Thus, feedback differs for each user, depending on the quality of self-explanations produced.

The self explanations analyzed in this paper are the final versions that the students provided for each sentence. Thus, they have been affected by the feedback of the system in that the final self-

explanations reflect better quality protocols than would otherwise have been provided under spontaneous circumstances. However, the system tends to reduce the difference between high and poor quality self explanations because there is a certain threshold for the acceptance. In this sense, the effects of individual differences reported in this paper are unlikely to be artifacts of the system's feedback.

Students self-explained two texts in the practice phase, "Stages of Thunderstorm Development" and "Origin of Coal." The present analysis focuses on self explanations for the thunderstorm text. This text, which was extracted from a school textbook, has 13 sentences and 197 words, with Flesch-Kincaid Grade level of 9.4.

Procedure

Individual difference measures were collected shortly before iSTART training. Students completed the prior knowledge test followed by the Gates-MacGinite reading test. They were given 15 minutes to complete each assessment. The students then completed the training with iSTART program. During the practice phase, they provided explanations to the Thunderstorms text.

Coding

Students typed their self-explanations, which were automatically recorded in the database. Two independent coders analyzed the self-explanations in terms of the following five dimensions: 1) presence of comprehension monitoring; 2) presence of paraphrasing (none, topic identification, repetition, and paraphrasing); 3) distance of paraphrasing from the target sentence; 4) accuracy of the paraphrasing; and 5) presence of elaborations.

Coding of comprehension monitoring assessed whether self-explanations incorporated the monitoring of students' understanding. Explanations were coded for the presence or absence of comprehension monitoring statements (e.g., 'I don't understand X'). The presence of paraphrasing was judged on students' attempt to restate the target sentence in their own words. For this coding, a self explanation was categorized as one of the following: 1) a paraphrase that was a restatement of the sentence using different words, 2) a repetition of the sentence that was lexically too similar to the target sentence, 3) a simple topic identification (e.g., 'this is about storms'), or 4) no paraphrase, repetition, or topic identification. If the explanation was categorized as a paraphrase, the paraphrase was further coded for *accuracy* and *distance* from the target sentences. *Accuracy* has three levels (inaccurate, partially accurate, and accurate); and *distance* has two levels (distant and close). Close paraphrases were closely aligned to the original sentence in terms of sentence structure and/or content words. Distant paraphrases contained the same semantic content as the target sentence, but did not have the same sentence structure or content words.

Coding of the elaborations was based on whether the self-explanations included any ideas that were not explicitly present in the target sentence. Once a self-explanation was found to contain an elaboration, it was further coded for the nature of its *contribution:* 1) relevant to the comprehension of neither the current sentence nor the overall text; 2) relevant and contributes to the comprehension of only the target sentence; and 3) relevant and contributes to a global level of comprehension that goes beyond the current sentence (e.g., actively building the large picture depicted by overall text). We also coded the elaborations in terms of their source and accuracy. However, since the present analysis does not focus on these aspects, they are not described here (see Best et al., 2004).

Reliability of the coding was evaluated using Cohen's Kappa and simple agreement (when the coding is binary). Reliability between the coders was 85% or above for all coding dimensions. Disagreements were resolved via a discussion between the coders.

Results

To explore the role of the reading skill and prior knowledge, we adopted a median split method; students were divided into high and low reading comprehension skill, or high and low-knowledge groups, using the median scores of The Gates-MacGinite test or Prior Knowledge test. The correlation between the Gates-MacGinite test and the prior knowledge test was high, $r = 0.604$, $p < .001$.

Our data indicated that students' often attempted to paraphrase (91.0%) and elaborate (41%), but seldom expressed comprehension monitoring (4%). Thus, the subsequent analysis focuses on paraphrase and elaborations.

We used analysis of variance (ANOVA) to analyze the students' use of the strategies. The univariate ANOVAs comprised reading skill (high or low) or knowledge (high or low) as the between-subjects factor and strategy type (e.g., paraphrases) as the dependent variable.

Frequency distribution of strategy use

Our first analysis investigated the frequency of four types of strategy used by different types of readers (low and high reading skill or knowledge students). For this analysis, we classified all the self-explanation into one of four categories: 1 =

Repetition or topic identification only; 2 = Paraphrasing only; 3 = Elaboration I (irrelevant or current sentence); and 4 = Elaboration II (knowledge building).

It is important to note that elaboration (both type I and II) may or may not contain paraphrasing. Elaboration I and Elaboration II were treated separately because knowledge building elaborations are indicative of the investment of a greater effort to understand the text (i.e., building a more global representation of the text). Irrelevant elaborations were coded under Elaboration I because they indicate that the student is investing an effort to integrate the information into their knowledge structures.

The levels of the classification scheme reflect an increase in the construction of integrated and global representations of the situation described by the text. For example, repetition does not require any integration because it only involves rewriting the text information. In contrast, paraphrasing requires the restatement of the situation using different words or sentence structure, revealing how students understood the meaning of the sentence. Similarly, Elaboration I indicates that students are making an effort to understand the target sentence by relating, integrating, or comparing the information in the sentence with what they already know. Finally, Elaboration II involves effort to integrate information appearing on a multiple sentences into a coherent model. Therefore, this analysis can examine the degrees of constructive activities carried out by the student.

The first analysis investigated the self-explanation strategies used by skilled and less skilled readers. As shown in Table 1, skilled readers were more likely to use elaboration strategies whereas less skilled readers were more likely to repeat or paraphrase only.

We performed two separate ANOVAs, assessing the frequency with which skilled and less skilled readers used elaboration types I and II. Skilled readers produced more current sentence focused elaborations (elaboration I), $F(1, 39) = 6.75$, $MSE = .053$, $p = .01$, and knowledge building elaborations (elaboration II), $F(1, 39) = 7.6$, $MSE = .003$, $p < .01$, than did less skilled readers. The difference between skilled and less skilled readers in current sentence focused elaboration (Elaboration I) is not solely attributable to irrelevant elaborations included in Elaboration I because the difference remained marginally significant after excluding irrelevant elaborations: (less skilled readers $M=.22$ $SD=.22$) and (skilled readers $M=.33$ $SD=.20$), $F(1, 39) = 2.95$, $MSE = .043$, $p = .094$.

Table 1. Strategy use and comprehension skill

Strategy use	Less Skilled	Skilled
Repetition/Topic identification	.08 (.07)	.03 (.07)
Paraphrasing	.62 (.20)	.46 (.23)
Elaboration I	.29 (.23)	.46 (.22)
Elaboration II	.01 (.02)	.05 (.07)

Note: Standard deviations are in parentheses.

The previous analysis was repeated with knowledge as the between-subjects variable. As shown in Table 2, there were few differences in the distribution of strategies used by high and low-knowledge readers. ANOVAs confirmed this conclusion: there was no difference in the frequency with which low-knowledge and high-knowledge students used Elaboration I, $F(1,39) = 1.04$, p = ns, or Elaboration II, $F(1, 39) = .017$, p = ns. There was no difference, again, in Elaboration I even after excluding irrelevant elaborations: low-knowledge ($M= .28$ $SD =.24$) and high-knowledge ($M= .28$ $SD = .19$) students.

Table 2. Strategy use and knowledge

Strategy use	Low Knowledge	High Knowledge
Repetition/Topic identification	.07 (.06)	.04 (.09)
Paraphrasing	.55 (.27)	.53 (.20)
Elaboration I	.35 (.26)	.40 (.23)
Elaboration II	.03 (.06)	.03 (.10)

Note: Standard deviations are in the parentheses.

Variety of strategy use

Next, we were interested in how skilled and less skilled readers and high and low-knowledge readers differed in terms of the diversity of the strategies they use in self-explaining the 13 sentences of the text.

We hypothesized that less skilled readers would be relatively uniform in their strategy use (i.e., use only one type of strategy). In contrast, skilled readers would frequently change their strategy use (i.e., adapt their strategies to different sentences). On the other hand, we predicted that knowledge level would make little difference in terms of the variety of strategies students' used.

To conduct this analysis, we counted how many of the aforementioned strategies (paraphrase, type I elaboration, and type II elaboration) each student used to self-explain the 13 sentences. We did not count repetition/topic identification as a strategy because it is a default technique. Accordingly, the

score each student obtained varied from 0 (no strategy used) to 3.

The analysis showed that reading skill was an important determiner with regard to the variety of self-explanation strategies used. An ANOVA indicated that skilled readers used a greater variety of self-explanation strategies (M = 2.4, SD = 0.6) than did less skilled readers (M = 2.0, SD = 0.5), F(1, 39) =5.9, MSE = .277, p = .02.

On the other hand, the analysis based on readers' knowledge indicated that there was no reliable differences in the range of self-explanation strategies used by high (M = 2.3, SD = 0.5) and low-knowledge students (M = 2.1, SD = 0.3), F(1,39) = 1.45, ns.

Effect of prior knowledge and reading skill on the quality of paraphrases

Thus far, our analyses have indicated that reading skill, rather than prior knowledge is an important factor in determining the frequency of elaborative inferences and variety of self-explanation strategies students employ. Does this mean that prior knowledge does not play an important role in the reading comprehension process? According to our argument, and existing literature, prior knowledge should have a large influence on comprehension level of expository texts. In order to examine the effect of prior knowledge on comprehension, we analyzed the quality of paraphrases. Given that paraphrasing involves describing the gist of a sentence using one's own words, the quality of paraphrases should reflect the students' understanding of sentence meaning.

Our analysis focused on two different qualities related to successful paraphrasing: 1) accuracy of the paraphrase and 2) distance of the paraphrase. For accuracy, a score of 0, 0.5 and 1.0 was assigned for inaccurate, partially accurate, and accurate paraphrases, respectively. The two sets of univariate ANOVAs on the accuracy scores indicated that there were no effects of individual differences. This rather disappointing result is possibly due to the fact that the target sentence was available for reference while students self-explained the sentence.

Turning to the distance of paraphrase, we compared the frequency of distant paraphrases produced by high and low-knowledge and/or by skilled and less skilled students. Two sets of univariate ANOVAs on the frequency of distant paraphrases indicated that distant paraphrases occurred more frequently for high-knowledge (M = 0.63, SD = 0.22) than low-knowledge students (M = 0.44, SD = 0.24), F (1, 39) = 8.153, MSE = .051, p <.01. Also the main effect of reading comprehension skill was marginally significant, with more distant paraphrases produced by skilled readers (M = 0.61, SD = 0.29) than less skilled readers (M = 0.47, SD = 0.24), F (1, 39) = 2.891, MSE = .057, p =.097.

We also examined accuracy of distant and close paraphrases by dividing all of the items into distant or close paraphrases, and analyzing whether the accuracy differed across distant and close paraphrases. The analysis revealed that accuracy does not differ between distant (M =.62, SD = .22) and close paraphrases (M =.69, SD = .20), F(1, 38) = 2.215, p > 0.1, suggesting that distant paraphrases are not necessarily less accurate. Overall, these analyses indicate that students' prior knowledge has a larger effect on the production of distant paraphrases. Given that producing a distant paraphrase without distorting the meaning of the sentence requires accurate comprehension of the sentence, this finding confirms previous findings for effects of knowledge on comprehension level of the expository text.

Discussion

Overall, the analyses support our prediction that reading comprehension ability is closely associated with the effort and strategies that readers expend to understand the expository text, whereas knowledge is more closely associated with the actual comprehension level of the material (as indicated by the distance of the paraphrase analysis). Skilled readers' self-explanations tend to include more constructive activities, such as elaborative inferences and linking different parts of the text to obtain a "larger picture." This finding is remarkable because it demonstrates that skilled readers' are able to generate these elaborative and bridging inferences even when they are dealing with relatively unfamiliar materials (i.e., an expository text about thunderstorm as opposed to narrative texts used in Gates-MacGinite test). One interpretation of this finding is that skilled readers possess skills/strategies to effortfully activate relevant information from relatively unfamiliar text-based information (McNamara, in press). This ability is associated with constructive activities such as bridging inferences, and elaborative inferences. Use of these types of strategies, either naturally or after being trained to do so, contributes positively to learning from expository texts.

One limitation of our study is that it focuses solely on the processes readers employ while reading the text, and hence, does not directly show learning gains for skilled readers. However, research supports the assumption that greater use of elaboration is associated with learning gains (Chi, 2000; McNamara, in press).

There are two contrasting views regarding how elaborations contribute to learning: the incomplete text view and the self-repair view (Chi, 2000). These views differ critically with respect to whether (or to

what extent) the accuracy of readers' elaborations affect leaning. In line with Chi's (2000) view, our assumption here is that elaborations facilitate learning, regardless of whether they are accurate (see also, McNamara, in press). But, of course, we do not rule out the likelihood that there are several different ways in which elaborations can contribute to leaning. Accuracy of elaborations may well have important implications for the learning process, particularly when the reader does not have the opportunity to repair inaccurate elaborations based on information encountered later in the text.

In conclusion, the present research highlights the important role active reading strategies play in the comprehension of and learning from expository texts. Given that active strategies are beneficial, future work should explore, in more detail, the reader related factors (e.g., metacognition, knowledge on the strategies, etc) that underlie the use of the strategies, and the text-related factors (e.g., sentence difficulty, that affect active reading.

Abstract

Whereas reliance on information from one's proximal social environment for generalizing about the population has often been associated with erroneous judgments, this information is often valuable and can be exploited for making accurate inferences. The social circle heuristic is a judgment mechanism in which the content and structure of people's social networks are used for making inferences about frequencies in the population in a paired comparison task. Because the heuristic has a stopping rule, judgments generated by it will often be based on small samples sizes. In this paper we present experimental evidence that shows both that the social circle heuristic can compete with a more thorough strategy, and that people actually apply it.

Samples as Reflections of the Environment

Scarcity of information is one of the central properties of everyday decision making. For many judgment problems in the real world, neither direct knowledge of the to-be-judged values nor complete knowledge of all relevant facts that might help predict the correct value are available. Instead, inferences have to be made under uncertainty, based on information that is more or less predictive of the criterion. What processes underlie people's inferences in such situations? Recent approaches to judgment under uncertainty that acknowledge the bounded rationality of humans have advanced the notion of *fast and frugal decision making* (Gigerenzer, Todd, & The ABC Research Group, 1999). The heuristics proposed by this program are based on Brunswik's (1955) idea that judgments are made on the basis of cues that are probabilistically related to the target criterion. As Gigerenzer et al. (1999) have shown, such mechanisms can be astonishingly accurate despite using only a limited amount of information.

Typically, fast and frugal heuristics rely on cues that are qualitatively different from the criterion (e.g., considering whether or not there is rent control in a city to predict which of two cities has a higher homeless rate). In the case of frequency judgments, however, the target criterion can be inferred by sampling instances of it from a population. For example, which first name occurs more often in the population: Martin or Simon? Or, does bladder cancer or renal cancer have a higher annual incidence rate? For these inference problems concerned with environmental frequencies, it is possible that—rather than accessing proximal cues—samples consisting of instances of the criterial event are drawn from the proximal environment. As such, samples can also serve as "keys to assessing the distal environment" (Fiedler, 2000, p. 661), and in the absence of direct knowledge about the environment, these "reflections" of the environment are used to infer its latent properties.

That humans use proximal samples when making inferences about the entire population has been argued in various forms. For instance, in one interpretation of the availability heuristic (Tversky & Kahneman, 1973; see also Sedlmeier, Hertwig, & Gigerenzer, 1998), frequencies in the environment are judged by accumulating easily accessible instances of the target event (e.g., Lichtenstein, Slovic, Fischhoff, Layman, & Combs, 1978). Judgment phenomena such as the false consensus effect (Ross, Green, & House, 1977) or the optimistic bias (Weinstein, 1980), have been attributed to the employment of the availability heuristic, and the use of such a small-sample-based heuristic has therefore been associated with the fallibility and irrationality of human decision making.

In contrast, we ask how humans can achieve fairly accurate judgments in spite of the scarcity and cognitive boundedness they have to face in the real world, and examine what processes contribute to this achievement (cf. Krueger & Funder, in press). Elaborating on the idea of sample-based judgments, we propose and test a simple heuristic for paired comparisons that exploits frequency information in one of people's most proximal environment: their social network.

The Social Environment as Sample Space

People's inferences have been shown to be strongly sensitive to information in their social environment. Prominent examples are attitude formation (e.g., Fishbein & Ajzen, 1975), conformity behavior (Hirshleifer, 1995; Latané, 1981) or risk frequency judgments (Benjamin, Dougan, & Buschena, 2001; Hertwig, Pachur, &

Kurzenhäuser, 2003). Furthermore, there is evidence that information obtained from individuals is accessed and used more readily than is the same information obtained in an abstract, statistical format when making judgments (Borgida & Nisbett, 1977)—even when it is pointed out that the concrete individual represents a highly unrepresentative instance (Hamill, Wilson, & Nisbett, 1980).

Apart from the well-known vividness argument, information obtained about concrete individuals could receive special prominence for several reasons: First, as no mediating factor can distort it, information directly obtained or observed about the members of one's own social network is highly *reliable*. Second, the observations of instances of the target criterion are per se a *valid* indicator of the criterion. Further, the information is easily *accessible*, as information about social network members represents a constantly recurring and thus well-rehearsed event. Finally, observations of criterial events in one's social environment are *naturally sampled*, that is, encountered sequentially and represented as natural frequencies. This format has been shown to foster probabilistic reasoning (Hoffrage, Lindsey, Hertwig, & Gigerenzer, 2000).

Based on these reasons, we propose that people use their social network as a sample space to search for information they use to draw numerous inferences. Specifically, we propose one heuristic, the social circle heuristic, which makes inferences about which of two events occurs more frequently in the entire population: With the heuristic, instances of the events in question are sampled from a person's social network.

How Social Circles Guide Search and Stop Search

In light of the computational limitations of human cognition and the fact that inferences often have to be made without an exhaustive search of available information (Simon, 1956), the question of when to stop information search arises. In other words, when does one stop sampling from one's social network?

An individual's social network is no homogenous entity of identical types of relationships. Rather, one can argue that social networks have a hierarchical structure, with the relationships that a person has to the members of his or her social network differing in genetic relatedness, frequency of contact, emotional closeness, content of contact, and function (e.g., Milardo, 1992). Collapsing across these dimensions, we will differentiate among the following social circles: family, friends, and acquaintances.

A central idea of the social circle heuristic is that the structure of the social network is used during the sampling process, that is, the heuristic exploits the hierarchical structure of the social environment to guide and stop the sampling process. A popular notion in social network research has been to represent the hierarchical structure of a social network as concentric circles (Moreno, 1936; Kahn & Antonucci, 1980), with the person whose network is described in the focal circle, and persons of increasing "distance" to the person occupying increasingly peripheral circles. For instance, one's family might fall in the circle second closest to the middle, friends in the third circle, and one's acquaintances in the outer circle. As described in the next section, the social circle heuristic works by sequentially sampling instances of the events in question from the different circles, starting with the focal circle. As soon as the search of a complete circle favors one of the two alternatives, the sampling process is terminated and no further circles are looked up. Note that moving outwards, the number of the circles' members increases monotonically, and, as a consequence, so too does the sample size on which an inference can be based.

The Social Circle Heuristic

After defining the sample space and its structure, we are now in the position to describe the social circle heuristic in more detail. Consider the following inference problem: Which disease occurs more often in the population, hepatitis or tuberculosis? The social circle heuristic is a heuristic for such pair comparisons in which events (or characteristics) are judged according to their population frequency.

The heuristic consists of four building blocks and starts with the recognition heuristic (Goldstein & Gigerenzer, 2002).[1] The social circle heuristic has a search rule, which specifies where to search, a stopping rule, which specifies when to stop sampling, and a decision rule, which specifies how to make an inference based on the information gathered through sampling (for different building blocks of heuristics see Gigerenzer et al., 1999).

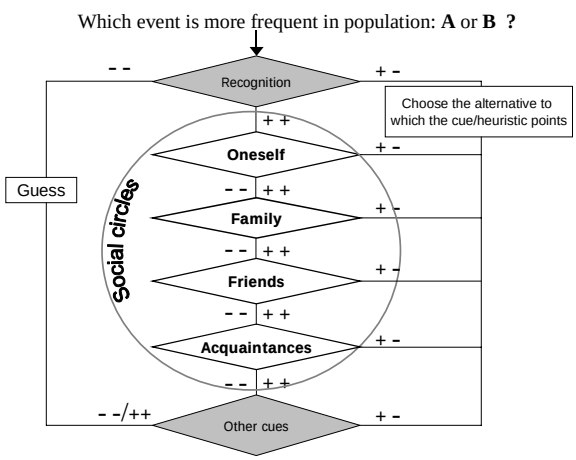

Figure 1: Flow chart of the social circle heuristic and the relationship of the sampling process to the recognition principle and inferences based on other cues (such as Take the Best; Gigerenzer & Goldstein, 1996).

It operates as follows:

Step 0 – Use the *recognition heuristic*. If the name of only one of the two events is recognized, then predict that the recognized one is more prevalent than the

[1] This latter point also illustrates how fast-and-frugal heuristics can be combined by nesting.

unrecognized one. If the names of both events are recognized, recruit the social circle heuristic.

Step 1 – *Search rule*: Search the social circle for instances of the events, running sequentially through the circles, starting with the focal circle.

Step 2 – *Stopping rule*: If search within a circle favors one event, stop search. If; within a circle; the same number of instances is found for both events, continue the search in the next circle.

Step 3 – *Decision rule*: Predict that the event for which a higher number of instances is found is the more prevalent in the population. If the sampled information does not discriminate between the alternatives (and no other information is known), then guess after the last circle is searched.

Due to the stopping rule, the search process will often be terminated early, and an inference based on information gathered with the social circle heuristic will be derived from samples of small sizes. Note that this also implies that as soon as search is stopped at a particular circle, information in more peripheral circles that might overturn the decision, is not considered. In this sense, the heuristic is non-compensatory. To rely on small samples has often been seen as unreasonable ("belief in the law of small numbers"; Tversky & Kahneman, 1971), and only recently a few authors have highlighted the possible value of such a strategy (e.g., Dawes, 1989; Fiedler & Kareev, 2004; Kareev, 2000).

How Accurate Is the Social Circle Heuristic?

In order to test the accuracy of the social circle heuristic, we conducted a computer simulation where the task of the heuristic was to judge which of two events, A or B, occurs more frequently in the entire population. For this task, the heuristic could search for instances of the events in its spatial vicinity. The population consisted of 2,500 agents, represented in a 50×50 matrix in which each cell represented one agent (see Figure 2, which shows the environment simplified to a population with 100 agents in a 10×10 matrix). We used the city block metric to define the distance between the agents. For instance, in Figure 2—which shows the social network of agent #45 in a population of 100—agent #44 is at a distance of 1 from agent #45, agent #34 is at a distance of 2 from agent #45, agent #33 is at a distance of 3 from agent #45 etc. It is assumed that each agent's social network consists of 40 other agents that differ with regard to their distances to the agent. Thus, an agent could maximally sample information about 41 agents (including himself). This social network is divided into different social circles: Circle 1, that only includes the agent itself, Circle 2, including all neighboring agents with a distance of 1 (4 agents), Circle 3, including all neighboring agents with a distance of 2 (8 agents), and Circle 4, including all neighboring agents with a distance of 3 or 4 (28 agents).[2]

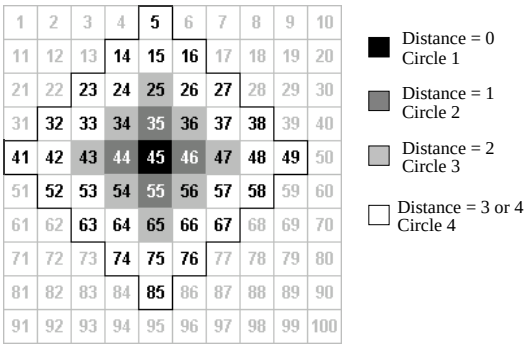

Figure 2: Environment in the computer simulation (here simplified as a 10×10 population).

Two environments were used to test the performance of the social circle heuristic. In the first environment, instances of 10 event categories were distributed randomly across the 2,500 agents (see Figure 3). The 10 events mimicked the frequency distribution of a real world environment used in the experiment (discussed further below): occurrences of infections in Germany. As can be seen from Figure 3, the distribution of the proportions of the infections is very skewed and falls into a J-shaped distribution, a pattern found in many real-world domains (Hertwig, Hoffrage, Martignon, 1999). The proportions of the 10 most frequent infections (from a set of 24) were chosen because their proportional distribution could be represented in a population of 2,500 agents. The most frequent event was set at a frequency of 2,000; the 9 other events were distributed according to this anchor and the proportions reported by the Robert Koch Institute (for details see Pachur, 2002).

Secondly, we constructed an environment in which the same overall number of instances in the population was distributed across the 10 event categories such that the frequency across the 10 events was linearly increasing. As a result, this linear environment and the skewed environment differed substantially with regard to the dispersion of the frequency distribution. We were interested in the effect of the frequency distribution of the events as this property can have an effect on the success of a strategy (Hertwig, Hoffrage, Martignon, 1999).

To make an inference, the social circle heuristic starts with Circle 1 and looks whether event A or B is present. If one is and the other not, no further circles will be looked up, irrespective of what information is present in the other circles, and it will be inferred that the sampled event is more frequent in the population. If neither of the events is present in Circle 1, the agents in Circle 2 will be looked up. If one

[2] The matrix was a wrapped environment, that is, the agents at the borders had neighbors at the opposite side. For instance, in Figure 2, the left-hand neighbor of agent #41 is agent #50.

event occurs more frequently in Circle 2, search is stopped and an inference is made after looking up only four agents. The same rule applies to Circle 3. Only if the number of instances in the first three circles does not discriminate, then Circle 4, and thus the maximum number of 41 agents will be looked up. If even circle 4 does not discriminate, one of the events is picked randomly.

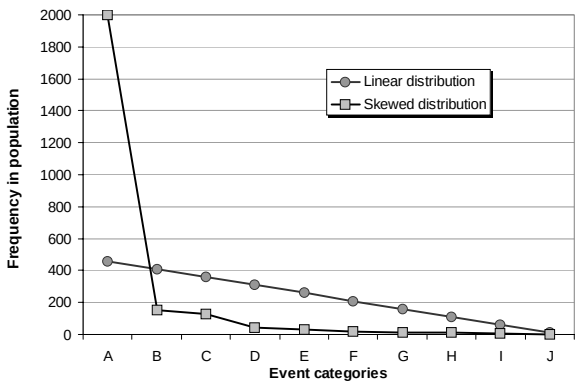

Figure 3: Distribution of the 10 events in the two environments used in the computer simulation.

As a benchmark for the social circle heuristic, its performance was compared with the performance of an exhaustive sampling strategy. For an inference of whether event A or event B occurs more often in the entire population, this strategy, normatively more appropriately, always looks up all 41 agents in the social network (that is, this strategy aggregates information across all circles). The event for which more instances can be sampled is inferred to be more frequent in the entire population. If an equal number of instances is sampled for both events, or if no instances can be sampled at all, one of the events is picked randomly.

For each of the two environments, the random distribution of the 10 events (totalling around 2,400 instances) was repeated 100 times, and each time 100 agents were picked randomly as starting points for the two strategies. At each run, the 10 events were combined in a pair comparison (yielding 45 pairs) and the task was to infer which event is more frequent in the entire population.

How well does the simple social circle heuristic perform compared to the exhaustive sampling strategy? In the skewed environment, derived from a real-world distribution, surprisingly, both strategies showed an identical proportion of correct inferences with a median of 77.8% (arithmetic means: social circle heuristic 76.3%, exhaustive sampling strategy 77.5%). Showing a similar level of performance, the social circle heuristic looked up, on average, only 24.7 agents, which is approximately 55% of the amount of information that the exhaustive sampling strategy used (which always looks up all 41 agents).

In the linear environment, the picture was different: here the exhaustive strategy clearly achieved a higher accuracy than the social circle heuristic. Whereas the social circle heuristic a median of 75.6% correct choices (mean 75.2, *SD* =8.9), the exhaustive strategy 84.4% (mean 83.1, *SD*=6.3).

Table 1 shows the performance of the social circle heuristic in more detail. Because of the stopping rule, the social circle heuristic terminated for some inferences the search at Circle 1, for some at Circle 2, for some at Circle 3, for some at Circle 4, and for some a guess had to be made. The second column of Table 1 reports for each circle the percentage of choices for which search was stopped at the circle. The social circle heuristic had to guess in 31.6% of the cases (whereas the exhaustive sampling strategy had to guess in 33.6% of all choices). The rightmost columns shows the percentage of correct inferences for these choices. Note that in the skewed environment, contrary to normative expectations, the accuracy *decreases* from Circle 1 to Circle 3. In the linear environment, in contrast, the accuracy increased.

Table 1: Proportion and accuracy of choices after search was terminated for the SCH in the two environments. The ns in the first column refer to the number of agents looked up.

Circles	% of choices stopped at each circle		% of correct choices	
	Skewed	Linear	Skewed	Linear
Circle 1 (n=1)	19.2	18.8	95.7	69.7
Circle 2 (n=5)	13.2	38.4	88.2	74.0
Circle 3 (n=13)	13.8	26.2	84.2	78.1
Circle 4 (n=41)	22.3	13.7	85.5	85.8
Guessing	31.6	3.0	50.0	50.0

Thus, we have accumulated a number of arguments for the usefulness of the social circle heuristic. First, it is a simple strategy that can be assumed to be easily performed by a boundedly rational agent. By restricting the search process and the amount of information on which an inference is based to a minimum, the social circle heuristic allows for very quick judgments. Second, as we have seen, it performs equally well as a more thorough strategy that takes much more information into account, and this performance seems to hinge on the statistical structure of the environment. Overall, the social circle heuristic achieves an astonishingly high proportion of correct inferences. But can we find evidence for people's use of such a simple and efficient strategy for making inferences about event frequencies?

Do People Use the Social Circle Heuristic?

The 24 infectious diseases (the proportions of 10 of these were also used in the computer simulation) for which official records are kept by the Robert Koch Institute were combined in a complete paired comparison (yielding 276 pairs), and 40 participants were asked to choose the infectious disease that has a higher annual incidence rate in Germany. After this test, participants indicated for each infection and each of their circles (self, family, friends, and

acquaintances) how many, if any, people in their circles had been affected by the infection. They also indicated whether they recognized the name of the infection. From this information, we calculated how often participants had an opportunity to choose in accordance with the social circle heuristic and determined which prediction the social circle heuristic made in each of these cases (only pairs where both infections were recognized and the reported number of instances in the social network discriminated between the two infections were included). Overall, only relatively little occurrences of the infections were reported by the participants, which is not surprising given the rarity of infections. The social circle heuristic made predictions for 33 participants, and was applicable (i.e., discriminated between the infections), on average, with 11.1% of all choices. Figure 4 shows how often these 33 participants made a choice in accordance with the prediction of the social circle heuristic.

For each participant, the bar indicates the percentage of choices that were in line with the prediction of the social circle heuristic. Overall, the median proportion of inferences in accordance with the social circle heuristic was 79.5% (mean 77%, *SD*=15.9). It seems fair to conclude that the social circle heuristic did quite a good job in describing participants' judgments (focusing on those in which it was applicable).

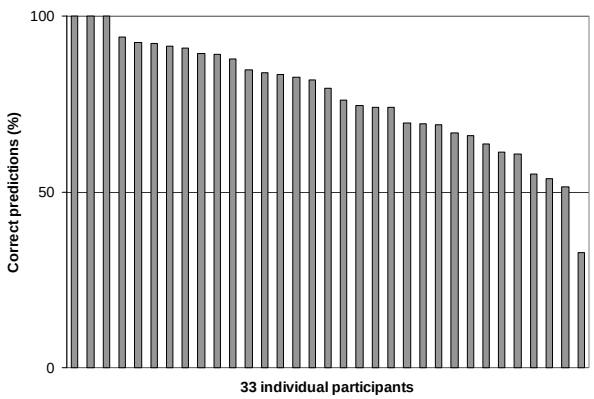

Figure 4: How often the 33 participants who reported instances of the infections in their social network made choices in accordance with the social circle heuristic.

How Ecologically Rational Is the Social Circle Heuristic?

The social circle heuristic is a psychologically plausible strategy: people appear to use it when trying to infer with of two risk events is more frequent. But how accurate a strategy is the heuristic when applied to the infections and based on the occurrences of the infections recalled by our participants? In other words, how ecologically rational are the inferences of the social circle heuristic in the task that our participants solved? In a second analysis, the predictions of the social circle heuristic for each individual were compared with the correct choices, that is, according to the actual incidence rates (averaged values from a 5-year period were used to eliminate year-to-year fluctuations).

An index for the ecological validity was defined as the number of correct inferences made by the social circle heuristic divided by the number of pairs where it was applicable. This index was calculated separately for each participant. The median ecological validity was .83 (mean .78), indicating that, overall, strictly following the social circle heuristic when it was applicable would have led to an accuracy of over 80% correct choices.

In contrast, how did the non-adherence to the social circle heuristic affect participants' performance? As indicated by the ecological validity index, strictly following the social circle heuristic would have yielded over 80% correct choices (which is far above the performance the participants achieved overall). Analyzing the choices that were in line with the predictions of the social circle heuristic and those that were not in line with it, it turned out that when the participants could apply the heuristic and did, they achieved on average 83.4% (*SD*=18.5) correct choices, whereas when they could but did not apply the heuristic, they achieved on average only 45% (*SD*=25.5) correct choices.

To be able to evaluate the accuracy of the social circle heuristic for the domain of infections, we also tested the strategy that always takes all instances that our participants reported into account. The exhaustive strategy showed a very similar fit with our participants' choices (median 81.8% mean 77.6% of choices in line with the predictions of this strategy), but was applicable in slightly fewer cases. In terms of ecological validity, the predictions of this strategy achieved no higher accuracy than the social circle heuristic (median ecological validity of .83, mean .79), which is in line with the results of the computer simulation.

Discussion

In the real world, inferences from small samples need must not be less accurate than inferences from larger samples. In this paper we investigated, both in a computer simulation and in an empirical study, a simple decision mechanism that exploits a person's social network as an easily accessible sample space for judging event frequencies in paired comparisons. The results show that the social circle heuristic allows one to judge accurately, with simple search, stopping, and decision rules, the environmental frequencies of randomly distributed events in a paired comparison task. At the same time, this mechanism describes people's choices rather well. Thus, the performance of the social circle heuristic provides another instance for the argument that small samples can be an efficient basis for judgments in the real world (cf. Fiedler & Kareev, 2004; Kareev, 2000).

This paper was intended to explore the appropriateness of this heuristic in an environment that has a naturally occurring statistical structure, and it was shown that the heuristic works particularly well in such an environment. A question for future research is why the heuristic works so well under these conditions and how it performs in environments in which events occur in clusters.

By virtue of its reliance on the structure of social networks, the social circle heuristic represents another example of a judgment policy in which the mind is a mirror image of the environment. The social circle heuristic thus follows in the footsteps of the pioneering work by Egon Brunswik (1955), John Anderson (e.g., Anderson & Schooler, 1991), and Roger Shepard (e.g., 1994).

Symbolizing Quantity

Praveen K. Paritosh (paritosh@cs.northwestern.edu)

Northwestern University, 1890 Maple Ave,
Evanston, IL 60201 USA

Abstract

Quantities are ubiquitous and an important part of our understanding about the world – we talk of engine horsepower, size, mileage, price of cars; GDP, population, area of countries; wingspan, weight, surface area of birds, and so on. In this paper, we present cognitively plausible symbolic representations of quantity and principles for generating those representations. Bringing together evidence in linguistics and psychology, we argue that our representations must make two kinds of distinctions – *dimensional*, those that denote changes of quantity, e.g., large and small; and *structural*, those that denote changes of quality, e.g. boiling point and poverty line. We present results of a pilot experiment that suggests that there is a significant agreement between people about the dimensional distinctions. We then describe a computational model CARVE, which is a system that learns to make dimensional and structural distinctions on quantities by being exposed to examples.

1 Introduction

Our knowledge about quantities is of various kinds – we understand that there are `Expensive` and `Cheap` things, that Canada is `larger` (in area) than the USA, that basketball players are usually `tall`, that the `boiling point` of water is `100 degrees Celsius`. A key part of such knowledge seems to be a *symbolization* of the space of values that a quantity can take. By symbolization, we mean identifying and naming intervals and points in the space of values of a quantity. Some examples include `tall` and `short` for the quantity of height of people; `poverty line, lower class, middle class` and `upper class` for income of people; `freezing point` and `boiling point` for the temperature of water.

These symbolizations and their mapping onto quantitative values seem to be determined by a mixture of personal experience (e.g., what I consider to be `spicy` in regards to food), society (e.g., middle class), science (e.g., phase transitions). Some are task-specific – one makes more distinctions than freezing and boiling for bath water. Furthermore, some of these symbolizations have been said to be vague [Varzi, 2003], in the sense that it is not possible to tell exactly at what value of height one becomes tall, and is not tall if any less than that. Given these concerns, finding systematic principles behind such symbolizations seems to be a daunting task, and has not been tackled head-on in cognitive science. That said, there is a vast literature that bears on these issues. In this paper, we address the following two fundamental questions about people's knowledge of quantities –

1. *Representational*: What do our representations of quantity look like? Or, what representational machinery is needed to make the distinctions that we do?
2. *Computational*: How are these representations built with experience?

Large scale knowledge representation efforts like Cyc [Lenat and Guha, 1989] refer to quantities either purely numerically, or using ad hoc representations. Most existing computational models of retrieval and similarity cannot use numerical representations [Falkenhainer et al, 1989; Holyoak and Thagard, 1989; Hummel and Holyoak, 1997; Goldstone and Rogosky, 2002], leading to quantitative information being ignored in computation of similarity. There are models in case based reasoning [Ashley, 1990; Leake, 1996; Ram and Santamaria, 1997] that use numeric information, but they employ ad hoc similarity metrics that are not psychologically grounded. A major motivation of this work is to generate cognitively plausible symbolic representations of quantity that will enhance computational models of similarity, retrieval and generalization.

The rest of the paper proceeds as follows: We next present relevant research from Linguistics, Psychology, Qualitative Reasoning, and models of similarity and retrieval, which provide both background and motivation. Section 3 reports results of a pilot experiment measuring just how vague our notion of large, medium and small is. Section 4 proposes an answer to the representational question above. Section 5 describes CARVE, a computational model for building such representations. We conclude with future work in section 6.

2 Background and Motivation

2.1 Linguistics

In language, one of the ways these symbolizations get represented is by relative adjectives like `large` and `tall`. Relative adjectives are different from absolute adjectives like `rectangular`, `red` and `married` in the sense that (1) they can imply varying degrees of the property in question, as opposed to all-or-none for the absolute adjectives, and (2) their meaning varies with context, e.g., `tall` means different things in context of men and buildings.

These adjectives have been variously called degree, relative, gradable or dimensional adjectives [Bierwisch 1987]. Here we will stick to the term dimensional adjectives, emphasizing our focus on those that denote quantity. It has been proposed that dimensional adjectives denote measure functions that maps from objects to quantity values/ intervals [Kennedy, 2003]. It has long been

recognized by linguists that dimensional adjectives convey an implicit reference to a norm or a standard associated with the modified noun [Sapir, 1944]. This implies two steps in interpreting a phrase like "a large *x*" where *x* can be a country/ insect/ etc.: (1) *x* establishes a *comparison class*. A comparison class is a set of objects that are in someway similar to *x*. For instance, in some cases, this comparison class might be the immediate superordinate of the subject [Bierwisch, 1971]. How to obtain the comparison class is an open question. Staab and Hahn (1998) propose a computational model that uses knowledge about correlations to determine comparison classes on the fly. (2) Once the comparison class has been found, a *standard of comparison* is computed for the class. It is usually believed that this is the norm value of the property for the comparison class, but Kennedy (2003) observes that it can also be the minimum or maximum (e.g., full and open).

The norm in step 2 has not been spelled out in this literature. In cases where we are referring to stable taxonomic categories like insects and countries, it is believed to be some kind of central tendency. But clearly, it is more than a central tendency, since that would imply that most things in this world will be either large or small, as not many will be exactly equal to the norm.

2.2 Psychology

2.2.1 Context sensitivi ty

Rips (1980) considers two hypotheses about how absolute and relative adjectives might be stored in memory – Pre-Storage and Computational model. For absolute adjectives like `married` and `pink`, he accepts the pre-storage model, where these predicates are stored with the concept they apply to. But because of context dependence of relative adjectives like `big`, e.g., in, "Flamingos are big", he argues against storing these predicates in memory. We might have a predicate `pink` attached to flamingo, but in order to decide a flamingo is larger than an eagle, we might need a predicate `is-larger-than-an-eagle` associated with flamingo, which then deescalates into having infinitely many of those like `is-larger-than-turnips` and so on. He also observes that relative adjectives don't propagate in a isa hierarchy – e.g., Grasshoppers are large insects does not imply Grasshoppers are large animals, but if you replace 'large' by 'green', the implication is right. He then shows reaction time and error rates for verifying the truth of statements containing relative adjectives which supports a different model. In his 'computational model' no relative information is stored. Attached to every predicate is a normal value, e.g. with insects, a normal size of quarter inches. An object is called large if it is bigger than this normal size. Once again the problem is that just storing the norm doesn't tell you when the object can be classified as large. The representation that we propose in section 4 solves his concerns with pre-storage models.

2.2.1 Reference Points

The psychological reality of such special reference points on the scale of quantity has been shown in various domains. Rosch (1975) argued for the special status of such "cognitive reference points" by showing an asymmetry – namely that a non-reference stimulus is judged closer to a reference stimulus (e.g., the color off-red to basic-red) than otherwise, while such relationship between two non-reference stimuli is symmetric. Existence of landmarks to organize spatial knowledge of the environment, similar asymmetries [Holyoak and Mah, 1984 among others]. Other relevant psychological studies that support the existence of reference points come from categorical perception [Harnad, 1987] and sensitivity to landmarks [Cech and Shoben, 1985]. Brown and Siegler (1993) proposed the *metrics and mappings* framework for real-world quantitative estimation. They make a distinction between the quantitative, or metric knowledge (which includes distributional properties of parameters), and ordinal information (mapping knowledge).

2.2.2 Models of Retrieval, Similarity and Generalization

There is converging psychological evidence for structured models of retrieval, similarity and generalization.

The structure-mapping engine (SME) [Falkenhainer *et al*, 1989] is a computational model of structure-mapping theory [Gentner, 1983]. Given two structured propositional representations as inputs, the *base* (about which we know more) and a *target*, SME computes a *mapping* (or a handful of them). MAC/FAC [Forbus *et al*, 1995] is a model of similarity-based retrieval, that uses a computationally cheap, structure-less filter before doing structural matching. It uses a secondary representation, the content vector, which summarizes the relative frequency of predicates occurring in the structured representation. The dot product of content vectors for two structured representations provide a rough estimate of their structural match. SEQL [Kuehne *et al*, 2000] provides a framework for making generalizations based on comp uting progressive structural overlaps of multiple exemplars.

One limitation of these models – and of other models of analogical processing (e.g., ACME [Holyoak and Thagard, 1989, LISA [Hummel and Holyoak, 1997], ABSURDIST [Goldstone and Rogosky, 2002]) – is that they do not handle numerical properties well:

Retrieval: Just as `Red` occurring in the probe might remind me of other red objects, a bird with wing-surface-area of 0.272 sq.m. (that is the Great black-bucked gull, a large bird) should remind me of other large birds. This will not happen in the current model, unless we abstract the numeric representation of wing-surface-area to a symbol, say, `Large`.

Similarity: A model of similarity must be sensitive to quantity.For example, in current matchers, two cars which are identical in all dimensions have the same similarity as two that differ in some dimensions, if other aspects of their representations are identical.

Generalization: A key part of learning a new domain is acquiring the *sense of quantity* for different quantities. E.g., from a trip to the zoo, a kid probably has learnt something about sizes of animals.

A symbolic and relational representation of the kind we propose here would make models of analogical processing more quantity-aware.

2.3 Qualitative Reasoning

Qualitative reasoning research seeks to understand human-like commonsense reasoning without resorting to differential equations and real-valued numbers. There is a substantial body of research in QR that has shown that one can, indeed, do powerful reasoning with partial knowledge. Qualitative reasoning has explored many different representations: status algebras (normal/abnormal); sign algebra (– , 0, +), which is the weakest representation that supports reasoning about continuity; quantity spaces, where we represent a quantity value by ordinal relationships with specially chosen points in the space; intervals and their fuzzy versions; order of magnitude representations; finite algebras, among others. While these representations are very promising for cognitive modeling, there has been little psychological work to date on this.

3 Experiment

We conducted a pilot experiment to see how much people agreed on what they would call large, small or medium. We expected agreement across subjects on their labeling. Furthermore, we expected to find out how people go about mapping these symbols to quantity values in a specific scenario – being presented with all the examples at once. And if people indeed agreed on their partitioning, then we expected to gain insight about where they drew the boundaries.

Method

The experiment consisted of two tasks – *Size Labeling* task and *Country Naming* task. In the size labeling task, subjects were presented with an outline political map of Africa. The countries were numbered from 1 through 54, and at the bottom of the map were 54 numbered blanks. They were given the following instruction – "On the following page you will find a map of Africa. All the different countries are shown and numbered. For each country, we want you to think if you will call it LARGE, MEDIUM or SMALL on the basis of size (land area) as shown in the map. Below the map you will find numbered index of all the countries on the map. Please place your answer (LARGE/ MEDIUM/ SMALL) in the blank next to it. Please fill out all the blanks."

At the end of this task, they did the country naming task. Here they were presented another copy of the map, and were told to name as many of the countries as they could. The participants were 19 graduate students at Northwestern University.

Results and Discussion

We found significant agreement across the subjects. Subjects could correctly name very few countries (mean 6 out of 54 countries, *sd* = 6.5). This suggests that prior knowledge should be irrelevant, and their judgments were based on examining the map.

To see how much subjects agreed about their choices, we extracted the most frequent choice for each country, and the percentage of times that was chosen across subjects (e.g, for both Seychelles and Algeria this is 100%, as the most frequent choice was always picked, for Kenya it is 79% which is how often it was called medium). In figure 1 we show the most frequent, second most frequent and the least frequent choice and how often they were chosen. The most frequent choice was chosen an average of 81.2% of the times, and the second most frequent choice was chosen 18.5%, and the least frequent 0.3% of the times. The difference between most frequent choice and the second most frequent choice is statistically significant ($t(53)=12.92$, $p<0.01$).

Subjects seem to do the task in a clustering fashion. They would pick either small/large and start marking out the clearly small/large countries, then countries at the other end of size and then consider the cases in between.

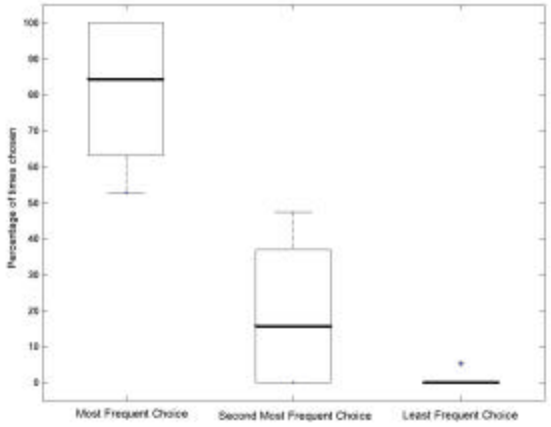

Figure 1. Agreement across subjects on their most frequent choice. The most frequent choice is 81.2%, significantly higher than the second and third chosen size labels.

4 Representation

A representation of quantity allows us to make certain distinctions – numbers allow us to make too many, and dividing the range of values into two equal sized parts doesn't necessarily provide useful distinctions. Representations do not arise in vacuum. They are molded by the kinds of reasoning tasks we perform with them (reasoning constraints), and the things we are trying to represent (ecological constraints). We propose representations based on existing evidence and arguments from these constraints.

4.1 Reasoning Constraints

The three distinct kinds of reasoning tasks involving quantities are –

1. Comparison: These involve comparing two values on an underlying scale of quantity, e.g., "Is John taller than Chris?" Our knowledge of how the quantity varies (its distribution), and linguistic labels like `Large` and `Small`, are but a compressed record of large number of such comparisons. The semantic congruity effect [Banks and Flora, 1977] is the fact that we are better and faster at judging the larger of two large things than the smaller of two large things. Part of the account from experiments involving adults learning novel dimension words, by Ryalls and Smith (2000) is the fact that in usage, we make statements like "X is larger than Y" more often than "Y is smaller than X", if X and Y are both on the large end of the scale.

