FOREWORD

These proceedings hold the talks, posters, tutorials, and symposia presented at the 26th annual meeting of the Cognitive Science Society. The conference took place in Chicago, Illinois, at the Westin River North Hotel, August 4-7, 2004.

Each year, the CogSci conference chairs highlight a particular area of cognitive science – we chose to highlight *higher-order cognition*. This is reflected in our choice of Susan Goldin-Meadow and Doug Medin as our two plenary speakers, and Larry Barsalou and Art Markman for a debate on embodied cognition, as well as in the themes of the invited symposia: language and thought, qualitative reasoning, higher-order cognitive neuroscience, and large-scale representation systems. The rest of the program was determined by the submissions we received, and by the reviewers' enthusiasm for them.

In total, we received 370 submissions of 6-page papers, publication-based abstracts, and symposia. Of these, 115 were accepted for presentation as a talk or symposium, and 150 were accepted for poster presentation. We also received over 150 member abstract submissions, which by design were only lightly reviewed, and almost all of which were accepted.

Chairing a CogSci conference is a lot of work! We couldn't have done it without a lot of help from many people. We would especially like to thank the following:

The Governing Board, for inviting us to chair the meeting.
The Program Committee, for managing the review process.
The almost 500 reviewers, for providing professional reviews.
Wayne Gray, for helpful advice on all aspects of conference organization.
Chris Schunn and Rick Alterman, for their advice as chairs from earlier years.
Frank Ritter, for organizing and coordinating the tutorial program.
Frank Lee, for coordinating the student volunteers.
Deborah Gruber, for her help with local arrangements and the proceedings.
Jonathan Cohen and Jennifer Stedillie, for coordinating conference preparation.
James Stewart, for heroic responsiveness in operating the reviewing website.
The student volunteers at Northwestern University and the University of Chicago, especially Fey Parrill (UC) and Kate Lockwood (NU).
Dan Veksler, for producing a roommate-matching website at very short notice.
Ken Nielsen, for designing the poster.
Rebecca Asburst, for creating the logo, and Kathleen Braun, for designing the T-shirt.
Our sponsors: The Robert J. Glushko and Pamela Samuelson Foundation; Northwestern University; ONR; DARPA; AFRL; the University of Chicago; CHI Systems; and Trends in Cognitive Sciences.
The plenary speakers, Susan Goldin-Meadow and Doug Medin.
The debaters, Larry Barsalou and Art Markman.
And above all, the authors, symposium participants, and attendees.

About the Society

The Society is a non-profit professional organization, and its main activities are sponsoring an annual conference, publishing the journal Cognitive Science, and promoting research interactions across traditional disciplinary boundaries. The Society was incorporated as a non-profit professional organization in Massachusetts in 1979.

The Cognitive Science Society, Inc. brings together researchers from many fields that hold a common goal: understanding the nature of the human mind. The Society promotes scientific interchange among researchers in disciplines comprising the field of Cognitive Science, including Artificial Intelligence, Linguistics, Anthropology, Psychology, Neuroscience, Philosophy, and Education.

Abstract

CHREST (Chunk Hierarchy and REtrieval STructures) is a comprehensive, computational model of human learning and perception. It has been used to successfully simulate data in a variety of domains, including: the acquisition of syntactic categories, expert behaviour, concept formation, implicit learning, and the acquisition of multiple representations in physics for problem solving. The aim of this tutorial is to provide participants with an introduction to CHREST, how it can be used to model various phenomena, and the knowledge to carry out their own modelling experiments.

Developing detailed process models of cognitive phenomena is important to the development of cognitive science, as only then can cognitive theories be used to generate quantitative predictions for complex phenomena. The history of computational modelling includes many diverse approaches, from models of single phenomena (such as Young and O'Shea's model of subtraction), to integrated models covering a wide range of different phenomena (such as Soar and ACT-R), to over-arching principles, which guide the development of models in disparate domains (e.g. connectionist approaches, or embodied cognition).

The EPAM/CHREST tradition, which forms the heart of this tutorial, has been providing significant models of human behaviour since 1959. Early models of EPAM provided the impetus to develop the chunking theory, which has been an important component in theories of human cognition ever since. Focusing on learning phenomena, EPAM and CHREST place a great emphasis on how the model's information is learnt through interactions with an external environment. Thus, EPAM/CHREST models are typically developed from large quantities of naturalistic input. For example, in modelling expert perception of chess players, actual chess games are used.

Historically, CHREST is derived from the EPAM (Elementary Perceiver and Memorizer) model of Feigenbaum and Simon (1984). In both models, learning happens as the creation and elaboration of a discrimination network. In addition, CHREST has mechanisms for the automatic creation of schemata and for the creation of 'lateral links', which can be used for creating elementary productions or elementary semantic links. CHREST can thus be situated between production systems such as Soar and connectionist systems. Just as EPAM was the computational embodiment of the key aspects of the chunking theory (Chase & Simon, 1973), CHREST implements the essential aspects of the template theory (Gobet & Simon, 2000). In spite of its historical and contemporary importance, and the diversity of domains in which modelling has been successfully carried out, the number of people who use or understand the principles and operation of an EPAM/CHREST model remains small.

The tutorial is structured so that participants will:

1. Acquire a comprehensive understanding of the CHREST computational model and its relation to the chunking and template theories of cognition;
2. Explore some key learning phenomena supporting the chunking theory by taking part in a verbal-learning experiment;
3. Attempt to match their own data with the performance of a CHREST model of verbal learning; and
4. Be introduced to the implementation of CHREST in sufficient detail to begin modelling their own data.

We have chosen a verbal-learning experiment (serial-anticipation method) for introducing participants to CHREST for the following reasons: the experiment is historically important; it was one of the motivations behind the development of EPAM; it can be carried out in a short period of time; striking learning phenomena are readily observable, in spite of the brevity of the experiment; the motivation and requirements for the experiment are generally clear; and, finally, it illustrates some key features of the EPAM/CHREST architecture.

ACT-R Tutorial

Niels A. Taatgen (taatgen@cmu.edu)
Psychology, Carnegie Mellon University
5000 Forbes Av., Pittsburgh, PA 15213 USA

ACT-R (Anderson, Bothell, Byrne, Douglass, Lebiere & Qin, in press) is a cognitive theory and simulation system for developing cognitive models. It assumes cognition emerges through the interaction of a procedural memory of productions with a declarative memory of chunks and independent modules for external perception and actions. Since its release in 1997, ACT-R has supported the development of over 100 cognitive models, published in the literature by many different researchers. These models cover topics as diverse as driving behavior, implicit memory, learning backgammon, metaphor processing, and emotion. We have recently developed a new version, ACT-R 5.0 that is more interruptible, achieves greater across-task parameter consistency, has better mechanisms of production learning, and is more in correspondence with our knowledge of brain function. The tutorial has no prerequisite knowledge, and is intended to on the one hand give an overview of the theory, and on the other hand offer some direct demonstration of ACT-R models. Although a half day is not sufficient to cover all material, it can wet the appetite for the full ACT-R tutorial that is available on http://act-r.psy.cmu.edu/. This website also provides for the necessary software, and overview of researchers using ACT-R, and it has a list of ACT-R publications (many of them downloadable).

During the tutorial, following Taatgen, Lebiere and Anderson (submitted) five popular research paradigms within ACT-R will be used as a vehicle to explain the architecture:

Instance learning

Learning by retrieving old experiences from memory, similar to Logan's instance theory.

Utility learning

Learning which of several available strategies is optimal by keeping track of costs and probability of success.

Working Memory Capacity

Models in which the amount of spreading activation is varied, which can explaining individual differences in working memory capacity

Perceptual/Motor constrained processing

Models in which the main factor in explaining human performance lies in the limitations of their perceptual and motor systems.

Rule learning

Models in which new production rules are learned on the basis of combination of old rules and substitution of declarative knowledge.

Although these individual research paradigms have produced interesting models by themselves, the full potential of the architecture can only be seen when they work together in models of complex cognition.

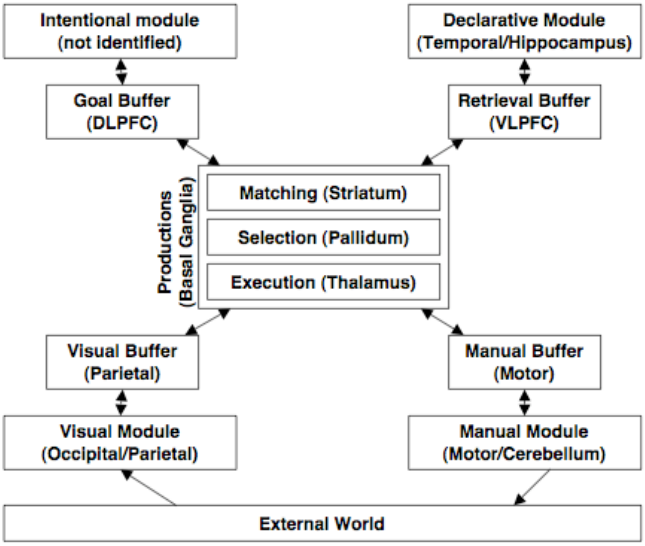

Figure 1: Overview of the architecture

Development of Executable Cognitive Agents Using the COGNET Architecture and *i*GEN™ Toolset

Wayne Zachary (wzachary@chisystems.com)
CHI Systems, Inc.
1035 Virginia Drive, Fort Washington, PA 19034-3701

Michael A. Szczepkowski (mszczepkowski@chisystems.com)
CHI Systems, Inc.
1035 Virginia Drive, Fort Washington, PA 19034-3701

COGNET/*i*GEN™ is a set of software tools (i.e., a workbench) that enables human performance specialists to develop, test and deploy *cognitive agents* -- software components that exhibit a level of intelligence that mimic human thought processes. Cognitive agents represent the logical transition of research on human information processing to practical application. Cognitive agents also represent a new and growing paradigm for research in decision support, intelligent human-computer interfaces, intelligent tutoring, etc. From an application perspective, cognitive agents empower the user by combining the speed, efficiency and accuracy of the computer with the decision-making capacity, experience and expertise of human experts. From a research perspective, they allow cognitive models to be applied to problems of enhancing the interaction between people and information technology in complex work environments.

COGNET/ *i*GEN™ incorporates computational models of human cognitive processes as a basis for designing and building software agents. At the same time, COGNET/ *i*GEN™ incorporates many practical approaches from software and systems engineering to maximize its ability to meet real-world cognitive agent application needs. This makes it fundamentally different from cognitive architectures, which have been developed as vehicles to test cognitive theories (e.g., ACT-R and theories of memory; EPIC and theories of dual tasking and task performance).

This workshop introduces participants to the concepts of cognitive agents and to the COGNET/ *i*GEN™ method and tools for cognitive agent development and prepares them to undertake the development of cognitive agents applications. This tutorial provides COGSCI attendees with a view of the COGNET/ *i*GEN™ cognitive architecture that emphasizes the unique properties of COGNET/ *i*GEN™. It also provides an introduction to the concepts and methods involved in cognitive agents and their development, providing participants with an important perspective linking theory and practice.

The workshop begins with an examination of three major uses for cognitive agents:

- Intelligent training and tutoring – specifically, the use of cognitive agents to provide:
  - embedded models of the student/trainee to track student progress against the knowledge required for the skill being trained;
  - an embedded instructor/tutor that can manage presentation of information, sequence instruction, and provide feedback/remediation; and/or
  - synthetic teammates to facilitate practice and teamwork in a simulated work environment.
- decision support and electronic performance support, in the form of work-centered intelligent interfaces that assist a worker or decision maker in such functions as attention management, situation awareness, and/or contextualizing decision strategies;
- human performance simulation, in the form of simulations of system users to aid design engineering and design evaluation, and/or synthetic players for mission simulations and/or interactive games.

Examples of each type are provided.

The workshop then covers COGNET as a cognitive-agent architecture based on cognitive theory. COGNET is compared to other computational architectures that embody theories of human thought and reasoning, and the features of COGNET that support cognitive agent development are identified. Particular focus is given to the features unique to COGNET/ *i*GEN™ – including metacognition, flexible granularity, and expert-level knowledge structures – and to the constructs that specifically focus on cognitive agent requirements – temporal management, micromodels, parallel execution threads, and external application interfaces. The modeling strategies by which the system can be used to represent complex behaviors such as teamwork, coaching, and cognitive workload self-reporting are discussed, as are the development tools available to support modeling and the integration of models into larger simulations, federations, or other applications.

For more information on the COGNET methodology and *i*GEN™ toolset, go to http://www.cognitiveagent.com.

Rumelhart Symposium

ACT-R as a Unified Architecture of Cognition: A Symposium in Honor of John R. Anderson

Organizers: Kevin Gluck (kevin.gluck@mesa.afmc.af.mil) Air Force Research Laboratory
Wayne D. Gray (grayw@rpi.edu) Rensselaer Polytechnic Institute

This symposium highlights the utility of the ACT-R theory as a tool for basic and applied cognitive science research. Four colleagues of this year's Rumelhart Prize winner, John R. Anderson, will describe how his ACT-R theory has enabled and inspired their research.

An Activation-Based Model Of Sentence Processing As Skilled Memory Retrieval

Richard Lewis (rickl@umich.edu)
University of Michigan

This talk presents a theory and ACT-R-based model of human sentence comprehension that embodies the following claim: Sentence comprehension consists of a series of cue-based retrievals from short-term (and long-term) memory, subject to similarity-based interference and activation decay. ACT-R does not merely serve as an implementation language for the theory; rather it serves as the vehicle for bringing sentence processing into detailed contact with general and independently established principles of memory and skilled behavior. These principles, together with some representational assumptions from linguistic theory, provide explanatory accounts of many parsing phenomena (such as difficulty on embeddings and locality and recency effects), and generate novel predictions which can be empirically tested. Experimental work on several languages is summarized. The work includes experiments that examine the effects of interference and decay on distinct components of sentence processing, experiments that distinguish activation decay and distance-based accounts, and experiments that begin to answer one of the basic questions motivated by the theoretical framework: exactly what kinds of similarity (syntactic, semantic, phonological, positional) matters in sentence processing?

This is joint work with Shravan Vasishth, Julie Van Dyke, and JJ Nakayama. No linguistic or psycholinguistic background will be assumed.

Information Foraging Theory And The Rational Analysis Of Human-Information Interaction

Peter Pirolli (pirolli@parc.xerox.com)
Xerox PARC

Information foraging theory has been developed to provide rational analyses of how people adapt to the task of obtaining useful information to meet their ongoing goals, and how technology can be better designed to improve human-information interaction. Several ACT-R models have been developed to model human-information foraging theory. The information foraging approach will be illustrated by recent models of interaction with the Web.

ACT-R and Driving

Dario D. Salvucci (salvucci@cs.drexel.edu)
Drexel University

As a complex but ubiquitous task, driving serves as an excellent domain for both testing and applying cognitive architectures such as ACT-R. For several years we have worked to model driver behavior in ACT-R with two main branches of research. First, we have developed a computational integrated driver model that navigates realistic highway environments, accounting for various aspects of driver behavior including eye movements between regions of the visual environment and steering profiles through curves and lane changes. Second, we have worked to predict the potential for driver distraction from secondary tasks such as dialing cellular phones or even primarily cognitive tasks. Both lines of research are helping to shape a more general theoretical account of human multitasking within the ACT-R architecture, and at the same time, demonstrating how such architectures can facilitate the development of practical tools that infer driver intentions and predict driver distraction for new in-vehicle devices.

Embedded Cognition through Production Compilation

Niels A. Taatgen (taatgen@cmu.edu)
Carnegie Mellon University

Embedded cognition refers to the fact that our reasoning processes are not only driven by plans and goals in our heads, but also, or maybe even mainly, by interacting with the environment. The challenge is to develop a cognitive system that strikes the right balance between being driven by its internal goals and by opportunities in the environment. In order to explore this challenge, we have looked at a particular subdomain: following instructions. In experimental tasks participants typically are given instructions in a list-like fashion. For many tasks, strictly following the instructions will lead to brittle and rigid behavior. We will look at two examples that represent two ends of the spectrum of complexity: a basic dual-task and a complex real-time dynamic task. Both tasks have been modeled in the ACT-R cognitive architecture using the production compilation mechanism to achieve embeddedness.

Motivation

Qualitative reasoning research creates computational models that capture aspects of reasoning about continuous systems, including space, time, and dynamics. It has tackled problems ranging from understanding human mental models of everyday systems to creating systems that can do engineering design and create scientific models. The original motivations for the field came mostly from cognitive science: Creating accounts of human causal reasoning about physical systems. However, over time the fields have grown more separate. This symposium is part of a bridge-building effort, to create more dialogue between these two communities for their mutual benefit.

Gautam Biswas: We have been developing computer-based learning systems where students teach computer agents. These teachable agents provide important structures to help shape the thinking of the *learner-as-teacher*. Each agent manifests a visual structure that is tailored to a specific form of knowledge organization, and has related underlying qualitative reasoning mechanisms that helps the agent interact with the learner, and provide explanations on how well it has understood the material it has been taught. This framework lets us build on well-known teaching interactions that organize student activity (e.g., teaching by "laying out," teaching by example, teaching by telling, teaching by modeling), and keep the start-up costs of teaching the agent very low (as compared to programming). We illustrate the effectiveness of our approach through Betty's Brain, a teachable agent that makes her qualitative reasoning visible through a concept map.

Bert Bredeweg: Conceptual models are an important means for developing and communicating knowledge, particularly concerning the behavior of (physical) systems. But how can the use of such models be facilitated and adapted to the specific needs of people via software? Part of the answers lies in the use of qualitative models and their simulations. Such models provide a rich ontology to capture conceptual models of how humans explain system behavior. Now that these techniques are reasonably well understood interesting questions emerge concerning the automated use of them in aiding learners to develop, share, and communicate knowledge. This requires the design of graphical workbenches to work with such models and the development of smart agents that support a learner in "doing the right thing."

Ronald W. Ferguson: Diagrammatic reasoning is cognitively interesting because it involves the interaction of our powerful and seemingly task-independent visual system with knowledge about culturally-specific cognitive artifacts. Interpretation of new diagram types must be learned, but once learned, take on the character and ease of perception. Recent research in Qualitative Spatial Reasoning (QSR), which examines the development and inferential power of spatial relationships, may help explain why diagrammatic reasoning works this way, and even allow us to characterize what makes a diagram effective. We explore this claim using our GeoRep system as an example of integrating QSR with cognitive models of vision and problem-solving.

Peter Struss: Helping to understand ecological systems, to analyze the reasons for the deterioration of our environment and climate and to propose counteractions provides an important challenge to knowledge-based systems. Modeling artifacts and diagnosing why and how man-made devices fail to perform as expected is an important application area of model-based and qualitative reasoning which is based on a rigorous logical theory. Extending this foundation to natural systems turns out to be not straightforward, emphasizes the needs for conceptual and qualitative modeling formalisms, and the problem solving techniques face a different level of complexity. We will discuss the challenges and directions of potential solutions using an example at the transition between technical and natural systems, namely water treatment processes.

Bruce Sherin: Bruce Sherin's research includes investigations of conceptual change in science and external representations in science and mathematics. Bruce will serve as the discussant for the Symposium.

Language and Thought

Motivation

After decades of neglect, the language and thought hypothesis—that the language we speak may influence the way we think—has recently enjoyed a resurgence of interest. This new wave of language and thought research capitalizes on gains in our linguistic knowledge of cross-linguistic semantic patterns and in the range and subtlety of psychological techniques now available. This new research has tackled a wide range of content areas, including space, time, motion, causality, the nature of the object concept, and theory of mind. This symposium presents methods and recent findings in this arena.

Lera Boroditsky

Different languages divide the color spectrum in different ways. Does this lead speakers of different languages to perceive colors differently? Results of several experiments suggest that color language can influence people's color judgments even in conditions when all color stimuli are present at the same time and need not be stored in memory. Language appears to be involved online during simple color-discrimination tasks such that effects of language can be selectively disrupted by verbal interference (but not spatial interference). Further, color discrimination performance across a boundary that exists in one language but not another can be altered by linguistic interference only for the language group that codes that linguistic distinction. Finally, as the color discrimination tasks become simpler and faster, effects of linguistic interference disappear. These results suggest that language is involved online in a large number of low-level perceptual discriminations, but also that not all color discrimination is affected by language.

Jill DeVilliers

This paper will address the issue of possible connections between language development and thought using the case of Theory of Mind. There are multiple ways to construe connections between language and false belief reasoning, only some of them causal. The argument will be that the data are compatible with a causal connection for a specific aspect of language knowledge linked to recursion of sentences, but that this does not rule out other potential facilitatory effects of language.

John Lucy

Researchers in language and thought must constantly deal with the problem of devising truly matched instruction procedures. This paper discusses the efforts of Lucy and his colleagues to develop a nonverbal triads procedure: that is, a procedure that avoids using words like “same,” “similar,” “(more) like’” etc. The resulting procedure then does not depend on using translation equivalents in other languages, and offers a useful alternative for working with children and with deaf subjects. Some preliminary empirical results from new work will be described.

Phil Wolff

This research is on causal verbs and reasoning across languages. The concept of CAUSE has frequently been treated as a conceptual primitive in the linguistic, philosophical and psychological literatures. Given this assumption, one might expect that the meaning of words encoding the concept of CAUSE should be relatively consistent across languages. In contrast to this assumption, This research shows how the meaning of the verb “cause” and related verbs may differ significantly across languages, e.g., English, Russian, and German. In addition, it suggests that these differences in meaning might reflect underlying differences in the way causal events are categorized non-linguistically.

Symposium: The Diversity of Conceptual Combination.

MODERATOR

Fintan Costello (Fintan.Costello@ucd.ie),
Department of Computer Science, University College Dublin,
Dublin, Ireland.

SPEAKERS

Fintan Costello (Fintan.Costello@ucd.ie),
Department of Computer Science, University College Dublin,
Dublin, Ireland.

Christina Gagne (cgagne@ualberta.ca),
Department of Psychology, University of Alberta,
Edmonton, Alberta.

Zachary Estes (estes@uga.edu),
Psychology Department, University of Georgia,
Athens, Georgia.

Edward Wisniewski (edw@uncg.edu),
Department of Psychology, University of North Carolina,
Greensboro, North Carolina.

Introduction

A fundamental aspect of everyday language comprehension is the interpretation of novel compound phrases through conceptual combination: a mechanism that is engaged whenever people interpret phrases like "sand gun", "cactus fish" or "pet shark". Conceptual combination is a diverse and complex cognitive process: people are able to combine concepts in a variety of different ways (for example, a "sand gun" is a tool that sprays sand, while a "cactus fish" is a fish with prickly spines, and a "pet shark" is a shark which is also a pet). This diversity is reflected in the number of quite different theories of conceptual combination that have recently been proposed by, for example, Wisniewski (Wisniewski, 1997), Gagné (Gagné & Shoben, 1997), Estes (Estes & Glucksberg, 2000), and Costello (Costello & Keane, 2000). The aim of this symposium is to gather current researchers on conceptual combination to discuss both the diversity of ways in which concepts can combine, and the diversity of theories that have been put forward to account for conceptual combination.

Diversity of Combination Types

Combined concepts are often divided into three types: relational combinations (such as "sand gun"), which assert a relation linking the two concepts being combined; property combinations (such as "cactus fish"), which transfer a property from one concept to the other; and conjunctive combinations (such as "pet shark"), which describe something that is an example of both combining concepts. These types are quite loose, however, and are by no means definitive or all-inclusive. In this symposium, speakers will address questions such as

- Why do concepts combine in different ways?
- How significant are the different combination types?
- Are some combination types more important than others?

Relationship between Theories of Combination

Recent theoretical accounts of conceptual combination are strikingly different from each other, ranging from Gagne's CARIN theory (which uses a standard set of 16 relational templates such as X-HAS-Y or X-ABOUT-Y to interpret compound phrases), to Wisniewski's Dual-Process theory (which suggests that compound interpretation involves both a scenario-construction mechanism and a structural-alignment mechanism similar to that used in analogies), to Costello's Constraint theory (which describes conceptual combination as a process of constraint satisfaction subject to the pragmatic requirements of communication using compound phrases). Symposium speakers will address questions such as

- Why are the various theories of combination so different?
- What common ground do these theories share?
- How do these theories relate to each other?
- Can we come up with an integrating framework to unite these theories?

Conclusion

By bringing together researchers taking different approaches to conceptual combination, this symposium will give a useful synthesis of the current state of conceptual combination research. By directly addressing the diversity of concept combination, the symposium may provide the basis for a more unified view of this important and fascinating part of human thought and language.

Lattimore Hall, Rochester, NY 14534

This symposium will consist of four presentations of recent work that examine the cognitive aspects of 'social resonance' in interaction. By social resonance, we mean the state of being that pertains when individuals engaged in face-to-face communication feel strongly connected. The studies we will present elaborate and extend a wealth of findings, primarily from social psychology and anthropology, on a set of closely related concepts; e.g., 'interpersonal sensitivity' (Hall & Bernieri, 2001), 'social glue' (Lakin, et al., 2003), 'interactional synchrony' (Bernieri & Rosenthal, 1991), empathy (Sonnby-Borgstrom, et al. 2003, Nishio, 2002), and 'socially distributed cognition' (DuBois, 2000). In choosing the term SOCIAL RESONANCE, we seek to emphasize the *dyad* or *group* as a focal level of analysis and theory. Resonance also evokes the dynamic interplay of behaviors, multi-modally, between participants in real time interactions. The social psychological notion of 'rapport,' as well as recent-era reformulations of anthropologist Malinowki's (1923) construct, 'phatic communion,' resemble the sense of social resonance we employ here:

> "… all the different communicative strands, speech, gesture, posture, body movements, orientation, proximity, eye contact, and facial expressions … woven together to form the fabric of conversation," (Laver, 1975).

Social resonance has been the focus of research across quite a range of scientific disciplines. Its presence in interaction is ascertained on the basis of behavioral observables that occur singly and in clusters, or in patterns of alternation or sequential unfolding across an interval of interaction. Examples include mimicry or 'mirroring' of various nonverbal behaviors, interactional rhythm in conversation, and syntactic priming. The work presented here takes up where many social psychological and anthropological treatments of resonance phenomena leave off, by examining its impact on real-time cognitive processing; specifically, on processes of language production and comprehension. Our studies illuminate, through close analysis of the multi-modal (speech and gesture) aspects of human interaction, what psycholinguistic processing mechanisms may be triggered by, facilitated by--or, conversely---remain inactive, or even be inhibited by, respectively, presence or absence of social resonance.

Kimbara and Parrill present recent work on the interaction between gestural mirroring (specifically, cases in which a speaker appears unconsciously to adjust her use of gesture space, in accord with her interlocutor's use of space, to create matching nonverbal expression of spatial layouts) and 'structural priming' (Bock, 1986), or, the ways in which one speaker's choice of syntactic construction influences the subsequent choice of construction on the part of her interlocutor. Webb examines types of metaphoric gestures (McNeill, 1992), spontaneously produced by speakers addressing an audience, with respect to their roles in managing the interactive context (Bavelas, 1992). Welji and Duncan examine gestures in spontaneous narrative discourse, comparing interlocutors who are strangers (less socially resonant) with interlocutors who are friends (more resonant). Franklin and Duncan demonstrate perturbation of social resonance, as a function of cognitive load, in dyads where one member is instructed to deceive the other about the visual and narrative content of a cartoon story eliciting stimulus, viewed on video.

The symposium aims to explore abduction (inference to explanatory hypotheses), an important but neglected topic in scientific reasoning. The aim is to integrate philosophical, cognitive, and computational issues. The main thesis is that abduction is a significant kind of scientific reasoning, helpful in delineating the first principles of a new theory of science. The status of abduction is very controversial. When dealing with abductive reasoning misinterpretations and equivocations are common. What are the differences between abduction and induction? What are the differences between abduction and the well-known hypothetico-deductive method? What did Peirce mean when he considered abduction a kind of inference? Does abduction involve only the generation of hypotheses or their evaluation too? Are the criteria for the best explanation in abductive reasoning epistemic, or pragmatic, or both? How many kinds of abduction are there? The symposium aims to increase knowledge about creative and expert inferences. The study of these high-level methods of abductive reasoning is situated at the crossroads of philosophy, epistemology, artificial intelligence, cognitive psychology, and logic; that is at the heart of cognitive science.

More than a hundred years ago, the great American philosopher Charles Sanders Peirce coined the term "abduction" to refer to inference that involves the generation and evaluation of explanatory hypotheses. The study of abductive inference was slow to develop, as logicians concentrated on deductive logic and on inductive logic based on formal calculi such as probability theory. In recent decades, however, there has been renewed interest in abductive inference from two primary sources. Philosophers of science have recognized the importance of abduction in the discovery and evaluation of scientific theories, and researchers in artificial intelligence have realized that abduction is a key part of medical diagnosis and other tasks that require finding explanations. Psychologists have been slow to adopt the terms "abduction" and "abductive inference" but have been showing increasing interest in causal and explanatory reasoning.

Thus abduction is now a key topic of research in philosophy of science. First, this symposium ties together the concerns of philosophers of science and logicians, showing, for example, the connections between formal models and abduction (Meheus, Woods and Gabbay). Second, it lays out a useful general framework for discussion of various kinds of abduction (Magnani), such as model-based and manipulative abductions. Third, it develops important ideas about aspects of abductive reasoning that have been relatively neglected in philosophy of science, including the role of testing in abductive inference (Aliseda), and the interrogative model of inquiry and the role of different kinds of why-questions and strategic principles employed in attempts to find and construct answers also at the computational level (Sintonen and Paavola, Addis and Gooding). The clarification of these topics aims to increase knowledge about some aspects of explanatory reasoning and hypothesis formation very relevant in many epistemic tasks.

1. If we stress the concept of *model-based and manipulative abduction* (Magnani), creative inferences in science can be seen as formed by the application of heuristic (strategic) procedures that involve all kinds of good and bad inferential actions and both internal and external representations, and not only the mechanical application of rules.

2. Recent *logical models* can illustrate in a rigorous way how these (strategic) abductive steps are combined with deductive steps (Meheus, Woods and Gabbay).

3. Common to all abduction problems is a cognitive target that cannot be hit on the basis of what the abducer presently knows. Abductive hypotheses do not enhance a reasoner's knowledge. Abduction, accordingly, is ignorance-preserving inference. These abductive processes are dynamical (Woods and Gabbay).

4. The "abductive steps" are also analyzable in terms of responses to surprising singular or general facts, showing a connection to *explanation-seeking why-questions* (Sintonen and Paavola).

5. The importance of *experimental verification for hypotheses evaluation* in science is stressed by the relationship between abduction and pragmatism in Peirce (Aliseda).

6. Abduction cannot be thought of in isolation from the two other type of inference (deduction and induction/validation) identified by Peirce. Computer models of scientific behaviour and music conversation suggest that in simulation of abduction requires the use of mixed strategies using random actions as suggested by game theory (Addis and Gooding).

Cognitive Neuroscience: What does it tell us about high-order cognition?

Jay McClelland (jlm@cnbc.cmu.edu)
Carnegie Mellon University

Ken A. Paller (kap@northwestern.edu)
Northwestern University

Paul J. Reber (preber@northwestern.edu)
Northwestern University

Mark Jung-Beeman (mjungbee@northwestern.edu)
Northwestern University

Andrew Ortony (ortony@northwestern.edu)
Northwestern University

Motivation

Cognitive neuroscience has generated considerable excitement among cognitive scientists. It offers a new route to understanding the mind. But some have argued that the current techniques of cognitive neuroscience apply mainly to perceptual-motor and attention tasks. This symposium considers the contribution cognitive neuroscience can make to the study of high-order cognition.

Jay McClelland

Formulating cognitive theories in terms of neural computations

Cognitive Neuroscience is a relatively new field defined differently by different people. One activity that might fall under the rubric of cognitive neuroscience is the effort to formulate cognitive theories in terms of the underlying neural computations. This effort, I will suggest, may ultimately lead to theories that are not only grounded in neuroscience but also more satisfactory as accounts of cognitive phenomena. I will exemplify the approach with my own work on the development of the complementary learning systems theory of learning and memory. The work draws on insights from neurophysiology, neuroanatomy, neuropsychology, and connectionist modeling to develop an overall theory of learning and memory

Ken Paller

A cognitive neuroscience perspective on memory with and without awareness

Patterns of memory impairment in patients with amnesia suggest that memory for facts and events depends on a process of "cross-cortical storage" that is not required for other forms of memory. This neuropsychological evidence provides a theoretical foundation for understanding memory phenomena like recollection (the conscious experience of remembering facts and events) and priming (a type of item-specific implicit memory). Building on this foundation, measures of brain activity have revealed distinct brain potentials and brain activations that are associated with recollection of episodic memories versus certain types of priming. This cognitive neuroscientific approach thus constitutes an appropriate way to investigate the neurocognitive events that make "memory-with-awareness" so different from "memory-without-awareness."

Paul J. Reber

Cognitive (neuro)science: Models of recognition and categorization

Categorization and recognition have been investigated with a variety of approaches that have led to very different conclusions. Dissociations reported in the patient literature suggest separate representational systems. A resolution is proposed based on integrating key computational features of Nosofsky & Zaki's (1998) exemplar-based model with the Complementary Learning Systems (CLS) theory, a neural network model of memory system organization (McClelland, McNaughton & O'Reilly, 1995). Functional neuroimaging studies of categorization and recognition with healthy participants (Reber et al., 1998a,b, 2003) provide evidence supporting the two-system CLS theory. Integrating computational approaches with both behavioral and neuroscience data thus leads to a better account of recognition and categorization than any single approach.

Mark Jung-Beeman

Imaging higher-order language comprehension and insight problem solving: What and how from where?

Neuroimaging of higher-order cognition offers two advantages: First, it can provide a relatively covert measure of processing; and second, cortical location information can constrain or expand cognitive theories regarding component processes. In one set of studies, we used fMRI signal in specific cortical regions as markers for two component processes in drawing inferences: semantic integration, and semantic selection. We thus observed the engagement of these processes while people comprehended stories, without requiring a concomitant "probe task." In another line, we studied insight processes in verbal problem solving and found involvement of an area of the right temporal lobe, similar to that observed in the inference experiments.

Andrew Ortony (Discussant)

Andrew Ortony's work has ranged from computational modeling to philosophy. His current research is on emotion and cognition.

Large-scale Knowledge Representation Resources for Cognitive Science Research

George A. Miller

Suite 100, 3721 Executive Center Drive, Austin, TX 78731 USA

Pat Hayes
Institute for Human and Machine Cognition
40 South Alcaniz Street, Pensacola, FL 32502

Motivation

One of the unique features of cognitive science has been its emphasis on understanding how people represent and use knowledge. Unfortunately, knowledge representation can be quite difficult if one is starting from scratch. Having "off the shelf" representation systems that can be used for investigations can make new types of cognitive modeling efforts possible, at a scale that would otherwise be impossible. The participants in this symposium each represent a different approach to building such representational resources.

George A. Miller: WordNet is a lexical database that contains 146,900 English nouns, verbs, adjectives, and adverbs that are now organized by semantic relations into 117,500 meanings, where a meaning is represented by a set of synonyms (a synset) that can be used to express that meaning. An entry in WordNet consists of a synset, a definitional gloss, and (sometimes) one or more sentences illustrating usage. The semantic relations used to organize words and entries are synonymy and antonymy, hyponymy, troponymy and hypernymy, meronymy and holonymy. A currently active project, the disambiguation of definitional glosses, will be discussed.

Charles J. Fillmore: The FrameNet project is morphing from a lexicon-building project to a system capable of providing a layer or two of semantic annotation for full sentences. My remarks will summarize the kinds of information the FrameNet database can provide now, and what it should be able to offer in the not too distant future, for researchers in language engineering and cognitive science. FrameNet is moving toward greater coverage of the lexicon, adaptation to specialist vocabularies, more systematic treatment of multiword expressions, and provisions for incorporating a wide variety of (non-core) grammatical constructions.

Martha S. Palmer: Recently, a consensus has been achieved as to a task-oriented level of semantic representation to be layered on top of the existing Penn Treebank syntactic structures: The Proposition Bank, or PropBank. PropBank consists of argument labels for the semantic roles of individual verbs and similar predicating expressions such as participial modifiers and nominalizations. This talk will describe the PropBank verb semantic role annotation being done at Penn for both English and Chinese. The annotation process will be discussed as well as the use of existing lexical resources such as WordNet, Levin classes and VerbNet. Comparisons with similar projects, including the FrameNet Project at Berkeley and the Prague Tectogrammatics project, will be made.

Doug Lenat: Cognitive Science research could benefit from large-scale representational building blocks. One such building block is a broad ontology of, well, everything. Another one, resting on that, is a formal axiomatization of most of the meaning of most of those concepts; i.e., millions of axioms about those hundreds of thousands of terms. These two pieces have been worked on for twenty years -- and the better part of a person-century of effort -- as Cyc. It's been highly proprietary so far, with a small tip of its ontology exposed as OpenCyc. Starting this summer, though, Cyc is being made available in its entirety for R&D purposes for free, courtesy of Ron Brachman at DARPA's IPTO. In this presentation I will briefly describe this ResearchCyc ontology and KB, and some initial utilities provided with it (inference engine, English-Cyc lexicon, interfaces), how this might fit in with the other infrastructure elements being described in this panel, and how these might leverage your work.

Pat Hayes

Pat Hayes, the discussant for this symposium, has the unique distinction of having inventing two of the most widely-used representations for change, the *situation calculus* (with John McCarthy) and *histories*. He is a Fellow of the American Association for Artificial Intelligence and the Cognitive Science Society.

The inter-relationship between spatial cognition and gestures

Introduction

One of the most interesting and frequent questions within cognitive science is "What type of mental representation is used when people solve problems/make decisions/think/etc.?" This symposium will explore the issue of mental representation within the area of spatial cognition by examining how people gesture within the context of a spatial task (e.g., mental animation, scientific analysis, construction, etc.).

Spatial Transformations and Gestures
(Greg Trafton, Susan Trickett, and Cara Stitzlein)

How do experts think about complex data spaces? We examined experts in three domains (meteorology, submarine, fMRI) as they solved a difficult domain problem. We found that, consistent with previous research, they created complex spatial mental representations (e.g., mental models) and used spatial transformations to mentally manipulate these representations. When we examined the gestures that these experts spontaneously made, we found that many of their gestures occurred while performing spatial transformations. We suggest that these gestures were outward manifestations of what they were thinking that facilitated their problem solving.

Gesture use while thinking about Machines
(Mary Hegarty, Sarah Mayer and Sarah Kriz)

We examined the use of gestures while people solved "mental animation" problems in which they have to predict the motion of a mechanical device from static diagrams. In "think aloud" experiments, participants gestured on more than 90% of problems (although they were not instructed to gesture), and their gestures communicated information that was not stated in words.

In another experiment, participants were asked to think aloud while solving problems (communication group), just solved the problems (control group), or solved the problems while tapping a spatial pattern (dual task group). Although the communication group gestured the most, gestures were also frequent in the non-communicative situation experienced by the control group.

The dual-task group had poorer performance than the control group, suggesting that prevention of gesturing impaired performance. These preliminary results suggest that gestures function both in the process of inferring motion from static diagrams and in communicating the results of this inference process.

Gestural Models for Self and Others (B. Tversky, H. Taylor, K. Emmorey, J. Heiser, & S. Lozano)

Three paradigms show that gestures can convey spatial information effectively both for self and for others. People's oral spatial descriptions include gestures that reflect the perspective taken on the space; they also provide a model of the space for the listener. The information in the words is not sufficient without the gestures. Listeners, too, gesture while hearing spatial descriptions from unobservable speakers; these gestures appear to help establish a spatial mental model for the listener. People's explanations of how to put something together include gestures that convey the structural relations of the object and actions needed for assembly, information that facilitates performance of communicator and receiver.

The role of gestures in a theory of spatial representation
(Chris Schunn, Lelyn Saner and Tony Harrison)

In many complex problems, there is a significant visual or spatial component to the problem solver's representations. Neuropsychological and cognitive work has suggested that there are several fundamentally different ways in which problem solvers can represent visual/spatial information---flat vs. 3-dimensional, near vs. far, approximate vs. detailed. Each of these differences can have a strong influence on problem-solving behavior. We have a theory, ACT-R/S (Harrison & Schunn, 2001), for how these features are strongly correlated in one of three possible visual/spatial representations, how the representations are selected, and how the representations influence behavior. We have been using analyses of gestures to diagnosis their representation choice. Our talk will illustrate how our theory of spatial representation influences our use of expert and novice problem solvers's gesture data to infer representations beyond previous analyses and how our theory of spatial representations has been changed by the gesture data.

The Consequences of Spatial Gestures (Justine Cassell)

Evidence from house descriptions, route descriptions, and the description of complex objects jives with earlier studies showing that roughly 50% of gestures convey content that is not redundant with the content of speech. These complementary gestures have consequences for later speech in that they may be referred back to – both via gesture and via speech – by both the speaker and the listener. I address a number of questions about the role of gesture in the semantics of ongoing talk, and their role in spatial cognition: how do we predict what aspects of spatial scenes will be described in gesture vs. speech, the form that these spatial descriptions will take in gesture, and how these features are represented by the participants in a discourse in such a way as to serve as the context for later speech.

Situating Abstract Concepts

Lawrence W. Barsalou (barsalou@emory.edu)
Department of Psychology
Emory University, Atlanta, GA 30322 USA

Katja Wiemer-Hastings (katja@niu.edu)
Department of Psychology
Northern Illinois University, DeKalb IL 60115 USA

Roughly speaking, abstract concepts such as *TRUTH* refer to entities that are neither purely physical nor spatially constrained (Wiemer-Hastings, Krug, & Xu, 2001). Such concepts pose a classic problem for theories that ground knowledge in modality-specific systems (e.g., Barsalou, 1999, 2003a,b). Abstract concepts also pose a significant problem for traditional theories that represent knowledge with amodal symbols. Surprisingly, few researchers have attempted to specify the content of abstract concepts using feature lists, semantic networks, or frames. It is not enough to say that an amodal node or a pattern of amodal units represents an abstract concept. It is first necessary to specify the concept's content, before beginning the task of identifying how this content is represented.

Hypotheses

A common assumption is that abstract and concrete concepts have little conceptual content in common, if any. Alternatively, we propose that concrete and abstract concepts share important similarities. In particular, we propose that they share common situational content, namely, information about agents, objects, settings, events, and mental states (Hypothesis 1). Where concrete and abstract concepts differ is in their specific foci within background situations. Whereas concrete concepts focus on objects and settings, abstract concepts focus on events and mental states (Hypothesis 2). As a result of these different foci, the representations of abstract concepts are more complex, being less localized in situational content (Hypothesis 3). Finally, because the content of abstract concepts is grounded in situations, modality-specific simulations could, in principle, represent it (Hypothesis 4).

Method

In an exploratory study, we assessed the content of three abstract concepts: *TRUTH, FREEDOM,* and *INVENTION*. These concepts were compared to three concrete concepts—*BIRD, CAR,* and *SOFA*—and also to three intermediate concepts—*COOKING, FARMING,* and *CARPETING*. We first asked participants to produce properties typically true of these concepts. We then analyzed these properties using two coding schemes, one that coded small protocol units, and a second that coded large ones.

Results

For the complete results, see Barsalou and Wiemer-Hastings (in press). Both coding analyses offered support for Hypothesis 1, namely, common situational content was produced across concrete, intermediate, and abstract concepts. For all concepts, participants tended to describe background situations, including information about entities, settings, events, and mental states. Indeed the similarities between concepts were more striking than the differernces.

Both analyses also offered support for Hypothesis 2, namely, concrete and abstract concepts differed in their situational foci. Whereas concrete concepts focused more on objects, locations, and behaviors, abstract concepts focused more on social aspects of situations (e.g., people, communication, social institutions) and mental states (e.g., beliefs. complex relations). Intermediate concepts lay in between.

Consistent with Hypothesis 3, conceptual structures were most complex for abstract concepts. Abstract concepts were most likely to contain deep hierarchies of large conceptual clusters organized by complex relations.

Regarding Hypothesis 4, we see no reason that the content of abstract concepts cannot be represented in simulations. Because their content is perceived in the situations that involve abstract concepts, it could, in principle, be reenacted later when representing them. Clearly, much further research beyond this exploratory study is necessary.

Notes on the Negative Side of Rationality: Critical Principles

Mark H. Bickhard (mark@bickhard.name http://www.bickhard.ws/)
Lehigh University, 17 Memorial Drive East, Bethlehem, PA 18015

A central but neglected aspect of rationality is its negative aspect: knowledge of error. Knowledge of error warrants and motivates criticism, so it constitutes knowledge of principles of criticism, or *critical principles* (Bickhard, 1991, 2001a, 2002; Bickhard & Campbell, 1996a). I will outline a model of rationality, grounded essentially in an interactive, agent based model of representation and cognition (Bickhard 1993, 1996, 1998a, 1998b, 2001b; Bickhard & Campbell, 1996b; Bickhard & Terveen, 1995), that gives central place to such negative knowledge, and show how it solves and dissolves multiple problems. It puts creative interaction and problem solving at the center of the nature of mind, rather than portraying reason trying to rule the passions. It is a non-foundationalist model, thus avoiding the problem of the rational warrant for the foundations of rationality. Nevertheless it is self-consistent in the sense that being rational is itself rational, but without having to demonstrate that rationality leads closer to truth. It accounts for logic as a natural development of rationality given reasonable additional assumptions, such as that of language and of the possibility of conscious reflection, and, thus, renders logic as a rational creation rather than the essence of rationality.

In this talk, I will focus on logic as rational construction rather than as the center of rationality. Historically, logics have been developed of greater and greater power, but no logic can construct a logic more powerful than itself. If logic were the essence of rationality, therefore, the history of logic would necessarily be arational. In this model, logic emerges as an inherently wide, natural domain of possible error and of means of avoiding those errors, and thus avoids that problem, as well as the many other problems of foundationalism. This model also naturally situates higher order logics and modal logics within the broader framework. I will not be addressing the technical details of these points, but will outline the basic perspective.

If there is time, I will also outline another realm of advantages of this model of rationality: It dissolves several problems in the philosophy of science, such as the perplexities involved in notions of progress, of realism and truth, and of induction.

Role of pattern recognition and search in expert decision making

Fernand Gobet (fernand.gobet@brunel.ac.uk)
Department of Human Sciences, Brunel University
Uxbridge, Middlesex, UB8 3PH UK

The study of expert behaviour has attracted widespread attention since the seminal work of de Groot (1965) and Chase and Simon (1973). Of particular interest is how experts, even under time pressure, can make relatively good decisions in spite of strong limits in their computational capacities. A substantial amount of research has focused on chess playing, as this domain offers a well-validated and ecological measure of expertise (the Elo rating). Obviously, this question has important repercussions beyond game playing, and extensive research has been carried out about decision making in domains such as fire fighting, medical diagnosis, and aviation (e.g., Zsambok & Klein, 1997).

While the importance of both recognition and search mechanisms is generally accepted, researchers disagree as to their relative importance. De Groot (1965) showed that even chess grandmasters seldom look at more than 100 possible continuations of the game before choosing a move. This number is vastly smaller than the number of legal moves (on average, for a middlegame position, the number of legal continuations six ply deep is about 1.8 billion, and increases exponentially for greater depths). De Groot (1965) also found that top-level grandmasters do not search reliably deeper than candidate masters, although more recent data suggest that masters search slightly deeper, on average, than weak amateurs (e.g., Gobet, 1998). De Groot (1965) as well as Chase and Simon (1973) propose that recognition, by allowing knowledge to be accessed rapidly, enables look-ahead search to be highly selective. Holding (1985), by contrast, argued that the main determinant of chess skill is the ability to plan ahead by search, rather than reliance on recognition of positional patterns.

Support for the role of pattern recognition in expert behaviour comes from two main lines of research: (a) perception and memory, and (b) decision making. Evidence from perception and memory indicates that experts can rapidly recognize the key features of a problem, and that there are important differences between experts' and non-experts' eye-movements (de Groot & Gobet, 1996; Gobet, de Voogt & Retschitzki, in press). Research has also shown that experts have a remarkable memory for domain-specific material (Chase & Simon, 1973; de Groot, 1965; de Groot & Gobet, 1996). Interestingly, their superiority extends to the recall of random positions, although the skill difference is then much smaller than with game positions. CHREST, a detailed computer model of pattern recognition, has accounted for these results (de Groot & Gobet, 1996; Gobet & Simon, 2000; Gobet & Waters, 2003).

The second line of evidence comes from rapid decision making (e.g., Zsambok & Klein, 1997). In particular, research with chess players suggests that grandmasters can play at a high level even under severe time pressure (e.g., Gobet & Simon, 1996). SEARCH, a computational model based on CHREST, accounts for several data from expert problem solving, such as how average depth of search increases as a function of skill (Gobet, 1997).

Recently, proponents of the predominant role of search processes have collected data aiming at undermining the importance of pattern recognition. In particular, Chabris and Hearst (2003), using data from rapid chess and blindfold chess, have questioned Chase and Simon's (1973) and Gobet and Simon's (1996) account. In this talk, I'll show that Chabris and Hearst's (2003) data, far from invalidating theories based on pattern recognition and selective search, actually support them.