2. Classification: These involve making judgments about whether a quantity value is equal to, less than or greater than a specific value, e.g., Is the water boiling?, Will this couch fit in the freight elevator?, etc. Usually, such classifications involve comparisons with interesting points (called *limit points* in QR) in the space of values for a quantity, where conditions on either side are qualitatively distinct. The metaphor of *phase transitions* describes many such interesting points, although such transitions in everyday domains are not as sharply and well defined as in scientific domains (consider poverty line versus freezing point).

3. Estimation: These involve inferring a numerical value for a particular quantity, e.g., How tall is he? What is the mileage of your car? This is the activity that has the strongest connection to quantitative scales – one can go a long way in accounting for the above two without resorting to numbers, but estimation involves mapping back to numbers [Subrahmanyam and Gelman, 1998]. Knowledge of interesting points on the scale might play an important role in estimation, for example in providing *anchors* to *adjust* from [Tversky and Kahmenan, 1974].

These tasks are not completely distinct – classification involves comparison, and estimation might be used in the service of classification. Two interesting aspects of our representations follow from these constraints:

1. Our representations must keep track of interesting points on the scale of quantity, to classify, as well as to estimate.
2. Labels like `large` ease making comparisons, as they setup implicit ordinal relationships (it is larger than most objects).

4.2 Ecological Constraints

Our representational framework must be capable of capturing the interesting ways in which a quantity varies in real-world instances of it. Below we present two different kinds of constraints on values a quantity can take –

1. Distributional Constraints: Most quantities have a range (a minimum and a maximum) and a distribution that determines how often a specific value shows up. For example, the height of adult men might be between 4 and 10 ft, with most being around 5-6.5ft. More than just the norm, we can usually talk about the `low, medium, high` for many quantities, which seems to be a qualitative summary of the distributional information. There is psychological evidence that establishes that we *can* and *do* accumulate distributions of quantities [refer to Malmi and Samson, 1983; Fried and Holyoak, 1984; Kraus *et al*, 1993; among others, for more]. Given a distribution of values for a quantity, the next question of how we partition these distributions has not been raised at all.

2. Structural Constraints: Quantities are constrained by what values *other* quantities in the system take, its relationship with those other quantities, via its relationships with them[1]. For instance, for all internal combustion engines – as the engine mass increases, the Brake Horse Power (BHP), Bore (diameter), Displacement (volume) increases, and the RPM decreases. These constraints represent the underlying mechanism, or causal model of the object. Limit points decompose values into regions where the underlying causal story is different (e.g., ice starting to melt, at the freezing point), which induces extremely important and interesting distinctions of *quality* on the space of quantity.

These two ecological constraints point us to the two different kinds of information about quantities, which must be parts of our representations –

1. Distributional information about how the quantity varies.
2. Its role in and relationship to the underlying structure/mechanism, and the points at which there are changes in underlying structure.

4.3 Proposed Representation

There are two kinds of distinctions that our representation of quantity must make –

1. *Dimensional partitions:* Symbols like `Large` and `Small`, which arise from distributional information about how that quantity varies.
2. *Structural Partitions:* Symbols like `Boiling Point` and `Poverty Line`, that denote changes of *quality*, usually changes in the underlying causal story and many other aspects of the objects in concern.

These partitions may manifest as intervals centered around a norm, or by boundaries demarcating transitions. Let's look at dimensional partitions in more detail. Dimensional adjectives like `large` depend upon the context. Consider area of African countries – in our experiment, people agree that Algeria is large, and Swaziland is small, Kenya is medium sized. We represent this as follows –

```
(isa Algeria
     (HighValueContextualizedFn
          Area AfricanCountries))
```

`High/Medium/LowValueContextualizedFn` are functions that take two arguments – a quantity and a context argument and return a collection of objects. So in the above example `HighValueContextualizedFn` denotes the

[1] Comic books, mythology, and fantasy, for example, have the freedom to relax this constraint – a character can be arbitrarily strong, large, small or be able to fly, even though the physical design of the character might not be able to support it.

collection of large African countries, and the isa statement says that Algeria is an instance of that collection. The `LowValueContextualizedFn` similarly lets us represent the negative end, for instance small and cheap.

4.3.1 Relationship to Fuzzy Logic

The dimensional partitions are reminiscent of linguistic variables in fuzzy logic [Zadeh 1965]. Fuzzy variables can take on values like `Large`, `Medium` and `Small`; and allow us to represent overlapping range of values for these symbols. Fuzzy logic thus provides a framework to represent what `Large` means. The specific mapping of `Large`-ness to area of countries, for instance, is a choice of the person building the representation, and is not in the scope of fuzzy logic. Our focus here is that mapping. So dimensional partitions are the answer to the question – what do people mean when they say "a large country," specifically, what is the mapping between `Large` and the values of area?

5 Computational Modeling

We are developing a computational model, called CARVE, as an account of the generation of both dimensional and structural partitions. At this writing, CARVE is partially implemented. The input to CARVE is a set of examples represented as collections of facts in predicate calculus. Countries are an interesting domain for testing CARVE as there are many quantitative parameters with rich causal and structural relationships[2]. The cases for each of these countries were built by extracting facts about them from the Cyc knowledge base. Additional quantitative facts about attributes like population, literacy, etc., were extracted from the CIA Factbook knowledge base [Frank *et al*, 1998] and added to these cases. There were on average 108 facts per case.

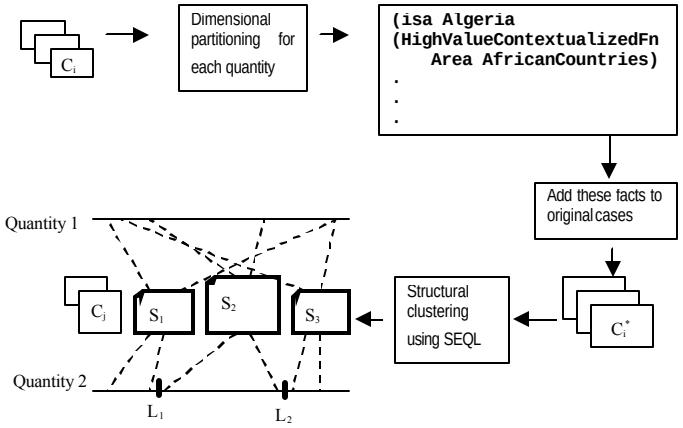

Figure 2. A schematic overview of how CARVE computes dimensional and structural partitions.

[2] Alas, not all of this rich structural knowledge is already represented in our knowledge bases.

Dimensional Partitioning

CARVE takes as input a set of cases. For each quantity, we extract all the numeric values for it in our input cases. Given these values, the job of the dimensional partitioning step is to find three partitions, corresponding to `Low`, `Medium` and `High` ranges of the values that the quantity takes.

These partitions are currently generated using a k-means clustering algorithm. It is possible to plug in different heuristics that partitions the values into ranges of values. Heuristics based on central tendency and percentiles do not work for zipf like distributions which we see in many of the quantities (e.g., GDP, population, area) associated with countries. For such distributions, means and variances are not intuitively meaningful at all.

The k-means clustering algorithm fits with what people did in our pilot experiment. On an average across subjects, the dimensional partitions computed by CARVE agreed with people 74% of the times (sd=27). More empirical data is needed to conclude what set of heuristics people use to make these partitions, and when they work. We believe that depending upon the distribution of data, people will use different partitioning strategies. The clustering scheme used is useful across different kinds of distributions and can be used incrementally without a priori knowledge of distributions.

For each fact about the value of a quantity, we then add a `High/Medium/LowContextualizedValueFn` to the case depending upon which range that numeric value fell in. These facts are used in the next step.

Structural partitioning

SEQL [Skorstad *et al*, 1988; Kuehne *et al*, 2000] provides a framework for making generalizations based on computing progressive structural overlaps of multiple exemplars. The goal of structural partitioning is to find the structural clusters in the cases (for instance, groups of developing and underdeveloped nations) and project these clusters on to various quantity dimensions. The cases produced at the end of the dimensional partitioning step are given as input to SEQL. In figure 2, we see the output of SEQL as three generalizations S_1, S_2 and S_3 and some leftover cases that did not fit any of those. Let's consider two quantities $Quantity_1$ and $Quantity_2$. The projection of a cluster on a quantity is the range of values for that quantity in the cluster. For $Quantity_1$, we see that the projections from all the three generalizations overlap. On the other hand, the projections of the generalization on $Quantity_2$ are non-overlapping. We have marked by L_1 and L_2 the boundaries for these ranges. Notice the predictive power of knowing that for a specific case the value of $Quantity_2$ is less than L_1. We not only know about the quantity value, but about the generalization to which the case belongs, and so can predict a lot of other causal properties of it. For instance, when you know that a country is a developing country, there are rich causal predictions you can make.

The algorithm above has been implemented in CARVE. Unfortunately, because of the lack of rich causal/ relational

knowledge in the cases, it does not yet find any interesting structural partitions. Structural partitions are a reflection of our deep understanding of the causal and correlational structure of examples. In science, phase transitions, and structural distinctions in socio-economic dimensions were not easily discovered. We hope that by adding more knowledge we will get better structural partitions.

6 Conclusions and Future Work

Based on cognitive and linguistic evidence, and arguments from reasoning and ecological constraints, we presented symbolic representations for quantity. We find significant agreement between subjects on dimensional partitions. We presented a computational model for automatically generating these representations.

Currently all the cases are given as input to CARVE. One important way to extend this will be for it to incrementally build and update its representations. Further, we need to create rich structured cases with causal and correlational information and test CARVE.

Distortions of perceptual judgement in diagrammatic representations

David Peebles (D.Peebles@hud.ac.uk)
Department of Behavioural Sciences, University of Huddersfield,
Queensgate, Huddersfield, HD1 3DH, UK

Abstract

An experiment is reported which investigates the distorting e ects of various graphical features in three different diagrammatic representations of the same information. The experiment revealed signi cant distortions in users' perceptual judgements of distance both between the di erent diagrams and within each diagram. The results of the experiment are interpreted as indicating the crucial role of anchor points such as axis tick marks along dimensions.

Introduction

Presenting large, complex data sets to a broad and non-specialist audience is a challenging task if one is to be sure that the information is to be interpreted in an appropriate manner. Choosing the most suitable representation for a particular communicative goal is an important aspect of the task and designers of information artefacts must be aware of how the low-level visual features of individual graphical representations can facilitate or hinder the interpretation of information.

Many studies have shown that the perception of one or more graphical elements in a figure can be distorted by the relationships between them (see, e.g., Deręgowski, 1980; Schiffman, 1995). A famous example is the Müller-Lyer illusion shown in Figure 1a which illustrates how perceptual judgements of line length can be distorted by the acuity of angles subtended by connecting lines. In this illusion, the line on the right of Figure 1a is perceived to be shorter than that on the left, although their lengths are actually the same.

Distortions in the perception of line length can also be caused by a number of so-called *contrast illusions*, for example the parallel lines illusion (Jordan & Schiano, 1986; Schiano, 1986) in which viewers of two parallel lines can perceive the lengths of the lines to be closer than they actually are (assimilation) or more different than they actually are (contrast), depending on the ratio of the line lengths and the distance between them. An example is shown in Figure 1b in which the perceived lengths of the lines in each pair are distorted by the length of the line next to it so that viewers see the lengths of the two paired lines as being more similar than they actually are. This has the effect of distorting the perceived length of the right-most line in each pair to make that on the right of the figure seem shorter than that on the left when, in fact, their lengths are the same.

Previous research has shown that visual illusions can have a strong effect on people's perceptual judgements in commonly used diagrams (e.g., Poulton, 1985). Zacks, Levy, Tversky and Schiano (1998) studied, among other things, the effect of the length of neighbouring elements on judgements of bar height and magnitude comparison in bar charts and their experiments demonstrated that the accuracy of participants' judgements depended of the relative height of the target bar and neighbouring graphical elements.

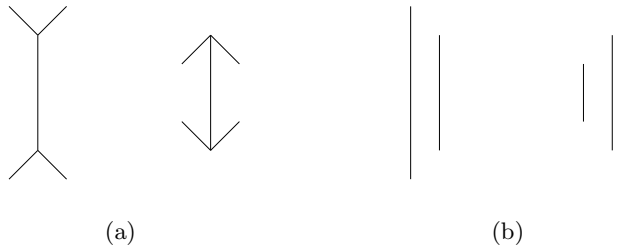

Figure 1: Two visual illusions affecting the perception of line length: (a) The Müller-Lyer illusion, (b) The parallel lines illusion.

In addition to issues relating to visual features, diagram designers must also be mindful of user familiarity. Using a form of diagram that is unfamiliar to a target audience can be problematic as users must expend additional cognitive effort to learn the new representation, something that could discourage engagement with the diagram or result in misinterpretation. Employing a novel representation can be justified, however if it can be demonstrated that the particular representation of information provided by the diagram facilitates a specific set of interpretive tasks. For example, in a series of experiments, Peebles and Cheng (2001, 2002, 2003; Peebles, Cheng, & Shadbolt, 1999) compared the representational and computational properties of two types of Cartesian coordinate (x,y) graph which, according to participant ratings, varied significantly in terms of their familiarity. Our experiments demonstrated that users of the less familiar graph type were able to retrieve information and solve certain problems significantly faster than users of the more familiar form. Eye movement and modelling analysis showed that this was because the graphical format of the unfamiliar representation facili-

tates certain basic reading and lookup procedures.

These issues are not only of academic concern. They have been brought into the public arena recently by the decision of the UK government to publish its national police performance data in the form of a set of diagrams that are relatively unfamiliar to the general public. With much media attention and at a reported cost of £70,000 (approx. US $128,688), the UK government developed the *performance monitor* (Police Standards Unit, 2003, 2004[1]), a variation of a diagram otherwise known as a *spidergram*, *radar* or *kiviat* chart. The purpose of the performance monitor is to present in summary form performance data for individual police forces in five key areas or "domains" (citizen focus, promoting public safety, resource usage, investigating crime, and reducing crime) and to allow easy comparison with average performance computed from a set of police forces most similar to the individual force in terms of socio-economic, demographic and geographic makeup.

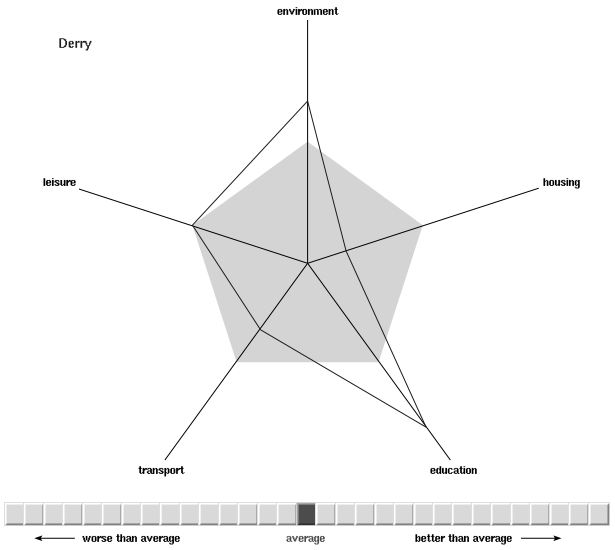

Figure 2: Kiviat chart used in the experiment.

An example of such a diagram is shown in Figure 2. This diagram is taken from the experiment reported here but it is identical in form to the police performance monitor. The subject matter of the diagrams was changed for the experiment to the (fictitious) performance of UK local authorities in five domains (the environment, housing, education, transport and leisure), each of which is indicated by a point on a spoke. The points are connected by straight lines to form a pentagon and the regular shaded pentagon represents the average performance of a set of most similar local authorities. Better performance is shown further out from the centre.

In the most recent version of the police performance report, the central performance monitor diagram has been augmented with five bar charts that illustrate the spread of performance for the most similar police forces in each of the domains. The bar charts are similar in form to the one displayed in Figure 3. In the police performance bar charts, each bar represents the value on that domain of one of the forces from which the average has been computed.

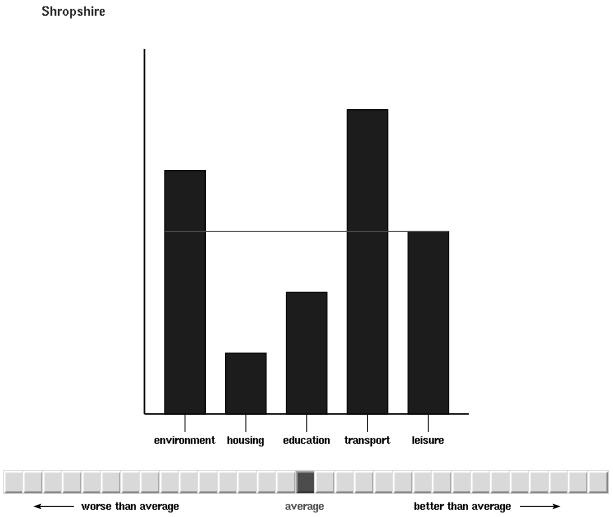

Figure 3: Bar chart used in the experiment.

One striking feature of both the kiviat and bar charts used in the police performance report is the lack of any tick marks on the spokes or axes. Usually the purpose of a scale of numbered tick marks on a chart or graph is to provide numerical values relating to locations in the chart. When numerical values are not deemed necessary, (perhaps because the purpose of the chart is simply to display relative magnitudes), tick marks still provide an objective reference frame within which to compare lengths. Without such a reference frame, it may be the case that perceptual judgements of quantities such as line length become more susceptible to distortion by visual illusions.

For example, in kiviat charts, the two lines connecting a point on a spoke with the two points on the adjacent spokes form a wide range of shapes and angles. In the absence of anchoring tick marks on the spokes, it may be the case that perceptual judgements of distance will be distorted by these angles and shapes by processes analogous to those involved in the Müller-Lyer illusion. Similarly, in bar charts, the lack of tick marks may also permit distortions in perceptual judgements of distance to occur because of the parallel lines illusion.

Another widely used diagram that shares many properties with bar charts is the line graph (see Figure 4), the main obvious difference being that points plotted against the y-axis are joined by lines rather than being represented as the top of a column. In the context of this study, however, an important consequence of this difference is that judgements of distance would not be

[1] A hypertext version of the current Home Office document is available on the Web as `performancemonitors.html` at `http://www.policereform.co.uk/docs/`

susceptible to the parallel lines illusion in line graphs.

Experiment

The primary purpose of the performance monitors and bar charts is to allow a rapid visual comparison of an individual institution's performance with a meaningful average. This could be either at a global level (i.e. to determine how much better or worse than average the institution is overall), or at the level of specific domains. The purpose of the experiment reported here is to determine whether the perceptual judgement of this distance for a particular target domain is affected by the values of the surrounding domains.

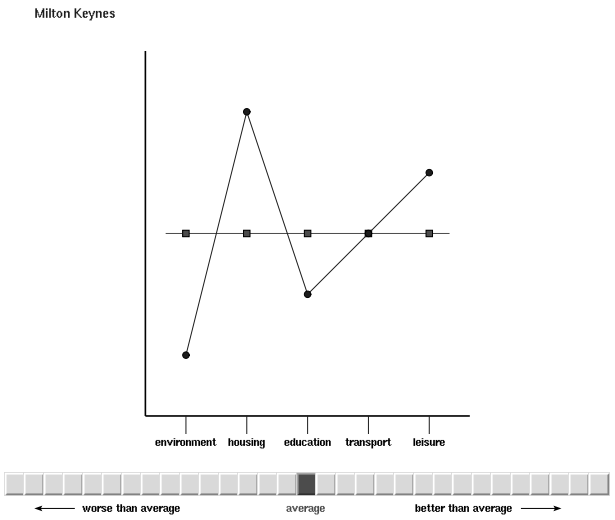

Figure 4: Line graph used in the experiment.

Method

Design The experiment was a mixed design with one between-subjects variable and two within-subjects variables. The between-subjects variable was the type of diagram used (kiviat chart, bar chart, or line graph). The within-subjects variables were the value of the target domain that subjects were required to rate and the values of the two domains adjacent to the target domain.

Participants Sixty-three members of staff from the University of Huddersfield took part in the experiment. The occupations of participants varied from academic, clerical and technical positions to graduate students.

Materials The experiment was conducted using three identical PC computers with 17-inch (43-cm) displays. The stimuli used in the experiment were diagrams similar to those in Figures 2–4. The information content of the diagrams was the performance of 150 UK local authorities across five domains.

In order to generate a manageable range of values, the spokes of the kiviat chart and the y axes of the bar chart and line graph were divided into six equally sized sections numbered 0 to 6 (although these divisions or numbers were not visible to the participants). The numbers 0 and 6 were situated at the bottom and top of the y axes and the centre and outermost points of the kiviat spokes respectively. Only the numbers 1 to 5 were used in the experiment and the locations of these on the diagrams can be seen in Figures 2–4. For example in Figure 2, Derry council has a housing value of 1, a transport value of 2, a leisure value of 3, an environment value of 4, and an education value of 5. The locations of the values on the y axes of the bar chart and line graph are illustrated in Figure 3, where Shropshire council has a housing value of 1, an education value of 2, a leisure value of 3, an environment value of 4, and a transport value of 5.

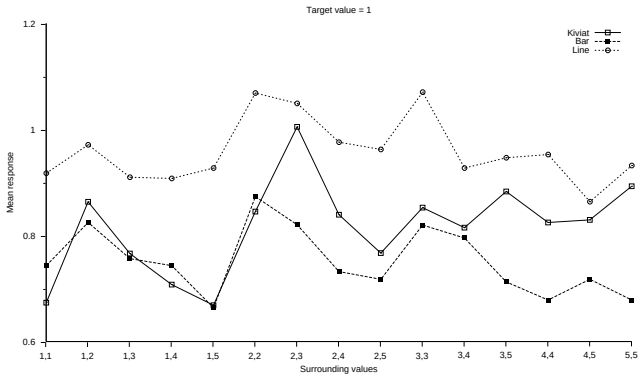

Figure 5: Mean response to target 1, all three diagrams.

The average value was the number 3 located at the centre of the y axes and kiviat spokes. In the bar chart this was represented by a horizontal red line and in the line graph as the same red line with red squares as markers (to conform to the format of the line graph). In the kiviat chart, the average was represented by a red regular pentagon formed by joining the centre points on the five spokes. This produced a kiviat chart identical to those used in the police performance document.

Below each diagram was a scale consisting of 31 buttons. The centre button in the scale was the same red colour as the average marker on the diagrams and underneath it was written the word "average" in red. The 15 buttons on either side of the centre button allowed the scale to be divided into six equally sized units, each containing four buttons. Below the scale were two arrows indicating that increases in performance were represented by buttons further to the right of the scale.

To test the full range of target and neighbouring lengths, each of the five target values was combined with the 15 possible permutations of two adjacent values (1,1; 1,2; 1,3; 1,4; 1,5; 2,2; 2,3; 2,4; 2,5; 3,3; 3,4; 3,5; 4,4; 4,5; 5,5) to create a total of 75 triplets.

In the kiviat charts, each domain spoke has an adjacent domain on either side but in the bar charts and line graphs, two domains (environment and leisure) have only one adjacent domain. To ensure that the target domain on each trial had an adjacent domain on either side, therefore, if the target value was 1, 2, 4, or 5, the target

domain was selected randomly from housing, education, and transport, as these had two adjacent values in the bar and line graphs. If the target value was 3, however, the target domain was randomly selected from all five domains. The values of the two remaining domains not adjacent to the target domain were randomly allocated a value of between 1 and 5. Responses to the target value of 3 were not to be included in the analysis as they were expected to be rapid and accurate for all graph conditions as this value was marked on both the graph and the scale.

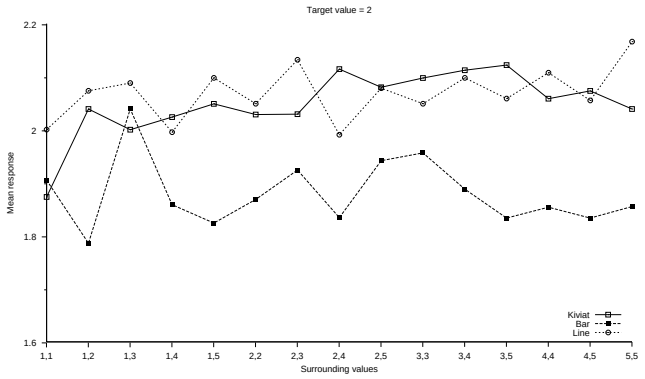

Figure 6: Mean response to target 2, all three diagrams.

Procedure Participants were randomly allocated to one of the diagram conditions. Before starting the task, participants were shown an example of the diagram they were to use and given as much time as they required to become familiar with it. The format of the example was the same for each diagram and was modelled closely on the format used in the Home Office document. When the participant had finished studying the example, the experimenter then explained the diagram further, explaining the subject matter, highlighting salient points and making sure that they were completely familiar with it. Participants were then told that on each trial of the experiment their task was to judge how much better or worse than average the performance of a particular authority was on a given domain. Participants were also shown how to enter their judgement by clicking the mouse on the scale below the diagram. It was stressed to participants that they should attempt to respond as rapidly but also as accurately as possible.

On each trial of the experiment, the target domain was first presented in the centre of the screen for 1500 ms, after which it was removed from the screen and replaced by a diagram. As soon as the participant had clicked the mouse cursor on one of the scale buttons the diagram was removed from the screen and, after a pause of 500 ms, the next target domain was presented for a new trial. Response times were recorded from the onset of the diagram to the mouse click on a scale button. Participants saw all 75 triplets twice—a total of 150 trials—in random order and were given the opportunity to take a brief, self-terminated break after 50 and 100 trials.

Results

Participants' responses were coded to re ect the underlying scale of the diagrams. A response click on the button to the extreme left of the scale was given the value 0 and each successive button was incremented by 0.2 to end at a final value of 6 at the extreme right of the scale.

An initial examination of the data revealed the existence of several outlying values that were not associated with a specific participant or condition but were sufficiently large to distort the mean for a specific cell. To reduce the in uence of these outliers, the 42 values in each cell were standardised and those cases at the extreme end of the distribution (i.e. with a z score greater than 3.29, $p < .001$, two-tailed test) were discarded (Tabachneck & Fidell, 2001). From the original set of 9450 data points, this procedure resulted in the removal of 165 cases (1.75%) of the response data and 128 (1.35%) cases of the RT data. Data from the target value = 3 condition were not included in the analysis because, as predicted, responses were almost entirely accurate for all of the diagrams.

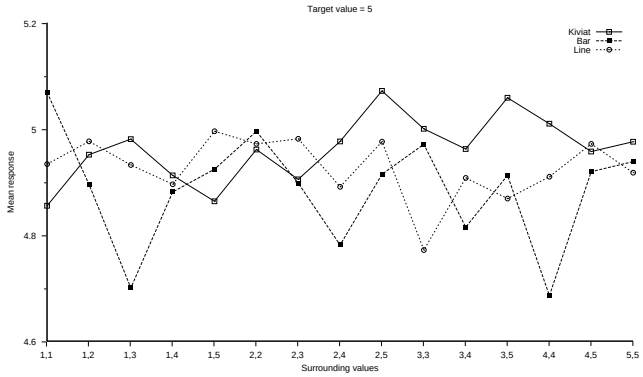

Figure 7: Mean response to target 5, all three diagrams.

An analysis of variance (ANOVA) was carried out on the response data. In the ANOVA, Mauchly's test of sphericity was significant for the target value (Mauchly's $W = .23$, $df = 5$, $p < 0.01$) and adjacent values (Mauchly's $W = .25$, $df = 104$, $p < 0.01$) so the more conservative Greenhouse-Geisser test was used in the analysis. The ANOVA showed that there was a significant main effect of the diagram used, $F(2, 59) = 15.48$, $p < .001$, the target value $F(1.66,97.66) = 4847.11$, $p < .001$ and the adjacent values, $F(9.87,582.49) = 3.96$, $p < .001$, together with significant interactions between the adjacent value and diagram, $F(19.75,582.49) = 2.84$, $p < .001$, and between target value and adjacent value, $F(16.07,974.94) = 2.51$, $p < .01$. The ANOVA also revealed a three-way interaction between diagram, target value and adjacent value, $F(32.13,974.94) = 1.56$, $p < .05$. Although response times were also recorded, due to lack of space, the data are not reported here. The main difference observed was that responses were slower in the kiviat condition than in the other two, probably due to the greater degree of unfamiliarity.

The complex effects revealed by the ANOVA are most

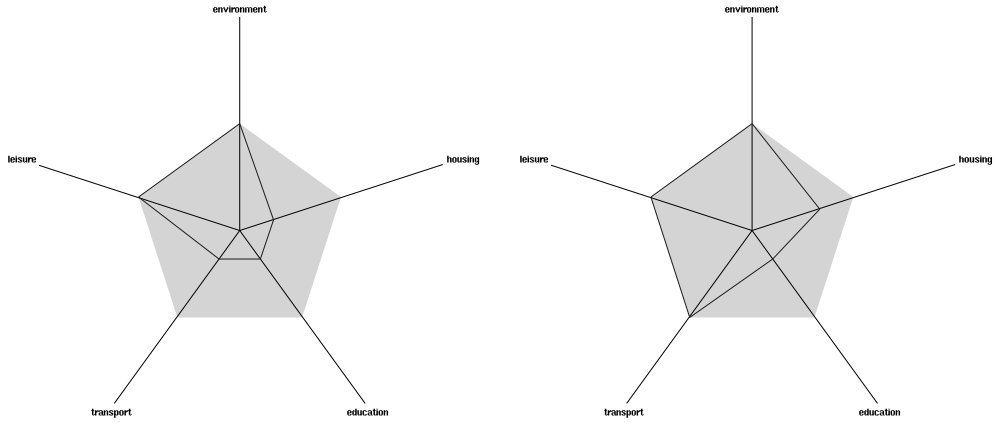

Figure 8: Kiviat charts illustrating a target value of 1 (education) with adjacent values 1,1 (left) and 2,3 (right).

clearly illustrated in Figures 5–7 which present the mean response for target values 1, 2, and 5 respectively as a function of the adjacent values. In these graphs, each labelled tick mark on the y-axis represents a button on the scale. The graphs show a large degree of variation in responses to individual target values both for individual diagrams and between the different diagram types.

One of the most striking differences in responses between the diagrams is shown in Figures 5 and 6, both of which show that participants viewing the line graphs consistently perceive target values of 1 and 2 to be closer to the average than bar chart users, despite the fact that the values are represented at exactly the same locations in the coordinate system in the two diagrams. This marked difference between the graphs is not present for target values of 4 and 5, however, and this may provide a possible explanation. Unlike points in a line graph, bars are attached to and proceed from the x-axis and so form a concrete object. When comparing the distance between the top of a bar with the mean line, therefore, participants' attention is drawn to the length of the bar in comparison to the height of the mean line, (rather than to the distance between them), which may serve to accentuate the perceived difference. In contrast, participants using the line graph may simply attempt the more accurate procedure of judging the distance between the points on the plotted and mean lines.

According to this account, the lack of such a major difference when the target values are 4 and 5 is because users of the bar chart are still judging the length of the bar but, this time are comparing it to the mean line below it. This is very similar to the procedure carried out by the line graph users in that both are judging the same distance. At the moment this is a plausible hypothesis that remains to be tested in a further eye movement study.

Figure 5 also illustrates the wide range of responses that users of the kiviat chart gave to the same target value. It is clear that the perception of the difference between the target value 1 and the mean value 3 is affected by values of the adjacent domains. To provide a clearer demonstration of this effect, two of the diagrams resulting in widely differing ratings are shown in Figure 8. In both diagrams, the target value of 1 is represented on the education domain. The chart on the left has adjacent values of 1,1, for which the mean rating is 0.67, whereas that on the right has adjacent values of 2,3, given a mean rating of 1.0. A t-test shows the difference between these ratings to be significant $t(60.11) = 3.10$, $p < .001$. Figure 5 shows that participants viewing the kiviat charts perceive the target value of 1 to be much closer to the average when surrounded by the values 2 and 3 than for any other combination but that the surrounding values of 1 and 1 were perceived as relatively far from the average. Although a precise explanation for this is still being considered, it is clear that the shape produced by the lines connecting the target value and the adjacent values has a distorting effect on viewers' perception of distance. Figure 5 shows that this effect is not a simple linear function in which greater adjacent values result in a larger perceived target value.

The distortion of perceived distance in the bar chart condition is perhaps best illustrated in Figure 7 which reveals a wide range of responses to the target value 5. As with the kiviat charts, the pattern of results does not conform to a simple analysis. At least one example, however, may be best explained by reference to the parallel lines illusion. The two bar charts in Figure 9 were given ratings at the extreme ends of the range. Both represent a target value of 5 on the education domain and the chart on the left has adjacent values of 1,1, for which the mean rating was 5.07, whereas that on the right has adjacent values of 4,4, given a mean rating of 4.69. A t-test shows the difference between these ratings to be significant $t(76.02) = 3.88$, $p < .001$. The target domain in the chart on the left of Figure 9 was perceived as being further away from the average line than that in right-hand chart. This can be explained in

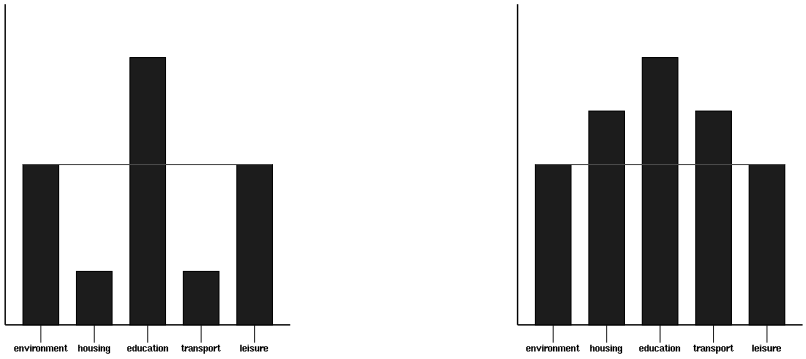

Figure 9: Bar charts illustrating a target value of 5 (education) with adjacent values 1,1 (left) and 4,4 (right).

terms of the parallel lines illusion as it re ects the phenomena of contrast and assimilation described earlier. The target domain in the left-hand chart is seen as being larger because it contrasts with two relatively small adjacent values. The target domain in the right-hand chart, however, was perceived as being smaller because viewers perceived the lengths of the target and adjacent bars to be closer than they actually are (assimilation). It is also interesting to note in Figure 7 that this pattern of responses is not found in the line graph condition.

Discussion

The results of this experiment provide concrete evidence of distortions in perceptual judgements of distance in two graphical representations of a type currently being employed to present public data in the UK. Specifically, the three examples clearly illustrate that simple comparative judgements between two points on a dimension can be significantly affected by the values of adjacent variables. Further work is required before firm conclusions can be drawn but from this initial analysis it seems that, as currently designed, the kiviat and bar charts in the UK government's police monitoring documents may be susceptible to the distorting effects highlighted here.

The use of anchor points, typically tick marks on axes, is generally seen as a way of facilitating the accurate reading of locations relative to a scale. Whether the incorporation of such anchor points into these diagrams reduces the distortions in distance judgements observed in this experiment is to be tested in a future study.

Abstract

We propose a general framework for reasoning and deciding in uncertain scenarios, with possibly infinite source of information (open world). This involves representing ignorance, uncertainty and contradiction; we present and analyze those concepts, integrating them in the notion of *lack of confidence* or *perplexity*. We introduce and quantify the *strength of the beliefs* of an agent and investigate how he can do explicit *epistemic actions* in order to supply information lacks. Next we introduce a simple distributed game (RBG) and we use it as a testbed for comparing the performance of agents using the (classical) "expected utility maximization" and the "perplexity minimization" strategies.

Introduction

In an "open world" uncertainty and ignorance are difficult categories to deal with; how much can I be certain of a belief of mines? how much information there is that I have not considered and I should?

The first aim of the present work is to provide an analysis of epistemic dimensions such as *strength of belief*, *uncertainty*, *contradiction* and *ignorance* (or ambiguity). A special focus will be given to the third dimension. In Economical literature the notion of ignorance has been extensively investigated (Shackle, 1972) and ways to quantify it have been proposed (Shafer, 1976). In those approaches "lack of information" has been shown to affect the decision process and ambiguity aversion in subject has been identified; see Camerer & Weber (1992) for a review of the literature on decisions under ambiguity. We will argue in the following analysis that Ignorance is a subjective evaluation of actual lack of information on the basis of cognitive *evidential models*. The agent has a model (script) of his sources that allows him to evaluate that a certain type and a certain number of sources can provide *sufficient information* for reducing ignorance close to zero. In this way the strength of the belief and the (perceived) ignorance are two different measures, the second belonging to the meta-level. The second aim of the present work is to investigate the decision dynamics in an open world, with conflicting beliefs and multiple sources of information. We will formalize the process that leads the agent to acquire new information from the world (from witnesses) and that leads the agents to be "ready" to decide. We will claim that this process involves strength of beliefs that are relevant for deciding, as well as uncertainty and ignorance. The results of the current work are suitable e.g. for MAS environments, where an agent has to take decisions in open worlds.

The Red-or-Blue Card Game (RBG)

We introduce a simple distributed game that is suitable for Multi-agent system simulations as well as for human experiments: the agents (players) have to bid on the color of a card (red or blue) and they have many sources of information (their perception and potentially infinite witnesses); the game can last an indefinite number of turns. The bidding game is the following: a card is shown (very quickly) to the player; it can be either red or blue and the player has to bid on the right color (he starts with 1000 *Credits*). We assume that he cannot be totally sure of his own perception (e.g. it is shown very quickly, or the lights in the room are low), but he is able to provide a degree of certainty about the color. Before bidding he can ask for help to a (potentially) infinite number of witnesses that have observed the scene and provide the answer "red" or "blue" (without degrees of certainty); those new information can lead the agent to confirm or revise his beliefs. Asking a witness has not a cost in Credits but it costs 1 *Time*. Credits and Times can be aggregated in different ways.

When he decides that he is "ready", he can bid from 0 to 10 Credits on the color he wants. The true card color is shown: if he was right, he gains two times the bid; otherwise he loses the bid. The game lasts an indefinite number of turns; between the turns, depending on the result, the agent can revise the *reliability* he attributes to his sources: his perception and the witnesses (depending for example on the number of correct answers they provided) as well as his SCAI. Besides, his perception and the witnesses have *true reliability* values that determine the average correctness of their answers. True values are not known by the player; at the first game round they are initialized and they do not change during the game. At the end of the game the agent will collect a certain amount of Credits; a set of reliability values for his sources; a SCAI and he will have spent a

certain amount of Time. Using this game as a testbed, we compare different kinds of agents having many possible heuristics in order to collect information and Credits[1].

Theoretical Foundations

We present first an *evidential* notion of ignorance: ignorance is determined by the lack of belief sources. In our approach, following the cognitive approach of Castelfranchi (1995), the *strength of a belief* (i.e. how much I rely on one of my beliefs) depends on the *reliability* of its sources (i.e. the beliefs it is grounded on). Sources include: direct experience (such as perceptive evidences); information provided by other agents; reasoning (about other beliefs) and categorization (reasoning about classes and similarities). Since in an open world in principle there are infinite sources to take into account, the agent can never conclude that his own ignorance is zero. We propose in the present model a solution to the problem of ignorance quantification by identifying *Classes of Ignorance Acceptance* that reduce ignorance to finite values.

Uncertainty and contradiction have the same status of the notion of ignorance: they are meta-cognitive notions, i.e. agent's evaluations about his own "epistemic state". We are interested in this paper in investigating how those different epistemic states affect the decision process, and especially how they affect the way the agent decides to execute a pragmatic action (e.g. bet) or an epistemic one (e.g. query). For example, if the agent feels to be too much ignorant or uncertain he can decide to query, to bid a little amount, or not to bid at all. Here we describe the epistemic dimensions.

Ignorance

Intuitively ignorance depends on how much information I have with respect to how much it exists; in an open world there is a potentially infinite number of witnesses that have not been questioned; so if we calculate ignorance in this way the agent has always the maximum degree of ignorance. *The agent does not know how many witnesses he can consider at most* or better *he does not know how he can reduce his ignorance close to zero.* A qualitative and cognitive analysis is here required. Here we shift the issue to an evidential and subjective level[2]. We introduce the notion of *Structure of Classes of Acceptable Ignorance* (SCAI).

Classes of Acceptable Ignorance

Each agent has a SCAI that includes several *Classes of Acceptable Ignorance* (CAI) that include one or more sources (e.g. Witnesses), each having its reliability value. For instance, CAI_1 = (witness 1, witness 2, witness 3) could be one of those classes. Classes of acceptable ignorance can be intersected and unified (see Fig. 1): they have the normal properties of sets in set theory.

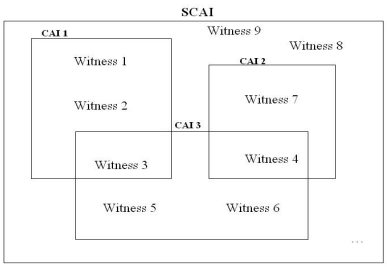

Fig. 1 Structure of Classes of Acceptable Ignorance (SCAI).

The agent knows that testing all witnesses in a given class is enough for making the ignorance acceptably close to value zero. Imagine for example that the agent wants to know if tomorrow will rain or will be sunny. He has several classes of acceptable ignorance. For instance he can believe that by acquiring information about tomorrow's weather from source 1 = "New York Times" and source 2 = "CNN" is enough for making ignorance acceptable. Moreover, the following points are crucial for understanding how the relation between SCAI and agents works.

A. The agent has explicit models (meta-level) of Classes of Acceptable Ignorance as shown in Fig.1. There are witnesses who are included in classes of acceptance but also witnesses who are not included in any class.

B. The agent can also make "queries" to witnesses who are not in the SCAI. Indeed the number of classes is finite even if, according to the agent, the set of witnesses he can make a query is indefinite. The agent can make a query to whatever witness even if this witness is not included in the structure of ignorance. In principle the agent can ask witness_10000 and he will always get an answer. Witnesses that are not in the structure do not have a value of reliability. A default value is assigned to them (through feature value assignment) whenever a query is made to them. After the query the witness belongs to the SCAI as a witness who is not included in any CAI (for example witness 8 in Fig.1).

C. The value of Ignorance is calculated at a meta-level whereas the value of reliability of a witness is calculated at a base-level.

[1]Since it is an "open world" (there are an infinite number of witnesses and an indefinite number of turns) it is not possible to perform full search. More, it is not possible to perform a long-term maximization because the agents don't know when the game will end (this condition is called "shadow of the future").

[2] Our notion of ignorance is very close to the notion of ambiguity identified in some recent economical and psychological literature where is stressed that decision making is affected by the decision maker's evaluation of his or her actual available information and competence to make judgments in specific domains (Heat & Tversky, 1991). Instead, our notion of ignorance is quite far from *Sample Space Ignorance* in Support Theory (Tversky & Koehler, 1994) where it is claimed that people do not follow the extensional logic of conventional probability theory. In Support Theory an agent can actually "ignore" actual information in the sense that he is not explicitly evaluating that evidences concerning a certain event e1 are also evidences concerning another event e2. Indeed it has been shown that unpacking (making information available for explicit evaluation) a compound event into disjoint components tends to increase the perceived likelihood of that event. An immediate implication is that unpacking an hypothesis and/or repacking its complement will increase the judged likelihood of that hypothesis.

Quantifying Ignorance through SCAIs

Class-Ignorance is given for each class at a certain point of a query sequence ($q_1,\ldots, q_n$) and is defined as the total number of witnesses in the class *minus* the number of tested witnesses in that class, weighted for the inverse of the total number of witnesses in the class**.**

Absolute-Ignorance is defined as the minimal value of Class-Ignorance among all CAIs.

Class-Ignorance (Class n, q_i) =
(n.wit. (Class n, q_i) - n.queried.wit. (Class n, q_i) $_{\text{Agent x, qi}}$)/ n.wit. (Class n, q_i) $_{\text{Agent x, qi}}$
Absolute-Ignorance (q_i) =
Min $_{\text{Class x}}$ (Class-Ignorance (Class x, q_i) $_{\text{Agent x, qi}}$)

We have already pointed out that after a query is made to a witness who does not belong to SCAI, the witness will be included in SCAI as a witness who is not included in any class (such as witness 8 and 9 in Fig.1). The measure of Absolute-Ignorance is not fixed: it depends on the single agent categorization and classes organization. That measure varies through learning, as new witnesses are added.

Uncertainty

Uncertainty is a measure of the difference between the value of strength of the belief "the card is red" and the value of strength of the belief "the card is blue". When the difference is 0 the value of uncertainty is maximal, when the difference is 1 the value uncertainty is minimum. This dimension takes into account the difficulty of deciding when the two strengths of beliefs are too close.

Contradiction

Contradiction is a (logical) inconsistency in a belief set; for example I can not believe consistently that (in the previous example) the ball in an urn is both red and black. In a normal (statistical) analysis there is contradiction if the sum of the two strengths of beliefs is more than 1. In the evidential approach the threshold of perceived contradiction (α) can be fixed at different values depending on cognitive biases (e.g. more or less contradiction tolerant).

If(Strength.belief(CardRed, q_i) +
Strength. Belief(CardBlue, q_i)) $\leq \alpha$ then
Perceived.contradiction(q_i) = 0

If(Strength.belief(CardRed,q_i) +
Strength.Belief(CardBlue,q_i)) $> \alpha$ then
Perceived.contradiction(q_i) =
(Strength.belief(CardRed,q_i) +
Strength.Belief(CardBlue,q_i)) – α

Perplexity

Ignorance, Uncertainty and Contradiction are three meta-level epistemic information that an agent can take into account in order to "decide if he is ready to decide". In order to model this kind of decisions we propose to integrate ignorance, uncertainty and contradiction in a single measure called **Perplexity** (i.e. lack of confidence). In calculating Perplexity, the three dimensions can be aggregated in different ways, depending on some more cognitive biases (e.g. Agents that are biased to consider ignorance, or contradiction, or uncertainty). The basic heuristic is summing them (and normalizing).

Value of Information: Epistemic Actions

An Epistemic Action (EpA) is *any action aimed at acquiring knowledge from the world*; any act of active perception, monitoring, checking, testing, ascertaining, verifying, experimenting, exploring, enquiring, give a look to, etc. (Castelfranchi & Lorini, 1998). The notion of epistemic action has been extensively considered both in psychology and in economics. The centrality of this notion comes from the fact that epistemic actions have a role in different cognitive functions. In the present model an Epistemic Action is always towards a witness (i.e. making a query). Epistemic Actions are directed either to reduce perplexity (or one of its dimensions) given a certain "perplexity aversion" threshold of the agent (first function); or to acquire new information in order to make a better decision (second function).

In both cases a value is assigned to epistemic actions. The first value is a measure of the capacity of a given witness of reducing perplexity: we call it *informativeness*. The second value is called *value of information* and has been extensively investigated in economical literature in the sense of "how much the agent is disposed to pay for obtaining that information?" In that approach a possible way to calculate the value of information is given with respect to utility functions. These two notions can lead to different decision strategies; in order to compare them, we have designed the simulative testbed "Red-or-Blue Card Game" (see above).

Considering the Sources

Strength of beliefs depends on its sources (perception; more or less reliable witnesses). Those sources are not all equal: in order to represent their relative contribute, we aggregate them using Fuzzy Cognitive Maps (Kosko, 1986). In order to represent the fact that there are diverging sources (and they aggregate in a different way with respect to converging ones) our FCMs have two "competing" branches for representing the competing beliefs "the card is red" and "the card is blue". FCMs are additive fuzzy systems with feedback, having nodes and edges. The weight of the nodes represents the strength of a belief (e.g. "I am pretty sure that the card is red"); the edges are weighted and they represent the impact of a belief over another. The FCM that we use can be seen as divided into two branches, each aggregating the values either for "red" or "blue". These nodes receive input from intermediate nodes ("perception for red" and "witnesses for red" the first; "perception for blue" and "witnesses for blue" the second); these edges are weighted by two fixed factors κ, λ representing the relative impact of perception and witnesses. The nodes "perception for red" and "perception for blue" assume either the value 0 or 1 depending on the perceptual input; their edges have the value of *perception reliability* (according to the agent). The "witnesses for red" and "witnesses for blue" nodes receive as input the information of the queried witnesses (either 0 or

1); the edges between each witness and "witnesses for <color>" have the value of the *witnesses' reliability*. There are also negative-weighted edges between the "red" and "blue" nodes, as well as for each source. In this way the contribute of diverging sources is modeled, because each positive evidence in a branch counts also as a negative one in the other branch. So, starting from the input values (the contributes of perception and the queried witnesses) the FCM calculates the final values for the strength of belief in "the card is red" and "the card is blue". There is not fixed "sum 1" between the two final values, so it is possible to model contradictory beliefs (that the agent can reduce performing epistemic actions). The FCM structure is the same for all the agents, but at each step it can be updated (e.g. modifying the impact of the edges, i.e. reliability values).

Player Agents and Decision Strategies

Here we describe three classes of decision strategies, implemented into three Agents. *Normative Agent* and *Satisficing Agent* do not use the notions of ignorance, uncertainty and contradiction. *Perplexity Reducing Agent* uses them in order to select the witness to be tested.

Normative Agent

A normative agent decides either to bet a certain amount of credits on a given option (either "the card is red" or "the card is blue") or to make a query to a specific witness as follows (this agent is not affected by perplexity).

The agent calculates the value of information obtainable from a given witness for all witnesses in the Structure of Classes of Ignorance Acceptance. *The value of information obtainable from witness z* is determined as: the average of the max value of expected utility given the information "the card is red" given by wit. z (which impacts on the agent's beliefs) and the max value of expected utility given the information "the card is blue" given by wit. z *minus* the max value of expected utility given the actual information. Afterwards the agent is able to decide. If the max value of information obtainable from witnesses is more than 0 then the agent decides to make a query to the witness who maximizes that value; otherwise he decides to bet a quantity y of credits on "the card is x" that maximizes his actual expected utility. We have not included the costs of making a query in the utility function (we assume only the cost in Time).

Potential-Chosen-Bet (q_i) = BET.yONx
such that
$\text{Max}_{x,y}$ (Strength.belief (x, q_i) credits (y, q_i))

where x is either "the card is blue" or "the card is red" and y is whatever sub-amount of the total amount of credits at a given point in the query sequence ($q_1,\ldots, q_n$). This agent has a very time consuming policy (minimizing the lack of information) and is not well suited for real time situations. Another agent can be introduced that limits Time spent.

Value-Information (wit.z, q_i) =
($\text{Max}_{x,y}$ ((Strength.belief (x, q_{i+1}) ← speech (wit.z, CardRed, q_{i+1})) credits(y, q_i)) + $\text{Max}_{x,y}$ ((Strength.belief (x, q_{i+1}) ← speech (wit.z, CardBlue, q_{i+1})) credits(y, q_i)))/2 – $\text{Max}_{x,y}$ (Strength.belief (x, q_i) credits (y, q_i))

Effective-Choice (q_i) =
1. If $\text{Max}_{\text{wit. z}}$ (Value-Information (wit.z, q_i)) > 0 then Effective-choice (q_i) = QUERY.wit. z such that $\text{Max}_{\text{wit. z}}$ (Value-Information (wit.z, q_i))
2. If $\text{Max}_{\text{wit. z}}$ (Value-Information (wit.z, q_i)) ≤ 0 then Effective-choice (q_i) = BET.yONx such that $\text{Max}_{x,y}$ (Strength.belief (x, q_i) credits (y, q_i))

Satisficing Agent

The Satisficing Agent makes sequential search through the witnesses in his SCAI. He starts with a given threshold γ for expected utility. At each step, he randomly calculates either the expected utility value associated with BET.yONx or the expected utility value associated with BET.yONx after that a given witness will be questioned. This value is the average of the expected utility value associated with BET.yONx in case the witness will say "Red Card" and the expected utility value associated with BET.yONx in case the witness will say "Blue Card". The first option during the sequential search that overcomes threshold γ is chosen. If no suitable option is found after *n* (fixed value) steps, the agent lowers the threshold of a certain value Δδ. With respect to the Normative Agent, the Satisficing Agent makes less queries and it is better suited for open worlds (Simon, 1990).

Perplexity Reducing Agent

The Perplexity Reducing agent has the goal to reduce the level of perplexity below a given threshold δ before betting. Since the only way to reduce perplexity is through queries, the agent starts choosing the witness to test**:** he makes a sequential search on witnesses and takes the first witness whose information is able to reduce perplexity under the threshold. If not suitable witness is found, the agent reduces the value of the threshold of a certain value Δδ and restarts with the same strategy. The expected capacity of a witness of reducing (or augmenting) perplexity represents the expected informative contribute of the epistemic act of querying him. This value is called *expected informativeness* and it is calculated as the actual value of perplexity *minus* the average of the value of perplexity after that witness z says "the card is red" and the value of perplexity after that witness z says "the card is blue"[3].

Expected-Informativeness (wit.z, q_i) =
(Subj.unconfidence(q_i)) – ((Subj.unconfidence(q_{i+1}) ← speech (wit.z, CardRed, q_{i+1}))+ (Subj.unconfidence(q_{i+1}) ← speech (wit.z, CardBlue, q_{i+1})))/2

Expected informativeness is quite different from the *value of information* as defined for the Normative Agent. The difference between those two definitions indicates two different theoretical perspectives: while the Normative Agent maximizes utility values (for bidding) the Perplexity Reducing Agent uses a cognitive theory of sources in order

[3] It follows from the definition that there could be negative values of expected informativeness.

to consider the contribute of the witnesses in the cognitive dimensions of uncertainty, ignorance and contradiction. The Perplexity Reducing Agent is implicitly biased to make queries to witnesses that are in the CAIs, since by definition they lower the value of absolute ignorance more than witnesses that are not in any CAIs. The Perplexity Reducing Agent should be combined with the two others agents (Normative or Satisficing). Once the level of perplexity is under the threshold, he could decide either which color and how much to bid or decide to make a query to another witness using his optimization methods. However, in order to simplify our experiments we did not allow perplexity reducing agents to carry on making queries to witnesses once the degree of perplexity was reduced under the threshold δ. This simplification is plausible for maintaining completely distinct the 2 different functions of epistemic actions: the function of *perplexity reduction* and the function of *"increase" of expected utility*.

Learning During the Game

The RBG game has many turns, so it is possible to learn between them. In the epistemic perspective, it is interesting to model how agents revise information about sources of beliefs.

Updating Reliability Values

All the agents have a representation of the witnesses reliability and are able to update these values depending on past interactions. Since reliability updating strategies are outside the scope of this paper, we used a linear statistical heuristic for all players: witnesses' reliability is lowered if they furnished a wrong advice, augmented otherwise, of a fixed amount $\Delta\phi$.

Updating Classes of Acceptable Ignorance

The Perplexity Reducing Agent is also able to change its SCAI adding or removing the witnesses in the Classes of Acceptable Ignorance. At the beginning of the game the SCAI is set randomly (e.g. the one shown in Fig.1) and it can be updated after each turn extending or contracting its CAIs. Imagine that the agent has queried in sequence w1, w2, w3, w4, w8 before deciding. Imagine he has verified that after the second test the value of perplexity has not changed so much (i.e. less than a threshold α). Since w1 and w2 belong to the same Class1, Class1 can be *contracted* eliminating w2 (that resulted not very informative). Imagine also he has verified that after the fifth test the value of perplexity has changed quite a lot (over a threshold β). Since w4 and w8 do not belong to the same Class, the class of w4 can be *extended* adding w8, that proved to be so informative. We do not describe here the full algorithm for CAIs contraction and extension[4]. We want only to present verbally its structure.

1. Given a previous sequence of queries $(q_1,\ldots, q_n)$, if during that sequence there were two queries q_i and q_{i+1} for *witness A* ← q_i and *witness B* ← q_{i+1} and witness A and witness B belong to the same CAI *x* and the degree of perplexity did not vary so much (in absolute value given threshold α) from q_i to q_{i+1} then the *witness B* is taken out from CAI *x*.
2. Given a previous sequence of queries $(q_1,\ldots, q_n)$, if during that sequence there were two queries q_i and q_{i+1} for *witness A* ← q_i and *witness B* ← q_{i+1} and witness A belongs to CAI *x* whereas witness B belongs to the SCAI but not to CAI *x*, and the degree of perplexity varied a lot (in absolute value given threshold β) from q_i to q_{i+1} then *witness B* is inserted into CAI *x*.

Experimental Setting and Variables

Here we show the comparison between three players: Normative (N), Satisficing (S), Perplexity Reducing (E). There are also two baselines: Random Bidder (B1) that chooses at random to test or to bid (and how much); and Perceptive Bidder (B2) that bids only according to his perceptive input.

The three independent variables we use are: *perception reliability (PR)*; *average witnesses reliability (AWR)*; *witnesses' convergence (WC)*. The first one describes how reliable in absolute is the perception of the agent; the second one indicates how reliable are in average the witnesses answers. They reflect also the "difficulty" of the task. The third one describes how convergent are the answers of the witnesses; this influences the final uncertainty value. We have built three scenarios: *good perception* (where PR is higher than AWR); *good witnesses* (the inverse); *high uncertainty* (where WC is set to a low value, and PR and AWR have the same value)[5].

Results and Discussion

In the following tables we present the preliminary results of our experiments (for Credits and Time) of the three Scenarios (250 simulations, 100 bid turns)[6]. As an indirect

[4] The variable ϕ for reliability updating, as well as thresholds α e β in classes of Acceptable Ignorance updating depend from cognitive biases towards belief revision. It is relevant to notice that for relatively high values of α and relatively low values of β and ϕ the agent is relatively *closed-minded* and conservative (he is less biased to revise the structure of classes of acceptance and the reliability values). But for relatively low values of α and relatively high values of β and ϕ the agent is relatively *open-minded*. This distinction is very close to the typology of cognitive epistemic styles in (Sorrentino et al., 1986).

[5] We use many thresholds and variables in our model: *Close Mind agents* vs. *Open Mind agents* in SCAI revision strategies (thresholds α and β); *strong* vs. *weak* need for low degree of perplexity (threshold δ); *degree of satisfaction* in expected utility (threshold γ); different way to weight different kinds of sources (bias towards perception or witnesses). In order to eliminate their effects we have randomly varied them through the experiments (three dimensions for each variable on average).

[6] The simulations were performed using the cognitive architecture AKIRA, developed at ISTC-CNR (http://www.akira-project.org/).

measure of "algorithm performance", we introduced also Hypothesis Time: it measures how many witnesses an Agent has considered (but not questioned) before deciding.

Table 1: *Good Perception Scenario*.

Agent	Credits	Time	H. Time
B1	**981**	**102**	**0**
B2	**1202**	**0**	**0**
N	1641	**6112**	**112453**
S	**1388**	**987**	**13936**
E	1622	409	10681

Table 2: *Good Witnesses Scenario*.

Agent	Credits	Time	H. Time
B1	**1009**	**101**	**0**
B2	**799**	**0**	**0**
N	1306	**9207**	**144582**
S	**1102**	**997**	**19103**
E	1298	603	13190

Table 3: *High Uncertainty Scenario*.

Agent	Credits	Time	H. Time
B1	**1007**	**99**	**0**
B2	**999**	**0**	**0**
N	**1803**	**8834**	**137866**
S	1551	**1156**	**21033**
E	1563	673	15943

In the first and second Scenarios the Perplexity Reducing Agent performs very well with respect both to gained Credits and temporal measures (Time and Hypothesis Time): it performs at the same level of Normative agent with respect the final amount of credits but his temporal measures are much better. The comparison with the Satisficing agent is even better. Not surprisingly, in the third Scenario he needs to query more witnesses and it is not able to perform as the Normative. Results in **bold** are significant with respect to the Perplexity Reducing Agent. These results show that Perplexity Reducing Agents are very suited in open world conditions where search of new information is in general very costly.

Moreover, a qualitative analysis allows to get a nice result about SCAIs updating: the final SCAIs are in average populated with small CAIs of very reliable witnesses: the average reliability changes from 0.5 to 0.7 in the three scenarios and the number of witnesses remains less to 20 in all simulations. The fact that final CAIs are small and include reliable witnesses is in accordance with the way we learn about belief sources. The more you know an environment, the less you need to question. Moreover, you prefer to question very reliable sources.

Conclusions and Future Work

We have proposed a theoretical foundation of some cognitive categories such as ignorance, uncertainty and contradiction that are generally difficult to quantify in an open world. We have introduced a MAS game (RBG) as a simulation setting in order to compare many agents that take or do not take into account epistemic dimensions. Our preliminary results show that perplexity reduction is a good heuristic for dealing with open world scenarios, and the Structure of Classes of Acceptable Ignorance can be used in order to quantify ignorance and reasoning about it. It would be interesting to test mixed decision strategies (e.g. considering the perplexity in the utility function; or using the Perplexity Reducing Agent as a filter). Another interesting direction is comparing simulation data with data from human experiments; actually the RBG game is being used as an experimental setting in order to collect such data.

Acknowledgments

We are indebted to Cristiano Castelfranchi for many insightful discussions about Ignorance and Uncertainty.

Reinforcement Learning of Dimensional Attention for Categorization

Joshua L. Phillips & David C. Noelle
({JOSHUA.L.PHILLIPS,DAVID.NOELLE}@VANDERBILT.EDU)
Vanderbilt University
Nashville, TN 37235 USA

Abstract

The ability to selectively focus attention on stimulus dimensions appears to play an important role in human category learning. This insight is embodied by learned dimensional attention weights in the ALCOVE model (Kruschke, 1992). The success of this psychological model suggests its use as a foundation for efforts to understand the neural basis of category learning. One obstacle to such an effort is ALCOVE's use of the biologically implausible backpropagation of error algorithm to adapt dimensional attention weights. This obstacle may be overcome by replacing this attention mechanism with one grounded in the reinforcement learning processes of the brain's dopamine system. In this paper, such a biologically-based mechanism for dimensional attention is proposed, and the fit of this mechanism to human performance is shown to be comparable to that of ALCOVE.

Introduction

Human category learning performance cannot be easily explained without recourse to a mechanism for selective dimensional attention (Shepard et al., 1961). Dimensional attention is the cognitive process which emphasizes task relevant stimulus dimensions while deemphasizing others. Thus, contemporary formal models of categorization, such as the Generalized Context Model (GCM) (Nosofsky, 1984), have incorporated adaptable dimensional attention parameters. By adjusting these parameters in a category-specific fashion, the GCM has repeatedly provided excellent fits to human data reflecting the frequency (or probability) with which each stimulus is recognized as an instance of a target category. When the GCM is applied to experimental results, dimensional attention parameters are freely varied to optimize the model fit. This means that, while the GCM provides a powerful account of learned categorization performance, it offers no explanation for how dimensional attention is adjusted over the course of learning.

This shortcoming of the GCM has been addressed by a connectionist model called ALCOVE (Kruschke, 1992). ALCOVE incorporates the GCM's formalization of category knowledge, but it also provides a precise algorithm for modifying the attentional "weight" assigned to each stimulus dimension, based on feedback provided to learners on their categorization judgments. In a typical category learning experiment, learners are presented with stimulus objects, one at a time, and are asked to make classification judgments for each. Immediately following each judgment, feedback is provided, typically informing the learner of the correct category label for the preceding stimulus. Once learning is complete, categorization judgments on transfer stimuli, for which no feedback is provided, can provide a window into the structure of the learned category knowledge. The ALCOVE model uses the feedback provided during training to calculate an "error signal", which is simply the difference between the category assignment made by the model and the specified "true" category. A variant of the backpropagation of error learning algorithm (Rumelhart et al., 1986) is used to communicate this error signal to an early stage of stimulus encoding, and this backpropagated error signal is used to adjust ALCOVE's *dimensional attention weights*. Like the GCM, ALCOVE provides good fits to human performance data on learned categories. Unlike the GCM, ALCOVE provides a detailed account of how dimensional attention is shaped by experience.

ALCOVE has been proposed as a model of *psychological* processes, with virtually no aspiration to explain the neural basis of human category learning. Despite this fact, the empirical successes of ALCOVE and its connectionist formalization make the model a tempting candidate for a coarse characterization of associated brain mechanisms. Perhaps ALCOVE can be refined, with each of its proposed psychological mechanisms mapped onto a corresponding detailed account of the underlying neural machinery. One feature of ALCOVE that stands in the way of such a theoretical reduction is its use of the backpropagation of error algorithm in order to learn dimensional attention weights. This powerful learning algorithm has long been criticized for its lack of biological plausibility (Crick, 1989), suggesting that the brain cannot be adapting dimensional attention based on such a gradient-based technique (c.f., O'Reilly (1996)).

As a first step toward a biological model of category learning, we replaced the backpropagation-based dimensional attention mechanism used by ALCOVE with a reinforcement learning mechanism intended to reflect the role of the brain's dopamine (DA) system in learning. This role for dopamine has been formalized by other researchers in terms of an algorithm called *temporal difference (TD) learning* (Sutton, 1988; Montague et al., 1996). Versions of ALCOVE which adapt dimensional attention weights using the biologically supported TD

learning method, instead of the more computationally powerful but biologically implausible backpropagation method, were found to fit human performance data about as well as the original ALCOVE. Thus, this work offers a more biologically realistic model of the adaptation of dimensional attention without sacrificing accuracy in accounting for human categorization behavior. Also, the ability to capture human performance with the highly stochastic TD learning method suggests that cognitive mechanisms for adapting dimensional attention may not need to be particularly precise.

Background

ALCOVE Architecture

The ALCOVE (Kruschke, 1992) model of category learning is a feedforward connectionist model that involves three layers of processing units (see Figure 1(a)). The input layer consists of a set of units that each correspond to a single dimension in the stimulus psychological space. Explaining the structure of this perceptual representation is outside of ALCOVE's scope. When fitting ALCOVE to human data, multidimensional scaling (MDS) techniques are typically applied to collected stimulus similarity ratings in order to discern the psychological space used by human learners (Shepard, 1962a; Shepard, 1962b). Each input unit has its own dimensional attention weight, α_i. These weights are non-negative scalar values that modulate the amount of attention paid to the corresponding stimulus dimension. Higher α_i values magnify the differences between stimuli along the given dimension, making them easier to discriminate based on that dimension. As learning progresses, these weights are adjusted via the backpropagation of error algorithm.

The hidden layer in ALCOVE contains a set of units that are arranged in psychological space, one for each training *exemplar*. The activation level of each hidden unit is determined by the following equation:

$$a_j^{hid} = exp\left[-c\left(\sum_i \alpha_i \left|h_{ji} - a_i^{in}\right|^r\right)^{r/q}\right]$$

where a_j^{hid} is the activation of hidden unit j, c is the specificity of the hidden units, α_i is the attention weight for input unit i, h_{ji} is the preferred stimulus input for hidden unit j along stimulus dimension i, a_i^{in} is the activation value of input unit i, r is the psychological distance metric, and q is the similarity gradient. Hidden unit activity is at a maximum when the inputs match the preferred stimulus of the unit (i.e., a_i^{in} matches h_{ji}). This activation fades exponentially as the stimulus becomes more distant from the preferred exemplar in psychological space, with the c, r, and q parameters controlling exactly how activation decreases with psychological distance.

Finally the output layer contains a set of units receiving activation from the hidden layer via *association weights*. Each output unit corresponds to a category label that might be assigned to a stimulus. These units are standard linear units, with their activation levels, a_k^{out}, computed as the sum of exemplar unit activation levels, a_j^{hid}, weighted by the corresponding association weights, w_{kj}. Output unit activations are mapped onto response probabilities using an exponential Luce choice rule:

$$P(K) = exp\left(\phi a_K^{out}\right) / \sum_k exp\left(\phi a_k^{out}\right)$$

where $P(K)$ is the probability of selecting category K for the current stimulus, and ϕ is a gain term. These response probabilities may be used to compare network responses with human performance data.

After the presentation of each stimulus and the consequent outputs are produced, the output unit corresponding to the correct response is presented with a target activation level of $+1$, and other units are presented with targets of -1. An error signal consisting of the difference between a_k^{out} and these targets is used to adjust weight values (though output units that "overshoot" their target values are assigned zero error). The association weights are then adjusted using this error signal directly (i.e., using the delta rule), but the selective attention weights are adjusted based on a backpropagated error signal. The resulting weight update equations are:

$$\Delta w_{kj}^{out} = \lambda_w \left(t_k - a_k^{out}\right) a_j^{hid}$$

$$\Delta\alpha_i = \lambda_\alpha \sum_j \left[\sum_k \left(t_k - a_k^{out}\right) w_{kj}\right] a_j^{hid} c \left|h_{ji} - a_i^{in}\right|$$

where Δw_{kj}^{out} is the adjustment value for the association weight from hidden unit j to output unit k, $\Delta\alpha_i$ is the adjustment value for the attention weight for input unit i, λ_w and λ_α are the learning rate parameters for the association weights and attention weights, respectively, and t_k is the target value for output unit k.

Temporal Difference Learning

Electrophysiological studies of the dopamine neurons of the basal ganglia have suggested that the firing rates of these cells code for *changes in expected future reward* (Shultz et al., 1997). This is particularly interesting because a measure of change in expected reward is the key variable of a reinforcement learning method called *temporal difference (TD) learning* (Sutton, 1988). This has led a number of researchers to develop TD learning models of the role played by the midbrain dopamine system in learning (Barto, 1994; Montague et al., 1996).

In the TD framework, a continuous reward value (r) is delivered on each time step (t), with positive reward being desirable. A neural system called the *adaptive critic* learns to predict expected future reward (V), given features of the current situation. When future rewards are exponentially discounted by a factor, γ (between 0 and 1), with immediate rewards being valued more than temporally distant ones, the change in expected future reward between two consecutive time steps is given by:

$$\delta(t) = r(t) + \gamma V(t) - V(t-1)$$

This δ value is called the *temporal difference (TD) error*. The global TD error value can be used to drive learning in the adaptive critic, improving predictions of future reward, and it can also be used to adapt connection weights in neural networks which select actions, pushing those choices toward actions that regularly lead to reward. Models of this kind have been used to explain motor sequence learning in the striatum (Barto, 1994) as well as other forms of learning. We propose that this form of reinforcement learning may also be used to learn dimensional attention weights that lead to correct categorization responses and, thus, reward.

Modeling Approach

Applications of TD learning typically focus on choosing an action from a discrete set. There is currently no clear understanding of how to apply these methods to domains in which a continuous output is needed. Dimensional attention weights are continuous parameters, however, so some modification to standard TD learning is needed to apply this technique to the adaptation of dimensional attention. We have devised two novel connectionist architectures to accomplish this. Our strategy encodes attentional weight vectors (with one α_i weight per dimension) across a single layer of standard connectionist processing units, called the *attention map* layer. Each unit in this layer possesses a fixed preferred attentional weight vector, and activation of a unit encourages the use of that unit's preferred dimensional attention weights. The activation level of each unit is largely determined by its individual bias weight, and the TD learning method is used to adapt these bias weights so as to optimize reward.

At the start of each trial, each of these attention map units is activated, to some degree, by its bias weight. The units then compete to determine the set of dimensional attention parameters to be used by ALCOVE, and the result of this competition is a set of such attention weights. ALCOVE then processes the current stimulus in its usual fashion, producing a categorization judgment. ALCOVE's association weights are then modified in the usual way, using the delta rule, but the dimensional attention weights are handled differently. If ALCOVE confidently chooses the correct category, it is rewarded. Otherwise, it is not. The TD error, δ, is calculated based on this reward signal, and this error is used to modify the bias weights of all active attention map units.

Two different architectures for the attention map layer were investigated. The first of these used *conjunctive coding*, resulting in a *localist* representation of dimensional attention. Under this scheme, the preferred attentional weight vectors of processing units were distributed evenly throughout the weight vector space. Thus, each unit corresponded to a position in attention weight vector space, and the positions of all of the units in the attention map layer formed a uniform grid in this space. On each trial, a simple winner-take-all competition determined the one unit whose preferred weight vector would specify the distribution of attention for that trial. Learning occurred only for the winning unit, using the following weight update equation for its single bias weight:

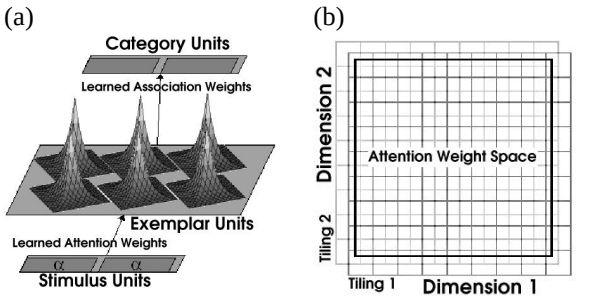

Figure 1: (a) ALCOVE Network Architecture. (b) Tile Coding Of The Attention Map Layer — A single unit is centered in each tile.

$$\Delta w_i \;=\; \lambda_r\,(r - a_i)\; f'(net_i)$$

where λ_r is the attention map learning rate, r is the reward for the current trial, a_i is the activation value of the winning attention map unit, and $f'(net_i)$ is the derivative of the unit's activation function (which was the standard logistic sigmoid). Note that this is the standard method for updating weights based on TD error, under the condition of absorbing reward (i.e., we don't predict reward past the end of the trial). In this case, a_i acts as our reward prediction ($V(t-1)$), and we do not predict beyond this trial, so $V(t) = 0$ and $\delta = r - a_i$. A reward value (r) of $+1$ was delivered to the network on trials in which ALCOVE selected the correct category label and produced a confident response (i.e., all output units within 0.5 of their targets). A reward of 0 was delivered, otherwise.[1]

Our second attention map architecture used *tile coding*, resulting in a *distributed* representation of dimensional attention. In this case, the attention map layer was partitioned into disjoint *tilings*, where each tiling contained a set of units with preferred dimensional attention weight vectors that uniformly spanned the full weight space. The preferred weight vectors of the units in the various tilings were not identical, however, because each tiling was "offset" from the others, as shown in Figure 1(b). To precisely represent a position in the attention weight space, one unit in each tiling is activated, with the overlap in the *tiles* surrounding the positions of these units determining the dimensional attention weights to be used. This kind of distributed representation was originally used in the Cerebellar Model Articulation Controller (CMAC) (Albus, 1975), and improved generalization in TD learning systems has been

[1] An obvious alternative reward schedule involves stochastically making category judgments based on $P(K)$ and rewarding any correct judgment. While we are currently investigating this approach, it is likely that it will produce behavior that deviates substantially from that of standard ALCOVE. Dimensional attention weights do not change much in ALCOVE until the network starts to make strong responses. This is part of the "three-stage learning" profile that ALCOVE exhibits. Our reward schedule encourages this pattern of learning.

found to result from their use (Sutton, 1996). Previous models have used such representational schemes to encode network inputs, but here they have been used in a novel way to select dimensional attention weights. As in the conjunctive coding architecture, each attention map unit is activated by a bias weight, and a competition ensues between units. In the tile coding scheme, the most active unit across all tilings restricts activity in the other tilings to those that are close to the winning unit (i.e., units whose tiles overlap with that of the winning unit). This competitive process is recursively applied to tilings that do not contain the winning unit until one unit is active in each tiling, and the tiles corresponding to these units all overlap. The attention weight vector at the center of this overlapping region is then used by ALCOVE to process the current stimulus. Once feedback is provided, reward is calculated as in the conjunctive coding case, and TD learning is used to adjust the bias weights of all of the winning units in the attention map layer.

In standard ALCOVE, the initial attention weights are often set to be all equal and to sum to one. This effectively emphasizes all dimensions equally at the start of training. We selected initial bias weights in the attention map layer so as to form a similar initial bias in our models. The unit in the attention map whose preferred attention weight vector matched ALCOVE's standard initial attention weights was given a maximum bias weight (0.05), and the bias weights assigned to other units fell off in a Gaussian fashion as the distance from this peak increased (in attention weight space), bottoming out at -0.05. A small amount of uniformly sampled noise was then injected into each bias weight, and the result was clipped to the $[-0.05, 0.05]$ range. The variance of the Gaussian and the range of the injected noise were free parameters of the model.

Results

In order to assess the ability of our reinforcement-based dimensional attention mechanism to account for human performance, we applied our models to several previously reported category learning studies. The performance of our modified version of ALCOVE was compared to that of the standard version of ALCOVE and to the performance of the GCM. In all cases, the values of dimensional attention weights were bound between zero and one. (This was only a new upper bound for ALCOVE, which standardly forces these weights to be nonnegative.) In all of the learning models, weights were updated after every simulated trial.

Dimensional Attention & Learning Difficulty

Shepard et al. (1961) examined the effect of category structure on the relative speed with which a category is learned. Stimuli were composed of three easily separable binary dimensions, for a total of eight possible stimuli. Six category structures were examined, ordered approximately by increasing number of relevant dimensions. Thus, the Type 1 category structure requires attention to only one binary dimension to solve the task, the Type 2 structure requires that only two of the dimensions be attended, while Types 3, 4, 5, and 6 all require attention to all three, in order of increasing dimensional significance. The speed with which humans learn these categories matches this ordering of tasks, but models that lack a dimensional attention mechanism fail to learn Type 2 categories faster than some of the more difficult categories. Kruschke (1992) showed that ALCOVE, with its adaptive dimensional attention mechanism, learned Type 2 tasks at a relative rate comparable to human learners. We have replicated these simulations (using bounded attention weights and learning after every trial), and the results are shown in Figure 2.

We applied our reinforcement learning version of ALCOVE to these six categorization tasks. Since stimuli had three dimensions, the attention weight space was three-dimensional. The conjunctive coding model used a $15 \times 15 \times 15$ unit topology in its attention map layer (3375 units total), while the tile coding model used five tilings of $9 \times 9 \times 9$ units each (3645 units total). The results of these simulations are shown in Figure 2. Note that our models learn Type 2 categories faster than the higher numbered types, just as ALCOVE does. Model parameter values were manually selected to produce performance that matched the category learning times exhibited by ALCOVE. These results demonstrate that TD learning can adapt dimensional attention weights so as to speed category learning.

Categorization of Continuous Separable Stimuli

In order to demonstrate the ability of our models to quantitatively fit human performance on categorization tasks involving stimuli with continuous and separable dimensions, we applied these models to an experiment conducted by Nosofsky (1986) . The stimuli in this experiment consisted of semicircles that varied in size and contained a radial line oriented at different angles. These stimuli were to be categorized as members of one of two categories, and four different category structures were explored (see Figure 3). The frequency with which each of the sixteen possible stimuli were placed in a target category was measured after training, and the GCM was fit to these response probabilities.

We fit both standard ALCOVE and our reinforcement learning models to this data, as well. Since the stimulus space was two-dimensional, our models used a two-dimensional attention map layer. In the conjunctive coding case, a 15×15 unit topology was used (225 units total), and the tile coding model used 9 tilings of 5×5 units each (225 units total). While both schemes used the same number of units, the tile coding model discretized the space with a much greater resolution. Stimuli were presented to the models using the MDS code found by Nosofsky. Free parameters of the models were fit to Nosofsky's Subject 1 data for each category structure separately. A simple hill-climbing optimization algorithm on sum-squared error was used.

The quality of the resulting fits are summarized in Table 1. While the original ALCOVE model provided the

Conj. Code	98.44%	98.16%	92.51%	99.57%	97.94%	98.53%
Tile Code	98.25%	97.27%	91.15%	99.15%	97.80%	97.30%

Table 2: Model Fits To Nosofsky (1987) – Percent Variance Accounted For

best overall fits, our models matched the data almost as well, and all general trends in the ALCOVE and GCM fits are present in our models. This suggests that our mechanisms for learning dimensional attention can quantitatively capture human performance on learning tasks that require selective attention to separable dimensions.

Categorization of Continuous Integral Stimuli

Integral stimulus dimensions often entail a difficulty in focusing attention on individual dimensions. Despite this fact, Nosofsky (1987) showed that models equipped with a dimensional attention mechanism fit human categorization performance on such stimuli slightly better than models that lacked such a mechanism. This study involved 12 different color chips which varied in saturation and brightness. Six different category structures were used, and these are shown in Figure 3. The frequency with which each of the 12 stimuli were placed in a target category was measured after training, and, once again, the GCM was fit to these response probabilities.

We applied both the original ALCOVE and our reinforcement learning versions to this human data. The same attention map layer sizes as used in the previous simulations were used here, and, as before, MDS representations of the stimuli were presented to the models. A summary of the model fits is shown in Table 2.

The GCM provides the best fits to the data in this study. It seems that the ALCOVE model and our models had trouble learning Category Structure 3. This is a difficult category structure which benefits little from selective attention to specific dimensions. Note, however, that the fits of our reinforcement learning models are close to the standard ALCOVE fits, and our models continue to exhibit the same trends in learning as ALCOVE.

Discussion

Our results show that established computational models of the brain's dopamine system can provide an adequate replacement for the biologically implausible backpropagation of error method for adapting dimensional attention during category learning. The new models were able to learn useful dimensional attention weights from their less-informative global reinforcement signal. This suggests that cognitive mechanisms for allocating dimensional attention may not be as precise as those posited by the original ALCOVE model.

One noteworthy feature of our reinforcement learning models was their tendency to exhibit fluctuations in performance over training, rather than smooth and monotonic learning as displayed by the original ALCOVE model. If each network model is to mirror the performance of an individual learner, these performance fluctuations may reflect stochasticity commonly observed in individual behavior. Also, if performance is averaged across multiple "simulated individuals", smooth learning curves, like those generated by ALCOVE, are produced.

Our models encoded dimensional attention weights in a fairly conjunctive fashion, with individual units in the attention map layer specifying levels of attention for all of the dimensions. This is needed because the appropriateness of attention to one dimension depends on how attention is allocated to the other dimensions. Such a conjunctive encoding requires very large attention map layers, however, and this may limit the scalability of this approach. In order to address this issue, we are currently exploring more compact distributed representations for dimensional attention weight vectors.

Eventually we hope to modify ALCOVE to make use of additional biologically plausible mechanisms of neural computation. This work represents the first step in this process, identifying a biologically realistic method for governing dimensional attention.

Abstract

Recent evidence suggests that perceivers have consistent intuitions regarding the boundedness properties of objects and events (Solomon, Proctor, & Rips, in preparation). This paper presents a self-paced reading study examining the speed and accuracy with which readers draw such telicity inferences during on-line language comprehension. Participants read sentences containing either a consumption verb ("consume") or an observation verb ("monitor") followed by either a mass or a count object ("ice water" vs. "ice cube"). Each sentence ended with an adverbial phrase that was either consistent or inconsistent with the telicity of the preceding event description ("in" or "for" adverbials), along with a comprehension question. Reading-time results suggest that comprehenders are slow to draw telicity inferences, even when the type of verb unambiguously determines the telicity of the sentence. However, responses to post-sentential comprehension questions suggest that verb and noun information together have a surprisingly robust influence on comprehenders' telicity inferences, even in the face of supposedly unambiguous adverbial information. Together, these results suggest that comprehenders make use of all relevant information in making telicity inferences, but that they do so much more slowly than strongly incremental models of natural language understanding would predict (e.g., Marslen-Wilson & Tyler, 1980).

Introduction

We readily distinguish two types of physical entities in the world—individuated objects and substances. We refer to these two types of entities with different types of nouns: substances are often referred to with mass nouns (e.g., tea) and objects with count nouns (e.g., cat). These distinctions seem to rest on the boundaries of the physical entities: count nouns typically refer to objects with well-defined boundaries, such as *mouse* or *iceberg*, while mass nouns typically refer to substances[1] without clear boundaries, such as *mud* or *water*.

The domain of events can be divided up similarly. Events can be classified according to whether or not they have an endpoint, or temporal boundary. Actions described by atelic verbs have no inherent endpoint or boundary; these actions have the potential to go on without end (e.g., singing). Verb phrases describing atelic or unbounded events go naturally with *for* adverbials, which describe the duration of an event, and less naturally with *in* adverbials, which presuppose the endpoint of an event. "She sang for an hour" sounds much more natural than "She sang in an hour." Actions described by telic verbs such as *delivering*, on the other hand, have an inherent endpoint; once an object has arrived at its destination, delivering has reached its end, and cannot logically continue. Verb phrases describing telic or bounded events go naturally with *in* adverbials and less naturally with *for* adverbials: "She delivered the package in an hour" sounds much more natural than "She delivered the package for an hour." These distinctions among verbs or verb phrases are commonly referred to as lexical aspect (e.g., Vendler, 1967; Dowty, 1979).

The current experiment explores how these lexical aspect distinctions are computed during sentence comprehension. It also examines when perceivers draw inferences about the boundedness of events, just as they must draw inferences about the boundaries of physical entities (see Solomon, Proctor, & Rips, in preparation). There has been some previous work exploring the cost of modifying or retracting such inferences once they have been drawn: Piñango, Zurif, and Jackendoff (1999) and Todorova, Straub, Badecker, and Frank (2000) demonstrate that encountering information (such as a *for* adverbial) that forces an event to be construed as atelic causes processing difficulty if previous information had suggested it was telic. The current experiment uses this effect to explore when telicity inferences are drawn on-line.

[1] It should be noted, however, that this distinction between mass and count nouns does not strictly coincide with the substance/object distinction. Jackendoff (1991) notes that, in addition to substances, aggregates of individuated objects can act like mass nouns. For instance, the terms *cattle* and *change* behave like mass terms, even though each refers to individuated objects (cows and coins, respectively) and not to an unindividuated substance.

Parallels Between Noun and Verb Contrasts

Several authors have noted that strong parallels exist between mass nouns and atelic events, and between count nouns and telic events (Bach, 1986; Langacker, 1987; Vendler, 1967). Just as masses have no intrinsic physical bound, atelic events, such as *running*, *painting*, or *watching*, have no intrinsic temporal bound. In contrast, just as counted objects have inherent physical boundaries, telic events, such as *delivering*, *drowning*, or *walking a mile*, all have an intrinsic temporal bound. One cannot continue delivering after a package has reached its destination, drowning after one is dead, or walking a mile after that distance has been crossed. Once the endpoint is reached, the action is completed. The present experiment is concerned with one subtype each of atelic and telic verbs: activities and accomplishments, respectively.

Another key parallel between actions and objects involves the extent to which a part of an object or action can be considered to be in the same category as its whole. For both masses and activities, a subpart (down to some lower limit) of the whole is qualitatively equivalent to the whole—any part of chocolate sauce is still chocolate sauce, just as any part of eating is eating. This subpart or subinterval property (Bennett & Partee, 1978) does not hold for counted objects and accomplishments, however—any part of an aluminum boat is not, itself, an aluminum boat, nor is any part of lighting a fire (e.g., crumpling up newspaper) itself lighting a fire.

Interactions Between Noun and Verb Boundaries

The physical boundaries of objects influence the temporal boundaries of events affecting them. Several authors have noted that the telicity or boundedness of an event often depends on whether the verb describing it takes a mass or count noun as its object (Pustejovsky, 1991, 1995; Verkuyl, 1993). When a consumption verb, such as *eat*, takes a count noun as its object, readers should infer that the VP is an accomplishment—the depletion of the object must end when the object's boundary is reached. When such a verb takes a mass noun as its object, however, the VP is an activity—since the substance is unbounded, the depletion could potentially go on indefinitely. These telicity shifts only hold for a subset of verbs such as consumption and creation verbs, which describe events that cannot easily be repeated and that entail an irreversible effect on their objects (Krifka, 1998). Verbs that do not entail an irreversible effect on their objects should not demonstrate such an aspectual shift. For example, whether a mass or count noun appears as the object of a verb of observation (e.g., watching) should not have an effect on the VP's telicity—the action of watching a mug should be just as unbounded as the action of watching soup.

To date, there is limited evidence regarding how perceivers draw these telicity inferences during comprehension. Solomon and her colleagues (in preparation) provide evidence from off-line reasoning tasks suggesting that readers are sensitive to the boundedness of different events, and that their reasoning about event boundedness parallels their reasoning about the boundedness of physical objects. Further, readers make inferences about lexical aspect on-line, re-interpreting their default assumptions regarding the boundedness of an event in order to bring it in line with the temporal characteristics of the context in which it appears (Piñango et al., 1999; Todorova et al., 2000). For example, "jump" might be interpreted to be an iterative action when it appears in the sentence "He jumped all day."

Studies examining aspectual coercion have demonstrated that sentential aspect is sensitive to parts of the sentence other than the verb. However, they do not directly examine how the boundedness of a verb's object or the verb itself is capable of influencing telicity inferences. If perceivers draw inferences about a sentence's temporal profile incrementally, they should show early sensitivity to the difference between observation verbs (whose boundedness does not depend on the properties of the following object) and consumption verbs (whose boundedness does depend on the object). Similarly, if perceivers are actively and predictively computing telicity based on verb and object information, they should show evidence of an interaction of verb and object information at the position of the object: perceivers' comprehension of a sentence should be affected by whether an object is a mass or count noun only if the verb preceding it is a consumption verb, not if it is an observation verb. Strongly incremental views of language understanding (e.g., Marslen-Wilson & Tyler, 1980; Clark, 1996) predict such early inferencing.

Overview

Is it the case that when we read a sentence in which an (unbounded) activity verb, describing the consumption of its object, takes a (bounded) count noun as its object, we then interpret the sentence as if the verb phrase were bounded? If, for instance, we read "Carol ingested Henderson Foods' rice *cake* merrily for ten minutes" will we interpret that action as being more temporally bounded than we would if we had read that she had ingested Henderson Foods' rice *cereal*? When do we make these inferences? Do we begin to draw inferences regarding telicity as soon as we encounter a verb? Do we compute a sentence's aspect as soon as we have both the verb and noun information? Or do we hold off making inferences until all potentially informative information is available, until late in the sentence? Previous results suggest that drawing telicity inferences can be cognitively costly (see Piñango, et al., 1999; Todorova, et al., 2000); the present experiment uses this finding to address these questions.

The Experiment

We presented participants with sentences describing characters either consuming or observing a mass or a counted object (see Table 1 for examples). Sentences were divided into five segments, and participants read through

Table 1: Sample Set of Sentences

	Segment 1	Segment 2	Segment 3	Segment 4	Segment 5	Adverb	Verb	Noun
a	Leslie consumed	Polar Purity's	ice water	with zeal	for eight minutes.	For	Telic	Mass
b	Leslie consumed	Polar Purity's	ice cube	with zeal	for eight minutes.	For	Telic	Count
c	Leslie monitored	Polar Purity's	ice water	with zeal	for eight minutes.	For	Atelic	Mass
d	Leslie monitored	Polar Purity's	ice cube	with zeal	for eight minutes.	For	Atelic	Count
e	Leslie consumed	Polar Purity's	ice water	with zeal	in eight minutes.	In	Telic	Mass
f	Leslie consumed	Polar Purity's	ice cube	with zeal	in eight minutes.	In	Telic	Count
g	Leslie monitored	Polar Purity's	ice water	with zeal	in eight minutes.	In	Atelic	Mass
h	Leslie monitored	Polar Purity's	ice cube	with zeal	in eight minutes.	In	Atelic	Count

these sequentially at their own pace while their reading times were recorded. The first segment contained either a consumption or an observation verb, while the third segment contained either a mass or a count noun. A fourth segment consisted of a manner adverbial, which served as a wrap-up segment. The final segment specified an interval of time, preceded by either a *for*-adverbial (e.g., for eight minutes) or *in*-adverbial (e.g., in eight minutes). Recall that these adverbials typically appear with VPs describing activities and accomplishments, respectively, and rarely with the opposite type of event.

If incremental views of language understanding are correct that readers will begin to draw inferences about the temporal profile of a described event as soon as they encounter relevant information, we would expect to find an effect of verb at the first segment. Specifically, we would expect to find that reading times for segments containing observation verbs (e.g., "Leslie monitored") would be longer than those for segments containing consumption verbs (e.g., "Leslie ingested"). Observation verbs license immediate telicity inferences (since the telicity of such events is independent of noun information later in the sentence), but the telicity of consumption verbs depend on noun information. Such a cost could conceivably continue through the second and third segments.

Furthermore, if inferences about an event's aspect are occurring early on-line (as in the incremental view) and are associated with a processing cost, then we would expect to find slowed reading times at the third and/or fourth segment (near the time of the object noun information) of sentences containing consumption verbs. In the case of Leslie, for example, if there were immediate processing costs associated with integrating noun and verb boundary information, we would expect participants to be slower to read that she had consumed "ice cube" than "ice water." Such a cost could conceivably carry over to the following segment, in which case we would expect slower reading of "with zeal" among readers who had read the count version relative to those who had read the mass version.

If, on the other hand, participants delay drawing inferences about the telicity of described events until all relevant information is available (until after verb and noun information has been encountered), we would not expect to see an effect of verb at the first segment, nor would we expect an interaction between noun and verb later on.

In the absence of slowing at segments three or four, we could still determine that inferences about aspect were being made based on a combination of a consumption verb with a mass or count noun if we were to find slowing due to mismatching of grammatical information at segment five. If participants are making inferences about the aspect of the sentences (e.g., inferring that eating a chocolate bar is an accomplishment) and are then presented with a final adverb (e.g., for ten minutes) that contradicts this inference, their reading times at that final segment may be slowed.

As an additional test of readers' inferences about the aspect, we presented participants with a follow-up question immediately after they had read through each sentence. For example, after reading about Leslie consuming ice water, participants were presented with the question, "After four of those eight minutes, had Leslie actually ingested Polar Purity's ice water?" The questions were modeled after an inferential test (Dowty, 1979) that distinguishes between activities and accomplishments by assessing whether the subinterval property applies to the action. If a participant believes that the action was an activity, he or she should be willing to ascribe the subinterval property to it. We thus expected that participants would be more likely to respond "yes" to the follow-up question after they had read about Leslie consuming ice water than if they had read about Leslie consuming Polar Purity's ice cube, since the consumption of a bounded object should lead participants to interpret the action as telic. Observation verb sentences should have the subinterval property ascribed to them regardless of whether they contain a mass or count noun, as the action has no effect on the object. We expected the pattern for sentences ending with the in-adverb to be qualitatively similar to that for sentences ending with the for-adverb. However, overall likelihood of an atelic response should be lower for *in*, given the strong association of in-adverbials with telic actions.

Methods

Procedure In this study, participants completed a self-paced reading task. They read through sentences, presented on a computer screen while we recorded their reading times. We instructed participants to read through each segment at their normal pace, and to progress through the segments by pressing the spacebar. The segments appeared sequentially

and disappeared from view once they had been read; participants could not return to a previously-viewed segment.

A follow-up question appeared immediately after participants had read the final segment of the sentence. The follow-up question appeared with two possible responses ("yes" and "no" for the experimental sentences), one appearing on the left, and the other on the right. For each list, participants saw "yes" on the left for half of the experimental sentences, and "no" on the left for the other half. We instructed participants to press one key (d) if they felt that the response on the left was correct and another (k) if they felt that response on the right was the better choice.

Each participant saw the sentences and their associated follow-up questions in a different random order.

Materials We constructed 80 sentences, all describing a character performing some action on an object or substance over a specified interval. For each of these sentences, we varied the type of verb (observation verbs vs. consumption verb), the boundedness of the noun (mass vs. count noun), and the final adverb (for X minutes vs. in X minutes), yielding a set of eight variations on each of the 80 base sentences. Each sentence contained five segments (an example set of segmented sentences appears in Table 1). The 640 experimental sentences were separated into eight lists, such that each of the eight variations of any given base sentence was assigned to a different list, and each list contained ten of each of the variation types. Thus, participants saw only one version of each base sentence, but saw an equal number of each of the verb/noun/adverb combinations. Each list also contained 32 additional sentences, unrelated to the experimental sentences, which served as filler items (e.g., "At the break, | Emily | had already | finished the memo, | to her boss's relief.")

Follow-up questions were constructed for all the sentences. The follow-ups asked whether the character had *actually* completed the specified action halfway through the mentioned interval (an example set of follow-up questions is presented in Table 2). If, during the course of reading a sentence, the participant inferred that the described event was atelic, then the subinterval property should apply, and the expected response would be "yes". If, on the other hand, the participant inferred that the described event was telic, he or she should respond "no".