Group Path Formation

Robert L. Goldstone (rgoldsto@indiana.edu)
Andy Jones
Michael E. Roberts
Cognitive Science Program, Indiana University
Bloomington, IN. 47405

Communal Path Construction

When people make choices within a group, they are frequently influenced by the choices made by others. One reason for this is that the actions of other people changes the environment in which a person makes their choices. In many domains, initial pioneers reduce the costs for followers who subsequently pursue the same path.

Our concrete instantiation of this situation is group path formation where people travel between destinations with the travel cost for moving onto a location inversely related to the frequency with which the location has been visited by others. In this situation, people may detour from straight paths connecting destinations to take advantage of frequently visited, hence inexpensive, paths. At a group level, the mathematics of "Minimal Steiner Trees" describes optimal path systems for connecting a set of destinations. A Minimal Steiner Tree (MST) is the set of paths that fully connects a set of destinations using the minimal amount of total path length. Finding minimal MSTs is a notorious NP-complete problem, with all known, provably optimal algorithms requiring an exponential increase in computation as the number of destination points increases linearly (Garey, Graham, & Johnson, 1977). However, analog devices such as soap films over wire frames have been shown to spontaneously create MSTs. Do groups of people create path systems that approximate MSTs as well?

Path Formation Experiment

59 Indiana University undergraduates were divided into 8 groups. The participants in each group were given the task of traveling between randomly sampled cities from a set of 3-4 cities. Participants were told to try to maximize their total number of points. Points were earned by successfully reaching destination cities, and were deducted for travel costs associated with each visited square on the map. The travel cost for a square was inversely related to the number of times all individuals previously visited the square, with recent visits reducing travel costs more than older visits.

As participants moved between cities, they saw their own locations as red triangles, other participants' locations as yellow circles, and the moment-by-moment cost of each map square color-coded with brightness representing ease of travel. Cities were arranged in triangular or rectangular configurations.

Results and Modeling

There were systematic deviations from beeline pathways in the direction of MSTs for all of the configurations of cities, however the participants' paths never converged upon MSTs. Greater deviations of beeline paths (see the solid lines in Fig. 1) toward MSTs (dashed lines) were found for the isosceles than the equilateral triangle arrangement of cities. In Fig. 1, the more often a square is visited, the brighter it appears. Furthermore, greater pro-MST deviations were found for a small rectangle than a large rectangle possessing the same proportions. Finally, asymmetric pro-MST deviations were observed, with greater deviations for participants traveling from City A to City B than traveling from City B to City A.

All three of these deviations from beeline pathways can be explained by Helbing, Keltsch, and Molnár's (1997) "Active Walker" model of pedestrian motion. This agent-based model includes equations for environmental changes produced by walking on paths that make the paths more accessible for subsequent walkers. At every time step, each walker in a group moves in a direction that compromises between moving toward the destination and moving toward heavily trafficked locations. This model and our experimental groups both establish path systems that lie between beeline and MSTs, with the deviation from beeline paths influenced by the topology of the destinations, the duration of travel, and the absolute scale of the world.

Why Is Word Learning Related to List Memory? Empirical and Neuropsychological Tests of a Computational Account

Prahlad Gupta (prahlad-gupta@uiowa.edu)
Department of Psychology; University of Iowa
Iowa City, IA 52242 USA

Introduction

A growing body of evidence indicates that human word learning, nonword repetition, and immediate serial recall (ISR) abilities are related in some way (e.g., Baddeley et al., 1998). It seems clear why word learning might be related to nonword repetition: every known word was once a nonword to a particular learner, so greater facility in processing nonwords should lead to greater facility in eventually learning them. But why might nonword repetition and list recall be related?

Nonwords as Lists

One possibility is that a nonword is processed like a list when first encountered, and is thus directly dependent on list sequencing mechanisms. If this were the case, we would expect to observe serial position effects in repetition of the sequence of sounds comprising nonwords, just as in ISR of lists of words. We conducted three experiments to examine syllable serial position effects in repetition of individual polysyllablic nonwords, and obtained significant primacy and recency in all three experiments (Gupta, 2004).

Testing Alternate Models

There are two possible explanations of these results in terms of our previous computational work (Gupta, 1996). The two formulations can be distinguished by differing predictions with regard to correlations between ISR, nonword repetition, and word learning. The original formulation explains the fact that these correlations arise developmentally but predicts their absence in adults. An alternative formulation predicts that such correlations obtain not only developmentally, but also in adults. We conducted two experiments to examine whether ISR, nonword repetition, and word learning are correlated in adults (Gupta, 2003). The results indicated that the developmental relationships between all three abilities also exist in adults, thus supporting the revised model over the original model.

Neuropsychological Investigation

The revised version of our model incorporates the view that there is a functional relationship between the abilities, all of which invoke the same sequencing mechanisms. If this is really the case, we would expect relationships between these abilities to obtain even following early neurological injury across a variety of lesion sites. This is because in the case of early lesions, there is a real possibility for remission of deficits as a result of neural reorganization; persistence of correlations would thus support the hypothesis of an underlying functional relationship. We examined this question by administering tests of word learning, nonword repetition, and ISR to 5-10 year old children who had suffered perinatal brain injury across a variety of sites, and to age-matched controls (Gupta et al., 2003). The results indicate that the relationships between ISR, nonword repetition, and word learning are exhibited even under conditions of early brain injury. These findings thus provide further support for the functional architecture of our revised model.

These various lines of evidence together clarify how common sequencing mechanisms may underlie both nonword processing and immediate list recall, thereby offering an explanation of why word learning is related to list memory.

Does Gesture Play a Special Role in the Brain's Processing of Language?

Spencer D. Kelly (skelly@mail.colgate.edu)
Department of Psychology—Neuroscience Program, Colgate University
13 Oak Dr., Hamilton, NY 13346 USA

Corinne Kravitz (ckravitz@mail.colgate.edu)
Department of Psychology—Neuroscience Program, Colgate University
13 Oak Dr., Hamilton, NY 13346 USA

Background

People of all ages, cultures, and backgrounds gesture when they speak. What function do these hand movements serve? Although there is consensus that gesture plays an important role in language production, there is considerable theoretical debate as to what role gesture plays in language comprehension (Clark, 1996; Kelly, 2001; Kelly, Barr, Church, & Lynch, 1999; Krauss, 1998; Krauss, Morrel-Samuels, & Colasante, 1991; McNeill, 1992). At the core of this debate is the fact that previous research has relied on indirect behavioral measures that do not provide access to the underlying neurocognitive processing of speech and gesture. The present research addresses this issue by using a more direct neurocognitive measure: event-related potentials (ERPs). ERPs measure electrical brain activity and have been used successfully in previous research on the neural processing of language.

Methods

In Study 1, adult participants watched videos of speech and gesture, in which the gesture conveyed the same, complementary or different information as the accompanying speech. ERPs were recorded to the speech in these different gesture contexts. In Study 2, participants watched videos similar to Study 1, but the gesture was replaced with digitally-inserted visual information (a vertical or horizontal line representing different dimensions of the objects) that either conveyed the same, complementary or different information as the speech. The goal of Study 2 was to determine whether the results from Study 1 were due to gesture *per se*, or simply any visual information that preceded speech.

Results

The results from Experiment 1 have been published (Kelly, Kravitz & Hopkins, in press) and reveal that gestures not only influence ERPs to speech, but also that the gesture influence is late (N400) and early (sensory, P1-N1 and P2 components) in the brain's processing of speech. This suggests that gestures may affect not only high-level semantic processing of speech, but also low-level phonological processing as well.

Study 2 is currently in progress to determine whether the results from Study 1 are unique to gesture, or whether any meaningful visual information will have a similar impact on the brain's processing of speech.

Discussion

Researchers know very little about the neural time course of how gestures influence speech comprehension. This question bears on important theoretical issues in language research: are there aspects of language processing that are impervious to contextual influence? When does a gestural context influence the neural processing of language? In addition, the results will address a debate in the literature about the "specialness" of the relationship between speech and gesture in language processing (McNeill, 1992). Finally, by taking ERPs to speech using real-time, multimodal videos, this project makes an important methodological contribution to the neuroscientific investigation of language processing.

Acknowledgments

The authors thank Colgate University for their generous support of undergraduate research.

Phonology without Phonemes

James L. McClelland (jlm@cnbc.cmu.edu)
Department of Psychology and Center for the Neural Basis of Cognition, Carnegie Mellon
115 Mellon Institute, 4400 Fifth Avenue, Pittsburgh, PA 15213 USA

Overview

Theories of language structure generally provide two things: a list of allowable units of various types, and rules or constraints that determine how the various units may be combined to create larger units. Together the units and rules determine which larger units are part of the language and which are not. In general, acceptability is an all-or-nothing proposition: A given proposed larger unit either is or is not acceptable according to this approach.

In this talk I will argue instead that at there are neither rules nor units and that the acceptability of particular possible utterances is a matter of graded constraint satisfaction. The particular utterances I will consider are the word-forms of English. The argument will draw heavily on the prior work of Joan Bybee (2001) as well as on work with Karalyn Patterson (McClelland and Patterson, 2002a,b) and Gary Lupyan (Lupyan and McClelland, 2003) and continuing work with Bybee, Lupyan, Catherine Harris, and Brent Vanderwyk. Two aspects of this effort that will be discussed in this talk are described below.

Constraints on English Word Forms

The idea that candidate word forms have graded goodness values has been introduced by Kessler and Treiman (1997). Work currently in progress with Brent Vanderwyk extends this idea, accounting for the relative probabilities of the different word bodies that occur in stressed monomorphemic monosyllabic words. More traditional work by Harris (1994) describes a set of rules that dictate which phoneme sequences are legal in English and which are not. However, the analysis seems incomplete in that there are many sequences that are legal but which occur relatively infrequently (e.g., sequences of the form *_vpt* where *v* is a short vowel and the '_' indicates the missing word onset), while there are other sequences that occur very much more frequently (e.g. sequences such as *_vnd*, *_vnt*, *_vld*, *_vlt*, and *_vst*). Harris himself allows that some forms are less preferred than others but offers no systematic way to address this.

According to our analysis, word bodies may involve a (partial or complete) closure with the lips (as in *cuff* or *cup*), with the tip of the tongue (as in *bass* or *cat*), or with the back of the tongue (as in *tack*), or no closure at all (as in *bee*). Each closure adds a complexity cost (with labial and back closures adding more than tip closures), but embellishments of a closure already paid for are relatively cheep. Thus, adding nasality to a tongue tip closure (as in *hint* as compared to *hit*) costs relatively little while the combination of a labial closure and a tip closure is more expensive, thus explaining the relative prevalence of *_vnt* compared to *_vpt*. At the time of this writing we have been able to use these ideas to account for nearly 90% of the variance in the frequencies of occurrences of different English word bodies.

Language Change and Morphology

Bybee (2001) has argued that language change transcribed as a shift from one phoneme to another reflects an underlying continuity of gestural change. Gary Lupyan and I have been exploring models of language change that capture the ways in which a graded constraint on the length of a word form gradually results in the creation of quasi-regular past tense forms like did, said, had, and made. Such forms are treated as exceptions listed in the lexicon by rule-based approaches such as Pinker (1999); in our model, they arise from fully regular forms from a graded constraint that tends to result in the gradual shortening of very frequent forms. What is lost in shortening is not completely arbitrary; some sign of the regular past tense inflection is preserved in nearly all cases, while the vowel is shortened or a consonant is deleted from the regular form. Recent work extending our approach to account for a variety of aspects of the evolution of the English past tense system, building on Lupyan and McClelland (2003), will be presented.

Abstract

It is a truism of everyday life that anger and fear affect cognition. In high-risk perceptually complex contexts, such as air combat, the effects of negative arousal on performance can be significant and potentially catastrophic. To better understand the interaction between emotion and cognition, we studied the effects of negative emotional stimuli on pre-attentive sensorimotor gating and selective attention in 39 healthy adults, as well as their relationship to neural, cardiac, and endocrine variables associated with the arousal response. Subjects were tested for pre-pulse inhibition under neutral and arousal conditions, as well as on emotionally-valent Flanker and Stroop tasks. Physiological arousal reactivity was measured using functional MRI, 24-hour EKG, electrodermal activity, cortisol testing, and dexamethasone suppression. Subjects were clinically assessed for levels of anger, anxiety, and perceived stress. Affect-valent conditions were induced using the International Affective Picture Scale, the Morphed Eckman Facial Stimuli, and affect-valent words matched for length and frequency. All conditions were counter-balanced for order. Our results indicate that even under relatively mild emotional challenge, the introduction of negative emotion significantly affected nearly all components of our cognitive battery, and correlated with changes in heart rate and electrodermal activity. Pre-attentive sensory gating and habituation were diminished, which may reflect the underlying neural conditions necessary for an increased orienting response. On tasks that required selecting a target in the presence of distractors, such as the Flanker Task, arousal had the effect of reducing both response time and accuracy. Our results were also consistent with our previous research on the higher-order effects of arousal on reasoning, indicating that individuals make decisions with less information under emotional arousal. On tasks such as the Stroop, in which orienting to the source of arousal conflicts with selective attention to a target, response time was lengthened. Importantly, the effects of negative arousal were widely variable across individuals, falling roughly into classes of individuals who showed strong physiological arousal response with strong cognitive effect, individuals who showed little physiological arousal response with little cognitive effect, and individuals who showed strong physiological arousal response with little cognitive effect. It is the third group that we are investigating most closely with fMRI, to determine which limbic feed-back mechanisms produce the most efficient cognitive performance under stress. This information, in turn, will permit more effective screening for high-risk environments to select only those individuals that are "hard-wired" for neural aptitude during fear.

Background

Emotional arousal primes the organism for imminent danger by increasing the orienting response, which permits the organism to find and focus on the source of danger. Once oriented to the source of danger, emotional arousal strengthens attention to the source of danger and diminishes attention to stimuli unrelated to its source, narrowing the amount of peripheral information simultaneously accessible with the target. This two-pronged approach has both costs and benefits: cognition is limited with respect to breadth, with the individual attending to less information at a time, but is more flexible in terms of the ability to switch attention from one target to another. Under most dangerous conditions in our evolutionary past, these costs and benefits were appropriate for survival: in the presence of a predator, it makes sense to focus on the predator, to ignore peripheral information such as ambient noise, and to be able to quickly switch attention between two or more predators that together present a collective threat.

While the cognitive changes associated with arousal in humans are appropriate for predator/prey contexts, most states of arousal (fear, stress, anxiety) in modern societies today occur under far different circumstances, in which the source of arousal is often not a concrete palpable entity to which one can readily orient. Even individuals in actually dangerous situations, such as fighter pilots in combat, protect themselves by defying their instincts: a fighter pilot needs to attend not only to the "predator" shooting at him, but equally to the myriad of dials and instruments that keep his plane aloft and his artillery engaged. Thus, while emotional arousal can benefit cognitive performance by increasing focused attention on a target and decreasing attention to distracting irrelevant information, emotional arousal today can just as often wreck havoc on cognitive performance by triggering the orienting response in the absence of an appropriate target and by disregarding potentially relevant peripheral stimuli ("tunnel vision").

Easterbrook, in 1959, seems to have been the first to fully articulate the hypothesis that arousal produces attentional narrowing, while Bacon (1974) was instrumental in relating attentional narrowing to the orienting response. Their hypotheses have since been

supported by a wide range of studies on humans and animals that used induced arousal by reward (Bruner et. al, 1955), electric shock (Cornsweet, 1969), loud noise (Hockey, 1970a), threatening words (Combs & Taylor, 1952), test anxiety (Rockett, 1956), and pre-parachuting anxiety (Hammerton & Tickner, 1967) on various tests of information processing. Research on selective attention in actual dangerous environments, in which simulation acted as the control for arousal, demonstrate that the tendency to overlook incidental (peripheral) cues in real-life situations can have severe implications for actual performance. Significant decline in performance has been shown for complex tasks that were performed during combat (Walker & Burkhardt, 1965), during deep-sea diving (Baddeley, 1972), as well as during realistically-simulated experiments in which subjects thought they were in mortal danger and were required to perform selective attention tasks (Berkun et. al, 1962) (Weltman & Egstrom,1971).

While useful and informative, these early experiments had several limitations, the most prominent of which was that they investigated mean performance effect without considering the effects of individual variability. Yet the factors that predict vulnerability or resilience to the cognitive effects of arousal have tremendous practical importance, particularly in screening for occupations that require complex cognitive processing under dangerous conditions. Other limitations were the failure to discriminate between selective attention and orienting responses, two processes that are presumed to be linked but nonetheless distinct, as well as the failure to distinguish between the effects of arousal on pre-attentive sensory gating versus the effects of arousal on attentive selective attention, two processes that intuitively might be linked but whose relationship has not been extensively studied.

The purpose of our study was therefore threefold. Our first aim was to establish or replicate findings on mean cognitive changes that occur in the general population in the context of mild emotional arousal; specifically pre-attentive sensory gating (emotional pre-pulse inhibition), selective attention (emotional flanker task), and orienting (emotional Stroop task). Our secondary aims were to compare the role that emotional arousal plays in selective attention and the orienting response, and to evaluate the interaction of sensorimotor gating and selective attention. Our third aim was investigate the effects of individual variability, specifically relating to neural, endocrine, and subjective assessment of baseline stress, anxiety, and anger, on task performance.

Methods

Subjects: We tested 39 adults (18 male, 21 female) between the ages of 18 and 50 (mean = 30.92; SD = 9.103). All subjects were screened and shown to be free from neurological and DSMIV Axis I &2 psychiatric illness using the Schedule for Affective Disorders – Lifetime Version (Endicott & Spitzer, 1978).

Tasks: We used pre-pulse inhibition (PPI) as a pre-attentive measure of sensorimotor gating. PPI, which has been well validated under non-emotional conditions, measures the inhibition of the startle response when an ordinarily startling stimulus is immediately preceded by a "pre-pulse," and is thought to reflect pre-attentive thalamic "gating" of non-novel stimuli. We used standard acoustic methods, as per Blumenthal (1993). During the task, subjects viewed stimuli presented on a 21-inch computer screen in a completely dark room. The visual protocol consisted of a two-minute orienting cross on a black background, followed by 48 pictures from the International Affective Picture Scales (IAPS) (Lang, Bradley, & Cuthbert, 1995), counter-balanced for order. These IAPS pictures were Neutral during one session and Negative Arousal during the other session. Sessions were also counter-balanced for order, with a duration of 4 minutes, 58 seconds each. The sessions were separated by a 15 minute unrelated task, to avoid habituation or "bleeding" between the conditions. Inter-trial intervals were calculated to prevent a trial commencing less than 2s before or after a picture change, to avoid the picture change itself acting as a pre-pulse. Data was produced separately for Neutral and Negative Arousal conditions, allowing for comparison between the two conditions.

We used a modified Flanker (Fan et al., 2001) to investigate affect-valent selective attention, as well as an emotional Stroop task (D'Alfonso et al., 1999) to measure affect-valent orienting response. During all three tasks, the subject was monitored for EKG and respiration. Physiological data were collected and recorded via the Biopac Systems MP150 module. Subjects performed the tasks under two conditions, Neutral and Negative Arousal, at the same time on two consecutive days, counter-balanced for order. All three tasks used emotionally-valent words (Times New Roman 66 pt. Font) to induce the two conditions. Words for the two conditions were matched for frequency and word length, and came from lists used in previous studies (Dalgleish, 1995, John, 1988, McKenna, & Sharma, 1995). Subjects performed the tasks on a computer, sitting 24 inches from the screen. The tasks were scored for both accuracy and average response time, calculating total score as well as scores for the first and last thirds to measure habituation effects.

The Flanker Task was adapted from the Attentional Network Task (Fan et al., 2001). For each affect conditions, the subject was presented with a series of 48 stimulus pairs. The first screen of the pair was an emotionally-valent word, presented for 1s. The second screen of the pair presented a series of 5 white arrows on a black background. The subject was instructed to identify the direction of the middle arrow by pressing a right or left button on a keypad. The subject's response immediately advanced the task to the next stimulus pair. There were 12 variations for arrow appearance, relating to position on screen, congruence, and direction of arrows, which were programmed to present randomly.

For the Stroop Task, during each affect condition the subject was presented with 60 words that were printed in one of four different colors: Red, Green, Yellow and Blue (15 for each group). The words were presented pseudo-randomly such that no color was repeated twice in a row. The subject was instructed to press the key corresponding to the color of the word shown. A practice run made up of symbols instead of words was presented before the task in order to get the subject comfortable using the keypad without looking down at the keys.

Neuroimaging data was acquired with a 3T Siemens system at the Nathan S. Kline Institute for Psychiatric Research in Orangeburg, New York. During scanning, subjects viewed a series of facial stimuli with negative (angry and fearful) and neutral expressions. Passive viewing of an orienting cross was used as a control condition. The subject's head was secured in a custom-made head-holder and headphones were provided for magnet noise attenuation and for experimenter/subject communication. 198 T2*-weighted coronal echoplanar images (EPI) were acquired covering the frontal and temporal lobes, with TR=3000ms, TE=40ms, Flip angle = 90º, Matrix=64x64, and a FOV=224mm. Our voxel size was 3.5 mm^3 and 31 contiguous coronal slices were obtained.

Following the EPI, we collected 31 T2*-weighted gradient-echo (GE) images which were used in the data-analysis process to correct for distortion found in the EPI images. The parameters for the gradient-echo sequence were TR=3000ms, TE=40ms, Matrix=64x64, with a FOV=224mm. Again our voxel size=3.5mm^3, and 31 contiguous coronal slices were acquired.

Anatomic information for regions of interest (ROI) analysis was obtained with an MP-RAGE sequence. T1-weighted images were collected with TR=3000ms, TE= minimal, Flip angle = 18º, Matrix=256x192 (zero filled to 256), and a FOV=250mm. The voxel size was .9 mm x .9 mm x 1.3 mm and 120 contiguous sagittal slices (zero filled to 128) were obtained. For our image processing we used the 198 EPI images, 31 GE images, and 128 MP-RAGE images collected during the scanning session. The primary steps of the image processing were: motion correction, distortion correction, spatial normalization, smoothing, and statistical analysis. First, the EPI images were realigned, using an estimation of head movement, relative to the last image (the last image is used because it immediately precedes the GE sequence). The EPI files were co-registered and re-sliced using a sinc interpolation to generate a mean EPI image as well as registered EPI images. The mean EPI image was registered to the GE, a distortion-free image, in order to generate a warp file that will be applied to all the EPI images to correct for distortion. The next step was spatial normalization in which the images were transformed to a standard anatomical space (Talairach and Tournoux, 1988) using a T1 brain template. This procedure facilitates intersubject comparison. Finally, images were smoothed with a 7 mm Gaussian kernel (twice the voxel size) so that they were appropriate for statistical analyses.

Salivary samples were obtained at 10am and 4pm for cortisol levels; in addition, we administered 1mg of dexamethasone and measured 10am salivary cortisol the following morning.

Self-report of baseline State/Trait Anxiety and Perceived Stress were obtained using scales by Spielberger (1970) and Kuiper (1986), respectively.

Analysis

To evaluate the effects of arousal on the entire group's mean accuracy and response time, we performed a repeated measures analysis of variance, with arousal and difficulty level as the independent measures, and performance accuracy and response time as the dependent measures. Because of consistent order effects, described below in the Results section, we included testing order (whether the neutral or the arousal condition occurred first) as a covariate. To evaluate differences between tasks, we performed a bivariate correlational and linear regression analyses; task*condition*physiological variables interactions were assessed using MANOVA. To further evaluate differences between subjects, and their relationships to physiological variables, we first separated subjects into K-mean clusters, based on their fMRI activation of the left amygdala in response to neutral and aversive visual stimuli. Clusters were defined as non-responders, who showed minimal activation of the left amygdala in response to both neutral and aversive stimuli, selective high responders, who activated in response to aversive but not neutral stimuli, and non-selective high responders, who responded highly to both aversive and neutral stimuli. Using these clusters, we then performed a between-group analysis of variance to determine whether different clusters corresponded with significantly different task performance.

Results

Mean Performance Under Arousal

As shown in Table 1, arousal had a significant impact on mean cognitive performance. Prepulse inhibition was reduced an average of 3% ($p = 0.057$, $F = 3.88$) under the arousal condition, particularly in the second half, and showed diminished habituation under arousal. Increase in baseline-corrected skin conductance ($p = 0.000$, $F = 22.418$), a measure of sympathetic nervous system activation, and decrease of baseline-corrected heart-rate ($p = 0.041$, $F = 4.519$), a measure of parasympathetic nervous system activation, confirmed validity of the visual stimuli in causing an emotional response. Response time was significantly shortened for the Flanker Task ($p = 0.000$, $F = 18.022$), with accompanying decrease in accuracy; Flanker Task Efficiency (accuracy/response time) was reduced an average of 3% during the arousal condition. On the Flanker Task, congruence had a significant impact on performance: the incongruent condition had lower accuracy and longer response times than the congruent condition, which in turn had lower accuracy and longer response times than

the control condition. Response time was significantly lengthened for the Stroop task ($p = 0.000$, $F = 18.271$) in the arousal condition, with accuracy virtually unaffected; Stroop Task Efficiency (accuracy/response time) was also reduced by an average of 3% during the arousal condition.

Selective Attention versus Orienting Response

We found that efficiency on the Stroop Task, which measures the strength of the orienting response to an emotionally-valent stimulus, and efficiency on the Flanker Task, which measures the ability to focus on a (neutral) target and ignore distractors under emotionally-valent conditions, were related, as predicted. The correlation was stronger for the neutral condition ($r = 0.386$; $p = 0.015$) and weaker for the arousal condition ($r = 0.284$; $p = 0.068$). The difference between the two conditions likely resulted from subjects' performance on the orienting task being more affected by arousal ($F = 18.088$; $p = 0.000$) than their performance on the selective attention task ($F = 13.020$; $p = 0.001$). Since both tasks used similar emotionally-valent stimuli (words), these results suggest that arousal is more directly tied to the orienting response than to selective attention.

Sensorimotor Gating versus Selective Attention

While both PPI and performance on the Flanker Task were affected by arousal, the arousal condition had a stronger effect on the Flanker Task ($F = 13.020$; $p = 0.001$) than on pre-pulse inhibition ($F = 3.767$; $p = 0.061$). Our correlation and cluster analyses did not show either a direct, inverse, or hierarchical relationship between their pre-pulse inhibition and performance on the Flanker task, suggesting that pre-attentive and attentive cognitive filtering are distinct processes, mediated by different neural networks.

Individual Variability

We found a large range of variability on all cognitive variables between our healthy test subjects. For example, on the Pre-Pulse Inhibition (PPI) Task, 58% showed a relative decline in PPI under the arousal condition (ranging from 2% to 9% decreased PPI), while 42% showed a relative increase in PPI under the arousal condition (ranging from 1% to 2% increased PPI). On the Flanker Task, while 47% of all subjects showed a relative decline in efficiency under the arousal condition (ranging from 3% to 58% decline), another 51% showed a relative increase in efficiency under the arousal condition (ranging from 1% to 34% improvement). Two percent had identical scores on the neutral and arousal conditions. On the Stroop Task, 60% of all subjects showed a relative decline in efficiency under the arousal condition (ranging from 1% to 36% improvement), another 38% showed a relative increase in efficiency under the arousal condition (ranging from 3% to 27% improvement. Two percent had identical scores on the neutral and arousal conditions. Thus results, including our own, that report a mean decrease in sensorimotor gating and cognitive efficiency for selective attention and orienting tasks under arousal are statistically correct but are missing an interesting and potentially important part of the picture.

As shown in Figures 1, 2, and 3, our cluster analyses indicate that neural reactivity was a significant factor in predicting whether individuals' cognition (specifically sensory gating and selective attention) was positively or negatively affected by arousal (for overall, trend: $p = 0.106$, $F = 3.000$; for Flanker Task: $p = 0.037$, $F = 6.250$). For pre-attentive sensorimotor gating, selective attention, and orienting, individuals who showed selective high activation of the amygdala to aversive visual stimuli showed improvement on the arousal condition, while individuals who showed non-selective high activation of the amygdala to both neutral and aversive visual stimuli showed strong decline on the arousal condition. Non-responders, those individuals who showed minimal amygdala activation to either condition, showed small decline on the arousal condition.

Endocrine and subjective perception of baseline perceived stress were predictive of mean performance and physiological reactivity (electrodermal activity and heart rate). Afternoon (4pm) cortisol levels had significant between-subject effects for heart rate ($p = 0.043$, $F = 4.270$) and electrodermal activity ($p = 0.051$, $F = 4.270$), as well as a trend between-subjects effect for PPI ($p = 0.100$, $F = 2.947$). Post-dexamethasone cortisol, a measure of endocrine negative feedback loops, was related to mean PPI for both conditions ($p = 0.029$, $F = 5.432$). Mean PPI decreased with subjective perception of baseline perceived stress ($p = 0.087$, $F = 44.000$). For example, individuals with Perceived Stress Scale scores that clustered around 4.50 ("Low Stress," SD = 2.393) on the Perceived Stress Scales showed mean PPI of 50.993, individuals with scores that clustered around 13.18 ("Moderate Stress," SD = 2.538) showed mean PPI of 42.222, and individuals with scores of 21.33 ("Pronounced Stress," SD = 2.739) showed mean PPI of 26.314. On the Stroop Task, Low Stress individuals showed mean response times of 924.809 ms, Moderate Stress individuals showed mean response times of 935.104 ms, and Pronounced Stress individuals showed mean response times of 979.127 ms. This pattern was not observed for the Flanker Task, although Low Stress individuals still showed shorter response times than Pronounced Stress individuals ($p = 0.009$, $F = 5.650$).

There were no prominent age or gender effects.

Conclusions

Our study of emotional arousal's impact on cognition demonstrates that even the mild arousal induced in a controlled laboratory setting is sufficient to show consistent changes under two conditions, both of which are common in actually dangerous contexts. For tasks performed under conditions of arousal but without the possibility of orienting to the aversive stimulus (such as the Flanker Task), we recorded decrease in response time

and accuracy. For tasks with the possibility of orienting to the aversive stimuli but which require attending away from the aversive stimulus (such as the Stroop Task), we saw no loss of accuracy, but recorded significant increase in response time. Our analysis indicates that selective attention, which is fully attentive, and the orienting response, which is only semi-attentive, are related. Prepulse inhibition, which is wholly pre-attentive, was not correlated with either the Flanker or the Stroop Tasks. Finally, our analysis of variability indicates that, while most individuals are negatively influenced by arousal, others are not. Our use of neural clusters suggests that it is the *selectivity* of the neural arousal response, rather than its amplitude, that corresponds with the direction of impact; future studies examining neural activation and performance under more severe stress may shed light on the practical implications of these results.

Figures

Table 1: Estimated Marginal Means for Cognitive/Physiological Measures During Neutral & Arousal Conditions

Measure (N = 39)	Condition	Mean	Std. Error
Prepulse Inhibition	neutral	40.486	4.481
	arousal	39.173	4.854
Flanker Task Acc	neutral	.970	.010
	arousal	.966	.012
Flanker Task RT	neutral	652.208	43.341
	arousal	637.963	37.253

Embodied Cognition and The Nature of Mathematics: Language, Gesture, and Abstraction

Rafael E. Núñez (NUNEZ@Cogsci.Ucsd.Edu)
Department of Cognitive Science, 9500 Gilman Drive
La Jolla, CA 92093-0515 USA

The Cognitive Science *of* Mathematics

Mathematics is a highly technical domain, characterized by the fact that the very entities that constitute it are idealized mental abstractions. These entities cannot be perceived directly through the senses. Even the simplest entity in, say, Euclidean geometry (i.e., a point, which only has location but no extension,) can't actually be *perceived*. This is obvious when the entities in question involve infinity (e.g., limits, least upper bounds, mathematical induction, infinite sets, points at infinity in projective geometry and so on) where, by definition, no direct experience can exist with the infinite itself. Lakoff and Núñez (1997, 2000) and Núñez (2000a, 2000b, in press), inspired by theoretical principles of embodied cognition and using mainly techniques from cognitive linguistics (especially cognitive semantics) have suggested that these idealized abstract technical entities in mathematics are created by the human imaginative mind via a very specific use of everyday bodily-grounded cognitive mechanisms such as conceptual metaphors, conceptual blends, analogical reasoning, fictive motion, aspectual schemas, and so on (see also Núñez & Lakoff 1998, in press). Mathematics is, according to this view, a specific powerful and stable product of human imagination. The claim is that a detailed analysis of the inferential organization of mathematical concepts, theorems, definitions, and axioms (Mathematical Idea Analysis) provide cognitive foundations of mathematics itself. From this perspective, mathematics *is* the network of bodily-grounded inferential organization that makes it possible. The study of these foundations and their extended inferential organization constitutes one of the most important goals of the cognitive science of mathematics.

Towards Convergent Empirical Evidence: Gesture and Conceptual Mappings

So far the work by Lakoff & Núñez on the cognitive science of mathematics has been based mainly on cognitive semantics, focusing on the conceptual mappings (conceptual metaphors, blends, metonymies, frames, etc.) that model the inferential organization of mathematical concepts. Some important questions, however, remain open:

1. Are the mathematical concepts considered by Lakoff & Núñez to be metaphorical (e.g., least *upper* bound, space-*filling* curve, point *at infinity* in projective geometry, etc.) simply cases of "dead" metaphors with no actual metaphorical semantic content? In other words, is the meaning and inferential organization of these concepts fully characterized by their *literal* formal mathematical definition (as it is often claimed in mathematics proper)?

2. If the answer to (1) is negative, what then is the psychological reality of the suggested conceptual metaphors involved?

In this presentation I intend to address these two questions by:

a) Focusing on cases in mathematics where *dynamic* language is used to refer to mathematical objects that, within mathematics proper, are completely defined in *static* terms via the use of universal and existential quantifiers and set-theoretical entities. For example, when treating limits of infinite series classic mathematics books often make statements like this one: "We describe the behavior of s_n by saying that the sum s_n *approaches* the limit 1 as n *tends* to infinity, and by writing $1 = 1/2 + 1/2^2 + 1/2^3 + 1/2^4 + \ldots$" (Courant and Robbins, 1978, p. 64). This statement refers to a sequence of discrete and static partial sums of s_n (real numbers), corresponding to successive discrete and static values taken by n. Technically, numbers, as such, don't move, therefore no dynamic language should provide any literal meaning in cases like this one.

b) Providing evidence from gesture studies, supporting the claim that the conceptual metaphorical nature of these mathematical linguistic expressions is indeed psychological real, operating under strong real-time and real-world constraints. I will build on the increasing evidence showing the extremely close relationship between speech, thought, and gesture production at a behavioral (McNeill, 1992), developmental (Iverson & Thelen, 1999; Bates & Dick, 2002), neuropsychological (McNeill & Pedelty, 1995; Hickok, Bellugi & Klima, 1998), psycholinguistic (Kita, 2000), and cognitive linguistic level (Lidell, 2000; Núñez & Sweetser, 2001).

I will argue that the dynamic component of many mathematical ideas is constitutive of fundamental mathematical ideas such as limits, continuity, and infinite series, providing essential inferential organization for them. The formal versions of these concepts, however, neither generalize nor fully formalize the inferential organization of these mathematical ideas (i.e., ε-δ definition of limits and continuity of functions as framed by the arithmetization program in the 19th century). I suggest that these deep cognitive incompatibilities between dynamic-wholistic entities and static-discrete ones explain important dimensions of the great difficulties encountered by students when learning the modern technical version of these notions (Núñez, Edwards, and Matos, 1999). In order to support my arguments I will analyze converging linguistic and gestural data involving infinite series, limits and continuity of functions, showing the crucial role played by conceptual metaphor and fictive motion (Talmy, 1996) in constituting the inferential organization of these fundamental concepts.

Conceptual muddles: Truth vs. Truthfulness, Logical vs. Psychological Validity, and the non-monotonic vs. defeasible nature of human inferences.

Walter J. Schroyens (Walter.Schroyens@psy.kuleuven.ac.be)
Laboratory of Experimental Psychology, University of Leuven
Tiensestraat 102, Leuven, B-3000, Belgium

Deductive logic is concerned with logical validity (henceforth 'L-validity'). An inference is L-valid only when it must necessarily be true *if* the premises are true. This classic definition has a built-in truth-assumption. The truth of L-valid inferences is always a hypothetical truth, not a factual truth. This means that the factual truth of the premises and/or conclusion does not affect L-validity and that a L-valid inference cannot become L-invalid by adding new information. Technically speaking, deductive logics are *monotonic*. This stands in apparent contrast with the psychological evidence to the contrary, showing that the premise or conclusion believability affects the reasoning process. Common-sense reasoning is *defeasible* and *non-monotonic* in nature. A conclusion that is believed to be true at one point can be considered false later, and an inference that is considered valid at one point can later be revoked and re-evaluated as invalid. (Note that we used the unqualified term 'valid', not 'L-valid'). Consider, e.g., the classic benchmark example: "If it is a bird, then it can fly. Tweety is a bird. Hence, Tweety can fly." This is a L-valid argument. Assuming it is true that 'if something is a bird, then it can fly' and assuming that Tweety is a bird, it follows necessarily that it would be true that Tweety can fly. People will nonetheless retract the conclusion that 'Tweety the bird can fly' when being given the information that Tweety is in fact an ostrich.

Some theorists have created polemics between what they call 'logic theories' and their own probabilistic theories of human reasoning. The core argument against theories of human deduction is their presumed incapability of dealing with the defeasibility of common-sense reasoning. I will argue that there is only an *apparent* contrast between logic's monotonicity and common-sense reasoning's defeasibility. It is only when we are sure that people are reasoning hypothetically that defeating an inference would show that the monotonicity of deductive logics is problematical.

Let us assume that people aim to establish L-validity. If so, people are abandoning the truth-assumption when defeating an inference. The existence of ostriches falsifies the claim that 'if something is a bird, then it can fly. It is not always true that when something is a bird, it can fly. If people abandon the truth-assumption when confronted with the added information, they are shifting from one notion of validity (i.e., L-validity) to another notion of validity (let's call it P-validity). This means that they are not changing an *L-valid* inference into a *L-invalid* inference, but are changing an L-valid inference into a *P-valid* inference. This example indicates that though defeasible, common-sense reasoning is not necessarily non-monotonic.

Theorists who argue against logic theories contest that questioning the literal truth of, e.g., 'if it is a bird, then it can fly' is involved in defeasible reasoning: "surely [this] mischaracterizes people's cognitive attitude towards this and a million other commonsense generalizations" (Oaksford & Chater, 1998, p. 5). This claim as regards the psychological 'truthfulness' of a logically false conditional is not congruent with reality. We asked 150 first-year psychology undergraduates to judge whether the conditional is strictly speaking false when the context either did or id not include TF cases. These cases reflect situations where the antecedent is satisfied while the consequent is not (e.g., birds that do *not* fly). When there were TF cases, 83% of them said it is strictly speaking false. In case there were no such falsifying TF cases, 89% said the conditional was true. Moreover, with the false conditionals, 91% selected a conditional of the form 'if p then possibly q' as the best description of the situation. With a true conditional, 93% effectively preferred 'if p then q' as the best description. This first study used abstract materials (coloured figures). In a second study we asked 44 first-year psychology students to "think about the fact that for instance ostriches and penguins are also birds (and can not fly)." Thirty-eight (86%) of them judged the conditional to be false. In short, the falsity of the conclusion 'Tweety flies' in real everyday inference, license the conclusion that "if it is a bird, then it can fly" is a false utterance.

To ground their intuition pump, Oaksford and Chater (1998) appeal to the comforting idea that there is true commonsense knowledge. "If our commonsense descriptions of the world and of ourselves are not candidates for truth then precious little else of what we call our commonsense knowledge of the world will be candidates for truth. We would then be in the paradoxical position of having to provide a system of human inference that is always based on false premises but which is nonetheless apparently capable of guiding successful action in the world!" (Oaksford & Chater, 1998, p. 5). There is really only an apparent contradiction (a paradox), not a contradiction. It is not problematical that there is preciously little (if any) knowledge that is strictly true. The induction problem still exists: every generalization is a potential over-generalization. However, the fact that some birds do not fly does not make it senseless to use the generalization that birds fly. An absolute truth is universally applicable, but if something is not universally applicable then this does not imply that it is inapplicable. It might be inapplicable (applicable to none) or applicable to some (but not all). The demonstrable fact that most of our commonsense generalizations are false (i.e., not strictly true), marks that they only have a certain degree of truth: They are false, but applicable. Verity is not verisimilitude.

The Relations Between Causal (x2) and Counterfactual Reasoning, the Hindsight Bias and Regret (and the kitchen sink)

Barbara A. Spellman (spellman@virginia.edu)
Department of Psychology, University of Virginia, P.O. Box 400400
Charlottesville, VA 22904-4400 USA

The research areas of causal and counterfactual reasoning, hindsight bias and regret, have often been studied in isolation, sometimes studied in pairs, and occasionally studied in triads. I suggest that there are common mechanisms shared by these judgments that explain how, when, and why they will (a) be similarly or differently affected by information and (b) influence each other.

To start, I distinguish two types of causal reasoning: the types of judgments we make in science when we have multiple examples of causes and effect and the types of judgments we make in law when we want to figure out the cause of a one-time only event. In the former, an important cue to causality is covariation -- a cause is something that increases the probability of an effect above its usual probability. I then draw an analogy to the latter -- and assume that a causality judgment about a person or event is a function of how much that person or event increases the probability of the eventual outcome above its "baseline" probability (i.e., its natural probability of occurring).

$$C \approx p(Oafter) - p(Obefore)$$

The equation above represents how a causality judgment is a function of the estimated probability of the eventual outcome occurring after the target cause has occurred [p(Oafter)] and the estimated probability of the eventual outcome occurring before the target cause has occurred [p(Obefore)].

But for one-time events, how can people make probability judgments? I suggest that such judgments rely on pre-existing knowledge -- especially of previous covariations and causal mechanisms -- and counterfactual reasoning. The equation below expands the one above by putting each estimate over 1 (i.e., p(Oafter) + p(~Oafter) = 1).

$$C \approx \frac{p(Oafter)}{p(Oafter) + p(\sim Oafter)} - \frac{p(Obefore)}{p(Obefore) + p(\sim Obefore)}$$

That causality relies on counterfactual information in this manner explains the "if-only" and "even-if" effects -- ways in which considering counterfactuals affects causal judgments. For example, if someone takes an unusual route home, and then is in a car accident, she might think "If only I had taken my usual route." That counterfactual thought would increase the estimate of p(~Obefore), decrease the fraction on the right, and increase the causality assigned to the decision to take the unusual route.

The relation to the hindsight bias is clear: When do people make these probability estimates? Typically after events have unfolded. Thus, the hindsight bias is implicit in causality judgments. However, these equations also suggest ways in which the hindsight bias can be de-biased and, in particular, which kinds of counterfactuals should be most effective in doing so.

Finally, I argue that regret is both a counterfactual and causal emotion -- it depends on knowing that what you might have done could have changed an outcome. Our studies compare measures of causality with measures of regret. We find that regret depends on the difference between an actor's perceived causality for the (negative) outcome given his actual decision and the imagined causality for that outcome had an alternative decision been made. (Again, such causality judgments are made in hindsight.) Our experiments use this relation to explain "action" and "inaction" effects in regret judgments.

I hope to relate these analyses to other types of reasoning.

Does the practice of meta-cognitive description facilitate acquiring expertise?

Masaki Suwa (suwa@sccs.chukyo-u.ac.jp)

Expertise as Differentiation

How do people acquire expertise? Studies on machine learning in artificial intelligence have captured some aspects of human learning. But its limitation lies in that the representation of the target domain needs to be given in advance and fixed during the process in order for a learning mechanism to work. Contrarily, the ways people represent the external world evolve as they become experts. Experts are able to differentiate and perceive some features and relations in the world that would be meaningless to novices. This means that acquisition of expertise can be regarded as a process of becoming able to perceive what was not evident before. Gibson and Gibson (1955) described a similar process, in relation to expertise, in their case, wine-tasting: "Perceptual learning, then, consists of responding to variables of physical stimulation not previously responded to" (p. 34). The expertise-as-differentiation view was not necessarily discussed in studies on chess in which expert performance was explained by chunks (e.g. Chase and Simon, 1973).

Our previous studies on expert-novice differences in design showed similar findings. Designers draw sketches in the early design phase. Sketches are not only a record of generated ideas but also a stimulus for new ones. The success of a design process hinges on differentiately perceiving features and relations in sketches and generating interpretations of them. We found that expert designers were more capable of associating features and relations with functional issues (Suwa and Tversky, 1997). Further, perceiving features and relations unheeded before, which is difficult to do for novices, was the major driving-force for the generation of ideas for an expert designer (Suwa, 2003).

Hypothesis: The Practice of Meta-cognitive Description will Foster Differentiation

Then, what kind of cognitive practices in a target domain help become able to differentiately perceive features and relations in the external world and interpret them? We have made a hypothesis that self-awareness of and thereby meta-cognitive descriptions of what one has perceived and conceived of will foster the ability of differentiation and thus facilitate acquisition of expertise (Suwa and Tversky, 2003). Anecdotal evidence comes from the domain of sports. A Japanese player in Major Baseball League, named Ichiro, said in a TV interview that it is through a persistent effort of describing how he has perceived the ball and how his body has reacted and hit it that he had become one of the most productive hit-maker. Our finding (Suwa and Tversky, 2003) that expert designers are better at a meta-cognitive skill of reorganizing perception and generating interpretations than novices is also supportive.

We have recently obtained empirical evidence from the case study of singing a song. A participant in the experiment continued to sing a song for 4 months, recording his voice in every trial of singing. During the period, he continued describing meta-cognitively, in the form of writing in a notebook, how he was utilizing his throat, breath and tongue and how that helped express his feeling and emotion. Evaluation of all the trials of singing by three musicians after 4 months revealed that his performance exhibited a U-shape learning curve, i.e. getting better in the beginning, then turning worse sharply and gradually getting better and better toward the end. This indicates that he was climbing steps toward acquiring expertise. An interesting finding is that the evaluation scores of the recorded songs correlated in a statistically significant manner with the amount of meta-cognitive descriptions accumulated for about one month up to the time of every trial of singing. This suggests that the practice of meta-cognitive description had a latent effect, not an instant one, on his performance.

We interpret this in the following manner. A meta-cognitive description is a kind of narrative created by self. Its validity is not assured anyhow. Important is, however, the practice of meta-cognition itself, not its validity. A meta-cognitive description as a narrative will effectively drive differentiation of features and relations in the external world, and thereby encourage the next cycle of meta-cognitive description. This cycle will lead up to acquiring expertise.

Acknowledgments

I am grateful to Barbara Tversky for insightful discussions.

Task Interruption: Resumption Lag and the Role of Cues

Erik M. Altmann (ema@msu.edu)

Abstract

The consequences of interrupting someone in the middle of a complex task are of considerable practical and theoretical interest. We examine one behavioral measure of the disruption caused by task interruption, namely the *resumption lag*, or the time needed to "collect one's thoughts" and restart a task after an interruption is over. The resumption lag (in our task environment) was double the interval between uninterrupted actions (3.8 s vs. 1.9 s), indicating a substantial disruptive effect. To probe the nature of the disruption, we examined the role of external cues associated with the interrupted task, finding that cues available immediately *before* an interruption facilitate performance immediately *afterwards* (reducing the resumption lag). This *cue-availability* effect suggests that people deploy preparatory perceptual and memory processes, apparently spontaneously, to mitigate the disruptive effects of task interruption.

Introduction

For better or worse, interruptions are part of everyday life. For better, interruptions are an essential part of efficient communication, among people and between people and machines. For worse, interruptions can be annoying, and can seem disruptive. For example, the annoyance of unwanted telephone solicitations drove the recent overwhelming popularity of "do not call" registries in the United States. Similarly, consider the "software assistant" included in Microsoft products in the late 1990s. If Word, for example, detected what it thought was a letter being drafted, it would freeze the keyboard and demand to know if the user needed "help" — a feature that in more recent editions of the software is no longer enabled by default.

There are many parameters to how an interruption is structured — including interruption duration, for example, or whether the interrupted person has control over interruption timing (McFarlane & Latorella, 2002) — and there is also a range of different behavioral measures on which the assess the impact of an interruption. In one classic result, Zeigarnik (1927/1938) found that interrupted tasks were actually remembered better, in terms of recalled detail, than tasks that were allowed to run to completion. In more applied work, however, interruptions have been found to have detrimental effects on situational awareness in dynamic task environments like aviation (Latorella, 1996), where losing one's place in a checklist during takeoff, for example, can have catastrophic results (NTSB, 1988).

The current study examines the disruptive effects of interruption in terms of the time needed to resume the primary (interrupted) task after the secondary (interrupting) task is complete. In less formal terms, we examine the time needed to collect one's thoughts, or pick up the thread again, when an interruption is over and we can return to what we were doing before. There is surprisingly little research focused on this measure, and what there is is distributed across a variety of domains and paints no clear picture of whether interruptions are disruptive or not. For example, in a study of interruption of administrative and clerical workers, disruptive effects of interruption were difficult to detect (Zijlstra, Roe, Leonora, & Krediet, 1999), and interruption in a simple question-answering task can actually improve performance, measured in terms of overall accuracy and time-on-task (Speier, Vessey, & Valacich, 2003). In the mainstream cognitive psychology literature, research on "task switching" (Monsell, 2003) would seem to be relevant, as studies in this domain typically focus on the "switch cost" associated with shifting from one task to another. However, this literature is perhaps not so aptly named; the "tasks" used in task-switching studies take a few hundred milliseconds to complete, with switch cost a small and not particularly relevant fraction of that (Altmann, in press). We are interested in higher-level tasks with greater ecological validity, where switch cost is measured not in tens of milliseconds, but in seconds or longer.