Table 2: Sample Set of Follow-up Questions

a, e	After four of those eight minutes, had Leslie actually consumed Polar Purity's ice water?
b, f	After four of those eight minutes, had Leslie actually consumed Polar Purity's ice cube?
c, g	After four of those eight minutes, had Leslie actually monitored Polar Purity's ice water?
d, h	After four of those eight minutes, had Leslie actually monitored Polar Purity's ice cube?

Participants Forty-eight undergraduate students enrolled at Northwestern University participated in this experiment. Participation was part of a course requirement in an introductory psychology course. All participants were native English speakers.

Results

An examination of the reading time data suggests that readers did not begin generating telicity inferences as soon as they encountered the relevant verb or verb+object information. Reading times were, however, longer for sentences in which the final adverbials were inconsistent with the telicity of the preceding verb+object combination, indicating that the verb+object information was used in generating inferences about the telicity of these described events. Responses to follow-up questions suggest that these inferences were surprisingly robust: even in cases where the sentence-final adverbial conflicted with the telicity of the preceding verb phrase, participants showed some evidence of having stuck with their original telicity inference.

Analyses on reading times and responses to follow-up questions were computed separately using participants and items as random factors.

Reading-Time Analyses Mean reading times for each segment are presented in Figure 1. Reading times that were over 10 seconds or under 100 milliseconds were excluded from the analysis. These responses consisted of less than 2% of the data.

Segment-by-segment reading time analyses revealed a significant effect of verb type at segment one ($F_P(1,47) = 7.21$; $F_I(1,79) = 4.11$, $p < .05$ for both); however, this effect was in the direction opposite to that expected under a strongly incremental view—observation verbs were read more quickly than consumption verbs. There was no evidence of additional inferencing work going on in the atelic conditions.[2]

Also speaking against the predictions of an incremental account is the finding that there were no significant differences at segment three (the count/mass noun segment) or segment four (the manner adverbial segment), indicating there is no immediate processing cost associated with drawing telicity inferences based on the integration of noun and verb information.

Despite the lack of immediate processing, an examination of the reading times for the final segment (see Figure 2) provides some evidence that participants were combining the verb and noun information to generate inferences about the telicity of the events. Analyses of segment five reading times reveal evidence of processing costs when participants encounter grammatical information conflicting with telicity inferences. A 2x2x2 repeated measures

[2] This main effect may have been the result of a confound with word frequency—the mean frequency (Kučera & Francis, 1967) of the observation verbs was significantly higher than that of the consumption verbs ($t(59) = 3.64$, $p < .01$).

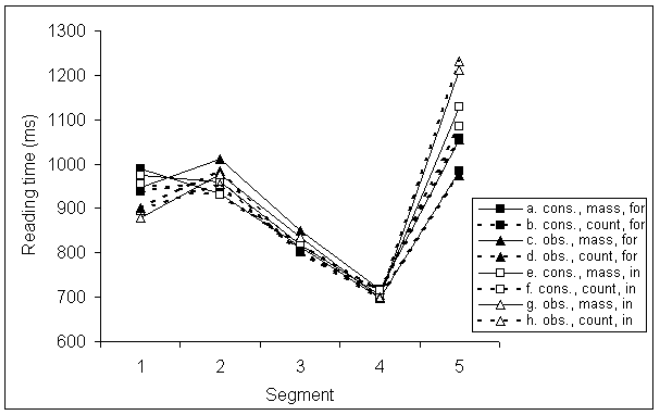

Figure 1: Mean Reading Times

ANOVA revealed a three-way interaction between noun, verb and final adverb ($F_P(1,47) = 4.29$, $F_I(1,79) = 4.46$, both $p < .05$). This interaction reflects both the relatively long segment five reading times for sentences whose final adverbs conflict with the telicity information contained in earlier segments (types e, g, and h). This difference was confirmed with planned contrasts ($F_P(1,47) = 11.23$, $F_I(1,79) = 33.01$, $p < .01$ for both).

Looking at the for-adverbial conditions alone, there was a two-way interaction of verb and noun type with slower reading times for sentences with consumption verbs and count nouns than sentences with consumption verbs and mass nouns, though it was only marginally significant in the items analysis ($F_P(1,47) = 9.72$, $p < .01$; $F_I(1,79) = 3.71$, $p < .06$). This suggests that participants had successfully drawn telicity inferences based on verb and noun information earlier in the sentence.

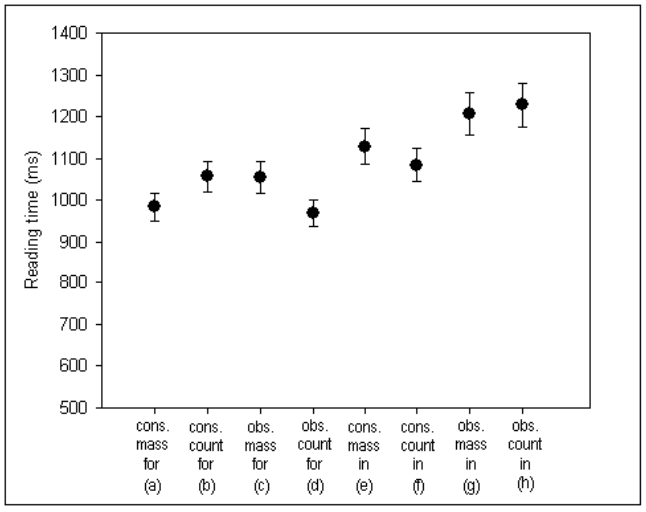

Figure 2: Reading Times for Segment 5

Follow-up Question Data Responses to the follow-up questions indicate that the participants were sensitive to the experimental manipulations. Repeated measures ANOVAs revealed main effects for final adverb ($F_P(1,47) = 66.84$; $F_I(1,79) = 757.12$, both $p < .001$), verb ($F_P(1,47) = 64.08$; $F_I(1,79) = 131.67$, both $p < .001$) and, though only marginal in the items analysis, for noun ($F_P(1,47) = 4.27$, $p < .05$; $F_I(1,79) = 3.14$, $p = .08$). This pattern of responses indicated that, as expected, participants were more likely respond "yes" (indicating an atelic interpretation) to the questions following sentences that contained *for* adverbs, atelic verbs, and mass nouns than they were for sentences containing *in* adverbs, telic verbs, and count nouns, respectively (see Figure 3). There were no significant interactions. Planned t-tests comparing responses to questions following mass and count versions of the critical consumption/for sentences revealed that participants were more likely to attribute the subinterval property to an event if it involved the consumption of a mass than a counted object, though the difference was only marginal in the items analysis ($t_P(47) = 2.23$, $p < .05$; $t_I(79) = 1.97$, $p = .05$), indicating that they were more likely to treat a consumption/mass action as an activity than a consumption/count action. This pattern occurred despite the presence of the for-adverbial, which should force an atelic interpretation.

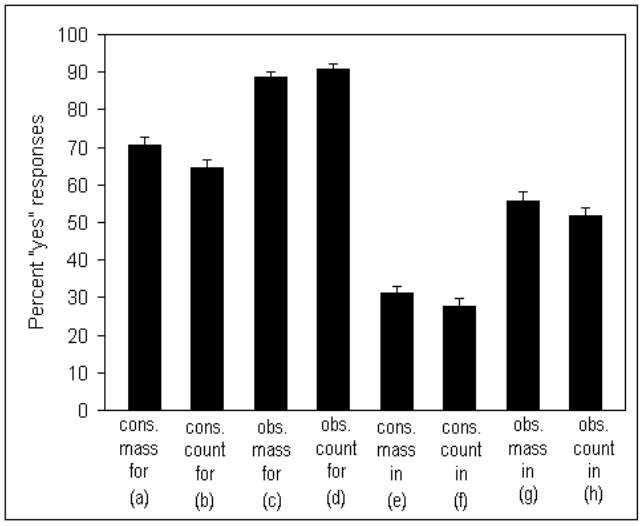

Figure 3: Follow-up Question Responses

General Discussion

An incremental view of language understanding would predict that participants should begin drawing telicity inferences as soon as those inferences are licensed by the text. In the current study, such a view predicts that participants should show slowed reading times at the first segment (the verb segment) for observation verbs (relative to consumption verbs) since such verbs license immediate inferences about the telicity of the events they describe, whereas consumption verbs do not. The present study found little support for this prediction—the main effect of verb found at the first segment was in the opposite direction of that predicted.

An incremental view further predicts an interaction between noun and verb at the third and fourth segments (the noun and manner adverbial segments). If drawing inferences about the telicity of a VP based on verb and noun boundaries were costly, we would expect to see a slowing in reading times as soon as conflicting information appeared (e.g., when a count noun followed a consumption verb). This prediction also failed—there was no such interaction. Nevertheless, participants were using the combined verb and object information to make inferences about the boundedness of events. Both reading time differences at segment five and responses to follow-up questions provide support for these inferences. In the former case, reading times increased when a final adverbial was inconsistent with the verb+object combination. In the latter case, participants were more likely to agree with the subinterval property for the consumption of a mass than for the consumption of a counted object.

Conclusions

Earlier work shows that there is a processing cost for drawing inferences about the telicity of events (Piñango et al., 1999; Todorova et al., 2000). The present study investigated the time course of such inference-drawing. Two strong possibilities presented themselves at the outset: participants could either make inferences early, as the relevant information was presented to them (as in an incremental account) or, alternatively, they could hold off making telicity inferences until late in sentence processing, when all information was available (minimally, until after verb and noun information was available; Pustejovsky, 1991, 1995; Verkuyl, 1993). The reading time results from the present study support the second alternative—there is no indication that participants made rapid use of either the verb or verb+object information to draw boundedness inferences. Instead, it seems that all the costly inferencing work was carried out at the final segment. This finding is consistent with other work: for example, Todorova and her colleagues (2000) find no cost for combining a telic verb (such as *send*) with a bare plural noun (such as *letters*), even though the bare plural forces an atelic interpretation for the verb phrase. The absence of such a cost is surprising under strongly incremental views of natural language interpretation (Marslen-Wilson & Tyler, 1980; Altmann & Kamide, 1999). This pattern is also consistent with the possibility that drawing (or delaying) inferences regarding telicity may be a relatively cost-free process, much as delaying choosing among different metonymic or metaphoric uses of a polysemous noun (such as *newspaper*) (Rayner & Frazier, 1989). In the domain of telicity, participants are willing to hold off on doing costly inferences until they are forced to make an interpretation.

Abstract

Traditionally, cognition has been regarded as the outcome of internal cognitive processes manipulating mental representations. More recently, however, it has become clear that cognition cannot be separated from the social and material environment in which people live and act, and that in many cases cognition is distributed among individuals and environmental properties. One important aspect has turned out to be artefacts and their use, and there is growing interest in understanding how tool use affects cognition. However, even with this increased awareness of the role of artefacts, the focus has mainly been on the cognitive processes and representations of individuals, while the social role of artefacts has received less attention. An ethnographically inspired field study**,** observing a hospital's children admission unit, was conducted to investigate the way individual and collaborative work are affected by the use of artefacts within a given social context. The results indicate that the use of artefacts is closely coupled to the social environment, that to some degree social interactions are transformed into more indirect, individual processes, and that artefacts are crucial for high-level processes such as memory and coordination.

Introduction

Most work in cognitive science has for a long time been based on a general consensus that cognition is best described and analysed in terms of *internal*, often symbolic, representations and computational processes manipulating them. Thus, cognition has been considered to take place largely within the individual mind, with a focus on mental representations and processes, while the environment largely has been reduced to inputs and outputs (e.g., Pylyshyn, 1990). However, since the mid-1980s there has been a growing awareness that individuals are socially and culturally situated and that the environment needs to be considered in order to understand cognition (Clancey, 1997; Clark, 1997; Hendriks-Jansen, 1996; Hutchins, 1995; Suchman, 1987). Humans are, for instance, very proficient in using environmental properties as cognitive aids (Clark, 1997; Kirsh, 1995, 1996), and there is growing interest in finding out how artefacts/tools affect cognition (e.g., Preston, 1998). The terms artefact, tool, and tool use are not particularly well defined, even though there are numerous definitions, resulting from differing focuses in different areas (see, e.g., Gibson & Ingold, 1993; Neuman & Bekerman, 2000; Preston, 1998). In this paper, artefact and tool are used, in accordance with much of the literature, more or less interchangeably.

Despite an increasing interest in cognition and artefacts (see, e.g., Norman, 1993), there is so far a limited understanding of the way artefacts affect the individual within a social context. The present paper aims to contribute to the understanding of the way people are affected by artefacts, and the role artefacts can have in a certain social context. A field study was conducted in a Swedish hospital, at the children's admission, where artefacts (as it turned out) constitute an important part of work tasks. The results indicate that artefacts play an important role in the social context, in a manner different from their role when considered in relation to an individual.

The next section elaborates in some more detail work on situated, distributed and social cognition that constitutes the background for the work of the present paper. Then methods, analysis, and results are described, followed by a discussion.

Situated, Distributed, and Social Cognition

Situated cognition has become an influential approach in many different areas, such as artificial intelligence (e.g., Brooks, 1999), cognitive anthropology (Hutchins, 1995), cognitive psychology (e.g., Barsalou, 1999), and developmental psychology (e.g., Thelen & Smith, 1994). Although there is not yet any universally accepted notion or definition of 'situatedness' (cf. Clancey, 1997; Wilson, 2003; Ziemke, 2002), generally speaking there is an agreement that cognition is a continuous process (e.g., perception-action-loops) with changing boundaries, and that cognition is more than what takes place within the individual mind (e.g., Clark & Chalmers, 1998; Clark, 1999; Susi et al., 2003). The context in which human activities take place is equally important. Hence, there is a growing interest in understanding the role of scaffolds or 'wideware', i.e., external structures such as artefacts, in cognition (e.g., Clark, A., 1997, 1999, 2003; Hutchins, 1995). In itself an

artefact may not be much, but coupled with human cognitive abilities artefacts can become powerful tools, and it has been argued that they extend cognitive abilities such that 'thinking' cannot be reduced to internal cognitive processing (Chalmers & Clark, 1998). Hence, the use of scaffolds or (cognitive) artefacts amplifies cognition. However, it has been pointed out that artefacts actually do not amplify cognition as such (Cole & Griffin, 1980; Hutchins, 1995). Even though a tool may appear to amplify cognition, it is really a coordination of different cognitive processes, which can be aided by using appropriate tools, but no cognitive ability, or process, has been amplified. Other considerations on the topic of artefacts and cognition concern, for instance, that tool use extends the body and a person's body schema (Bateson, 1972; Berti & Frassinettis, 2000; Maravita et al. 2001; Maravita & Iriki, 2004). We are also spatial beings, and, subsequently, all actions are taken in relation to the environment (Kirsh, 1995). People continuously organise and reorganise, for instance, their work environments to reduce the cognitive effort needed.

For a long time tool use and technology were degraded to 'by-products' of cognitive evolution (Saito, 1996), but with increased knowledge it has become clear that artefacts and their use have a considerable effect on cognitive processes. This issue received much attention already by Vygotsky and his followers (see, e.g., Gal'perin, 1969; Haenen, 1996; Vygotsky, 1978, 1981). However, in order to understand this relation further research is needed concerning questions such as what makes an object become a tool, and the development of tool use behaviour (Preston, 1998).

The fact that artefacts, for a long time, have received relatively little attention in cognitive science is somewhat surprising. Nowadays they are commonly described as the "the other major form of cognitive mediation between individual and world" (Preston, 1998, p. 514), besides language, but obviously language has always played a much more central role in cognitive science. Artefacts also played a crucial role, as controlling behaviour from the outside, in the cultural-historical school in psychology, in particular the work of Vygotsky (1978, 1981), but with the advent of cognitive science attention, for the abovementioned reasons, for a long time shifted towards internal, individual processes and representations.

Recent work on *distributed cognition* (Hutchins, 1995) has in some sense rediscovered the integral role that artefacts play in both individual and collaborative cognitive processes that are distributed over people and the material resources they use. This view takes an interest in the way information is represented, transformed, and propagated in the material and social environment. That way, cognitive processes can be described in terms of functional relationships between brains, other people, and external objects. The role of artefacts as mediators of social cognition, however, is far from being fully understood. The present paper considers cognition from a situated and distributed perspective, i.e., it views high-level cognition as resulting from a close interplay between brain, body, and the social and material environment in which humans live and act.

Like most of cognitive science, research in *social cognition* has traditionally focused on individual cognitive processes involving social information, such as attention, perception, and memory, and the internal representations they generate or manipulate (e.g., Augoustinos & Walker, 1995; Fiske & Taylor, 1984; Gilbert, Fiske & Lindzey, 1998). Hence, few studies have taken a situated perspective (Semin & Smith, 2002). However, people are also *socially* situated, which means, one the hand, social interaction between individuals, and, on the other hand, that cognition is situated within a wider social and cultural context (Lave, 1988; Wertsch, 1993; Semin & Smith, 2002). Hence, besides interactional aspects, cognition is also affected by (cultural) artefacts (Levine & Resnick, 1993). Due to the fact that they constitute part of a culture's intellectual history, their use actually turns even seemingly individual activities into a social process as artefacts are affected by social aspects (Resnick, 1993). As pointed out by Hutchins (1995, p. xiv), "human cognition is not just influenced by culture and society, but ... is in a very fundamental sense a cultural and social process".

Case study

Most research on cognition and artefacts has to a large extent focused on the individual (e.g., Norman, 1991, 1993) while contextual and environmental aspects largely have been disregarded**,** with some notable exceptions (e.g. Hutchins, 1995). Subsequently there is a limited understanding as to how artefacts affect the individual within a social context. Further research is needed that considers both social interactions and tool use to gain further understanding of the relation between artefacts, individual, and social cognition. Accordingly, the underlying question for the present study was "*how does tool use affect individual cognitive processes within a social context*"? The term 'artefacts' in this case refers to objects that are significant for everyday work tasks, while 'cognitive processes' here refer to high-level processes such as attention, memory, and coordination.

Method and Setting

In order to investigate the above questions, a field study was conducted at the children's admission in a Swedish hospital. Such work places are indeed highly *social* work places: well functioning daily work requires well-organised cooperation between the members of the staff, as well as between different wards. The work tasks at the children's admission are individual in the sense that most work is carried out individually. For example, parents and children arriving at the admission would usually first meet an administrator who registers their arrival, then a nurse who, for example, might draw a blood sample, and eventually a doctor. At the same time though, all these individual activities are, of course, socially situated and have a strong coupling to the social and environmental context.

In the children's admission, we chose (a part of) the central office (which functions as a communication,

coordination, and administrative centre), as the setting for the study. The office has three units: a reception, an administrative unit, and a unit where all incoming phone calls are handled. The study was limited to the *administrative unit* (see Figure 1), since it is a central place for much of the daily activities, and nurses frequently visit this unit. There are always three to four nurses working at the same time, and the study focused mainly on their work. However, other people also visit the administrative unit during the day, e.g., doctors who come by to collect patient records. The main part of the nurses' work consists of taking care of patients that have an appointment, as well as urgent cases that appear during the day. They also handle administrative tasks, phone counselling, and patient-related tasks, e.g. drawing blood samples. Each member of the staff is responsible for certain tasks, but must also be aware of the others' tasks and responsibilities in order to coordinate their work. On an overall level, the daily routine consists of registering patients on their arrival, and getting each patient's medical record from the archive. Patients that are expected during the day are listed on a patient list. A nurse carries out an initial examination (weight, etc.), and if the patient has a doctor's appointment, he or she is shown into a consultation room. In cases where some kind of a sample needs to be drawn or collected, the doctor notifies a nurse.

The study was inspired by *cognitive ethnography* (Hollan et al. (2000), with observations (moderate participation; DeWalt & DeWalt, 2002), video recordings, and interviews. The combination of such techniques provides a means for gaining insight into the interactions between people and their use of artefacts, and subsequently cognitive processes. The staff was informed that the office was the subject of a study, and the time when it was to take place. Initial interviews were conducted to gain information about the staff, their work tasks, and the setup of the office. Observations were made during two days, and when necessary, questions were asked during the observation. During the observations the office was also videotaped. When all material had been analysed, another interview took place to verify that, e.g., work tasks had been correctly understood.

Analysis and Results

The videotaped material (three hours in total) and notes taken during the observations were analysed from the perspective of the staff's work tasks and activities, and the function of artefacts used in relation to the identified activities.

A highly social work setting, such as the observed children's admission, requires well functioning cooperation, interaction, communication, shared knowledge about routines, others' tasks, etc. In this particular setting the staff uses various artefacts with varying functions, which requires an additional interpersonal understanding of their different functions. In the present study a number of artefacts turned out to be crucial with respect to processes such as coordination of the ongoing work. However, due to space limitations, only a few artefacts are discussed here in some detail.

Most activities in the administrative unit take place around a small table, on which various items are kept and placed (cf. Figure 1). The structure of the office unit also provides structure to the work tasks since the artefacts draw attention to what is going on and what needs to be done.

Patient's record One of the most important artefacts in this particular setting is the patient's medical record. Basically, it is a folder containing a collection of documents with information about a patient. All the documents are sorted in a specific manner in order to reduce the effort of finding the right information (a document out of its proper placement causes disturbances in the work-flow), and when a patient visits the children's admission new information is added. The patient record has several functions, besides the obvious one of storing information about patients. Clearly, no single person could keep all the information in the head, and there is no need to either, as the patient record provides an external memory (on some rare occasion a patient's medical record has been displaced, which caused serious problems). As different people handle the patient record, more information is added to it, and its contents (the representations) become transformed. Commonly, patients do not meet the same nurses and/or doctors each time they come to the children's admission, but information concerning the patient is transferred between staff members through the patient record, which functions as a 'communicator' between different people. That way the contents of a patient's record transform intrapersonal knowledge to interpersonal knowledge shared by several people. The patient records also contribute to an overall coordination of work processes since, depending on where a patient record is placed, it causes different people to take different actions. Placed in the reception's tray, it triggers a nurse to take the patient record into the administrative unit**,** while placed in a tray labelled with a doctor's name it informs the doctor that a patient is waiting, etc.

The patient list Another highly crucial artefact is the *patient list* placed on the wall above the small table (cf. Figure 1) (another list is in the reception, but that was not included in the study). The list actually consists of nine smaller lists (together referred to as the patient list), each corresponding to a consultation room (each doctor uses the same consultation room throughout the day). Thus the list tells, not only who is coming when, but also in which room the patient will be received and by whom. The list also contains information about each patient and the measures to be taken. The list is computer-generated, and during the day the nurses make additional markings by hand. The markings consist of symbols that are typically understood only by the staff. For instance, a certain symbol next to a name on the list means that the patient is waiting in the consultation room (which the list concerns), another symbol means that a doctor has been delayed, and yet another one means that the patient has left the admission. All markings are made in red so that they are highly visible and easy to perceive. During the observation it became clear that the nurses had no difficulties in understanding the added markings, and hence the list provides a means for communication and

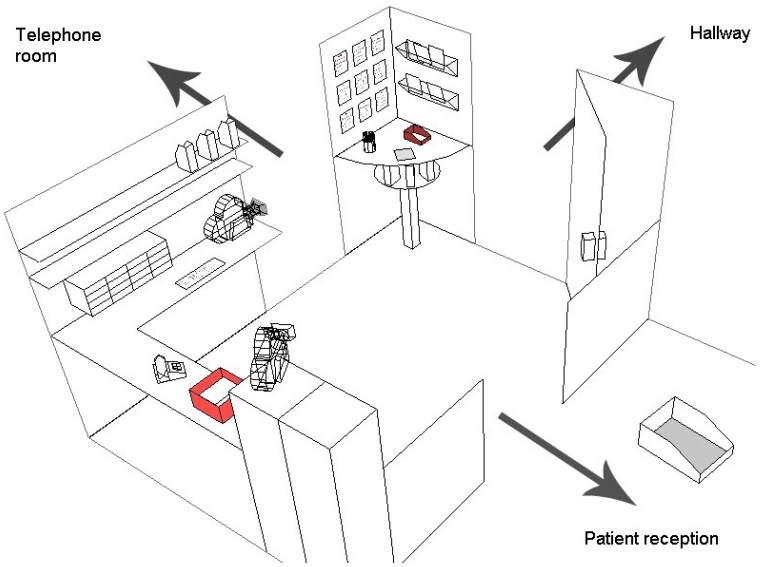

Figure 1. The observed administrative unit. In the upper corner is the small table with a tray (follow-up instructions), and with labelled trays on the shelf below. On the left wall above the table is the patient list(s). On the bench to the lower left is the (orange) tray for filled in sample documents. The cameras indicate the two placements of the (one) camera during the observation.

coordination between people, even when they do not interact directly.

Another function of the list is that it provides a (shared) external memory, providing everyone with the same necessary information. No one needs to memorise the information, as it is 'there' all the time, visible to those who need it, as they need it. As symbols are added to the list, the information becomes transformed and it is propagated from one individual to another when needed. The list also provides an overview and a visualisation of the consultation rooms, and each doctor only needs to pay attention to that part of the list that is related to their room, which in turn delimits the amount of information that needs to be attended to.

Paper trays There are a number of trays[1] in the office, each with its own function(s) and assigned meaning. As patients are registered on their arrival, their medical records are withdrawn and placed in a paper tray in the reception. A patient's record in the tray is a signal to the nurses that a patient has arrived. The patient records are brought by the nurses to the administrative unit, and, eventually, they are placed in trays labelled with the name of the doctor that the patient is going to see. Usually there are four to five doctors working at the same time, and their (labelled) trays are placed on a shelf under the small table (cf. Figure 1). Trays belonging to doctors who are not on duty are placed somewhere else (top shelf to the left of the small table, cf. Figure 1). During the day each doctor collects the patient records that are placed in their tray. When a sample needs to be drawn or collected, the doctor notifies it by leaving follow-up instructions in a blue tray (to the right on the small table in Figure 1). When a nurse has performed the procedure, a filled-in document concerning the sample is placed in an orange tray (on the bench to the lower left in Figure 1). Thus, the spatial arrangement of the trays (and other artefacts) contributes greatly to structuring the ongoing work.

Besides containing documents, the trays have several other functions. For instance, rather than having to keep each ongoing process of the work place in memory, the trays, and their contents, provide information about what is going on and matters that need to be taken care of, thereby providing an external memory. The trays also serve as a means of indirect communication between individuals. The nurses, for instance, do not have to tell a doctor, in person, that a patient is waiting. Instead that information is mediated through the contents of the labelled tray. That way each person can attend his or her own individual work tasks, while at the same time, on an overall level, the indirect communication contributes to a well-functioning operation. The trays also limit the amount of information that needs to considered. A doctor, for instance, only needs to pay attention to *one* labelled tray (or *one* part of the patient list).

Other artefacts There are also a number of other artefacts, equally important but taken for granted to the extent that they become 'invisible' (Gauvain, 2001). One such artefact that should be mentioned here is the small table (Figure 1), which plays a crucial role in the organisation of the daily work. Such a common artefact might seem trivial to discuss, but in this case it is an important part of the spatial arrangement that contributes to the overall structure of work tasks (cf. Kirsh, 1995). People know that it is the place where things that are used or needed often, are kept, and that it is a place for important information. Thus it provides, e.g.,

[1] The items containing documents that are discussed in this paragraph are not all paper trays in the real sense of the word, but are here, for simplicity sake, collected under the label of 'trays'.

an external memory, and people often take a glance at the table before leaving the room, to see if they left anything there as they entered the room (as is often done), or if there is something they need to take care of. The table is also used as a message board, where people leave notes for others.

Discussion

The question guiding our study was "how does tool use affect individual cognitive processes within a social context?". One perspective of interest in the present analysis is the ecological perspective (Gibson, 1986), since an artefact's function is closely related to its appearance (affordance). However, due to space limitations that discussion has been left out in this paper.

Obviously, a two-day study has its limitations, and can only provide a rough understanding of the complexities of a work setting, artefacts, the relations between individuals and social contexts, etc. Nevertheless, despite possible shortcomings, this study is an important step in what we consider an important research direction. Even limited studies can provide valuable insights, and this particular study illustrates some aspects of the relation between artefacts, individuals, and social context.

On a general level, the study shows the importance of the artefacts used in this particular setting, and the way they contribute to a well-functioning operation where much of the activities are coordinated in an implicit manner. It can also be argued that just how powerful artefacts are becomes evident only when considered within the social context in which they are used. Some artefacts, such as a patient list, only make sense to and are understood by those who use them (cf. Levine & Moreland, 1993). As it turned out, it is not only the way an artefact is used that is important for cognition, but also *where* it is used (cf. Kirsh, 1995). The environmental structure and spatial arrangements partly determine the function and the meaning of an artefact. For instance, the labelled trays have different meanings depending on where (on which shelf) they are placed, and patient records trigger different activities depending on where they are placed (cf. also Clark, H., 2003). Artefacts also provide a scaffold for different cognitive processes depending on *who* the user is, i.e., the user's role in the overall social arrangement. Artefacts play an important role as organisers: the state of an artefact (e.g., a tray that is empty, or not) helps the individuals to organise their work, and on the social level they contribute to coordination, cooperation and structure. Some artefacts make information available and visible, and contribute to the propagation of information between people and artefacts.

As discussed by Hollan et al. (2000), the activities of a group cannot be fully understood from the individual's perspective, rather the functional relationships of people and artefacts need to be considered. Thus, individual actions cannot be explained without considering what others are doing, the interpersonal codes, knowledge, and shared understanding of the functions of all the artefacts they use (e.g., Leont'ev, 1978; Thompson & Fine, 1999). Another important aspect is the way artefacts transform individual processes into social processes, and vice versa. For instance, when a nurse adds a marking to the patient list the information becomes part of a social activity and individual knowledge becomes shared knowledge (in a sense propagated 'on demand' only). Likewise, social or shared activities may become individual activities, e.g., when the nurse attends to information added by others.

To summarise, the artefacts analysed in this study function as mediators of distributed social cognition, i.e., they constitute or facilitate shared memory, coordination, communication, and sharing of information. Many artefacts have the same, or similar, functions¸ which however vary depending on *who* is using them, *where* (spatially) they are used, their functional coupling to other artefacts, and the social context. As illustrated in this paper, artefacts in many cases transform social interactions into individual processes, but at the same time they also mediate the indirect interaction of these processes¸ and thus maintain their social nature (cf. Susi & Ziemke, 2001).

This study has illustrated that, in order to understand artefacts and their role in individual and social cognitive processes, we need to consider artefacts, individuals, the social context, and their functional interrelations. Much of the work addressing these issues, including this paper, has been presented in the form of examples, anecdotal evidence, case studies, etc. Future work will have to further address the development of a more systematic, principled understanding of the role that artefacts play in distributed social cognitive processes.

Making Graphical Inferences: A Hierarchical Framework

Raj M. Ratwani (rratwani@gmu.edu)
George Mason University

J. Gregory Trafton (trafton@itd.nrl.navy.mil)
Naval Research Laboratory

Abstract

A hierarchical framework suggesting how graph readers go beyond explicitly represented data to make inferences is presented. According to our hierarchical framework, graph readers use read-offs, integration and pattern extrapolation to make inferences. Verbal protocol data demonstrates high-level differences in the way inferences are made and eye track data examines these processes at the perceptual level.

Introduction

Imagine a scientist examining Figure 1 in order to infer which county in California is going to be hit next by the flu epidemic. How would the scientist go about making this prediction?

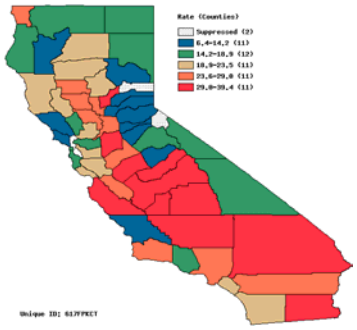

Figure 1. Cases of the flu in California.

Making inferences from graphs is considered one of the more complex skills graph readers should possess. According to the National Council of Teachers of Mathematics (NCTM) the simplest type of question involves the extraction or comparison of a few explicitly represented data points (read-offs) (*NCTM: Standards for Mathematics*, 2003). A more difficult question is an integration question where multiple data points need to be extracted and integrated by some mental operation. The most difficult type of question requires the graph reader to make inferences from the graph. Because the information is not explicitly represented in the data, the graph reader is forced to extrapolate from the current data to make a prediction (Trickett, Ratwani, & Trafton, under review).

How do graph readers go beyond the explicitly represented data to make inferences from graphs? Less is known about how inferences are made from graphical representations, despite the importance of having this skill. Most of the classical theories of graph comprehension (Kosslyn, 1989; Lohse, 1993; Pinker, 1990) do not go into detail about how integration and inferences are made, but instead focus on read-offs from fairly simple graph types. One of the reasons that current theories of graph comprehension do not have much to say about making inferences from graphs is the paucity of data. There are, in fact, very few empirical papers that have systematically investigated how graph readers make inferences from graphs.

We propose a hierarchical framework of graph comprehension for how these different types of questions (read-off, integration, inference) are answered. The most basic type of information extraction is the read-off of explicitly represented data. The more difficult integration of information requires the use of read-off's and spatial transformations (Trafton, Marshall, Mintz, & Trickett, 2002; Trickett & Trafton, in press). For example, in order to integrate information in choropleth graphs (see figures 1 and 2), graph readers read-off specific data points and use spatial transformations by forming clusters of proximate same colored counties and then reason with and compare those clusters (Ratwani, Trafton, & Boehm-Davis, 2003). Finally, in order to make inferences from graphs, we believe graph readers use the same processes used to integrate information (read-off's and spatial transformations) and in addition use pattern extrapolation and mental models (Trafton et al., 2002).

Going beyond the limits of the current data in order to make an inference requires the use of extrapolation (Bott & Heit, 2004); when graph reader's go beyond the limits of visible data, pattern extrapolation may be used. Pattern extrapolation is a process by which graph readers examine known data points and then, based on the pattern of these data points, make an inference.

While the hierarchical framework suggests what cognitive processes graph readers will use when extracting different types of information from graphs, graph readers are likely to use the simplest process to extract the information they desire. For example, when integrating information, if possible, graph readers will use mostly read-offs because read-offs are a simple way of extracting information from graphs and require very little cognitive effort in comparison to spatial transformations or mental model building. Similarly, if a graph reader needs to integrate information from a graph, they are not likely to need to build mental models and extrapolate patterns.

In this paper, we examine which processes are used to make inferences from graphs. We focus on inferences because read-offs are quite well understood (Kosslyn, 1989; Lohse, 1993; Pinker, 1990), there is a preliminary framework for integration of graphical information (Ratwani, Trafton, & Boehm-Davis, 2003), but there are no theories that can adequately describe how inferences are made. Previous research examining graphical inferences has focused on the use of mental models, spatial transformations

and the role of domain knowledge (Hegarty, Shimozawa, & Canham, under review; Trafton et al., 2000). We are interested in how all of these processes are combined in order to make inferences from graphs. In this paper, we focus on read-offs, integration and pattern extrapolation because it is relatively straightforward to identify read-offs, integration, and pattern extrapolation and much more difficult to identify spatial transformations or mental model building.

If the hierarchical framework of graph comprehension is correct, graph readers will make inferences by reading-off explicit information, using pattern extrapolation and integrating information. Experiment 1 serves to explore higher-level thinking about how graph readers make inferences from graphs by using the protocol analysis methodology. Experiment 2 further investigates the processes used to make inferences by using an eye tracker to examine graph readers' eye movements.

Experiment 1

The first experiment was designed to explore the types of processes graph readers use to make inferences from multiple choropleth graphs. Choropleth graphs depicting population densities were selected for use in this experiment; these graphs use different colors, shades of gray, or patterns to represent different quantities. Choropleth graphs were chosen for multiple reasons. First, they are more complex than the graph types used in more traditional studies of graph comprehension and better reflect how graphs are used in the real-world. Second, these particular graphs do not require a great deal of domain knowledge and can be presented to undergraduates without much training. Finally, choropleth graphs represent a class of graphs that are commonly used by scientists in such domains as meteorology, geology and oceanography.

Method

Participants

Three George Mason University undergraduate psychology students served as participants for course credit. Informed consent was received from all participants.

Materials

Twenty sets of choropleth graphs were created; each set consisted of three conceptually related graphs. The graphs in each set displayed the population densities of fifty fictitious counties. The first graph in each set displayed the population from the year 1990, the second graph displayed 1995 and the third graph displayed the population from the year 2000 (See Figure 2 for an example). Only one county in each set of graphs was labeled with a county name (referred to as the target county) in order to reduce search time. Previous studies found that graph readers spent a great deal of time searching for the county of interest when every county was labeled (Ratwani et al 2003). One inference question was asked of each set of graphs: What will the population of the target county be in the year 2005?

Design

Five sets of graphs showed a clear decrease in the overall population densities from 1990 to 2000 while the population of the target county did not change in any of these graphs. These counties surrounding the target county had a powerful contextual indication that the population was decreasing. Five sets of graphs showed a clear increase in the overall population densities from 1990 to 2000 while the population of the target county did not change. These counties surrounding the target county had a powerful contextual indication that the population was increasing. Ten of the sets of graphs served as fillers and were removed from all analyses; the populations were jumbled and had increasing, decreasing or no clear pattern to the population movement across the graphs. The purpose of these sets was to randomize the patterns of increasing and decreasing population in the ten sets of interest. The order in which the twenty sets of graphs were presented was randomized for each participant. The increasing and decreasing sets were combined in the analyses below.

Procedure

All participants first read the question for the set of graphs they were about to view and then examined the graphs. For example, the participant would read the question, "What will the population of county x be in the year 2005?" After reading the question the participant would then view the graphs from the three time periods and make their prediction. This process continued for each of the twenty sets of graphs.

The participants could view each of the graphs for as long as they desired, and the participants were permitted to look back to any of the graphs within a particular set as needed. Each graph was presented on a single sheet of paper. After answering each question, the participant went on to the next set of graphs. Each participant provided a talk-aloud protocol (Ericsson & Simon, 1993) as they examined the graphs and answered the questions. The participants' verbal protocols and the graphs they were examining were videotaped.

Coding Scheme

Transcriptions of the verbal protocols were made prior to data analysis. The first step was to segment the protocols into individual utterances. Utterances were defined as a single thought and utterances that were not germane to the task at hand were coded as "off task" and eliminated from further analysis. Each remaining utterance was then coded according to our hierarchical framework. The utterances were coded as either being a **target read-off** (extracting information regarding the target county of interest only) or **integrative** (extracting general trend information from the graph). All the answers were, by definition, inferences. There were no non-target read-off's in any of the utterances made by the participants. Table 1 shows examples of each utterance type.

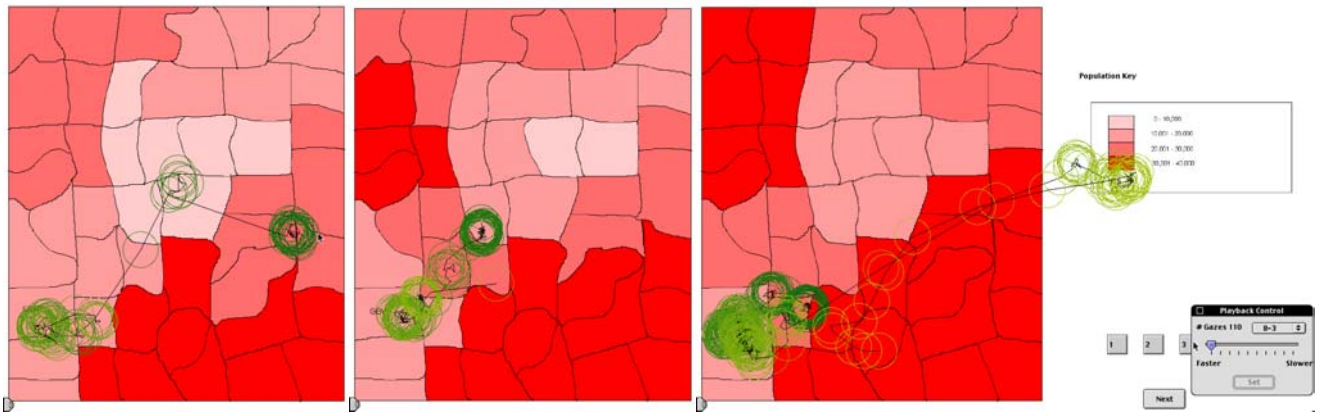

Figure 2. Graphs depicting population growth from 1990, 1995, and 2000 (left to right).

Code	Example
Target read-off	In 1990 Stow County was 20,000 to 30,000
Integrative	All the other areas are increasing in population

Table 1: Examples of each extraction type.

Results and Discussion

Our main goal was to explore how graph readers made inferences from graphs. We first examined the types of extractions made by each graph reader and then compared these extractions to the answer given to the inference questions. The participants gave a numerical answer indicating that the population of the target county would either change or not change. Of the three participants, one participant made change responses the majority of the time, one participant made non-change responses the majority of the time and one participant had mixed responses. Thus, graph readers were not always using the same strategy to make these inferences. When participants made a change response, their inference was in the direction consistent with the surrounding counties. For example, when the participant made a change response and inferred that the population of the target county would grow in the future, the surrounding counties were also growing.

As figure 3 suggests, when graph readers said the population of the target county would not change in the future all of their extractions were target read-offs. When graph readers said that the target county would change in the future, the graph readers made some target read-offs but made a significantly greater number of integrative extractions, $\chi^2(1) = 4.9$, $p < .05$. In addition, when a non-change response was given, graph readers made a significantly greater number of target read-offs than when a change response was made, $\chi^2(1) = 8.02$, $p < .01$.

The verbal protocol data indicates that when graph readers performed mostly target read-off's they made a non-change response to the inference questions. That is, despite the fact that the powerful overall context of the three graphs suggested that the population was increasing (for example), the graph reader inferred that the population of the target county would not change in the future. However, when graph readers looked beyond the target and used the global context of the graphs the graph readers used context to infer that the growth would continue to the target county and that the target county would change in the future.

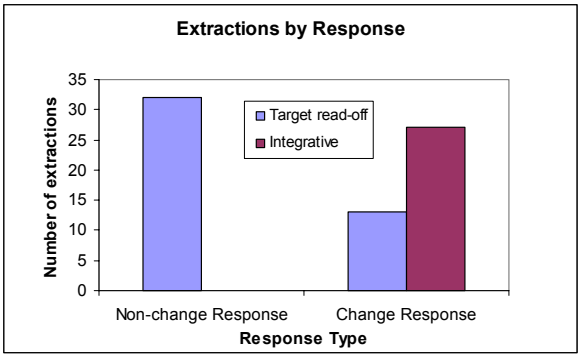

Figure 3: Number of extractions by response.

These data suggest there are differences in the way people think about making inferences. Based on the type of extractions the graph reader made, their response could be categorized as either inferring a change or not inferring a change in the future population. There appear to be two general ways in which graph readers made inferences from these graphs. One way was to focus only on the target county in each of the three time periods and, based on how the population changed in the target county, an inference was made as to the future population. For example, if the target county did not change population in any of the three time periods then it would not change in the future. This no change response appears to be based solely on pattern extrapolation of the target county. Alternatively, when making change responses, graph readers appeared to be making read-off's for pattern extrapolation and taking into

consideration the contextual influences of the graph. Some aspects of the global context of the graph were being integrated with the population of the target county in order to make the inference. When participants made change responses, their verbal protocol data is consistent with an interpretation of them creating a dynamic mental model: participants were imagining the growth in the counties extending to nearby counties, eventually "hitting" the target county. While we are not directly measuring mental model formation in this paper, we are interested in what information is needed to form those mental models.

Based on our hierarchical framework, we would expect graph readers to make inferences by both reading-off information for pattern extrapolation and integrating information. It appeared that when graph readers made a non-change response, they extracted target information only, noticed it did not change, and extrapolated that it would not change in the future. They did not seem to explicitly extract information from nearby counties. Graph readers who made a change response appeared to be using read-offs, pattern extrapolation and integration as our hierarchical framework suggests.

Experiment 1 showed that people had different strategies when answering inference questions: a change strategy and a non-change strategy. It could be that at the perceptual level these strategies are identical. For example, it could be that participants who made a no-change answer did, in fact, look all over the graph but decided to simply ignore that information, or assume that the target county was the most important determinant of future change. Additionally, the protocol data did not show how or what types of information was extracted by change-response participants. Experiment 2 investigates these issues.

Experiment 2

How, then, did participants make inferences from these graphs? By performing a small task analysis, it is obvious that when information needs to be integrated, it can be integrated in at least two ways: within a specific graph and between related graphs. If a participant integrates information within a specific graph, the participant would presumably examine nearby counties to see how their population was different from the target county. If a participant integrates information between related graphs, the participant would probably examine graphs that had changed over time.

Experiment 2 will explore three main issues. First, do participants who answer change and non-change have different perceptual strategies? Second, what types of integration do change participants engage in (within graphs, between graphs, or both)? Third, what is the proportion of read-offs and integration used in order to answer inference questions and how do those proportions relate to the answers that participants gave?

Method

Participants

Thirteen George Mason University undergraduate psychology students served as participants for course credit. Informed consent was received from all participants.

Materials

The same sets of graphs used in the first experiment were used in the second experiment. In this experiment the materials (graphs and questions) were displayed on a computer screen. Eye track data was collected using an LC Technologies Eye gaze System eye tracker operating at 60Hz (16.7 samples/second).

Design

The design was the same as Experiment 1.

Procedure

The procedure was very similar to that used in Experiment 1; however, the use of the computer and eye tracker did necessitate some changes. The participants were seated at a comfortable distance from the monitor and used a chin rest. Participants first were calibrated on the eye tracker. Participants were then shown the question at the top of a blank screen and read the question out loud. Previous studies (Ratwani et al., 2003) have shown that the process of collecting eye track data was not hindered by the participant talking. After reading the question the participant proceeded to the first graph. The interface allowed the participants to progress from graph to graph within a set with a button-click. The participants were instructed to say their answer out loud when they made their inference. After answering the question, the participant could progress to the next question and set of graphs.

Coding Scheme

A gaze was defined from each sample being no more that 10 pixels in Euclidian distance from the center of gravity of the previous point for at least 100 milliseconds. Frequencies were created by counting the number of gazes to different areas of the graph. The areas of the graph that were coded were: the legend, the title of the graph, and the main part of the graph itself.

Participant's gazes to the main part of the graph were coded to examine how much reading-off and how much integrating the participants were doing. Gazes to the target county were coded to examine how often participants were making read-offs. Gazes to locations other than the target were coded in order to examine whether graph readers were integrating information within the graph. In order to capture how far away from the target county participants were gazing the location of the gaze relative to the target county was coded for. For example, if a participant gazed at a county that was three counties away from the target this distance was coded.

Integration of information between graphs was coded by examining areas of change relative to the previously viewed

graphs. If a gaze to the graph was to a county where the population value changed from a previously viewed graph this was coded for. For example, if the participant gazed to a county in 1995 that had changed in population relative to the map from 1990 then this was coded as a change gaze. Thus, the first map viewed by each participant in every set did not have any change gazes.

Results and Discussion

Experiment 2 was designed to examine what processes occurred at the perceptual level when graph readers made inferences from graphs. Specifically, we wanted to further investigate the process differences when graph readers made a change response as compared to when they made a non-change response.

The responses made by graph readers were mixed, but mostly (76%) change responses were made. The raw frequencies of gazes were normalized by dividing the frequency of gazes by the number of responses in either the non-change or change category.

There were no significant differences in the number of target gazes when participants made a non-change response as compared to a change response as figure 4 suggests, $\chi^2(1) = .34$, $p = .56$. Participants appeared to be reading off the same amount of target information regardless of what type of response they made. Thus, participants were reading off information nearly equally when making inferences.

However, participants who made change responses did more integration within the graph than participants who did not make change responses. As figure 4 suggests, those who made change responses on average made a greater number of gazes to counties other than the target, $\chi^2(1) = 4.52$, $p < .05$.

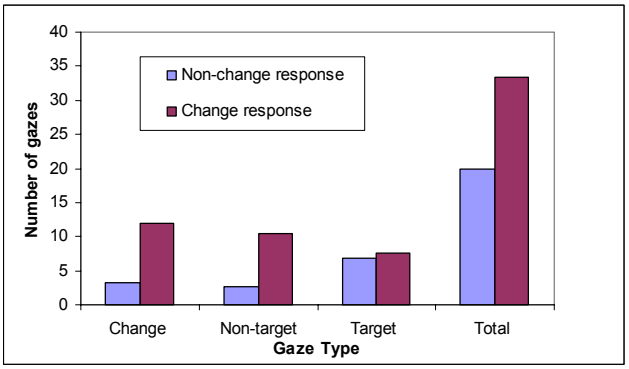

Figure 4. Number of coded gazes.

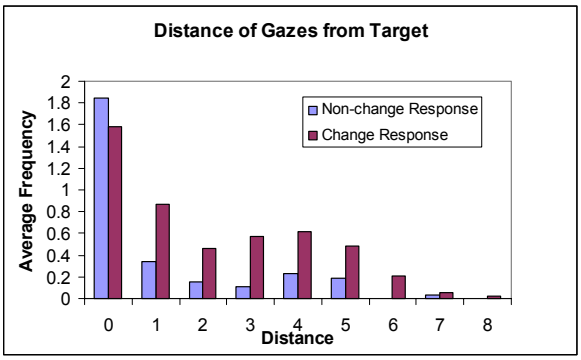
How far away from the target did participants look? In order to examine this issue, we created histograms showing the location of the counties that were gazed at based on the participants response. Figures 5 shows the frequency of gazes participants made to the target and to counties other that the target. The x-axis shows how far away the county gazed at was from the target. Zero represents the target and one through eight represent how far away the county gazed at was from the target. The patterns in these histograms are significantly different, $\chi^2(8) = 22.82$, $p < .01$, suggesting that when graph readers made a change response, they frequently looked at the target and counties away from the target, whereas graph readers who made a non-change response focused primarily on the target. Consistent with this interpretation, the proportion of change gazes to non-targets (68%) was far greater than the proportion of non-change gazes to non-targets (37%), $\chi^2(1) = 9.2$, $p < .005$. Graph readers who made a change response were frequently looking at counties as far as 6 away from the target county.

Did graph readers integrate information between graphs when they were making inferences? Integration between graphs was examined by looking at the number of gazes to areas of change from one graph relative to another. As figure 4 suggests, participants who made change responses made a significantly greater number of gazes to areas of change as compared to participants who made non-change responses, $\chi^2(1) = 4.88$, $p < .05$. This suggests participants who made change responses were integrating information between graphs by comparing the areas that changed in population.



Figures 5. Histogram of distance by response.

The process of integrating information between graphs is further supported be examining the number of times graph readers examined each of the three graphs. For example, some participants viewed each graph once; the sequence of graphs they looked at was 1→2→3. Whereas other graph readers examined each graph more than once and had a sequence such as 1→2→1→2→3→2→3. Participants who made change responses looked at the three graphs in each set more often in order to compare the counties that changed population between graphs, $\chi^2(2) = 5.24$, $p < .05$. Thus, graph readers who made change responses integrated information between graphs by paying attention to areas that changed in the graphs and looking at the graphs frequently in order to make these comparisons.

When participants made non-change responses, their eye movements suggest they are primarily examining the target county. These participants generally looked at each map only once. Furthermore, they appeared to be reading-off target county information in each graph, noticing the pattern does not change, and then using pattern extrapolation to infer that the pattern will not change in the future.

Graph readers making change responses appeared to read off target county information and also focused a great deal of attention on non-target counties. These gazes to non-target counties appeared to be a way to integrate the information from the other counties with the information about the target county. These graph readers also integrated information between graphs by paying attention to areas of change between the graphs. Finally, they compared areas of change to infer the future population by looking back and forth at the graphs in each set. This is suggestive evidence of the formation of dynamic mental models which may be used to understand how the contextual growth or decay is influencing the target county.

General Discussion

How do people make inferences from graphs? Most classic theories do not provide any mechanisms for making graphical inferences. These studies examined inferences at a high-level by focusing on graph reader's thought processes with the verbal protocol data and also at the perceptual level by examining graph reader's eye movements. These studies demonstrate that people certainly can make inferences, and that people make inferences in different ways. One way that people make inferences is to examine the specific object that will change over time (target county in our case). Depending on the type of change that is observed, a pattern is extracted and then extrapolated. In our studies, approximately a quarter of the answers conformed to this strategy. The remainder took context into account. That is, they observed the surrounding counties (especially the ones that changed from graph to graph) and presumably imagined the change affecting the target county.

Our hierarchical framework of graph comprehension is consistent with both views, though it is supported more strongly by the participants who made change answers. In order to make inferences, the hierarchical view framework suggests that people need to extract specific information from graphs (well described by most theories of graph comprehension), integrate information into a reasonable whole (in this case by combining information between and within graphs), use that information to extrapolate beyond the given data, mentally manipulate the graphical information by spatial transformations and build mental models. It is interesting that when non-change answers were made, only a subset of this framework was used: the evidence for integration in particular was quite weak. It seems that when non-change answers were given, participants simply took in the specific information for the target county, performed simple extrapolation, and then gave an answer. Using the surrounding counties was just not a priority for these participants.

Finally, how inferences are made from graphs is more complex than we have described here. Our hierarchical framework identifies the processes used to make inferences; however, further empirical data is needed to understand how read-offs, integration, spatial transformations, mental models and pattern extrapolation are combined in the process of making inferences. In addition the processes outlined by our hierarchal framework are likely to be dependent on many factors such as knowledge of the graphical display and domain knowledge (Hegarty et al., under review).

Abstract

The goal of this study was to extend prior reports of implicit learning in visual search (e.g., Chun & Jiang, 1999) by employing eye movement monitoring and reaction time measures to contrast implicit and explicit learning. Towards this end, participants' eye movements were monitored as they performed a visual search task in the 'change blindness' flicker paradigm. In each trial, participants were asked to detect a letter that differed in shape or color across otherwise identical alternating letter arrays. In a subset of trials, for some participants the background luminance covaried with target color (Color rule condition) and for other participants letter thickness covaried with target shape (Shape rule condition). In addition, half of the participants were told of the existence of a covariation (Informed group) and the other half were not notified of this regularity and in a post-experimental interview reported no awareness of this covariation (Uninformed group). In both groups, reaction time data indicated that visual search was facilitated for trials that contained the covariation, and eye movement data showed that participants guided eye movements to potential targets based on the covariation information. Further, Informed participants in the Color rule condition were able to use covariation information to a greater extent than those in the Shape rule condition. In contrast, no differential sensitivity across rule conditions was found for Uninformed participants. Implications to the study of implicit learning in visual search are discussed.

Introduction

Cognitive psychologists regularly differentiate cognitive processing as being either implicit or explicit in nature. However, there still exists debate in the field over whether these processes are indeed distinct (e.g., Shanks and St. John, 1994). One way to strongly support such a separation would involve demonstrating qualitative differences between these processes (e.g., Cheesman & Merikle, 1986; Dienes & Berry, 1997; Dixon, 1981; Neal & Hesketh, 1997; Reingold & Merikle, 1990; Shevrin & Dickman, 1980; Stadler & Frensch, 1994). As such, the present investigation attempts to make progress towards this goal by extending research demonstrating implicit learning in visual search (e.g., Chun & Jiang, 1999; Chun & Nakayama, 2000; Durgin, 1999; Flowers & Smith, 1998; Miller, 1991). For example, in a study by Chun and Jiang (1999), participants performed a visual search task where they were instructed to look for an object symmetric around the vertical axis. There were two display conditions: in the first condition each of the targets was paired with a distractor set and this pairing was preserved throughout the experiment, and in the second condition the pairings of distractor sets and targets was varied randomly across trials. Chun and Jiang (1999) reported that search efficiency in the consistent pairing condition was significantly better than in the randomized pairing condition. Importantly, an evaluation of participants' awareness of the experimental manipulation indicated that the benefit participants derived from consistent pairing reflected implicit rather than explicit learning. Based on these results Chun and Jiang argued that following implicit learning of the pairing of targets and distractor sets, distractor identity information (i.e., context information) could cue knowledge of target shape information, reducing search time.

In the present study we employed eye movement monitoring as an index of learning in addition to reaction time. Eye movements have been shown to be a tangible trace of perceptual and attentional processes, and represent an ideal indirect measure of processing which can be recorded unobtrusively, concurrent with direct discrimination measures of performance. This may allow for demonstrating dissociations between some aspects of eye movement behavior, such as saccadic selectivity, and overt task performance, such as reaction time. Employing such methodology, this research investigates whether we can learn to make a more efficient visual search based on a covariation that *across* search displays provides target identity information, as well as addressing how awareness of this information affects search performance. In addition, by employing multiple methodologies to empirically investigate implicit and explicit learning, we hope to make progress towards the goal of demonstrating qualitative differences between these processes.

To this end, we exploited a well-established finding in the eye movement and visual search literature that demonstrates a bias in the distribution of saccadic endpoints toward distractors that share stimulus dimensions and features with the target including color, shape, contrast polarity, and size (e.g., Findlay, 1997; Hooge & Erkelens, 1999; Pomplun, Reingold, & Shen, 2001, 2003; Pomplun, Reingold, Shen, & Williams, 2000; Scialfa & Joffe, 1998; Shen & Reingold, 1999; Shen,

Reingold, & Pomplun, 2000, 2003; Shen, Reingold, Pomplun, & Williams, 2003; Williams & Reingold, 2001). This finding is typically referred to as saccadic selectivity.

In the present study participants performed a visual search task in the 'change blindness' flicker paradigm (Rensink, O'Regan, & Clark, 1997). As shown in Figure 1, participants were asked to detect a letter (target) that differed in color (see Panel A) or shape (see Panel B) across otherwise identical alternating letter arrays. In a subset of trials, there was a covariation embedded in the task that reduced the target to half of the display items. Reaction times for the trials containing the covariation (Covariant trials), were compared to the reaction times obtained for the trials that did not contain covariation information (Random trials). In addition, half of the participants were told of the existence of a covariation (Informed group) and the other half were not notified of this regularity (Uninformed group). Learning of the covariation rule would be expressed by faster reaction times for the Covariant trials than for the Random trials. In addition, learning of the covariation rule would provide target identity information and may be manifested as a bias towards fixating on the letters that have the same shape or color as the target (i.e., saccadic selectivity). Finally, we were also interested in determining if there would be differential search performance across the Informed and Uninformed groups reflecting qualitative differences between implicit and explicit learning.

Methods

Participants

Forty-eight participants were paid $20 for their involvement in the two hour experiment: 24 participants searched for the letter that differed in shape and 24 participants searched for the letter that differed in color. Half of the participants in each group were informed of the covariation information (Informed group), while the other half were not (Uninformed group). Participants were tested individually, and all had normal or corrected-to-normal vision.

Apparatus

The eyetracker employed in this research was the SR Research Ltd. EyeLink system. This system has high spatial resolution (0.005°), and a sampling rate of 250 Hz (4 msec temporal resolution). The EyeLink headband has three cameras, allowing simultaneous tracking of both eyes and of head position for head-motion compensation. By default, only the participant's dominant eye was tracked in our study. The EyeLink system uses an Ethernet link between the eyetracker and display computers for real-time saccade and gaze position data transfer. In the present study the configurable acceleration and velocity thresholds were set to detect saccades of 0.5° or greater.

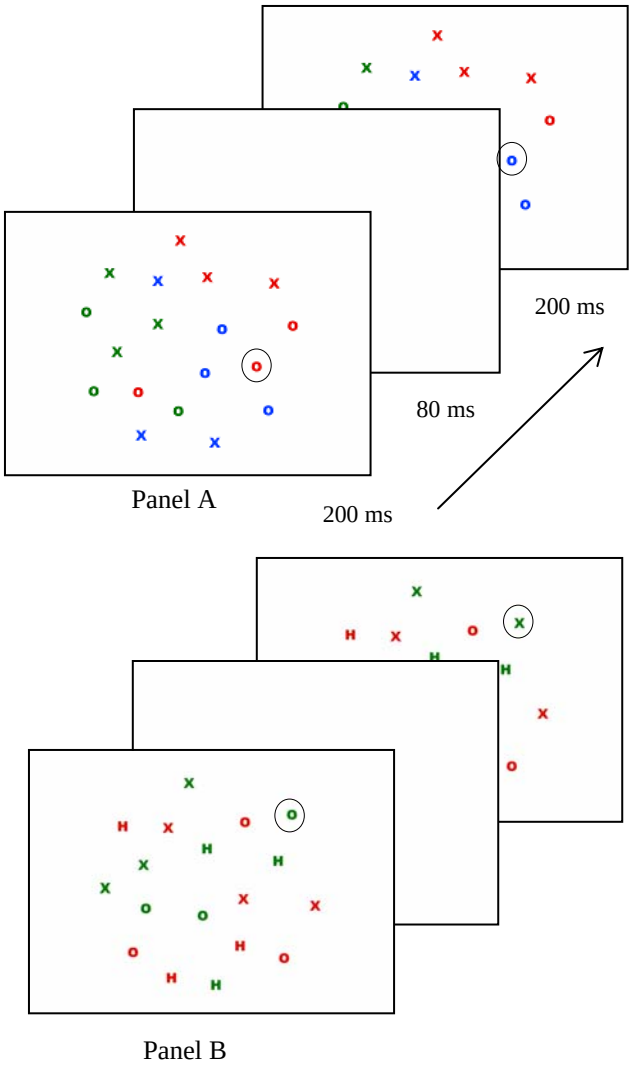

Figure 1: An illustration of the change blindness paradigm. Panel A shows a target changing color, and Panel B shows a target changing shape. The targets are circled for illustration purposes only.

Stimulus displays were presented on two monitors, one for the participant (a 17-inch Viewsonic 17PS) and one for the experimenter. The experimenter monitor was used to give feedback in real-time about the participant's computed gaze position. This feedback was given in the form of a cursor measuring 1° in diameter which was overlaid on the same image being viewed by the participant. This allowed the experimenter to evaluate system accuracy and to initiate a recalibration if necessary. In general, the average error in the computation of gaze position was less than 0.5° of visual angle.

Materials and Design

As shown in Figure 1, the change blindness flicker paradigm was used (Rensink et al., 1997). As can be seen, in each trial, the screen flickered between the

display and a blank screen (200ms display/80ms blank screen/200ms display). Displays were composed of 18 letters (1 target, 17 distractors) that were arrayed on three invisible concentric rings. On all trials there was an equal number of letters of each color and shape. The radii of the rings were 2.8, 5.6, and 8.3 degrees of visual angle (at a distance of 70 cm). The minimum distance between items was set at 3.5 degrees. Individual letters subtended 0.86 degrees both horizontally and vertically. Colors were matched in luminance and saturation (CIE coordinates: *x*, *y*, red: 0.578, 0.350, green: 0.327, 0.549, blue: 0.170, 0.117 and yellow: 0.446, 0.454). The location of the target and the configuration of the distractor items were randomized for every trial.

As the screen flickered, the participants' task was to detect the letter (target) that differed in color or shape. For trials where the target changed color, half of the displays contained an equal number of X's and O's (X/O displays), and half of the displays contained an equal number of C's and T's (C/T displays). In both cases, an equal number of red, green and blue letters was displayed, one of which was chosen at random to change color. For example, Figure 1, Panel A shows an X/O display where the target (which is circled for illustrative purposes) changes color from red to blue. In this trial the screen would alternate between the display with the red target letter, the blank display, and the display with the blue target letter, until the participant found the target. Alternatively, for trials where the target changed shape, half of the displays contained an equal number of green and red letters (green/red displays), and half of the displays contained an equal number of yellow and blue letters (yellow/blue displays). In both cases, an equal number of X's, O's, and H's was displayed, one of which was chosen at random to change shape. For example, Panel B shows a green/red display where the target changes shape from an O to an X. In this trial the screens would alternate between the given displays until the participant located the target changing shape.

In a subset of each of these types of trials, there was a covariation embedded in the task that reduced the possible target locations to half of the display items. Two covariation rules were used as illustrated in Table 1. In the Shape rule condition, the displays contained either thick letters or thin letters. Letter thickness predicted target shape in the Covariant trials, but not the Random trials. In the example in Table 1, X/O displays correspond to Covariant trials, in which thick letter displays predicted the target to be an X and thin letter displays predicted the target to be an O. In contrast, C/T displays correspond to the Random trials, in which letter thickness did not predict target shape.

In the Color rule condition, the displays contained either a light or a dark background. Background luminance predicted target color in the Covariant trials, but not the Random trials. In the example in Table 1,

Table 1: An illustration of the covariation rules for the Shape and Color conditions.

Rule Condition	Display type	Trials: Covariant	Trials: Random
Shape (Fig. 1 Panel A)	Thick Letter	X -> X	C -> C or T -> T
	Thin Letter	O -> O	C -> C or T -> T
Color (Fig. 1 Panel B)	Light Background	O -> X	O -> X or O -> X
	Dark Background	O -> X	O -> X or O -> X

green/red displays correspond to Covariant trials, in which a light background predicted the target to be green and a dark background predicted the target to be red. In contrast, yellow/blue displays correspond to the Random trials, in which background luminance did not predict target color.

Each participant performed 624 trials. The order of the stimulus displays was random under the restrictions that there be no more than 4 displays of a given display type or trial type in a row, and that each 48 trial block contained an equal number of trials of each display type and each trial type (Covariant, Random). Mapping of the display types to conditions was counterbalanced across participants.

Procedure

The experiment was run in a lighted room with a luminance of approximately 30 cd/m^2. Before beginning the task, the participants were informed that stimulus displays would consist of letters that would flash intermittently, and that their task was to search for and detect the single letter that was changing shape, for participants in the Color rule condition, or changing color, for participants in the Shape rule condition. Participants were asked to locate the target as quickly as possible and terminate the trial by maintaining fixation on the target. Participants then completed 48 practice trials, followed by 2 blocks of 288 experimental trials. Every 48 trials participants were given a rest break.

At the beginning of each trial, a fixation point was presented in the center of the computer screen in order to correct for drift in gaze position. A button press from the participant initiated the trial and it ended 700 ms after the participant fixated on the target (gaze-controlled response). The time between display onset and the participant's gaze-controlled response was recorded as the response time (RT). In addition, the participant's eye movements, monitored via the EyeLink tracking system, were recorded.

In order to compare explicit and implicit covariant rule learning, following completion of the practice block, half of the 24 participants in the each rule condition were told that there was a 100% covariation between the relevant features in one of the two display types (the Informed group). However, they were not told which display type contained the covariation. The other half of participants were not told anything about this relationship (the Uninformed group). At the end of the experiment a structured questionnaire was given to investigate awareness of the covariation.

Results

Reaction Time

For each participant and condition the mean RT was calculated, excluding those trials that were greater than 3 standard deviations from the mean. This resulted in less than 3% of trials being omitted. As Figure 2 reveals, RTs improved over the course of the experiment ($F\ (2, 88)$ = 101, p <.001) and were faster for Covariant than Random trials ($F\ (1, 44)$ = 31.6, p <.001). Importantly, participants improved more over time for Covariant trials than for Random trials, demonstrating a reaction time benefit for learning the covariation, $F\ (2, 88)$ = 3.87, p = .025. Moreover, this RT benefit of Covariant trials over Random trials was significant for both the Informed ($F\ (1, 22)$ = 96.9, p < .001) and Uninformed ($F\ (1, 22)$ = 9.40, p < .01) groups. There were no RT differences for the practice block across trial type ($t\ (1, 47)$ = .82, p > .4).

As can be seen upon further inspection of Figure 2, the instruction manipulation (Informed, Uninformed) affected the degree to which participants benefited from the covariation information. Specifically, there was a greater benefit for the Covariant trials over the Random trials for participants in the Informed group (mean difference = 1010 ms) as compared to participants in the Uninformed group (mean difference = 165 ms), $F\ (1, 44)$ = 53.1, p < .001. Further, Informed participants showed significantly greater RT advantages for Covariant trials than for Random trials in the Color rule condition (mean difference: 1520 ms, SE = 180) when compared to the Shape rule condition (mean difference: 500 ms, SE = 98.0), F (1, 22) = 24.7, p < .001). In contrast, the Uninformed participants showed no differential RT benefit across rule conditions (F (1, 22) < 1, mean difference: 155 ms, SE = 81.2, for the Color rule condition vs. mean difference: 175 ms, SE = 70.8, for the Shape rule condition). These differences manifested themselves as a trial type by instruction by rule condition interaction, $F\ (1, 44)$ = 20.1, p < .001.

Saccadic Selectivity

Saccadic selectivity was computed by assigning saccadic endpoints to the closest display item and calculating the percentage of saccades directed towards the 7 distractors out of the total of 17 distractors that shared shape with the target in the Shape rule condition or color with the target

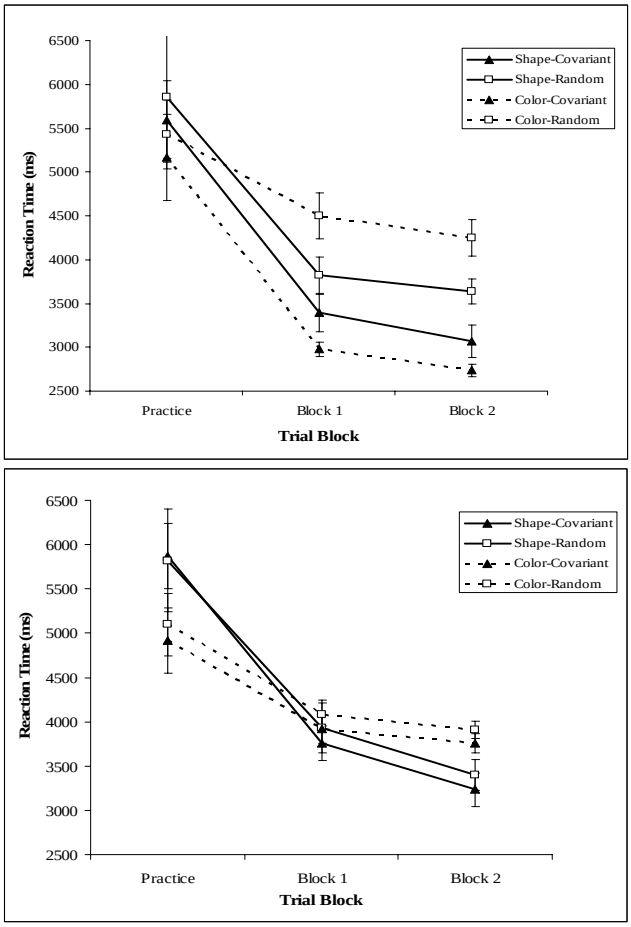

Figure 2: Reaction time by trial Block is shown for both the Covariant and Random trials by rule condition (Shape, Color). The top panel contains the results for the Informed group, and the bottom panel contains the results for the Uninformed group.

in the Color rule condition. Accordingly, chance performance on the saccadic selectivity measure (i.e., when all distractors have an equal probability of being fixated) was expected to be 47.06%. Consistent with this, saccadic selectivity was at chance (Mean = 47.06; all t's $(1, 47)$ < 1, p's > .5) for the Random trials over the course of the experiment. In contrast, as can be seen in Figure 3, while saccadic selectivity did not significantly differ from chance for Covariant trials for the practice block (Mean = 47.06; $t\ (1, 47)$ = 1.24, p > .2), participants' saccadic selectivity increased over time, demonstrating a behavioral consequence for learning of the covariation, $F\ (2, 88)$ = 81.3, p < .001. This bias towards fixating on the letters that had the same shape or color as the target occurred more strongly for the Informed participants ($F\ (1, 22)$ = 27.5, p < .001), than the Uninformed participants ($F\ (1, 22)$ = 10.3, p < .005). Further, Informed participants showed significantly greater saccadic selectivity in the Color rule condition (mean = 75.3%, SE = 1.57) as compared to the Shape rule condition (mean =

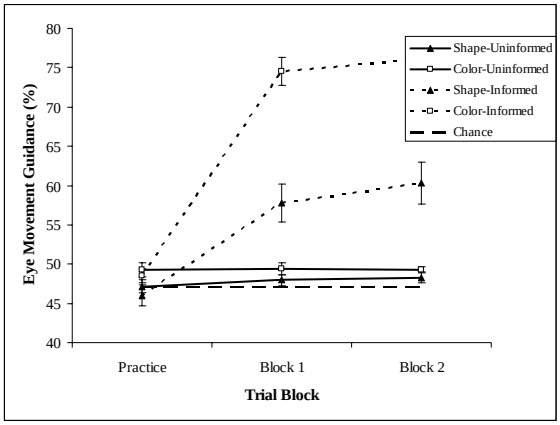

Figure 3: Percent eye-movement guidance by trial Block for the Covariant trials by group (Informed, Uninformed) and rule condition (Shape, Color). Chance guidance is shown by a dashed line at 47.08%. The practice block contains 48 trials, and Blocks 1 and 2 average 288 trials each.

59.1%, SE = 2.43), F (1, 22) = 31.5, p < .001). In contrast, the Uninformed participants showed no differential saccadic selectivity across rule conditions (F (1, 22) = 3.05, p = .095; mean = 49.3%, SE = .482 for the Color rule condition, mean = 48.2%, SE = .476 for the Shape rule condition). These differences manifested themselves as an instruction by rule condition interaction, $F\ (1, 44) = 25.71$, $p < .001$.

The effectiveness of the instructions was further evaluated by a retrospective report in the form of a structured questionnaire and intensive questioning. It was found that participants in the Uninformed group reported being unaware of the covariation, while those in the Informed group could explain the covariation, consistent with instructions. In fact, most Uninformed participants expressed disbelief when they were told of the covariation, reporting that they thought that letter thickness (for those in the Shape rule condition), or background luminance (for those in the Color rule condition), were irrelevant.

Discussion

In an attempt to make progress towards the goal of demonstrating qualitative differences between implicit and explicit processing, the present study employed eye movement monitoring as an index of learning, in addition to reaction time, to further explore implicit learning in the context of visual search. It was found that participants can enhance visual search efficiency by utilizing a covariation that provided target identity information, and that such learning occurs even when participants are uninformed and claim to be unaware of this information. Implicit learning was most strongly demonstrated by the response time measure. Specifically, for the Uninformed participants, while the RT measure showed savings for trials containing the covariant rule condition (165ms in both the Shape and Color rule conditions), only a slight saccadic selectivity (1% bias in the Shape rule condition and 2% bias in the Color rule condition) favoring relevant distractors was demonstrated. In contrast, participants who were informed of the covariation rule showed substantial learning of the covariation in the form of a reaction time advantage (500ms in the Shape rule condition and 1520ms in the Color rule condition) and saccadic selectively (12% bias in the Shape rule condition and 28% bias in the Color rule condition). Taken together, saccadic selectivity seems to be one mechanism by which Informed participants made their search more efficient, whereas the weak selectivity displayed by the Uninformed participants suggests that this was not the primary mechanism employed by this group. Future investigation into what other means the Uninformed participants were using to improve search efficiency is warranted. The different picture portrayed by the RT and saccadic selectivity results points to the importance of using multiple concurrent measures of performance in attempting to more conclusively document implicit learning and in attempting to better understand the mechanisms underlying variation in performance associated with the presence or absence of claimed awareness pertaining to the learned covariation.

The present finding of implicit learning in visual search is consistent with previous evidence using other visual search paradigms (e.g., Chun & Jiang, 1999; Chun & Nakayama, 2000; Durgin, 1999; Flowers & Smith, 1998; Miller, 1991). A benefit to our use of the change blindness paradigm was that it allowed us to create a methodology whereby no target-absent trials were needed and where the covariant rule involved a dimension that was seemingly irrelevant to the search task.

Finally, the rule condition (Color, Shape) differentially influenced performance in the Informed and Uninformed groups. Specifically, the Informed participants in the Color rule condition were able to use the covariation information to a greater extent than those in the Shape rule condition, as shown by both the RT and saccadic selectivity results (see Figure 2 and 3, respectively). In contrast, no such differential sensitivity across rule condition was found for the Uninformed participants for either of these measures. We believe that the demonstration of differential search performance across groups and conditions in the present study constitutes progress toward the crucial goal of establishing qualitative differences between implicit and explicit learning in the context of visual search.

Structure Dependence in Language Acquisition: Uncovering the Statistical Richness of the Stimulus

Florencia Reali (fr34@cornell.edu) and Morten H. Christiansen (mhc27@cornell.edu)
Department of Psychology; Cornell University; Ithaca, NY 14853 USA

Abstract

The *poverty of stimulus argument* is one of the most controversial arguments in the study of language acquisition. Here we follow previous approaches challenging the assumption of impoverished primary linguistic data, focusing on the specific problem of auxiliary fronting in polar interrogatives. We develop a series of child-directed corpus analyses showing that there is indirect statistical information useful for correct auxiliary fronting in polar interrogatives, and that such information is sufficient for producing grammatical generalizations even in the absence of direct evidence. We further show that there are simple learning devices, such as neural networks, capable of exploiting such statistical cues, producing a bias to correct *aux*-questions when compared to their ungrammatical counterparts. The results suggest that the basic assumptions of the poverty of stimulus argument need to be reappraised.

Introduction

How do children learn aspects of their language for which there appears to be no evidence in the input? This question lies at the heart of the most enduring and controversial debates in cognitive science. Ever since Chomsky (1965), it has been argued that the information in the linguistic environment is too impoverished for a human learner to attain adult competence in language without the aide of innate linguistic knowledge. Although this *poverty of the stimulus argument* (Chomsky, 1980; Crain & Pietroski, 2001) has guided most research in linguistics, it has proved to be much more contentious within the broader context of cognitive science.

The poverty of stimulus argument rests on certain assumptions about the nature of the input to the child, the properties of computational learning mechanisms, and the learning abilities of young infants. A growing bulk of research in cognitive science has begun to call each of these three assumptions into question. Thus, whereas the traditional nativist perspective suggests that statistical information may be of little use for syntax acquisition (e.g., Chomsky, 1957), recent research indicates that distributional regularities may provide an important source of information for syntactic bootstrapping (e.g., Mintz, 2002; Redington, Chater and Finch, 1998)—especially when integrated with prosodic or phonological information (e.g., Christiansen & Dale, 2001; Morgan, Meier & Newport, 1987). And while the traditional approach only tends to consider learning in highly simplified forms, such as "move the first occurrence of *X* to *Y*", progress in statistical natural language processing and connectionist modeling has revealed much more complex learning abilities of potential relevance for language acquisition (e.g., Lewis & Elman, 2001). Finally, little attention has traditionally been paid to what young infants may be able to learn, and this may be problematic given that recent research has demonstrated that even before one year of age, infants are quite competent statistical learners (Saffran, Aslin & Newport, 1996—for reviews, see Gómez & Gerken, 2000; Saffran, 2003).

These research developments suggest the need for a reappraisal of the poverty of stimulus argument, centered on whether they together can answer the question of how a child may be able to learn aspects of linguistic structure for which innate knowledge was previously thought to be necessary. In this paper, we approach this question in the context of structure dependence in language acquisition, specifically in relation to auxiliary fronting in polar interrogatives. We first outline the poverty of stimulus debate as it has played out with respect to forming grammatical questions with auxiliary fronting. It has been argued that the input to the child does not provide enough information to differentiate between correct and incorrect auxiliary fronting in polar interrogatives (Chomsky in Piatelli-Palmarini, 1980). In contrast, we conduct a corpus analysis to show that there is sufficiently rich statistical information available in child-directed speech for generating correct *aux*-questions—even in the absence of any such constructions in the corpus. We additionally demonstrate how the same approach can be applied to explain results from studies of auxiliary fronting in 3- to 5-year-olds (Crain & Nakayama, 1987). Whereas, the corpus analyses indicate that there is rich statistical information available in the input, it does not show that there are learning mechanisms capable of utilizing such information. We therefore conduct a set of connectionist simulations to illustrate that neural networks are capable of using statistical information to distinguish between correct and incorrect *aux*-questions. In the conclusion, we discuss our results in the context of recent infant learning results.

The Poverty of Stimulus and Structure Dependence in Auxiliary Fronting.

Children only hear a finite number of sentences, yet they learn to speak and comprehend sentences drawn from a language that can contain an infinite number of sentences. The poverty of stimulus argument suggests that children do

not have enough data during the early stages of their life to learn the syntactic structure of their language. Thus, learning a language involves the correct generalization of grammatical structure when insufficient data is available to children. The possible weakness of the argument lies in the difficulty to assess the input, and in the imprecise and intuitive definition of 'insufficient data'.

One of the most used examples to support the poverty of stimulus argument concerns auxiliary fronting in polar interrogatives. Declaratives are turned into questions by fronting the correct auxiliary. Thus, for example, in the declarative form '*The man who is hungry is ordering dinner'* it is correct to front the main clause auxiliary as in 1, but fronting the subordinate clause auxiliary produces an ungrammatical sentence as in 2 (Chomsky, 1965).

1. *Is the man who is hungry ordering dinner?*
2. **Is the man who hungry is ordering dinner?*

Children can generate two types of rules: a structure-independent rule where the first *'is'* is moved; or the correct structure-dependent rule, where only the movement of the *'is'* from the main clause is allowed. Crucially, children do not appear to go through a period when they erroneously move the first *is* to the front of the sentence (e.g., Crain & Nakayama, 1987). It has moreover been asserted that a person might go through much of his or her life without ever having been exposed to the relevant evidence for inferring correct auxiliary fronting (Chomsky, in Piatelli-Palmarini, 1980).

The purported absence of evidence in the primary linguistic input regarding auxiliary fronting in polar interrogatives is not without debate. Intuitively, as suggested by Lewis & Elman (2001), it is perhaps unlikely that a child would reach kindergarten without being exposed to sentences such as 3-5.

3. *Is the boy who was playing with you still there?*
4. *Will those who are hungry raise their hand?*
5. *Where is the little girl full of smiles?*

These examples have an auxiliary verb within the subject NP, and thus the auxiliary that appears initially would not be the first auxiliary in the declarative, providing evidence for correct auxiliary fronting. Pullum & Scholz (2002) explored the presence of auxiliary fronting in polar interrogatives in the Wall Street Journal (WSJ). They found that at least five crucial examples occur in the first 500 interrogatives. These results suggest that the assumption of complete absence of evidence for correct auxiliary fronting is overstated. Nevertheless, it has been argued that the WSJ corpus is not a good approximation of the grammatical constructions that young children encounter and thus it cannot be considered representative of the primary linguistic data. Indeed, studies of the CHILDES corpus show that even though interrogatives constitute a large percentage of the corpus, relevant examples of auxiliary fronting in polar interrogatives represent less than 1% of them (Legate & Yang, 2002).

Although the direct evidence for auxiliary fronting in polar interrogatives may be too weak to be helpful in acquisition—as suggested by Legate & Yang (2002)—other more indirect sources of statistical information may provide sufficient basis for making the appropriate grammatical generalizations. Recent connectionist simulations provide preliminary data in this regard. Lewis & Elman (2001) trained simple recurrent networks (SRN; Elman, 1990) on data from an artificial grammar that generated questions of the form 'AUX NP ADJ?' and sequences of the form 'A_i NP B_i' (where A_i and B_i represent a variety of different material) but no relevant examples of polar interrogatives. The SRNs were better at making predictions for correct auxiliary fronting compared to those with incorrect auxiliary fronting. This indicates that even without direct exposure to relevant examples, the statistical structure of the input nonetheless provides useful information applicable to auxiliary fronting in polar interrogatives.

However, the SRNs in the Lewis & Elman simulation studies were exposed to an artificial grammar without the complexity and noisiness that characterizes actual child-directed speech. The question thus remains whether the indirect statistical regularities in an actual corpus of child-directed speech are strong enough to support grammatical generalizations over incorrect ones—even in the absence of direct examples of auxiliary fronting in polar interrogatives in the input. Next, in our first experiment, we conduct a corpus analysis to demonstrate that the indirect statistical information available in a corpus of child-directed speech is indeed sufficient for making the appropriate grammatical generalizations in questions involving auxiliary fronting.

Experiment 1: Measuring Indirect Statistical Information Relevant for Auxiliary Fronting

Even if children only hear a few relevant examples of polar interrogatives, they may nevertheless be able to rely on indirect statistical cues for learning the correct structure. In order to assess this hypothesis, we trained bigram and trigram models on the Bernstein-Ratner (1984) corpus of child-directed speech and then tested the likelihood of novel example sentences. The test sentences consisted of correct polar interrogatives (e.g. *Is the man who is hungry ordering dinner?*) and incorrect ones (e.g. *Is the man who hungry is ordering dinner?*)—neither of which were present in the training corpus. We reasoned that if indirect statistical information provides a possible cue for generalizing correctly to the grammatical *aux*-questions, then we should find a difference in the likelihood of these two alternative hypotheses.

Bigram/trigram models are simple statistical models that use the previous one/two word(s) to predict the next one. Given a string of words or a sentence it is possible to compute the associated cross-entropy for that string of words according to the bigram/trigram model trained on a particular corpus (from Chen & Goodman, 1996). Thus, given two alternative sentences we can compare the probability of each of them as indicated by their associated cross-entropy as computed in the context of a particular corpus. Specifically, we can compare the two alternative

generalizations of doing auxiliary fronting in polar interrogatives, comparing the cross-entropy associated with grammatical (e.g., *Is the man who is in the corner smoking?*) and ungrammatical forms (e.g., *Is the man who in the corner is smoking*). This will allow us to determine whether there may be sufficient indirect statistical information available in actual child-directed speech to decide between these two forms. Importantly, the Bernstein-Ratner corpus contains no examples of auxiliary fronting in polar interrogatives. Our hypothesis is therefore that the corpus nonetheless contains enough statistical information to decide between grammatical and ungrammatical forms.

Method

Models For the purpose of corpus analysis we used bigram and trigram models of language (see e.g., Jurafsky & Martin, 2000). The probability P(*s*) of a sentence was expressed as the product of the probabilities of the words (w_i) that compose the sentence, with each word probability conditional to the last *n*-1 words. Then, if s = $w_1 \ldots w_k$ we have:

$$P(s) = \Pi_i P(w_i|w^{i-1}_{i-n+1})$$

To estimate the probabilities of $P(w_i|w_{i-1})$ we used the *maximum likelihood* (ML) estimate for $P(w_i|w_{i-1})$ defined as (considering the bigram model):

$$P_{ML}(w_i|w_{i-1}) = P(w_{i-1}w_i) / P(w_{i-1}) = (c(w_{i-1}w_i)/Ns)/(c(w_{i-1})/Ns);$$

where Ns denote the total number of tokens and $c(\alpha)$ is the number of times the string α occurs in the corpus. Given that the corpus is quite small, we used the *interpolation smoothing technique* defined in Chen & Goodman (1996). The probability of a word (w_i) (or unigram model) is defined as:

$$P_{ML}(w_i) = c(w_i)/Ns;$$

The smoothing technique consists of the interpolation of the bigram model with the unigram model, and the trigram model with the bigram model. Thus, for the bigram model we have:

$$P_{interp}(w_i|w_{i-1}) = \lambda P_{ML}(w_i|w_{i-1}) + (1-\lambda)P_{ML}(w_i)$$

Accordingly for trigram models we have:

$$P_{interp}(w_i|w_{i-1}w_{i-2}) = \lambda P_{ML}(w_i|w_{i-1}w_{i-2}) + (1-\lambda)(\lambda P_{ML}(w_i|w_{i-1}) + (1-\lambda)P_{ML}(w_i)),$$

where λ is a value between 0 and 1 that determines the relative importance of each term in the equation. We used a standard $\lambda = 0.5$ so that all terms are equally weighted. We measure the likelihood of a given set of sentences using the measure of cross-entropy (Chen & Goodman, 1996). The cross-entropy of a set of sentences is defined as:

$$1/N_T \Sigma_i -\log_2 P(s_i) \quad \text{(where } s_i \text{ is the i}^{th} \text{ sentence).}$$

The cross-entropy value of a sentence is inversely correlated with the likelihood of it. Given a training corpus, and two sentences A and B we can compare the cross-entropy of both sentences and estimate which one is more probable according to the statistical information of the corpus. We used Perl programming in a Unix environment to implement the corpus analysis. This includes the simulation of bigram and trigram models and cross-entropy calculation and comparisons.

Materials We used the Bernstein-Ratner (1984) corpus of child-directed speech for our corpus analysis. It contains recorded speech from nine mothers speaking to their children over 4-5 months period when children were between the ages of 1 year and 1 month to 1 year and 9 months. This is a relatively small and very noisy corpus, mostly containing short sentences with simple grammatical structure. The following are some example sentences: *Oh you need some space; Where is my apple?; Oh. That's it*'.

Procedure We used the Bernstein-Ratner child-directed speech corpus as the training corpus for the bigram/trigram models. The models were trained on 10,082 sentences from the corpus (34,010 word tokens; 1,740 word types). We wanted to compare the cross-entropy of grammatical and ungrammatical polar interrogatives. For that purpose, we created two novel sets of sentences. The first one contained grammatically correct polar interrogatives and the second one contained the ungrammatical version of each sentence in the first set. The sentences were created using a random algorithm that selected words from the corpus, and created sentences according to syntactic and semantic constraints. We tried to prevent any possible bias in creating the test sentences. The test sets only contained relevant examples of polar interrogatives of the form: "*Is* / NP/ (who/that)/ *is* / A_i/ B_i?", where A_i and B_i represent a variety of different material including VP, PARTICIPLE,NP, PP, ADJP (e.g.: *"Is the lady who is there eating?*"; "*Is the dog that is on the chair black?*"). Each test set contained 100 sentences. We estimated the mean cross-entropy per sentence by calculating the average cross-entropy of the 100 sentences in each set. Then we compared the likelihood of pairs of grammatical and ungrammatical sentences by comparing their cross-entropy and choosing the version with the lower value. We studied the statistical significance of the results using paired t-test analyses.

Results

We found that the mean cross-entropy of grammatical sentences was lower than mean cross entropy of ungrammatical sentences. We performed a statistical analysis of the cross-entropy difference, considering all pairs of grammatical and ungrammatical sentences. The cross-entropy difference was highly significant (t(99), $p<0.0001$) (see Table 1). These results show that grammatical sentences have a higher probability than ungrammatical ones. In order to compare each grammatical-ungrammatical pair of sentences, we defined the following criterion: When deciding between each grammatical vs. ungrammatical polar interrogative example, choose the one that has lower cross-entropy (the most probable one).

Table 1: Comparison of mean cross-entropy in Exp.1.

	Mean cross-entropy		Mean difference	t(99) p-value
	Gram.	Ungramm.		
Bigram	22.92	23.73	0.83	< 0.0001
Trigram	21.81	23.07	1.26	< 0.0001

A sentence is defined as correctly classified if the chosen form is grammatical. Using that criterion, we found that the percentage of correctly classified sentences using the bigram model is 92% and using the trigram model is 95%. Figure 1 shows the performance of the models according to the defined classification criterion. Of the 100 test sentences, the trigram model only misclassified the following five: *Is the lady who is here drinking?; Is the alligator that is standing there red?; Is the jacket that is on the chair lovely?; Is the one that is in the kitchen scared?; Is the phone that is in the office purple?*

The bigram model in addition to the above five sentences also misclassified the next three test sentences: *Is the bunny that is in the car little; Is the baby who is in the castle eating?; Is the bunny that is sleeping black?*

It is possible to calculate the probability of a sentence from the cross-entropy value. Figure 2 shows the comparison of mean probability of grammatical and ungrammatical sentences. We found that the mean probability of grammatical polar interrogatives is almost twice the mean probability of ungrammatical polar interrogatives according to the bigram model and it is more than twice according to the trigram model.

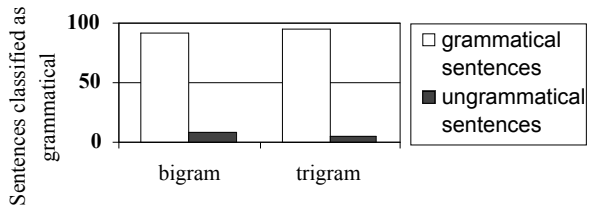

Figure 1: Number of sentences classified correctly (white bars) and incorrectly as grammatical (gray bars)

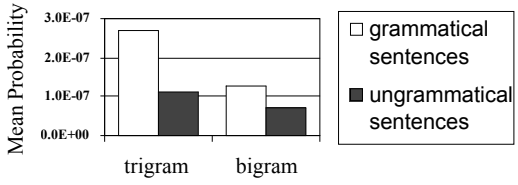

Figure 2: Mean probability of grammatical sentences vs. mean probability of ungrammatical sentences.

Experiment 2: Testing Sentences with Auxiliary Fronting Produced by Children

Although Experiment 1 shows that there is sufficient indirect statistical information available in child-directed speech to differentiate reliably between the grammatical and ungrammatical *aux*-questions that we had generated, it could be argued that the real test for our approach is whether it works for actual sentences produced by children. We therefore tested our models on a small set of sentences elicited from children under experimental conditions.

Crain & Nakayama (1987) conducted an experiment designed to elicit complex *aux*-questions from 3- to 5-year-old children. The children were involved in a game in which they asked questions to Jabba the Hutt, a creature from Star Wars. During the task the experimenter gives an instruction to the child: *'Ask Jabba if the boy who is watching Mickey Mouse is happy'*. Children produced sentences like a) *'Is the boy who is watching Mickey Mouse happy?'* but they never produced sentences like b) *'Is the boy who watching Mickey Mouse is happy?'*. The authors concluded that the lack of structure-independent errors suggested that children entertain only structure-dependent hypotheses, supporting the existence of innate grammatical structure.

Method

Models Same as in Experiment 1.

Materials Six example pairs were derived from the declarative sentences used in Crain & Nakayama[1](1987):

6. *The ball that the girl is sitting on is big*
7. *The boy who is unhappy is watching Mickey Mouse*
8. *The boy who is watching Mickey Mouse is happy*
9. *The boy who is being kissed by his mother is happy*
10. *The boy who was holding the plate is crying*
11. *The dog that is sleeping is on the blue bench*

The grammatical and ungrammatical *aux*-questions were derived from the declaratives in 6-11. Thus, the sentence '*Is the dog that is sleeping on the blue bench?*' belonged to the grammatical test set whereas the sentence '*Is the dog that sleeping is on the blue bench?*' belonged to the ungrammatical test set. Consequently, grammatical and ungrammatical test sets contained 6 sentences each.

Procedure The bigram/trigram models were trained on the Bernstein-Ratner (1984) corpus as in Experiment 1, and tested on the material derived from Crain & Nakayama (1987).

Results

Consistently with Experiment 1, we found that the mean cross-entropy of grammatical sentences was significantly lower than the mean cross entropy of ungrammatical sentences both for bigram and trigram models ($t(5)$ $p<0.013$ and $p<0.034$ respectively). Table 2 summarizes these results.

[1] As some of the words in the examples were not present in the Bernstein-Ratner corpus, we substitute them for semantically related ones: Thus, the words: "mother", "plate", "watching", "unhappy" and "bench" were replaced respectively by "mommy", "ball", "looking at", "crying" and "chair".

Using the classification criterion defined in Experiment 1, we found that all six sentences were correctly classified using the bigram model. That is, according to the distributional information of the corpus, all grammatical *aux*-questions were more probable than the ungrammatical version of them. When using the trigram model, we found that five out of six sentences were correctly classified.

Table 2: Comparison of mean cross-entropy in Exp.2.

	Mean cross-entropy		Mean difference	t(5) p-value
	Gram.	Ungramm.		
Bigram	26.99	27.89	0.90	< 0.013
Trigram	25.97	26.86	0.89	< 0.034

Experiment 3: Learning to Produce Correct Sentences with Auxiliary Fronting

While Experiments 1 and 2 establish that there is sufficient indirect statistical information in the input to the child to differentiate between grammatical and ungrammatical questions involving auxiliary fronting—including questions produced by children—it is not clear whether a simple learning device may be able to exploit such information to develop an appropriate bias toward the grammatical forms. To investigate this question, we took a previously developed SRN model of language acquisition (Reali, Christiansen & Monaghan, 2003), which had also been trained on the same corpus, and tested its ability to deal with *aux*-questions.

Previous simulations by Lewis & Elman (2001) have shown that SRNs trained on data from an artificial grammar were better at predicting the correct auxiliary fronting in *aux*-questions. An important question is whether the results shown using artificial-language models are still obtained when dealing with the full complexity and the general disorderliness of speech directed at young children. Thus, we seek to determine whether a previously developed connectionist model, trained on the same corpus, is sensitive to the same indirect statistical information that we have found to be useful in bigram/trigram models. SRNs are simple learning devices that have been shown to be sensitive to bigram/trigram information.