In operational terms, the dependent measure in the current study is the *resumption lag*, illustrated in Figure 1. The resumption lag is the time interval separating the end of the secondary task and the first subsequent action taken by the human operator in the primary task. We report first a comparison of this resumption lag to an estimate of the time interval that usually separates actions in the primary task, to give a sense of the absolute magnitude of the disruptive effect; to preview, the mean inter-action interval, in the highly interactive primary task we are using, is roughly 2 s, and the resumption lag is roughly 4 s, indicating a substantial disruption both in absolute and relative terms.

We then report on two factors that have the potential to reduce the resumption lag. Both focus on the *interruption lag*, also illustrated in Figure 1. The interruption lag is a brief transitional interval immediately preceding an interruption, during which the operator knows of the pending interruption but is not yet engaged by it. An example is the time between the phone starting to ring and the act of actually taking the call; during this interval, there is a brief opportunity to complete a thought, for example, or negotiate quickly with a conversation partner (physically present) how and when to resume after the call is over. Many real-world interruptions, even more urgent ones, afford a brief interruption lag; even when a fire alarm sounds, one is still likely to take time to save changes to an electronic document, for example, before evacuating.

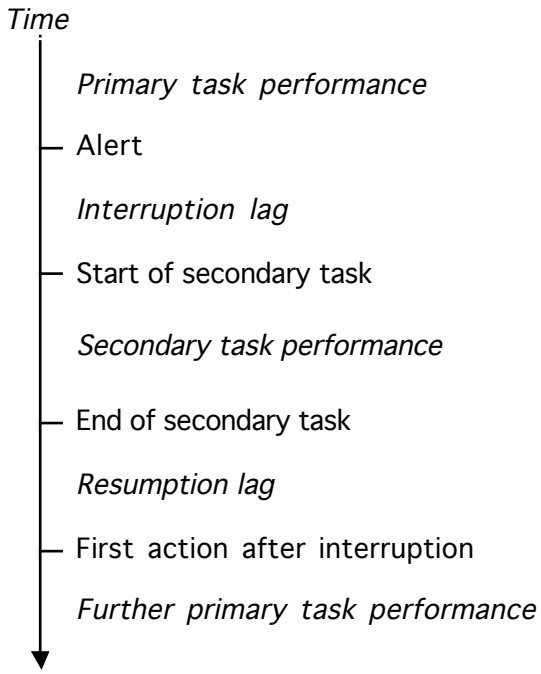

Figure 1: Time course of an interruption. For example, if the alert is the phone starting to ring, then the secondary task is the ensuing phone conversation.

Two characteristics of the interruption lag are examined here: (1) whether or not the primary task display is perceptually available during this brief period, and (2) the actual duration of this period. The relevance of these two factors is predicated on a memory model of what makes interruptions disruptive (Altmann & Trafton, 2002; Trafton, Altmann, Brock, & Mintz, 2003). The basic premise of the model is that during an interruption, the cognitive representations that support performance of the primary task will decay, in particular relative to the cognitive representations that support performance of the secondary task. Thus, when resuming the primary task, retrieval cues will be necessary to re-activate the relevant representations.

This memory analysis predicts, qualitatively, that the interruption lag — the brief interval *before* an interruption — has a crucial role to play in facilitating resumption *after* the interruption. During the interruption lag, when the operator is aware that he or she will soon be interrupted but can still focus mentally on the primary task, there is an opportunity to "prepare to resume," for example by prospectively encoding goals to accomplish at resumption (Trafton et al., 2003). To the extent that people do engage in such preparatory processing, it should help to have the primary-task display perceptually available during the interruption lag, to allow retrieval cues to be quickly accessed and accurately encoded. Thus, to build on earlier evidence that people do prepare to resume (Trafton et al., 2003), we asked here whether cue availability is a factor in this process. In the *cue* condition the primary task display was preserved during the interruption lag, whereas in the *no-cue* condition the screen went blank during the interruption lag (starting with onset of an alert signaling the pending interruption). Moreover, because processes like perceptual search and memory encoding take time, we varied the duration of the interruption lag across experiments, to examine what length of interruption lag would render cue availability effective in reducing the resumption lag.

Experiments

We conducted four experiments, with interruption lags of two, four, six, and eight seconds respectively. These values were based on evidence that an 8-second interruption lag is enough to allow people to (at least partially) prepare to resume (Trafton et al., 2003). The primary task involved planning and resource allocation subject to constraints, and thus involved a substantial amount of state information to be represented cognitively. The secondary task was less complex but nonetheless involved a series of tightly-spaced forced-choice decisions unfolding over a 30- to 45-second period. Interruption timing was under system, rather than operator, control, a factor that tends to aggravate the disruptive effects of interruption (McFarlane & Latorella, 2002).

The independent variable within each experiment was whether or not cues were available during the interruption lag. The main dependent variable was the resumption lag (Figure 1), but we also compare the resumption lag to the mean interval between primary-task actions, to estimate the overall disruptive effect of an interruption.

Method

Participants Ninety-six Michigan State University undergraduates participated in exchange for partial credit toward a course requirement. Each of the four experiments involved 24 participants, randomly assigned to the cue and no-cue conditions (described below).

Materials The primary task was a complex resource-allocation task (Trafton et al., 2003) in which participants were asked to defeat a set of simulated destinations using simulated tanks. Participants selected which destinations to attack and in what order, and issued tanks with appropriate amounts of fuel and munitions. Fuel was consumed in reaching a destination, and munitions were consumed in engaging it, but tank payload was limited, as was the total number of tanks and other resources available. Points were awarded for defeating destinations and subtracted for consuming resources.

Figure 2 shows a view of the primary-task display as it normally appears when the participant is doing the task. There is a central window with buttons for allocating tanks to missions, choosing destinations, and displaying a map with distances between destinations. There is also an area for displaying mission outcomes (whether a destination was defeated, whether a tank ran out of fuel, etc.) To the left are windows showing the supply pool (available fuel, munitions, and tanks) and windows for outfitting heavy and light tanks with varying amounts of fuel and munitions. To the right is a window showing the participant's scoring

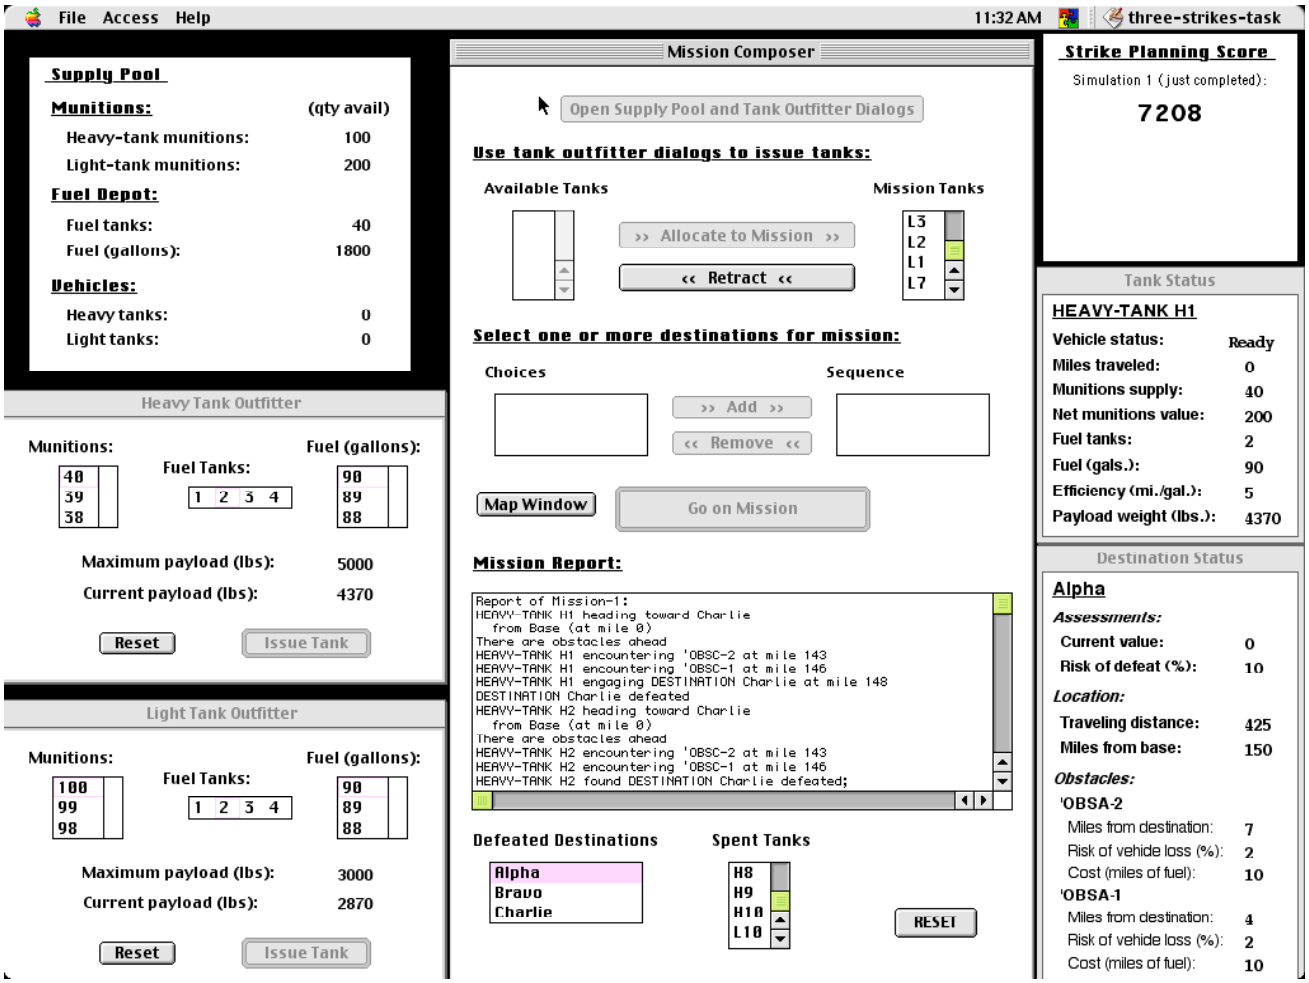

Figure 2: Screen shot of the primary task display during normal performance (see text for summary).

history from past simulations, and windows showing the status of selected tanks and destinations.

Figure 3 shows (at a more reduced scale) the state of the display during the interruption lag in the no-cue condition. To signal the pending interruption (and thus mark the start the interruption lag), an "eyeball alert" appeared in the top-right corner of the display. In the no-cue condition, the primary-task display was blanked out simultaneously with alert onset, whereas in the cue condition the primary-task display was preserved. In both conditions, with the start of the secondary task (and thus the end of the interruption lag), the primary-task display (whatever its state) was completely erased and replaced with the secondary-task display.

During the interruption lag, the cursor was hidden and disabled, so that all physical interaction with the primary task ceased. After an interruption, the primary-task display was reinstated in the same form it was in at the moment the eyeball alert appeared, with the following exceptions: The window that was active then — that is, the window that the participant was working in at the moment the alert appeared — was de-activated at task resumption, and the cursor was moved to the top-left corner of the screen. The effect was to eliminate the active window and the mouse cursor as

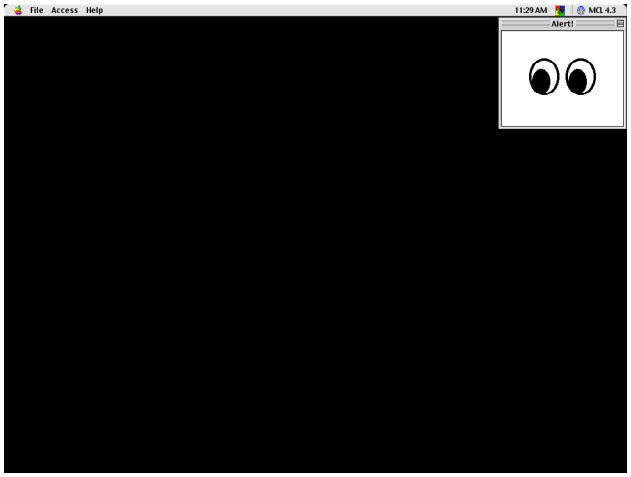

Figure 3: Screen shot of the primary task display during the interruption lag in the no-cue condition. The "eyeball alert" in the top right corner onsets at the start of the interruption lag and remains until start of the secondary task. In the cue condition the eyeball alert is identical but the primary task display (as in Figure 2) is preserved during the interruption lag.

retrieval cues that participants could deploy strategically to remind themselves of what they had been doing before the interruption, and therefore make resumption lag more sensitive to our experimental manipulations.

The secondary task involved evaluating "tracks," or targets on a radar screen, as friendly or hostile, according to attributes like speed and shape of icon (Trafton et al., 2003). A screenshot of the secondary-task display appears in Figure 4. Each instance of the secondary task lasted 30 to 45 seconds; afterwards, the participant was returned directly back to the primary task, as described above.

Design Interruption lag varied between experiments, as described above. Within each experiment, the independent variable was cue availability during the interruption lag (cue, no-cue), which was manipulated between subjects. The main dependent variable was resumption lag, the time from the end of the secondary task to the first subsequent action (mouse click) in the primary task. The other measure of interest, for comparison with resumption lag, was the inter-action interval, the mean time between actions in the primary task. Reported values for these measures are means of participant medians. For the inter-action interval, values below 1 s were discarded first, to eliminate anticipation errors, as well as ballistic components of motor plans, such as the second click of a double-click action.

Procedure Participants were tested individually, in sessions lasting roughly 90 minutes. A session began with a training period, in which participants learned to perform both tasks separately and were shown an example of how the computer would switch them from one task to the other and back again. After training, there were three 20-minute blocks of actual task performance. Within each block there were 10 interruptions, each triggered by a mouse click selected randomly to occur within a time window with quasi-random boundaries, to make interruption timing difficult for participants to predict.

At no point was the hypothetical function of the interruption lag in facilitating resumption mentioned to participants; thus, any effects of cue availability can be attributed to spontaneous use of preparatory strategies.

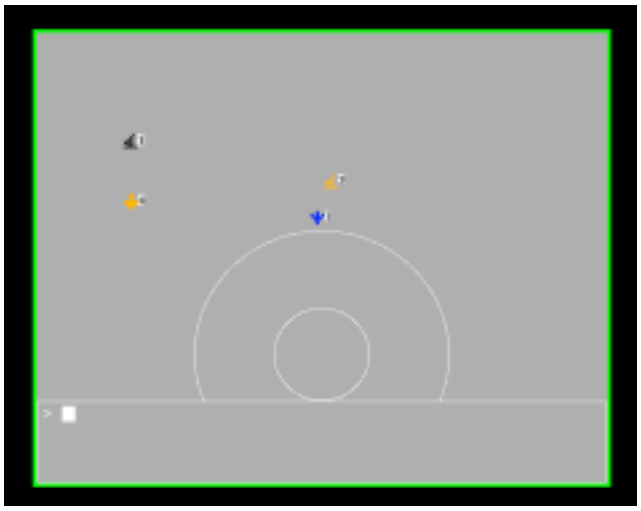

Figure 4: Screen shot of the secondary task display. Participants classified objects moving across a simulated radar display, according to color, shape, and speed.

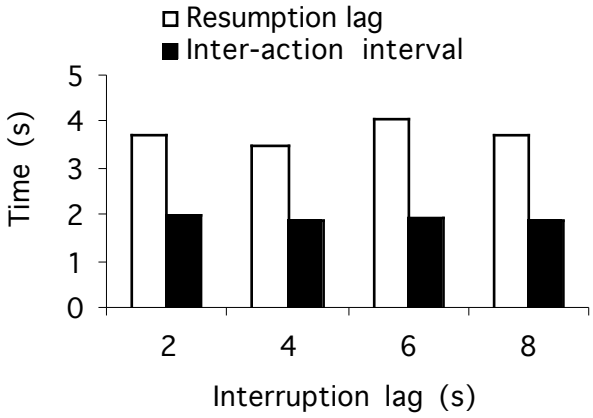

Figure 5: Resumption lag compared to inter-action interval, across experiments. The difference is an estimate of the disruption caused by task interruption.

Results We conducted two analyses of variance (ANOVAs) for each experiment. The first ANOVA, for which the data appear in Figure 5, compared mean resumption lag to mean inter-action interval; for all four experiments the difference was highly reliable, ps < .0001. The second ANOVA, for which the data appear in Figure 6, compared cue resumption lags to no-cue resumption lags. For 2- and 4-second interruption lags, there was no effect of cue availability, Fs<1. For the 6-second interruption lag, the cue-availability effect was marginal, $F(1,22)=4.1$, $p=.056$. For the 8-second interruption lag, the cue-availability effect was reliable, $F(1,22)=5.7$, $p<.03$.

We also conducted an omnibus ANOVA to compare across experiments, with cue availability and interruption lag as factors. The cue-availability effect was marginal, $F(1,88)=3.6$, p=.060, the interruption-lag effect was not reliable, $F(3,88)=1.2$, $p>.30$, and the two factors did not interact, $F(3,88)=1.4$, $p>.25$.

Discussion

The first empirical finding was that resumption lag is substantially longer than the mean interval between actions (Figure 5). This affords one measure of the disruptive effect of interruptions, at least in this highly interactive task in which, without interruption, actions occur at a rapid pace: The first action after an interruption took longer to execute than the first action after another primary-task action. In absolute terms, the resumption lag was 3.8 s – double the 1.9 s inter-action interval, which was measured rather conservatively by excluding all inter-action intervals under 1 s. This difference would appear to be of considerable practical interest in dynamic task environments, for example involving real airplanes or even automobiles traveling at highway speed, in which the world can look substantially different after an additional few seconds have elapsed.

The disruptive effect of interruption, as illustrated in Figure 5, was large and robust, which may agree with our intuitions about interruptions but doesn't necessarily agree

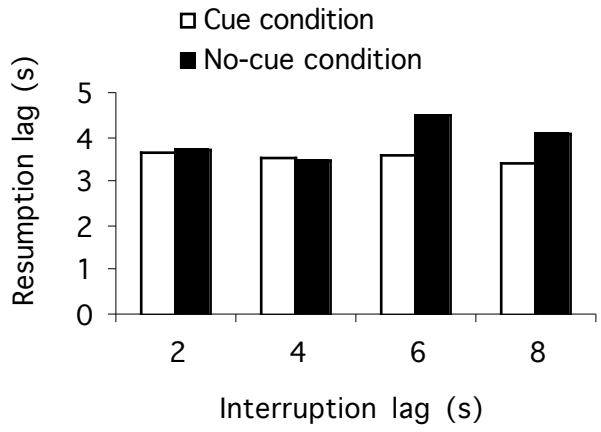

Figure 6: Resumption lag for cue and no-cue conditions, across experiments. The difference is is marginally reliable with a 6-second interruption lag and reliable with an 8-second interruption lag (see text).

with other controlled studies (e.g., Speier et al., 2003; Zijlstra et al., 1999). Three factors may have contributed to the robust effect measured here in terms of resumption lag. First, resumption lag is a local measure, taken immediately after every interruption; in contrast, other studies have reported global measures, such as overall time on task (Gillie & Broadbent, 1989; Speier et al., 2003). In our study, one global measure is a participants' total score over a session, but this was highly variable and showed no interpretable trends (so we did not report it). One specific problem with global measures is that they allow for compensatory strategies to work against the disruptive effects of interruption. Zijlstra et al. (1999), for example, speculate that their administrative workers compensated for interruption by using the time in between interruptions more efficiently.

A second factor may have been the relatively substantial cognitive state required to perform our primary task. In many scenarios in this task, beyond the resource-allocation tradeoffs involved, it was a challenge simply to piece together missions that would actually succeed in defeating destinations. In other studies, the primary task was simpler (Speier et al., 2003) and may have been more automated (Zijlstra et al., 1999), and therefore placed a smaller premium on maintaining complex representations in working memory.

Finally, a third factor may have been our implementation decision to trigger interruptions using mouse clicks, rather than strictly on the basis of time passage. Our rationale was that motor actions are often selected and programmed with the intention of achieving specific goals, so we reasoned that action-triggered interruptions would be more likely to disrupt these goals, which are one critical element of cognitive state; even in mundane tasks it's not uncommon to have "Now what was I doing?" moments, and it may be that these are more effectively induced by linking interruptions to actions rather than leaving interruption timing entirely to chance. Indeed, in Zeigarnik's (1927/1938) classic study, the experimenter was charged with judging when the participant was engrossed, in order to interrupt with the greatest impact.

The second empirical finding was that cue availability during the interruption lag (*before* the interruption) affected performance at task resumption (*after* the interruption, 30 to 45 s later), at least for longer interruption lags (Figure 6). One interpretation of this result, consistent with our memory analysis earlier, is that the various cognitive operations required to locate and encode retrieval cues during the interruption lag take somewhere between 6 and 8 seconds to complete (in our task environment). In other words, longer interruption lags afford enough time to link cognitive representations to external cues to facilitate retrieval later. However, this interpretation would also seem to predict that resumption lag in the cue condition should decrease at longer interruption lags, because cues are facilitating resumption. Instead, though, Figure 6 suggests that longer interruption lags drove an *increase* in resumption lag in the no-cue condition. Cue availability and interruption lag did not interact in the cross-experiment ANOVA, so the increase in no-cue resumption lags could be spurious, but given the exploratory nature of this work it seems useful to consider alternative accounts of why the cue-availability effect was limited to longer interruption lags.

One possible explanation of the increase in no-cue resumption lags might implicate changes in alertness or arousal – participants might simply have gotten bored, staring at a blank screen for 6 or 8 seconds. Some studies suggest that task interruption serves to increase arousal and stress, and thus improve overall (globally-measured) performance, at least on simple tasks (Speier et al., 2003); perhaps a long interruption lag, without visual information to focus on, moderates this effect. However, if arousal were to play a role in the cue-availability effect, it would remain to explain how a change in arousal *before* the interruption could affect performance *after* the interruption, tens of seconds later. Perhaps a drop in arousal caused participants' minds to wander in a way that activated irrelevant thoughts that in turn interfered with relevant cognitive representations. In such an account, however, memory would again play a central role in mediating the effect of pre-interruption variables on post-interruption performance.

One could explain the cue-availability effect without reference to memory processes if changes in arousal during the interruption lag persisted across the entire length of the interruption, to influence performance directly at task resumption. Secondary task performance was basically at ceiling for all subjects, so offers little evidence on this possibility. However, if arousal effects were to persist for the entire 30 to 45 seconds of the interruption, one might expect them to persist somewhat beyond as well, and then only gradually dissipate. This would predict that the time between the first and second action after the interruption would also reflect the cue availability effect. Revisiting our data, however, we found no difference, as a function either of interruption lag or cue availability, in the duration of the interval between the first and second actions after an interruption; this measure appears in Figure 7. It seems most likely, then, that even if cue availability and interruption lag interact to affect arousal before an interruption, memory

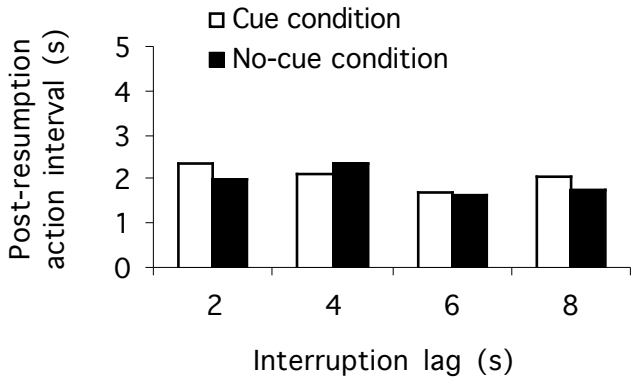

Figure 7: Inter-action interval between the first and second actions after an interruption, for cue and no-cue conditions, across experiments.

and/or perceptual processes mediate the delayed effect on task resumption.

At least two avenues of future work seem indicated to clarify the effects of our interruption-lag manipulations on speed of task resumption. First, it will be important to repeat these manipulations in context of a factorial design in which interruption lag and cue availability are fully crossed; here, one objection is that the cross-experiment comparison is potentially confounded by changes in the subject population.

Second, although the model that motivated these experiments emphasizes memory processes (Altmann & Trafton, 2002), there are alternative characterizations of why task resumption is time consuming. In particular, one account of automation deficit (Ballas, Kieras, Meyer, Brock, & Stroup, 1999) — like resumption lag, but measured in terms of accuracy — is that it reflects encoding of perceptual information (Kieras & Meyer, 1997) rather than memory retrieval. Thus, in our task environment it could be that the difference between the resumption lag and the baseline inter-action interval (Figure 5) simply reflects the cost of re-encoding the display, and that this re-encoding is what is facilitated by cue availability during the interruption lag. To distinguish between these accounts, one could vary the extent of the cognitive representations required to perform the primary task on one hand, and the perceptual complexity of the display on the other. Under a memory-retrieval model, the cue-availability effect should be linked to complex cognitive states, whereas under a perceptual-encoding model the effect should be linked to complex external displays; in our task environment, these two factors are confounded.

Whatever the ultimate explanation, the cue-availability effect shows an interesting link between what happens before an interruption and what happens later, after tens of seconds of intervening behavior. In practical terms, the effect suggests that interface designs, and possibly training interventions, could exploit cue availability in some way to facilitate resumption in task environments in which interruptions are frequent and seconds matter. In theoretical terms, probing this effect should help us develop constraints on models of memory, perception, and cognitive control as these functions are deployed in complex dynamic task environments.

Abstract

Analogous to Malt, Sloman, Gennari, Shi and Wang (1999) we examined the relation between linguistic categorization and similarity of artifacts by Dutch-speaking and French-speaking monolingual Belgians. We replicated the dissociation between naming and sorting found by Malt et al. (1999) for speakers of English, Chinese and Spanish. We also investigated the relation between the two naming patterns of bilingual Belgians, raised simultaneously in French and in Dutch, and how these naming patterns can be linked to the naming of the monolinguals. The results showed that the French and Dutch naming pattern of the bilinguals didn't parallel the respective naming patterns of the monolinguals, but rather merged into a common naming pattern.

Introduction

Research from several different traditions concerns the coupling of similarity and naming. However, different studies have resulted in contradicting conclusions. Some studies found that categorization judgments paralleled similarity judgments, for example the study of Smith and Sloman (1994). Other studies have shown a clear dissociation between similarity judgments and preferred category labels for novel objects. Keil (1989) and Rips (1989) presented participants with artifacts described as physically resembling one type of object, but having been made to be used as another type, or with animals looking like one type of animal but said to have internal parts of a different species. They both found that although objects were rated as more similar to the former, they tended to be categorized as the latter (see also Rips & Collins, 1993). Also studies that look at well-established lexical categories and make comparisons across speakers of different languages find substantial differences in naming objects, but only small differences in perceived similarity among the objects. For example, Kronenfeld, Armstrong and Wilmoth (1985) looked at the names given to various drinking vessels and the similarity among them judged by American, Japanese and Israeli participants. They found a dissociation between naming and similarity. However, the sample of objects used by Kronenfeld et al. (1985) was small and they did not attempt to assess whether the observed differences in naming paralleled the differences in perceived similarity.

Malt et al. (1999) carried out a larger-scale evaluation of the relation of perceived similarity among objects to the names they are given. They presented data from speakers of three different language groups: American, Chinese and Argentinean participants, speaking respectively English, Chinese and Spanish. The participants performed two tasks: they named 60 common containers (all mostly called 'bottle' or 'jar' in English) and they provided similarity ratings, by sorting the objects into piles based on three types of similarity: physical, functional or overall similarity. Speakers of the three languages showed substantially different patterns of naming for the set of containers, but they saw the similarities among the objects in much the same way. Malt et al. claim that the linguistic differences arise from differences in language-specific conventions and differences in language history.

The imperfect relation between naming patterns of a language and non-linguistic knowledge of objects and between the naming patterns of two different languages raises questions about how bilingually-raised individuals build and maintain their two lexicons. Do they maintain two distinct and native-like naming patterns, each with its own language-specific conventions or do the two competing

patterns merge into a single pattern that may not be fully native-like for either language. The latter might be due to individual cognitive constraints on memory capacity. One way to address this issue is to examine the two naming patterns of bilinguals to see how they relate to one another and to the naming patterns of corresponding monolinguals. Belgium, a bilingual country where French- and Dutch-speaking monolinguals live alongside bilinguals, who are brought up simultaneously in French and Dutch, live together, provides us with a laboratory to investigate this issue.

Two hypotheses are suggested concerning the naming patterns of bilingual Belgians: First, the French and Dutch naming patterns are kept separate and thus parallel the naming patterns of respectively the French-speaking monolinguals and the Dutch-speaking monolinguals. Second, the two naming patterns merge into one naming pattern and the bilinguals use just one single naming pattern both for the French and the Dutch naming.

Method

Participants

Thirty-two native speakers of Dutch, all students or research assistants at the Psychology Department of the Leuven University, and 29 native speakers of French, students at the Faculty of Law of the University of Liège, participated both in a naming and a sorting task (to be described below). Five participants of the Dutch-speaking group were retested for the naming, to check for within subject reliability. The time span between the test and the retest was approximately six months. The bilingual subjects consisted of 25 people whose father is Dutch-speaking and whose mother is French-speaking (14 out of 25) or vice versa (11 out of 25) and who have been raised in both languages. All of them were students (except one research assistant) at the university of Leuven, Brussels or Louvain-la-Neuve. The bilingual subjects performed the naming task twice (once in French and once in Dutch) and the sorting task once. They also completed a language history questionnaire, used to determine the participants' language background. Five bilinguals renamed the objects in French and five other bilinguals renamed the objects in Dutch after a time span of about six months.

The Dutch- and French-speaking monolingual subjects received course credit or participated as unpaid volunteers. The bilinguals were systematically paid for their participation.

Materials

Objects. There were 2 sets of stimuli, one consisting of 73 pictures of storage containers (as in Malt et al.'s study (1999)), the other consisting of 67 pictures of housewares for preparing food and serving food and drink. The objects of the first set were selected to be likely to receive the name 'bottle' or 'jar' in American English, or else to share one or more salient properties with bottles and jars. Translated into Dutch and French, the objects are likely to be called respectively 'fles' or 'bus' and 'bouteille' or 'flacon'.[1] For the second set, the 'dishes set', objects had been selected to be likely to be called 'dish', 'plate' or 'bowl' in American English. In Dutch, the objects are mostly called 'bord', 'schaal' or 'kom', in French 'assiette', 'plat' or 'bol'.[2]

The objects were all found at home, work, or in stores frequented by the researchers. For both sets, we made an effort to include objects that would represent a wide range of respectively bottles, jars and other similar containers (Set 1) and of dishes, plates, bowls and other similar housewares (Set 2). The wide range of objects allows a sensitive comparison of the naming patterns of the Dutch-speaking monolinguals, the French-speaking monolinguals and the bilinguals.

All objects were photographed in color against a neutral background with a constant camera distance to preserve relative size. In front of each object a ruler was included to provide additional size information. Because the labels on the objects were mostly both in Dutch and in French, no additional information about the nature of the content (e.g. ketchup) was necessary.

Language history questionnaire. A questionnaire was used to determine the language background of the bilingual participants. Questions were asked about age and sex; where the participant was raised; what language her mother and father speaks; what language she speaks with her mother and father and whether she systematically speaks the same language (Dutch or French) with her mother and the same other language (French or Dutch) with her father; what language was used at primary and secondary school, during leasure activities; which language she currently uses most and estimated proficiency for both languages. Proficiency estimates were obtained by asking the participants for each language to encircle a number between 1 ('not at all fluent: you can barely speak the language') and 7 ('very fluent: you can speak the language like a native speaker').

Procedure

Naming task. In the naming task, participants were asked to name each object of two sets of pictures (the bottles and dishes sets), after looking through all the pictures of the set to be named to familiarize themselves with the variety of objects in the set. The instructions were the same as in the naming task of Malt et al. (1999): They were asked to give whatever name seemed like the best or most natural name, and they were told that they could give either a single-word name or a name with more than one word. The instructions emphasized that participants should name the object itself

[1] It should be noted that we do not claim 'jar', 'bus' and 'flacon' to be translation equivalents or to cover the same group of referents. Referring to a dictionary, 'bus' is translated as 'can', 'flacon' as 'bottle'. 'Fles' and 'bouteille' are however translated unambiguously as 'bottle'.

[2] As for the bottles set, the corresponding names ('dish', 'bord' and 'assiette'; 'plate', 'schaal' and 'plat'; 'bowl', 'kom' and 'bol') 'are not assumed to be perfect translation equivalents.

and not what it contained. Each participant named first all the objects of one set (bottles set or dishes set) and then all the objects of the other set (dishes set or bottles set). The order of the two sets was counterbalanced. The bilingual participants named both sets in French and in Dutch. Hence, besides the order of sets also the order of languages was counterbalanced. Between the Dutch and the French version of the naming task, the pictures were shuffled.

After participants completed the naming task (once for the Dutch- and French-speaking participants, twice for the bilinguals), the pictures were again shuffled. The second task to be performed was the sorting task.

Sorting task. The large number of objects prevented us from collecting direct pairwise similarity judgments. Instead we asked the participants to sort the objects into piles. Based on these sorting data, we can calculate a derived measure of similarity for each pair of objects. Sorting was based on overall similarity. First, participants were asked to look through the pictures. The instructions for the sorting were as follows: 'I would like you to focus on the overall qualities of each container. This means that you focus on any feature of the container including what it looks like, what it's made of, how it contains the substance that is in it (in a stack, in separate pieces, as a single solid, as a liquid, with pouring capability, etc.[3]) or any other aspect of the container that seems important or natural to you. I would like you to put together into piles all the containers that you think are very similar to each other OVERALL. Note that we are interested in how similar the containers themselves are overall, not what is in the containers. Only put two pictures together if the containers are like each other in an overall way. DO NOT put pictures together just because the containers hold things that tend to be found together. For instance, if several containers contain health products, DON'T put them together unless you really think the containers themselves are alike in an overall way.'

Further, the participants were instructed to use as many piles as they wanted, but at least two different ones. They were not allowed to make a pile of only one picture, unless they really could not classify the object in one of the existing piles. They could take as much time as they wanted to complete the sort. In general, the sorting task took about 30 minutes.

Due to space restrictions, we will focus on the results of the bottles set only. However, the results with the dishes set were perfectly parallel to those of the bottles set.

Results

Replication of Malt et al.'s study

Comparison of linguistic category boundaries. For each name produced for each object, we first calculated its frequency separately for each language group. Only the head noun of the response was considered as the name given to the object. Diminutive forms of names and additional adjectives were disregarded. The first analysis is restricted to the dominant category names for each object: i.e. the most frequently produced name for each object.

Table 1 shows the Dutch and French dominant category names for the bottles set together with the number of objects out of 73 for which each name was dominant. To gain an insight into the similarities and differences between the Dutch and French categories, the French categories are described in terms of their Dutch composition.

Table 1: Linguistic categories for the bottles set of the Dutch- and French-speaking monolinguals.

French bottles (monolinguals)	**N**	**Dutch Composition (monolinguals)**
bouteille	16	13 flessen, 3 bussen
flacon	16	10 flessen, 3 bussen, 2 potten, 1 roller
pot	10	9 potten, 1 fles
boîte	7	3 dozen, 2 brikken, 1 blik, 1 pot
tube	6	4 tubes, 1 pot, 1 stick
spray	5	5 bussen, 1 spray
bidon	3	3 bussen
brique	2	1 bus, 1 doos
berlingo	2	2 brikken
biberon	1	1 fles
bombe	1	1 bus
canette	1	1 blik
pannier	1	1 mand
poivrier	1	1 molen
salière	1	1 vat

For Dutch-speaking monolinguals, there were three main categories: 'fles', 'bus' and 'pot'[4]. The three categories together encompassed 74 per cent of the stimulus set. The remaining names were given to only a few objects. The French-speaking monolinguals used a total of 15 categories. Three category names were dominant for at least 10 objects out of 73: 'bouteille', 'flacon', 'pot'[5]. The other names were restricted to a smaller number of objects.

When we look at the Dutch composition of the French categories, we find some resemblance in how the two languages classify the objects into linguistic categories: the largest part of the objects called 'pot' in Dutch (9/13) are put into one single French category 'pot'. All Dutch 'tubes' are put together into the French category of objects called 'tube'. On the other hand, there are also prominent differences between the naming patterns of both languages: The objects called 'fles' (# 25) in Dutch are mainly split up

[3] This information is only provided for the sorting of the bottles, since it is not applicable to the dishes.

[4] 'Fles' is translated as 'bottle', 'bus' as 'can' and 'pot' as 'pot' or 'jar'.

[5] 'Bouteille' is translated as 'bottle', 'flacon' as well, 'pot' as 'pot' or 'jar'.

into two different categories in French: 'bouteille' (# 13) and 'flacon' (# 10). The Dutch category 'bus' is not represented in a corresponding French category, but the objects are spread over 6 different categories ('bouteille', 'flacon', 'spray', 'bidon', 'brique' and 'bombe').

By looking at the dominant names, a lot of information in the data is lost. For the bottles set, only 5 objects were called by the same name by every Dutch monolingual and the same was true for the French monolinguals. Hence, it would be more useful to include all the names used for each object in the analysis. Therefore, in a second analysis, we calculated for each object the name distribution which can be described as the number of times each name was allocated to each object. Our intention was to compare the linguistic categories of the different language groups by comparing the naming distributions across the language groups. However, the naming distributions cannot be compared directly across the language groups since different language groups use different sets of names ($Dutch_{monolingual}$ versus $French_{monolingual}$). As an alternative, for each language group we compared the similarity of each object's name distribution to every other object's name distribution by using a Pearson correlation. The similarity in name distribution between two objects was calculated as follows: for each pair of objects within a language group, the correlation was computed across all the names between the name frequencies for both objects. For each language group, this resulted in 2628 correlations (for 73*72/2 pairs of objects). These correlations indicated the name distribution similarity between each possible pairing of the objects. The next step consists in correlating the 2628 name similarity values for the Dutch-speaking monolinguals with the corresponding 2628 name similarity values for the French-speaking monolinguals. This correlation mirrors the extent to which the two language groups correspond in the pairs of objects that have similar name distributions. The correlation between both monolingual language groups is 0.63: a substantial correlation, but far from perfect. Both the analysis of the dominant names and the correlation between the name distribution similarities confirm that the French- and Dutch-speaking monolinguals named the objects differently.

Comparison of the perceived similarity. The data from the sorting task were used to obtain a measure of similarity for each pair of objects. Pairwise similarity was recovered by counting for each pair of objects how many participants of a language group placed that pair of objects in the same pile. For each of both language groups, these calculations gave us 2628 pairwise similarity judgments. The similarity judgments of both groups were correlated. The resulting correlation of 0.87 -comparable to the mean estimated reliability of .92- indicates that the French- and Dutch-speaking monolinguals agree to a considerable extent on their perception of similarities among the objects.

Conclusion. For the two monolingual language groups, we found substantial differences in naming and no differences in sorting. These results replicate the findings of Malt et al. (1999) for speakers of three different languages.

Naming in bilinguals: Two hypotheses

How did the French and Dutch naming patterns of the bilinguals interrelate and how are they linked to the naming patterns of the respective monolingual language groups? One possibility is that the naming of the bilinguals follows that of the corresponding monolinguals, i.e. the French bilingual naming pattern equals the naming pattern of the French-speaking monolinguals and the Dutch bilingual naming pattern equals that of the Dutch-speaking monolinguals. Another alternative possibility is that the bilinguals use just one naming pattern, or in other words, that their naming patterns of their two languages converge into a single naming pattern. To decide between these hypotheses, we analyzed the data both on a group level and on an individual level.

Group-level analysis. Correlations were calculated among all the language groups ($Dutch_{monolingual}$, $Dutch_{bilingual}$, $French_{monolingual}$, $French_{bilingual}$) between measures of name similarity (i.e. name distribution similarities). Figure 1 shows the pattern of correlations.

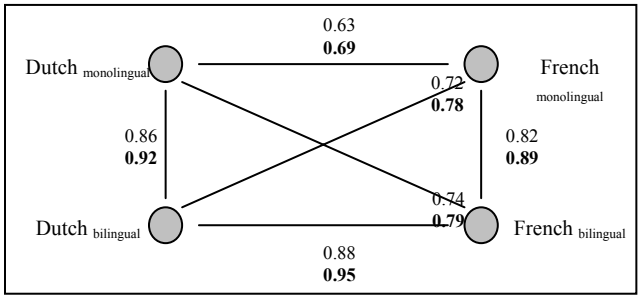

Figure 1: Pattern of correlations between the name distribution similarities of the language groups.[6]

When we compare the observed pattern of correlations with the patterns of correlations predicted by the two hypotheses (see Figure 2), we can conclude that the data are inconsistent with the two-pattern-hypothesis, since the correlation between the two naming patterns of the bilinguals (0.88) was significantly larger than the correlation between the naming patterns of both monolingual language groups (0.63), $Z = 21.82 > 1.96$. The data favor the one-pattern-hypothesis. Note however that some deviations from a single common naming pattern were observed. For example, it happens that a group of objects, with a single

[6] The upper r_{XY}'s are the Pearson correlations, the lower $\mathbf{r_{XY}}$'s (in bold) are correlations corrected for unreliability of the data ($r^*_{XY} = \frac{r_{XY}}{\sqrt{r_{XX}} * \sqrt{r_{YY}}}$ with r_{XX} the reliability of X and r_{YY} the reliability of Y).

name in Dutch ('fles') is subdivided into more than one category in French (e.g., 'bouteille' and 'flacon').[7]

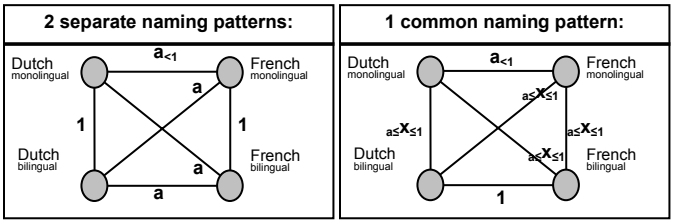

Figure 2: Patterns of correlations between the name distribution similarities of the language groups, predicted by the first and second hypothesis, respectively.

Individual-level analysis. On the individual level, object*object-matrices for each individual task, containing 0's and 1's with 0 indicating equal naming of both objects by the person performing the task and 1 indicating different naming of both objects- were correlated with each other. This resulted in 126*125/2[8] different correlations between all possible pairs of individual tasks. Next, the correlations were Z'-transformed to normalize the sampling distribution of the correlations. Then, the Z'-transformations of the correlations were analyzed in a randomized block factorial ANOVA design, with three factors: language (two levels: the subjects of the pair perform the naming task in the same language or in a different language), person (two levels: correlation between naming data of the same subject or of different subjects) and linguistic statute (three levels: both subjects are monolingual, one subject is monolingual, the other bilingual and both subjects are bilingual), resulting in a 2*2*3 design with unequal cell frequencies and three (structurally) empty cells (see Figure 3).

The results of the ANOVA confirmed the conclusions that were derived from the correlational group-level analysis. The three main effects –language, person, linguistic statute- were all significant, respectively $F(1,7866) = 23.29$, $p < .0001$, $F(1,7866) = 42.61$, $p < .0001$, $F(2,7866) = 8.15$, $p < .0005$) as was the interaction effect language*person*linguistic statute, $F(4,7866) = 25.05$, $p < .0001$. We tested the following crucial contrasts: μ_{221} versus μ_{223} (C1) and μ_{113} versus μ_{213} (C2). If C1 is significant, Hypothesis 1 is rejected, since according to the two-pattern hypothesis, the mean correlation between the naming of a French-speaking monolingual and the naming of a Dutch-speaking monolingual must be equal to the mean correlation between the French naming of a bilingual and the Dutch naming of a(-nother) bilingual. If C2 is significant, Hypothesis 2 is rejected, because the one-pattern hypothesis claims that the Dutch and French naming task of a (same) bilingual correspond equally well as the naming of that bilingual and the renaming (retesting) of the same bilingual in the same language. We found that C1 was significant, $F(1,7866) = 299.94$, $p < .0001$, and hence Hypothesis 1 is rejected. C2 was not significant, which means that Hypothesis 2 is retained.

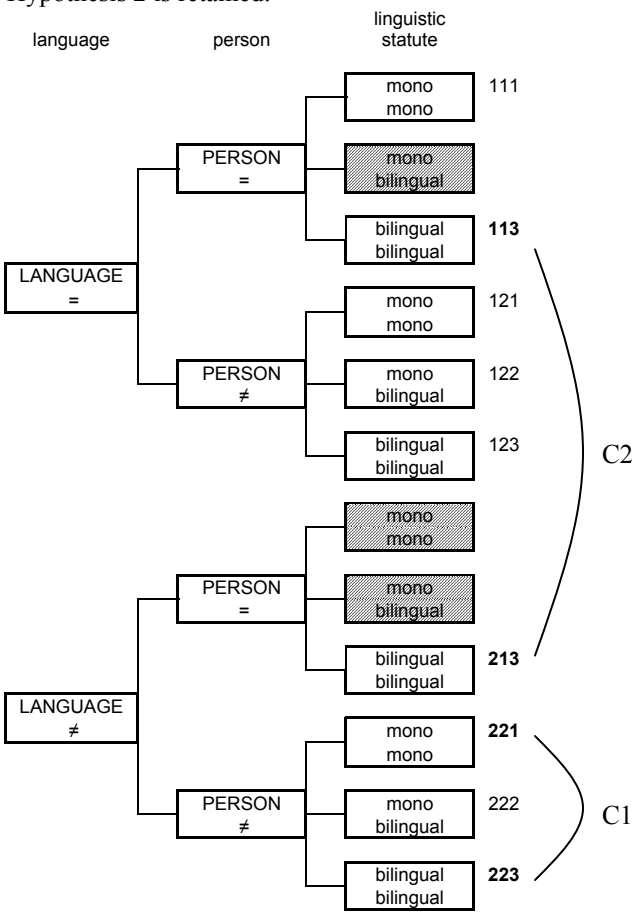

Figure 3: 2*2*3-factorial design with unequal cell frequencies and three empty cells.

General Discussion

The dissociation between naming and sorting, found by Malt et al. (1999) for three different language groups was replicated for the French-speaking and Dutch-speaking monolinguals: The analyses of the dominant names and of similarities among naming distributions revealed substantial differences in French-speaking and Dutch-speaking monolingual linguistic categories for the bottles set, while in contrast, no differences were found in their perceptions of the similarity among the objects, as revealed by the high correlation between the sorting data of both monolingual language groups. Hence, similarity cannot fully account for the observed naming patterns. Other factors must contribute to linguistic categorization. Malt et al. (1999) proposed that besides the contribution of similarity to naming choices,

[7] Remark that this kind of subdivisions occurs much more frequently between the monolingual naming patterns than between the bilingual naming patterns.

[8] 126 individual tasks: = 32 Dutch-speaking monolinguals + 5 retested Dutch-speaking monolinguals + 29 French-speaking monolinguals + 25 bilinguals (Dutch naming) + 5 retested bilinguals (Dutch) + 25 bilinguals (French naming) + 5 retested bilinguals (French).

mechanisms such as chaining, convention and pre-emption influence naming patterns.

Concerning the bilingual naming patterns, the data (at group and individual levels) reject the two-pattern hypothesis. So, we can conclude that the French and Dutch naming patterns of the bilinguals are not kept separate and hence don't parallel the naming patterns of the French and Dutch monolinguals, respectively. The data are more consistent with the one-pattern hypothesis, suggesting that the two naming patterns of the bilinguals merge into one. However, the data also show that the assumption of a perfect match between the naming patterns is too strong and that is should be attenuated, since bilinguals did not use the French and Dutch category names as perfect translation equivalents. Apparently, even if the two naming patterns of bilinguals deviate from the corresponding monolingual naming patterns, naming in each of both languages is still influenced by culture- and language-specific factors: bilinguals name the objects in a way that is consistent with the language in which they name the object. This is not so surprising, since language and culture can't be considered separately. On the other hand, the convergence of the two naming patterns on one naming pattern suggests that bilinguals do not only satisfy cultural and linguistic constraints, but also individual cognitive constraints: it is less demanding on the limited sources of memory to store only one set of mappings between objects and names. So, in a way, bilinguals do find a set of mappings between words and objects that meet linguistic, cultural and individual memory constraints.

Abstract

We compared recognition memory for pictures of family interactions in Indonesian – in which sibling terms are based on *relative age* – and English – in which sibling terms are based on *gender*. In Experiment 1, participants saw a set of pictures of family interactions and gave a verbal description of each picture. They later received a recognition test that included variants that altered either seniority relations or gender relations. The same method was used in Experiment 2, except that the recognition variants were changed to be *similar* families (with parallel relationships). During study, participants were asked either simply to remember the pictures (Experiment 2a) or to provide a verbal description (Experiment 2b). Results from both experiments suggest effects of language on memory, particularly when non-identical transfer is involved.

Introduction

The Whorfian Question

Does the language we speak influence the way we think? This question, out of favor for many years, has had a resurgence of interest (Gentner & Goldin-Meadow, 2003; Gumperz & Levinson, 1996). There is evidence (Bowerman & Choi, 2003; Sera et al., 2002; Choi, McDonough, Bowerman, & Mandler, 1999; Levinson, 1998) that linguistic distinctions may influence non-linguistic similarity and memory for scenes (but see Munnich, Landau, & Dosher, 2001; Li & Gleitman, 2002 for contrary evidence).