Method

Networks We used the same ten SRNs that Reali, Christiansen & Monaghan (2003) had trained to predict the next lexical category given the current one. These networks had initial weight randomization in the interval [-0.1; 0.1]. A different random seed was used for each simulation. Learning rate was set to 0.1, and momentum to 0.7. Each input to the network contained a localist representation of the lexical category of the incoming word. With a total of 14 different lexical categories and a pause marking boundaries between utterances, the network had 15 input units. The network was trained to predict the lexical category of the next word, and thus the number of output units was 15. Each network had 30 hidden units and 30 context units. All networks were simulated using the Lens simulator in a Unix environment. No changes were made to the original networks and their parameters.

Materials We trained and tested the networks on the Bernstein-Ratner corpus similarly to the bigram/trigram models. Each word in the corpus corresponded to one of the 14 following lexical categories from CELEX database (Baayen, Pipenbrock & Gulikers, 1995): nouns, verbs, adjectives, numerals, infinitive markers, adverbs, articles, pronouns, prepositions, conjunctions, interjections, complex contractions, abbreviations, and proper names. Each word in the corpus was replaced by a vector encoding the lexical category to which it belonged. We used the two sets of test sentences used in Experiment 1, containing grammatical and ungrammatical polar interrogatives respectively. However, as the network was trained to predict lexical classes, some test sentences defined in Experiment 1 mapped onto the same string of lexical classes. For simplicity, we only considered unique strings, resulting in 30 sentences in each test set (grammatical and ungrammatical).

Procedure The ten SRNs from Reali, Christiansen & Monaghan (2003) were trained on one pass through the Bernstein-Ratner corpus. These networks were then tested on the *aux*-questions described above. To compare network predictions for the ungrammatical vs. the grammatical *aux*-questions, we measured the networks' mean squared error recorded during the presentation of each test sentence pair.

Results

We found that in all ten simulations the grammatical set of aux-questions produced a lower error compared to the ungrammatical ones. The mean squared-error per next lexical class prediction was 0.80 for the grammatical set and 0.83 in the ungrammatical one, this difference being highly significant ($t(29)$ $p < 0.005$). Out of the 30 test sentences, 27 grammatical sentences produced a lower error than its ungrammatical counterpart. On the assumption that sentences with the lower error will be preferred, SRNs would pick the grammatical sentences in 27 out of 30 cases.

It is worth highlighting that the grammatical and ungrammatical sets of sentences were almost identical, only differing on the position of the fronted "is" as described in Experiment 1. Thus, the difference in mean squared error is uniquely due to the words' position in the sentence. Despite the complexity of child-directed speech, these results suggest that simple learning devices such as SRNs are able to pick up on the existing distributional properties showed in Experiment 1. Moreover, differently to Experiment 1, here we explored the distributional information of the lexical classes alone and thus the network was blind to the possible information present in word-word co-occurrences.

Conclusion

In the corpus analyses, we showed that there is sufficiently rich statistical information available *indirectly* in child-

directed speech for generating correct complex *aux*-questions—even in the absence of any such constructions in the corpus. We additionally demonstrated how the same approach can be applied to explain results from child-acquisition studies (Crain & Nakayama, 1987). These results indicate that indirect statistical information provides a possible cue for generalizing correctly to grammatical auxiliary fronting.

Whereas the corpus analyses indicate that there are statistical cues available in the input, it does not show that there are learning mechanisms capable of utilizing such information. However, previous results suggest that children are sensitive to the same kind of statistical evidence that we found in the present study. Saffran, Aslin & Newport (1996) demonstrated that 8 month-old children are particularly sensitive to transitional probabilities (similar to our bigram model). Sensitivity to transitional probabilities seems to be present across modalities, for instance in the segmentation of streams of tones (Saffran, Johnson, Aslin, & Newport, 1999). These and other results on infant statistical learning (see Gómez & Gerken, 2000) suggest that children have mechanisms for relying on implicit statistical information. SRNs are simple learning devices whose learning properties have been shown to be consistent with humans' learning abilities. Even though it was originally developed in a different context (Reali, Christiansen & Monaghan, 2003), our SRN model proved to be sensitive to the indirect statistical evidence present in the corpus, developing an appropriate bias toward the correct forms of *aux*-questions.

In conclusion, this study indicates that the poverty of stimulus argument may not apply to the classic case of auxiliary fronting in polar interrogatives, previously a corner stone in the argument for the innateness of grammar. Our results further suggest that the general assumptions of the poverty of stimulus argument may need to be reappraised in the light of the statistical richness of the language input to children.

Abstract

It is the usual case in cognitive modeling that a model's output is compared to the average of a number of subjects, in which case the enterprise of modeling is apparently to capture the behavior of the typical individual. Our approach is to administer two simple tasks to each subject, using performance on those tasks as measures of individual ability. Those measures are then used as the values for parameters in an ACT-R model of a more complex task, so that the model can predict individual performance on that task.

Introduction

Work in cognitive modeling, when it seeks validation in the performance of human subjects, is almost unanimously concerned with the average performance of many subjects. For many purposes, however, it is desirable to be able to model or predict *individual* performance. We present here the first work to use a fine-grained cognitive model to predict individual performance in a complex task.

The ACT-R architecture, the basis of a great deal of work in cognitive modeling, has a detailed, well-developed theory of cognition – perception, learning, performance, and so on (Anderson and Lebiere, 1998). The architecture by necessity contains a number of parameters that can be used to fix levels of performance in, e.g., memory, to realistic levels. The ACT-R community has by custom sought universal values for these parameters wherever possible, finding values work across tasks, optimizing how well the model fits the data of the average subject. These parameters are each *meaningful*, each parameter determining the model's behavior in one specific way. For example, there is a parameter called W that determines the sum of the activations of all the pieces of information that may be retrieved at any point in time. It therefore controls the model's working memory capacity. Extensive empirical work in ACT-R modeling (again, of the kind where the model was meant to predict the average subject) found that a W value of 1.0 produces very good fits with subject data.

It was later postulated, however, that the W parameter could be meaningfully varied in order to model individual differences in working memory capacity (Lovett, Reder, & Lebiere, 1999). This was later demonstrated empirically by using individual performance in one simple memory task to measure the W value that best fit the individual's performance. The diagnostic memory task is called MODS, or the modified digit span task. In each MODS trial, subjects are presented strings of digits to be read aloud in synchrony with a metronome beat and are required to remember the final digit from each string for later recall. After a certain number of digit strings are thus presented, a recall prompt cues the subject to report the memory digits in the order they were presented. Each subject's MODS score was used to estimate their individual W value, which was then plugged into an ACT-R model of a separate working memory task, and the model output was used to predict *individual* data on that second task (Daily, Lovett, & Reder, 2001).

Previous and concurrent work by other groups suggested a number of positive characteristics that might be combined into a single, more powerful methodology. ACT-R parameters had been manipulated (Taatgen, 2001) in a model of individual differences in learning, although the "individuals" in that work were simulated, and corresponded to *types* of individuals, not to actual subjects. In that work, performance in a complex task was related to individual difference parameters across the simulated individuals. Earlier work in modeling also accounted for relationships between ability in one task and ability in another, but making assessments on the group, not individual, level (Just, Carpenter, and Shell, 1990). A complementary approach measures individual performance on complex tasks, and utilizes statistical methods such as intercorrelation matrices, allowing predictions of individual performance on one task based upon measurements of performance on other tasks in the matrices, making no use of any particular theory of cognition (for example, Ackerman and Kanfer, 1993).

All of this previous work, we felt, pointed towards a methodology that combined a number of positive features from these complementary approaches into a

single, more comprehensive modeling paradigm. In the methodology we envisioned, one or more simple tasks could be administered to an individual, allowing us to estimate their individual parameters; then, by plugging the individual's parameter values into the ACT-R architecture, we could predict the individual's performance on any task for which an ACT-R model exists. Because ACT-R models produce predictions with a grain size of tens to hundreds of milliseconds, this provides us with a *detailed* model of individual performance, offering the potential for predictions on the trial level, or predictions of novel measures of performance that emerge from lower-level detail – potentially allowing predictions of almost any measure that can be made of subjects. Because our approach builds atop the platform of the rich ACT-R theory, it is realistic to expect that these individualized model runs will be somewhat meaningful in their details, not just a way to arrive at a final, aggregate performance metric of some kind.

In order to take the next step beyond the Daily, Lovett, & Reder study that involved only two simple memory tasks, we decided to pick a more complex, interactive task. In order to capture a broader spectrum of individual differences, we chose to measure two parameters per subject: the W parameter as well as a measure of perceptual and motor ability, henceforth referred to as P/M. This is not a part of the standard ACT-R architecture, but seemed to be an important kind of individual variation. Thus far, we have used only one parameter, which represents as though they were one individual perception and motor speed. We allow that those may covary freely among individuals, but we have so far had success using the one parameter alone for this.

The AMBR Task

Given the preceding considerations, we chose as our more-complex task the AMBR simulation, an air traffic control task that already had a foundation as a test bed for cognitive models in a project organized by the Air Force Research Laboratory (Gluck and Pew, 2001). This task already had an ACT-R model implemented (Lebiere, Anderson, and Bothell, 2001), which not only facilitated our project, but also provided a gauge of the modularity of our approach; ideally, we would be able to plug parameters into this off-the-shelf model and obtain good results without modifying it in any other way.

The task places the subject in the role of an air traffic controller whose job is to process aircraft (AC) as they enter and leave the airspace zone, central in the simulated radar display, for which he or she is responsible. This primarily consists of issuing, via a graphical interface, two commands to an AC as it enters one's zone from a neighboring zone of airspace, and issuing two commands to an AC as it departs for another zone. The same AC must thereby be issued a total of four commands if it passes into and subsequently out of the central zone during a scenario. In some cases, the AC will only enter the central zone, or only depart the central zone, during the duration of a scenario, in which case that AC will require only a total of two commands. In addition, a fifth type of command is required if an AC requests a speed change, which requires the subject to make a trivial judgment as to whether or not the AC is on course to catch, from behind, any other AC; if so, the speed change request should be denied, and otherwise, it should be accepted. AC arrivals can be detected both from the radar display and from text messages appearing in windows to the side of the display. Speed change requests can be cued only via text messages. The departure of an AC from the central zone can be detected only via the radar display. Under the assumption that AC are at different altitudes, however, collisions cannot take place in this simulation, nor do AC land or take off in the simulation. The subject is scored based on issuing all commands in a timely fashion that permits AC to move freely without ever reaching the border of the central zone while still awaiting one of the required commands. If an AC does reach the zone border without having received all necessary commands, it will go into a hold, thereby turning the AC red in the display, halting the AC's motion, and penalizing the subject 1 point. The score at the end of the run is the sum of the errors the subject makes, lower score thereby signifying better performance. Subjects were also penalized for making interface errors of the sort that the model never made. Subject and model performance levels can thereby be compared on the basis of hold errors. A static image of the display is visible in Figure 1.

We were required to modify one aspect of the AMBR task in order to eliminate uncontrolled strategic variation among the subjects. AMBR's original implementation has a more baroque scoring system where some errors lead to penalties of 1 point and other errors up to 50 points. In response to that scoring system, some subjects tried to avoid all errors while other subjects opportunistically allowed low-penalty errors when that helped them avoid any occurrences of high-penalty errors. That strategic variation was noticed only when some data had been collected; this is an indication of the subtle difficulties that can arise when modeling tasks at the level of complexity of AMBR. The difficulty of producing a suitably correct Cognitive Task Analysis was roundly reported by the four cognitive modeling groups involved in the AFRL's AMBR modeling project. Unconstrained by the need to need to coordinate with other groups, we changed the task.

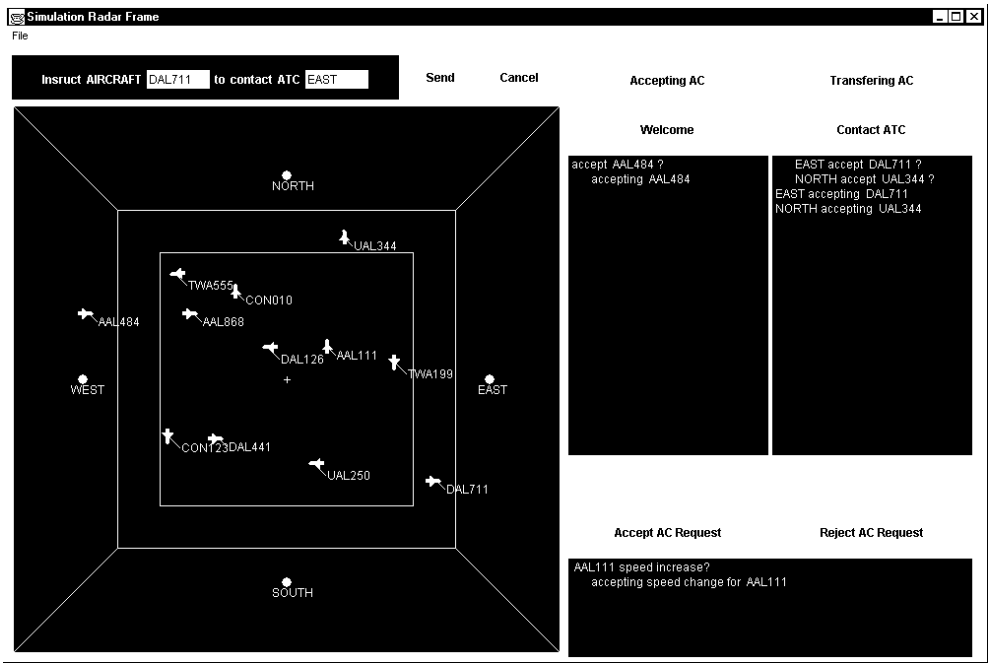

Figure 1: The AMBR Display

Sources of individual difference

Having introduced AMBR as our complex task, we acknowledge that the term "complex" is a relative one, and in seeking a complex task for our work, we were actually seeking an appropriate kind of complexity. We distinguish between distinct kinds of individual difference factors, postulating that **architectural differences** are those differences that pertain to relatively permanent characteristics of the individual, not shaped by particular episodes in the individual's experience. (We make no claims about how development shapes architectural differences throughout an individual's life.) **Knowledge-based differences**, on the other hand, can arise through specific instances of learning declarative information; the state of an individual's knowledge can only be described (or tested) in a very expansive manner, and this is not our enterprise. A third type of individual difference, **strategic differences**, could be broken down into either of the two previously mentioned types. It is not our goal to measure the encyclopedic total of an individual's knowledge, but we do anticipate that certain differences in how an individual chooses a strategy for a given task will depend upon and emerge from architectural differences. Cases where we can predict strategic differences based upon architectural differences will serve to validate our approach. We recognized that we would have trouble, however, with any task that invited strategic variation between subjects that could not be predicted from architectural differences. In such a case, our individual-difference approach would risk the same pitfalls that a non-individual-approach can lead to when subject strategies vary (Newell, 1973; Siegler, 1987).

Initial results

In two distinct experiments, with two sets of subjects, we applied the methodology of administering initial tests to measure the W and P/M parameters. The P/M parameter was actually calculated based upon the speed of mouse clicks in the AMBR training. Our procedures for calculating the parameters produce values of W and P/M which both have population means of about 1.0 and standard deviations of about 0.2 (for Carnegie Mellon undergraduates). High W means better working memory capacity, while high P/M means slower perceptual and motor responses – it is a multiplier, so that P/M = 1.2 means responses 20% slower than average). Therefore, where we find significant effects, W correlates negatively with error counts and P/M positively.

Subjects were trained on the AMBR task until they understood it quite thoroughly, and then participated in a number of AMBR scenarios, the data from which we compared to individualized model runs for each subject. Experiment 1 featured 10 AMBR scenarios, each 9 minutes long, and alternating between very easy and very difficult. Experiment 2 had 9 scenarios, each 4.5 minutes long, varying evenly along a continuum in terms of difficulty from easy to difficult. As an informal measure of difficulty, we have taken the number of AC per scenario times the average speed of those AC, divided by the scenario length. Using the idiosyncratic units of our simulations, Experiment 1 scenarios had difficulty ratings of 26 (easy) and about 180 (hard). Experiment 2 scenarios ranged in difficulty from 40 to 200.

It is instructive to note the analysis that would be performed if this were not an individual difference study. Aggregate group performance, measured in hold errors, as a function of scenarios was predicted well by the aggregate model runs (Experiment 1: r = 0.975; Experiment 2: 0.929). This was almost the same analysis, from the very same ACT-R model, presented in Lebiere, Anderson, and Bothell (2001), and used to argue for a good fit between subjects and model.

The model correctly predicted that the AMBR task, as originally conceived, is more sensitive to variation in P/M than in W. This is seen clearly in the correlations of subject holds with P/M (r = 0.658) and W (r = -0.266). Not only can the model be used to generate predictions for specific subjects, but it can also be used to probe the effects of one parameter by varying that parameter while holding the other one neutral (at the population mean of 1.0). (Note that holding one parameter fixed while varying another among the subjects is a very difficult practical matter.) This use of the model shows a strikingly greater effect upon holds from P/M than W. This is in agreement with data on the actual air traffic controller task (which, it should be noted, has several distinct differences from the AMBR task, not the least of which being that it involves voice communication, not a graphical user interface alone), which documents that only a small number of errors are due to memory failures (Billings and Cheaney, 1981).

Studies of AMBR traces reveal that the reason for this is that hold errors are primarily an outgrowth of time pressure when the time demands on a subject exceed the time that is available. For 3 of the 5 types of command in AMBR, the subject is shown the name of an AC in the text cue, and must click on the AC as part of the subsequent action sequence. Memory becomes a factor in AMBR performance primarily in that if a subject cannot remember the location of an AC based upon its name, then the display must be searched for the AC. This turns out to be a small factor because visual search is fast – slower than memory, perhaps, but the difference is on the order of a fraction of a second, while clicking in a command sequence takes several seconds whether the AC location is remembered or not. W, then, is logically a small factor in the original AMBR task, and for a small portion of the variance.

Designing for science

In order to improve upon the studies described above, we designed a follow-up study that modified the scenario difficulty, the measures of performance that we used, and even the task itself. It was obviously necessary to decrease scenario difficulty into the range for which the model produced a good fit to subject data. This also allowed us to use one performance measure that is more sensitive than hold errors – the reaction time between an action's cue and the subject's response to that cue (we used the time for an action sequence to end, meaning the third or fourth click in all). In order to emphasize the W effect relative to the P/M effect (since cognitive modeling, and not motor/kinesthetic modeling is our chief interest), we modified the task so as to create a greater penalty for failures in recall. We did this by removing AC names from the display by default, and showed the name of an AC only when the subject clicked on the AC. Moreover, only one AC name could be seen at a time, and this would appear after a delay. This change meant that the speedy visual searches of the earlier experiments would be impossible, and any failure to recall an AC's location would entail an excruciatingly slow manual search. This task modification also had the merit of giving us data on searches, and let us emphasize a performance measure that calculated what on what proportion of commands a subject found the correct AC on the first click. In other ways, Experiment 3 was similar to Experiments 1 and 2. Each subject was to participate in 5 AMBR scenarios that were easy – hold errors confound reaction time, so we needed them to be fairly rare in order to use RT as a performance measure. In the units of scenario difficulty mentioned earlier, all Experiment 3 scenarios gauged 17 or lower.

Before the study began, we ran the model, which was revised to allow for the task modification involving name-hiding, on the Experiment 3 scenarios, and it seemed not to work correctly. Instead of performing manual searches for AC names, it would *guess* which AC it was looking for and click through the entire action sequence without bothering to verify that it had clicked the right AC. While work on the model, to fix this "problem" was underway, the first subjects ran in the experiment. They behaved the same way. We had set the delay that one must wait, after clicking on an AC, for its name to appear, too long, and subjects preferred to hope that they had guessed right correctly rather than perform the laborious verification process. ACT-R came to the same conclusion based upon the undesirably large cost associated with clicks that required several seconds before the desired consequence took place. We modified the task again, shortening the delay before the name appeared, and both the model and the subjects performed manual search in the way we had hoped. This demonstrates one possible application of our approach – tasks (experimental or otherwise) can be *designed* with the model's predictions taken as a serious indicator of subject performance, individual or otherwise.

Experiment 3 produced the subject characteristics we had sought. Our three measures of individual

performance correlated significantly with W (Holds: r = -0.444; RT: r = -0.314; First-clicks: r = 0.314). P/M had about as large an impact on performance (Holds: r = 0.508; RT: r = 0.485; First-clicks: r = -0.172), but, as we desired, it did not dominate as in the first two experiments.

The result most central to our intent was the prediction of individual performance with model output (Holds: r = 0.461; RT: r = 0.436; First-clicks: r = 0.406). These correlations are distinctly less than what is often possible when averaging multiple model runs against the average of many subjects, but are very much in line with the kinds of correlations found in task intercorrelation matrix approaches (Ackerman and Kanfer, 1993; Joslyn and Hunt, 1998).

To demonstrate the possibility of precise, instance-level predictions, we looked at model predictions across all three experiments, as to whether or not, for each scenario, an individual subject would commit at least one hold error. The model predicted correctly 91.7% of the time, as detailed below in Table 1.

	Subject scenarios with errors	**Subject scenarios with no errors**
Model scenarios with errors	205	4
Model scenarios without errors	21	70

Table 1: Prediction of Error Situations

Future directions

For a variety of goals, both applied and scientific, it is and will be desirable to be able to predict individual performance on a fine-grained level. It seems certain that the methodology we are exploring will be expanded upon and utilized for such applications in the future. At present, it is possible to point to the range and extent of our successes and note the particular difficulties that individual difference modeling entails.

One avenue to explore is to involve a larger number of individual difference factors. ACT-R has many parameters built into it, and future work may be able to predict individual performance more accurately by making use of pre-tests besides the two we now use.

Because our model is fine-grained, it permits many measures of performance, on the subject, scenario, command, or click level. Ways in which the model fits, or alternately does not fit, subject data highlights many areas where future work is required. For example, we have observed in the subject data from Experiment 3 some phenomena of interest that the model does not predict. These include a correlation between higher W and the frequency with which a subject completes a sequence of command clicks *without* waiting for the AC name to appear. We believe that we can capture this with additional refinements to the model, taking advantage of ACT-R's utility-learning mechanisms. A second discrepancy between the subject data and the model predictions are that the model does not recall AC locations as well as the subjects do, and we believe that this stipulates that the model should include rehearsals of AC location between the time that information is learned and when it is needed. A third difference is that subjects often respond to Welcome commands, which are always the second of a pair of commands regarding a given AC, much faster than the model does. In fact, some subjects respond much faster than other subjects in this regard, and it is clear that strategic variation has intruded into our study – something that is difficult to prevent absolutely with a task of AMBR's complexity. In upcoming experiments, we will try to instruct all subjects to anticipate Welcome commands when they can, and will change the model so that it does so as well.

Subject phenomena that are not captured by the model, we believe, stem from the problem of deriving a valid Cognitive Task Analysis, which is known to be difficult for a novel, complex task. It is striking how much simpler AMBR is than many tasks (for example, *real* air traffic control), and yet how challenging it is to model it precisely. It has not only been a challenging task to which to extend the individual difference methodology from memory to more complex tasks; it is also at the right level of complexity for the next stages of work as we try to model it still more accurately and over a variety of task modifications.

Looking To Understand: The Coupling Between Speakers' and Listeners' Eye Movements and its Relationship to Discourse Comprehension

Abstract

While their eye movements were being recorded, participants spoke extemporaneously about a TV show whose cast members they were viewing. Later, other participants listened to these speeches while their eyes were tracked. Within this naturalistic paradigm using spontaneous speech, a number of results linking eye movements to speech comprehension, speech production and memory were replicated. More importantly, a cross-recurrence analysis demonstrated that speaker and listener eye movements were coupled, and that the strength of this relationship positively correlated with listeners' comprehension. Just as the mental state of a single person can be reflected in patterns of eye movements, the commonality of mental states that is brought about by successful communication is mirrored in a similarity between speaker and listener's eye movements.

Introduction

Imagine standing in front of a painting, discussing it with a friend. As you talk, your eyes will scan across the image, moving approximately three times a second. They will be drawn by characteristics of the image itself, areas of contrast or detail, as well as features of the objects or people portrayed. Eye movements are driven both by properties of the visual world and processes in a person's mind. Your gaze might also be influenced by what your friend is saying, what you say in reply, what is thought but not said, and where you agree and disagree. If this is so, what is the relationship between your eye movements and those of your friend? How is that relationship related to the flow of conversation between you?

Language use often occurs within rich visual contexts such as this, and the interplay between linguistic processes and visual perception is of increasing interest to psycholinguists and vision researchers (Henderson & Ferreira, 2004). As yet, however, such processes have been limited to experiments that examine the eye movements of the speaker or the listener in isolation. Language use, more often than not, occurs within a richer social context as well.

Direct eye contact between conversants plays an interesting, crucial role in coordinating a conversation (Bavelas, Coates, & Johnson, 2002), and in conveying various attitudes or social roles (Argyle & Cook, 1976). The focus of the current experiment, however, is cases such as those introduced at the outset, where conversants are not looking at each other, but at some visual scene that is the topic of the conversation. More common examples might be discussing a diagram drawn on a whiteboard, figuring out together how to do something on a computer, or talking during a movie.

Uniquely poised between perception and cognition, eye movements can reveal cognitive processes such as speech planning, language comprehension, memory, mental imagery and decision making. The current experiment investigates whether the eye movements of a speaker and a listener to a visual common ground can provide insight into a discourse.

Eye movement Research

Eye movements of a speaker

If a speaker is asked to describe a simple scene, they will fixate the objects in the order in which they are mentioned, around 900ms before naming them (Griffin & Bock, 2000; Meyer, Sleiderink, & Levelt, 1998). Since such pictures can be identified rapidly, it is argued that during this time speakers are not just retrieving words but selecting and planning which to use.

Eye movements of a listener

Eye movement research has shown that there is a tight interdependence between speech recognition and visual perception. Eye movements to potential referents for a word can provide evidence for a lexical item being recognized before the word is finished being spoken. The link between visual and linguistic processing can also be seen in eye movements that disambiguate syntactic structures (Tanenhaus, Spivey Knowlton, Eberhard, & Sedivy, 1995) and anticipate the future agents of actions (Kamide, Altmann, & Haywood, 2003). Recent studies of the eye-movements of a participant engaged in a conversation with another naïve participant reveal a remarkable sensitivity to the referential domains established by the task, the visual context and the preceding conversation (Brown-Schmidt, Campana, & Tanenhaus, 2004). Qualitatively, eye movement research reveals a very close, time-locked integration between visual and linguistic processing (Tanenhaus, Magnuson, Dahan, & Chambers, 2000). Although fixation times are heavily modulated by context, as a very rough quantitative guide, research suggests that listeners will fixate an object around 400-800ms after the name onset.

Eye movements of a thinker

Since participants will make systematic eye movements to entirely empty and uninformative regions of space when retrieving information from memory (Richardson & Kirkham, in press; Richardson & Spivey, 2000) or listening to a story (Spivey & Geng, 2001) it is clear that they can be governed by cognitive as well as perceptual processes. Influencing how the eye moves across an image can have profound effects on mental processes. Researchers have recorded the eye movements of participants interpreting an ambiguous picture in a particular way, or solving a difficult deductive problem from a diagram. Using low level visual cues, a second set of participants were then influenced to attend to the same regions of the picture. The second set of participants were more like to form the same interpretation of the ambiguous picture (Pomplun, Ritter, & Velichkovsky, 1996), and remarkably, were more likely to solve the deductive problem (Grant & Spivey, 2003). If forced similarity between participants' eye movements can result in similar cognitive states, then will the similar cognitive states that are brought about by successful verbal communication result in similar eye movement patterns between speaker and listener?

Experiment

Speech production and speech comprehension have previously been studied in separate eye tracking paradigms. Yet if both are indeed closely linked to eye movements, the eye movement patterns of two people engaged in a natural, unscripted conversation may bare some relationship to each other. Moreover, it raises the intriguing possibility that the strength of the relationship between conversants' eye movements will parallel the success of their linguistic relationship.

The current experiment approximates a conversation between naïve conversants by asking participants to speak spontaneously, with neither a script nor a rehearsal for an extended period of time about a TV show, whose characters were displayed in front of them. These speeches were then played back to other participants who were looking at the same display. Crucially, both the speakers' and the listeners' eye movements were tracked throughout. The listeners' comprehension was then measured by a series of content questions. Thus in addition to extending various eye movement-language results to natural, spontaneous speech, the current experiment was able to investigate a number of entirely novel hypotheses regarding the linkage between speaker and listener eye movements, and its relation to the listener's comprehension.

Methods

The first four participants recruited to take part in this experiment were designated as speakers, and the remainder were listeners. The methods for both stages will be described below.

Participants

40 Stanford undergraduates took part in the experiment in exchange for course credit.

Apparatus

An ASL 504 remote eye tracking camera was positioned at the base of a 17" LCD stimulus display. Participants were unrestrained, and sat approximately 30" from the screen. The camera detected pupil and corneal reflection position from the right eye, and the eye tracking PC calculated point-of-gaze in terms of co-ordinates on the stimulus display. This information was passed every 33ms to a PowerMac G4 which controlled the stimulus presentation and collected looking time data. Prior to the experimental session, the participants went through a 9 point calibration routine, which typically took between 2 and 5 minutes.

Speakers' voices were recorded by microphone, and listeners made responses using the two buttons of a mouse held in their lap.

Design – Speakers

The intention was to record participants speaking spontaneously about a TV show while looking at a picture of the cast members. In the first case, a picture of the 6 principal characters of the cast of the TV sitcom *Friends* was used. The characters were shown individual in 6 separate pictures. Potential speakers were asked if they knew they show and would like to talk about it, and two speakers were selected who were knowledgeable and reasonably gregarious. Speakers were instructed to 'Talk about the show for a couple of minutes. You could talk about the relationships between the characters, your opinion of them, or your favourite episode'. In the second case, two participants were shown a 5 minute scene from *The Simpsons* during which they undergo family therapy. These participants were then shown a picture of the five family members and their therapist. The participants were asked to 'Describe what went on in the scene and what you thought about it'.

As they spoke, the speakers' eye movements were tracked and their voices were recorded by microphone. These recordings were trimmed so that they were all roughly one minute long, and the text was transcribed for later analysis.

Design - Listeners

Participants listened while looking at the same picture of the six cast members that had been in front of the speaker. Since there could not be systematic looks to the cast members if the participant did not recognize any of them, participants were first asked if they were familiar with either show. On this basis, the listeners were presented with one or both of the *Friends* and *Simpsons* stimuli, and were randomly assigned one of the two speakers.

Listeners heard a minute of speech, and then a screen appeared warning them that the question period was about to start. In the four question trials, participants saw six solid grey circles or squares in the locations where pictures of the individual cast members had previously appeared. After a 1000ms pause, they heard a question and responded yes or

no using the two mouse buttons. There followed a 2000ms ISI during which the screen was blank.

The questions were recorded by the experimenter and were of the form, "Did the speaker say…?". The questions were designed such that they could not be answered on the basis of knowledge about *Friends* or *The Simpsons* alone, but were specific to the information mentioned (or not) by that particular speaker. The correct answer to half the questions was yes and half no.

Data Coding

Roughly half of our listeners were familiar with both TV shows and half knew the characters from only one. All analyses are based on 49 usable listener-speaker dyads. A further 9 cases were dropped due to problems with the equipment or the calibration procedure.

The eye movements of the speaker and of the listener during the minute of speech were analyzed in exactly the same way. The eye movement data relayed which, if any, of the six pictures were being fixated every 33ms. The data were cleaned for blinks and saccades across a picture - only stable fixations longer than 99ms were analyzed – and then expressed in terms of a sequences of gaze onsets and offsets in the six pictures.

The speakers' recordings were transcribed with onset times for each word spoken. In addition, words were flagged if they were names of any of the six characters pictured. Listener responses to the questions were coded for accuracy, and their looking times to each of the pictures while answering were calculated.

Results and Discussion

This experiment provided precise timing information about speakers' speech and gaze onsets, and listeners' gaze onsets. This information can depicted graphically in what we call a 'scarf plot', which represents a transcript of the speech together with the timing of word onsets and the eye movements of both speaker and listen. Figure 1 shows an nine second segment of a scarf plot for one speaker-listener dyad. Such eye movement data can be statistically analyzed and compared with the objective measure of the listeners' understanding of the speech provided by their performance answering four comprehension questions.

Before the detailed inferential analyses begin, it is useful to get a rough sense of the behavior being studied. On average, speakers used 160 words, only 12 of which were the names of the characters depicted. It is important to note that the speeches were not edited for content, and include all the deviations, hesitations and repetitions that are typical of just a minute of normal, spontaneous speech.

Speakers and listeners switched their gaze between pictures around 120 times. For each occasion, they spent about 500ms looking at the picture. Since the average eye fixation lasts 200-300ms, it is reasonable to assume that this represents two fixations within the same picture.

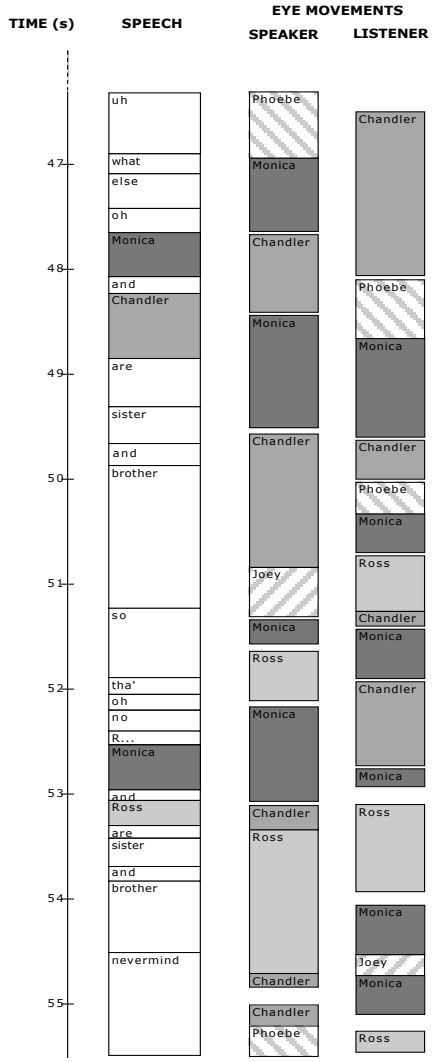

Figure 1. Scarf Plot of a 9 second segment of one dyad. The speaker's words are shown on the left, with nouns highlighted. The speaker's and listener's eye movements are shown in the middle and right columns respectively. Time is on the y axis, increasing down the page.

Speaker Fixations Prior To Naming

For each occasion that the speaker named character X, their eye movement data were consulted to find the point at which X was last previously fixated. The difference between the gaze onset and the name onset was computed for every name used by every speaker. On average, a character was fixated 860 ms prior to being named.

This lag is exactly in the range reported by the speech production literature (Griffin & Bock, 2000), where typically participants are explicitly instructed to describe a simple picture. We have found a lag of the same magnitude with spontaneous, natural speech, when participants are describing not what is front of them per se, but things that are not depicted - stories, opinions, relationships – that relate to those characters.

Relationship Between Speaker And Listener Eye Movements

To what degree were speaker and listener looking at the same thing at the same time?

We quantified this question by generating categorical cross-recurrence plots between the speaker and listener time series of fixations (Dale & Spivey, in submission). These plots permit visualization and quantification of recurrent patterns of states between two time series (see Shockley, Santana & Fowler, 2003, for a fuller introduction; see Eckmann, Kamphorst & Ruelle, 1987; Zbilut & Webber, 1992 for foundational treatises). In our case, the cross-recurrence plot portrays the extent to which dyad fixations are overlapping temporally.

To begin, windows of a given length are moved along each time series, forming individual windows at every time index. The windows of each time series are then compared to *all* those of the other time series (comparing *every* time index). At time index *i* for the first time series and *j* for the second, if their windows are sufficiently similar, a point *(i, j)* is recorded on a two-dimensional plot. By comparing every window in the first to the second time series, we can generate a full plot of points in which the two time series are close to each other – a cross-recurrence plot.

For simplicity, we used a window size of 1 for our analysis. By using a categorical metric (see Dale & Spivey, in submission, for details), we have the criterion that dyad fixations are recurrent if falling on the same object for 33ms. We generated plots using this metric between every speaker-listener pair. Figure 2 shows example cross recurrence plots between a speaker and (a) a listener who answered all comprehension questions correctly (b) a listener who answered few correctly, and (c) a listener with their eye movement data placed in a random order. There are three things to notice here. Firstly, the good listener has higher density in their plot, indicating more points of recurrence with the speaker. Secondly, both listeners have more structured plots compared to the randomized series. Lastly, one can see that for the two real listeners there is a higher density in the region on and below the *i=j* diagonal. This indicates that the speaker and listeners' eye movements overlapped more when the listeners' eye movements lagged behind the speakers.

We employed a further analysis to find out exactly what temporal lag between the listener and the speaker would produce the greatest degree of recurrence, or overlap, between their eye movement patterns. Listener time series were successively lagged by 330ms. On the line defined by $i = j$ in the plot (the *line of incidence*), any point indicates that *in the same temporal context* fixations are recurrent. Thus, by lagging the listeners' time series, and recording maximal recurrence along the line of incidence within each lag, we get a measure of the extent to which dyads' eye movements are related. Though our chosen window size is small, the results are quite compelling.

Figure 3 shows the degree of recurrence between speaker and listener at different time lags, averaged across all 49 dyads. We also randomized listeners' eye movement data and calculated its recurrence with the speakers'. This randomized series serves as a baseline of looking 'at chance' at any given point in time, but with the same overall distribution of looks to each picture as the real listeners.

A 2 (listeners/randomized listener) x 40 (lag times) ANOVA revealed a significant main effect of listener type ($F(1,45)=785.5$, $p<.0001$) and a main effect of lag ($F(40,1800)=25.2$, $p<.001$). Moreover, there was a significant interaction between the factors ($F(40,1800)=24.7$, $p<.001$).

Clearly, the real listeners are not looking around these displays randomly. Rather their eye movements are linked to the speakers', and this relationship has a temporal character. More precisely, the maximum recurrence between the speakers and listeners, the lag time at which their eye movements overlap the most, is at 1650ms

These results are exactly what one would expect from the combination of the speech production and speech comprehension eye movement literature. Typically, speakers will fixate an item 900ms before naming it and listeners will fixate an object around 800ms after the name onset. Very roughly this would suggest we would find a lag of 900+800=1700ms between speaker gaze onsets and listeners'. This derived value corresponds both to the exact lag that produces a maximum recurrence value, 1650ms, and the general region of higher recurrence in the 1000-2000ms range.

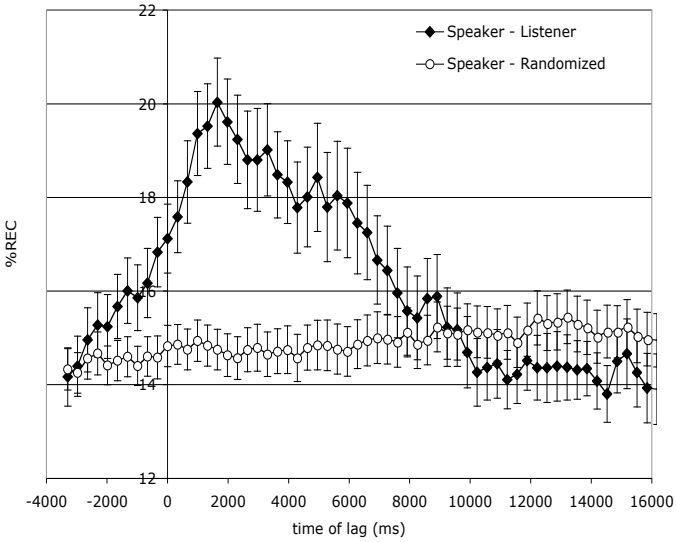

Figure 3. Cross recurrence at different time lags

The speech production and comprehension literatures, however, deal with cases where an object or person is explicitly named. Perhaps it is the case that the differences between critical and non-critical gaze onset lag distributions observed here are due mainly to the occasions when the speaker planned and spoke out loud a name of one of the characters pictured.

This question was addressed by examining a subset of the data. The name-subset includes only speaker fixations to person X that were immediately prior to the speech onset of name X. As noted previously, since there were on average 12 cases of name use, this constituted about 10% of the 120 fixations the average speaker made.

Figure 4A plots the recurrence at different time lags for the name subset of our data. The 2 (listeners/randomized listener) x 40 (lag times) ANOVA revealed a significant main effect of listener type ($F(1,45)=192.3$, $p<.0001$) and a main effect of lag ($F(40,1800)=28.1$, $p<.001$). As before, there was a significant interaction between the factors ($F(40,1800)=27.5$, $p<.001$).

For the subset of speaker fixations that precede a name, there is a highly pronounced difference between the speaker and the listener and the speaker and randomized looking. Once more, the greatest extent of this difference is just before 2000ms. Again, this would be predicted by the speech production and comprehension eye movement literatures. Is it the case, then, that the current experiment has simply replicated these name-use results using spontaneous speech?

To answer this question the data excluded from the name analysis above were analyzed in isolation. Figure 4B plots the 'non name dataset' that corresponds to the 90% of speaker fixations to person X which were not immediately followed by X being named out loud. The ANOVA showed a similar pattern of results: main effect of listener type ($F(1,45)=559$, $p<.0001$), a main effect of lag ($F(40,1800)=25.8$, $p<.001$). and a significant interaction between the factors ($F(40,1800)=25.0$, $p<.001$). Although subtracting the cases of name use from the full data set appeared to attenuate somewhat the differences between critical and non-critical gaze onset lags, it is certainly the case that these distributions still differ. In other words, it is not just the when the speaker names a character that speaker and listener eye movements are linked. It must be other properties of the discourse (implicit reference, anaphor, topics, agents, for example) which drive the speakers eye movements while they are being planned, and a few seconds later, influence the listener's eye movements once they are spoken.

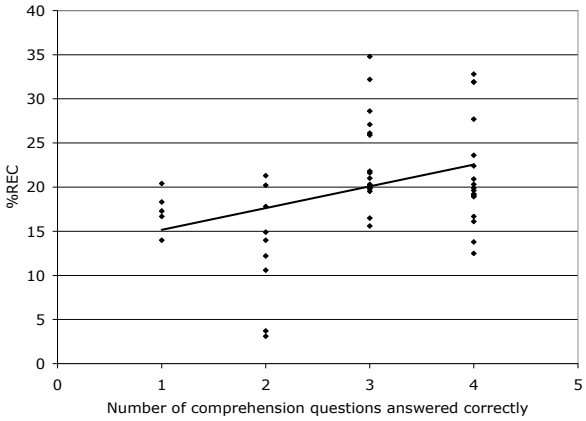

Figure 5. Correlation Between Speaker-Listener Eye Movements Coupling and Listener Comprehension

Speaker-Listener Eye Movement Linkage and Listener Comprehension

The degree to which eye movements were linked in a given speaker-listener dyad were compared with the listener's comprehension of what had been said. For each dyad, we computed the degree of recurrence (REC%) at a lag of 1650ms between speaker and listener. This is the lag that produced the greatest recurrence across our whole data set, and hence serves as a baseline to compare the linkage between individual speaker-listener dyads. The performance of listeners answering four comprehension questions was taken as an objective measure of how well they had comprehended the one minute of speech.

A regression analysis was performed on this data, and found that a linear fit had $r^2=0.14$. Although it may not account for a large portion of the variance in participants' behaviour, an ANOVA shows that this relationship is significant ($F(1,47)=7.39$, $p<.01$).

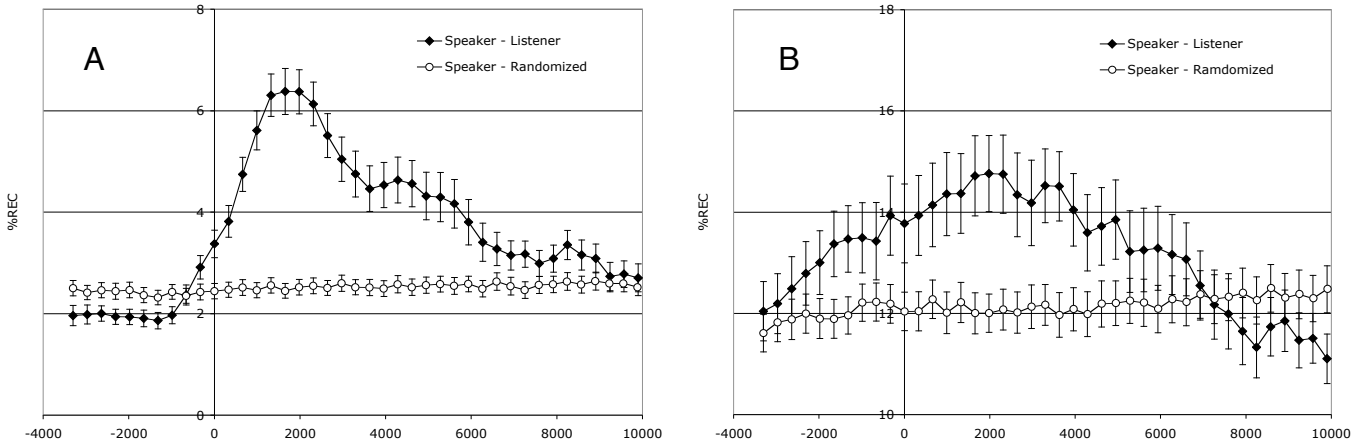

Figure 4. Cross recurrence at different time lags for (a) name fixations, (b) non-name fixations

General Discussion

The current experiment uses a naturalistic paradigm that elicits and presents spontaneous speech. The language-use in this experiment is grounded in the visual items presented on the display, but is not a description of them per se, or an explicit instruction relating to their presence or appearance. Nevertheless, this single paradigm replicates several results obtained in more constrained circumstances concerning the relationship between eye movements, speech production, and speech comprehension.

More importantly, this experiment provides what could be the first demonstration that during the production and comprehension of a spontaneous discourse, the eye movements of a speaker and a listener are coupled. Moreover, this relationship between eye movement patterns is not driven by cases in which the speaker explicitly names people who are depicted. It seems to be that the planning of more diverse types of reference and foregrounding may be influencing the speaker's eye movements, and, a few seconds later via the speech stream, influencing the listener's eye movements. Crucially, the strength of relationship between the speaker's and the listener's eye movements appears to predict the degree to which the listener successfully comprehended the speech.

Instances of new paradigms such as this inevitably raise many questions for future research. Is it the case that a tight coupling between speaker and listener eye movements is an overall indication of listener attentiveness, which also predicts listener comprehension? Or is it that by rapidly bringing their eyes to bear on the same item as the speaker, good listeners receive appropriate visual information that supports the verbal input? Or perhaps it is not so much that moving the eyes closely in step with a speaker brings in visual content, but rather it is an indication (or a cause) that the listener is using spatial information to cognitively structure the information in the same way as the speaker?

The close relationship between speaker and listener eye movements and the success of the discourse clearly aligns with a view of language use as a joint activity (Clark, 1996), in which successful communication is brought about by a successful coordination of information in the common ground. The human eye only receives detailed information from 2º of its visual field: therefore, if the speaker and listener are looking at exactly the same thing, then they are certainly sharing a higher, common ground.

Working Memory and Inhibition as Constraints on Children's Development of Analogical Reasoning

Abstract

We developed a picture-mapping task (Richland Picture Analogies, RPA) to examine the roles of inhibition and working-memory load on children's development of analogical reasoning. Children of ages 3-4, 6-8, and 13-14 were instructed to use relational correspondences between source and target pictures to select the target object corresponding most directly to a specified source object. The study examined age trends in children's proficiency with analogical reasoning. Relational complexity and perceptual distraction were manipulated to investigate how maturational constraints interact with each other and with age. Results indicate that children's development of the capacity to reason analogically interacts with increases in working-memory capacity and inhibitory control.

Children's higher-order reasoning skills are central to their ability to transfer knowledge from an initial learning context to future environments. This process enables children to understand novel situations and contexts, to build on their everyday learning experiences and to develop a flexible body of knowledge (Gentner, Holyoak & Kokinov, 2001; Gentner & Rattermann; 1991; Holyoak, Junn & Billman, 1984). Following Gentner (1983), analogy is defined as a conceptual strategy in which a source object is represented as similar to a target object, and correspondences are mapped between the two analogs. Although there is wide agreement that this conceptual process is central to children's everyday learning, the mechanisms underlying and constraining the development of analogical reasoning are not yet well understood.

The process of constructing an analogy requires a reasoner to represent source and target analogs, maintain both representations in working memory (WM; Hummel & Holyoak, 1997, 2003), and construct a mapping between elements of the source and target based upon correspondences between relations in each (Gentner, 1983; Holyoak & Thagard, 1989). Critically, the relational correspondences may compete with more superficial perceptual or semantic similarities between individual objects, requiring inhibitory control when relational and more superficial responses conflict (Gentner & Toupin, 1986; Morrison et al., 2004; Viskontas et al., in press).

Proposed Developmental Mechanisms

Researchers have proposed three developmental mechanisms to explain age-related changes in children's performance on analogical reasoning tasks: increased domain knowledge, a relational shift, and increased WM capacity for manipulating relations.

Goswami (1992, 2001) proposed domain knowledge as the primary mechanism underlying developmental changes in analogical reasoning. According to her relational primacy hypothesis, analogical reasoning is available as a capacity from early infancy, but children's analogical performance increases with age due to increased knowledge about relevant relations. This hypothesis was developed in reaction to Piagetian studies suggesting that children are unable to reason analogically prior to achieving formal operations, approximately at age 13 or 14 (Piaget, Montangero & Billeter, 1977). Piaget's tasks frequently involved uncommon relations, such as "steering mechanism", which would likely have been unfamiliar to younger children. In contrast, research has since shown children can reason analogically at much

younger ages (e.g. Gentner 1977, Holyoak et al., 1984). Goswami and Brown (1989) argued that children as young as 3 years old were successful on analogical reasoning tasks when they demonstrated knowledge about the relevant relations. Goswami and Brown presented children with complex versions of analogy tasks in which two physical, causal relations (e.g., cutting and wetting) were imposed on a source object "a" to become source object "b." Children were required to map on the basis of these relations to complete an analogy of the form a:b::c:d. The investigators found that children were fairly competent on these problems with 2 relational changes when they showed knowledge of the relations.

These data provided some evidence that domain knowledge is related to successful analogical reasoning, but the methodology of this study has been criticized.

Rattermann and Gentner (1998) found that when a substantial perceptual distractor was included in the Goswami and Brown stimuli, children younger than age five were likely to select a perceptual match in spite of knowledge of the relations and explicit analogy instructions. Gentner and Rattermann (1991; Rattermann & Gentner, 1998) posited that a "relational shift" occurs between the ages of four and five. Before the relational shift, they argue that children primarily attend to perceptual similarity and will reason on the basis of perceptual features if available. Following the relational shift, children can and do reason on the basis of relational features even when faced with perceptual distractors. The authors suggest that domain knowledge is integral to the relational shift, though the mechanism is not explicitly postulated.

An alternative explanation for the relational shift is that children younger than age five were unable to inhibit their responses to perceptual similarity, although they were aware that the task required attention to relational similarity. It is well-established that children's inhibition capacity develops with age (Diamond, Kirkham & Amso, 2002), and follows similar age-related patterns as does analogical reasoning. Accordingly, development of children's inhibitory capacity, one aspect of the human working memory system, may underlie children's patterns of success and failure on analogical reasoning tasks.

Finally, WM constraints have been proposed to explain developmental change in analogical reasoning. In particular, relational complexity has been argued to constrain children's performance on analogical reasoning tasks (Halford, 1993). Two primary definitions of relational complexity have been advanced. Zelazo et al, (2003, 1998; Frye & Zelazo, 1998; Frye et al., 1996) define complexity as the number of hierarchical rules that must be maintained in working memory in order to accomplish a task, a view proposed as Cognitive Complexity and Control (CCC) theory. For example, in the Dimensional Change Card Sort (DCCS) task, children were asked to follow a rule to sort by color (e.g., "if red ... here" and "if blue ... here") and a rule to sort by shape (e.g. "if rabbit... here" and "if boat...here"). Children ages 3-4 were successful on these sorting tasks when performing them separately, but failed when required to integrate these two within a higher-order rule.

Halford (1993; Andrews & Halford, 2003; Halford et. al, 2002) has argued that relational complexity is more generally a constraint on the number of distinct units of information that must be processed in parallel while being maintained in WM in order for a reasoner to complete a task. Using this metric of relational complexity, Halford has argued for a developmental continuum in children's relational complexity capacity such that until approximately age four, children can process binary relations (a relationship between two objects) but not ternary relations (relationships among three objects, equivalent to the integration of 2 binary relations).

The three hypotheses are not mutually exclusive, and the relationships among the empirical factors emphasized by each model have not been fully examined. The present project examines the interactions among the constraints at the heart of the three models: the role of domain knowledge, inhibition of perceptual distraction, and relational complexity.

Picture Analogy Task

We developed a set of materials for a picture-analogy task suitable for children across a wide age range. The general structure of the stimuli was modeled after those developed by Markman and Gentner (1993), with inclusion of additional controls and using content accessible to young children. Our picture set (Richland Picture Analogies, or RPA task; available from first author upon request) was designed to examine the impact of relational complexity and perceptual distraction (i.e., need for inhibition) on children from age 3 yrs, while controlling for domain knowledge. The RPA stimuli depict relational motion verbs of the type learned early in children's vocabulary acquisition (e.g., Golinkoff et. al., 1996; Golinkoff et al, 1995; Gentner, 1978). Relations were motion verbs with perceptually available meanings that are familiar to young children by the age of 3 (e.g., "kiss", "chase" and "feed"). The objects used to represent these relations were items regularly encountered by preschool age children, including humans, animals, and dolls. Counterbalanced versions of each picture set factorially varied number of relevant relations (1 or 2) and presence vs. absence of a perceptual distractor in a 2x2 design. Perceptual distractors were either exact matches to the source object located within the target picture or were slight variations of the same object (e.g., a cat chasing and a cat sitting). In the no distractor conditions, a neutral object replaced the featural match. The spatial location was held constant. Unlike in the Markman and Gentner stimuli, distractors were never placed in key relational roles (allowing perceptual and relational errors to be coded separately), and the number of objects in each picture was controlled.

Method

Participants

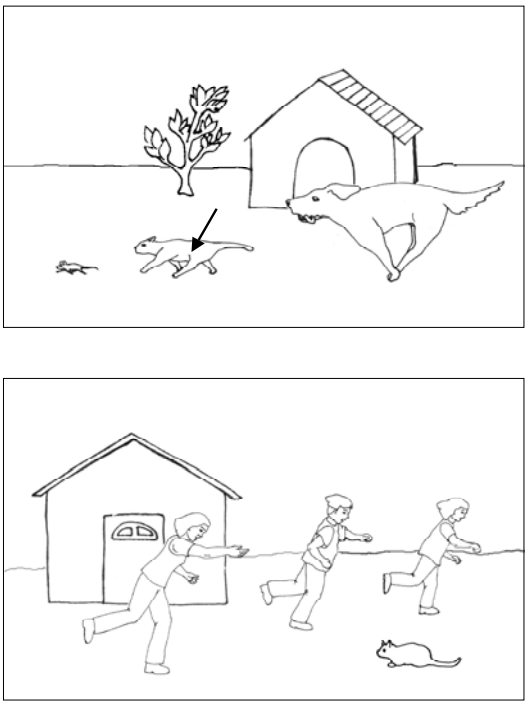
The participants were 68 children: 22 aged 3-4 years, 21 aged 6-8, and 25 aged 13-14. They were enrolled in preschool, elementary, and junior high school programs in the New York City and Los Angeles areas.

Materials and Design

The RPA task consists of 20 pairs of source and target pictures in which objects in the paired pictures depict the same relationship using unique objects. On a single page, participants viewed the two pictures in a set. An arrow pointed to a source object in the top picture, and the participant was asked to select the corresponding object in the bottom picture (cf. Markman & Gentner, 1993). For the example in Figure 1, the top picture represents "dog chasing cat chasing mouse" and the bottom picture represents "woman chasing boy chasing girl". If an arrow pointed to the cat, the correct relational response would be the boy in the bottom picture. All pictures contained extra items not depicting the relevant relationship, and the number of total objects was standardized across pictures per condition. Most image sets contain a total of five objects.

Four versions of each picture set were constructed in order to manipulate two variables in a 2x2 design. The first variable was the presence or absence of a perceptual distractor in the target picture, defined by strong featural similarity to an object in the source picture. The featural distractor was either an identical match to an object in the source picture or was the same object in a slightly different position. For example, in Figure 1 (top) the cat is depicted sitting in the target picture but is not involved in the chase. The featural distractor is never involved in the relational structure of the target picture. In Figure 1 (bottom), the correct relational response is the boy; however the participant must inhibit the featural match to make this choice. When present, the featural distractor spatially replaces an alternative object in the target picture. As a control to ensure that the featural distractors were indeed perceptually distracting, ten undergraduates were asked to select the most perceptually similar object to the target in the 2R-D version of each stimuli. Participants selected the intended featural match 96% of the time, indicating that the manipulation of perceptual similarity is valid.

The second variable was the number of relations, one or two, that participants were required to process simultaneously in order to accurately select a target object. When two relations were involved, the correct target object was both agent and recipient of a relation. For example, in Figure 1 the top picture represents "dog chases cat" and "cat chases mouse", whereas the bottom picture depicts "mom chases boy" and "boy chases girl". If the participant only considered one of the relations in each picture, there would be two equally plausible answer choices, and participants would be expected to perform at a 50% level at best. In this example the boy is the correct relational response because he (uniquely) is both being chased and is chasing. Making this determination requires integration of two binary relations in each picture.



Problem 2-2a

Figure 1. Sample stimuli, two relations with distractor (R2-D). The cat in the top picture (both chaser and chased) maps relationally to the boy in the bottom picture.

The 2x2 repeated-measures portion of the design generated four conditions: one relation, no featural distractor (R1-N), one relation with featural distractor (R1-D), two relations, no featural distractor (R2-N), two relations, featural distractor (R2-D). Packets of picture pairs for each participant were organized such that five examples of each condition were included in a random order. The assignment of specific picture pairs to each of the four conditions was counterbalanced across participants in each age group. The three age groups constituted an additional between-subjects factor. The dependent variable was participants' object choice within target pictures.

Procedure

The task was administered to participants in paper form. All participants were given two sample problems,

one involving one relation and the other involving two relations. The instructions stated that "a certain pattern exists in both the top picture and the bottom picture, and the child's job is to find this pattern." Following the first sample problem, (a 1R-D problem), it was explained that "some pictures have two parts of the pattern like that one, and others have three parts" (demonstrated subsequently in the 2-relation sample problem). The child was taught that an object in the top picture would be highlighted by an arrow, and they were to point or draw an arrow to the corresponding object in the bottom picture. For both sample problems, children were asked to point to the correct answer and then were given feedback. Feedback was repeated until they gave the correct answer. If they failed initially on both sample problems, their performance on the first 5 problems was used as criteria for exclusion. If participants failed on more than 3 problems, their data was excluded from analysis.

The problems were presented in random order following the sample problems. The task was administered to the 13-14 year old participants in groups; all other children were tested individually by a single experimenter.

Results

Figure 2 presents the proportion of correct relational responses for each of the four picture conditions as a function of age. An analysis of variance (ANOVA) was performed to examine the effects of age, relational complexity, and distractor condition on children's proportion of correct relational choices. The ANOVA revealed main effects of age, $F(2, 65) = 78.15$, $p<.001$, featural distraction, $F(1, 65) = 26.07$, $p<.001$, and relational complexity, $F(1, 65) = 24.83$, $p< .001$. These results establish that the RPA task is sensitive to age, that the picture manipulations were effective at creating distraction and increasing WM load, and that these constraints actively impede children's analogical reasoning.

Interactions were examined among age, relational complexity, and distraction. The interaction between age and distractor condition was reliable, $F(2, 65) = 3.15$, $p=.05$, whereas that between age and relational complexity was not, $F(2, 65) = .57$, $p= .57$. Importantly, the 3-way interaction was significant, $F(2, 65) = 3.28$, $p< .05$.

The pattern of interaction was investigated using repeated-measures ANOVAs for each age group separately. Results show that for the youngest children, ages 3-4, there was a main effect of relational complexity, $F(1, 21) = 4.44$, $p< .05$, a main effect of distractor, $F(1, 21) = 14.08$, $p<.01$, and a significant interaction between relational complexity and distraction, $F(1, 21) = 4.21$, $p=.05$. For the 6-7 yr old children there was a main effect of relational complexity, $F(1, 20) = 10.43$, $p< .01$ and of distraction, $F(1, 20) = 10.31$, $p< .01$, but no reliable interaction between these variables, $F(1, 20) = 2.71$, $p = .116$. Data for the 13-14 yr olds revealed a main effect of relational complexity, $F(1, 24) = 17.66$, $p< .001$ but not of distraction, $F(1, 24) = 2.21$, $p= .15$, nor was there a reliable interaction, $F(1, 24) = 1.67$, $p=.21$.

These data reveal that young children responded correctly well above chance on the one relation, no distractor condition; however, their accuracy fell when either a distractor or an added level of relational complexity (or both) was added. With age this pattern remained similar for 6-7 year olds, but as children reached adolescence, the negative effects of distractor and relational complexity were minimized.

Chance was calculated conservatively as the percent likelihood that a subject would select the correct relational match within the set of reasonable choices. These included relational errors and featural errors, but not extraneous objects. With this criteria, chance differed by condition reflecting the differential number of potential errors ranging from 50% (2 relevant possible answers) for 1R-N to 25% (4 relevant possible answers) for 2R-D. Paired *t*-tests revealed that the youngest children were above chance on all conditions (1R-N: $t(21) = 2.71$, $p< .05$; 2R-N: $t(21) = 2.43$, $p< .05$; 2R-D: $t(21) = 2.35$, $p< .05$) except for the 1R-D condition ($t(21) = 1.10$, $p=.29$).

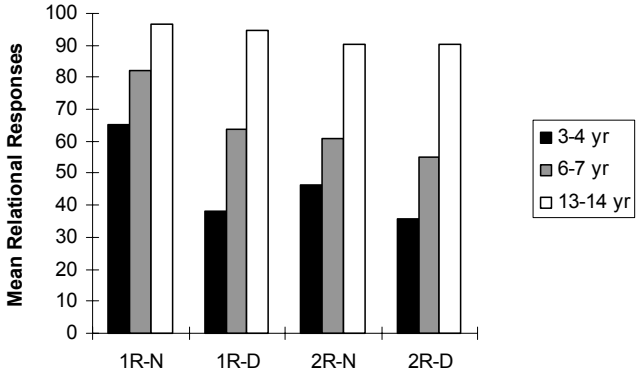


Figure 2. Proportion correct relational responses as a function of distraction and number of relations across age groups.

Error analysis

Children's responses were categorized into four types (see Table 1). Reponses were coded as either (1) relationally correct; (2) relational errors (an object in the correct relation but wrong role); (3) featural errors (the featural match in distractor conditions, or an unrelated object in the corresponding spatial location in no-distractor conditions); or (4) other errors. A repeated-measures ANOVA was performed to examine the relationship between age and participants' featural errors across the four picture conditions. Children's choice of

the featural match on the distractor conditions was compared with their choice of a non-featural, matched object in the same spatial location for the no distractor conditions. The main effect of age was reliable, $F(2, 65) = 49.78$, $p < .001$, as was the main effect of distractor, $F(1, 65) = 126.54$, $p < .001$, confirming that the featural match was an effective distractor. There was also a significant interaction between age and distractor, $F(2, 65) = 20.15$, $p < .001$, supporting the hypothesis that perceptual inhibition is a developmental constraint on analogical reasoning. No other interactions were reliable.

Table 1. Proportion of each response type across age and condition.

	Age	R1-N	R1-D	R2-N	R2-D
Correct Relational	3-4	65	38	46	36
	6-7	82	64	61	55
	13-14	97	95	90	90
Featural Errors	3-4	8	46	11	46
	6-7	0	25	4	27
	13-14	0	5	0	8
Relational Errors	3-4	15	9	6	9
	6-7	13	7	19	8
	13-14	2	1	4	4
Other Errors	3-4	9	4	21	6
	6-7	5	5	15	10
	13-14	2	0	4	5

A separate repeated-measures ANOVA was performed on relational errors. Note that there was one possible relational error choice in the R1 conditions, and two such possible error choices in the R2 conditions. The ANOVA revealed main effects of age, $F(2, 65) = 23.41$, $p < .001$, as well as relational complexity, $F(1, 65) = 59.56$, $p < .001$. There was also a significant interaction between the presence of a distractor and age on children's relational errors, $F(2, 65) = 5.85$, $p < .01$. At younger ages children made relational errors more frequently when there was no perceptual distractor available as an option. This finding suggests that young children unsure about the correct answer first attempted to make a feature-based selection; if no perceptually similar choice was available, then they made a guess among objects participating somehow in the relevant relation.

Discussion

Data from the RPA task at ages 3-4, 6-7 and 13-14 provide insight into the roles of relational knowledge, the relational shift, and maturational capacity in children's development of analogical reasoning. Patterns in participants' correct relational responses revealed main effects of age, distraction, and relational complexity, supporting the validity of the task manipulations. These main effects support theories of analogical reasoning development based on relational complexity and the relational shift.

Conversely, because the 3-4 year olds' performance on the 1R-N condition was high, their subsequent increases in errors in conditions with featural distraction or relational complexity provide support against the theory that domain knowledge alone is the mechanism underlying age-related development of children's analogical reasoning.

Interactions between age, distraction, and relational complexity indicate that in spite of children's capacity to perform analogical mapping based on these relations, as evidenced by their success on the R1-N condition, maturational factors may interact to constrain children's capacity to perform successfully on picture analogies that require more WM or perceptual inhibition.

Further, the error patterns suggest that perceptual distraction may be a primary constraint on children's reasoning and relational complexity a secondary constraint. Error analysis provided support for the claim that participants' patterns of failure were associated with age-related inhibition and relational complexity constraints. Participants were likely to make featural errors when the perceptual distractor was present, highlighting the validity of the distraction manipulation within the task. Supporting the relational shift hypothesis, at 3-4 yrs children were more likely to make featural responses when available than relational errors, even for the 2R-D condition, suggesting that inhibition was a more powerful constraint than relational complexity. However, relational errors were also made by children of all age groups, in highest numbers in the 2R-N condition, indicating that relational complexity is an important constraint on young children's analogical reasoning but may operate secondarily to featural distraction. One possible explanation for this is that inhibition is a core mechanism necessary for the WM system to operate on multiple relations (see Viskontas, in press)

The mechanism underlying featural distraction proposed by Rattermann and Gentner (1998; Gentner & Rattermann, 1991) is domain knowledge; however, this hypothesis is not supported by the current data, as the pictures were simple and counterbalanced across all conditions. The alternative explanation based on an inhibition mechanism is supported by the great difference between children's performance on the R1-N and R1-D conditions, as well as the similarity between the R1-D and R2-D conditions.

In sum, the RPA task provides a new paradigm for using children's interpretations of picture analogies to gather information about children's development of analogical reasoning, and specifically reveals interactions between the roles of perceptual inhibition/ distraction and relational complexity across age.

Acknowledgments

A Neural Model of Episodic and Semantic Spatiotemporal Memory

Gerard J. Rinkus (rinkus@comcast.net)
468 Waltham St.
Newton, MA USA

Abstract

A neural network model is proposed that forms sparse spatiotemporal memory traces of spatiotemporal events given single occurrences of the events. The traces are distributed in that each individual cell and synapse participates in numerous traces. This sharing of representational substrate provides the basis for similarity-based generalization and thus semantic memory. Simulation results are provided demonstrating that similar spatiotemporal patterns map to similar traces. The model achieves this property by measuring the degree of match, *G*, between the current input pattern on each time slice and the expected input given the preceding time slices (i.e., temporal context) and then adding an amount of noise, inversely proportional to *G*, to the process of choosing the internal representation for the current time slice. Thus, if *G* is small, indicating novelty, we add much noise and the resulting internal representation of the current input pattern has low overlap with any preexisting representations of time slices. If *G* is large, indicating a familiar event, we add very little noise resulting in reactivation of all or most of the preexisting representation of the input pattern.

Introduction

Any realistic cognitive model must exhibit both episodic and semantic memory. And, as emphasized by Ans, Rousset, French, & Musca (2002), it must demonstrate these properties for the spatiotemporal (or, sequential) pattern domain. Thus, the model must be able to recall, without significant interference, large numbers of spatiotemporal patterns, which we will call episodes, given only single presentations of those episodes. Furthermore, it must exhibit human-like similarity-based generalization and categorization properties that underlie many of those phenomena classed as semantic memory.

We propose a sparse, distributed neural network model, TESMECOR (Temporal Episodic and Semantic Memory using Combinatorial Representations), that performs single-trial learning of episodes. The degree of overlap between its distributed memory traces increases with the similarity of the episodes that they represent. This latter property provides a basis for generalization and categorization and thus, semantic memory. The model achieves this property by computing, on each time slice, the similarity, *G*, between the expected and actual input patterns and then adding an amount of noise inversely proportional to *G* into the process of choosing an internal representation (IR) for that time slice. When expected and actual inputs match completely, no noise is added, allowing those IR cells having maximal input via previously modified weights to be reactivated (i.e., fully deterministic recall). When they completely mismatch, enough noise is added to completely drown out the learned, deterministic inputs, resulting in activation of an IR having little overlap with preexisting traces.

The opposing purposes of episodic memory and pattern recognition (i.e., semantic memory)—i.e., remembering what is unique about individual instances vs. learning the similarities between instances—has led other researchers to propose that the brain uses two complementary systems. McClelland et al (1995) and O'Reilly & Rudy (1999) propose that the purpose of the hippocampus is to rapidly learn new specific information whereas the purpose of neocortex is to slowly integrate information across individual instances thus coming to reflect the higher-order statistics of the environment. The hippocampus then repeatedly presents its newly acquired memory traces to neocortex, acting as trainer facilitating the gradual transfer of information to neocortex during the period of memory consolidation. We point out that TESMECOR is not such a two-component model. Rather, it is a monolithic model, i.e., it has a single local circuit architecture and processing algorithm (envisioned as an analog of the cortical mini-column) that satisfies the opposing needs.

Episodic Spatiotemporal Memory

Rinkus (1995) introduced a neural network model, TEMECOR, of episodic memory for spatiotemporal patterns. As shown in Figure 1, the model's. Layer 1 (L1) consists of binary feature detectors and its layer 2 (L2) consists of competitive modules (CMs). The L2 cells are nearly completely connected via a horizontal matrix (H-matrix) of binary weights.

The model operates in the following way. On each time step, a pattern is presented to L1. On that same time step, one L2 cell is chosen at random to become active in each CM corresponding to an active L1 cell. In addition, the horizontal weights from the L2 cells active on the prior time slice to those that become active on the current time are increased to their maximal value of one. In this way, spatiotemporal memory traces are embedded in the H-matrix. Later on, if we reinstate a set of L2 cells that was coactive in the past while learning an episode, the remainder of that episode will be read out in time. That is, the model recalls spatiotemporal memories.

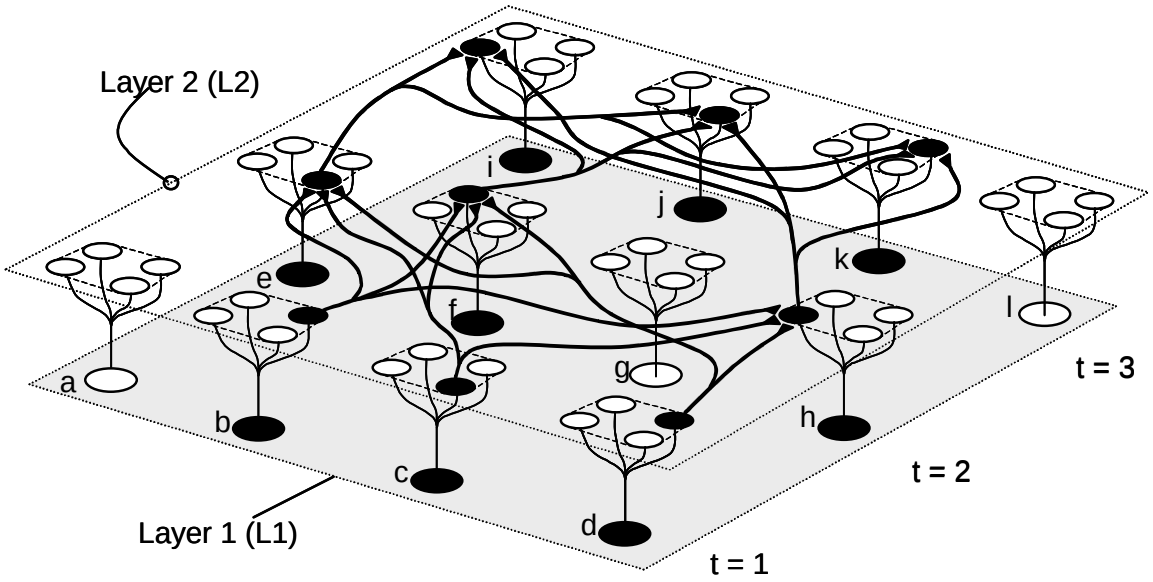

Figure 1: TEMECOR architecture showing how spatiotemporal memory traces are laid down amongst the horizontal connections of Layer 2. Features {b,c,d} are active at t = 1, {e,f,h} at t = 2, and {i,j,k} at t = 3. Each L2 cell has horizontal connections to all other L2 cells except those in its own CM. Only the connections increased while processing this particular spatiotemporal pattern (episode) are shown. Note that although this figure shows each time slice of the episode being handled by a separate portion of the network, this is purely to keep the figure uncluttered. In fact, all L1 cells and all L2 CMs are eligible to become active on every time slice.

TEMECOR exhibits high capacity, as shown in Figure 2, as well as other essential properties of episodic memory, e.g., single-trial learning. The model's beneficial properties derive principally from its use of a sparse distributed, or *combinatorial*, representational framework, a framework underlying many other models—Willshaw, Buneman & Longuet-Higgins, 1969; Lynch, 1986; Palm, 1980; Moll & Miikkulainen, 1995; Coultrip & Granger, 1994. The key to its high capacity is that by randomly choosing winners in the CMs, it minimizes the average overlap amongst the memory traces.

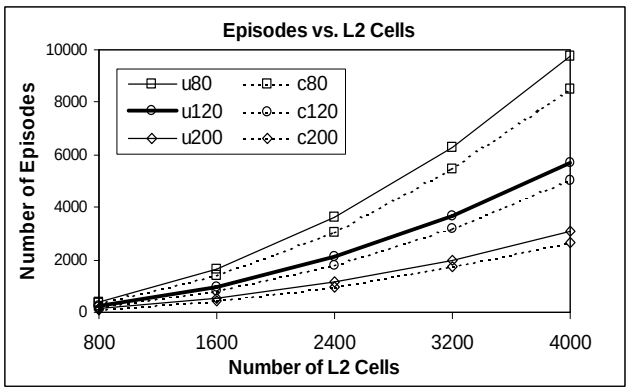

Figure 2: Capacity Results

Table 1 provides the data for the bold curve in the figure. It gives the maximal capacity, E, and other statistics for networks of increasing size, L. All episodes had T = 6 time slices and each time slice had S = 20 (out of M = 100) active features, chosen at random. The bottom row of the table shows that a network containing 4000 L2 cells, i.e., 100 CMs having K = 40 cells each, can store 5693 such episodes.

Table 1: Capacity Test Results

E	E/L	F	K	L	V	R_{set}	H
237	0.30	285	8	800	36	96.3	52.3
943	0.59	1132	16	1600	71	97.0	52.1
2104	0.88	2524	24	2400	105	97.0	51.8
3691	1.15	4430	32	3200	138	97.2	51.4
5693	1.42	6831	40	4000	171	97.4	50.9

Table 1 was generated as follows. For each K, the maximal number of episodes, E, which could be stored to criterion average recall accuracy, 96.3%, was determined. Recall accuracy, R_e, for a given episode e, is defined as:

$$R_e = (C_e - D_e)/(C_e + I_e) \quad (1)$$

where C_e is the number of L2 cells correctly active during recall of e^{th} episode, D_e is the number of deleted L2 cells, and I_e is the number of intruding L2 cells. The table reports R_{set}, the average of the R_e values for a whole set of episodes. All episodes were presented only once.

The other statistics in Table 1 are as follows. E/L is the ratio of stored episodes to the number of cells in L2, which increases linearly. F is the average number of instances of each feature across the entire set of episodes. V is the average number of times each L2 cell in a given CM became active to represent the corresponding feature. H is the percentage of weights increased, which is nearly

constant, at just over 50%, across rows. As we allow the fraction of weights to increase beyond 50%, more episodes are stored, but with a lower average recall accuracy due to the increase in intrusion errors resulting from saturation of the weights.

While TEMECOR exhibited the major properties of episodic memory it was not initially intended to model semantic memory and, due to its completely random method of choosing sparse internal representations at L2, it did not exhibit the generalization and categorization properties that underlie semantic memory. The successor version of the model, TESMECOR was developed to address this shortcoming (Rinkus, 1996).

Semantic Spatiotemporal Memory

TESMECOR is shown in Figure 3. It has some architectural differences with the original version (essentially, relaxations of some of the original's structural constraints) and a greatly modified winner selection process. The H-matrix of L2 is as before but the vertical projection is generalized. There is no longer a 1-to-1 correspondence between L1 cells and L2 CMs. Rather; each L1 cell connects to a fraction of all the L2 cells chosen at random in simulations. In TESMECOR, all CMs are active on every time slice. In addition, the bottom-up, or forward, connections (F-weights) and the top-down, or reverse, connections (R-weights) are now modeled separately and are modifiable.

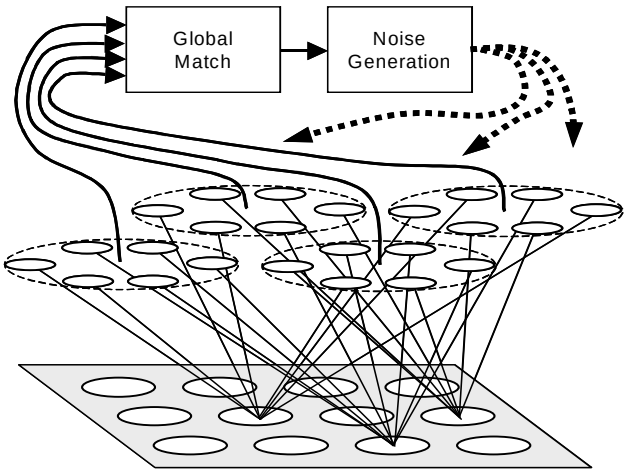

Figure 3: TESMECOR architecture.

The most significant change between TEMECOR and TESMECOR however is in the processing algorithm. Specifically, TESMECOR adds circuitry implementing spatiotemporal matching operations, both locally within each CM and globally over the entire L2. On each time slice, the global degree of match between the actual current input and the expected input, given the spatiotemporal context of the current input, modulates the amount of noise injected into the process of selecting which L2 cells will become active. The smaller the match, the more noise that is added and the greater the difference between the internal representation (IR) that would have become active purely on the basis of the deterministic inputs reflecting prior learning and the IR that actually does become active. The greater the match, the less noise added and the smaller the difference between the most highly implicated IR (on the basis of prior learning) and the actually chosen IR.

Figure 4 illustrates the basic principles by which the model computes, on each time slice, the degree of match, *G*, between its expected input and the actual input and then uses *G* to determine how much noise to add to the internal representation selection scheme. Figure 4a shows a pattern, A, presenting at t = 1. The H-weights are increased (represented by the dotted lines) from the active L1 cells onto an internal representation, IR_A, comprised of the three L2 cells that emerge as winners in their respective CMs. For purposes of this example, these three winners can be assumed to be chosen at random.

Figure 4b shows another pattern, B, presenting at t = 2. As with IR_A, IR_B can be assumed to be chosen at random. Here, we see the both H- and F-weights being increased.

Figure 4c shows another trial with pattern A presenting at t = 1. This time, IR_A becomes active due to the deterministic effects of the previously increased weights (which are now shown as solid lines). The cells of IR_A now send out signals via the H-matrix which will arrive at the other CMs at t = 2.

At this point, it is convenient to portray the t = 2 time slice in two steps. Figures 4d and 4e show these two steps. Figure 4d shows the signals arriving via the H-matrix at the same time that that signals arrive via the F-matrix from currently active L1 cells. Thus, the L2 cells in the three CMs on the right simultaneously receive two vectors each carrying possibly different expectations about which IR should become active (or equivalently, different hypotheses about what the current state of the world is). It is these two vectors that TESMECOR compares. In this particular case, the three cells of IR_B are receiving full support via the H-matrix. In other words, the temporal context says that IR_B should become active. However, these cells are receiving only partial support (two out of four L1 cells) via the F-matrix. Indeed, this is a novel input, pattern C, which has presented. Thus, the current spatial context does not contain sufficient information (given this network's history of inputs) to clearly determine what IR should become active. We represent this less-than-maximal support for IR_B by the gray shading of its cells. Because of this mismatch, i.e., $G < 1.0$, we add some noise into the winner selection process. The final result is that a different L2 cell than the one most strongly implicated by the deterministic inputs ends up winning the competition in one of the three CMs (the bottom right-hand one) active at t = 2. Thus, Figure 4e shows a new IR, IR_C, representing the novel pattern, C.

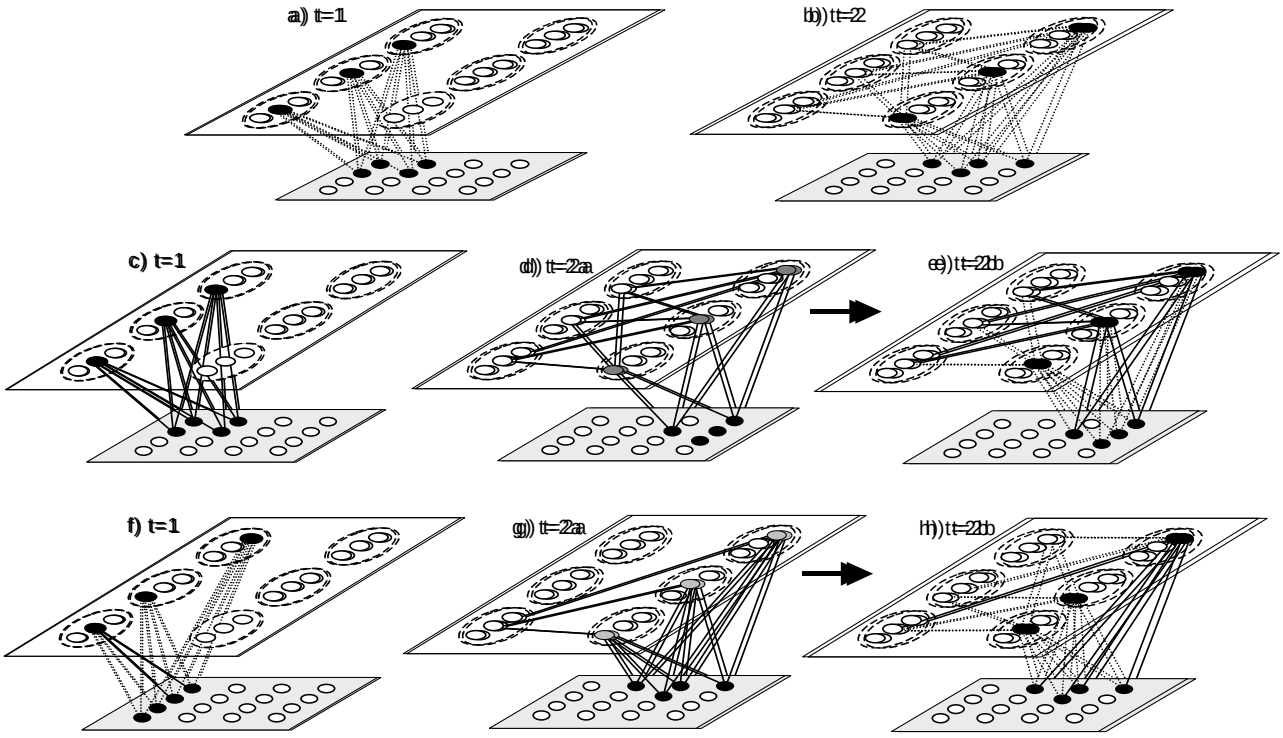

Figure 4: Sketch of TESMECOR's spatiotemporal pattern comparison and noise-modulated internal representation selection scheme. See text for explanation. As in Figure 2, the division of the L2 CMs into separate groups for different time slices is purely to avoid clutter. In the model's actual operation, all CMs are active on every time slice.

Figures, 4f, 4g, and 4h, show another possible scenario. This time, we will again present pattern B at t = 2. However a novel pattern, D, having only two features in common with A, presents at t = 1. As this is the first time slice of this new trial, there is no prior context vector active in the H-matrix. For concreteness, let's assume that this degree of mismatch causes a new winner to be chosen in two of the three CMs active at t = 1, resulting in a new IR, IR_D. When B presents at t = 2, the F-vector lends maximal support for IR_B but the H-vector has great uncertainty; only 1/3 of the maximal possible horizontal input arrives at the cells of IR_B. This seems like even a worse match than in Figure 4d (shown by an even lighter shading of the IR_B cells than in Figure 4d). Consequently, more noise is added to the winner selection process. Let's assume that this degree of mismatch leads to a new winner in two of the three CMs active at t = 2, resulting in a new IR, IR_{B*}, for pattern B.

With this example of the desired behavior in mind, we now give TESMECOR's processing algorithm, which is computed on each time slice for each L2 cell.

1. $$\psi_{i,t} = \sum_{j \in \Gamma_t} w_{ji} \tag{2}$$

2. $$\Psi_{i,t} = \frac{\psi_{i,t}}{\max(\max_{j \in CM}(\psi_{j,t}), {}^{F}\Theta_t)} \tag{3}$$

3. $$\phi_{i,t} = \sum_{j \in \Delta_{t-1}} w_{ji} \quad , t > 0 \tag{4}$$

4. $$\Phi_{i,t} = \frac{\phi_{i,t}}{\max(\max_{j \in CM}(\phi_{j,t}), {}^{H}\Theta_t)} \quad , t > 0 \tag{5}$$

5. $$\chi_{i,t} = \begin{cases} \Psi_{i,t}{}^{u} \Phi_{i,t}{}^{v} & , t > 0 \\ \Psi_{i,t}{}^{w} & , t = 0 \end{cases} \tag{6}$$

6. $$\mathrm{X}_{i,t} = \frac{\chi_{i,t}}{\max(\max_{j \in CM}(\chi_{j,t}), {}^{\chi}\Theta)} \tag{7}$$

7. $$\pi_{k,t} = \max_{j \in CM_k} \mathrm{X}_{j,t} \quad , 1 \le k \le Q \tag{8}$$

8. $$G_t = \sum_{k=1}^{Q} \pi_{k,t} \Big/ Q \tag{9}$$

9. $$p_{i,t} = \frac{f(\mathrm{X}_{i,t}, G_t)}{\sum_{j \in CM} f(\mathrm{X}_{i,t}, G_t)} \tag{10}$$

In step 1, each L2 cell, *i*, computes its total weighted input, $\psi_{i,t}$, from the set, Γ_t, of currently active L1 cells. In step 2, the ψ values are normalized within each CM. That is, we find the maximum ψ value, in each CM and divide all the individual values by the greater of that value and

F-matrix threshold, ${}^{F}\Theta_t$. ${}^{F}\Theta_t$ is needed to ensure that small feedforward signals are not amplified in subsequent normalization steps. ${}^{F}\Theta_t$ is a parameter that can vary from one time slice to the next but we omit discussion of this detail in this paper due to space limitations.

Steps 3 and 4 perform analogous operations for the horizontal inputs. In step 3, *i*, computes its total weighted input, $\phi_{i,t}$, from the set, Δ_{t-1}, of L2 cells active on the prior time slice. In step 4, the ϕ values are normalized within each CM. That is, we find the maximum ϕ value, in each CM and divide all the individual values by the greater of that value and an H-matrix threshold, ${}^{H}\Theta_t$. ${}^{H}\Theta_t$ is needed to ensure that small H values are not amplified in subsequent normalization steps. ${}^{H}\Theta_t$ also varies from one time slice to the next but again, space limitations force us to omit discussion of this detail. Note that steps 3 and 4 are only applicable on non-initial time slices (t > 0) of episodes.

Step 5 works differently on the first time slices of episodes than on the rest. When t > 0, we multiply the two pieces of evidence, $\Psi_{i,t}$ and $\Phi_{i,t}$, that cell *i* should become active but we do this after passing them through separate exponential filters. Since $\Psi_{i,t}$ and $\Phi_{i,t}$, are both between 0 and 1, the final $\chi_{i,t}$ values output from this step are also between 0 and 1. The exponential filters effect a generalization gradient: the higher the exponents, *u* and *v*, the sharper the gradient and the more sensitive the model is to differences between inputs (i.e., the finer the spatiotemporal categories it would form) and the less overlap between the internal representations chosen by the model. When t = 0, we do not have two vectors to compare. Instead, we simply pass the Ψ values through an exponential gradient-controlling filter. The three different exponent parameters, *u*, *v*, and *w*, simply let us fine-tune the model's generalization gradients. For example, we might want the model's sensitivity to featural similarity to be stricter at the beginning of episodes than on the successive time slices of episodes; thus we would set *w* higher than *u*.

In step 6, we normalize the combined evidence vector, again subject to a threshold parameter, ${}^{\chi}\Theta_t$, that prevents small values from erroneously being amplified. In step 7, we simply determine the maximum value, $\pi_{i,t}$, of the $X_{i,t}$ values in each CM. These π values constitute local, i.e., within each CM, comparisons between the model's expected and actual inputs. In step 8, we compute the average of these local comparison results across the *Q* CMs of L2, resulting in the model's global comparison, G_t, of its expected and actual inputs.

In step 9, we convert the $X_{i,t}$ values back into a probability distribution whose shape depends on G_t. We want to achieve the following: if G_t is 1.0, indicating that the actual input has perfectly matched the model's expected input, then, in each CM, we want to choose, with probability 1.0, the cell belonging to the IR representing that expected input. That cell, in each CM, is the one having the highest X value. Since, in general, other cells in that cell's CM could have non-zero or even high X values, we need to filter the values by an expansive nonlinearity, *f*, so that the cell with the maximal X value maps to a probability, $p_{i,t}$, of 1.0 and the rest of the cells end up mapping to $p_{i,t} = 0.0$. On the other hand, if $G_t = 0$, indicating that the actual input is completely unexpected in the current temporal context given all of the model's past experience, then we want to make all the cells, in any given CM, be equally likely to be chosen winner. Thus, in this case, *f* should be a compressive nonlinearity that maps all cells in the CM to $p = 1/K$, where *K* is the number of cells in the CM. Without going into details, the function, *f*, is a sigmoid that meets the above goals. In the last stage of step 9, we simply choose the winner in each CM according to the resulting distribution.

To summarize, on each time slice, every L2 cell compares two evidence vectors, the H-vector, reflecting the sequence of patterns leading up to the present time slice (temporal context), and the F-vector, reflecting the current spatial pattern (spatial context). These vectors are separately nonlinearly filtered and then multiplicatively combined. The combined evidence vector is then renormalized and nonlinearly filtered before being turned into a probability distribution that governs the final selection of L2 cells to become active. Note that this basic scheme can be extended to simultaneously compare other evidence vectors as well. This is one of our intended lines of future research: specifically, we will examine incorporating a hippocampal component to the model, which will provide a third evidence vector to the L2 cells.

The concept of controlling the embedding of internal representations (IRs) based on comparing the expected and actual inputs is common to other cognitive models, e.g., Grossberg (1987). However, TESMECOR's use of distributed IRs, rather than singleton IRs, requires a generalized comparison scheme. Specifically, with distributed IRs, there exists a range of possible degrees of overlap between IRs. We want to use that range to represent the spatiotemporal similarity structure of the environment to which the model has been exposed. Therefore, rather than having a single threshold for judging the similarity of the current input and expected inputs (e.g., ART's vigilance parameter), TESMECOR's continuous-valued similarity measure, *G*, is used to inject a variable amount of noise into the IR-selection process, which in turn allows for selecting IRs whose degrees of overlap are correlated with their spatiotemporal similarities.

Simulation Results

In this section, we provide the results of preliminary investigations of the model demonstrating that it performs similarity-based generalization and categorization in the spatiotemporal pattern domain.

The four simulations described in Table 2 were performed as follows. In the learning phase, E episodes were presented, once each. Each episode consisted of 5 time slices, each having 20 (out of 100) randomly selected features present. Then, perturbed versions, differing by *d* = 2, 4, 6, or 8 (out of 20) features per time slice from the original episodes

were generated. The model was then tested by presenting the first Z time slices of the perturbed episodes as prompts. Following the prompt time slices, the model entered a *free-running* mode (i.e. cutting off any further input) and processing continued from that point merely on the basis of signals propagating in the H-projection.

Table 2: Generalization/Categorization Results

Simulation	**E**	***d***	**Z**	R_{set}
1	27	2	1	92.3%
2	13	4	1	98.0%
3	7	6	1	98.3%
4	13	8	2	82.7%

These results indicate that the model was extremely good at locking into the trace corresponding to the most-closely-matching original episode. The accuracy measure, R_{set} (eq. 1) measures how close the recall L2 trace is to the L2 trace of the most-closely-matching original episode. The accuracy for simulation 4 (82.7%) may seem low. However, if the accuracy measure is taken only for the final time slice of each episode then it is close to 100% for all four simulations. The view taken herein is that given that the pattern to be recalled are spatiotemporal, the most relevant measure of performance is the measure of accuracy on the last time slice of the test episode. If the model can "lock into" the correct memory trace by the end of the recalled trace, then that should be sufficient evidence that model has recognized the input as an instance of a familiar episode.

Table 3: Per-Time-Slice L2 Accuracy for the Test Trials of Simulation 4 of Table 2

Episode	**T=1**	**T=2**	**T=3**	**T=4**	**T=5**
1	0.9	0.9	1.0	1.0	1.0
2	0.82	1.0	1.0	1.0	1.0
3	0.67	1.0	1.0	1.0	1.0
4	0.82	0.9	1.0	1.0	1.0
5	0.67	0.82	1.0	1.0	1.0
6	0.67	0.9	1.0	1.0	1.0
7	0.9	1.0	1.0	1.0	1.0
8	0.74	1.0	1.0	1.0	1.0
9	0.74	1.0	1.0	1.0	1.0
10	0.67	0.82	1.0	1.0	1.0
11	0.54	0.67	0.22	0.0	0.0
12	0.48	0.21	0.0	0.0	0.0
13	0.82	0.9	1.0	1.0	1.0

Table 3 shows the details of the simulation 4 in Table 2. Specifically, it shows the L2 accuracy on each time slice of each episode during the recall test. For each recall trial the model received a prompt consisting of degraded versions of the first two time slices of the original episode—specifically, 4 out of 20 features were substituted on each time slice (for a total of 8 featural differences). In all but two cases, the model 'locks into' the L2 trace corresponding to the most-closely-matching original episode (i.e., the episode from which the degraded prompt was created.

These simulations provide preliminary evidence that TESMECOR exhibits generalization, and in fact categorization, in the spatiotemporal domain, while at the same time exhibiting episodic memory since the episodes are learned with single trials.

Promoting Flexible Problem Solving: The Effects of Direct Instruction and Self-Explaining

Bethany Rittle-Johnson (bethany.rittle-johnson@vanderbilt.edu)
Department of Psychology and Human Development, Vanderbilt University
230 Appleton Place, Peabody #512, Nashville, TN 37203

Abstract

How do people learn flexible problem-solving knowledge, rather than inert knowledge that is not applied to novel problems? Both the source of the knowledge – instructed or invented – and a central learning process – engaging in self-explanation – may influence the development of problem-solving flexibility. Seventy-seven third- through fifth-grade students learned about mathematical equivalence under one of four conditions that varied on two dimensions: 1) prompts to self-explain and 2) invention vs. instruction on a procedure. Both self-explaining and direct instruction helped students to learn a correct problem solving procedure. Self-explanation promoted transfer, whereas direct instruction had both positive and negative effects on transfer. Overall, self-explanation is an important learning mechanism underling the acquisition of flexible problem solving with or without direct instruction.