The recent investigations have mostly centered around perceptual arenas such as space, time and motion. However, classic studies in anthropological linguistics suggest that there are also substantial differences in semantic categories in social arenas such as kinship (Romney & D'Andrade, 1964; Danziger, 2001; Foley, 1997). It is important to test whether these linguistic differences have cognitive consequences. There are direct studies of the cognitive effects of social semantics. Boroditsky and Schmidt (2000) found effects of linguistic gender on people's encodings of objects. For example, they taught Spanish-English and German-English bilinguals English names for objects (such as "Mary" for a table) and found that people retained the names better when the gender was consistent with the gender of the noun in their first language. In addition, bilinguals' English descriptions of the objects were consistent with the gender in their first language. Sera, et al. (2002) have also shown that gender retains semantic context in that cross-linguistic differences influence classification (Sera et al., 2002).

Our work explores an arena of social categories, namely kinship terms. As Malinowski (1930) noted, some dimensions seem likely to be universal in kinship systems—such as the gender of the person named, the age and/or generation relative to ego, and the gender of the linking relative. Nevertheless, kinship systems vary considerably in how these distinctions play out. Our study focuses on one pair of contrasting languages – English and Indonesian – which vary in the way they name sibling relations.

Indonesian makes a lexical distinction for whether a sibling is *older or younger*. The word *kakak* refers to older sibling while the word *adik* refers to younger sibling. For example,

(1)

Saya	mempunyai	seorang	kakak.
1st pers. sing.	have	one (person)	older sib

'I have an older sibling'

In contrast to English *brother* and *sister*, the Indonesian sibling terms *kakak* and *adik* are gender-neutral. When an Indonesian refers to his/her siblings, he/she speaks not in terms of sister and brother but rather of older and younger. Thus, "How's your older sibling (*kakak*)?" is as natural in Indonesian as "How's your brother?" is in English.

Of course, both languages can specify both gender and seniority if desired. An English speaker could refer to "your younger brother" and an Indonesian to "your male younger-sibling"

(2)

Adikmu	laki-laki
younger sib.-your	male

'your younger-sibling boy'

Thus, the Indonesian semantic system focuses on the relational seniority of siblings, whereas the English systems focus on gender. Our study investigates a) whether this linguistic difference matter to the way people think about family relations, and b) whether it affects the way people construe scenes involving families.

In our previous study (Anggoro & Gentner, 2003, Experiment 2) we used a recognition task to test whether the two languages induce different encodings. Indonesian and English speakers were shown a series of pictures: three kinship standards and their three corresponding family pictures, along with 21 other pictures (Figures 1 and 2). Participants were asked to remember the scenes for a later memory task. Recognition memory for the scenes was later tested using variants of the standard pictures. Memory for each standard was tested using two variants: the Seniority Variant, which preserved the seniority relation but altered the gender relation, and the Gender Variant, which preserved the gender relation but altered the seniority relation. There was a tendency for Indonesian speakers to make more false alarms to the Seniority Variants than to the Gender Variants, suggesting better memory for Seniority than for Gender. English speakers showed the reverse pattern. An ANOVA over language and variant type showed a marginally significant interaction between the two factors. Other results from the same set of studies also point to an influence of language on encoding and recognition. For example, relative to English speakers, Indonesian speakers showed greater sensitivity to changes in seniority than to changes in gender in a similarity task. These results suggest greater sensitivity to the dimension that is required in naming siblings in each language.

The Current Study

Slobin (1987) has suggested in his *thinking for speaking* hypothesis that "[when] constructing utterances in discourse, one fits one's thoughts into available linguistic forms." In our current work we seek to test whether verbally describing the pictures would strengthen the language effect. In addition, we further explored the effects of a more challenging task that involved nonidentical transfer.

Experiment 1

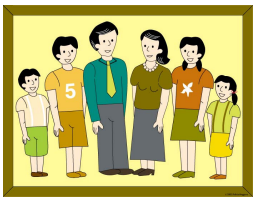
As in our previous study, Indonesian and English speakers were shown a series of pictures: the three kinship standards (as exemplified in the top picture in Figure 2) and their three corresponding family pictures (Figure 1), along with 21 other pictures (a total of 27 pictures). For each picture, participants were asked to describe the scenes and remember them for a later memory task. After a brief filler task, participants were given a recognition memory test. As in the previous study, the test included two variants: the Seniority Variant, which preserved the seniority relation but altered the gender relation, and the Gender Variant, which preserved the gender relation but altered the seniority relation

If describing the scenes leads participants' encodings to be influenced by the semantics of their kinship systems, then Indonesian monolinguals will be relatively more sensitive to changes in relative age than to changes in gender, as compared to English monolinguals. Specifically, if verbal description heightens the effects of semantic categories on encoding and recognition, then we should find a significant interaction between language and variant type.

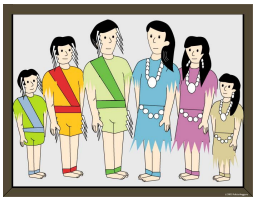
Method

Participants The participants were 15 Indonesian monolinguals and 13 English monolinguals, ranging in age from approximately 17 to 20 years old. Participants were either given credit or a small monetary compensation. Data from Indonesian speakers were collected in Jakarta, Indonesia. Data from English speakers were collected at Northwestern University and other areas near Chicago.

Materials The stimuli were three sets of pictures. One set (the Kitchen set) involved scenes of siblings performing a simple activity in the kitchen. The other two sets (the Ritual sets) involved ceremonies. Family pictures were used to introduce the 'characters' and make clear the sibling relations.



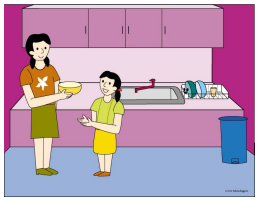
Family Picture for Kitchen Set



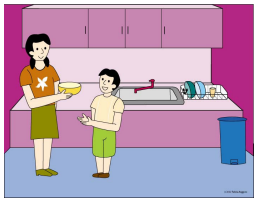
Family Picture for Ritual 1 Set

Figure 1: Family pictures used in the Kitchen and Ritual 1 sets.

The triad pictures consisted of one standard picture and two variants: the Seniority Variant, which preserved the seniority relation but altered the gender relation, and the Gender Variant, which preserved the gender relation but altered the seniority relation.



Standard
older sister gives bowl to younger sister



Seniority Variant
older sister gives bowl to younger brother

Gender Variant
younger sister gives bowl to older sister

Figure 2: The Kitchen set. In the Seniority Variant, the bowl still goes from the older to the younger sibling, but the gender of the younger sibling is altered. In the Gender Variant, the gender of both actors is the same as in the standard, but the bowl now goes from the younger to the older sibling.

Standard
younger brother gives crown to older sister

Gender Variant
older sister gives crown to younger brother

Seniority Variant
younger brother gives crown to older brother

Figure 3: Ritual 1 set. In the Gender Variant, the genders of both actors are the same as in the standard, but the crown now goes from the older to the younger sibling. In the Seniority Variant, the bowl still goes from the younger to the older sibling, but the gender of the older sibling is altered.

Procedure Participants were run individually in a quiet room. Instructions were given in Indonesian for the Indonesian speakers and English for the English speakers. For each set of stimuli, participants were first shown a family picture to ensure that they understood that the triad that followed only involved the children. (For the Ritual sets, the experimenter explained that the family lives on some island and they held a ritual each year. Then the standard was shown without further description.) For each standard, participants were asked to verbally describe what they saw in the picture. After participants had seen and described all of the standards, they were given a short break (approximately 10 minutes) during which they were asked to solve a few simple puzzles. Then they were given a yes-no recognition task. The two variants for each standard were intermixed in semi-random order among the fillers. The three standards that the participants had actually seen were given at the end of the test.

Results

As in the previous study, the key dependent measure is the mean proportion of times a participant responded 'yes' to each variant; i.e., the false alarm rates on the Gender Variants vs. the Seniority Variants. An ANOVA over Language and Variant Type showed a main effect of Variant Type ($F(1,26) = 7.21$, $p = .01$) such that participants made more seniority-preserving false alarms ($M = .29$) than gender-preserving ones ($M = .13$) and a main effect of language ($F(1,26) = 6.61$, $p = .02$), such that Indonesian speakers made more false alarms ($M = .29$) than English speakers ($M = .12$). As predicted, there was a significant interaction between the two factors ($F(1,26) = 4.90$, $p = .04$). Indonesian speakers made more false alarms to the Seniority Variants ($M = .42$, $SD = 30$) than to the Gender Variants ($M = .16$, $SD = .21$). English speakers showed no difference in false alarm rates (for Seniority Variants, $M = .13$, $SD = .17$, and for Gender Variants, $M = .10$, $SD = .21$).

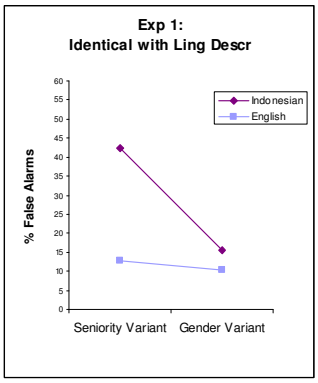


Figure 4: Results from Experiment 1.

Discussion

When participants described scenes verbally, they showed sensitivity to the dimension ensconced in their language on a subsequent recognition test. That is, Indonesians were significantly more able to reject variants that changed seniority relations than those that preserved seniority but changed gender. The results are stronger than those of our previous study (described above), in which linguistic descriptions were not elicited prior to the memory task. This suggests a 'thinking for speaking' effect whereby giving a linguistic description strengthens the effects of language on the encoding of the scenes. Interestingly, in this study the interaction appears to be driven by the Indonesian pattern; the English speakers showed roughly equal false alarms. However, the relative difference between the two language groups is as predicted: Indonesian speakers attended more to seniority than did English speakers. This pattern fits with our prediction of greater relative sensitivity to the dimension required in naming siblings.

One methodological point to note is that the nature of the design is limited in terms of the possible variants that we could devise for a given standard. This resulted in the Gender Variant being more perceptually similar to the Standard than was the Seniority Variant. In order to get around this problem, in the next study we decided to alter the identity match between the families in the pictures by

using a different family altogether for the variants. Thus, the variants did not retain the perceptual aspects of the Standard but were still designed to be relationally similar to the standard along either the seniority or gender dimension (see Figure 5). These new variants always embodied the same relationships as the previous variants. Thus the new variants fell further along the *literal similarity – analogical similarity continuum* (Gentner, 1989) than the original ones.

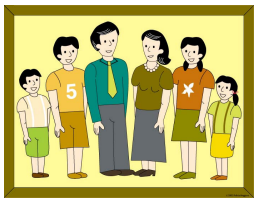
The analogous variants were used in a recognition task like the one described in Experiment 1. The idea was to test the strength of participants' "hold" of the relation and to see whether verbalization would influence the strength of the language effect. Of course, one might predict that participants would not false alarm at all to the analogous variants; after all, the variants depict different people altogether. On the other side, it seems possible that applying a linguistic description could invite a more abstract encoding, and that this could increase participants' propensity to recognize the same relation in different characters.

Indonesian and English speakers were shown a series of pictures: the three kinship standards and their three corresponding family pictures from Experiment 1, along with 23 other pictures. Participants were asked to remember the scenes for a later memory task. Recognition memory for the scenes was later tested using analogically similar Gender and Seniority Variants.

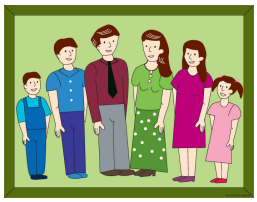
Experiment 2a

Participants Participants were 15 Indonesian monolinguals and 17 English monolinguals (not previously tested), ranging in age from approximately 17 to 20 years old. They were either given credit or a small monetary compensation. Data from Indonesian speakers were collected in Jakarta, Indonesia. Data from English speakers were collected at Northwestern University and other areas near Chicago.

Materials There were 29 study pictures (the three standard pictures from Experiment 1, their three corresponding family pictures, and 23 filler pictures). There were 67 test pictures (the three standards and all six of their variants, plus 58 fillers, as described below).

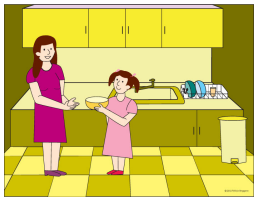


Identical Family Pict.

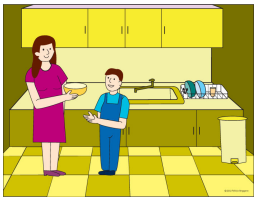


Analogous Family Pict.

Standard
older sister gives bowl to younger sister



Analogous
Seniority Variant
older sister gives bowl to younger brother



Analogous
Gender Variant
younger sister gives bowl to older sister

Figure 5: The Kitchen set, showing analogous variants used in Experiment 2.

Procedure As in Experiment 1, before each standard picture, participants were shown a family picture to ensure that they understood that the picture that followed involved only the children. (For the Ritual sets, the experimenter explained that the family lives on some island and held a ritual each year. Then the standard was shown without further description.) Participants were simply asked to remember the pictures. Then they were given a short break (approximately 10 minutes) during which they were asked to complete an unrelated paper-and-pencil task. Then they were given a yes-no recognition task. The two analogous variants for each standard were intermixed in semi-random order among the fillers. The three standards were given at the end of the test.

Results

An ANOVA over Language and Variant Type showed no significant main effects or interaction (all p's $> .1$). Qualitatively, there was a weak tendency for Indonesian speakers to make more false alarms to the Seniority Variants ($M = .36$, $SD = .32$) than to the Gender Variants ($M = .18$, $SD = .28$). The English speakers showed little difference between the two conditions (Seniority Variants, $M = .20$, $SD = .31$; Gender Variants, $M = .16$, $SD = .27$).

Experiment 2b

Participants Participants were 15 Indonesian monolinguals and 17 English monolinguals not previously tested, ranging in age from approximately 17 to 20 years old. They were either given credit or a small monetary compensation. Data from Indonesian speakers were collected in Jakarta, Indonesia. Data from English speakers were collected at Northwestern University and other areas near Chicago.

Materials Same as Experiment 2a.

Procedure Similar to Experiment 2b. The only difference is that during the study phase, participants were asked to verbally describe each scene, much like in Experiment 1.

Results

An ANOVA over Language and Variant Type revealed no significant main effects (all *p*'s >.1). As predicted, the ANOVA showed a significant interaction between the two factors ($F(1,30) = 5.16$, $p = .03$). There was a tendency for Indonesian speakers to make more false alarms to the Seniority Variants ($M = .18$, $SD = .28$) than to the Gender Variants ($M = .11$, $SD = .21$). The English speakers showed the reverse pattern; they made more false alarms to the Gender Variants ($M = .33$, $SD = .24$) than to the Seniority Variants ($M = .16$, $SD = .21$).

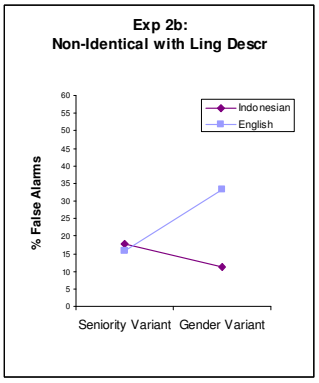


Figure 6: Results from Experiment 2b.

Discussion

The results from Experiment 2 suggest that for this more challenging task, cross-linguistic effects on encoding and recognition was only evident when participants were asked to verbally describe the scenes. In Experiment 2a, the effects of semantic categories on recognition seemed to be "masked" by the more challenging non-identical transfer task. When participants described the scenes verbally, however, as in Experiment 2b, this effect resurfaced. The pattern from the previous study was also found here: Indonesian speakers showed greater relative sensitivity to changes in seniority than to changes in gender in recognition memory, whereas English speakers showed the reverse pattern, as evidenced by the marginally significant interaction between language and variant type. As in Experiment 1, this pattern suggests greater sensitivity to the dimension that is required in naming siblings in each language.

Overall, we find a pattern of stronger results when people gave verbal descriptions of the scenes. Their descriptions, which typically included kinship terms, seem to heighten effects of language on encoding and memory. Using the identical family variants, the interaction between language and variant type (which was only marginal in our previous study) was significant in Experiment 1. Using the analogous variants (Experiment 2), the interaction between language and variant type was only significant when participants were instructed to use linguistic description. Our overall results suggest that the difference in the semantic patterns of the two languages may lead to differences in the way speakers encode situations – even nonlinguistic perceptual scenes. These results are consistent with the *thinking for speaking* idea in that actively using a language influences encoding and recognition memory.

Our thinking-for-speaking pattern of result is consistent with previous research showing that cross-linguistic differences influence judgments of spatial pictures (Gentner & Feist, submitted) and motion events (Malt, Sloman, & Gennari, 2003), but only when participants were asked to use linguistic description. However, it is also important to note that some studies have shown effects of cross-linguistic semantic differences on nonlinguistic performance without asking participants to first verbalize the scenes (e.g., Boroditsky, Ham, & Ramscar, 2002; Levinson et al., 2002). Indeed, in our own previous studies in this arena, we found cross-linguistic effects in similarity judgments and word extension without the use of verbalization. The similarity task was a simple triad judgment task and the word extension task was a novel name given to a standard picture and participants were asked to extend the novel name. In neither case were participants asked to describe the scenes themselves (Anggoro & Gentner, 2003). Interestingly, a comparison of the present results with our prior results (in which no verbal descriptions were elicited) (Anggoro & Gentner, 2003) suggests that in some cases, the predicted pattern are qualitatively stronger when prior verbalizations are elicited.

General Discussion

In conclusion, our findings suggest that linguistic differences in kinship terms (specifically, sibling terms) influence the way people encode and remember scenes and perceive similarities among them. Overall our results suggest that the actual verbalization of these semantic distinctions strengthens the cross-linguistic effects. Since in our previous work, cross-linguistic effects were found with or without linguistic description, the most intriguing aspect of our current findings is that this influence of verbalization appears stronger when the variants were *non-identical* to the standard[1]. The use of language may be particularly important in cases where the bridge between initial encoding and later experience is somewhat more abstract. Gentner (2003) has suggested that one role of language in

[1] Cross-experiment analyses of recognition results comparing participants who had initially given linguistic description of the scenes with those who had not (Anggoro & Gentner, 2003) showed a stronger pattern in the predicted direction for analogous pairs, especially among English speakers.

cognition is to facilitate memory access between situations that are not superficially similar but can be categorized in similar ways, as in the case of relational meanings.

Thus, our findings may provide a link between work in language and thought with work on analogical processing. Finally, our findings provide evidence that the use of language can influence encoding not only in spatial domains but also in the social arena.

Acknowledgments

This research was supported by NSF-ROLE award 21002/REC-0087516 and by the Culture, Language, and Cognition group at Northwestern University. We would like to thank Jeanne Arijanti, SMU PSKD in Jakarta, Ronnie Rios, Vini Putri, and Kathleen Braun for their assistance with data collection and other stages of this project. Abstract

Studying the communication patterns of scientists can give us insight into how science actually works. We argue that methodological differences between different scientific fields should lead to recognizable differences in how scientists in these fields use language to communicate with one another. This paper reports on a corpus-based study of peer-reviewed journal articles in paleontology and physical chemistry which used techniques of computational stylistics to compare the rhetorical styles used in the two fields. We found that indeed the two fields are readily distinguishable based on the stylistic character of their articles. As well, the most significant linguistic features of these distinctive styles can be connected directly to differences posited by philosophers of science between 'historical' (such as paleontology) and 'experimental' (such as physical chemistry) sciences.

Introduction

It has become clear in recent years that communication among different scientists working in a laboratory is critical for scientific success (Dunbar 1995). The particular uses of language by scientists serve to create a "collaborative space", whose worldview makes possible communication about complex observations and hypotheses (Goodwin 1994). Linguistic analysis has also been shown to elucidate features of scientific problem solving, as in Ochs et al.'s (1994) study of physicists' metaphoric talk of travel in a variety of graphical spaces.

At the same time, philosophers of science are increasingly recognizing that the classical model of a single "Scientific Method" (usually based on that of experimental sciences such as physics) does a disservice to sciences such as geology and paleontology, which are no less scientific by virtue of being historically oriented. Instead, it is claimed, differences in method may stem directly from the types of phenomena under study (Cleland, 2002). *Experimental* science (such as physics) attempts to formulate general predictive laws, and so relies heavily on repeatable series of controlled experiments which test hypotheses (Latour & Woolgar 1986). *Historical* science, on the other hand, deals with *contingent* phenomena, studying specific phenomena in the past in an attempt to find unifying explanations for effects caused by those phenomena (Mayr 1976). Because of this, reasoning in historical sciences consists largely of *reconstructive* reasoning, as compared to the *predictive* reasoning from causes to possible effects characteristic of experimental science (Gould 1986; Diamond 1999).

In this paper, we take some first steps towards analyzing the linguistic features of scientific writing in experimental and historical science, using several types of linguistically-motivated document features together with machine learning methods. Our goal is to examine if linguistic features that are indicative of different classes of scientific articles may be usefully correlated with the rhetorical and methodological needs of historical and experimental sciences. This paper describes a corpus-based study of genre variation between articles in a historical science (paleontology) and an experimental science (physical chemistry), with methodological differences as mentioned above. We hypothesize that corresponding rhetorical differences between articles in the respective fields will also be found. Standard methods of computational stylistics were used, confirming this hypothesis. Further, we defined a set of linguistically-motivated features for use in genre classification, based on systemic functional principles. These features enable a more nuanced examination of the rhetorical differences, allowing us to correlate these linguistic differences with the methodological differences posited by philosophers of science.

We note that the work reported here is only a first step, and more extensive studies of larger and more varied corpora of scientific papers will need to be undertaken in order to more firmly determine the links between scientific rhetoric, methodology, and cognition.

Hypotheses

Based on prior work in the philosophy and history of science we thus formulate our main hypothesis:

> ***H1*****:** *Stylistic features will distinguish more strongly between articles from different kinds (historical or experimental) of science than between articles from different journals in the same kind of science.*

We also formulate more detailed hypotheses regarding what sorts of rhetorical features we expect to be most significant in distinguishing articles in the different fields, based on posited methodological differences between historical and experimental sciences, as follows. First, a key element of *historical* reasoning is the need to differentially weight the evidence. Since any given trace of a

past event is typically ambiguous as to its possible causes, many pieces of evidence must be combined in complex ways in order to form a confirming or disconfirming argument for a hypothesis (termed *synthetic* thinking by Baker (1996)). Such thinking is, as Cleland (2002) argues, a necessary commitment of historical science (as opposed to experimental science), due to the fundamental asymmetry of causation. A single cause will often have a great many disparate effects, which if taken together would specify the cause with virtual certainty. Since all the effects cannot actually be known (as some are lost in the historical/geological record), evidence must be carefully weighed to decide between competing hypotheses (the methodology sometimes known as "multiple working hypotheses"). Experimental sciences tend, on the other hand, to adhere more or less to a "predict and test" methodology, in which manipulative experiments are used to confirm or disconfirm specific hypotheses (Cleland 2002). We therefore hypothesize:

***H2a*:** *Writing in historical science has more features expressing the weight, validity, likelihood, or typicality of different assertions or pieces of evidence*

***H2b*:** *Writing in experimental science has more features typical of explicit reasoning about predictions and expectations.*

Note that the presence or absence of linguistic features that can be linked to reasoning of a particular type is not by itself evidence of such reasoning. However, a consistent pattern of many of these features (as shown below) together aligned with the dichotomy proposed in *H2* strongly argues for such differences, which future research will attempt to elucidate in greater detail.

The Corpus

The study reported here was performed using a corpus of recent (2003) articles drawn arbitrarily from four peer-reviewed journals in two fields: *Palaios* and *Quaternary Research* in paleontology, and *Journal of Physical Chemistry A* and *Journal of Physical Chemistry B* in physical chemistry (chosen in part for ease of electronic access). *Palaios* is a general paleontological journal, covering all areas of the field, whereas *Quaternary Research* focuses on work dealing with the quaternary period (from roughly 1.6 million years ago to the present). The two physical chemistry journals are published in tandem but have separate editorial boards and cover different subfields of physical chemistry, specifically: studies on molecules (*J. Phys Chem A*) and studies of materials, surfaces, and interfaces (*J. Phys Chem B*). The numbers of articles used from each journal and their average (preprocessed) lengths in words are given in Table 1.

Table 1. Journals used in the studies with number of articles and average words per article.

Journal	# Art.	Avg. Words
Palaios	116	4584
Quaternary Res.	106	3136
J. Phys. Chem. A	169	2734
J. Phys. Chem. B	69	3301

Study 1: Distinctiveness

Methodology

We first test hypothesis *H1* by testing on our corpus whether paleontological and physical chemistry articles are stylistically distinctive from each other. The method was to represent each document as a numerical vector, each of whose elements is the frequency of a particular lexical feature of the text. We then applied the SMO learning algorithm (Platt 1998) as implemented in the Weka system (Witten & Frank 1999), using a linear kernel, no feature normalization, and the default parameters. (Other options did not appear to improve classification accuracy, so we used the simplest option.) SMO is a support vector machine (SVM) algorithm; SVMs have been previously applied successfully to text categorization problems (Joachims 1998). Generalization accuracy was measured using 20-fold cross-validation[1].

Features

For this first study, we used a set of 546 functions words taken en masse from the stop-word list of the popular research information retrieval system AIRE (Grossman & Frieder 1998); this procedure ensured task and theory neutrality. The set of function words used are similar to those used in many previous studies, such as Mosteller and Wallace's (1964) seminal stylometric work[2]. Each document was thus represented as a vector of 546 numbers between 0 and 1, each the relative frequency of one of the function words.

Results and Discussion

Table 2 shows results for binary classification between each pair of journals in our corpus, giving the percentage of test articles erroneously classified (in 20-fold cross-validation) using linear SMO learning and function-word frequencies as features. We first note that average accuracy on test documents from different fields (historical vs. experimental) was at least 97%, indicating excellent discriminability (far above chance). At the same time, the two physical chemistry journals are quite indistinguishable, as 34% is slightly *greater than* the error of always choosing the majority class (since 69/238=29% of those

[1] In *k*-fold cross-validation (Mitchell 1997) the data is divided into *k* subsets of equal size. Training is performed *k* times, each time leaving out one of the subsets, and then using the omitted subset for testing, to estimate the classification error rate; the average error rate over all *k* runs is reported. This gives quite a stable estimate of the expected error rate of the learning method for the given training size (Goutte 1997).

[2] Relative frequencies of function words, such as prepositions, determiners, and auxiliary verbs, have been shown in a number of studies to be useful for stylistic discrimination, since they act as easily extracted proxies for the frequencies of different syntactic constructs, and also tend not to covary strongly with document topic.

Table 2. Error rates for linear SMO using function word features for pairs of journals using 20-fold cross-validation.

	Historical		Experimental	
	P	***QR***	***PCA***	***PCB***
Palaios	--	10%	**0.4%**	**1%**
Quat Res	10%	--	**2%**	**3%**
Ph Ch A	**0.4%**	**2%**	--	34%
Ph Ch B	**1%**	**3%**	34%	--

articles are from *Phys. Chem. B*). In the case of *Palaios* vs. *Quat. Res.* we get an average error rate of 10%, an order of magnitude higher than any error rate in the cross-disciplinary case. Hence these results support *H1*, in that articles across disciplines are more easily distinguished than articles within a single discipline (from different journals). Of course, the 10% error rate obtained for distinguishing the two paleontology journals is far less than the 48% we would get by majority class classification, which points to a subsidiary distinction between these two journals. This is not unreasonable, given that *Quat. Res.* deals with a specific subset of the topics in *Palaios*[3]. We leave this question, however, for future research.

Study 2: Systemic Variation

Methodology

In order to more precisely analyze the rhetorical differences between articles in the two fields a follow-up study used as features the relative frequencies of sets of keywords and phrases derived from consideration of notions of systemic functional linguistics (Halliday 1994).

Systemic functional linguistics (SFL) construes language as a set of interlocking choices for expressing meanings: "either this, that, or the other", with more general choices constraining the possible specific choices. For example: "A message is either about doing, thinking, or being; if about doing, it is either standalone action or action on something; if action on something it is either creating something or affecting something pre-existent," and so on. A *system* is a set of options for meanings to be expressed, with *entry conditions* denoting when that choice is possible – for example, if a message is not about doing, then there is no choice possible between expressing standalone action or action on something. Each option has also a *realization specification*, giving constraints (lexical, featural, or structural) on statements expressing the option. Options serve as entry conditions for more specific subsystems.

[3] This may be related to the fact that *Quat. Res.* contains more articles than *Palaios* using chemical and radiochemical assaying, since such techniques are only applicable to younger remains from the Quaternary Period; such tools in fact are similar to the experimental techniques seen in physical chemistry. Indeed this is corroborated by the fact that the error rate between Quat Res and the PC journals was higher than Palaios and the same PC journals. More detailed study of the specific articles will be needed to test and refine this hypothesis.

By viewing language as a complex of choices between mutually exclusive options, the systemic approach is particularly appropriate to examining variation in language use. A systemic specification allows us to ask the following type of question: In places where a meaning of general type A is to be expressed in a text (e.g., "a message about action"), what sorts of more specific meanings (e.g., "standalone action" or "action on a thing") are most likely to be expressed by different types of people or in different contexts? A general preference for one or another option, when not dictated by specific content, is indicative of individual or social/contextual factors. Such preferences can be measured by evaluating the relative probabilities of different options by tagging their realizations in a corpus of texts (Halliday 1991).

As features, then, in the absence of a reliable systemic parser, we use keywords and phrases as proxy *indicators* for various systems. For example, an occurrence of the word "certainly" usually indicates that the author is making a high-probability modal assessment of an assertion. The drawback of this approach is lexical ambiguity, since the meaning of such keywords can depend on context. We reduce the effect of ambiguity, however, by using as complete a set of such *systemic indicator* keywords/phrases as possible for each system we represent, and also by using only measures of *comparative* frequency between the aggregated features. In addition, since we use very large sets of indicators for each system, it is unlikely that such ambiguity would introduce a systematic bias, and so such noise is more likely to just reduce the significance of our results instead of biasing them. Preprocessed articles in our corpus were each converted into a vector of 101 feature values (relative frequencies of system options) and the same learning protocol (using SMO) was used as in Study 1.

Features

The systemic features we used are based on options within three main systems, following Matthiessen's (1995) grammar of English, a standard SFL reference. Indicator lists were constructed by starting with the lists of typical words and phrases given by Matthiessen, and expanding them to related words and phrases taken from Roget's Interactive Thesaurus[4] (manually filtered for relevance). Keyword lists were constructed entirely independently of the target corpus. We used systems and subsystems within: CONJUNCTION, linking clauses together (either within or across sentences); MODALITY, giving judgments regarding probability, usuality, inclination, and the like; and COMMENT, expressing modal assessments of attitude or applicability. MODALITY and COMMENT relate directly to how propositions are assessed in evidential reasoning (e.g., for likelihood, typicality, consistency with predictions, etc.), while CONJUNCTION is a primary system by which texts are constructed out of smaller pieces, and so may be expected

CONJUNCTION	Extension	Enhancement
COMMENT	Validative	Predictive
MODALITY/**Type**	Modalization	Modulation
Modalization: Manifestation	Implicit	Explicit
Modulation: Manifestation	Explicit	Implicit

to reflect possible differences in overall rhetorical structure[5]. These systems and the indicators we used are described more fully in the Appendix.

Results and Discussion

We first check inter-class discriminability (*H1*), testing the results of Study 1 above. Table 3 presents classification error rates averaged over 20-fold cross-validation. In all four **cross**-disciplinary cases, error rates are 17% or less, while in the two **intra**-disciplinary cases, accuracy is noticeably lower; *Palaios* and *Quat. Res.* are significantly less distinguishable at 26% error, while *J. Phys. Chem. A* and *J. Phys. Chem. B* are entirely undistinguishable[6]. This further supports hypothesis *H1*, as above. Moreover, consistency with Study 1 results helps to validate the approach taken in this study.

We now consider what consistent picture, if any, emerges of the rhetorical difference between the two classes of scientific articles (paleontology and physical chemistry) from the patterns of feature weights in the learned models. To do this, we ran SMO on the entire corpus (without reserving test data) for each of the four pairs of a paleontology with a physical chemistry journal, and ranked the features according to their weight for one or the other journal in the weight vector. We call a feature *strong*, if it was among the 30 with the highest absolute weights out of 101 features for the same class in models learned for all journal pairs. Among strong features, some striking patterns emerge, shown in Table 4.

[5] Other textual/cohesive systems, such as PROJECTION, TAXIS, THEME, and INFORMATION cannot be easily addressed, if at all, using a key-word-based approach.

[6] Error rates are higher for this feature set than for the function words due to the smaller number of features—clearly there are some stylistic differences that our systemic features do not capture.

First, in COMMENT, we see a preference for Validative comments by paleontologists and one for Predictive comments by physical chemists. This linguistic opposition directly supports both hypotheses *H2a* and *H2b*, related to methodological differences between historical and experimental sciences. As noted, the historically-oriented paleontologist has a rhetorical need to explicitly delineate the scope of validity of different assertions, as part of synthetic thinking (Baker 1996) about complex and ambiguous webs of past causation (Cleland 2002). This is not a primary concern, however, of the experimentally-oriented physical chemist; her main focus is prediction: the predictive strength of a theory and its predictive consistency with the evidence.

Next, we consider the (complicated) system of MODALITY. At the coarse level represented by the simple features, we see a primary opposition in Type. The preference of the (experimental) physical chemist for Modulation (assessing what 'ought' or 'is able' to happen) is consistent with a focus on prediction and manipulation of nature, and supportive of hypothesis *H2b*. The (historical) paleontologist's preference for Modalization (assessing 'likelihood' or 'usuality') is consistent with the outlook of a "neutral observer" who cannot directly manipulate or replicate outcomes, and is thus supportive of hypothesis *H2a*.

This same pattern is also seen within the complex paired features combining values for modality **Type** and **Manifestation**. Implicit variants are more likely to be used for options that are well-integrated into the expected rhetoric, while Explicit realizations are more likely to be used for less characteristic types of modal assessment, as more attention is drawn to them in the text. Keeping this in mind, note that Modalization is preferably Implicit in paleontology but Explicit in physical chemistry; just the reverse holds for Modulation. This shows that Modalization is integrated smoothly into the overall environment of paleontological rhetoric, and similarly Modulation is a part of the rhetorical environment of physical chemistry.

Finally, in the textual system of CONJUNCTION, we see a clear opposition between Extension, indicating paleontology, and Enhancement, indicating physical chemistry. This implies that paleontological text has a higher density of discrete informational items, linked together by extensive conjunctions, whereas in physical chemistry, while there may be fewer information items, each is more likely to have its meaning deepened or qualified by related clauses. This may be indicative that paleontological articles are more likely to be primarily descriptive in nature, requiring a higher information density, while physical chemists focus their attention more deeply on a single phenomenon at a time. At the same time, this linguistic opposition may also reflect differing principles of rhetorical organization: perhaps physical chemists prefer a single coherent 'story line' focused on enhancements of a small number of focal propositions, whereas paleontologists may prefer a multifocal 'landscape' of connected propositions. Future work will

include interviews and surveys of the two types of scientists to investigate these hypotheses.

Related Work

Previous work has investigated the relationship between choice probabilities and contextual factors. For example, Plum & Cowling (1987) demonstrate a relation between speaker social class and choice of verb tense (past/present) in face-to-face interviews. Similarly, Hasan (1998) has shown, in mother-child interactions, that the sex of the child and the family's social class together have a strong influence on several kinds of semantic choice in speech. These previous studies involved hand-coding a corpus for systemic-functional and contextual variables and then comparing how systemic choice probabilities vary with contextual factors via multivariate analysis. By contrast, this study uses large numbers of neutral features and machine learning to automatically build accurate classification models.

Further, by examining differences between systemic preferences across scientific genres, we are quantitatively analyzing differences in register. *Register* denotes functional distinctions in language use related to the context of language use (Eggins & Martin 1997), and may be considered to comprise: *mode*, the communication channel of the discourse; *tenor*, the effect of the social relation between the producer and the audience; and *field*, the domain of discourse. We focus in this paper on the field-related distinction between historical and experimental science, with mode and tenor held relatively constant, by using articles written by working scientists drawn from peer-reviewed journals. Our results indicate that the difference in the types of reasoning needed by historical and experimental sciences leads to correlated differences in rhetorical preferences (perhaps best understood as 'functional tenor' (Gregory 1967)).

Conclusions

We have shown how machine learning techniques together with linguistically-motivated features can be used to provide empirical evidence for rhetorical differences between writing in different scientific fields. Further, by analyzing the models output by the learning procedure, we can see what features realize the differences in register that are correlated with different fields. This provides indirect evidence for methodological variation between the sciences, insofar as rhetorical preferences can be identified which are linked with particular modes of reasoning. This study thus provides empirical evidence for those philosophers of science who argue against a monolithic "scientific method".

Future work will include validating these results against a larger corpus of articles including more scientific fields, as well as incorporating more involved linguistic processing—the rhetorical parsing methods developed by Marcu (2000) are an important step in this direction. Methods for discovering rhetorically important features such as the subjectivity collocations of Wiebe et al. (2001) may also be helpful. Further, the current study treats each article as an indivisible whole. However, as noted by Lewin et al. (2001) in their analysis of social science texts, the rhetorical organization of an article varies in different sections of the text—future work will include studying rhetorical variation across different sections of individual texts, by incorporating techniques such as those of Teufel and Moens (1998).

Appendix: Systems and Features

CONJUNCTION

On the discourse level, the system of Conjunction serves to link a clause with its textual context, by denoting how the given clause *expands* on some aspect of its preceding context. Similar systems also operate at the lower levels of noun and verbal groups, while denoting similar logico-semantic relationships, e.g., "*and*" usually denotes "additive extension". Options within Conjunction are as follows:

- Elaboration: Deepening the content of the context
  - Appositive: Restatement or exemplification
  - Clarifying: Correcting, summarizing, or refocusing
- Extension: Adding new related information
  - Additive: Adding new content to the context
  - Adversative: Contrasting new information with old
  - Verifying: Adjusting content by new information
- Enhancement: Qualifying the context
  - Matter: What are we talking about
  - Spatiotemporal: Relating context to space/time
    - Simple: Direct spatiotemporal sequencing
    - Complex: More complex relations
  - Manner: How did something occur
  - Causal/Conditional:
    - Causal: Relations of cause and effect
    - Conditional: Logical conditional relations

Note that the actual features by which we represent an article are the frequencies of each subsystem's indicator features, each measured relative to its siblings. So, for example, one feature is Elaboration/*Appositive*, whose value is the total number of occurrences of Appositive indicators divided by the total number of occurrences of Elaboration indicators (Appositive + Clarifying). The relative frequencies of Elaboration, Extension, and Enhancement within Conjunction are also used as features.

COMMENT

The system of Comment is one of modal assessment, comprising a variety of types of "comment" on a message, assessing the writer's attitude towards it, or its validity or evidentiality. Comments are generally realized as adjuncts in a clause (and may appear initially, medially, or finally). Matthiessen (1995), following Halliday (1994), lists eight types of Comment, which we give here along with representative indicators for each such subsystem.

- Admissive: Message is assessed as an admission
- Assertive: Emphasizing the reliability of the message
- Presumptive: Dependence on other assumptions
- Desiderative: Desirability of some content
- Tentative: Assessing the message as tentative
- Validative: Assessing scope of validity
- Evaluative: Judgment of actors behind the content
- Predictive: Coherence with predictions

MODALITY

The features for interpersonal modal assessment that we consider here are based on Halliday's (1994) analysis of the Modality system, as formulated by Matthiessen (1995). In this scheme, modal assessment is realized by a simultaneous choice of options within four systems[7]:

- Type: What kind of modality?
  - Modalization: How 'typical' is it?
    - Probability: How likely is it?
    - Usuality: How frequent/common is it?
  - Modulation: Will someone do it?
    - Readiness: How ready are they (am I)?
    - Obligation: Must I (they)?
- Value: What degree of the relevant modality scale?
  - Median: In the middle of the normal range.
  - High: More than normal
  - Low: Less than normal
- Orientation: Is the modality expressed as an Objective attribute of the clause or as Subjective to the writer?
- Manifestation: Is the assessment Implicitly realized by an adjunct or finite verb, or Explicitly by a projective clause?

The cross-product of these subsystems gives many modality assessment types, each realized through a subset of indicators. *Simple* features are each option in each system above (e.g., Modalization/*Probability* opposed to Modalization/*Usuality*), while *complex* features are pairwise combinations of such simple features. The indicator set for each such feature is the intersection of the indicator sets for the two component features. Frequencies were normalized by the total set of occurrences of both primary systems (Modalization and Value in the previous example).

[7] Note that we did not consider the system of POLARITY, since it cannot be properly addressed without more sophisticated parsing.

Domain-Specificity in Shape Categorization and Perception

Benjamin J. Balas (bjbalas@mit.edu)

Abstract

We examine the influence of domain-specific knowledge on the process of learning and representing simple visual categories. Depending on whether subjects' construe simple objects as living kinds or machines, they show differential sensitivity to the importance of basic shape features. In particular, subjects who treated the objects as machines placed less importance on coarse shape differences unrelated to the described function of the objects in both categorization and productive (drawing) tasks. These findings suggest that domain-specific functional understanding of objects may influence the formation of shape categories, and perhaps the perception of these shapes.

Introduction

It is typical in the study of pattern recognition to discuss the classification of objects as though they are a relatively homogeneous class of stimuli. Many sets of 2D and 3D shape primitives have been proposed, all with the goal of describing how a wide variety of forms can be catalogued by a small set of simple building blocks (Hoffman & Richards, 1986; Biederman, 1987). Special-purpose mechanisms are seen as add-ons that are only used to process particularly interesting and ecologically significant stimuli. The nature of these specialized processes has also been explored, and there is much debate over what defines a "special" class of stimuli (Yin, 1969; Diamond & Carey, 1986; Gauthier & Tarr, 1997).

The suggestion that object recognition only employs unique processes for a small minority of object classes stands in stark contrast to work concerned with the formation and application of domain-specific theories (Carey, 1985). It has been suggested that knowledge of particular domains (like biology, physics, or psychology) may substantially affect the reasoning employed in a range of tasks. Given that theory-based reasoning may guide performance in complex scenarios, it may also be possible that human observers possess theories concerning the visual properties of objects in various domains that affect the way they recognize and represent object categories. Should this prove to be the case, it may suggest that general accounts of object recognition are too coarse, in that they fail to consider the richness of subjects' visual knowledge of a particular object category.

It is important to establish exactly what we mean when we suggest that subjects may possess theories about visual properties of objects that affect perception. We envision a simple hierarchy of object knowledge (Figure 1) ranging from high-level theories to low-level perception of shapes. At the top is amodal knowledge of particular domains. At this level (L1), abstract facts about objects in a broad domain (e.g., "artifacts") are stored propositionally (as in, "Machines are often built in factories to precise specifications"). At the second level (L2), object categories are defined in terms of the visual properties shared by members of common groups. This knowledge could be symbolic ("Tigers have stripes") or encoded in terms of visual measurements ("Tigers have lots of contrast energy at a particular spatial frequency"). Finally, at the bottom level (L3) lies the representation constructed in perceiving an object as a category instance, expressed in terms of its visual features such as size, shape, color, etc. Our work set out to explore the possibility that abstract knowledge at the highest level of this hierarchy could affect representations underlying both shape categories (L3 → L2) and shape perception (L3 → L1).

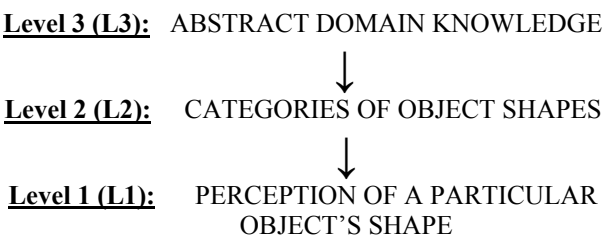

Figure 1: A schematic view of the relationships between domain theories and perception.

Previous experiments by Goldstone (1994) have demonstrated the influence of categorization on perception (L2 → L1). After forming categories of simple objects based on perceptual attributes (like luminance), subjects' ability to discriminate between luminance levels was altered to support the newly learned perceptual groups. No abstract domain knowledge (L3) was implicated in these studies. Kelemen and Bloom (1994) demonstrated an influence of domain knowledge on the representation of shape categories (L3 → L2), but did not look at influences down to L1. Their stimuli were uniform circles that could vary both in size and color. Subjects who were told the circles were microscopic animals preferred to categorizethem according to color, while those who construed them as machines preferred to categorize based on size.

Visual categorization relies on the ability to learn object attributes that vary more across categories than within them, and to accurately measure those attributes in new images.

Knowing that an object is a member of a particular domain (say "living things") may bias the observer to expect particular patterns of variability. The Kelemen and Bloom study, as well as Keil's work (1998), have both shown that color is expected to be useful for categorizing living things. We suggest that different aspects of shape may also be differentially weighted to categorize objects in different domains. The abstract (Level 3) knowledge observers possess about animals' growth and movement as well as knowledge about artifact construction may lead to influences on representations of shape categories (Level 2), and the ability to make fine-grained perceptual distinctions at Level 1.

Another possibility relevant to the categorization of living and non-living things concerns the influence of functional information on shape perception. It has been proposed that function helps set the core meaning of artifact concepts, and perceived shape may be relevant to artifact categorization primarily to the extent that it supports a functional interpretation (Bloom, 2000). A theory of non-living things may not induce any *a priori* preferences for particular visual features, but rather, flexibly bias resources towards functionally relevant information. Function may also influence which shape features are perceived to be important for biological categories, but in different ways. Landau et al. (1998) have shown that people will be more tolerant of certain non-rigid shape variation when classifying objects construed as animals (relative to those construed as artifacts).

In sum, our studies here ask two main questions not addressed in previous work. First, how far down in the hierarchy of Figure 1 do domain-specific conceptual influences extend? In particular, do they extend down to perceptual representations of individual objects? Second, what is the range of conceptual influences? Specifically, is there a role for functional understanding in forming representations of shape categories and individual shapes? In the spirit of Kelemen and Bloom, we have created novel 2-D shapes that we have named "Marcons" and "Draxels." These two populations of objects both consist of ellipses whose perimeters have been modified to contain sinusoidal bumps (Figure 2). The result is a set of stimuli that can be distinguished both by coarse shape information (ellipse eccentricity) and fine details (the frequency and/or amplitude of the bumps). This allows us to explore subtler aspects of object appearance than previous studies have done, and provides us with the ability to easily attribute function to shape properties.

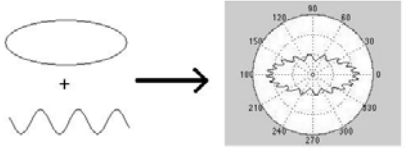

Figure 2: Constructing a Draxel.

In the experiments we present, subjects were asked to learn the distinction between Draxels and Marcons. While both groups are given identical information about the behavior of these objects and the function of particular features, some subjects are told that the stimuli are nanomachines and others are told they are amoeba-like animals. In Experiment 1, we use productive data (subjects' drawings) to determine whether domain knowledge influences perceptual representations. Drawings are a particularly useful tool in that they require subjects to make their perceptual representations explicit. In Experiment 2, we look for the effects of domain knowledge on category representations through a more controlled categorization task.

Experiment 1

We begin by presenting the results of a learning task in which subjects learn to discriminate between Marcons and Draxels. We assess the nature of their post-learning representations of the two kinds of object by collecting drawings from all subjects, and examining the extent to which differences in elongation and 'bumpiness' are expressed.

Methods

Stimuli 32 Marcons and 32 Draxels were hand-drawn on 2 ⅛" x 2 ¾" cards for this task using Crayola™ magic markers. A stencil was used to enforce a major/minor axis ratio of 2.9:1 for Draxels compared to a 2:1 ratio for Marcons. Bumps were applied to the perimeter of each ellipse such that Draxels contained 2.9 bumps/cm and Marcons contained 2.0 bumps/cm. The length of the major axis could take on one of 8 values for both Draxels and Marcons, and a dual-color contour was applied to the perimeter of the finished figures. The figures were also depicted at four different orientations (0, 90, +20, -20 degrees from vertical). No conjunction of color, size, and orientation was diagnostic of object identity, leaving only ellipse eccentricity and bump frequency as useful criterion for discrimination.

Subjects 24 naïve subjects (9 men, 15 women) were recruited from the MIT community to participate in this task. Subject age ranged from 18-40 years of age.

Procedure Subjects were initially presented with a brief introductory paragraph explaining that Marcons and Draxels were either unicellular organisms (Animals condition) or nanomachines (Machines condition). In both cases, the two kinds of object were said to participate in "agricultural revitalization" by grabbing onto various chemical compounds with their bumps, and redistributing them across depleted soil. Subjects were told that Marcons and Draxels were quite similar, but that experts could identify them very accurately despite the range of individual sizes, shapes, and colors in which the objects appeared.

After reading this paragraph, subjects were shown one example each of a Marcon and Draxel on an 8 ½" x 11" placemat. These two items were the same dimension as the largest exemplars in the stimulus set mentioned previously, but were depicted with a novel dual-color contour. Subjects were presented with the shuffled deck of 64 cards, and asked to sort the pile into two stacks such that Draxels were on one side and Marcons on the other. Subjects were permitted to take as much time as they liked to sort the cards.