Introduction

Everyday, we are faced with new problems to solve. How do we complete our income tax return, write a new resume, or find a new route home given recent road construction? When faced with a problem repeatedly, we often develop procedures for solving the problem, i.e. step-by-step methods for solving the problem. Ideally, we learn flexible, relatively abstract procedures that we can appropriately apply to a variety of tasks so that we do not need to invent new procedures when task conditions shift. Flexible, abstract, knowledge is also a key characteristic of expertise (Chi, Feltovich, & Glaser, 1981). Thus, understanding how people develop flexible, abstract knowledge is crucial for understanding learning and development and for designing learning environments to support flexibility.

Unfortunately, people of all ages and across a large range of domains often gain inert knowledge instead – knowledge that is not applied to new situations (see Bransford, Brown, & Cocking, 2001 for a review). For example, physics students typically fail to use knowledge of physics principles, such as Newton's Laws, to solve everyday problems (Halloun & Hestenes, 1985). Indeed, even scientists sometimes fail to use their scientific knowledge to solve mundane tasks (Lewis & Linn, 1994).

How do people learn flexible knowledge, rather than simply gaining inert knowledge, and how can we support this learning? In the current study, two processes were evaluated: 1) The source of new knowledge – invention or direct instruction and 2) A potential mechanism underlying flexible learning - generating self-explanations for why and how things work.

Invention vs. Instruction

Where do new procedures come from? Typically, we invent a procedure through problem exploration or we learn a procedure from others (e.g. via imitation or direct instruction). Major theories of learning and philosophies of education differ in their emphasis on the sources of new procedures. The current paper focuses on one source of knowledge from other people – direct instruction – and compares it to inventing procedures on ones own.

Invention and learning from direct instruction can both lead to learning of the target behavior or knowledge (e.g. Judd, 1908). However, a major concern with discovery learning is that a substantial proportion of learners never invent a correct procedure or engage in correct ways of thinking (Mayer, 2004).

Another critical issue is the relative effectiveness of each source of knowledge for supporting flexible, generalizable knowledge. Direct instruction on a procedure can lead people to learn the procedure by rote, to make nonsensical errors and to be unable to transfer the procedure to solve novel problems (e.g. Brown & Burton, 1978; Hiebert & Wearne, 1986), whereas when people invent procedures, they often use the procedures flexibly in new situations (Hiebert & Wearne, 1996). Thus, there appears to be a trade-off between instruction improving problem solving on a restricted range of problems but potentially harming flexible problem solving on a broader range of problems. The current study evaluates the pros and cons of direct instruction versus encouragement to invent a procedure on a single task and evaluates the role of self-explaining as a learning mechanism under both conditions.

Self-Explaining

A potential mechanism underlying the impact of instruction and invention on procedural flexibility (and learning more generally) is learners' attempts to generate explanations for why and how things work. Successful learners typically generated explanations while studying worked-examples to problems. These explanations included identification of gaps in understanding and linkages to previous examples or sections in the text (Chi, Bassok, Lewis, Reimann, & Glaser, 1989). Subsequent research indicates that learners ranging from 5-years-old to adulthood in domains ranging from number conservation to computer programming can learn more if they are prompted to generate self-explanations (Aleven & Koedinger, 2002; Bielaczyc, Pirolli, & Brown, 1995; Chi, de Leeuw, Chiu, & LaVancher, 1994). These findings are cooborated by findings from classroom-based research on individual differences and on cross-cultural

differences in teaching practices (Stigler & Hiebert, 1997; Webb, 1991). In all cases, generating explanations is associated with greater learning. Thus, generating explanations to explain how or why things work is a critical learning process across the lifespan and across domains.

However, the informal theories or working hypotheses that learners develop are not always correct. Rather, learners often develop incorrect theories, and engaging these incorrect theories is critical to supporting learning (Bransford et al., 2001). Evidence from a variety of domains indicates that learners' incorrect informal theories are resistant to change and often persist after formal instruction that contradicts their theories (e.g. Halloun & Hestenes, 1985).

Prompting students to generate explanations for incorrect, as well as correct, solutions, beliefs, etc, may be one method for helping learners overcome incorrect prior knowledge. For example, Siegler (2002) found that prompting students to explain both correct and incorrect solutions led to greater procedural flexibility than only explaining correct solutions. In the current study, learners in the self-explanation condition were prompted to explain both correct and incorrect solutions to maximize the effectiveness of the explanation condition.

Prompting students to self-explain has been used in conjunction with a variety of sources of new information (reading a text, studying worked example, problem-solving with feedback), but has not been used in combination with direct instruction on a correct procedure nor has prior research directly compared the role of self-explaining under different sources of new knowledge. Prompting students to engage in an effective learning process after direct instruction may help students to understand and generalize the procedure. Similarly, prompts to self-explain may help students to invent and generalize correct procedures when they do not receive direct instruction (Siegler, 2002).

The current study

These issues were evaluated in the context of children learning to solve problems that tap the idea of mathematical equivalence. Mathematical equivalence is a fundamental concept in both arithmetic and algebra. Unfortunately, most children in elementary and middle school do not seem to understand equivalence, and this poses a major stumbling block for students' success in algebra (Kieran, 1981). Novel problems such as 3+4+5=3+__ challenge students' naïve understanding of equivalence in a familiar arithmetic context, and approximately 70% of fourth- and fifth-graders do not solve these problems correctly (Alibali, 1999; Rittle-Johnson & Alibali, 1999). In the current study, third through fifth graders learned to solve these mathematical equivalence problems under one of four conditions based on two factors: 1) direct instruction on a correct procedure vs. prompts to invent a new way to solve the problems and 2) prompts for self-explanations vs. no prompts.

Method

Participants. Initial participants were 121 third- through fifth- grade students from an urban, parochial school serving a working- to middle-class population. In line with previous studies using mathematical equivalence problems, 34 students (29%) solved at least half of the mathematical equivalence problems correctly at pretest and thus were excluded from the study. One student was excluded because he did not take the pretest, and 9 students were excluded because they were absent on the day of the delayed posttest, so they could not be included in the repeated-measure analyses. The final sample consisted of 37 third-graders, 22 fourth-graders, and 18 fifth-graders.

Design. Students were randomly assigned to one of four conditions based on crossing two factors: 1) instruction on a correct procedure or prompts to invent a procedure and 2) prompts to self-explain correct and incorrect solutions or no prompts. There were 20 participants in the *instruction + explain* condition, 21 students each in the *invent + explain* and *instruction-only* conditions, and 15 students in the *invent-only* condition (unequal group sizes due to random differences in absenteeism at the delayed posttest).

Procedure. Students completed the pretest in their classrooms. Students who solved at least half of the mathematical equivalence problems incorrectly participated in a one-on-one intervention session. During the intervention session, there were 3 phases: warm-up, intervention (instruction problems and practice problems, all with accuracy feedback), and follow-up. At the end of this session, students completed the immediate paper-and-pencil posttest. Approximately 2 weeks later, students completed the delayed paper-and-pencil posttest in their classrooms.

Intervention session. All problems presented during this session were in standard format (see Table 1). At the beginning of the session, students solved two warm-up problems, explained how they had solved each problem, and were told whether they had solved the second problem correctly to motivate students to try to figure out correct ways to solve the problems. During the intervention phase, all students solved 8 problems. On all problems, students explained how they solved the problem and then were told if they had solved it correctly. The first two problems were the instructional problems and were both in the format A+B+C=A+_ (*A+ problems)*. For students in the instruction conditions, the experimenter explained a correct, add-subtract, procedure for solving the problem. For the problem 4+9+6 = 4+__, the experimenter said: "You can add the 4 and the 9 and the 6 together before the equal sign (gesture a "circle" around the 3 numbers), and then subtract the 4 that's over here, and that amount goes in the blank. So, try to solve the problem using this strategy." Students in the invention conditions were asked to try to figure out a new way to solve the problems.

Table 1: Procedural Knowledge Problem Types.

Problem Type	Problem Format
Standard	A+B+C=A+__ (A+) A+B+C=__+C (+C)
No repeated addend	A+B+C=D+__ A+B+C=__+D
Subtraction too	A+B-C=A+__ A+B-C=__ - C
Swap sides	A+__=A+B+C __+C=A+B+C

Next, students solved 6 practice problems that alternated between the two standard problem formats (see Table 1). After solving each of these problems, students were also told the correct answer to the problem. Students in the explain conditions were then prompted to try to explain a correct and an incorrect solution. They were shown the solution that two students at another school had gotten – one correct and one incorrect – and were asked to explain both how each student had gotten the answer and why each answer was correct or incorrect. The intervention trials were presented on a laptop computer that recorded accuracy and solution times. At the end of the intervention, students solved two follow-up problems without feedback and explained their solutions.

Assessments. The pretest, immediate posttest and delayed posttest were identical except that only a subset of the procedural knowledge problems were presented at pretest. The *procedural knowledge* assessments contained 4 types of problems, as shown in Table 1. Letters stand for numbers and indicate when a number was repeated within a problem. The standard problem formats were used during the intervention. One instance of each of the standard and no repeated addend problems was presented on the pretest. One instance of each of the problems in Table 1 were presented on the posttests. Students were encouraged to show their work when solving the problems. The 5 items on the *conceptual knowledge* assessment are shown in Table 2.

Table 2: Conceptual Knowledge Assessment Items

Item	Coding (2 pts)
Define equal sign	Mention "the same" or "equal" (2pts)
Rate definitions of equal sign: Rate 4 definitions as "always, sometimes or never true"	Rate "two amounts are the same" as "always true" (2 pts) or "sometimes true" (1 pt)
Group Symbols: Place symbols such as =, +, <, & 5 into three groups	Group =, >, and < together (2 pts)
Recognize use of equal sign in multiple contexts: Indicate whether 8 problems such as 8=2+6 and 3+2=6-1 make sense	7 or 8 correct (2 pts); 6 correct (1 pt)
Correct Encoding: Reproduce 4 equivalence problems from memory	Correctly reproduce problem (.5 point each)

Table 3: Procedures for Solving Equivalence Problems

Procedures	Sample student explanation
Correct Procedures	
Equalize	"I added 8 plus 7 plus 3 and I got 18 and 8 plus 10 is 18."
Add-subtract	"I did 8 plus 7 equals 15 plus 3 equals 18 and then 18 minus 8 equals 10"
Grouping	"I took out the 8's and I added 7+3."
Incorrect Procedures	
Add all	"I added 8+7+3+8, which is 26"
Add to equal sign	"8 plus 7equals15, plus 3 is18."
Incorrect Grouping	"I added 8 plus 7."

Coding. On the procedural knowledge assessments, students' percent correct was used (arithmetic slips were ignored). Students' verbal explanations during the intervention were used to code students' procedure use on those problems (see Table 3). On the conceptual knowledge assessment, each item was scored from 0-2 points for a possible total of 10 points (see Table 2).

Results

The effects of condition were assessed on three outcomes: procedural learning, procedural transfer, and conceptual knowledge. Procedural learning was assessed 3 times: verbally at the end of the intervention and on the immediate and delayed posttests. Procedural transfer and conceptual knowledge were assessed twice – on the immediate and delayed posttest. Results were evaluated for each outcome using repeated-measures ANOVAs with time of assessment as a within-subject factor and instruction vs. invention and prompts to explain (yes/no) as between subject factors. Pretest conceptual and procedural knowledge were included in all analyses as covariates.

Procedural Learning

First, consider procedural learning, which was assessed using problems identical in form to those presented during the intervention (see Table 1). As shown in Figure 1, generating explanations and, to some extent, receiving instruction led to greater accuracy on the learning problems. There was a main effect for explaining, F (1, 71) = 6.11, p = .02, η_p^2 = .08, and a marginal effect for instruction, F (1,71) = 2.84, p = .10, η_p^2 = .04, and no interaction between the two conditions and no effects of time of assessment.

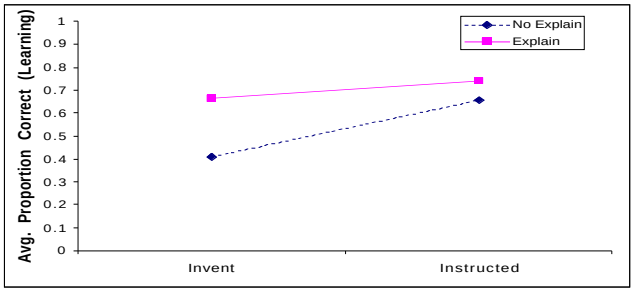

Figure 1: Effect of condition on learning problems

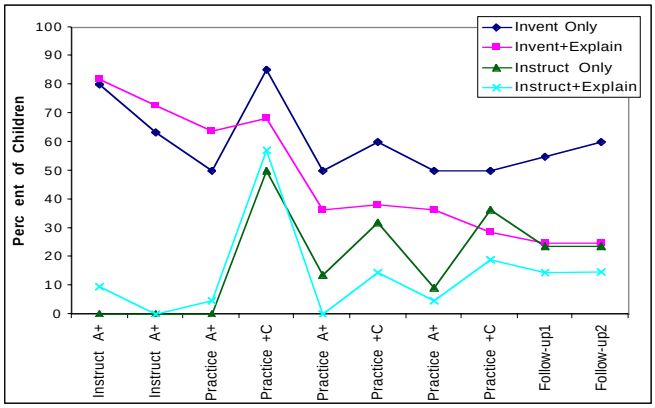

Figure 2: Incorrect procedures: Trial-by-trial use during the intervention and follow-up, by condition.

Inspection of students' procedure use during the intervention provided insights into learning pathways (see Table 3 for a description of each procedure). First, consider students' use of incorrect procedures. As shown in Figure 2, during the instruction phase (first two problems), students in the instruction condition quickly abandoned their incorrect procedures whereas most students in the invention conditions persisted in using incorrect procedures. During the practice phase, when students first encountered a problem in a different format (+C problem), there was a sharp return to using incorrect procedures. Students in the instruction condition continued to struggle with the +C problems, especially if not prompted to self-explain. Students in the invent-only condition struggled across problems – at least 50% continued to use incorrect procedures, whereas students who were prompted to self-explain steadily decreased in use of incorrect procedures.

Next, consider students' use of the correct instructed procedure – add-subtract (see Figure 3). Students in the instruction conditions quickly learned the add-subtract procedure and many students persisted in using this procedure across a majority of problems. However, a third of the students did not apply the procedure when the surface structure of the problem changed (+C problems), even though the procedure required only a very minor adaptation. Of students in the invent conditions, about 15-20% invented and used this procedure. Next, consider the other commonly used correct procedure – grouping (see Figure 4). Students in the invent conditions gradually increased their use of this procedure. Prompts to explain also helped

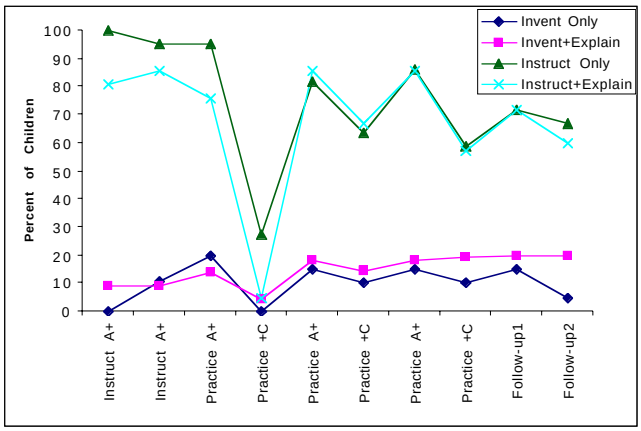

Figure 3: Use of Add-Subtract procedure trial-by-trial during the intervention and follow-up, by condition.

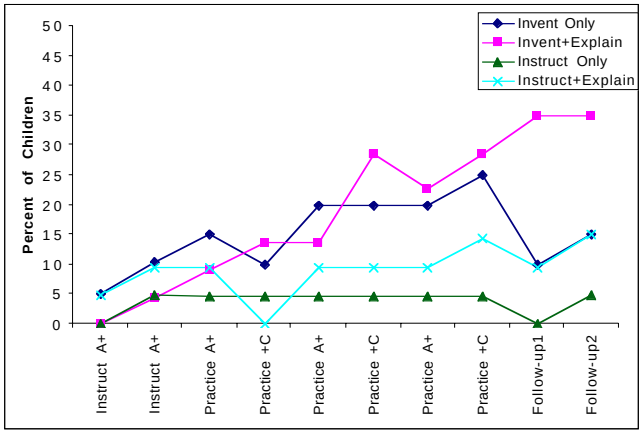

Figure 4: Use of Grouping procedure trial-by-trial during the intervention and follow-up, by condition.

students to invent and maintain use of the procedure on the follow-up problems. Finally, students in the invent conditions also used the equalizer procedure on 12% of intervention trials, whereas students in the instruct+explain condition used it on 6% of trials and students in the instruct-only condition used it on less than 1% of trials.

Overall, over half of students in the invent-only group did not learn a correct procedure through feedback alone. Less than a quarter of students in the other conditions had similar difficulty. Rather, direct instruction quickly led children to adopt a correct procedure, and prompts to explain helped students to invent new procedures.

Procedural Transfer

Next consider students' ability to transfer their procedures to novel problems (see Figure 5). Overall, there was a main effect of explaining $F(1, 71) = 3.93$, $p = .05$, $\eta_p^2 = .05$ and no overall effect of instruction, interaction between the two, or effect of test time. Prompts to explain supported transfer of procedures to novel problems, but instruction vs. invention did not have a general effect on transfer (although see below for an important caveat). Inspection of success on individual problems suggested that the impact of

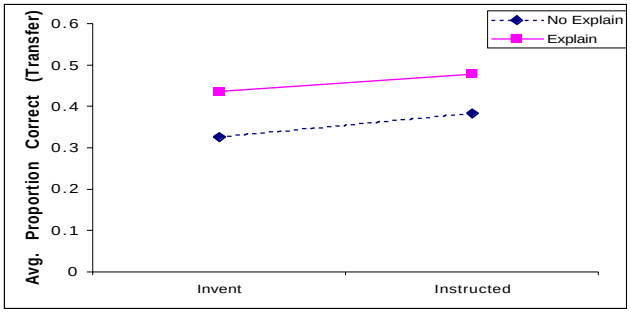

Figure 5: Effect of condition on transfer performance

condition varied by problem type. To evaluate this, a second repeated-measures ANOVA was conducted with transfer problem type (no repeated addend, including subtraction, swapping sides; see Table 1) as an additional within-subject factor. Indeed, there was an interaction between problem type and instruction, F (2, 142) = 9.37, p < .001, η_p^2 = .12, but no interaction of explaining with problem type. Follow-up analyses indicated that instruction improved performance on problems without a repeated addend, F (1, 71) = 7.89, p = .006, η_p^2 = .10. The instructed procedure did not need to be modified to solve problems without a repeated addend. Instruction had no reliable effect on the other problem types. However, focusing on the most difficult individual problem (A+B-C=_-C), receiving instruction actually harmed performance, regardless of explaining, F (1,71) = 13.12, p = .001, η_p^2 = .16. For example, on the delayed posttest, very few of the students who received instruction solved the problem correctly, whereas at least a third of students in the invent conditions solved the problem correctly (see Figure 6). This may be because the invented grouping procedure is easier to apply to this problem than add-subtract.

Conceptual Improvement

Finally, there was no effect of condition on gains in conceptual knowledge. Although students as a whole made small gains in conceptual knowledge from pretest to immediate posttest (m = 2.9 vs. 3.1 out of 10), t(76) = 2.0, p =.05, and made even great gains after a delay (m = 3.8), t(76) = 5.7, p < .001, the amount of gain did not vary by condition.

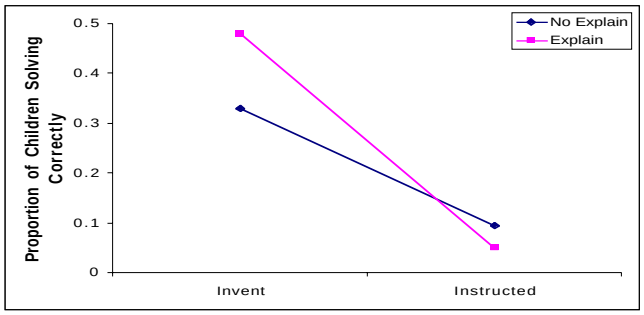

Figure 6: Effect of condition on hardest transfer problem, A+B-C=_-C, at delayed posttest

Discussion

Self-explanation is a critical learning mechanism that leads to greater procedural flexibility. The current findings converge with past findings that better learners spontaneously produce self-explanations and that prompting learners to generate explanations leads to greater learning (Aleven & Koedinger, 2002; Bielaczyc et al., 1995; Chi et al., 1989; Chi et al., 1994). The current findings expand past research by demonstrating that self-explanation is an important learning mechanism regardless of instruction. For students who received direct instruction on a correct procedure, prompts to self-explain had little influence on the use of the instructed procedure. Rather, the prompts promoted generation of additional correct procedures. Indeed, 57% of students in this condition used at least two correct procedures during the intervention, compared to only 24% of students who received instruction but were not prompted to explain. Using multiple procedures is a common feature of development and is beneficial to performance (Siegler, 2002). Prompts to explain under invention conditions also promoted invention of a correct procedure (Siegler, 2002).

Overall, students in the explain conditions were better able to solve transfer problems, regardless of instruction. Analysis of students' explanations revealed that students rarely explained the rationale for why a solution was correct. Approximately 8% of explanations included mention of equal sides or the importance of the equal sign. Rather, most why explanations where ambiguous or described the procedure for solving the problem. Combined with the finding that explanations did not influence conceptual learning, this suggests that prompts to self-explain on a problem-solving task promote exploration of alternative procedures but not reflection on conceptual-underpinnings of the procedure. Self-explanations are one promising mechanism for explaining why some learners make improvements in conceptual understanding after learning a new procedure while others do not (Rittle-Johnson & Alibali, 1999), but the current study does not support this hypothesis.

The current findings have important implications for the debate between use of direct instruction vs. encouragement to invent procedures. There are serious limitations to relying on people inventing correct procedures without guidance on effect learning processes. Half of the students in the current study never invented a correct procedure when receiving feedback on the correct answers alone. Some prior research has suggested that feedback is critical to supporting invention during exploration, but even this level of support was insufficient for many learners (e.g Lacher, 1983). In comparison, as in previous studies, direct instruction supported rapid adoption of a narrowly used procedure (e.g. Alibali, 1999). A third of the students in the instruction groups failed to generalize the add-subtract procedure even when receiving feedback during the intervention, and instruction only supported transfer to a very similar problem that required no adaptation to the

procedure. On the hardest problem, having received instruction interfered with problem solving. Overall, direct instruction by itself appears to be a quick route to inert knowledge. However, promoting engagement in effective learning processes, such as self-explaining, helped students to avoid many of the downsides of both invention and direct instruction.

Overall, it is not the source of procedure, but rather engagement in a fundamental learning process, self-explanation, that is important for promoting flexible problem-solving.

Abstract

When unfamiliar non-speech sounds and visual input co-occur, they often compete for attention, with auditory input overshadowing visual information for infants and young children (Robinson & Sloutsky, in press; Sloutsky & Napolitano, 2003). The current study investigated whether labels and familiar sounds also compete for attention with corresponding visual information in infancy. The results indicate that, unlike unfamiliar, non-speech sounds, labels do not compete for attention with corresponding visual information at 16-months of age: 16-month-olds ably encoded both auditory and visual information. At the same time 8-month-olds only encoded the labels. When infants were familiarized to the same non-speech sounds that overshadowed visual input in Robinson and Sloutsky's study, 16-month-olds encoded both auditory and visual information, whereas, 8-month-olds continued to encode only the sounds. These findings, in conjunction with the findings of Robinson and Sloutsky (in press) and Sloutsky and Napolitano (2003), point to an important developmental progression in processing of auditory and visual information.

Introduction

Language plays an important role in conceptual development. When two entities share a common label, children are more likely to perceive these entities as being more similar to each other (Sloutsky & Lo, 1999), more likely to group these entities together (Sloutsky, Lo, & Fisher, 2001), and more likely to make inferences from one entity to the other (Gelman & Markman, 1986; Sloutsky, et al., 2001).

The effect of linguistic input on categorization appears very early in development. Even 9-months-olds were purported to benefit from linguistic input when forming object categories (Balaban & Waxman, 1997). In particular, it has been argued that "…from the onset of acquisition, object naming and object categorization are linked. Infants across the world begin the task of word learning equipped with a broad, universal expectation that directs them to link novel words to commonalities among objects." (Waxman, 2003, p. 213).

For example, in Balaban and Waxman's (1997) study, 9-month-olds who heard labels or content-filtered speech (which retained the original prosodic pattern) were more likely to categorize entities at the basic-level than children who only heard sounds. Therefore, it appears that hearing the same linguistic input associated with different exemplars helps infants group these exemplars together. Labels can also help infants detect differences between objects (Xu, 2002). Here, 9-month-olds are more likely to differentiate two objects when the two objects are associated with different labels. Thus, hearing the same label associated with different exemplars helps infants group these objects together, and hearing different labels helps infants differentiate the objects.

Various mechanisms have been proposed in an attempt to explain the importance of linguistic input on conceptual development. Language-specific explanations suggest that children understand that entities belong to categories, and labels highlight categories (Gelman & Markman, 1987). Labels may also be weighed heavier than other features such as appearance because children may be attentive to the prosody of human speech (Balaban & Waxman, 1997). From a general-auditory explanation, labels may initially be weighed heavier than other features because labels are presented to the auditory modality. Moreover, auditory information receives privileged processing early in development (Robinson & Sloutsky, in press; Sloutsky & Napolitano, 2003).

In support of a general-auditory explanation, Sloutsky and Napolitano (2003) demonstrated that modality preference changes throughout development: Four-year-olds are more likely to attend to auditory input, whereas adults are more

likely to attend to visual input. This finding suggests that the greater attention to auditory information may explain, in part, the effects of labels.

More recently, Robinson and Sloutsky (in press) extended these findings with infants as young as 8-months of age. Here, infants were familiarized to an auditory-visual compound stimulus ($AUD_{old}VIS_{old}$). After familiarization, infants were presented with four different test trials ($AUD_{old}VIS_{old}$ and $AUD_{new}VIS_{new}$), which served as within subjects controls and ($AUD_{new}VIS_{old}$ and $AUD_{old}VIS_{new}$), which were used to determine if infants were primarily attending to auditory, visual, or both auditory and visual components during familiarization. If infants attend to a specific component during familiarization, looking should increase when that component changes at test. In sum, infants increased looking when either the auditory component or both components changed ($AUD_{new}VIS_{old}$ and $AUD_{new}VIS_{new}$); however, infants at 8-, 12-, and 16-months of age did not increase looking when only the visual component changed ($AUD_{old}VIS_{new}$). This finding suggests that infants were primarily attending to the auditory input during familiarization. At the same time, infants amply encoded the visual component when it was presented in isolation, which suggests that the auditory component overshadowed the visual component.

These results point to auditory dominance early in development and they have several important implications. Most importantly, auditory dominance effects can provide a coherent account for many of the previous findings. Recall that it has been argued that common labels help infants detect commonalities between objects, and different labels help children differentiate objects. Although infants in Robinson and Sloutsky (in press) study were presented with non-speech sounds, the pattern of results are identical to what would be expected if infants were presented with linguistic labels (i.e., the same visual stimulus that was presented during familiarization was perceived as new when paired with a new sound and a new visual stimulus was perceived as old when paired with the old sound). In short, it seems possible that under both speech and non-speech auditory input conditions, infants rely primarily on the auditory information.

The aim of Experiment 1 was to test this hypothesis by investigating whether linguistic labels, similar to the non-speech sounds (Robinson & Sloutsky, in press), overshadow visual input. In particular, if linguistic input is weighed heavier than visual input because it represents auditory information then non-speech sounds and labels should reveal similar patterns of results.

Experiment 1

Method

Participants Nineteen 8-month-olds (5 boys and 14 girls, *M* = 249 days, *Range* = 231 - 280 days) and nineteen 16-month-olds (6 boys and 13 girls, *M* = 489 days, *Range* = 470 - 501 days) participated in this experiment. Parents' names were collected from local birth announcements, and contact information was obtained through local directories. All children were full-term (i.e., > 2500g birth weight) with no auditory or visual deficits, as reported by parents. A majority of infants were Caucasian. Seven infants were not included due to fussiness, and 10 infants were excluded because they did not reach the training criterion indicated below.

Apparatus Infants were seated on parents' laps approximately 100 cm away from a 152 cm x 127 cm projection screen, which was located approximately 5 cm above the infant's eye level. A Sony DCR-TRV40 camcorder was used to capture infants' fixations and was projected to one of two Dell flat panel monitors in the observation room. An NEC GT2150 LCD projector was mounted on the ceiling approximately 30 cm behind the infant (130 cm away from the projection screen). Two Boston Acoustics 380 speakers were 76 cm apart from each other and mounted in the wall. The speakers and camcorder were concealed by black felt and located directly below the projection screen. Two small lights were located behind the infant to ensure that the room was dimly lit throughout the entire procedure. In an adjacent room, a Dell Dimension 8200 computer with *Presentation* software was used to present stimuli to the infants, as well as to record the onset and offset of infant's visual fixations. Fixations were recorded online by pressing a button on an Excalibur 10-button gamepad when infants were looking at the stimulus and releasing the button when infants looked away from the stimulus. A second Sony DCR-PC120 camcorder was used to record the video stream of the infant from the monitor indicated above, as well as to record the image of the stimulus presentation on a second Dell flat panel monitor. This split screen recording was used to establish interrater reliability.

Stimuli Each infant was familiarized to an auditory-visual compound stimulus ($AUd_{old}VIS_{old}$) and tested on four auditory/visual combinations ($AUD_{new}VIS_{old}$, $AUD_{old}VIS_{new}$, $AUD_{new}VIS_{new}$, and $AUD_{old}VIS_{old}$). The auditory components consisted of two infant-directed nonsense labels (vika and kuna), which were presented at 65-68 dB. The visual components

consisted of two three-shape patterns (circle, pentagon, triangle, and cross, octagon, square), and were projected to 25 cm x 7 cm in size. Previous research has demonstrated that infants can discriminate these visual stimuli when presented in isolation; however, they are overshadowed by unfamiliar non-speech sounds (Robinson & Sloutsky, in press; Experiment 2).

Procedure The procedure consisted of 10 familiarization trials, 2 test trials, 3 retraining trials, and 2 more test trials. Each familiarization trial consisted of a compound stimulus that appeared for 1000 ms and disappeared for 500 ms. Each stimulus appeared five times during each trial (7500 ms trial duration). After familiarization, infants were present with 4 different test trials ($AUD_{new}VIS_{old}$, $AUD_{old}VIS_{new}$, $AUD_{new}VIS_{new}$, and $AUD_{old}VIS_{old}$). Test trials were 12 s in duration and were randomized so that each test stimulus had an equally likely chance of appearing as the first test trial, last test trial, etc. The retraining trials were the same as familiarization trials and were used to remind infants of the familiarization stimulus. Retraining trials always appeared between the first two and last two test trials. Fixations were recorded online by an experimenter for all training, test, and retraining trials. A random sample of 25% of the infants were coded offline by experimenters who were blind to the auditory and visual components presented to infants. No differences were found between subjects coded on- and offline.

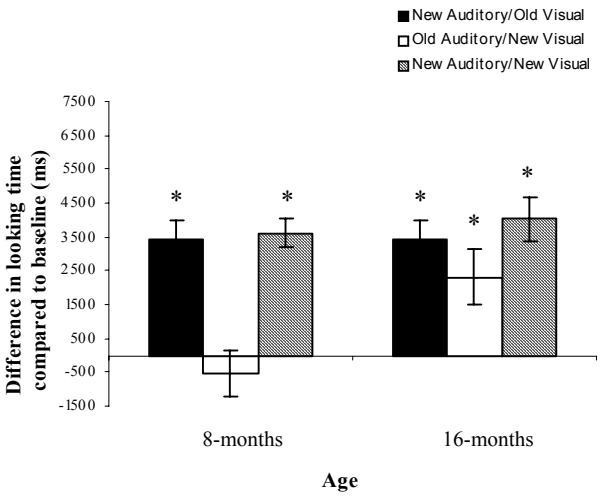
Results and Discussion

Training Criterion. Only infants who demonstrated a novelty preference at test were included in additional analyses (i.e., looking to $AUD_{new}VIS_{new} > AUD_{old}VIS_{old}$). As reported above, 10 infants did not reach this criterion.

Test Trials. Analysis of test trials focused on whether infants were primarily attending to auditory and/or visual input during familiarization. A difference score was calculated by taking the accumulated looking to each test stimulus and subtracting it from baseline (e.g., the effect of changing the auditory component = $AUD_{new}VIS_{old} - AUD_{old}VIS_{old}$). Thus, positive numbers indicate that looking increased as a function of changing a specific stimulus component, which suggests that infants encoded that modality during training. As can be seen in Figure 1, at 8- and 16-months of age, looking increased when the auditory component changed and when both auditory and visual components changed, one-sample ts > 0, ts > 5, ps < .001. In contrast, only the 16-month-olds increased looking when the visual stimulus changed, one-sample t > 0, t (18) = 2.88, p < .01.

A 2 (Age: 8-months, 16-months) x 3 (Test Trial: $AUD_{new}VIS_{old}$, $AUD_{old}VIS_{new}$, $AUD_{new}VIS_{new}$) revealed an effect of Test Trial and also confirmed the Age x Test Trial interaction, Fs > 5, ps < .01. At 8-months of age, changing the auditory component had a larger effect than changing the visual component, $DIFF_{AUDnewVISold}$ = 3435 ms > $DIFF_{AUDoldVISnew}$ = -552 ms, paired t (18) = 5.87, p < .001. This difference, however, attenuated at 16-months of age ($DIFF_{AUDnewVISold}$ = 3403 ms = $DIFF_{AUDoldVISnew}$ = 2318 ms), paired t (18) = 1.40, p > .1.

Figure 1. Effects of changing labels and visual stimuli in Experiment 1



Note: *Difference score > 0, p < .01. Error bars represent standard errors.

It is important to note that, although the nonsense labels overshadowed visual input at 8 months of age, these same visual stimuli were ably encoded by 8-months-olds when presented in isolation (Robinson & Sloutsky, in press). In contrast, 16-month-olds encoded both the auditory and visual components. This pattern of results is strikingly different from those reported by Robinson & Sloutsky. In particular, when the same visual stimuli were paired with unfamiliar non-speech sounds (laser and static sounds), 8- , 12-, and 16-month-olds only encoded the auditory component. Thus, the results from the current experiment, in conjunction with Robinson & Sloutsky, demonstrate that both speech and non-speech sounds overshadow visual input at 8-months of age. In contrast, by 16-months of age children encode both auditory and visual components; however, only when the auditory input consists of speech sounds. While revealing interesting developmental differences in effects of label on processing of visual information, the current study did not elucidate the nature of these effects.

Experiment 2

The goal of Experiment 2 was to determine whether the effect of label stems from language-specific properties or from general-attentional effects. From a language-specific perspective, the different pattern of results at 16-months of age between Experiment 1 with those reported in Robinson & Sloutsky (in press) could stem from privileged processing of linguistic input. In particular, it is possible that linguistic information does not compete for attention with corresponding visual information, which allowed 16-month-olds to process both auditory and visual information. However, it is also possible that human speech represents a familiar class, and even familiar non-speech sounds do not compete for attention with corresponding visual input. Although very few empirical studies, if any, have compared processing of familiar sounds with linguistic input early in development, there is preliminary neurophysiological evidence with adults suggesting that familiar non-speech sounds are processed in the brain similarly to words (Cycowicz & Friedman, 1998). Thus, the goal of Experiment 2 is to determine if stimulus familiarity can account for differences between Experiment 1 and Robinson & Sloutsky (in press).

Method

Participants Twenty 8-month-olds (10 boys and 10 girls, *M* = 252 days, *Range* = 245 - 269 days) and ten 16-month-olds (4 boys and 6 girls, *M* = 490 days, *Range* = 474 - 504 days) participated in this experiment. Recruitment procedures and demographics were identical to Experiment 1. Two infants were not included due to fussiness, and 13 infants were excluded because they did not demonstrate a novelty preference (i.e., $AUD_{new}VIS_{new} > AUD_{old}VIS_{old}$).

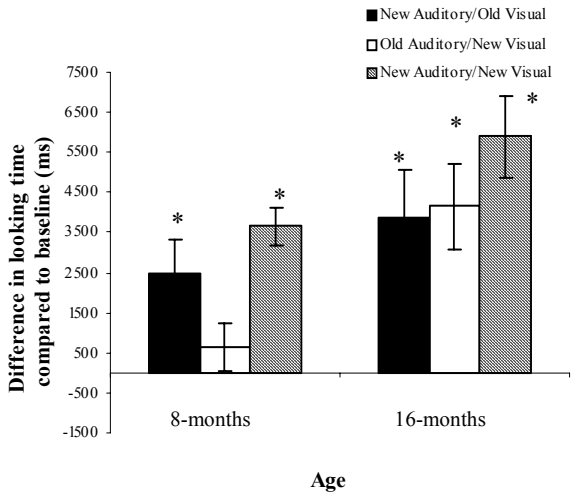
Stimuli and Procedure With two exceptions, the procedure was identical to Experiment 1. First, the nonsense labels were replaced with non-speech sounds (laser sound and static sound). Note that these same sounds overshadowed the three-shape patterns in Robinson & Sloutsky (in press). Second, and most importantly, children were familiarized to the non-speech sounds prior to the actual experiment. In the current experiment children sat on parent's laps and heard each non-speech sound 10 different times. As with the actual experiment, the auditory stimulus was presented at 65-68 dB, and each auditory stimulus lasted for 1000 ms. Auditory stimuli were presented in pairs and pseudorandomized so that infants heard the same stimulus at least twice in a row and no more than 4 times in row. In addition, the non-speech sounds were not associated with the three-shape patterns or any visual stimulus. This ensured that children in Experiments 1 and 2, and children in Robinson & Sloutsky (in press) all had equal experience with the three-shape patterns. After infants heard each sound 10 times, infants were given a 4 minute distracter task in which they looked at realistic pictures of animals. After the distracter task, infants were then presented with the main experiment.

Results and Discussion

As in Experiment 1, a difference score was calculated by taking the accumulated looking to each test stimulus and subtracting it from baseline. As can be seen in Figure 2, the pattern of results are very similar to Experiment 1. That is, both age groups increased looking when either the auditory component changed or when both auditory and visual components changed, one-sample *t*s > 0, *t*s > 3, *p*s < .01, and only the 16-month-olds increased looking when the visual stimulus changed, one-sample $t > 0$, $t(9) = 3.86$, $p < .01$.

A 2 (Age: 8-months, 16-months) x 3 (Test Trial: $AUD_{new}VIS_{old}$, $AUD_{old}VIS_{new}$, $AUD_{new}VIS_{new}$) revealed an effect of Test Trial, $F(2, 56) = 7.72$, $p < .001$. Here, children looked longer when both components changed ($DIFF_{AUDnewVISnew}$ = 4401 ms) than when only the auditory component changed ($DIFF_{AUDnewVISold}$ = 2940 ms) or when only the visual component changed ($DIFF_{AUDoldVISnew}$ = 1819 ms), paired *t*s > 2.5, $p < .01$. The above analyses also revealed an effect of Age, $F(1, 28) = 5.93$, $p < .05$, with 16-month-olds (*M* = 4631 ms) accumulating more looking across test trials than 8-month-olds (*M* = 2264 ms).

Figure 2. Effects of changing familiar sounds and visual stimuli in Experiment 2



Note: *Difference score > 0, $p < .01$. Error bars represent standard errors.

General Discussion

The results from the two experiments in conjunction with Robinson & Sloutsky (in press) demonstrate that unfamiliar non-speech sounds, familiar non-speech sounds, and nonsense labels all overshadow visual input at 8-months of age. That is, 8-month-olds do not discriminate visual stimuli when these images are paired with auditory input; however, they ably discriminate the same images when presented in isolation (Robinson & Sloutsky, in press). In contrast, 16-month-olds encode both the auditory and visual components; however, only when the visual stimuli are paired with labels or familiar sounds. Interestingly, the non-speech sounds that children heard in Experiment 2 were the same non-speech sounds that overshadowed the three-shape patterns in Robinson and Sloutsky's study. These findings demonstrate that, at 16-months of age, just hearing an auditory stimulus a few times affects the way children attend to auditory and visual input. These findings also demonstrate that familiar sounds and labels have similar effects on processing of auditory and visual information at 8- and 16-months of age.

Overall, the current study expands previous research concerning the development of attention, the role of familiarity in the auditory modality, and possible mechanisms underlying the effect of labels on conceptual development.

One potential explanation of the developmental differences found in the current study concerns the notion that attentional biases and attentional resources change considerably throughout development. There is a growing body of research demonstrating that younger children are more likely than adults to demonstrate a preference for auditory input and more likely to encode only one modality (Robinson & Sloutsky, in press; Sloutsky & Napolitano, 2003). Currently, there are several possible mechanisms that may explain this developmental pattern. First, it is possible that young children lack attentional resources that are needed for simultaneously processing auditory and visual input. However, it is also possible that young children either habituate to and/or process auditory information faster than visual information. Future research will need to address this issue.

The current study also introduces the notion that familiar sounds and labels may play a similar role early in development. Although there is neurophysiological work demonstrating that familiar sounds are processed in the brain similarly to words (Cycowicz & Friedman, 1998), the current study provides behavioral evidence for this notion in infancy. One interesting question concerns the idea that labels may represent a familiar class of auditory stimuli. This would explain why labels and familiar sounds have similar effects in the adult brain, as well as in the current study.

At a more general level, it is well known that linguistic input plays a large role in conceptual development. However, it is uncertain how and when labels become special. Even as young as 9-months of age, hearing the same label associated with different exemplars helps infants group these objects together, and hearing different labels helps infants differentiate objects (Balaban & Waxman, 1997; Xu, 2002). Interestingly, 8-month-olds in the current study demonstrated the same pattern of results when presented with unfamiliar non-speech sounds (Robinson & Sloutsky, in press), labels, and familiar sounds. This suggests that young children may initially rely on various types of auditory information (sounds and labels), and this initial preference for auditory input may help bootstrap labels into a special status.

Abstract

We use artifact analysis to describe the process of scientific dissemination in a community-based program that informs parents and professional caregivers about early childhood development. We define this program as a network of information management and our unit of analysis are the sociocultural activities of dissemination, and the artifacts that shape them. Drawing upon activity theory, social networks theory, and distributed practice, we describe and analyze the impact, evolution, and sociocultural nature of understandings, goals, values, artifacts, actions, events, and organizational elements. Our data were collected through observations, field notes, focus groups, artifact collection, and stimulated recall interviews. Results suggest that as artifacts move from one environment to another, their role changes, often resulting in a loss or distortion of information. We describe how and why these problems are overlooked and the potential problems they may create.

Studies of scientific dissemination are rich sources of information about cognitive processes situated in a sociocultural context. The dissemination process has been almost completely the domain of large corporate, government, or academic entities—universities, pharmaceutical companies, the National Institute of Health, media networks, and the like. The role of lay people and their communities has been largely one of end-user, with the assumption that they could be expected to act as recipients of information rather than disseminators; a passive role at the bottom of the organizational structure (Epstein, 1996)

The importance of community involvement in education, advocacy, and decision making has been growing over the past decade (Minkler & Wallerstein, 2002). At the local level, the project team identifies community needs through community engagement (Minkler & Wallerstein, 2002), an approach to research and intervention characterized by its use of the community as a unit of identity, action and analysis. Communities may be formed around geography, socioeconomic status, shared emotions, or common goals. Facilitators are community members who bring scientific information to the attention of local end-users, translate concepts and terms, and help end-users apply the information in making personal decisions.

Facilitators can also inform disseminators and scientists about end-user interests and needs; thus, ideally, information can flow in both directions. However, facilitators need aid in finding and organizing information, contextualizing scientific findings, applying them to local situations, providing emotional support, and serving as advocates and spokespeople. In short, facilitators need support to provide support, in terms of content, culturally relevant delivery, and information management. There is growing evidence for community-based dissemination, scientific communication that is culturally responsive, accounts for audiences' prior knowledge and ability/willingness to acquire new knowledge, and is flexible enough to fit diverse goals, resources, and interests. (e.g., Minkler & Wallenstein, 2003; Shonkoff & Phillips, 2000; Wilcox, Hadley, & Bacon, 1998).

This creates interesting questions regarding reasoning in community engagement setting, especially in regard to facilitators and outreach personnel. They are, on a number of dimensions, in limbo. Regarding the scientific content, they are neither experts nor novices; they usually have some teaching or outreach experience, but they often have never functioned in this role with this population before. They are engaged in scientific dissemination, but they are not part of the groups usually studied in the context of dissemination studies, such as scientists, media, or teachers.

Research on community-based interventions also offers interesting opportunities for dissemination research. A main reason is that facilitators are engaged in a process that requires a quick turnaround; their training may last few weeks or months and they are soon ready to work in the field. Updates, refresher courses, and additional training are put to work within a similar timeframe. This allow us to watch the inflow and outflow of information in a way that we cannot with dissemination agents whose timeline involves years of training or experience, such as a journalist, scientist, or social worker.

In short, community engagement and community facilitators are playing an increasingly important role in scientific dissemination, they are unusual in a number of ways, and they also provide opportunities to watch the dissemination process in a compressed format. Of course, this can both create unusual patterns and behaviors that are not seen in other areas of dissemination, but it does not necessitate uniqueness. Therefore, it is initially important to examine the ways in which this format repeats patterns in other spheres of scientific dissemination, and the ways in which it reinvents these patterns or creates new ones.

To construct a framework for this comparison process, we draw upon multiple streams of dissemination research in attempting to cover the ambiguous position of facilitators

and community engagement. This includes novice reasoning about scientific information in structured settings (Sandoval, 2003; Schank & Ranney, 1995), and informal settings (Zimmermann, Bisanz & Bisanz, 1998), lay advocacy and policy involvement (Epstein, 1996; Margolis, 1996), scientists reasoning among themselves (Latour, 1987), and interactions between lay people and experts (Lemke, 1990). Using this framework, we examine a community engagement program providing parents and professional caregivers with information about new psychological and neuroscientific research on early childhood learning and development.

Sites & Program Description

The program that we have been following, *The First Teacher Project* (*FTP*), is part of a larger initiative started in the city of Chandler, AZ in 2002, *The Steps to Learning Initiative* (*StL*). Funded by an Early Learning Opportunities Act Grant from the U.S. Department of Education, *StL* was created to educate the community about the importance of early literacy and learning, develop stronger links among service providers working with children and families in the Chandler community, create a comprehensive network of early childhood programs, and make information and programs more affordable and accessible. The grant was secured and is overseen through the Mayor's Literacy Task Force, and administered by the Chandler Public Library. Other partners include the Chandler Unified School District and the Chandler (East Valley) Regional Hospital.

Chandler is one of the fastest growing cities in Arizona, with a large traditionally underserved population. In the 2000 Census, Chandler had one of the largest Latino populations in the state, ranging from 25% to over 50%, depending on neighborhood (Morrison Institute, 2001). It is also an economically diverse city, home to Intel and Motorola, but also to a federally-designated Enterprise Zone. Eighty percent of Zone residents are Latinos and 68% of households are monolingual Spanish. Seventy percent of students qualify for free or reduced-price lunch, 50% of families earn less than $5,000/year, and almost 50% of adults lack a high school diploma.

The *FTP* component of *StL* focuses on children's development from ages 0 to 3. The program focuses on sensory development, bonding and attachment, cognitive skills such as categorization and language, and the value of play and pretense. The information provided can be used to identify developmental delays, sensory deficits, and other problems early on, as well as providing parents of mainstream children with new perspectives on their children's learning and development. *FTP* involves disseminating a significant amount of scientific information, much of it relatively new even to scientists in the relevant fields. Topics include neural pruning, synaptic formation, plasticity, limbic and cortical functions, biological and psychological aspects of temperament and language acquisition.