After each round of sorting, the experimenter determined what false classifications were made, and presented these items to the subject for further study (grouped underneath their proper place on the sorting mat) before they were shuffled back into the deck for the next round. Subjects sorted the cards until they made fewer than 8 errors, or until they had sorted through the entire deck 4 times.

When the card-sorting task had been completed, subjects were then presented with new instructions asking them to produce drawings of Draxels and Marcons. 8 examples of each object were requested, with the additional instruction that their drawings should depict what they believed "typical" members of each category looked like, and that their set of 8 drawings should attempt to cover the range of variations that existed within each category. After completing their drawings, subjects were given a brief questionnaire asking them to rate on a 1-10 scale how important were various visual features in their concepts of these two classes, and to enumerate in free-response style the differences they perceived between the two kinds of objects.

Results

Learning Rates To determine if either group showed a particular affinity for learning to discriminate between Marcons and Draxels, we examine the number of errors made by each group after their first and second rounds of sorting. These two rounds are of particular importance in that they indicate to what extent the task is difficult with only one example of each object type and how much improvement each group undergoes by viewing a population of labeled examples.

A two-way ANOVA, with sorting round and domain as factors, revealed only a main effect of sorting round ($p < 0.05$). Subjects improve from across rounds, but neither group was particularly better at performing the discrimination between Marcons and Draxels, nor benefited more than their counterparts from receiving multiple labeled examples after their first round of sorting. We note that of the 24 participants who performed this learning task, 6 subjects (3 Animals, 3 Machines) were unable to reach our performance criterion of fewer than 8 mistakes after 4 rounds of sorting. We take this to mean that the difficulty of this initial task was intermediate, and unrelated to the domain of the objects.

Post-Learning Questionnaire Subjects' responses to the post-experiment questionnaire were analyzed to determine if there were differences between the Animal and Machine groups' explicit feature preferences. A two-factor ANOVA was run on subjects' ratings of the importance of shape differences between the two object categories, with feature type as one factor (elongation v. bumps) and subject group (animal v. machine) as the other factor. No main effects were found in the analysis, but a significant interaction ($p < 0.05$) was found between feature type and subject group. Subjects in the Animal group rated eccentricity as a more important feature, compared to subjects in the Machine group who preferred to use the bumps. (Table 1)

Table 1:
Mean ± SD ratings of feature importance (1-10 scale)

	Animals	Machines
Elongation	8.3 ± 4.1	6.5 ± 2.6
Bumps	6.8 ± 2.0	8.8 ± 3.0

Subjects' Drawings Using these responses as a guide, we turn next to the drawings of Marcons and Draxels produced by subjects after learning. (Figure 3) The eccentricity and number of bumps/cm for each figure was measured by first inscribing the largest ellipse possible inside the bumpy contour. If a particular drawing was sufficiently irregular that this proved impossible, that figure was excluded from the analysis. Only 4 out of 384 drawings (all from different subjects) were excluded in this fashion. Eccentricity was determined for each figure by measuring the major and minor axes of the inscribed ellipse, and the number of bumps/cm was determined by counting the number of bumps on the drawing and dividing by its perimeter. We use the YNOT approximation of the perimeter of an ellipse (Maertens & Rousseau, 2000) here, which was also used in the creation of the stimuli.

For each subject, we then compute the mean values of both eccentricity and bumps/cm for Marcons and Draxels across all eight drawings. The difference between these means is taken for each feature type, and divided by the maximum standard deviation of that feature within an object population. In this way, we express the differences in Marcon and Draxel shapes as a function of the separation and spread of the populations produced by each individual subject(Table 2).

Table 2:
Normalized differences between Marcon and Draxel features (Mean ± SD)

	Animals	Machines
Elongation	1.93 ± 0.98	0.79 ± 1.04
Bumps	2.42 ± 1.55	2.31 ± 1.27

A two-way ANOVA was performed on these measurements, using feature type and subject group as factors. A main effect of feature type was found, (bumps > eccentricity, $p < 0.05$) with a marginally significant effect of

subject group (Animals > Machines, $p < 0.08$). No significant interaction was found. However, to tease apart the contributions of each feature type to the weak effect of perceived domain, we conducted a further analysis for simple main effects across the Animal and Machine groups. We find in this analysis that subjects in the Animal condition expressed differences in eccentricity significantly more than subjects in the Machine condition ($p < 0.05$), while no such difference exists for the expression of bump density ($p > 0.8$).

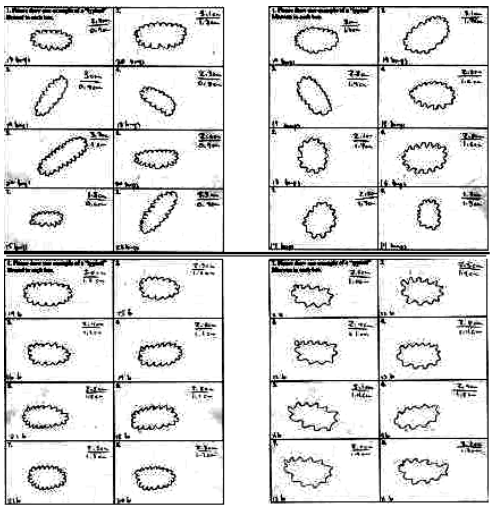

Figure 3: Examples of Draxels (left) and Marcons (right) created by subjects in the "Animals" condition (top) and the "Machines" condition (below). Note the lack of elongation differences in the lower drawings.

Discussion

Subjects' ratings of feature importance indicate an intriguing interaction between domain and the visual features perceived to be important. The drawings produced after completing the learning task show significantly more exaggeration of bumps across both domains, as well as significantly more expression of elongation differences in the Animal condition compared to the Machine condition. Bumpiness was not significantly more exaggerated in the Machine group compared to the Animal group, as one might expect from the interaction in subjects' ratings, yet there are some interesting qualitative differences in the way differences in bumpiness are expressed. Subjects in the Machine condition often pointed out subtle differences between the two categories that were not expressed or described by subjects in the Animal condition. Subjects in the Machine condition often pointed out aspects of bump symmetries and asymmetries that they felt were important to the task, and often included these details in their drawings (Figure 4). Though these features are not directly related to the difference in bump frequency, and therefore did not contribute to our quantitative analysis, it is interesting to see how these features appear in the drawings of Machine subjects while remaining almost wholly absent from the drawings of Animal subjects. It may be that more aspects of bump shape need to be explicitly considered when constructing stimuli and examining subjects' drawings.

We note that both of these effects may be a consequence of the introductory scenario given to subjects at the beginning of the task. By indicating that the bumps had a particular functional importance, the representation of bump differences may have been weighted more heavily in both groups. It is interesting to note that in the Machines condition, this seems to have resulted in an overall tendency to ignore additional shape differences. The significance of elongation differences in this group may have been compromised by the direction of functional information away from these features.

Experiment 1 provides us with direct evidence that domain knowledge can influence shape categorization (L3 → L2, in Figure 1). Evidence for effects of L3 on L1 (perceptual shape representations) is only indirect, insofar as subjects are thought to produce drawings by translating a Level 2 representation into perceptual primitives. This is an important distinction, since Level 2 representations may be more symbolic ("Draxels are skinnier than Marcons") rather than truly visual ("Draxel elongation is about 3:1"). A valuable next step would be to measure perceptual abilities directly using psychophysical methods (e.g., Goldstone, 1994), thereby establishing a more direct L3 → L1 link.

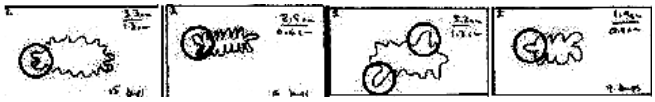

Figure 4: Over-expression of symmetry and asymmetry in "Machines" subjects. Draxels are at left, Marcons right.

Experiment 2

In our second task, we pursue possible domain-specific differences in shape processing using a more controlled task. Rather than relying on subjects' drawings, we use a triad task in which subjects are asked to classify a new object given labeled examples of our two categories. This second task allows us to more closely align our findings with the color/size asymmetry noted by Kelemen and Bloom, and allows us to balance the freedom given to subjects in Experiment 1 with a more constrained environment.

Subjects in this task are asked to make classifications given first a single example of each class, and then multiple examples of each class. Use of a single example allows for a relatively pure measure of subjects' prior beliefs concerning what visual features are important to the task, while multiple examples gives us some sense of what (if anything) changes when subjects are given evidence of what features vary across a population of objects. We look for evidence of the interaction between domain and perceived relevance of features suggested by our previous experiment, while also investigating whether or not the domain-general preference for expressing differences in bumpiness persists in a task in

which the two feature types are pitted directly against one another. In terms of our proposed hierarchy, we are looking for influences of Level 3 on Level 2, without examination of Level 1 representations in any form.

Methods

Stimuli For this task, a subset of the original stimuli were used. 4 Draxel/Marcon pairs of different color schemes were selected, with 2 pairs taken from the largest items in the original set, and the remaining 2 pairs being of intermediate size. All of these stimuli appeared at horizontal orientation to ensure that subjects would only consider shape information when making their decisions.

Additionally, two novel stimuli were created for each pair to serve as 'unclassified' items. Each novel item matched both their parents' color and size, but would match their Draxel parent for one feature type (say, elongation), and their Marcon parent for the other (bump frequency, in this example). The two stimuli in each "hybrid" pair were complementary, such that each "Draxel elongation/Marcon bumps" item had a partner with the opposite pattern of feature inheritance.

Subjects 64 subjects participated in this task, drawn from the MIT community.

Procedure Each subject read the same short description of Draxels and Marcons presented in our first task. Subjects were then told that they were being asked to help classify a new object that was either a Draxel or a Marcon, but currently unlabeled. Subjects were told that their initial answer would be based on the observation of only one example each of a Draxel and a Marcon, and that after their first response they would be given multiple examples to look at regardless of their first answer. To ensure that subjects did not feel undue pressure to change their answer given new information, all stimuli to be presented to the subject were laid face-down on the table before any responses were solicited. In this way, we minimize the possibility that subjects' might consider the new stimuli as additional information selected by the experimenter to guide them to a particular answer.

Subjects were first shown one example each of a Draxel and a Marcon, (Figure 5) matched for all attributes except eccentricity and bump frequency. A new item was then shown, drawn from one of the two hybrid stimuli created for that initial pair of stimuli. This third item matched the color and overall scale of both original examples. Subjects were then asked to classify the new item as a Draxel or a Marcon.

After their response was recorded, they were shown the three remaining examples of Draxels and Marcons. Subjects were asked a second time for a response, which was then recorded prior to rewarding the subject with M&M's for volunteering. The initial pair of examples displayed, as well as the particular probe used as the third stimulus were balanced across subjects, as was the left-right arrangement of Draxels and Marcons.

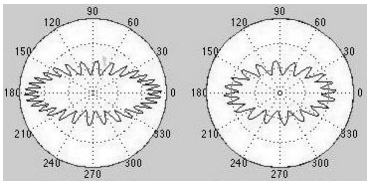

Figure 5: Digital versions of Draxels (left) and Marcons (right). Actual stimuli were hand-drawn, but we present these more regular, schematic images for clarity.

Results

On subjects' first judgments, 21 subjects in the Animals condition choose to categorize the novel stimulus by referring to the bump frequency of the examples, with 11 favoring eccentricity. In the Machines condition, 25 subjects used the bumps as a diagnostic feature, with 7 participants using the elongation of the ellipse. A chi-squared test reveals that these two distributions do not differ from each other. However, an additional goodness-of-fit test shows that the distribution of responses in the Machines condition differs from chance ($p < 0.05$), while the responses of subjects in the Animals condition do not.

Moving on to consider the responses given by subjects after viewing multiple examples, we see that 19 subjects in the Animals condition favor bump frequency for classification, compared to 13 individuals who prefer to use eccentricity. In the Machines condition, the corresponding numbers are 27 and 5 subjects respectively. Unlike the single-example data, these two distributions do differ from one another by a chi-squared test ($p<0.05$). Also, the responses of the Machines subjects differ from chance while the other responses do not.

In each group of subjects, only two subjects changed their mind when presented with multiple examples of the object classes. This indicates that our efforts to minimize undue pressure on the subjects to change answers suceeded, and that subjects were confident in their classifications.

Discussion

In our triad task, we continue to see domain-specific differences in the preference for different aspects of object shape. In correspondence with our results from Experiment 1, we see that subjects in the Animals condition do not significantly prefer one feature type to another. Moreover, as a whole, subjects who perceive the objects as machines have a greater tendency to ignore differences in elongation in favor of differences in bump frequency.

Additionally, in both conditions we see the same overall bias towards using bumps that characterized subjects' drawings in Experiment 1. The distribution of responses in the Animals condition is never different from chance in this study, making it difficult to draw a firm conclusion on this matter. However, the qualitative agreement between the pattern of results obtained here and those obtained in Experiment 1 suggests that the effects we observe genuinely

reflect people's representations of these categories, rather than task artifacts.

General Discussion

Two studies demonstrated that perceptual representations of simple visual shape categories differ depending on whether the stimuli are conceived of as living or non-living things. Our results show a difference in how various shape features are weighted across domains, but they do not yet speak to the origins of those differences. The difference could be simply one of spatial scale, or it could reflect deeper differences in how function or shape variation is conceptualized in different domains. We conjecture that the functional description of the objects plays a driving role in the effects we observed. In a pilot study, we have presented subjects with the same stimuli and task of Experiment 2, eliminating only the instruction sheet's explicit description of bump function. Preliminary results indicate that this manipulation eliminates the domain effects we see here, in that both "animal" and "machine" subjects appear equally to favor the bumps for categorization, and at a level equal to "machine" subjects in Experiment 2. Hence, for these shape stimuli, functional information appears to exert a greater influence when the objects are construed as living kinds, and its primary role appears in *decreasing* the distinctiveness of the bumps for classifying these two kinds of microorganisms. The bumps may be seen as pseudo-pods, non-rigid appendages of the microorganisms that are used to grab compounds but are not essential shape features that are stable across time in an individual, let alone as a distinctive feature for classifying objects into kinds. This interpretation is consistent with our data, although subjects' post-experiment surveys did not mention any explicit reasoning of this sort. Further research is needed to determine precisely how functional knowledge and shape representations interact here, but it is intriguing to speculate that intuitive domain theories are guiding implicit inferences concerning the possible dynamic aspects of simple shapes.

The potential effects of exposing subjects to multiple examples of an object class are also worth exploring further. In this task, we see very little change in subjects' behavior from one response to the other, but the number of observations they are allowed to make is still quite small. If presented with an extremely large population of Marcons and Draxels, subjects might undergo a more profound evolution of shape processing strategies. We note that in the Experiment 1, subjects gained far more experience with Marcons and Draxels than those that participated in our triad task. Subjects in the Animals condition also expressed an explicit preference for elongation rather than bumps in that task, which we did not see in Experiment 2. The difference between these two patterns of response may be related to the size of the observed population of each object class. The possible interaction of statistical reasoning given a population of novel objects and prior beliefs about feature relevance may prove to be a rich area for further research.

Conclusions

Taken together, these studies demonstrate that the categorization and perception of simple visual stimuli may be affected by the domain in which these objects are construed, functional reasoning about object properties, and by the amount of experience one has with a particular stimulus set. Understanding all of these influences, both as separate mechanisms and as a coherent whole, may lead to a richer understanding of human object categorization and the perception-cognition interface.

Abstract

We describe an incremental, two-stage probabilistic model of human parsing for German. The model is broad coverage, i.e., it assigns sentence structure to previously unseen text with high accuracy. It also makes incremental predictions of the attachment decisions for PP attachment ambiguities. We test the model against reading time data from the literature and find that it makes correct predictions for verb second sentences; however, the model is not able to account for reading times data for verb final structures because attachment preferences in our training data do not match those determined experimentally. We argue that this points to more general limitations with our type of probabilistic model when it comes to realizing processing strategies that are independent of the data the parsing model is trained on.

Introduction

Experimental results show that human sentence processing is sensitive to different types of frequency information, including verb frame frequencies (e.g., Garnsey et al. 1997), frequencies of morphological forms (e.g., Trueswell 1996), and structural frequencies (e.g., Brysbaert & Mitchell 1996). Probabilistic parsing models are an attractive way of accounting for this fact, as they provide a theoretically sound way of combining different sources of frequency information into a coherent model. Typically, these models are hybrid models, combining symbolic knowledge (e.g., phrase structure rules) with frequency information (e.g., rule probabilities gleaned from a corpus).

In particular, probabilistic parsers have been used successfully to model attachment decisions in human sentence processing. Early models demonstrated the viability of the probabilistic approach by focusing on a small selection of relevant syntactic constructions (Jurafsky 1996; Hale 2001). More recently, *broad coverage* models have been proposed (Crocker & Brants 2000; Sturt et al. 2003) that can deal with unrestricted text. These models are able to account for the ease with which humans understand the vast majority of sentences, while at at the same time making predictions for sentences that trigger processing difficulties.

However, existing probabilistic models deal exclusively with English data, and thus fail to address the challenges posed by the processing of head final constructions in languages such as Japanese (e.g., Kamide & Mitchell 1999) or German (e.g., Konieczny et al. 1997). In this paper, we address this problem by presenting a probabilistic model of human sentence processing in German. The model is broad coverage, i.e., it generates accurate syntactic analyses for unrestricted text. Furthermore, it makes predictions for PP attachment ambiguities for both head initial and head final sentences. The model consists of two probabilistic modules: a syntactic module that proposes an initial attachment, and a semantic module that evaluates the plausibility of the proposed attachment, and corrects it if necessary.

We evaluate our model on reading time data for PP attachment, i.e., for structures in which a prepositional phrase can be attached either to a noun phrase or a verb. In German, PP attachment ambiguities can occur in two syntactic configurations: in verb second sentences, the verb precedes the NP and the PP as it does in English (see (1)).

(1) Iris tröstete den Jungen mit dem Lied.
Iris comforted the boy with the song.
'Iris comforted the boy with the song.'

(2) (daß) Iris den Jungen mit dem Lied tröstete.
(that) Iris the boy with the song comforted.
'(that) Iris comforted the boy with the song.'

In verb final sentences (which occur as subordinate clauses), the NP and the PP precede the verb (see (2)). As sentence processing is incremental, this means that an attachment decision has to be made before parser reaches the verb (and the frequency information associated with it). These structures therefore provide an interesting challenge for probabilistic models of sentence processing.

Reading studies (e.g., Konieczny et al. 1997, whose materials we use) have shown that in verb second sentences, the PP is preferredly attached according to the subcategorization bias of the verb (as in English). In verb final sentences, where verb frame information cannot be accessed until the end of the sentence, the PP is preferentially attached to the NP site.

The Model

Our parsing model consists of two modules: one is a syntactic module based on a probabilistic parser, which also has access to a probabilistic verb frame lexicon. This module guarantees broad coverage of language data and a high accuracy in parsing unseen text. The other module is a semantic module that uses probabilistic information to estimate the plausibility of the analyses proposed by the syntactic module.

The model uses a syntax-first processing strategy: The syntactic module proposes a set of analyses for the input and ranks them by probability. The semantic module then computes the semantic plausibility of the analyses and ranks them by plausibility score. If there is a conflict between the decisions made by the two modules (i.e., the top-ranked analyses differ), this is interpreted as a conflict between syntactic preference and semantic plausibility and increased processing effort is predicted.

Syntactic Module

Modeling Syntactic Preferences The syntactic module consists of a probabilistic left-corner parser which relies on a probabilistic context free grammar (PCFG) as its backbone. A PCFG consists of a set of context-free rules, where each rule $LHS \rightarrow RHS$ is annotated with a probability $P(RHS|LHS)$. This probability represents the likelihood of expanding the category *LHS* to the categories *RHS*. In order to obtain a mathematically sound model, the probabilities for all rules with the same left hand side have to sum to one. The probability of a parse tree T is defined as the product of the probabilities of all rules applied in generating T.

Figure 1: Example of a PCFG

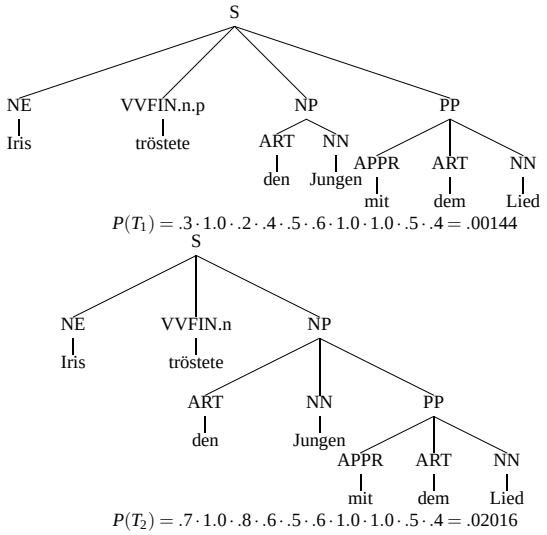

Figure 2: Example of trees generated by a PCFG

An example for a PCFG is given in Figure 1. This grammar contains the rules required to generate the two readings of (1). The readings are displayed in Figure 2, which also lists the parse probabilities, obtained by multiplying the probabilities of the rules used to generated a given tree.

This examples illustrates how PCFGs can be used for disambiguation: the two readings involve different rules (and rule probabilities), and therefore differ in their overall probabilities. In this example, reading T_2 is predicted to be preferred over T_1. Note that the grammar in Figure 1 incorporates verb frame probabilities: *tröstete* 'consoled' can either be a VVFIN.n (finite verb with an NP complement) or VVFIN.n.p (finite verb with an NP and a PP complement). The probabilities attached to these lexical items correspond to the psycholinguistic notion of *verb frame bias*, i.e., the probability of the verb occurring with a given subcategorization frame. The overall probability of an analysis is determined not only by verb frame bias, but also by structural probabilities attached to the phrase structure rules. This is a way of modeling structural disambiguation preferences (in this example, there is a bias for attachment to the NP). A PCFG therefore provides a principled way of integrating lexical preferences and structural preference, as argued by Jurafsky (1996).

Training and Test Data A PCFG is typically trained on a syntactically annotated corpus. For German, a suitable corpus is available in the form of Negra (Skut et al. 1997), a 350,000 word corpus of newspaper text. The Negra annotation scheme assumes flat syntactic structures in order to account for free word order in German. For example, there is no VP node dominating the main verb. Instead, subject, objects and modifiers of the main verb are its sisters, and all are direct daughters of the S node (see Figure 2). This means that scrambling phenomena simply alter the sequence of sisters in the tree, and do not involve movement and traces.

We checked the PP attachment preferences in Negra and found that in 60% of all sentences containing a verb and an NP object followed by a PP, the PP is attached to the verb. The corpus therefore reflects a general attachment preference for verb attachment. Additionally, we found that the subcategorization preferences for the verbs in our materials were reversed with regard to the preferences obtained by Konieczny et al. (1997) in a sentence completion task: the verbs that had a bias towards the NP-PP frame in the corpus exhibited an NP frame bias in the completion study, and vice versa.

For all subsequent experiments, Negra was split into three subsets: the first 90% of the corpus were used as training set, the remainder was divided into a 5% test set and a 5% development set (used during model development). Sentences with more than 40 words were removed from the data sets (to increase parsing efficiency).

The syntactic module was realized based on Lopar (Schmid 2000), a probabilistic parser using a left-corner parsing strategy. A grammar and a lexicon were read off the Negra training set, after empty categories and function labels had been removed from the trees. Then the parameters for the model were estimated using maximum likelihood estimation. This means that the probability of a rule $LHS \rightarrow RHS$ is estimated as $P(LHS \rightarrow RHS) = f(LHS \rightarrow RHS)/N$, which is the number of times the rule occurs in the training data over the total number of rules in the training data. Various smoothing schemes are implemented in Lopar to address data sparseness, see Schmid (2000) for details. We also complemented the Negra verb frame counts with frame probabilities from an existing subcategorization lexicon (Schulte im Walde 2002), as the Negra counts were sparse.

Semantic Module

Modeling Semantic Plausibility The semantic module determines whether an attachment decision proposed by the syntactic module is semantically plausible by deciding whether the PP is more likely to be semantically related to the preceding verb or to the preceding noun.

Our semantic model rests on the assumption that "semantic plausibility" or "semantic relatedness" can be approximated by probabilistic measures estimated from corpus frequencies. Previous work provided evidence for this assumption by demonstrating that co-occurrence frequencies obtained from various corpora (including the web) are reliability correlated with human plausibility judgments (Keller & Lapata 2003).

Training and Test Data Ideally, the same training data should be used for the syntactic and the semantic module; however, this was not possible, as the semantic module requires vastly more training data. We therefore used the web to estimate the parameters of the frequency based measures (see Keller & Lapata 2003 for a detailed evaluation of the reliability of web counts). For the selectional preference method, we used one year's worth of text from the ECI Frankfurter Rundschau corpus as training data. This unannotated corpus is the basis for the Negra corpus, but it is much larger (34 million words). The corpus was parsed using a parser very similar to the syntactic module. Tuples of verbs and head nouns of modifying PPs were then extracted according to the structures assigned by the parser.

The development and test set for the semantic module were taken from the set of 156 items from Experiments 1 and 2 of Konieczny et al. (1997). The development set consists of 68 randomly chosen sentences, the remaining 88 sentences are used as a test set. The items from Experiment 1 vary word order (verb second and verb final), verb subcategorization preference (bias for NP frame or for NP-PP frame), and attachment (to the NP or verb), which is disambiguated by the semantic implausibility of one alternative. In Experiment 2, verb subcategorization preference was not varied. The development set was used to compare the performance of different semantic and syntactic models and to set the parameters for one semantic models. The final performance will be reported on the unseen test set.[1]

Plausibility Measures In computational linguistics, a standard approach to PP attachment disambiguation is the use of configuration counts from corpora (e.g., Hindle & Rooth 1991). To decide the attachment of n_{PP}, the head noun of the PP, to one of the attachment sites (the verb v or n_{NP}, the noun phrase), we compare how probable each attachment is based on previously seen configurations involving n_{PP} and the attachment sites. In many approaches, the the preposition p is also taken into account.

As outlined above, we used web counts to mitigate the data sparseness that such a model is faced with. In this approach, corpus queries are replaced by queries to a search engine, based on the assumption that the number of hits that the search engine returns is an approximation of the web frequency of the word in question (Keller & Lapata 2003). Of course text on the web is not parsed, which makes it difficult to identify the correct syntactic configurations. We follow Volk (2001) in assuming that string adjacency approximates syntactic attachment reasonably well, and simply use queries of the form `"V PP"` and `"NP PP"`. The search engines used were `www.altavista.de` and `www.google.com` (restricted to German data). Google generally outperformed AltaVista (presumably because it indexes more pages); the results reported below were obtained using Google counts.

We experimented with a variety of plausibility measures (*site* ranges over the two attachment sites, v and n_{NP}):

(a) $\frac{f(site,p)}{f(site)}$, the Lexical Association Score (LA), computes how likely the attachment site is to be modified by a PP with the preposition p.

(b) $f(site,p,n_{\text{PP}})$, Model 1 of Volk (2001), relies on the raw trigram co-occurrence frequencies to decide attachment.

(c) $\frac{f(site,p,n_{\text{PP}})}{f(site)}$, Model 2 of Volk (2001), takes into account that high-frequency attachment sites are more likely to co-occur with PPs.

(d) $log_2\left(\frac{f(site,n_{\text{PP}})}{f(site)f(n_{\text{PP}})}\right)$, Pointwise Mutual Information (MI) measures how much information about one of the items is gained when the other is seen. This measure has previously been used for the related problem of identifying collocations (words that appear together more often than chance, Church & Hanks 1990).

(e) $\frac{f(site,n_{\text{PP}})}{f(site)} \cdot \frac{f(site,n_{\text{PP}})}{f(n_{\text{PP}})}$, Combined Conditional Probabilities (CCP) is similar to MI. It squares the joint probability term to give it more weight.

[1]Since for all models except one no parameters were set on the development set, we had to maintain a fixed development-test split to ensure the test set remained truly unseen.

As will be explained below, we experimented with these measures in isolation, but we also combined them with Clark & Weir's (2002) approach for computing selectional preference from corpora. This approach relies on a lexical data base to compute the semantic similarity between lexical items.

Results

Syntactic Module

As mentioned in the introduction, the present modeling effort was guided by the idea of building a broad coverage model, i.e., a model that explains why human sentence processing is effortless and highly accurate for the vast majority of sentences; at the same time, the model should account for psycholinguistically interesting phenomena such as processing difficulties arising from attachment ambiguities. Incrementality is crucial for predictions of this type. In its original form, the Lopar parser used for the syntactic module is not incremental and was therefore modified to achieve partial incrementality. It now outputs its ranking of the attachment alternatives in two stages: after processing the PP and at the end of the sentence. This provides a record of incremental changes in the attachment preferences of the model when processing the critical region for which Konieczny et al. (1997) report eye-movement data (the noun of the PP in Experiment 1 and the PP object in Experiment 2).

To evaluate the broad coverage of the model, we ran the syntactic module on our unseen Negra corpus test set. The model was able to assign an analysis to 98% of the sentences. As is standard in computational linguistics, we tested the accuracy of the model by measuring labeled bracketing: to score a hit, the parser has to predict both the bracket (the beginning or end of a phrase) and the category label correctly. We report labeled recall, the number of correctly labeled brackets found by the parser divided by the total number of labeled brackets in the test corpus, and labeled precision, the number of correctly labeled brackets found by the parser divided by the total number of labeled brackets found by the parser.

The model achieved a labeled recall of 66.65% and a labeled precision of 63.92%. It is similar to the baseline model of Dubey & Keller (2003), who report a maximum labeled recall and precision of 71.32% and 70.93%.

To further evaluate the syntactic model, we tested it on the test set generated from Experiments 1 and 2 of Konieczny et al. (1997). This allows us to determine whether the syntactic module is able to correctly resolve the PP attachment ambiguities even without access to any semantic information.

Table 1 shows the parser's decisions at the PP for verb final and verb second sentences. We report the number and the percentage of correct attachments per condition. In the verb final condition of Experiment 1, the parser always attached the PP to the verb. No verb frame information is available to guide the decision when the PP is processed, so the baseline is random guessing (50%). In verb second sentences, the parser can use the subcategorization preference of the verb, which leads to the correct attachment in 50% of all cases. The parser indeed reaches this baseline. In Experiment 2, the parser again always attaches the PP to the unseen verb in verb final sentences. In the verb second condition, there is a marked preference to attach according to verb bias, but only 42% of attachments are correct over both conditions.

	Verb final	Verb second
Experiment 1		
NP frame, V bias	7 (100%)	2 (29%)
NP frame, NP bias	0	5 (83%)
NP-PP frame, V bias	5 (100%)	3 (60%)
NP-PP frame, NP bias	0	2 (33%)
% correct	50%	50%
Experiment 2		
NP frame, V bias	9 (100%)	1 (11%)
NP frame, NP bias	0	5 (56%)
% correct	50%	33%
Baseline	50%	50%

Table 1: Syntactic module: correct attachment decisions at the PP for the test set from Experiments 1 and 2

Measure	CCP	MI	LA	Volk 1	Volk 2
Development Set					
# correct	23	22	17	22	21
% correct	67.6%	64.7%	50%	64.7%	61.7%
Test Set					
# correct	21	23	–	23	27
% correct	50%	54.8%	–	54.8%	64.3%
Baseline	50%	50%	50%	50%	50%

Table 2: Semantic module, verb second: results of the plausibility measures on the development and test set

Semantic Module

Verb Second Sentences As a next step, we evaluated the semantic module, again on the data derived from Experiments 1 and 2 of Konieczny et al. (1997). We again used the chance baseline (50%) that the syntactic module was unable to outperform.

The verb second sentences arguably constitute the standard case for PP attachment: Both possible attachment sites have been seen before the attachment has to be decided. In a first attempt, the five plausibility measures introduced above were tested on the development set. Table 2 shows that the CCP measure performed best, while the Lexical Association measure failed to beat the baseline. The CCP measure should therefore be chosen to model semantic attachment in verb second sentences. However, on the test set (see Table 2), the best and worst measure changed places. This time, the Volk 2 measure performed best. No measure significantly outperformed the others or the baseline.

As the performance of the CCP measure on the test set was disappointing, we experimented with a second approach that combines the Volk 2 model of PP attachment with a model of selectional restrictions. We used Clark & Weir's (2002) approach, which was extended to German by Brockmann & Lapata (2003), whose implementation we used. Relying on a semantic hierarchy (in our case: GermaNet, Hamp & Feldweg (1997)), the Clark & Weir algorithm finds the statistically optimal superclass (concept) for input nouns given a verb and the relation between noun and verb. The probability of a concept *c* given a verb *v* and relation *rel* is computed as:

$$(3) \quad P(c|v,rel) = P(v|c,rel)\frac{P(c|rel)}{P(v|rel)}$$

To find the best concept for a $\langle n,v,rel\rangle$ triple, at each step up the hierarchy, the probability estimate for the new concept is compared to that of the original concept. When the estimates differ significantly, the lower concept is assumed for the noun. The parameters of this algorithm are the statistical test used (χ^2 or G^2) and the α value which determines the level of significance required for the test. The G^2 test proved more suitable for our task, while a variation of α value had no noticeable effect.

	Prior	Average			
Measure	CCP	CCP	MI	Volk1	Volk2
Development Set					
# correct	12	11	8	9	11
% correct	60%	55%	40%	45%	55%
Test Set					
# correct	24	20	22	23	25
% correct	57.1%	47.6%	52.4%	54.8%	59.5%
Baseline	50%	50%	50%	50%	50%

Table 3: Semantic Module, verb final: Results on the development (Exp. 1) and test set (Exp. 1 and 2)

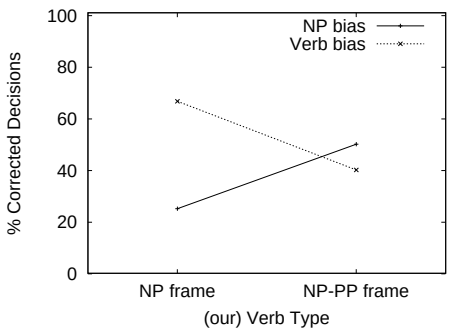
We used the development set to estimate a threshold value for the attachment decision. Coverage on the test set was only 48% due to sparse data. Whenever the Clark & Weir method did not return a value, we backed off to the decision made by the Volk 2 model (which is the most consistently performing model). Recall that this model has a 64% precision on the test data while the chance baseline is 50%. The combined model reaches 67% precision on the same data (precision for the selectional preference model alone is 70% for 48% of the data). This model performs best numerically (though not significantly so) and was used in the final model.

Verb Final Sentences A particularly interesting case arises with respect to verb final sentences (see (2)): at the critical region (once the PP has been processed), the verb is not available yet, which means that the plausibility of the combination of the verb with the head noun of the PP cannot be computed at this point. Konieczny et al. (1997) found processing difficulty in these cases when the PP was an implausible modifier of the noun, so apparently immediate semantic evaluation sets in and has to be accounted for.

In the verb final case, we therefore have to estimate the plausibility of the PP head noun modifying the NP as opposed to an unseen verb. One way of doing this is to average over the results for the PP head noun and every possible verb to obtain a generic value for verb attachment. We restrict ourselves to just the verbs in the test and development set. This backoff approach was realized for four models.

An alternative is to use the prior probability of the PP head noun as an estimate of its conditional probability with every possible verb. The prior probability of the PP head noun is its frequency divided by the size of the corpus, $f(n_{\mathrm{PP}}/N)$. In the case of web counts, N is the number of all documents searched. This figure was empirically estimated as proposed by Keller & Lapata (2003). Note that this method of backoff is possible only for the CCP measure, because the probabilities to be estimated for the other methods are too complex.

Table 3 gives the results on the development set for the items from Experiment 1. The items from Experiment 2 could not be tested as the averaging procedure is extremely costly in terms of web queries. The CCP model with simple backoff to the prior shows the best results at 60% correct attachments. We therefore used it for the final evaluation to predict attachments for verb final sentences. Table 3 also lists the results on the test set for items from Experiments 1 and 2. CCP with backoff to the prior performed better than most models that use averaging, and substantially outperforms CCP with averaging. The best model is Volk 2 with averaging. Again, no measure outperforms the baseline of 50% correct attachments or the other models.



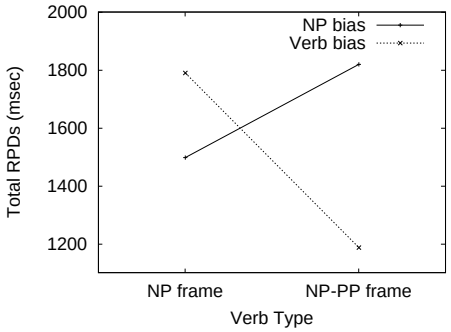


Figure 3: Exp. 1, verb second: Predictions of the combined model (left) compared to the Konieczny et al. (1997) data (right)

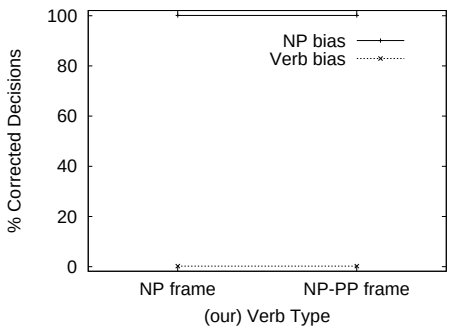

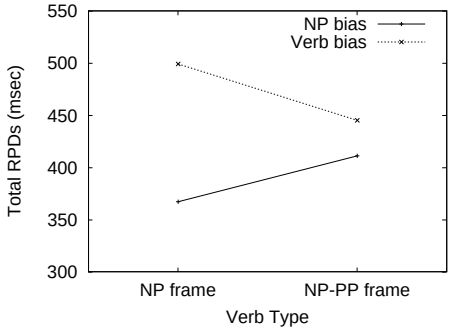

Figure 4: Exp. 1, verb final: Predictions of the CCP/Prior model (left) compared to the Konieczny et al. (1997) data (right)

Combined Model

In the previous sections, we evaluated the syntactic and semantic module separately. We found that the syntactic module performs at the level of the chance baseline of 50%, while the semantic module achieves an accuracy of up to 67% for verb initial sentences and 60% for the verb final sentences. A more interesting question is how well the model accounts for the processing difficulties that are evident in the eye-movement data reported by Konieczny et al. (1997). As mentioned at the beginning of the Results Section, our model makes predictions for the critical region used by Konieczny et al. (1997) (the PP). Recall also that we assume that a conflict between syntactic preference and semantic plausibility predicts increased processing effort.

As explained in the section on Training and Test Data above, the subcategorization variable was reversed for our data: where Konieczny et al. (1997) assume an NP-PP frame bias, we found a preference for the NP frame in our corpus (and vice versa). Below, our model's predictions are labeled with the preferences found in our data, while data from Konieczny et al. (1997) are labeled with the preferences they found. Figure 3 compares the predictions of our model with Konieczny et al.'s results in Experiment 1 for verb second sentences.[2] The graph for our model gives the percentage of correct decisions by the semantic module that are in conflict with the the decisions of the syntactic module. Such conflicts predict longer reading times, and the more conflicts in a condition, the higher we expect the average reading times to be. The figure shows that our model predicts the data pattern found by Konieczny et al. (1997) (who report regression path durations, RPDs).

[2]Note that our results are on the unseen subset of the items only, while the reading times are on all items.

In verb final sentences (Figure 4), the syntactic module always predicts verb attachment, so correct decisions for NP attachment by the semantic module always lead to a conflict. This pattern does not correspond to the Konieczny et al. (1997) reading data, which show a general preference to attach to the NP. Figure 5 shows a replication in principle of the reading time data in the verb second case. In Konieczny et al.'s (1997) pretests, all the verbs subcategorized for an NP and a PP, while in our data, they preferredly subcategorize for just an NP. Our model predicts longer reading times for the NP frame when subcategorization preference and semantic disambiguation are mismatched, which is what Konieczny et al.'s (1997) show for the NP-PP frame. The verb final case again fails: Instead of predicting preferred attachment to the NP (Matched bias for our data, Mismatched bias for Konieczny et al.'s data), the model predicts verb attachment.

Discussion

While our model replicates Konieczny et al.'s (1997) reading time results for PP attachment in the verb second case, it fails to account for reading times of verb final sentences. This failure is caused by the syntactic module which always predicts verb attachment in verb final sentences, while there is a human preference for NP attachment in these cases.

The behavior of the syntactic module is influenced by two factors. One is the probability of phrasal rules such as S → NE VVFIN.n.p NP PP. The second factor is a verb-specific frame bias, which manifests itself as probabilities for lexical rules such as VVFIN.n.p → *tröstete*. In verb second sentences, the verb's frame probability together with the phrasal rule probability determines the analysis proposed by the syntactic module. In verb final sentences, however, only the phrasal probabilities are used (as the verb is not yet avail-

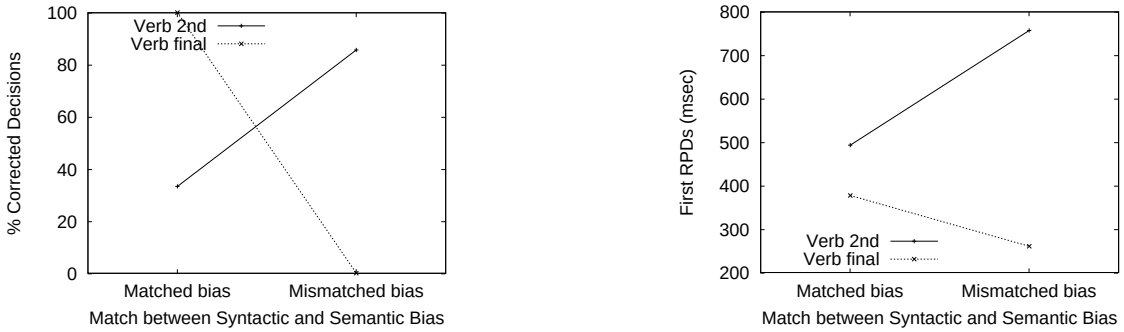

Figure 5: Exp. 2: Predictions of the combined model (left) compared to the Konieczny et al. (1997) data (right). Verbs subcategorize for an NP frame in our data and for an NP-PP frame in the Konieczny et al. data.

able), so the syntactic module makes the same prediction for all verb final sentences. This prediction is incorrect because the general PP attachment bias in the corpus is to the verb, rather than to the NP as in the reading time data.

This points to a more general problem with probabilistic models: They can only be as good as the training data. It is therefore vital to check relevant properties of the training corpus in comparison to experimental data when developing probabilistic models. Balanced corpora that consist of language data from different sources are more reliable in this respect than newspaper corpora such as the Negra corpus.

This means that the failure to model the verb final data is not a failure of probabilistic models per se; our approach would be in principle capable of modeling the general attachment preference to the NP in verb final sentences, if the attachment preference in the training data corresponded to that in the experimental results. Thus, our results strengthen the case for probabilistic models by showing that they can be applied even to head final constructions.

It is important to note, however, that our explanation of the German PP attachment data in terms of biases in the training corpus is at variance with explanations in the literature. For instance, Konieczny et al. (1997) proposes a strategy of *Parameterized Head Attachment* to explain why the parser prefers to attach incoming material (such as the PP) to existing sites (such as the verb). This strategy, which aims at the immediate semantic evaluation of the input, is designed to cope with head final structures in general, not only in the case of PP attachment. A basic PCFG model such as the one used in this paper is not able to implement such a general strategy.

Conclusions

We have presented a two-stage model parsing model that accounts for PP attachment in German. The model is able to assign correct sentence structures to unseen text and predicts average reading times in verb second sentences. For verb final sentences, the model fails to correctly predict the reading time data. The reason is that our training corpus exhibits a general bias for attaching PPs to the wrong attachment site (to the verb instead of the NP). In principle, however, our model would be able to account for the data in the verb final case if the training data were consistent with experimental findings. Our findings therefore strengthen the case for probabilistic models of language processing by showing their applicability to head final structures. At the same time, they demonstrate that probabilistic models can be highly sensitive to idiosyncrasies in the training data.

Mapping individuation to mass-count syntax in language acquisition

Abstract

Various theories propose that count nouns are distinguished from mass nouns by their specification of individuation. We present evidence that, while 3-year-old children acquiring language extend words differentially on the basis of mass-count syntax, they quantify over individuals for both novel mass and count nouns. We suggest that children may begin acquisition with an underspecified representation of mass noun semantics, permitting quantification over both individuals and continuous quantities. Also, children may rely on ontologically based biases to guide quantification.

Introduction

In English, the specification of number sends a ripple through the language, determining a word's status as mass or count, licensing the use of plural morphology, and selecting among measure terms such as *many* and *much*. Children begin to show signs of such knowledge early in language acquisition, with plural production and comprehension emerging as early as 2 years of age (Brown, 1973; Cazden, 1968; Ferenz & Prasada, 2002; Gordon, 1988), sensitivity to the mass-count distinction evidenced by around 2;6 years (see Soja, 1992), and the use of measure terms like *more* and *less* emerging between 2;6 and 3 years of age (Donaldson & Balfour, 1968; Gathercole, 1985; Palermo, 1973).

The mass-count distinction provides a particularly interesting case of number specification, because it entrains important consequences for both the syntax and semantics of noun phrases. For example, count terms like *cat* can take the plural morpheme (e.g., *cats*) follow cardinal numbers (e.g., *one cat, two cats, three cats*), and be modified by quantifiers like *these, those, few* and *many* (e.g., *many cats*). Mass terms, on the other hand, can occur in none of these environments and can be distinguished by their use with terms like *much* and *little* (e.g., *I don't eat much porridge*). According to most accounts, this distributional difference corresponds to a semantic distinction whereby count nouns quantify over individuals and mass nouns quantify over non-individuals (e.g., Bloom, 1994, 1999; Gordon, 1985; Link, 1998; Quine, 1960; Wisniewski, Casey, & Imai, 1996). For example, Bloom proposed that children might begin acquisition with bidirectional mappings between syntax and semantics, as in (1), resulting in a categorical effect of number specification in noun phrases:

(1) a. count noun ↔ individual
b. mass noun ↔ non-individual

However, such mappings may not provide the full story of what children know about the mass-count distinction. As noted by Barner and Snedeker (2004), mass syntax may not have a strong interpretation like count syntax, but may be semantically unspecified and allow reference to either individuals or non-individuals. In their study, Barner and Snedeker observed that 4-year-old children and adults interpreted many mass and count nouns in the way predicted by the mappings in (1). For example, participants judged three tiny shoes to be *more shoes* than one giant shoe and one giant portion of butter to be *more butter* than three tiny portions. However, they also based judgments on number for "object-mass" terms like *furniture, jewelry, mail,* and *clothing*, which children begin to produce by around 4 years of age. In each case, participants judged six tiny objects to be more than two giant ones. Thus, count syntax led to quantification on the basis of number, while mass syntax quantified over both continuous quantities and certain individual objects.[1] As a result, it was concluded that object-mass terms like *furniture* must allow quantification over individuals due to a lexical specification of number, which is normally found in count syntax. Expressions that house this feature quantify over individuals, while those that do not assume a default interpretation of quantifying over a continuous extent (see Borer, 2004, for a similar proposal). This view is schematized in (2):

(2) a. count syntax → individual
b. mass syntax ↔ no number specification

If the dimension of measurement of mass terms is specified in part by lexical semantics as these results suggest, children may need some amount of experience with

[1] But not all objects. Terms that can be used as either mass or count (e.g., *string/s, chocolate/s, paper/s, stone/s*) quantified by number as count nouns and by continuous extent as mass nouns.

particular mass terms before using them to specify a measuring dimension. This raises the question of what mass syntax contributes to the early interpretation of noun phrases, and whether children's interpretation of mass nouns differs from that of adults at any stage of development. For example, before acquiring exceptions like *mail* and *furniture*, do children respect mappings as in (1), or is mass syntax semantically unspecified throughout development?

Two sources of evidence regarding this question suggest conflicting conclusions. First, studies of word extension indicate that children are biased to map novel count terms to physical objects and mass terms to non-solid substances. In a study by Soja (1992), English children aged 2;6 extended novel words on the basis of shape for solid objects 90% of the time when presented with count syntax, but only 76% of the time with mass syntax. For non-solid substances, children extended novel words on the basis of substance 91% of the time when presented with mass syntax, and 51% of the time when given count syntax (see also Soja, Carey, & Spelke, 1991, and Imai & Gentner, 1997). Thus, children in her study shifted their extension of novel terms according to their use in mass or count syntax.

However, results from Gathercole (1985) suggest that young children may not distinguish the referential consequences of mass and count syntax. In her study, Gathercole found that children aged between 2;6 and 5;6 quantified mostly by number for both count nouns and mass nouns. In fact, even children as old as 5;6 failed to reliably quantify by continuous extent for mass nouns, unlike the 4-year-olds in Barner and Snedeker (2004), who quantified by continuous extent for both solid and non-solid stimuli named with mass syntax (e.g., *some string*; *some mustard*). These differences are difficult to interpret, since only Gathercole tested both mass and count terms within subjects, and because stimuli used in the studies were common household objects and may have varied in familiarity and lexico-semantic properties.

In any case, the results from Gathercole's study are difficult to reconcile with those from Soja's study of word extension, and thus it remains unclear how children represent the semantics of the mass-count distinction early in acquisition. Also unclear is how the different types of knowledge used in each task are related in young children's linguistic representations. While for adults it seems necessary that word extension should predict quantification (e.g., only words that refer to discrete things quantify over individuals) such links between content and quantification may not yet be established in the minds of 2 or 3-year-olds.

No previous study has explicitly tested the quantification of mass-count syntax for novel terms (i.e. where prior lexical knowledge does not play a role). As a result, previous studies have also not examined the relationship between quantification judgments and word extension for the same objects and substances. However, both of these measures are needed in order to properly assess children's early interpretation of mass-count syntax, before lexical exceptions such as object-mass terms (e.g., *mail, silverware*) arise. For this reason, the present study assessed children's and adult's interpretation of novel mass and count terms in both word extension and quantity judgment paradigms.

Also, it remains an open question how object-mass terms come to quantify over individuals, and what the precise nature of lexical information is that distinguishes mass nouns like *mail* from mass nouns like *string*. Various researchers have suggested that factors such as complexity of structure, occurrence of multiple individuals in spatio-temporal contiguity (Wisniewski, Casey, & Imai, 1997), and shared function (Prasada, 1999) might characterize object-mass terms. The present study examined this question via the manipulation of stimulus complexity and solidity in each of the testing paradigms.

Experiment 1

The first experiment examined three main questions. First, does mass syntax have a strong interpretation early in acquisition, as measured by both word extension and quantity judgment? To examine this question, participants were tested with both methods for the same novel objects, with either mass or count syntax. Second, using this method we explored how the word extension and quantity judgment tasks are related, and whether they make use of the same underlying logical resources. Third and finally, we explored whether an object's relative complexity predicts quantification over individuals when used in mass syntax. What lexical properties, if any, might characterize object-mass nouns like *mail* and *furniture*? This question was tested by varying the shapes and substances of novel referents in the word extension and quantity judgment tasks, to include simple and complex solid objects.

Method

Subjects

Participants were 24 Harvard undergraduates and 32 children ranging in age from 3;0 to 3;6 (mean = 3;3).

Procedures and Stimuli

Each testing session comprised four trials. In each trial the participant was introduced to a novel object and heard the object named with a novel term at least four times using either unambiguous mass syntax or unambiguous count syntax on all four trials. Half of the participants were shown four simple objects and half were shown four complex objects, all of which we will call "standard" objects. The four simple standard objects were: (1) a half egg shape made of red sculpy; (2) a kidney bean shape made from painted-green das; (3) a cork shape made from black Crayola-Magic; (4) an arrow shape made from terracotta. The four complex standard objects were: (1) a gear made from orange playdo; (2) a brass t-shaped plumbing fixture; (3) a suede texture-painted reamer; (4) a clay milk pump stand. The names for these objects, always presented with either mass or count syntax (between subjects), were *fem, tannin, dak,* and *tulver*. Thus, for each trial, the

experimenter introduced the novel object by saying, for example "Oh look, this is some/a fem. Have you ever seen any fem(s) before? Do you think you have some fem(s) at home? That is some/a nice fem isn't it".

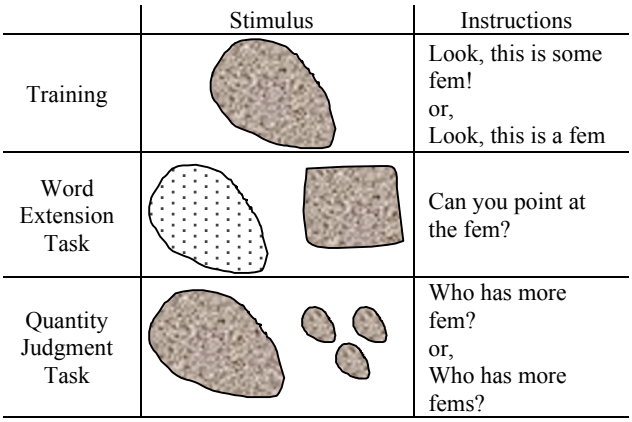

Figure 1. An example of a training trial, word extension trial and quantity judgment trial (shaded oval represents a red sculpy half-egg, white oval represents a styrofoam shape alternative, and shaded square represents a red sculpy substance alternative; small ovals represent mini half-eggs).

Following the naming of each object, participants were asked two questions, the order of which was varied systematically (see Figure 1). First, in the word extension task (see Soja, Carey, & Spelke, 1991), participants were shown two additional objects, one which matched the standard in shape, the other in substance, and were asked to choose which of the two the novel word named: "Show me some/a fem". Second, in the quantity judgment task (see Barner & Snedeker, 2004), participants were shown two characters (Farmer Brown and Captain Blue), one who was shown with the standard object and the other who was shown with three miniature versions of the object. The standard objects had a greater overall mass and volume than the three miniature objects, but were otherwise identical in shape and substance. The side on which the standard or miniatures were shown was varied systematically. Participants were told, "Farmer Brown has some/a fem(s) and Captain Blue has some/a fem(s) too. Who do you think has more fem(s)?" For both tasks, participants pointed to indicate their response. Procedures were identical for adults and children.

Results and Discussion

Word extension trials

Responses for the word extension task were coded in terms of how many times (out of four) each participant extended a word on the basis of shape.

For adults, two main results were obtained (see Figure 2). First, adults used mass-count syntax to guide word extension, extending count terms by shape 3.5 times on average (87.5% overall), compared to only 1.08 times on average (27% overall) for mass syntax, F (1, 16) = 31.1, p < .001. Second, adults also showed a main effect of stimulus type, extending novel words for complex objects 2.83 times on average (71.8%), compared to 1.75 times on average (43.8% overall) for simple objects, F (1, 16) = 6.3, p < .05. There were no interactions.

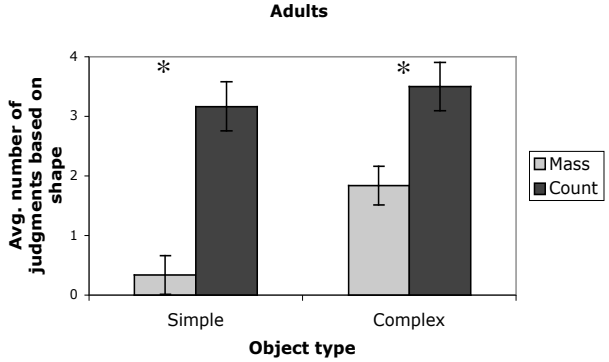

Figure 2. Word extension by adults for novel mass and count nouns.

These results indicate that adults use syntax to guide word extension, but that extension is also influenced to a large extent by the relative complexity of stimuli. Thus, mass-count syntax does not appear to be the sole factor determining word extension behavior for adults. More general properties of referents appear to play a role.

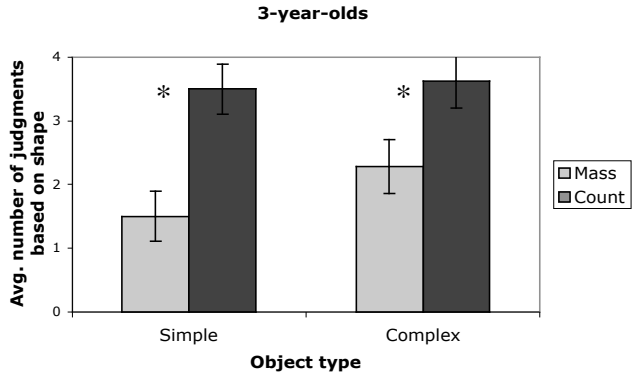

Figure 3. Word extension by 3-year-old children for novel mass and count nouns.

The children also used mass-count syntax to guide word extension (see Figure 3). They extended novel count terms by shape 3.56 times on average (89% overall), compared to 2 times on average (50% overall) for novel mass nouns, F (1, 24) = 16.9, p < .001. However, children showed no main effect of stimulus type, and no significant interactions.

Quantity judgment trials

Responses for the quantity judgment task were coded in terms of how many times (out of four) each participant chose the array with the greater number of objects. For adults, two main results were obtained (see Figure 4). First, as was the case with word extension, adults used mass-count

syntax to guide quantity judgment, using count terms to quantify by number 3.75 times on average (93.8% overall), compared to .67 times on average (16.8%) for mass nouns, F (1, 16) = 85.6, $p < .001$. Second, adults quantified by number 2.67 times on average (66.8% overall) for complex items, which was significantly more than the 1.75 times on average (43.8%) for simple items, F (1,16) = 7.6, $p < .05$. This difference appeared to be due in part to adult's interpretation of mass syntax. While adults quantified by number for some mass nouns that named complex objects, they never did so for mass nouns that named simple objects. This is interesting, since it suggests that for adults object complexity may be sufficient to permit individuation using mass syntax (i.e. the use of object-mass terms).

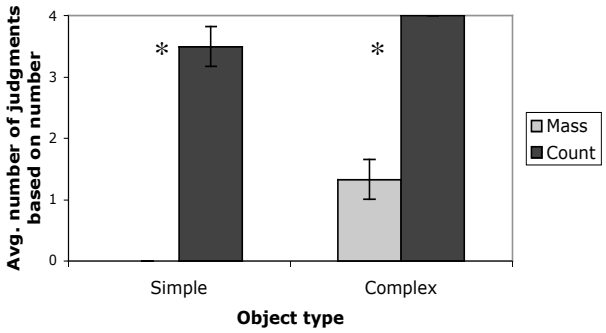

Figure 4. Quantity judgment by adults for novel mass and count nouns.

In contrast to adults, children quantified mostly by number for both simple and complex objects, for both mass and count syntax (see Figure 5). As a result, children showed no significant effect of syntax, F (1, 24) = 2.2, $p > .1$, nor of stimulus type, F (1, 24) = .09, $p > .8$.

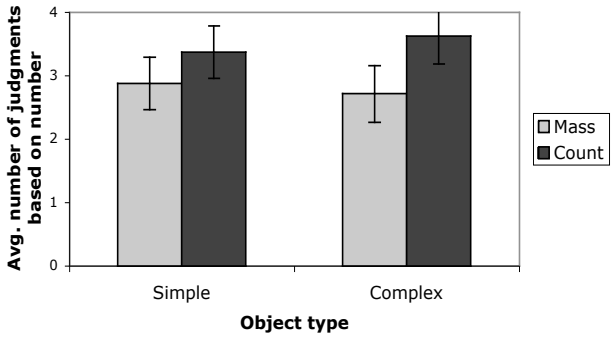

Figure 5. Quantity judgment by 3-year-old children for novel mass and count nouns.

The results of Experiment 1 indicate that while both children and adults used mass-count syntax to guide word extension, only adults appeared to use this information to guide quantity judgment. This suggests that word extension and quantity judgment may tap discrete logical resources. Among the possible explanations for this are: (1) an incomplete understanding of mass-count syntax, (2) a problem interpreting the term "more", or (3) a bias to quantify by number for discrete physical objects. These possibilities are examined in Experiment 2.

Experiment 2

The results of Experiment 1 are consistent with the idea that the interpretation of mass syntax is unspecified from early in acquisition, and allows quantification over individuals or non-individuals. However, the results are also consistent with several other possibilities, including a response bias to quantify by number regardless of syntax, or an interpretation of "more" as quantifying only by number. To rule out these possibilities, we tested participants with non-solid substances. If responses in Experiment 1 were due to either a response bias or a strong interpretation of "more", then responding on the basis of number should persist for both mass and count nouns. However, a change in children's quantification for only mass syntax would represent evidence that children modulate judgments based on mass-count information, but allow quantification over individuals when referents are construed as such. This, in turn, would support the claim that mass syntax, but not count syntax, has an unspecified interpretation regarding individuation.

Method

Subjects

Participants were 16 Harvard undergraduates and 23 children ranging in age from 3;0 to 3;6 (mean = 3;3).

Procedures and Stimuli

Procedures for Experiment 2 were identical to those used in Experiment 1. However, solid stimuli were replaced with non-solid substances. The standard substances were: red media mixer, green butter, orange paint, and brown hair gel.

Results and Discussion

Results suggest that only the adults used mass-count syntax to guide word extension (see Figure 6). Adults extended count nouns by shape 2.57 times on average (64% overall) and mass nouns 0.5 times on average (13% overall), a difference that was marginally significant, F (1, 12) = 4.8, $p < .06$. Children extended count nouns by shape 1.82 times on average (46% overall) and mass nouns 1.42 times on average (36% overall), which was not significant.

However, both the 3-year-olds and adults appeared to use mass-count syntax to guide quantity judgment (see Figure 7). Adults based judgments on number 3.83 times on average for count syntax (96% overall) and 0.5 times on average for mass syntax (13% overall). This difference was significant, F (1, 12) = 40, $p < .001$. Children based judgments on number 1.82 times on average for count syntax (46% overall) and 0.5 times on average for mass syntax (13% overall), a difference that was marginally significant, F (1, 23) = 4.1, $p < .06$. There was also a large effect of task order, F (1, 23) = 11.7, $p < .05$, that reflected a much greater distinction of mass-count syntax when

quantity judgment was tested after word extension. Children who were given the tasks in this order quantified by number 2.67 times on average for count syntax (compared to .8 times in the alternative order) and 0 times on average for mass syntax (compared to 1 time on average in the alternative order).

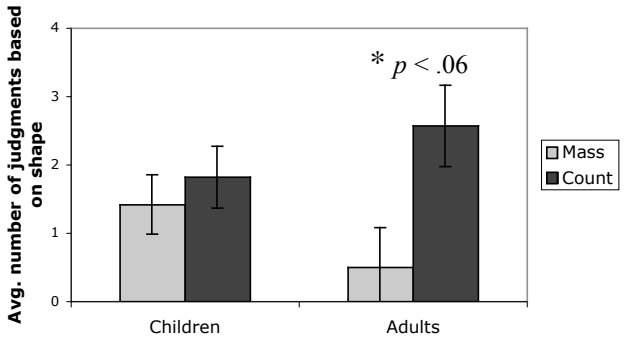

Figure 6. Word extension by 3-year-olds and adults for mass and count nouns that label non-solid substances.

A review of the word extension data revealed a similar trend, where performance on word extension more closely resembled adult performance when it followed quantity judgment, suggesting an overall effect of accumulated input on mass-count sensitivity over the course of the experiment.

Overall, results suggest that children have more than one interpretation for the word "more", but that its meaning is shifted primarily by the ontological category of referents, rather than mass-count syntax.

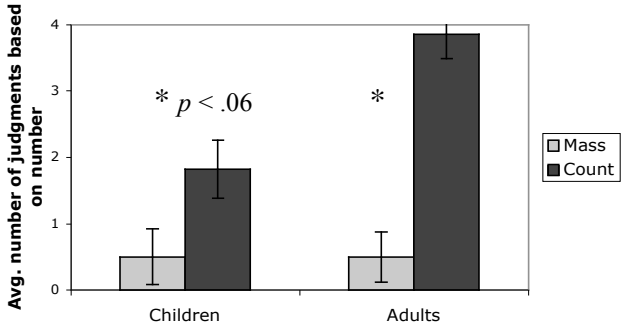

Figure 7. Quantity judgment by 3-year-olds and adults for mass and count nouns that label non-solid substances.

General Discussion

Experiment 1 revealed two main results. First, for the word extension task, both children and adults used mass-count syntax to guide their judgments, extending count terms on the basis of shape and mass terms on the basis of substance. This replicates results found for English-speaking 2.5 year olds (see Soja, 1992). Second, for solid objects, adults used mass-count syntax to guide quantity judgment and used mass nouns to quantify over individuals only for complex objects. Children, however, interpreted both novel mass and count terms as quantifying by number regardless of referent type, suggesting a lack of strong quantificational interpretation for mass syntax.

Results from Experiment 2 indicated that children could use mass-count syntax to guide quantification for non-solid substances. Across conditions, children's interpretation of mass syntax appeared more affected by referent type than the interpretation of count syntax. The number bias found in Experiment 1 disappeared mainly for mass nouns when referents were changed from discrete physical objects to non-solid substances.

Table 1
Summary of results for Experiments 1 and 2
(✓ = effect of syntax; ✘ = no effect of syntax)

	Solids		Non-solids	
	W.E.[1]	Q.J.[2]	W.E.	Q.J.
3-year olds	✓	✘	✘	✓
Adults	✓	✓	✓	✓

[1] Word extension
[2] Quantity judgment

These results (summarized in Table 1) have three important consequences. First, children appear to employ distinct mechanisms for performing quantity judgments and word extensions. The main source of this difference, and of the difference between children and adults in this study, was children's treatment of simple solid objects. While both adults and children quantified by number for mass nouns that referred to complex objects, only children quantified by number for mass nouns that referred to simple objects and that were extended by substance. Interestingly, these results appear to be consistent with observations that young children are biased to enumerate spatio-temporally defined individuals when counting segmented objects (e.g., counting a fork cut in half as two forks; see Shippley & Shepperson, 1990; Wagner & Carey, 2003). In these tasks, children are unable to use criteria of individuation for specific words, despite being able to correctly extend them. By analogy, when performing quantity judgments, children seem to ignore criteria of individuation for newly learned words and instead employ the more primitive criteria of the "object" sortal (Xu, 1997). Children appear to base quantification on spatio-temporal individuals whenever arrays are composed of physical objects, and only later in acquisition use specific sortal information to guide judgments.

It should be noted that although a spatio-temporal bias may account for the content of individuals that children quantified (i.e. rather than specific sortal knowledge) it cannot explain the failure of mass syntax to determine the dimension of measurement. Our evidence suggests that 3-year-olds are only beginning to understand the effect of mass-count syntax on quantification, and that they do not have strong syntax-semantics mappings of the type proposed by Bloom (1999). Thus, this study provides further evidence children never use one-to-one mappings

between syntax and semantics of the type proposed by Bloom (1999). Instead, it seems that only count syntax is ever truly specified for a uniform interpretation (Barner & Snedeker, 2004).

Given children's difficulty using syntax to guide quantity judgment, how do they succeed with word extension? Minimally, the task requires an ability to distinguish mass and count distributional frames and to determine a novel word's criteria of application, or content. One possibility is that these two types of knowledge are sufficient for solving word extension, and may operate somewhat independently of actual mass-count semantics. For example, children may observe that a novel term like *blicket* has been used in the same syntax as a word like *plastic*, for which shape is an irrelevant dimension, and therefore extend the word on the basis of substance. Novel word extensions may be made on the basis of correlations between mass-count syntax and previous extensions, and may be the product of simple mappings between content and syntax, bypassing noun phrase quantification altogether.

Based on this, our results suggest an ability to use mass-count syntax to guide word extension by 2;6 (e.g., Soja, 1992) may not reflect mature knowledge of mass-count semantics. Even by 3;6, children are only beginning to understand the full effect of mass-count syntax on quantification, which arguably defines the distinction. Early in acquisition, children may approximate adult behavior conditions by exploiting correlations between content and distributional frames, and by employing ontologically based biases for interpreting quantifiers like "more". Sometime between 3;6 and 4, children appear to recognize that count syntax specifies number as a dimension for comparison, and that in this way it differs from mass syntax (Barner & Snedeker, 2004). Mass nouns continue to be interpreted based on lexical properties, as shown by adults in this study, and never specify a uniform dimension for measurement.

Cultural Differences in the Cognition and Emotion of Conditional Promises and Threats – Comparing Germany and Tonga

Sieghard Beller (beller@psychologie.uni-freiburg.de)
Andrea Bender (bender@psychologie.uni-freiburg.de)

D-79085 Freiburg, Germany

Abstract

When addressing conditional inducements using a multi-level approach, several cognitive components appear to be of basic character: linguistic preferences for either a promise or threat are connected to the motivational background; the concepts themselves are unilateral and complementary; and emotional responses in subsequent interactions follow appraisal-theoretic predictions. Whether these apparently essential components really are basic was examined in a cross-cultural experiment conducted in Tonga. The results support the conceptual universality; however, in practice, the Tongan participants tended to avoid threats in favor of promises and indicated less anger following broken promises.

Introduction

In pursuing their own individual goals, people occasionally feel a need to change the behavior of others accordingly. When asking to have one's intentions considered is not of much use, a strategy often chosen is to formulate a conditional promise or threat. For instance, a mother longing for silence may tell her noisy son: "If you are quiet for the next hour, I will give you an ice-cream." Or, being already unnerved, she may say instead: "If you are not quiet for the next hour, there will be no TV this afternoon!" Being intrigued by the pleasant anticipation of an ice-cream the boy might feel motivated to fulfill her request; if she then fails to keep her promise, his positive affects will turn negative.

Conditional promises and threats operate, as these introductory examples show, with goals, expectations, incentives or penalties, and obligations (cf. von Wright, 1962). They express personal motives and are formulated in a specific linguistic manner (Fillenbaum, 1978). They demand a decision whether or not to cooperate, and subsequent actions are often followed by emotional reactions. In order to efficiently work as inducements, knowledge about these components needs to be – and usually is – shared among the partners of an interaction.

But is this knowledge also shared across cultures? In other words, is the understanding of conditional inducements culture-specific or do conditional promises and threats belong to the core concepts of human thinking and acting that are universally equal? If the latter is the case, are there certain aspects of conditional inducements that vary across languages and cultures? Will the interactions subsequent to inducements universally elicit emotional reactions, and if so, are the same emotions then elicited, or will appraisals – and thus the emotional reactions – differ?

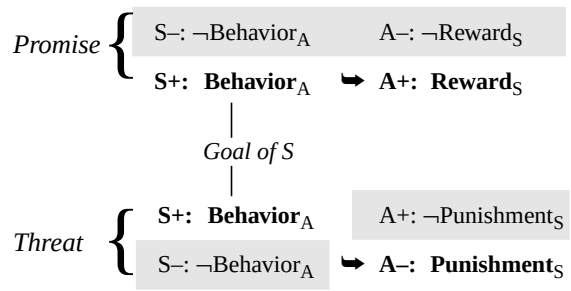
In the reasoning tradition, the analysis of people's understanding of conditional promises and threats focuses on the conditional relation (e.g., Evans & Twyman-Musgrove, 1998; Newstead, Ellis, Evans & Dennis, 1997). By evaluating the inferences that people draw from such statements with the yardstick of propositional logic, it was possible to identify several extra-logical factors: the temporal order of the actions, the promisor's control of the incentive, and the directionality. While this approach helps to detect effects of particular contents on reasoning, it is not sufficient to explain them. To overcome this limitation, a broader multi-level approach was recently proposed and empirically tested (Beller, 2002; Beller, Bender & Kuhnmünch, 2004; cf. Beller & Spada, 2003). It builds on a motivational analysis of why conditional inducements are used, and integrates linguistic, deontic, behavioral and emotional aspects.

So far, most of the experimental data has been gathered in "Western" cultures, leaving the question of whether consensus on conditional inducements may extend beyond cultural boundaries open. To tackle this question, we therefore replicated one of our German experiments in a culture that largely differs from our individualistic Western culture: the Polynesian Kingdom of Tonga. Before presenting the results, we will address the theoretical background and give a short description of relevant aspects of Tongan culture.

Components of Conditional Inducements

Conditional promises and threats are speech acts (Searle, 1969) that are motivated by personal goals (i.e. to obtain something with another person's support) and expectations of this person's behavior. The speaker (S) wants an addressee (A) to perform a certain behavior with a positive value for the speaker (S+: Behavior_A). The speaker must expect that the addressee is *not* willing to show this behavior voluntarily (S–: $\neg\text{Behavior}_A$); otherwise an inducement would not be necessary. Thus, the speaker has to induce a behavioral change, which can be motivated in two ways: by promising to reward the desired behavior (➥ A+: Reward_S) or by threatening

to punish the undesired behavior (➥ A–: Punishment_S). These consequences should be under the speaker's control and should not occur for any other reason, as otherwise they would not be able to develop their motivational effect. The different motivational background of promises and threats are summarized in the following schemas (grey boxes depict the expected actions without the inducement):



In both cases, the addressee can freely decide whether to cooperate or not; the speaker then responds to the addressee's behavior, that is, the actions are ordered temporally. Further, the speaker may use a conditional "If P, then Q" to express the inducement. A conditional points out a necessary consequence "Q" of an antecedent possibility "P", and that is exactly what the speaker intends to do on the motivational level. The canonical formulations are:

"If you do P [S+], then I will reward you with Q [A+]"
"If you do P [S–], then I will punish you by Q [A–]".

Due to the temporal order of the events, neither of the conditionals is reversible, and yet they are tightly interwoven. The speaker always announces (explicitly or implicitly) that he or she will react positively after the addressee has shown the desired behavior, and negatively otherwise. The threat may thus be interpreted as implying the complementary promise

"If you *refrain* from doing P [S+],
then I will *not* punish you by Q [A+]."

While the addressee can freely decide whether to cooperate or not, the speaker cannot. If the addressee cooperates, the speaker is *obligated* to cooperate as well, and when intentionally violating this obligation, the speaker cheats the addressee.

Because the addressee is induced to change a planned behavior – and may experience a positive or negative consequence – the respective interaction will most probably elicit an emotional reaction, as the event has considerable goal relevance (Lazarus, 1991). According to appraisal theories (cf. Ellsworth & Smith, 1988; Roseman, Antoniou & Jose, 1996; Scherer, 1997), joy should be elicited when the addressee obtains what was promised to him or her, relief in the case of avoided punishment, and anger in the case of being cheated.

These linguistic and emotional predictions were confirmed in two studies with German samples (Beller, 2002; Beller, Bender & Kuhnmünch, 2004). Participants preferred the canonical conditionals as appropriate formulations for an intended promise or threat. These are understood as not reversible, but as implying the complementary threat (or promise). The emotional reactions were chosen by the participants as predicted by appraisal theories. The question remains, though, of how these components are defined by members of a completely different culture, particularly one in which individualism is not as marked as in "Western" culture. Will their linguistic preferences and emotional reactions converge with – or diverge from – those obtained in Germany?

The Context of Social Interactions in Tonga

The Kingdom of Tonga, an island state in the Southwestern Pacific with a Polynesian culture, is inhabited by roughly 100 000 people. The island group of Ha'apai, where the data was collected, is one of its most traditional areas with approximately 10 000 people living on two main islands and fifteen outer islands.

Tongan society is hierarchically structured with older people having higher rank than younger ones, sisters higher than brothers, and nobles higher than commoners. While this rank is ascribed through birth, status can be acquired through individual efforts. However, these individual efforts need to pursue common interests, and among the most prestigious behavior is therefore engaging in social activities, keeping social ties and complying with social norms (Bernstein, 1983; Marcus, 1978). Social harmony is particularly emphasized and consequently, negative emotions such as anger (*'ita*) or envy (*meheka*) as well as open conflicts are disapproved of. Failing to restrain one's negative emotions is shameful and may diminish one's social status (Morton, 1996). Cooperation and sharing with others are core values. In exchange situations, certain (though mostly implicit) rules apply, depending for instance on the object of the deal or the participants' relative social status and rank (e.g. Bender, 2002; Evans, 2001).

Most of this contextual knowledge still does not reveal how Tongans understand and deal with conditional promises and threats. In principle, we presumed that the basic *understanding* of conditional inducements does not differ across cultures, but that their *use* may differ: depending on what is socially more accepted, either promises or threats may be preferred. With regard to appraisal processes, we further presumed a similar pattern of emotional responses. Taking into account the disapproval of socially disruptive behavior, however, we also expected a smaller proportion of both threats and indication of anger in the Tongan sample.

Experiment

In order to investigate the impact of culture on understanding and dealing with conditional inducements, we replicated a study we had conducted on linguistic preferences and emotional reactions in Germany (Beller, Bender & Kuhnmünch, 2004, Experiment 1) in Tonga.

Method

Participants. Sixty-seven students from two classes of St. Joseph's College in Pangai participated in the experiment. St. Joseph's College is the second largest of four secondary schools in the district center of the Ha'apai island group. Thirty-one students were male and thirty-five female (one did not indicate his or her gender). The mean age was M = 15.4 years (SD = 0.83; *range*: 14-17 years). Both classes received a small gift for their participation in the form of a contribution (50 pa'anga, approximately 33 US dollars) to their class funds.

Materials. As in the original study, we used two pairs of questionnaires that referred to a situation in which a boy would like to obtain something from a schoolmate. Sione wants to borrow Finau's bike, while Finau wants Sione to help him with his homework. Within each pair, the speech act was varied. In the first pair, Sione was in the role of the speaker and used either a promise to reach his goal (promise version) or a complementary threat (threat version). In the second pair, the role allocation was switched, with Finau now in the role of the speaker trying to reach his goal either by a (reversed) promise or by a complementary threat. Each questionnaire comprised four tasks.

(1) In the *formulation task*, the individual goals of both boys were given. For example, the promise version of Sione's inducement reads as follows (threat version printed in square brackets): *Usually, Finau doesn't lend his bike to his schoolmates. However, Sione wants to borrow it today. Sione tries to reach this goal by promising [threatening] Finau [with] something. Sione knows that Finau would like his help with his homework today, but usually Sione does not help him [and usually Sione helps him]*. The instructions then required the participants to choose the most appropriate conditional for the speaker's promise [threat] from four possible formulations: the canonical, the complementary, and the two reversed statements.

Each of the other three tasks first presented the speech act in canonical form, for example: *Sione promised: "Finau, if you lend me your bike, then I will help you with your homework" [Sione threatened: "Finau, if you do not lend me your bike, then I will not help you with your homework."]* (2) The *sequence task* asked participants to identify the typical sequence of actions once the conditional promise or threat has been uttered: Will Finau or Sione be the first to decide to act? (3) The *inference task* asked participants to draw the most probable conclusion from the given canonical conditional: What follows – the complementary, the reversed, or the reversed-complementary conditional? (4) The *emotion task* stated that the addressee has fulfilled the speaker's goal. The instruction then required participants to indicate first the speaker's action when "keeping the rule" (vs. "not keeping the rule") and second, the addressee's feeling towards the speaker afterwards. Four critical emotions were given (Tongan translation in brackets): joy (*fiefia*), relief (*fiemālie*), sadness (*loto-mamahi*), and anger (*'ita*). For exploratory purposes, we also included shame (*mā*), un-amusement (*ta'eoli*) and anxiety (*manavahē*), as these emotions seem to be particularly salient in the Tongan context. Participants were instructed to choose the most appropriate emotion.

All materials were presented in the participants' native language, that is Tongan in this study and German in the original study. Both languages have close equivalents to the English terms "promise" and "threat", and the situations described are familiar in both cultures.

Design and procedure. A between-subject design was used. Participants were randomly assigned to one of the four experimental conditions (n = 16 or 17 for each) corresponding to the four questionnaires. The data collection took place in the classrooms. Each participant received a booklet with a general instruction and the four tasks in the following order: formulation, sequence, inference, and emotion task. Participants were instructed to answer all questions in the given order, and they were granted as much time as they needed.

Results

As we found only marginal differences between the two promise versions and between the two threat versions, the data is reported in aggregated form. The comparative data of the German study is taken from Beller, Bender and Kuhnmünch (2004, Experiment 1).

Formulation task: We expected participants to choose the *canonical* promise or threat. The formulation preferences are shown in Table 1. In the German sample, on average 89.2 % of the participants chose the canonical form equally for promises and threats ($\chi^2(1, N = 65) = 1.34$; $p = .247$). The Tongan results differed from this in two respects. First, the canonical conditional was chosen less frequently (52.2 % on average), and second, this difference mainly resulted from a specific formulation preference: while most Tongan participants also preferred the canonical promise, many of them indicated that, when a *threat* was to be made, the speaker should rather use the complementary *promise* instead ($\chi^2(1, n = 52) = 6.10$; $p = .014$).

Sequence task: We expected both conditional promises and threats to be understood as unilateral speech acts that imply a typical action sequence: the addressee

Table 1: Proportions of choosing each conditional as the speaker's adequate promise or threat.

	Germany		Tonga	
Conditional	Promise (n = 32)	Threat (n = 33)	Promise (n = 33)	Threat (n = 34)
Canonical	**.94**	**.85**	**.64**	**.41**
Complementary	.06	.15	.12	.38
Reversed	–	–	.18	–
Rev.-complementary	–	–	.06	.21

Table 2: Proportions of choosing the most adequate implication of a given promise or threat.

	Germany		Tonga	
Conditional	Promise (n = 33)	Threat (n = 31)	Promise (n = 33)	Threat (n = 34)
Canonical	*given*	*given*	*given*	*given*
Complementary	**.88**	**.84**	**.48**	**.65**
Reversed	.09	.16	.45	.21
Rev.-complementary	.03	–	.06	.15

first decides whether or not to cooperate. The predicted sequence was chosen by 87.8% of the participants in the German sample (N = 66) and by 74.6% in the Tongan sample (N = 67) aggregated across all four task versions ($p < 0.001$ based on the binomial distribution with $r = 1/2$ being the probability of guessing).

Inference task: We expected participants to choose the *complementary* conditional "*If not*-P *then not*-Q" as the most appropriate inference from a given canonical promise or threat "*If* P *then* Q". The results are shown in Table 2. In the German sample, 85.9 % of the participants inferred the predicted conditional on average. There was no significant difference between promises and threats ($\chi^2(1, n = 63) = .648$; $p = .421$). Again, the Tongan data differed from the German data – the complementary conditional was chosen less frequently (56.7 % on average) – and this difference again resulted from a specific inferential preference. While most Tongan participants also preferred the complementary conditional as the most reasonable inference from a threat, many of them – consistent with their formulation preference – avoided inferring the complementary *threat* from a promise in favor of the reversed *promise* ($\chi^2(1, n = 60) = 3.79$; $p = .051$).

Table 3: Proportions of choosing emotional reactions of the addressee (+ positive; – negative) when the speaker did vs. did not keep the rule.

		Germany		Tonga	
Emotion		Promise (n = 33)[a]	Threat (n = 33)[a]	Promise (n = 33)	Threat (n = 34)
		The Speaker Kept the Rule			
Relief	(+)	.27	.52	.21	.29
Joy	(+)	.67	.18	.70	.62
Others	(–)	.09	.30	.09	.09
		The Speaker Did Not Keep the Rule			
Sadness	(–)	.09	.06	.48	.53
Anger	(–)	.94	.91	.27	.26
Others	(+/–)	–	–	.24	.21

[a] Due to missing/double answers, the proportions do not always add up to 1.00 in these columns.

Emotion task: Participants were first required to decide which action the speaker has to take in order to keep "the rule" (i.e., to cooperate given that the addressee cooperated before) or not to keep "the rule" (i.e., to react defectively even though the addressee fulfilled the speaker's goal). Almost all participants indicated the appropriate action (all participants in the German sample and 96.3% in the Tongan sample, aggregated over both questions; n = 134 answers).

How does the addressee respond emotionally after the speaker did or did not keep "the rule"? The results of the emotion tasks are shown in Table 3. In line with appraisal theories of emotion, the addressee was said to feel a positive emotion if the speaker kept the rule (85.8 % positive vs. 14.2 % negative), and a negative emotion was said to result if the speaker did not keep the rule (3.0 % positive vs. 97.0 % negative; $\chi^2(1, n = 267$ answers) = 185.3; $p < 0.001$).

Separate analyses were performed for the cooperative and the non-cooperative situation in both samples. The dependent variable "emotion" was classified into three categories in both cases: relief, joy, and all other emotions in the cooperative situation, and sadness, anger, and all other emotions in the uncooperative situation.

In the German sample, keeping the promise resulted in joy (joy: 66.7 %; relief: 27.3 %), while in the case of an avoided threat, relief predominated (joy: 18.2 %; relief: 51.5 %; $\chi^2(1, n = 54) = 10.65$; $p = 0.001$). Interestingly, 24.2 % of the participants indicated that the addressee feels angry, apparently because the addressee was "forced" to cooperate by a threat, as described by Heilmann and Garner (1975). In the Tongan sample, the addressee was quite uniformly said to feel joy (joy: 65.7 %; relief: 25.4 % on average), independent of the speech act ($\chi^2(1, n = 61) = 0.604$; $p = 0.437$).

In cases where the speaker did not keep the rule, we expected a difference between the two cultures with regard to the attribution of anger. The data supports this prediction. While the German participants predominantly ascribed anger (anger: 92.4 %; sadness: 7.6 %), half of the Tongan participants indicated that the addressee will feel sad in this situation (anger: 26.9 %; sadness: 50.7 %; $\chi^2(1, n = 118) = 43.9$; $p < 0.001$).

Discussion

The cultural comparison revealed many commonalities in the understanding of conditional promises and threats, but also some characteristic differences.

First, both German and Tongan participants chose formulations and inferences with the addressee's action in the antecedent proposition in accordance with the typical action sequence "addressee first". The Tongan participants, however, tended to avoid explicit threats and preferred to use promises instead.

Second, conditional inducements have a potential for emotional interactions in both cultures. Positive and

negative emotions were generally attributed in line with appraisal-theoretic predictions. Consistent with findings from another domain (Bender, 2001), indication of angry reactions is largely reduced in Tonga: in Germany, anger clearly predominated over sadness after the speaker's defection, while the Tongan sample showed the reversed pattern, with sadness twice as frequent as anger. While we had expected a difference for the negative emotions, we had not expected any difference for the positive ones, but found that the German students distinguished between joy and relief depending on the speech act whereas the Tongan participants did not.

In general, the differences found in the Tongan sample can be explained by the cultural background.

The tendency of roughly half of the participants to avoid threats in favor of promises is in accordance with respective social rules. In addition, as cooperation and particularly sharing with others are core values in Tongan society, threats may simply be not appropriate as a means of initiating an exchange.

A conclusion from the affective differences is not as easy to draw. With regard to the emotional reaction upon the speaker's non-cooperation, two explanations are conceivable: the lack of anger indication may either be due to the fact that anger is socially not acceptable or that it arises less often in such situations. The latter could be the case if not fulfilling one's obligation to reciprocate is regarded as so unusual that this failure is appraised differently, thus giving rise to different emotions.

Taking together findings from other domains allows us to presume that our Tongan participants may indeed have appraised the described event differently from the German sample. Several studies have indicated that – despite the culture independence of most appraisal dimensions – cultural differences do occur with regard to goals and values and with regard to certain appraisals that involve rather complex concepts such as causation or responsibility (e.g., Mauro, Sato & Tucker, 1992; Norenzayan, Choi & Nisbett, 1999). The latter concepts are directly relevant for anger as this emotion is elicited if another person is held personally responsible for a negative event. Personal responsibility, however, is not as easily ascribed in some cultures as it is in Western ones. Particularly in cultures with an interdependent self-concept (cf. Markus & Kitayama, 1991), causal attributions are more often also made in view of the circumstances (cf. Morris, Nisbett & Peng, 1995). The ambivalent or rather open description of the experimental scenario may thus lead to two different interpretations of the speaker's non-cooperation: in Germany, participants may interpret the scenario as involving a rather high level of personal responsibility, while the Tongan participants may also take circumstances into account. This difference would then result in diverging emotional responses: a dominance of angry reactions in Germany, but one of sad reactions in Tonga. This interpretation is supported by findings from a subsequent experiment in Germany (Beller, Bender & Kuhnmünch, 2004, Experiment 2) in which we varied personal responsibility: Anger dominated in situations with high personal responsibility and decreased in favor of sad reactions in situations with low responsibility.

The different indications of joy versus relief upon mutual cooperation after a threat also reflect cultural differences. On the one hand, this may again be due to different appraisal patterns. Focusing on the positive outcome of cooperation elicits joy (as in the Tongan sample), while focusing on the transition from an expected negative outcome to the final positive one elicits relief (as in the German sample). On the other hand, the difference may also have lexical origins. There is no Tongan word that precisely translates as "relief". The word we chose (after discussing the content scenarios with our Tongan partners) was *fiemālie*. This comes closest to "relief", but also encompasses "to be easy in mind, contented, satisfied, free from pain, discomfort or sorrow". These connotations could also be the reason why some of our Tongan participants did not choose *fiemālie* in the particular situation.

This last point highlights a particular difficulty of language-based cross-cultural research: even if terms exist that have the same core meaning across languages, they often contain a spectrum of connotations that do not map. Although well known (e.g., Tihanyi, 2002), this problem is not easy to resolve. While a linguistic tool has been developed in recent years for identifying and describing such differences in meaning (Wierzbicka, 1993, 1999), there is no way to circumvent them. Data interpretation thus requires the differences in meaning to be noted, and may indeed even profit from this insight into different semantic fields of a concept.

As we have seen, conditional inducements are fairly complex concepts as they involve personal values and goals, a social consensus on reciprocity and obligations, the consideration of the situational context, and an estimation of the addressee's goals and the appropriateness of the chosen inducement. Complex concepts by no means *generally* converge across cultures, as has been shown to be the case, for instance, with concepts of causality (Boyer, 1996; Morris, Menon & Ames, 2001), concepts of the self (Kanagawa, Cross & Markus, 2001), or even spatial concepts (Levinson, 1996). Our cross-cultural comparisons suggest, though, that concepts of deontic social norms (Bender & Beller, 2003) and of promises and threats comparable to ours do exist in a completely different culture. When used to induce an exchange, however, they are used somewhat differently, and subsequent interactions may result in different emotional responses.

In a certain sense, the results of the study produced more questions than they answered. For this reason, a replication of the second experiment by Beller, Bender and Kuhnmünch (2004), which addresses the ascription of responsibility more thoroughly and includes deontic aspects, is being conducted in Tonga. As it is part of an anthropological inquiry into the cultural context of promises and threats, participant observation and in-depth interviewing will provide further data that may bolster the ecological validity of our present results.

Acknowledgments. The data collection took place during field research of the second author in Tonga, which was funded by a grant from the Deutsche Forschungsgemeinschaft (DFG). We would like to thank Josef Nerb, Hannah Swoboda, and Stefan Wahl as well as Dan Sperber for discussion and valuable comments on earlier versions of this paper. We are particularly indebted to Moana and Sione Faka'osi for the Tongan translation of the material, for the opportunity to conduct the research at St. Joseph's College in Pangai, and for their unfailing support.

Retrieval Structure Construction During Reading: Experimentation and Simulation

Abstract

The aim of this study was to investigate the construction of a retrieval structure during reading, according to the hypothesis that text macrostructure is used in Long-term working memory (Ericsson & Kintsch, 1995) to maintain encoded information in an accessible format. We first designed an experiment for testing the hypothesis that retrieval structure is a macrostructure of the text. Then, we conceived and run a model inspired by CI-LSA Framework (Kintsch, Patel & Ericsson, 1999) in which a generalization process create macropropositions. Results are that simulation data were found to be highly correlated with participants' data.

Macrostructure as Retrieval structure

Classical view of working memory assumes that during reading relevant information is stored in a Short Term Memory Buffer (STMB; Baddeley, 2000; Kintsch, 1988). In contrast, Ericsson & Kintsch (1995) argued that during reading, readers could encode information in an accessible format in a retrieval structure in long-term working memory (LTWM) consisting of retrieval cues associated with encoded information in Long Term Memory (LTM). Ericsson and Kintsch (1995) showed that clearing STMB by using a reading interruption procedure (Glanzer, Fisher & Dorfman, 1984) does not lead to comprehension impairment. We have also shown that the more a text is familiar, the more readers can construct an efficient LTM retrieval structure based on the content of the text (Bellissens & Denhière, 1998; Denhière & Bellissens, 1999).

A CI-LSA Framework has been proposed (Kintsch, 1998 ; Kintsch, Patel & Ericsson, 1999) to explain LT-WM intervention in the comprehension process. The main characteristic of this framework is the combination of a model of semantic memory, LSA (Landauer & Dumais, 1997), and of a model of comprehension, CI (Kintsch, 1988).

LSA represents potential signification of words belonging to a textual corpus in a semantic space. In the semantic space, vectors represent the words and the cosine of the contained angle of two vectors is an estimation of their respective words similarity. The more the cosine is close to 1, the more the two words are considered as semantically similar. The cosine similarity can be used to weight links in an associative network in which each node is a word. In CI, the use of associative network is the way to represent activated knowledge associated with concepts and propositions derived from text processing. Hence, architecture of a text segment representation in CI-LSA is a network that comprehends propositions and concepts (nodes) linked with each other by relations (links) weighted by LSA cosine. This CI-LSA combination improves the previous comprehension model proposed by Kintsch (1988) by the fact that LSA can model knowledge base in CI.

While Ericsson and Kintsch (1995) assumed that the episodic structure of a text could be a retrieval structure, Kintsch, Patel and Ericsson (1999) did not explain exactly how the CI-LSA framework simulates the construction of a retrieval structure. We assume that each text segment processing results in an individual episodic trace. We propose that the set of episodic traces generated by the text processing is replaced by a macrostructure, resulting from the application of a generalization process (O'Reilly & Rudy, 2000). This generalization process generates macropropositions that are associated with the encoded information for further use as semantic retrieval cues. We argue that if two relevant segments of a text, associated with such retrieval cues, are given after a reading interruption, readers should easily reinstate these retrieval cues and counteract the interruption effect. For example, imagine an individual reads a text about the invention of a

machine. He/she reads that the machine has a particular function. Then, the text says that the machine includes one component with a specific function, then a second component with an other specific function. At this moment, the reading is interrupted and then resumed after the presentation of a probe sentence. After Ericsson and Kintsch (1995) and Bellissens and Denhière (2003), the probe sentence should help reader for reinstated semantic cues in STM associated with information encoded in LTM when the previous text has been processed.

The present paper tries to explain how this reinstatement usually occurs and how the reinstatement depends on the organization of the retrieval structure. As we assume that the construction of the retrieval structure is a generalization process, we predict that a sentence mentioning the two components of the machine is a better probe sentence than a sentence comprising two distinct facts: the machine function and the function of a machine component; Indeed, the first type of probe sentence relies on a particular part of the retrieval structure of the text, a macroproposition: machine usually possesses components. The second relies on two separated parts of the macrostructure: the functions of the machine and its component.

What we have just described is a formal view of the conditions we constructed for the following experiment. We predict that if a categorical probe sentence (CAT) is inserted after a reading interruption, readers should resume the reading faster than with a functional probe sentence (FUN).

Table 1: Texts facts

Nb	Sentence
Title	The /Machine/
1	The /Machine/ was invented in /Date/ by /Inventor/
2	The /Machine/ possesses a /Component 1/ to /Component 1 Function /.
3	The /Machine/ is mainly used to /Main Function of the Machine/.
4	The /Machine/ possesses a /Component 2/ to /Component 2 Function /.
5	This component thus contributes to the function of the /Machine/.
6	Since its invention, the /Machine/ is an equipment that was modernized.
7	The modernization of the /Machine/ was useful for the development of /Human Domain/.
CAT	The /Machine/ possesses a /Component 1/ and a /component 2/ to /Component 2 Function /.
FUN	The /Machine/ is used to /Main Function of the Machine/ and possesses a /Component 2/ to /Component 2 Function /.
ORI	The /Machine/ possesses a /Component 2/ to /Component 2 Function/.

Experiment

Participants

Participants were 64 students from Université de Provence, Aix-en-Provence, France.

Materials and Procedure

Twelve pairs of experimental texts and eight pairs of filler texts were generated. A text pair consisted of a main text, an interrupting text, and five comprehension questions. The main experimental texts and the main filler texts described a machine (e.g., the automobile, the elevator, the phonograph, etc.). The main experimental texts all had the same structure (see, Table 1) but the main filler texts did not. The interrupting texts were stories totally unrelated to the main texts.

An experimental trial included the presentation of the main text, the interrupting text, and five text comprehension questions. It began with the self-paced display of the main text, sentence by sentence. An experimental trial included the presentation of a main text, an interrupting text, and five text comprehension questions. It began with the self-paced display of the main text, sentence by sentence. To go on to the next sentence, the reader had to press the space bar on the keyboard. Sentence 2 of the main texts mentioned a machine component and its particular function. Sentence 3 stated the general function of the machine. Sentence 4 gave a second machine component and its particular function. Then a message saying "Attention! Reading time is limited" ("Attention ! Lecture en temps fixé") appeared on the screen. This message stayed on the screen for 1500 ms and meant that the interrupting text would start on the next page. The interrupting text was displayed sentence by sentence for a fixed amount of time (4500 ms per sentence). After the presentation of the interrupting text, a message saying "Attention! Reading time no longer limited" ("Attention ! Lecture en temps libre") appeared on the screen.

Then, one of 4 Probe sentences was displayed: either (i) the original Probe Sentence that was the sentence 4 of the main text (ORI), or (ii) categorical Probe Sentence that contained the two machine components and the second component specific function (CAT), or (iii) a functional Probe Sentence that contained the general machine function, the second component and its specific function (FUN); or (iv) a without Relation Sentence that was a new sentence (WRE). Following the display of the probe sentence, a critical sentence 5 was then displayed. Sentence 5 contained an anaphoric device; the referent was the machine component mentioned in sentence 4 (see, table 2).

In each list, 50% of the main texts were interrupted: Filler texts were never interrupted.

At the end of reading, participants were asked to answer 4 comprehension questions about the main text and 2 comprehension questions about the interrupting text. Second question was the critical question for assessing understanding because its correct answer depends on the encoding of the correct antecedent to anaphora in the fifth sentence.

In the control condition, the first part of the main texts was not displayed; and in the experimental condition, all materials were presented.

Results

Control condition. In the control condition, the first part of the text was not presented. Results are that the critical sentence was read faster in the cued conditions than in the without relation condition, 4221 ms vs. 4597 ms, $F(1,31) = 3,6$ $p<.05$. The critical sentence was read at a same rate in the ORI, CAT and FUN conditions. Note that the sixth sentence was read faster in the probe sentence conditions than in the WRE condition, 3488 ms vs. 3823 ms, $F(1,31) = 4,86$ $p<.05$. Percentage of correct answers to the critical question was greater in the FUN condition than in the CAT condition, 85% vs. 55%, $F(1,31) = 6,49$ $p<.05$ and was greater in the probe sentence conditions than in the WRE condition, 76% vs 42 %, $F(1,35) = 7,8$ $p<.01$.

Table 2: example of text (translated from French)

Nb	Sentence
Title	The elevator
1	The elevator was invented in 1859 by the American Otis.
2	The elevator possesses a sliding door to protect the users from the outside.
3	The elevator is mainly used to reach the floors of a building.
4	The elevator comprises a solid winch that controls the rise of the cabin.
5	This component thus contributes to the utility of the elevator.
6	Since its invention, the elevator is equipment that was modernized.
7	The modernization of the elevator was useful for the development of the residences.
CAT	The elevator possesses a sliding door and a solid winch that controls the rise of the cabin.
FUN	The elevator is used to reach the floors of a building and comprises a solid winch that controls the rise of the cabin.
ORI	The elevator comprises a solid winch that controls the rise of the cabin.

Experimental condition. The critical sentence was read faster in the CAT condition than in the FUN condition, 3869 ms vs. 4437 ms, $F(1,31) = 9.33$ $p<.01$.

The percentage of correct answers to the critical question was greater in the probe sentence condition than in the WRE condition, 55.6% vs. 36.0%, $F(1,31) = 3.9$ $p<.05$., but there was no difference between the CAT and the FUN conditions.

Simulation with CI-LSA+Generalisation Framework

Procedure

Construction Phase. We assumed that a text segment could be represented as an associative network consisting in an explicit and an implicit representation. Explicit representation is the result of a predication analysis of the segment. Implicit representation contained the assumed activated knowledge associated with the concepts and the propositions embedded in the text segments. In the model, the implicit representation was made of all of the nearest neighbors (n=2), taken in an LSA space (General reading up to 1st year college), of each of the concepts and propositions represented in the explicit network. Explicit network was weighted by using the rules provided by Kintsch (1988): link weights between propositions and argument, embedded propositions, and proposition that shared an argument were equal to 1 while others were equal to zero. Implicit network was weighted by using cosine similarity from LSA space. If between two vectors, expressing elements of the net, cosine was .20, the weight of their link in the network was .20.

Integration Phase. This phase is described in Kintsch (1988). Here, the integration phase simulated activation spreading in the net. When the network was settled, the more connected information got the greatest final activation value and for that reason remained in a short-term memory buffer, for the next sentence processing.

Short term working memory. Short-term working memory was involved in the construction and integration phases and in the accessibility of the most activated information. Short-term memory in the model is a temporary memory buffer. It contained the most activated information at the end of a processing cycle. We transformed all final activation values in z-notes. Let a be the average of the activation values, e the standard deviation of the distribution v_i the final activation value of a node I, the z-note of I is:

$$z_i = (v_i - a)/e.$$

Only the nodes with z-notes above a given constant were kept in the Short-Term Memory buffer. Hence, the number of elements in the buffer varied as a function of a limited amount of activation and of the network weighting.

In order to simulate a reading interruption as in the experiment, we emptied the memory buffer: We did not keep any nodes of the last processed sentence.

Long-term working memory. Long-term working memory was a retrieval structure consisting in encoded information and macropropositions associated with it. To simulate the construction of a retrieval structure, we build up a matrix containing in row, all activated information during the different processing cycles and, in column, the different processing cycles. Each cell of the matrix contained the final activation value of an element in a given cycle. If the element was not activated in the given cycle, the cell contained a zero. Hence, this matrix contained all episodic memory vectors. To this matrix was applied a singular value decomposition to simulate a generalization process. The decomposition resulted in three matrices (see, Landauer & Dumais, 1997) but we use the matrix representing the coordinates of each element in a memory space. The elements belonging to that space were projected in a two-dimensional space by reducing its dimensionality. The procedure resulted in a two-column matrix. The macrostructure matrix was the product of the two-column matrix and its transposed matrix. The macrostructure matrix was considered as a generalization of the episodic memory traces encoded from the text.

Table 3 : reading times (RT) and activation forces (AF) of the critical sentence and the probe sentence in Original (ORI), categorical (CAT) and functional (FUN) conditions.

	Critical sentence			Probe sentence		
	ORI	CAT	FUN	ORI	CAT	FUN
RT	14,29	13,16	15,09	8,96	6,94	6,04
AF	11,36	13,76	11,07	11,80	16,66	17,87

Macropropositions reinstatement and reading resumption. After a reading interruption, we assume that readers might be able to readily retrieve mental representation of the text from long-term working memory by reinstating cues associated with encoded information. In the model, macropropositions were reinstated in the short-term memory buffer and were used as context to process the next sentence. As in the experiment above, we used three kind of probe sentences. In a first step, we constructed for each, an episodic trace. As they resume some parts of the previous text, their representation shared information with previous sentences that now belonged to the macrostructure matrix. But the shared information was not as such important for each probe sentence. In the categorical condition, information given by the probe sentence referred to a categorical macroproposition "machine has component", while in the functional condition, the probe sentence referred to "machine has a function" and "component has a function". In a second step, we multiplied the episodic vector trace of the probe sentence by the macrostructure matrix. The result of the product was an echo vector. We z-transformed the coordinates of the echo vector and only kept the z-notes above 1.5. The respective nodes were taken to make part of the critical sentence network. In a final step, activation spread in the critical sentence net.

For each probe sentence, and for the critical sentence, in each condition, we calculated an activation force. The final activation values of each sentence were z-transformed and we summed all the z-values above 0.

Results

We applied this procedure to three experimental texts. For each sentence, the mean activation force and the mean reading times per character and proposition are presented in the table 3. First, for each text, and in each of the probe conditions, the anaphora antecedent was retrieved from the macroproposition structure. Second, the activation force obtained by the model can predict the reading times obtained by participants. The correlation between reading times and activation forces were negative and significantly different to zero, $r=-.83$, $z(6) = -2.0$, $p < .05$.

Discussion

As predicted, the CAT sentence led to a faster critical sentence reading time than does the FUN sentence. This difference is not due to the fact that the CAT sentence contained two potential antecedents for the anaphora in critical sentence. First, the difference appeared only when the first part of the main text was presented. Second, although in control condition, the percentage of correct answers was greater in the FUN condition than in the CAT condition, this difference was not found in the experimental condition. This result indicates that without the first part of the text, readers did not discriminate the right antecedent from the categorical cue sentence. Moreover, in control condition, the presentation of the WRE sentence exerted an effect on the critical sentence 5 and on the sentence 6 reading times. This indicated that, in the control condition, subject could not rely on a retrieval structure built in LTM to counteract irrelevant information effect on text processing. It results that when the readers have the opportunity to construct a retrieval structure, a categorization of two pieces of information (the two machine components) had occurred during text processing, based on meaning overlap between the two learning episodes: sentence 2 and sentence 4.

The CI-LSA+generalisation framework could explain how a retrieval structure was build up: During reading, each sentence of the text was processed and stored in episodic memory. Then, as a function of meaning overlap between them, sentences representations were associated to the same semantic macroproposition in

LTM or were not associated. The remaining question is when does generalization process occur during reading? Does it occur during the encoding process or during the retrieval process ? Research has to answer these question in the future. Nevertheless, generalization process and more generally integration process appear to be necessary processes for building the retrieval structure that permits texts comprehension.

Abstract

Two experiments were conducted in order to test the effects of cue predictability on serial dependencies in response times and response durations. Predictability in the timing (Experiment 1) and identity (Experiment 2) of response cues was manipulated. Results of both experiments showed that long-range dependencies in response times were stronger when cues were predictable versus unpredictable. By contrast, long-range dependencies in response durations were unaffected by cue predictability. Results are discussed in light of five hypotheses about the source of long-range dependencies in human behavior.

Introduction

In most psychological experiments, the variability in human behavior is divided into two categories: some variations in measurement are explained by the experimental factors, and other variations are not. The latter category is often termed *error variance*, and it usually does not play a role in theorizing about the psychological processes under examination. One reason why researchers ignore error variance is because they often assume that it is effectively random, or possibly the product of mundane factors such as practice, fatigue, or perseveration. These assumptions lead one to think of error variance as uninformative or, at best, irrelevant.

A growing body of experimental results has recently prompted some researchers to pay closer attention to the ostensibly random fluctuations in human behavior. It appears that, contrary to popular belief, these fluctuations tend to exhibit patterns that persist over time. A transparent way to think about these patterns is through the *autocorrelation* function. Suppose that X_t is a time series of measurements taken from a participant in an experiment. The autocorrelation of this time series is defined as (Wagenmakers, Farrell, & Ratcliff, in press),

$$C(k) = \frac{E[\{X_t - \mu\}\{X_{t+k} - \mu\}]}{E[\{X_t - \mu\}^2]},$$

where $E[]$ is expected value, μ is the mean of X_t, and k is some number of measurements between the time series and an offset copy of itself.

If measurements are strictly independent of each other, then $C(k)$ is zero for all $k > 0$. The time series is not correlated with itself at any offset, and hence, there are no persisting patterns in the fluctuations. This condition is often referred to as *white noise* (see top series in Figure 1), and it is common to assume that error variance is some type of white noise (e.g., Gaussian). However, it turns out that measurements of human behavior are often not characterized by white noise. Instead, they exhibit serial dependencies such that $C(k)$ is positive for some $k > 0$.

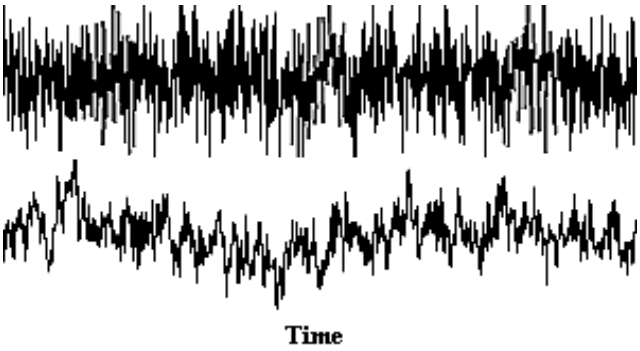

Figure 1: Illustrations of white noise (top) and pink noise (bottom; from Gilden, 2001).

Serial dependencies have been found in a wide variety of human behaviors (for a review, see Van Orden, Holden, & Turvey, 2003). With respect to the study of perception and cognition, serial dependencies have been found in experiments on mental rotation (Gilden, 1997), lexical decision (Gilden, 1997), perceptual learning (Wagman, Dahle, & Schmidt, 2002), simple reaction time (Ward & Richard, 2001), and visual search (Aks, Zelinsky, & Sprott, 2002).

A major question about these findings concerns the kind of dependencies that were observed. The authors of these studies interpreted their findings as evidence for a particular kind of serial dependency often referred to as *long-range dependency,* of which *1/f noise* or *pink noise* are special cases (see bottom series in Figure 1). In a long-range dependent series, $C(k)$ is positive and decreases as a power of k,

$$C(k) = |k|^{-\gamma}, \qquad 0 < \gamma < 1.$$

Long-range dependency is of special interest because it appears to be ubiquitous in nature (see Van Orden et al., 2003), and it has some intriguing properties such as fractal structure, i.e., a change in the time scale of measurement does not affect the distributional properties of a long-range dependent time series. Long-range dependencies have motivated a number of general theories about the sources of fluctuations in human behavior, and these theories were the focus of the current experiments.

However, before the theories are addressed, it must be noted that long-range dependencies can be difficult to distinguish from *short-range dependencies*, in which *C(k)* decreases exponentially with *k* (Wagenmakers et al., in press),

$$C(k) = \phi_1^{|k|},$$

where $-1 < \Phi_1 < 1$. Although *C(k)* declines more quickly in short-range dependent series compared with long-range dependent series (hence their names), the difference in rates of decline can be rather small. Nonetheless, short-range dependent series have very different properties (e.g., they can be generated by simple autoregressive processes), and they lead to different kinds of theories about fluctuations in human behavior. Therefore, Wagenmakers and his colleagues argued that empirical tests of long-range dependency must treat short-range dependency, rather than white noise, as the null hypothesis. Using this more stringent criterion, Wagenmakers et al. still found long-range dependencies in measurements of human behavior under a variety of experimental conditions. Their findings and analyses confirm that long-range dependency is a real phenomenon.

Explanations of Long-Range Dependence

Why do fluctuations in human behavior exhibit long-range dependencies? Only certain kinds of processes are known to produce long-range dependencies (for a review, see Wagenmakers et al., in press). The ostensibly special status of long-range dependencies has prompted researchers to search for general properties of human behavior that might explain their source(s). Here we review five explanations that have been offered.

Three Time Scales. Any specific observation of long-range dependence can be mimicked mathematically by the combination of three sources of white noise that operate on different time scales, each scale separated by an order of magnitude. In the context of perceptual and cognitive processes, Ward (2002) has suggested that unconscious, preconscious, and conscious processes may be three such sources of white noise whose combination is observed in fluctuations of human behavior.

While the transparency of this explanation is appealing, it is somewhat brittle because any three particular scales of white noise will mimic long-range dependence *only* for a single, particular scale of measurement (see Van Orden et al., 2003). What this means is that three-scale accounts must be fit to data posthoc. By contrast, true long-range dependence exists over all scales of measurement (within the limits of the system in question) due to its fractal structure. Long-range dependence in human behavior has, in fact, been found across a range of scales of measurement (for a review, see Van Orden et al., 2003).

Many Short-Range Dependencies. Granger (1980) showed that, under certain circumstances, the summation of many short-range dependent series can produce a true long-range dependent series. Ding, Chen, and Kelso (2001) proposed that long-range correlations found in timing tasks (and, by extension, in other kinds of tasks) may be the result of such summations. Their argument was based on the premise that cognitive processes are supported by large-scale networks of neural processes. Ding et al. reasoned that, in at least some cases, such neural networks will be characterized by large sets of short-range dependent processes. If the timing of behavior is driven by the summation of these processes, then fluctuations in timing will exhibit long-range dependence.

Ding et al. (2001) made the further statement that more difficult tasks require larger numbers of short-range dependent processes. This statement leads to the prediction that long-range dependencies will be stronger in more difficult tasks. In support of this prediction, they reported two timing tasks in which participants were asked to match their rates of tapping with the beat of a metronome. In one condition, participants were asked to tap in synchrony with the metronome. In another condition, participants were asked to tap at the midpoint between each pair of beats (i.e., to syncopate). Syncopation is a more difficult tapping task (e.g., less stable; see Kelso, DelColle, & Schner, 1990) compared with synchronization, and fluctuations in syncopated tapping exhibited stronger evidence of long-range dependence compared with synchronized tapping.

Mental Set. Gilden (2001) proposed that experimental tasks whose demands are relatively consistent across trials invoke a "mental set" in the participant. Gilden's definition of mental set entailed the repeated formation of mental representations necessary to perform the task. When the task is consistent, Gilden proposed that a dynamic of memory is created by this repetition such that memory components interact on multiple time scales. Under some circumstances, interactions of this nature have been shown to generate long-range dependencies (e.g., see Jensen, 1998).

Gilden (2001) left the nature of his proposed memory components unspecified, but his hypothesis was nonetheless formulated in sufficient detail to make a testable prediction. If mental set is broken by sudden changes in task demands, then the hypothesized dynamic of memory would not have an opportunity to form, and long-range dependencies in response fluctuations should disappear. Gilden tested this prediction by measuring series of reaction times to color or shape discriminations when each of these tasks was blocked, compared with a mixed condition in which participants had to switch between tasks across trials. Gilden found evidence of long-range dependence in the blocked conditions, but not the mixed conditions. These findings were consistent with his mental set explanation of long-range dependence.

Strategy Shifts. By definition, a long-range dependent series is stationary in the sense that its distributional characteristics do not change over time. However, a long-range dependent series can be difficult to distinguish from some kinds of non-stationary series that go through changes in their distributional characteristics over time.

It is probably true that any given experimental task can be performed in a number of ways, despite any and all efforts to make the task demands as explicit and precise as possible. If each means of performing a task is termed a "strategy", then it is very possible that a participant will change his or her strategy for performing a task over the course of an experiment. If strategy shifts occurred repeatedly over the course of measurement, they would have the potential to mimic long-range dependence. Wagenmakers et al. (in press) presented a computational demonstration of how strategy shifts (shifts in response criteria, in this case) can create non-stationary fluctuations in response times that mimic long-range dependencies.

Interaction-Dominant Dynamics. Van Orden et al. (2003) proposed that, at a very general level, humans are composed of many component processes that all interact on multiple time-scales. Their proposal was based on the fundamental idea that the structure and complexity seen in human behavior is a phenomenon of self-organization, and that self-organizing systems are ones that have interaction-dominant dynamics. They argued that it is these dynamics, intrinsic to human beings (and many other types of systems), that give rise to long-range dependencies in human behavior.

As general as they are, the ideas put forth by Van Orden and his colleagues (2003) lead to a testable prediction. If long-range dependence is the intrinsic signature of self-organization in human behavior, then any perturbations to behavior caused by external factors should disrupt the intrinsic dynamics, thereby obscuring their signature. Van Orden et al. argued that the results to date on long-range dependencies in human behavior (e.g., as cited in the other explanations listed here) are consistent with this prediction.

Current Experiments

Two experiments are reported here that were designed to explore a factor that was predicted to modulate the degree of long-range dependence in RT fluctuations. The factor was motivated by the explanations just listed. In particular, we tested whether sources of variability *external* to the participant would reduce the degree of long-range dependence in fluctuations of human behavior. Key presses were the measured behaviors, and sources of external variability were manipulated by the degree of *cue predictability*.

In Experiment 1, predictability in the timing of response cues was manipulated to be either completely predictable or completely unpredictable. When cues were predictable, fluctuations in response times were driven primarily by the participant. The cues themselves had little bearing on behavior because they were entirely redundant; participants knew that the next cue would always appear one second after the previous response (see Methods section). By contrast, when the timing of cues was unpredictable, the timing of responses had to be driven primarily by the cue itself, rather than any expectancies internalized by the participants.

If long-range dependence is internal to human behavior, then external variability should mask it. This idea is consistent with some previous explanations of long-range dependence (see Discussion section). This idea also leads to a further prediction that is quite counterintuitive. Participants were asked to press a key as soon as they perceived a cue. Thus, the task demands were satisfied when the finger moved down and the key made contact with its sensor. The task made no demands on when participants should lift their finger off the key. Therefore, fluctuations in the *durations* of key presses should be free to reflect internal variability, provided that the timing of the downward motion can be dissociated from timing of the upward motion. If so, we should observe *no* effect of predictability on the degree of long-range dependency in response durations.

In Experiment 2, sources of external variability were introduced by a different means. The *identity* of cues, instead of the timing of cues, was manipulated to be predictable or unpredictable. Two different cues signaled two different responses. Cue identity was made predictable or not by giving a preview or not of each upcoming cue. Analogous to the manipulation of predictability in Experiment 1, the preview manipulated the degree to which behavior was driven by the cues themselves, versus expectancies about the cues.

Experiment 1

Participants. Eighteen participants were recruited for the experiment. Sixteen were undergraduates who participated for course credit, and two were graduate students who were compensated for their participation.

Procedure. Each participant saw one block of predictable cues and one block of unpredictable cues, with block order counterbalanced across participants. Participants were instructed to press the space bar with their dominant hand as quickly as possible every time they saw an "X" flash on the screen. Demonstrations and practice blocks were given before each experimental block. Participants were instructed to wait till they saw an "X" before responding; if they pressed the space bar before a cue appeared, they heard a warning tone. Each block consisted of 1100 cues and took about 25 minutes to complete. The experimenter stayed in the room with the participant throughout the experiment. Participants took a short break between blocks.

Participants were seated about two feet away from a CRT monitor, and each cue appeared for about 50 ms in the center of the screen in Times New Roman font. A pair for visual flankers appeared immediately following each cue, and remained on the screen until the participant pressed the space bar. The flankers provided a redundant cue that the computer was awaiting a response (in case the participant missed a cue by accident).

Each subsequent cue was timed relative to the previous response. In the predictable condition, the next cue always appeared 1 s after the previous response was given. In the unpredictable condition, the timing of the next cue was sampled randomly from an exponential distribution with a mean of 1 s, a minimum of 1 ms and a maximum of 12 s. The exponential distribution was used because it has a flat hazard function, which means that the probability of receiving a cue was constant as a function of wait time (Simpson et al., 2000). The time from cue to key press was recorded (response time), as well as the length of time that participants pressed each key (response duration).

Results

To illustrate the time series structures that were typically observed, the series of response times for one participant in the predictable and unpredictable conditions are shown in Figure 2. The series of response durations for this participant are shown in Figure 3.

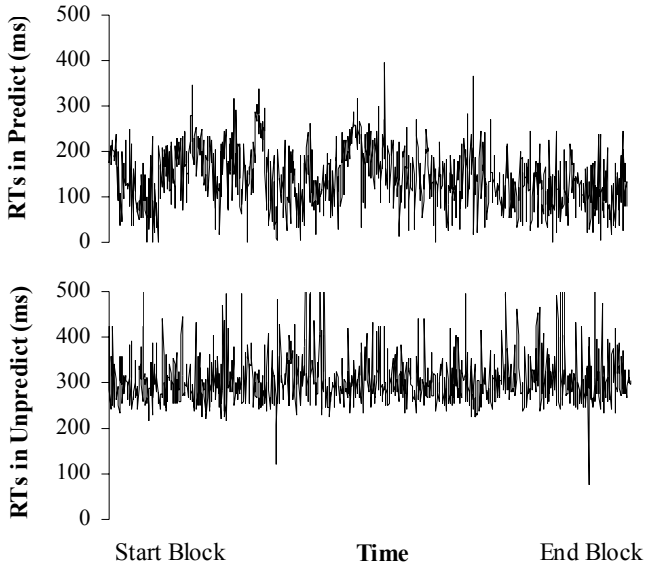

Figure 2. Response times for one participant in the predictable (top) and unpredictable (bottom) conditions of Expt 1 (responses above 500 ms have been truncated).

Averaged across participants, the percentage of anticipatory responses was 1.99% in the unpredictable condition, and 3.9% in the predictable condition. All anticipatory responses were removed from the analyses. The mean correlation of response times with response durations was r = .02 in the unpredictable condition, and r = -.21 in the predictable condition.

Spectral analyses are standardly used to measure the degree of long-range dependence in a time series, and we adopted the method of spectral analysis described by Holden (unpublished; also see Gilden, 1997). In particular, outliers were first removed from each time series (values > 1000 ms or outside 3 SDs of each participant's mean for each measure in each condition). Then, linear and quadratic trends were removed to avoid dependencies caused by practice or fatigue. A power spectrum was then computed over 1024 of the remaining data points, and log frequency was regressed against log power. The slope of this regression line in log-log coordinates was used as a measure of serial dependence: more negative slopes correspond to stronger degrees of serial dependence.

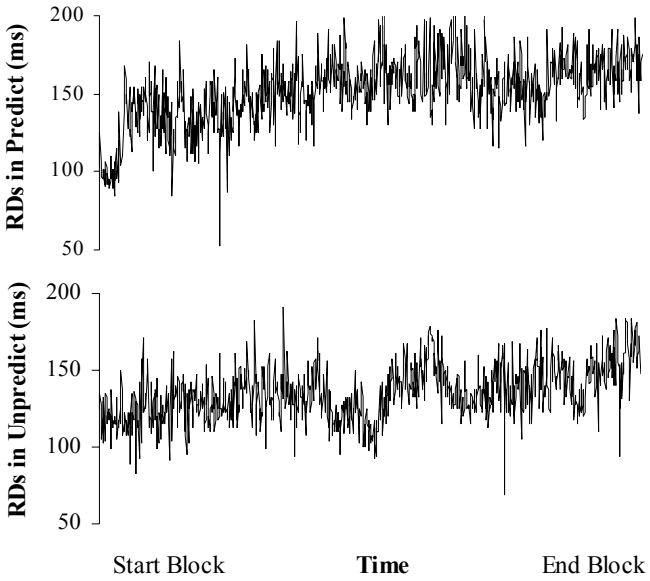

Figure 3. Response durations for one participant in the predictable and unpredictable conditions of Expt 1.

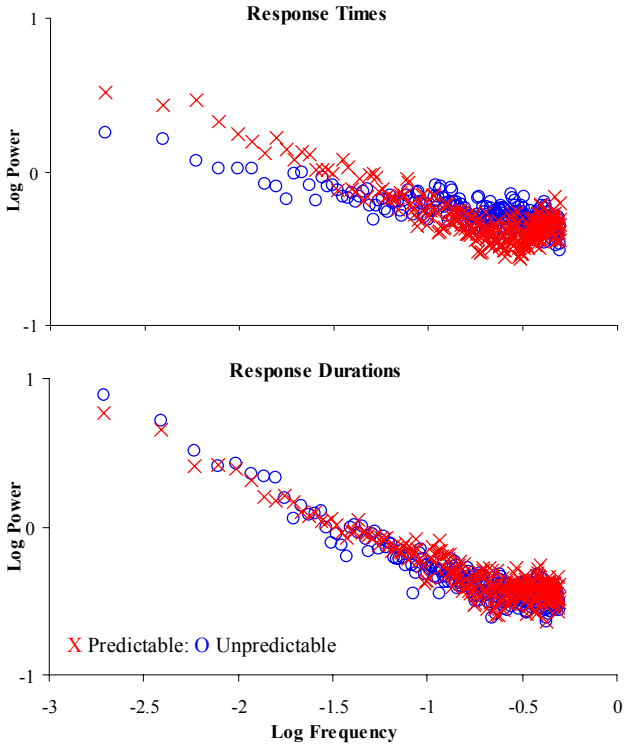

Figure 4. Aggregate spectral plots for Expt 1.

The aggregate power spectra, averaged across participants for each condition, are plotted in Figure 4. For response times, slopes in the predictable condition were reliably more negative than slopes in the unpredictable condition, $t(17)$= 4.26, $p < .001$. For response durations, there was no reliable difference in slopes, $t(17) < 1$. Moreover, slopes for

response durations were reliably more negative than slopes for response times, $t(35) = 7.21$, $p < .001$.

Experiment 2

Participants. Eighteen undergraduates participated in the experiment in exchange for course credit.

Procedure. The procedure was identical to that used in Experiment 1, except for the following changes. The response cue was either '>' or '<', and participants were instructed to press the right arrow key for the former, and the left arrow key for the latter. Flankers appeared on either side of the response cues as signals to respond, and the flankers always appeared 1 s after the previous response was given. In the preview condition, the next response cue always appeared immediately following the previous response; thus, participants had 1 s to process the cue and prepare their response. In the no-preview condition, each cue appeared in conjunction with its signal to respond; thus, participants had to process the cue and choose their response as quickly as possible.

Results

Averaged across participants, the percentage of anticipatory responses was .03% in the unpredictable condition, and .45% in the predictable condition. The percentage of errors was .80% and .27%, respectively. All anticipatory responses were removed from the analyses, but the few errors were retained. The mean correlation of response times with response durations was $r = .05$ in the unpredictable condition, and $r = -.08$ in the predictable condition.

The aggregate power spectra are plotted in Figure 5. For response times, slopes in the predictable preview condition were reliably more negative than slopes in the unpredictable no-preview condition, $t(17) = 2.31$, $p < .05$. For response durations, there was a small but unreliable difference in slopes, $t(17) = 1.80$, $p < .09$. Moreover, slopes for response durations were reliably more negative than slopes for response times, $t(35) = 3.55$, $p < .001$.

Discussion

Two experiments were reported in which long-range dependencies were measured as a function of cue predictability. Results showed greater degrees of dependency in series of response times when the cues were predictable, both in terms of timing and identity. By contrast, results showed large and comparable degrees of dependency in all series of response durations. The observed dissociation between response times and response durations was consistent with the idea that external sources of variability mask the long-range dependence that is intrinsic to human behavior.

It also appeared that the effect of predictability in cue timing (Experiment 1) was stronger than that in cue identity (Experiment 2), albeit further experiments are necessary to bear this out. One possible explanation is unpredictable timing introduces more external variability compared with unpredictable choice responding. However, to test this explanation, one would need to develop a more explicit means of parsing internal and external sources of variability.

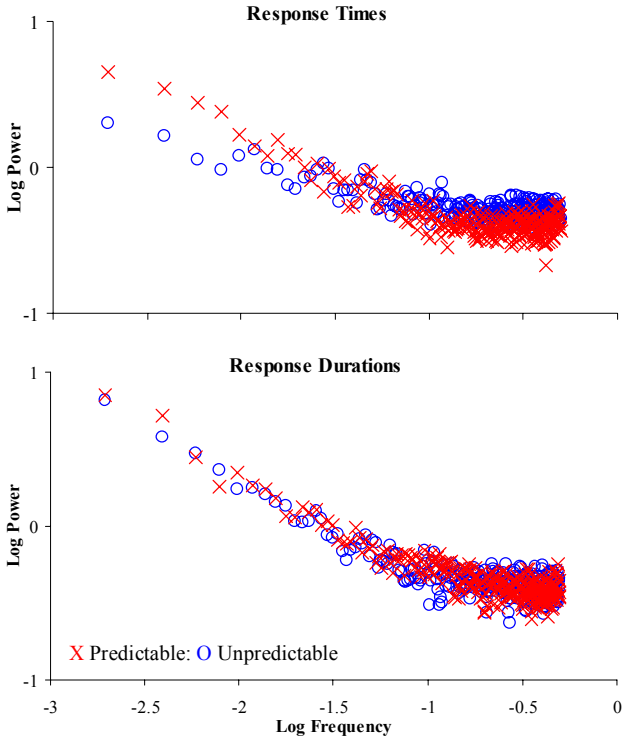

Figure 5. Aggregate spectral plots for Expt 2.

It is important to note that the hypothesis of long-range dependence was not explicitly tested against the short-range alternative in the current data. We did not conduct these tests because the IDD predictions could be tested without them. However, the long-range/short-range distinction is important, and we plan to address this issue in future work.

How do the current results bear on the five explanations of long-range dependence outlined in the Introduction section? We address this question here for each explanation in turn.

Three Time Scales. Sources of white noise on three different time scales could be used to mimic the long-range dependencies (or lack thereof) for each participant in each condition of the two reported experiments. However, these parameter fits would be posthoc, and they would offer no insight into the differences in degree of long-range dependence between experimental conditions.

Many Short-Range Dependencies. As noted earlier, this explanation leads one to predict that greater degrees of long-range dependence should be found in more demanding tasks. The unpredictable conditions were clearly more demanding because their mean RTs were much greater. However, the unpredictable conditions showed *lesser* degrees of long-range dependence compared with the predictable conditions. Moreover, summations of short-range dependencies appear to offer no insight into the observed differences in dependencies between response times and response durations.

Mental Set. Gilden (2001) proposed that long-range dependencies should be weaker when a person's mental set is repeatedly broken or interrupted. One could imagine that participants were able to maintain a more stable mental set in the predictable conditions compared with the unpredictable conditions, which would make the current results consistent with the mental set explanation. It is less clear how the mental set explanation would apply to the differences in long-range dependence between response times and response durations. One would presumably have to propose that these behaviors are governed by different mental sets, but given the close physical relationship between a button press and its release, the idea of different mental sets seems implausible. The bottom line is that the mental set explanation is not yet formulated to the point where it might offer insight into the current results.

Strategy Shifts. Wagenmakers et al. (in press) conjectured that participants might be more apt to shift strategies, and therefore exhibit long-range dependencies in their behaviors, when they are bored. Participants were almost certainly bored in all of the current experimental conditions, but one could argue that the predictable conditions were more boring than the unpredictable ones. If so, the finding that long-range dependencies in response times were stronger in the predictable conditions is consistent with the strategy shifts explanation. However, one would have to apply this explanation to response durations as well, and there was no such effect on long-range dependencies in this measure. It remains to be seen whether a strategy shift explanation could be made to account for these results.

Interaction-Dominant Dynamics. This explanation states that long-range dependencies come from the interdependent dynamics that underlie the self-organization of human behavior. These dynamics are hypothesized to be perturbed by external forces. If sources of external variability are thought of as external forces, then all the results reported herein are consistent with the interaction-dominant dynamics explanation. Predictability was a force on response times, but not response durations, because the task made demands on the former but not the latter.

In conclusion, the current results are, for the time being, most consistent with the interaction-dominant dynamics explanation. Of course, these explanations are all in their infancy; it would be an overstatement at this point to refer to them as theories. Be that as it may, the results were clear and far from trivial to explain. We believe that further empirical and theoretical investigations into the sources of long-range dependence in human behavior will prove to be valuable to studies of perception and cognition.

Acknowledgments

We thank Anthony Novak for his assistance with data collection, and Guy Van Orden and Jay Holden for helpful conversations about the theory and methodology surrounding long-range dependence. The work was funded in part by NIH Grant MH55628, and NSF Grant 0239595.

Linguistic Untranslatability vs. Conceptual Nesting of Frames of Reference

Giovanni Bennardo (bennardo@niu.edu)
Department of Anthropology and Cognitive Studies Initiative, Northern Illinois University
DeKalb, IL 60115 USA

Abstract

This work focuses on the concept of frame of reference. Levinson (2003) suggested that spatial information encoded in one frame of reference cannot be translated into another one. While this is partially true in language, I argue for a nesting relationship between frames of reference at the conceptual level. A set of spatial concepts suggested by Lehman & Bennardo (2003) informs this investigation. In closing a new typology of frames of reference is proposed.

Introduction

The concept of frame of reference (FOR) is widely used in the literature about the mental and linguistic representations of spatial relationships. After a review of the terminologies used in different disciplines such as philosophy, linguistics, psycholinguistics, developmental and behavioral psychology, brain sciences, and vision theory Levinson (2003) proposed a definition of the concept and a typology of frames of reference.

A FOR is defined as a system of three coordinated axes that create a 3-dimensional space within which spatial relationships are established cognitively and expressed linguistically. Levinson's typology of FOR includes three systems labeled relative, intrinsic, and absolute. When a FOR is realized linguistically, the information coded in one FOR (e.g., 'the ball is behind me') is not translatable into another (e.g., 'the ball is south of me'). While I agree with most of the discussion presented by Levinson, I find problematic the untranslatability issue. I suggest that untranslatability only holds between linguistically instantiated FORs, while at the conceptual level they are nested into each other.

This investigation uses a set of spatial concepts found in Lehman & Bennardo (2003). This conceptual apparatus is the result of analyses conducted on English spatial prepositions, and languages like Burmese, Thai, Italian, and Tongan (Polynesian). After sketching the apparatus, the three FORs are analyzed ending with a suggestion about their conceptual contents and a new typology.

The conceptual apparatus

A computational approach to the general architecture of cognition was adopted to arrive at the set of spatial concepts suggested by Lehman & Bennardo (2003). Within this approach, cognition is conceived as computational (cf. Ballim & Wilks, 1992), thus generatively 'abstract'. Only the characteristics of the computational, or, relational spaces that make up what we call 'cognition' are reiterated in each cognitive module and not the specific characteristics of the substantive content that instantiate these 'abstract' relationships.[1]

A computational approach to cognition can be proposed by accepting compositionality without embracing a Fregean (logico-positivist) point of view and by turning to the domain of mathematics (e.g., algebra and geometry). In mathematics the primitives of a system are a set of axioms. These axioms generate indefinitely many theorems and each theorem can establish a foundation for yet another theorem. Furthermore, theorems may share parts with other theorems in a redundant manner. The set of relational properties of any cognitive system could be, then, nothing but a theorem derived from a set/s of other theorems. Such a system is compositional by definition.

The linguistic analyses in Lehman & Bennardo (2003) yielded the following set of spatial concepts.[2]
State: Object; Place Or Locus; Neighborhood: Vicinity, Contact, Interiority; Motion: Time; Direction; Path: Beginning, Body*, End, (Direction)*; Verticality: Angle: Unit, Quantity (+ or -); Horizontality: Visibility, Left or Right; Center; Part*. (*conceptual content of *Vector*)

Some concepts are not primitives, but rely on other concepts of the same group to function as their axioms. This is the minimal set of axioms that is necessary to account for the theorems (e.g. prepositions, directionals, spatial nouns) that make up the representations of spatial relationships in the languages analyzed.

The concept of Object is used with the meaning of any entity existing in a possible world, either concrete or abstract, e.g. table, idea. The place of an Object is the actual amount of Space that it occupies. In other words, a Place is the set of all points within the boundary of an Object (including the boundary points). The Locus of an Object in projective geometry is defined as the collapse of a Place onto any of its interior points. Then, a Locus is a neighborhood of possible projection points, the lower limit being one point. Thus, while a Place is defined by the size, shape, and specific geometry of the Object, a Locus is not and can be arbitrarily reduced to a point.

The concept of Neighborhood includes the concept of Vicinity (more than zero distance) between two Objects, the concept of Contact (zero distance) between them and the concept of Interiority, or, one Object in the interior of another. The Neighborhood's border is pragmatically determined. These concepts make up the concept of State.

The concept of Motion is an ordered sequence (consequently, with a Direction) of Places (of an Object)

[1] Hirschfeld & Gelman (1994) draw a similar distinction between 'module' and 'domain.'

[2] From now on a concept is indicated by initial capital letter.

in Time, bounded by two Places without either left or right directionality in a disjunctive fashion and never missing both. The concept of Path, instead, is a geometrical (purely spatial) description of motion 'abstracted' from Motion. The focus is not on the moving Object, but on the ordered sequence of Places, now considered as Loci. The concept of Motion is inextricably tied to Time, but the concept of Path is partially free from it. In fact, we can indicate a Path at $Time_1$ and then indicate another Path at $Time_2$ and state that they are the same without incurring a contradiction as would happen if the two parts of the comparison were two instances of Motion. The instances of time used in the construction of a Path are not unique, but they are repeatable.

Two features that Path also shares with Motion are ordered sequence and boundedness. The interior points of a Path are an ordered sequence of Loci with a Direction, that is, they are Vectors with a finite magnitude. This magnitude we call its Body and consists of a set of Loci whose members may at a limit be one, thus, overlapping with the first constitutive Locus. The boundary of a Path consist of two Loci, a Vector that lacks left directionality (Beginning), and one that lacks right directionality (End). Object and Place (axioms of State) participate in the construction of Motion. Locus, instead, participates only in the construction of Path. Thus, the difference between Place and Locus is used to separate the temporally bound Motion from the spatially bound Path.

Verticality and Horizontality were not analyzed in as much detail as State and Motion, and only some conceptual components are indicated. First, Object, Locus, and Vector (a Beginning, a Body or magnitude, and a Direction) participate in their composition. The concepts indicated for Verticality are Angle and Quantity (Increasing or Decreasing). The instantiation of one or other type of Quantity will determine the 'up' or 'down' Direction of a Vector. Angle and Quantity are also part of the concept of Horizontality together with those of Visibility and Left or Right. Visibility contributes to the construction of a 'front-back axis.' After this, Left or Right can be constructed. Finally, the two concepts of Center and Part were added after the analyses of Tongan directionals and spatial nouns (Bennardo, 2000).

The conceptual content of the Relative FOR

Levinson (2003) defines a relative FOR in this way:

> This [a relative FOR] is roughly equivalent to the various notions of viewer-centered frame of reference mentioned above (e.g. Marr's 2.5D sketch, or the psycholinguistics' 'deictic' frame). But it is not quite the same. It presupposes a 'viewpoint' V (given by the location of a perceiver in any sensory modality), and a figure and ground distinct from V. It thus offers a triangulation of three points, and utilizes co-ordinates fixed on V to assign directions to figure and ground. (Levinson, 2003, p. 43)

He continues by pointing out that the viewpoint V does not necessarily coincide with the speaker even though deictic uses can be considered 'basic' or 'prototypical.' (Levinson, 2003, p. 43)

The axiomatic distinction between the figure F (sensory input, Object) and the viewer V (or cognizer in any sensory channel) is conceivable as a primary one, but the distinction between viewer V and ground G can be dispensed with and be regarded as constructed at a later stage in the ontogenic sequence. Both the research on the visual system (Marr, 1982) and on the developmental sequence (Cohen, 1985; Pick, 1993; Bowerman & Levinson, 2001) point towards the primacy of a stage in which viewer V and ground G are conflated. It is exactly the capacity to assign independent sets of coordinates to objects that marks one of the milestones of cognitive development (Piaget and Inhelder, 1956). I feel, then, justified in suggesting this definition for the relative FOR.

A Basic relative FOR is one centered on the speaker, viewer, cognizer (viewer). From the viewer three axes (or six vectors) are constructed, one vertically and two on the horizontal plane (front-back and left-right). In other words, the viewer can be thought of as a point and as such it implies a field (space) around it. This field will be oriented. This orientation process takes into consideration gravity and several bodily characteristics, both static (orientation of face, eyes, etc.) and ambulatory (habitual direction of movement). The viewer necessarily (ontogenically) maps these axes onto himself/herself, that is, considers himself/herself the origin of these axes.

Any Object in this field will be described in relation to the viewer, thus viewer V and ground G are considered as conflated, rather, they have not yet been cognitively constructed as separated. If the viewer moves in any direction, the axes will move accordingly, keeping their origin on the viewer. These axes are an abstraction from 3-D and conic spaces that originate on the viewer and where the angular limit is 180˚. Each axis, in fact, stands for a collection of possible axes whose limits are provided by the following (on three sides) relevant axes.

The appearance of a second Object in the field of the viewer creates the double possibility of treating this latter in direct relationship with the viewer, thus, continuing to map the axes on the viewer, or relating the second Object to the first one. This latter case entails the possibility of assigning orienting axes to the first Object, thus making it function as if it were the viewer. The orientation of the axes mapped onto this Object are the same as that of the axes the viewer had mapped on himself/herself. That is, the coordinates of the viewer's field can be kept constant. The second Object (figure) is described as in relationship with the first Object (ground). The front or 'away' Vector of the viewer is now divided in two parts by the first Object. Then, a new possibility is created. The ground front-back axis may keep the same orientation of the viewer's field, thus, we get the Translation subtype of relative FOR (e.g., 'the ball is in front of [beyond] the tree'). Or the front and back mapping can be flipped so that the front of the first Object (ground) faces the viewer, thus, yielding the Reflection subtype of relative FOR (e.g., 'the ball is in front of [facing viewer] the tree').

Both the Translation and the Reflection subtype of relative FOR are subtypes of the Basic relative FOR. In fact, their left and right assignments are congruent with those of the viewer. In other words, the first Object or ground is not yet considered as a point with an oriented field of its own, but is still tied to the field of the viewer.

It is not possible to arrive at the construction of the Translation and Reflection subtypes without using (consciously or unconsciously) a Basic subtype of relative FOR. In fact, there would be no axis to 'translate' or 'reflect' at all without having already constructed one in advance. And this can only have happened through the use of a Basic relative FOR.

This typology is suggested: a Basic, a Translation, and a Reflection relative FOR.[3] The label Basic highlights the ontogenic primacy of the construction in which viewer and ground G are conflated, that is, a set of coordinates is mapped onto the viewer by him/herself. The other two subtypes are derivative from the Basic and represent a move towards recognizing that Objects have relationships among themselves and not just with the viewer.

Let us now look into the conceptual content of the Relative FOR. We already know from the content of the conceptual apparatus that both vertical and horizontal axes are only the interaction of a subset, labeled Vector, of the concept of Path (Beginning, Body and Direction) with the two concepts of Verticality and Horizontality. The Beginning of these Vectors is a unique anchoring point (the viewer) that is a Locus because its geometric features are not relevant in the construction of the relative FOR (also, the Beginning of a Path is by definition a Locus). Another participating concept is Orthogonality that is the distinguishing factor between vertical and horizontal axes, and between front-back and left-right axes. Orthogonality contains Angle and Unit (degree) with a fixed Quantity attached to this last (90˚ degrees).

All the conceptual content so far listed brings with it other more finely grained content, and, specifically, Vector (as a subset of Path) and Locus. Moreover, this FOR assigns front and back to the Object that becomes the ground by mapping the viewer's coordinates onto it (see the Translation and Reflection subtypes). This mapping can be done by simply applying the 'repeat function' (as for the Translation subtype) or by applying the 'repeat function' and then letting Visibility determine which side is front or back (as for the Reflection subtype). The side that is not visible (beyond the Object) is the back in the same way as it is done for one's body.

The concept of Figure (any possible Object) is also a participant in this construction. Is this Object to be considered a Locus or a Place? Do its geometrical characteristics matter in constructing a FOR? Perceptually these geometrical characteristics are available, but do they play a role in the construction of the FOR? The answer is 'no.' Knowledge about the geometrical characteristics of the Figure does not seem to play any role in the construction of a FOR (see Talmy, 2000). What is relevant, instead, is the fact that a point, the Object, is being picked up in the world by means of a 'choice function' (clearly not provided by perception, but by our intentional thinking) and later put in a spatial relationship with either oneself or another Object according to a specific set of coordinates (in this case a relative FOR).

What does it mean to 'pick an object' in the world? In order to 'see'[4] an object our line of sight has to 'meet' it in the world. In order to think of this object as separated from our self, our line of sight has to be conceived as first leaving our eyes, then penetrating the outside world and finally meeting the object. In other words, the actual construction of any Object requires our use of the concept of Path, with a Beginning (self), Body (penetration of the world outside self), and an End (object in the world). It follows that Path needs to be postulated as participating in the construction of the Relative FOR.

The conceptual difference between the Basic and the Translation and Reflection subtypes of the relative FOR is the following. The two subtypes consider the viewer and two Objects (instead of only one), iteratively employing the concept of Path, a process that needs the use of the 'repeat' function. The coordinates of the oriented field of the viewer are still mapped onto the viewer. In the Translation type the front Vector is kept constant in orientation, while in the Reflection type its orientation is changed as a consequence of the salient use of the concept of Path (from viewer to Object) and Visibility.

The assignment of front and back that distinguishes between the Translation and the Reflection subtypes is left open to cultural variations. Since all the axiomatic conceptual material is already available (Locus, Path, Vector, etc.), the 'repeat' function can be arbitrarily applied to any of these concepts. However, minimally, the Translation subtype is conceptually simpler. In fact, it does not require the use of the concept of Visibility. Then, it is the salience of Visibility in specific cultures that may determine the preferred instantiation of one subtype over the other. Cases in point are Dutch (and English) speakers who habitually use the Reflection subtype (Levinson, 2003); Hausa and Tongan speakers who habitually use the Translation subtype (Hill, 1982; Bennardo, 2000); and Japanese speakers who use both (Levinson, 2003). This is a summary of the conceptual content of the Relative FOR. *Object; Locus; Path; Six Vectors, each with a Beginning (Locus of viewer, or anchor point), Body, Direction; Verticality; Horizontality; Visibility; Orthogonality, with an Angle, Unit (degree), Fixed Quantity (90˚ degrees).*

To this we need to add the 'choice function' used to construct an Object. For the Translation and Reflection subtypes, we must add also the 'repeat function' yielding two Objects and the construction of the front and back Vectors onto one of them. Both functions are axiomatic cognitive processes. For the Reflection subtype, repeated use of the concept of Visibility must be added.

The Intrinsic frame of reference

An Intrinsic FOR is one centered on an Object that is not the viewer. From the Object, three oriented axes (or six vectors) are constructed, one vertically and two on the horizontal plane. Any Object in the space defined by these coordinates is described in relation to the Object from which the space was constructed. When the Object

[3]The 180˚ rotation subtype of relative FOR in Levinson (2003) is not indicated here because within this work that subtype is considered as an instantiation of an intrinsic FOR.

[4]This discussion is limited to only visual input.

moves, the axes will move accordingly keeping their origin on the Object and the assigned orientation as well.

What differentiates the Relative and the Intrinsic FORs is that the Beginning of the Vectors is not from the viewer, but from an Object other than viewer. We have already seen that this is also the case for the Translation and Reflection subtypes of relative FOR. What is it that distinguishes these latter two FOR from the Intrinsic one?

The difference lies in the quality of the oriented field that is constructed for the Object or ground. This field is completely independent in orientation from the viewer; it is in other words a new separate field from that of the viewer. This difference has very important consequences, among which the most relevant is that the description of the spatial relationship between two Objects will be freed from references to the viewer. This, however, does not mean that the field of the viewer has not been used to construct the new field. Specifically, when we express linguistically a spatial relationship by utilizing an Intrinsic FOR, conceptually we must have used a Basic relative one in order to arrive at the construction of the first Object (Figure) and the second Object, making this latter a ground by constructing from it oriented axes.

What remains to be seen is how the axes of this new field are oriented. Typically the following three concepts have been associated with the Object that functions as ground in order to orient the axes mapped onto it: Animacy, Habitual Direction of Motion, and Habitual Use (Herskovits, 1986; Talmy, 2000). It is understood then that these three concepts participate in the construction of the Intrinsic FOR in a disjunctive fashion. That is, usually only one is necessary. It is, then, a specific characteristic of the Object picked to function as ground that determines the orientation of the axes mapped onto it. Only one axis need to be oriented, typically the frontal one, and the orientation of the others will follow.

Regarding the conceptual content of the Intrinsic FOR, all the content suggested for the Relative FOR needs to be postulated for the Intrinsic FOR as well. We also have to include the 'choice function' and the 'repeat function.' New concepts to be added are Animacy, Habitual Direction of Motion, Habitual Use (disjunctively used, even though they may overlap), and finally Part. In fact, the Object onto which the coordinates are mapped, needs to be assigned a 'front.' That is, a minimal subdivision of the Object into parts must be done.

The Absolute frame of reference

An Absolute FOR is neither centered on the viewer nor on an Object. First, the two Vectors related to the vertical axis are constructed. Second, on the horizontal plane one or more Objects (e.g., areas, points, landmarks) in the field of the viewer are chosen as orienting points. Third, either the viewer or any Object in its field is put into relationships with these Objects or fixed points.

Two examples of this system are the one that uses cardinal points, and the one that uses landward-seaward directions used by the speakers of many Oceanic languages. In many other cases the environmental features selected differ profoundly and may range from a mountain to a lake, or from a river to a building.

The process of selecting fixed orienting points in the environment requires minimally the activation of the Relative FOR. Once these fixed points have been conceptually established and agreed upon socially, these same points may function as an orienting framework between either one Object in the field of the viewer and one of the fixed points (e.g. North) or between any two Objects in the field of the viewer and one of the fixed points. We have already seen in the previous discussion of the other two types of FOR that the process of selecting/choosing an Object to function either as figure or ground implies the use of the concept of Path. For the construction of the absolute FOR, then, we need minimally either one or two Paths required for the construction of the Object or Objects to be put into relationship with any of the orienting fixed points. To these we have to add two (for the Oceanic system) or four (for the cardinal points system) Paths for the choice of the fixed points of reference.

Table 1 summarizes the conceptual content of the various types of FOR. A capital X indicates the presence of a concept in the construction of a FOR. For the concepts of Object, Path and Vector a number indicates how many times the concept is minimally used.

Table 1: The conceptual content of FORs

Concept/Axiom	Relative			Intrinsic	Absolute
	Basic				
		Transl	Reflect		
Locus	X	X	X	X	X
Object	1 + V	2 + V	2 + V	2 + V	1/2+2/4+V
Path	1	2	2	2	3/5 or 4/6
Vector	6	6	6	10	6
Verticality	X	X	X	X	X
Horizontality	X	X	X	X	X
Orthogonality	X	X	X	X	X
Visibility			X		
Part				X	
Animacy**				X**	
Hab Dir Mot**				X**	
Habitual Use**				X**	
Choice Funct*	X	X	X	X	X
Repeat Funct*		X	X	X	X

*These two are cognitive processes.
**Only one is necessary.

From Table 1 it can be seen how the conceptual axiomatic content of the Basic relative FOR is properly contained in its entirety in all the others, both subtypes (Translation and Reflection) and types (Intrinsic and Absolute). The Intrinsic and the Absolute are both derived from the Relative, although not in an ordered sequence. The Relative FOR, then, is suggested as an axiom for both the Intrinsic and the Absolute ones.

The Intrinsic and Absolute FORs are made of two different sets of concepts. The Intrinsic FOR expresses more attention to the nature of the Object functioning as ground (see the participation of the concepts of Part, Animacy, Habitual Direction of Motion, Habitual Use in

Table 1). The Absolute FOR, instead, expresses greater attention to the nature of the field (see the participation of a greater number of Objects and Paths in Table 1).

These findings are perfectly congruent with those of Baayen & Danziger (1994) and Levinson (2003) regarding a preferred use of the Intrinsic FOR by speakers of Mayan languages, where an extremely elaborate vocabulary also exists for describing parts of objects. Similar congruency can be highlighted with the findings of Levinson (2003) concerning the preferred use of the Absolute FOR by speakers of Australian Aboriginal languages where a very elaborate system of naming landmarks in one's environment has also been reported.

Finally, we look closely at the issue of 'untranslatability' among the various FORs suggested in Levinson (2003, p. 57-59). When we consider FORs as instantiated into linguistic expressions, it is true that in principle only two cases of translation are possible from one FOR to another (i.e., from either Absolute or Relative to Intrinsic). Do we deduce that there is 'untranslatability' among FORs at the conceptual level? Our discussion points towards a negative answer. In fact, the conceptual content of the Relative FOR has been suggested as an axiom for the Intrinsic and the Absolute ones. Thus, if at the linguistic level we find 'untranslatability' between FOR, at the conceptual level we find 'nesting.' Besides, the direction of the translatability from Relative and Absolute to Intrinsic correlates with one independent field in the former vs. two independent fields in the latter.

A Radial subtype of the absolute FOR

Bennardo (1996) reported the results of an investigation of the uses of FORs in Tongan language, spatial cognition, and culture. During this investigation a Radial subtype of absolute FOR was suggested as having a privileged status. This FOR consists in positing a center in one's field out of which movement is conceived either centripetally or centrifugally on any plane. This finding requires a reexamination of the typology of FORs. In particular, we need to look closer at the subtypes of the absolute FOR: Radial, Single Axis, and Cardinal Points.

For each of the three subtypes there are two cases to be considered. The first is when the ground is the viewer, e.g. "X is north of me.' The second is when the ground is an Object different from the viewer, 'e.g. X is north of Y.' Each case yields different conceptual content.

In the first case we need a Center that is the viewer and an Object (Figure). A Path from the viewer to the Object is also required as well as (minimally) a Vector made up of the Body of a Path and its End (centrifugal movement) or Beginning (centripetal movement). Either the End or the Beginning of this Path would be co-indexed with the Center. In the second case we have to add a second Object, which will function as Center, and a Path that is used to determine this Center (or second Object). The difference between the two cases is crucial. Choosing a Center different from viewer, makes possible the construction of a second field different from the one constructed around the viewer.

The conceptual content for the Single Axis subtype consists, in the first case, of one Object (Figure) plus two Objects (the two ends of the axis), the viewer, three Paths (from the viewer to the three Objects), and six Vectors (up, down, front, back, left, and right). In the second case, an Object for the new ground Object and a Path for its construction are added. A new field different from the viewer's is not constructed.

The conceptual content for a Cardinal Points subtype consists, in the first case, of one Object (Figure) plus four Objects (the cardinal points), the viewer, five Paths (from the viewer to the five Objects), and six Vectors (up, down, front, back, left, and right). An Object is added for the new ground Object and a Path for its construction. A new field different from the viewer's is not constructed.

Table 2: Conceptual content for types of Absolute FOR

	Concept		
Subtype of Absolute FOR	Object	Path	Vector
Radial 1	1 + V	1	1
Radial 2	2 + V	2	1
Single Axis 1	1 + 2 + V	3	6
Single Axis 2	2 + 2 + V	4	6
Cardinal Points 1	1+ 4 + V	5	6
Cardinal points 2	2 + 4 + V	6	6

In Table 2, the conceptual content of the Radial subtype is the simplest. The contents of the two Radial subtypes are also simpler than the content of the Basic subtype of the relative FOR in Table 1. Consequently, the axiomatic relation between the Relative, the Intrinsic, and the Absolute FORs needs some further attention.

A new typology of Frames of Reference

In discussing the relationships between the types and subtypes of FOR three parameters are considered. The first is the magnitude of the conceptual content, that is, the number of concepts necessary to derive each theorem. The second is the reference that will be made to axiomatic relationships. When the content of a FOR is completely contained in another, then the former will be considered an axiom of the latter. The third is the emergent properties that each FOR displays. Namely, it must be considered if a FOR is based on the construction of one or two fields.

The minimal conceptual content and the construction of only one field associated with the Radial 1 subtype of the absolute FOR make it the choice as the most basic. This FOR, then, is an axiom for all the other types and subtypes. Its great simplicity makes it highly context bound and hence very unlikely to be the only one that any individual/culture will have. Nonetheless, it represents a minimal stage of spatial organization assigned to the external world. Evidence from languages around the world suggests that this system is always used, i.e., in demonstrative systems.

Looking for a FOR at the second stage of complexity, or more precisely, the first theorem derived from a set of axioms whose content is at a limit only the Radial 1 axiom, we confront two options. The first is to choose the Radial 2 subtype of the absolute FOR, simple in conceptual content, though it uses two fields. The second

is the Basic relative FOR that is more complex conceptually (it needs six Vectors instead of one), but uses only one field. A decision is not strictly necessary at this juncture; both options are viable. Empirically, there are language speakers that choose to use prevalently one option only (e.g. English speakers choose a Basic relative FOR), and other that choose both (e.g. Tongan speakers).

We have stated that the Relative FOR functions as an axiom for the Absolute and the Intrinsic FOR, and for two subtypes of the Relative FOR. These latter keep the single field feature, but increase their conceptual content because of their complex treatment of the front-back axis.

The Single Axis and Cardinal Points subtypes of the absolute FOR and the Intrinsic FOR are obtained in substantially different ways. The two Absolute FORs represent an increased conceptual content from the Relative FOR and use a single field. This is confirmed by the fact that they both use the vertical axis. The Radial 1 and 2 subtypes did not have it in their conceptual content.

The intrinsic FOR is obtained by an increased conceptual complexity due to two other factors (besides the addition of the vertical axis). The first is a closer attention devoted to the Object that functions as figure. The second is the construction of two fields (the viewer's and the figure's). We have seen that the construction of two fields is part of the conceptual content of the Radial 2 subtype of the absolute FOR. Then, we suggest that the conceptual content of the intrinsic FOR is derived from the Basic subtype of the relative FOR, from the Radial 2 subtype of the absolute FOR, and from conceptual characteristics of the Object/Figure.

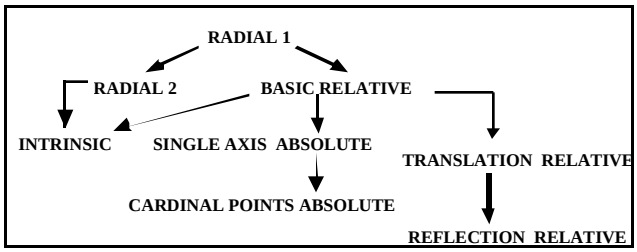

Figure 1: A typology of Frames of Reference

The arrows in Figure 1 indicates that the FOR receiving the content of another FOR treats this latter as an axiom of its conceptual content. Further conceptual material is added at each stage. Thus, the necessity of a new label for that particular type of FOR.

Conclusion

The first part of this work was devoted to the introduction of the conceptual apparatus that is the major theoretical tool employed in the analyses of the conceptual content of FORs. Each member of the typology of FORs suggested by Levinson (2003) was later analyzed. and a primary revision was suggested. Nesting of FORs was proposed at the conceptual level instead of untranslatability. Then, a Radial subtype of absolute FOR was introduced. This made clear that a further revision of the typology was needed. Finally, the revision resulted in the proposed typology of FORs in Figure 1. It is believed that this typology can be useful for further investigation of FORs.

Abstract

Various lines of research on language have converged on the premise that linguistic knowledge has as its basic unit pairings of form and meaning. The precise nature of the meanings involved, however, remains subject to the longstanding debate between proponents of arbitrary, abstract representations and those who argue for more detailed perceptuo-motor representations. We propose a model, Embodied Construction Grammar (ECG), which integrates these two positions by casting meanings as schematic representations embodied in human perceptual and motor systems. On this view, understanding everyday language entails running mental simulations of its perceptual and motor content. Linguistic meanings are parameterizations of aspects of such simulations; they thus serve as an interface between the relatively discrete properties of language and the detailed and encyclopedic knowledge needed for simulation. This paper assembles evidence from neural imaging and psycholinguistic experiments supporting this general approach to language understanding. It also introduces ECG as a model that fulfills the requisite constraints, and presents two kinds of support for the model. First, we describe two verbal matching studies that test predictions the model makes about the degree of motor detail available in lexical representations. Second, we demonstrate the viability and utility of ECG as a grammar formalism through its capacity to support computational models of language understanding and acquisition.

Introduction

Many theories of language take the basic unit of linguistic knowledge to be pairings of form and meaning, known as *symbols* or *constructions* (de Saussure 1916; Pollard & Sag 1994; Goldberg 1995; Langacker 1987). This view stems from the simple observation that language serves to convey meaning, using form. A speaker must thus know what linguistic forms are appropriate to encode the meanings s/he wishes to convey, and vice versa for an understander.

The nature of the meaning representations of linguistic units, however, remains very much at issue. Suggestions in the literature range from relatively abstract representations, including both feature structures (Pollard & Sag 1994) and logical representations (May 1985), to more concrete perceptual- or motor-based representations (Langacker 1987; Barsalou 1999; Glenberg & Robertson 2000).

Each of these approaches faces difficulties. Abstract symbol systems, whether feature-based or logical, invite the question of how (or even whether) they are ultimately linked to human perceptual, motor, affective, and other sorts of experience. There is strong evidence, seen below, that such embodied knowledge is automatically and unconsciously brought to bear during language understanding. Moreover, language users naturally make a broad range of associative and causal inferences based on language, a process not easily represented in an abstract symbol system.

Conversely, a theory of linguistic meaning cannot be based on perceptuo-motor information alone. Linguistic units can be combined in ways that are not strictly predictable from their semantic properties. Our ability to judge the grammaticality of sentences like Chomsky's (1957) classic *Colorless green ideas sleep furiously* example provides strong evidence of linguistic structure distinct from motor, perceptual, or other world knowledge. Additionally, our ability to understand sentences like *My pet chicken kissed me on the cheek* (even though chickens don't have lips, presumably a prerequisite for kissing) shows that grounded motor knowledge does not suffice to account for our ability to extract meaning from language.

One concrete solution to the drawbacks of purely abstract and purely perceptuo-motor approaches is to characterize mental representations as schematizations over modal knowledge (Fillmore 1982; Langacker 1987; Lakoff 1987; Barsalou 1999; Talmy 2000). This compromise view retains the best of both worlds: while language *use* involves the activation of perceptual and motor mechanisms, linguistic *units* themselves need only refer to schematic representations of these mechanisms. Proposals along these lines have inspired work investigating how the perceptual and motor structures underlying word meaning might be represented and schematized in computational models of human language processing (Regier 1996; Bailey 1997; Narayanan 1997). But the nature of the lexical and grammatical units that link these structures with linguistic forms has not yet been articulated precisely enough to support formal or computational implementation.

This paper synthesizes diverse evidence for an integrated view of language use and presents Embodied Construction Grammar (ECG), a formally specified instantiation of the approach. We begin by surveying evidence of the importance of perceptual and motor simulation in higher-level cognition, especially in language use. We then briefly outline the ECG formalism and show how it supports a model of human language use in which linguistic meanings serve to parameterize motor and perceptual structures. The remainder of the paper presents two kinds of support for the model. First, we describe a pair of verb matching studies

that test predictions the model make about the degree of simulative detail in lexical representations. Second, we demonstrate the viability and utility of ECG as a grammar formalism precise enough to support computational models of language understanding and acquisition.

Mental Simulation in Language Use

Evidence for simulation

Perceptual and motor systems play an important role in higher cognitive functions, like memory and categorization (Barsalou 1999; Glenberg & Robertson 2000; Wheeler, Petersen & Buckner 2000; Nyberg et al. 2001), as well as motor (Lotze et al. 1999) and perceptual (Kosslyn, Ganis & Thompson 2001) imagery. It would thus be surprising if there were no role for perceptual and motor systems in language use as well.

Some theorists have proposed that perceptual and motor systems perform a central function in language production and comprehension (Glenberg & Robertson 2000; Barsalou 1999). In particular, they have suggested that understanding a piece of language entails internally simulating, or mentally imagining, the described scenario, by activating a subset of the neural structures that would be involved in perceiving the percepts or performing the motor actions described.

Several recent studies support this notion of simulation in language understanding, based on the activation of motor and pre-motor cortex areas associated with specific body parts in response to motor language referring to those body parts. Using behavioral and neurophysiological methods, Pulvermüller, Haerle & Hummel (2001) and Hauk Johnsrude & Pulvermüller (2004) found that verbs associated with different effectors were processed at different rates and in different regions of motor cortex. For example (Pulvermüller et al. 2001), when subjects perform a lexical decision task with verbs referring to actions involving the mouth (e.g. *chew*), leg (e.g. *kick*), or hand (e.g. *grab*), areas of motor cortex responsible for mouth/leg/hand motion displayed more activation, respectively. Tettamanti et al. (ms.) have also shown through an imaging study that passive listening to sentences describing mouth/leg/hand motions activates different parts of pre-motor cortex (as well as other areas, specifically BA 6, 40, and 44).

Behavioral methodologies also offer convergent evidence for the automatic and unconscious use of perceptual and motor systems during language use. Recent work on spatial language (Richardson et al. 2003; Bergen To Appear) has found that sentences with visual semantic components can result in selective interference with visual processing. While processing sentences that encode upwards motion, like *The ant climbed*, subjects take longer to perform a visual categorization task in the upper part of their visual field; the same is true of downwards-motion sentences like *The ant fell* and the lower half of the visual field. These results imply that language, like memory, evokes visual imagery that interferes with visual perception.

A second experimental method (Glenberg & Kashak 2002), tests the extent to which motor representations are activated for language understanding. The findings from this approach have shown that when subjects are asked to perform a physical action in response to a sentence, such as moving their hand away from or toward their body, it takes them longer to perform the action if it is incompatible with the motor actions described in the sentence. This suggests that while processing language, we perform motor imagery, using neural structures dedicated to motor control.

A third method, used by Stanfield & Zwaan (2001) and Zwaan et al. (2002), investigates the nature of visual object representations during language understanding. These studies have shown that implied orientation of objects in sentences (like *The man hammered the nail into the floor* versus *The man hammered the nail into the wall)* affected how long it took subjects to decide whether an image of an object (in this case, a nail) had been mentioned in the sentence, or even to name that object. It took subjects longer to respond to an image that was incompatible with the implied orientation or shape of a mentioned object. These results imply that not just trajectory and manner of motion, but also shape and orientation of objects, are represented in mental simulations during language understanding.

Linguistic knowledge as a simulation interface

Language understanding seems to entail the activation of perceptual and motor systems, which work in a dynamic, continuous, context-dependent, and open-ended fashion. Linguistic form, by contrast, is predominantly discrete — a word either precedes another word or does not; a morpheme is either pronounced or not, and so on. How do linguistic representations pair relatively discrete linguistic forms with continuous, dynamic, modal perceptuo-motor simulations? The notion of *parameterization* offers an answer.

Grammatical knowledge governing the productive combination of linguistic units appears to draw primarily on schematic properties of entities and events (Langacker 1987; Goldberg 1995), such as whether an entity can exert force or move, or whether an action involves the exertion of force or causes motion. Thus, for the purposes of language understanding, which involves determining what linguistic units an utterance uses and how they are combined, it may be sufficient for words and morphemes to generalize over perceptual or motor detail and encode only the important, distinctive aspects of actions and percepts required to perform a simulation. These parameterized representations are not abstract, amodal symbols, since they are directly grounded in action and perception, but they are distinct from the simulative content they parameterize.

This simulation-based view of language understanding has immediate consequences for theories of language. Only meaning representations that can be usefully fed to the simulation are viable; at the same time, constructions are freed from having to capture the encyclopedic knowledge handled by simulation. This division of labor between the meaning representations of linguistic constructions and the detailed structures that support simulation provides the means for finite, discrete linguistic structures to evoke the open-ended, continuous realm of possible meanings that language users may communicate. ECG is a theory of language that conforms to these constraints.

Embodied Construction Grammar

Embodied Construction Grammar (Bergen & Chang To Appear; Chang et al. 2002) aims to be a theory of language suitable for integration in a grounded, computationally implemented, simulation-based theory of human language use. It resembles other Construction Grammars (Kay & Fillmore 1999; Goldberg 1995; Croft 2001) in counting form-meaning pairings as the basic linguistic unit, and in aiming for full coverage of linguistic behavior. But ECG also serves as precisely the interface between language and simulation described above. It thus differs from other grammatical theories in emphasizing the embodiment of the grammatical system: constructions pair schematic form representations with schematic meaning representations, which are further constrained to be abstractions over perceptual and motor representations that can be simulated, or over characteristics of simulations in general.

A detailed description of the formalism is given in Bergen & Chang (To Appear); ECG has also been applied to a wide range of linguistic phenomena, including argument structure, reference, predication, and morphology, in a variety of languages. We concentrate here on showing how the representational tools of ECG satisfy and exploit the constraints of a simulation-based approach to language understanding. We first describe the high-level interactions posited in the model between linguistic constructions and the dynamic processes of language understanding they support, and then illustrate these with a simple example.

The Language Understanding Process

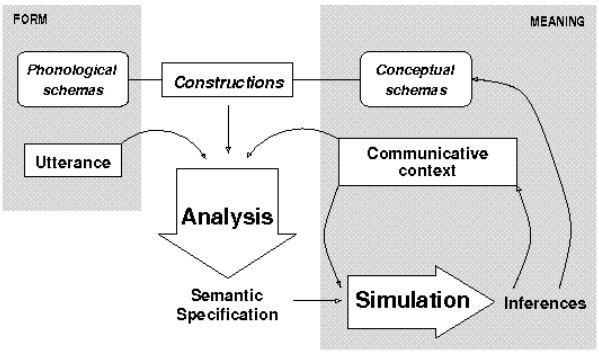

Figure 1. Language understanding in ECG.

The main source of linguistic knowledge in ECG is a large repository of constructions that express generalizations linking the domains of form (typically, phonological schemas and relations) and meaning (conceptual schemas and relations). Some constructions directly specify which perceptual and motor mechanisms to deploy, while others (especially larger phrasal and clausal constructions) specify how to combine the parameterized representations corresponding to different kinds of imagery. Still other constructions may affect the mode of simulation itself; the passive construction, for example, modulates what perspective is to be taken in the simulation of a given action.

There are also two main dynamic processes (large arrows in Figure 1) that interact with constructional knowledge during language comprehension. The first is the *analysis* process, which takes an input utterance in context and determines the set or sets of constructions most likely to be responsible for it. This process is thus roughly analogous to parsing, though it additionally incorporates contextual information, following Tanenhaus et al. (1995) and Spivey et al. (2001). The product of the analysis process is a structure called the *semantic specification* (or *semspec*), which specifies the conceptual schemas evoked by the constructions and how they are related. The second process is *simulation*, which takes the semspec as input and exploits representations underlying action and perception to simulate the specified events, actions, objects, relations, and states. The resultant inferences shape subsequent processing and provide the basis for the language user's response.

Embodied Construction Grammar in action

This section shows how the process just described would produce the appropriate simulation and resulting inferences for the sentence *Mary bit John*. The understander first tries to recognize the sequence of sounds in terms of form schemas. In speech or in sentences with novel or ambiguous word forms, this may require sophisticated categorization. Here, the forms are straightforwardly recognized as three form schemas ('Mary', 'bit', and 'John') with the appropriate temporal ordering relations among them, shown as vertical arrows on the left-hand side of Figure 2.

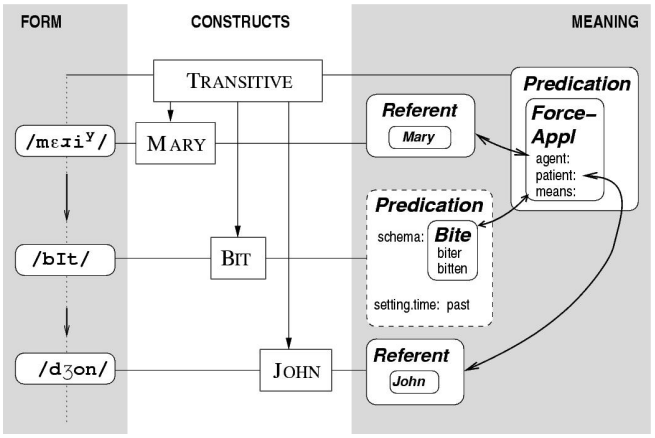

Figure 2: The (simplified) analysis of Mary bit John.

Next, the analysis process hypothesizes which constructions (instantiated as *constructs*) could account for the utterance; these are constructions whose form elements are present in the utterance. The four constructions relevant for this utterance are shown in the middle column of Figure 2. The JOHN and MARY constructions each bind some phonological form (on the left) with a particular schema for its referent (on the right). The BIT construction binds its phonological form with a predication that features a schema called Bite, which is the schematization of perceptual and motor knowledge about biting. Additionally, the predication is specified as being about the past, which will become relevant when inferences are propagated, after simulation.

The clausal TRANSITIVE construction binds together the forms and the meanings of the three lexical constructions, which serve as its constituents. On the form side, it specifies an ordering relation (Agent precedes Verb precedes Patient),

while on the meaning side, the clause is linked to a predication that encodes the application of force by some means, where that means is bound to the Bite schema, the agent is Mary, and the patient is John. The clausal construction thus contributes its own structure and schematic meanings, and effects bindings among these and those of its constituents. In our example, the analysis process succeeds in finding a set of constructions that match the utterance and whose different constraints fit together, or unify, in all three domains: form, meaning and construction.

The completed analysis process produces a semspec (consisting of the meaning schemas and bindings, shown in the right-hand column in Figure 2), which is used as input for the next step, the mental simulation of the described scene. The semspec indicates which perceptual and motor structures should be activated and how they are related. It might also specify other parameters of the simulation, such as the perspective from which to simulate. Our example is in the active voice, not passive (e.g. *John was bitten by Mary*), so would by default be simulated from Mary's perspective, resulting in the activation of a motor schema for biting (though features of the surrounding context could result in an "experiencer" simulation perspective instead).

Although our example omits many details of analysis and simulation (including how the model supports, e.g., reference resolution, construal, and sense disambiguation (for a discussion of these, see Bergen and Chang (To Appear)), it nonetheless demonstrates how ECG captures the idea of parameterization or schematization. A verb form like 'bit' centrally includes a Bite schema in its meaning; this schema is a parameterization over perceptual and motor knowledge about biting. To figure out who is biting whom — that is, to understand how the meaning of 'bit' relates to the meanings of the other words in the utterance — only very general knowledge about biting (that it is an action in which force is exerted by one participant on another) is required. The simulation process makes use of the perceptual and motor knowledge underlying this schematic representation, and provides detailed perceptual and motor content that can support inference and, on the current account, constitutes understanding.

The remainder of the paper offers support for the ECG model from two different sources: a pair of behavioral experiments testing a prediction of the model, and the implementation of the formalism within computational models of language acquisition and understanding.

Experiment: Embodied Verbal Representation

The ECG approach to language claims that verbal semantics involves the activation of detailed motor knowledge about performing or perceiving the relevant action. One reflection of this prediction might be in the representation of the effector used to perform the action described by a verb. To test this hypothesis, we performed two related behavioral experiments. In the first, subjects were shown a picture and then a verb, and asked to decide whether the word correctly described the picture. In the second, subjects were asked to decide whether two verbs had nearly the same meaning. We predicted that subjects would take longer to reject as matches an image-verb or verb-verb pair that depicted different actions using the same effector, compared to the case when the two non-matches used different effectors.

Method

Study 1. 39 native English speakers participated for course credit. They were told that they would see a picture of a person performing an action on a screen, followed by a verb, and were instructed to decide as quickly as possible whether the verb was a good description of the picture.

During each trial, subjects were presented a stick figure of a person carrying out an action for 1 sec, a visual mask for 450 msec, and a blank screen for 50 msec. Then the verb was displayed, and stayed on the screen until the subject pressed "yes" or "no". All verbs were presented in the center of the screen. All actions were predominantly performed using one of three effectors: foot, hand or mouth. More detailed discussion of the methodology can be found in Bergen, Feldman & Narayan (2003).

Study 2. 53 native English speakers participated on a volunteer basis or for course credit. They were told that they would see a word appear on a screen and were instructed to decide as quickly as possible whether a second word that appeared meant more or less the same as the first word.

During each trial, subjects were presented with a fixation cross in the center of the screen for 2 sec, followed by an English action verb for 1 sec, a visual mask for 450 msec, and a blank screen for 50 msec. Then the second verb was displayed, and stayed on the screen until the subject pressed "yes" or "no". All verbs were capitalized and presented in the center of the screen. Verb pairs in critical trials pertained to motor actions of the following categories:

Matching: Near-synonyms, e.g.
SCREAM and SHRIEK; DANCE and WALTZ

Non-matching, same effector: Verbs with clearly different meanings, using the same effector, e.g.
SCREAM and LICK; DANCE and LIMP

Non-matching, different effector: Verbs with clearly different meanings, using different effectors, e.g.
SCREAM and STEP; DANCE and YELL

More detailed discussion of the methodology can be found in Narayan, Bergen & Weinberg (2004).

Results

Study 1. Counting only replies that were correct and within 2s.d. of the mean for a given subject, mean reaction times were 751ms for different-effector mismatches, 799ms for same-effector mismatches, and 741ms for matches. Using a standard ANOVA, the difference between the mismatching conditions was found to be significant ($p<.0001$).

Study 2. Counting only replies that were correct and within 3s.d. of the mean for a given subject, mean reaction times were 930ms for different-effector mismatches, 1030ms for same-effector mismatches, and 1070ms for near-synonyms.

Following Clark (1973), we performed two ANOVAs, with subjects and items as nested random factors, and from these determined that the RT difference between the

mismatch conditions is significant (minF'(1,126)=9.0808, $p<0.005$). Post hoc tests showed that the non-matching different-effector condition is significantly different from the matching condition (minF'(1,126)=9.781), and the non-matching same-effector condition is not significantly different (minF'(1,126)=2.0002).

Discussion. Subjects took significantly longer to reject either a picture-verb pair as matches or a verb pair as near-synonyms when the two actions shared an effector than when they did not. Since this effect occurred when part of the task was non-linguistic (Study 1), this is unlikely to be a mere lexical effect. Moreover, the presence of the effect with purely linguistic stimuli (Study 2) means it is not due to strictly visual properties of the stimuli, either. Instead, these results suggest that understanding motion verbs goes beyond accessing abstract structures; modal information about bodily action, such as the effector used, is involved.

Importantly, the results imply that verb meaning does involve evoking modal motor representations: words encoding particular motor actions (kick, chew) contribute to the perceptuo-motor content of mental simulations.

ECG computational implementation

ECG is compatible in its broad outlines with a large body of linguistic and psycholinguistic research. But it is subject to the important additional constraint of being computationally precise. As we have described it, understanding even the simplest utterance involves multiple dynamic processes interacting with a variety of linguistic and embodied representations. Many of these are inspired by ideas from cognitive linguistics that have not been previously formalized, let alone used in any implemented system. It is thus crucial that we validate the framework by offering concrete implementations. In this section we briefly describe how the formalism serves as the lynchpin for computational models of linguistic use and acquisition.

Formally, the ECG construction and schema formalisms have much in common with other unification-based grammars (e.g., Pollard & Sag 1994), including notations for expressing features, inheritance, typing, and unification/coindexation; it also has additional mechanisms that increase its expressivity and flexibility.

As described earlier, the ECG formalism is designed to play a role in language understanding as the key interface between constructional analysis and the embodied simulation. Bryant (2003) describes an implemented construction analyzer that takes as input a grammar of ECG constructions and a sentence, and produces a semspec that provides the parameters for a simulation. The analyzer extends methods from syntactic parsing (particularly partial parsing and unification-based chart parsing) to accommodate and exploit the dual form-meaning nature of constructions. Specifically, it consists of a set of *construction recognizers*; each recognizer seeks the particular input form (or constraints) of its corresponding construction, and upon finding it checks the relevant semantic constraints. If multiple analyses are possible, the analyzer uses a *semantic density* metric to choose the analysis whose semspec is the most semantically coherent and complete. Thus, in constrast with typical language understanding systems in which syntactic parsing precedes semantic interpretation, the construction-based analyzer incorporates semantic constraints in parallel, reflecting the central role played by meaning in the ECG formalism.

The semspec produced by the analyzer provides parameters for simulation using active, modal structures. A broad range of embodied meanings have been modeled using *executing schemas* (x-schemas), a dynamic representation motivated in part by motor and perceptual systems (Narayanan 1997; Bailey 1997). X-schemas can model sequential, concurrent, and asynchronous events. The Bite schema, for example, parameterizes a Bite x-schema that captures the continuous mouth actions culminating in a particular forceful application of the teeth of the Biter to the Bitten. A simulation engine based on x-schemas has been implemented (Narayanan 1997) and applied to model the semantics of several domains, including verbal (Bailey 1997) and aspectual semantics (Chang, Gildea & Narayanan 1998), metaphorical inference (Narayanan 1999), and frame-based perspectival inference (Chang et al. 2002).

Although we have focused so far on language understanding, the ECG formalism is also designed to support a computational model of the acquisition of early phrasal and clausal constructions (Chang & Maia 2001; Chang 2004). This model takes ECG as the target representation to be learned from a sequence of utterances in context. Learning is usage-based in that utterances are first analyzed using the process described above; the resulting (partial) semspec is used along with context to prompt the formation of new constructions. The model has been applied to learn simple English motion constructions from a corpus of child-directed utterances, paired with situation representations. The resulting learning trends reflect cross-linguistic acquisition patterns, in particular the learning of lexically specific verb island constructions before more abstract grammatical patterns (Tomasello 1992). They also demonstrate how the ECG formalism serves as an interface between language comprehension and acquisition.

The implementations described here do not provide direct evidence of the cognitive reality of ECG. But they do demonstrate its utility and flexibility, and, by offering an integrated and precisely specified instantiation of simulation-based language understanding and use, serve as an existence proof for the overall approach.

Conclusions

If the embodied view presented above is correct, then the human capacity for language understanding relies on activating internal motor and perceptual simulations on the basis of linguistic input. These simulations can serve any of the purposes that linguistic information is conventionally put to — their content can be stored, thereby updating the internal knowledge base; their inferences can be propagated such that the understander can draw conclusions needed in discourse; or the actions they include can be performed in cases where the language involves instructions or requests.

The computationally viable and empirically supported model described above views linguistic units as pairings between schematic representations of form and schematic

representations of meaning. Those representations are not abstract and arbitrary; rather, they are tightly bound to the perceptual and motor substrates over which they generalize. This approach permits insights into how language is integrated with perceptual and motor knowledge in the cognitive system, and sheds light on what meaning means.

Abstract

We study how students hedge and express affect when interacting with both humans and computer systems, during keyboard-mediated natural language tutoring sessions in medicine. We found significant differences in such student behavior linked to whether the tutor was human or a computer. Students hedge and apologize often to human tutors, but very rarely to computer tutors. The type of expressions also differed—overt hostility was not encountered in human tutoring sessions, but was a major component in computer-tutored sessions. Little gender-linking of hedging behavior was found, contrary to expectations based on prior studies. A weak gender-linked effect was found for affect in human tutored sessions.

Introduction

How people interact with computers is of clear importance to the design of effective computer interfaces. The book *The Media Equation* (Reeves & Nass 1996) claims that people treat computer systems essentially the same as they treat people, though more recent work (Shechtman & Horowitz 2003; Goldstein et al., 2002) has raised serious questions about this conclusion. Differences between how people respond to human beings and how they respond to computers have been informally documented since the first experiments with natural language interfaces (Thompson, 1980). A better elucidation of the issues may improve intelligent systems design.

Specifically, understanding these issues better may aid in the development of more effective tutoring systems. In this paper, we study the differences between student reactions to our Intelligent Tutoring System (ITS), CIRCSIM-Tutor (Michael et al., 2003), and the human tutors on which it was modeled. Our goal is to characterize student hedges and expressions of affect and try to determine how our ITS could understand them and respond effectively.

We are motivated by experiments (Fox 1993) that suggest such differences for ITSs that carry out a natural language dialogue with the student. Fox carried out a "Wizard-of-Oz" experiment which showed students to be polite and friendly to human tutors when they met with them face-to-face, but decidedly rude to the same tutors when communicating with them over a slow computer link and told that a machine was tutoring them.

The current study has potentially important implications for the future development of our ITS. Investigation of how human tutors respond to student misery, frustration, and rage is the first step toward making systems more friendly and responsive. By contrast, our system's current response to student hedges and expressions of affect (as to any input it does not understand) is to tell the student what kind of input it is expecting. The result is dialogue like this:

Student: Clueless!
Tutor: Please respond with prediction table parameters.

Better understanding of how and when students express affect in tutoring sessions and the functions of such expressions in the discourse may lead to improvements in student modeling and hence tutoring effectiveness.

Background

Thompson's (1980) system was a pioneering natural-language interface designed to help U.S. Navy personnel load cargo onto ships. It thus attempted to delete all affective remarks, to avoid confusing the parser. Although the system was quite effective at its task, most of its affective input consisted of curses. By contrast, chat-oriented natural language interaction programs like ELIZA (Weizenbaum, 1966) and PARRY (Colby, 1975), can impress their users with simulated charm and intelligence, despite a lack of any deep understanding. Similarly, physicians experienced the natural language interface of Shortliffe's (1982) MYCIN and ONCOCIN programs as attractive, even though

input was restricted to one-word answers to questions.

The specific question of how to properly interpret student hedging in tutoring sessions was raised at the *NAACL Workshop on Adaptation in Dialogue Systems,* held as part of the 2001 meeting of the Association for Computational Linguistics. It was suggested that student hedges might provide useful information by reliably signaling student misconceptions. Our collaborators on the CIRCSIM-Tutor project at Rush Medical College are dubious about this suggestion, however. Ten years ago, after their first experiments with tutoring in cardiovascular physiology they resolved to stop commenting on hedges, because they felt that student hedging reflects personal communication styles more than any real confusion. Further experience has not changed their minds, although they respond with help and encouragement whenever they believe the student to be experiencing real distress (Bhatt 2004).

As well, there is an increasing recognition in the ITS community of the importance of affect. A full session at *Intelligent Tutoring Systems* 2002 was devoted to such issues (Aist et al. 2002; Kort & Reilly 2002; Vicente & Pain 2002). These papers all argue for the importance of responding to evidence of student distress. Our study is the first, to our knowledge, that explicitly studies student hedging of answers and expressions of affect by comparing human and computer tutorial sessions. Relevant in this context also is the recent general trend towards greater concern in the AI community with emotional aspects of intelligence, sparked mainly by the work of Breazeal and Brooks (Brooks et al. 1998; Breazeal 1998).

Goals and Hypotheses

We study response hedging and expressions of affect in human and machine tutoring sessions. This study incorporates both exploratory and hypothesis testing goals. The main exploratory questions that we investigated are as follows:

What kinds of hedged responses and expressions of affect do we see in human tutoring sessions?

What kinds of hedged responses and expressions of affect do we see in machine tutoring sessions?

How might the two kinds of tutoring interactions differ regarding student use of hedged responses and expressions of affect?

In addition, based on results in human/computer interaction (primarily Fox (1993) and Thompson (1980)), we formulate our main hypotheses:

H1a (Hedging Differs): *Student use of hedging differs depending on whether the tutor is a human or a computer system.*

H1b (Affect Differs): *Student use of affect differs depending on whether the tutor is a human or a computer system.*

The workshop discussion mentioned above also prompted us to investigate two subsidiary hypotheses about hedging, and how it may prove useful for student modeling:

H2a (Hedges Inform): *The presence of a hedge provides information regarding whether a student answer is right or wrong.*

H2b (Hedges Wrong)*: Hedged answers are almost always wrong and so provide near certain feedback for student modeling.*

Regarding the relevance of *H2b*, note that most computer tutoring systems cannot currently make use of 'weak' probabilistic information for student modeling, such as "hedged answers are 20% more likely to be wrong than non-hedged answers", but only more certain statements, such as "hedged answers are almost always wrong".

Gender-linked variation

Many previous studies, including Lakoff (1975) and Aries (1989), have reported that women hedge more than men, although interpretation of such claims is complex (Holmes 1984), since hedging can be a politeness or face-saving strategy, and not necessarily an expression of uncertainty. Of particular relevance are recent results on hedging in tutoring systems (Shah et al., 2002), which found that women hedge significantly more often than men when making initiatives in tutoring dialogues. If such differences are consistent, it should influence how tutoring systems interact with male and female students. We thus formulate:

H3a (Women Hedge): *Women hedge answers more often than men in tutoring interactions.*

Aries, Lakoff (1990) and Tannen (1990) all describe women as more likely to express emotion than men. Hence:

H3b (Women are Affectual): *Women use more affective expressions than men in tutoring interactions.*

Furthermore, Lakoff (1975) also describes women as apologizing more often. Thus we also consider whether:

H3c (Women Apologize): *Women apologize more often than men in tutoring interactions.*

Data Collection

Human/Human Tutoring Sessions

We collected transcripts of keyboard-to-keyboard human tutoring sessions (henceforth, *H/H sessions*) between students and their expert tutors on the subject of the baroreceptor reflex during November 1999. Sessions took place with the student and the tutor in separate rooms, communicating only via keyboard. The tutor for each session was either Joel Michael or Allen Rovick (both professors of physiology, the same tutor throughout each session), and the 25 subjects were paid volunteers, first year students at Rush Medical College enrolled in a physiology course. The data examined consists of over 51,000 words (over 12,000 lines) of student-tutor dialogue, from hour-long sessions (numbered K52-K76 in our corpus).

Human/Computer Tutoring Sessions

In November 2002, most of the first year class at Rush Medical College used CIRCSIM-Tutor (Michael et al., 2003) for one hour in a regularly scheduled laboratory session. Some students worked in pairs, some alone, so we wound up with only 66 transcripts (the *H/C sessions*), which we used as the basis for our findings about machine tutoring sessions. The system presents the same problems about the baroreceptor reflex as the human tutors and attempts to emulate their tutoring strategies. We have not yet attempted to analyze the differences between the single-user and paired sessions.

Methodology

Coding of Hedges

Hedges in the transcripts were hand-coded using a coding scheme based on the hedge types described in Shah's (2002) study of hedged initiatives. The first step was to examine transcripts of four H/H sessions (K52-K55) and to establish an initial categorization. This phase was performed collectively by Bhatt and Evens. Subsequently, the remaining twenty-two sessions were coded by each researcher independently. Each hedged instance was classed by one of the predefined types (Table 1). Inter-rater reliability was excellent, with a kappa of 0.97.

Following this initial coding and coder comparison, some hedge types were eliminated or aggregated into other types, and coding was standardized in all transcripts. Transcripts were electronically marked up using SGML tags, to facitlitate subsequent counting of hedges and hedge types for statistical analysis. The final list of hedge types, along with counts and examples of usage, is given in Table 1.

Table 1: Final list of hedge categories with definitions or examples of usage, with counts of occurrences as answers (**A**) and initiatives (**I**).

Hedge Type	A	I	Example
BELIEVE	6	0	*I believe*
EITHER_OR	2	0	*Either X orY*
EQUIVALENT	3	1	*it sounds as though*
EXPECT	12	0	*probably*
GUESS	10	1	*I guess*
KIND_OF	7	0	*Kind of*
MAYBE	4	4	*Maybe*
NOT_SURE	9	3	*I'm not sure*
Q1	61	11	Question mark after a statement
Q2	2	1	Question syntax with no "**?**"
SHOULD	1	0	*X should increase*
TAG	2	2	*It shouldn't X, should it?*
THINK	44	11	*I think*
THOUGHT	21	4	*I thought*
TRY	3	0	*I can try*

Table 2: Types of affect expressions in student responses and examples of usage, with counts of occurrences as answers (**A**) and initiatives (**I**).

Affect type	A	I	Example
AMAZEMENT	0	1	*Wow*
AMUSEMENT	0	1	*Ha ha*
APOLOGY	4	14	*Sorry*
COMPREHENSION	6	6	*I get it*
CONFUSION	1	7	*I'm a bit confused*
CONTEMPLATION	14	5	*Hmmm*
CURIOSITY	0	2	*I'm curious*
DIFFICULTY	0	2	*I'm having difficulty*
FEEDBACK	0	6	*That was helpful*
GRATITUDE	0	14	*Thank you*
GREETING	0	1	*Good morning*
PAIN	0	1	*Ouch*
REALIZATION	5	9	*Ahh*

Coding of Affect

For coding affect a similar procedure to that above was followed. Evens and Bhatt scanned the text comprising the sessions K52-K55 and searched for instances of student affect together, discussing potential instances. A set of categories was derived from these initial analyses, and the remaining sessions (K56-K76) were then coded independently by both researchers. The results were then discussed until a consensus was

reached on each instance. Table 2 lists the final categorization of the types of affect found in the data, with counts and examples. Transcripts were electronically marked up using SGML tags as above.

Parenthetically, identifying affect in student responses was quite straightforward. In fact, almost every expression of affect was explicitly signaled by the student. This is encouraging for the use of affectual cues by computer tutoring systems, since in a text-based medium it is very difficult, if not impossible, to deduce students' emotional states from implicit cues (such as sarcasm).

Results and Discussion

Hedging in Human Tutoring

Hedged answers occur on average 6.04 times per session (σ=3.77). The different kinds of hedges are given in Table 1. The two most common types by far (together accounting for more than half of all occurrences) are Q1, adding a question mark to an answer otherwise in statement form (possibly expressing a sort of "questioning intonation"), and THINK, expressing a modal likelihood assessment via grammatical metaphor.

The majority of hedged answers are correct (57.6%, N=151), and so hedging does not provide a clear-cut signal of misunderstanding on the part of the student, so the data do not support *H2b: Hedges Wrong*. However, an even larger majority of non-hedged answers are correct (80.1%, N=359). This difference is significant (one-sided p<0.001), supporting *H2a: Hedges Inform*. Indeed, wrong answers are almost twice as likely to be hedged than correct answers (42.7% versus 26.3%).

In contrast to other work, we found gender to make no significant difference in hedging answers, as women hedge answers an average of 5.46 times per session, whereas men do so 6.66 times, well within the statistical variation of our sample. Hence *H3c: Women Hedge* is not supported. No gender-linked difference was found for correctness of hedged answers either, with women and men averaging 59.1% and 56.2% correct for hedged responses, respectively.

Hedging in Machine Tutoring

Surprisingly, there was only a single hedge in all 66 H/C sessions, clearly supporting *H1a: Hedging Differs*. In this sole example the student hedges an answer with a spurious statistic "9/10" when "all", or no marker at all, would have been more correct:

S: 9/10 times the dr will dominate because the rr can't bring all the way back

Affect in Human Tutoring

Expressions of affect are fairly common in the H/H sessions; with large variations, however, between different students. Out of twenty-five sessions, twenty-two contained at least one instance of student affect, while three had none at all. The most common type is APOLOGY, with eighteen occurrences overall. Instances of affect occur 3.52 times per session (σ=2.65), with a very high level of variation between students.

Men and women express affect at similar overall rates, with average numbers of 3.66 and 3.38 occurrences per student, respectively, so *H3b: Women are Affectual* is not supported. On the other hand, although all thirteen of the sessions involving female students include at least one expression of affect, three of the male-student sessions do not. Fisher's exact test on these data gives p=0.096, so that we may (barely) reject the null hypothesis that the same fraction of men as women are likely to express affect in tutorial sessions. This supports a weaker version of *H3b*—although some men express a lot of affect, men are more likely than women to show no affect at all.

Considering just apologies (the overall most frequent expression of affect), χ^2 testing for two independent samples gives p=0.12, so the data do not permit rejection of the null hypothesis that men and women apologize at similar rates, and so we cannot support *H3c: Women Apologize*.

Affect in Machine Tutoring

There were more examples of affect than of hedging in the H/C sessions, but the 20 instances of affect found in 66 H/C sessions are still far fewer than the 88 instances found in just 25 H/H sessions. Moreover, only 12 sessions (18%) contained any affect at all, as opposed to 22 (88%) of the H/H sessions. Thus we find that our data clearly support *H1b: Affect Differs*.

Even more significant than the large difference in frequency of affect is the difference in the *kinds* of affect that students expressed when interacting with a computer system. We saw none of the kinds of affect listed in Table 2 that we found in the H/H sessions—affect-related expressions in the H/C sessions tended to be more confrontational than with a human tutor. Although some instances of affect did seem to be

genuine expressions of feeling, some seemed more designed to push and test the system. Glass (1999) reported even more hostile input to an earlier version of the system. We therefore classed such responses into 3 categories: Hostile (5 responses), Testing (4 responses), and Refusal-To-Answer (11 responses). For example, student T48 seemed to get annoyed with the system as these two "Hostile" excerpts indicate:

T: Why did you enter 'no change' for TPR?
S: you know why.
. . . .
T: Why is MAP still decreased?
S: I don't want to tell you.

T74 seems pretty annoyed too:

T: Why is MAP still decreased?
S: blalaal

However, student T60 is clearly trying to "test" the system:

T: Why did MAP change in the manner that you predicted?
S: In other words, <student's name> knows all...

So is T81, we think, but perhaps this was simple honesty:

T: Why did you enter 'no change' for TPR?
S: Nimesh said so

Conclusions

Our results clearly show strong differences in student use of hedges and expressions of affect, depending on whether they are being tutored by a human or a computer ITS. While all students hedge in sessions with human tutors, they do not hedge at all in the machine sessions (with one exception). This conclusion is also supported by experience with the Why2-ATLAS system (Rosé et al. 2002); Carolyn Rosé told us that they do not see hedging either, though they looked for it since they had also observed it frequently in human tutoring sessions (Rosé, personal communication). The progress of speech-enabled tutoring (Bratt et al. 2002) is of great interest; it is possible that a difference in communication modality can affect student hedging behavior. As well, decoding students' affect may be easier from speech, due to tonal and prosody cues (Forbes-Riley & Litman 2004).

One specific result of importance to ITS is that hedging is not a clear indication of student uncertainty or misunderstanding, as had been believed. Indeed, examination of the types of hedges most used by students leads us to believe that hedges are more connected to issues of conversational flow and politeness, rather than expression of uncertainty. This interpretation is implied by the two most common forms of hedges in our data; Q1 uses a question mark to demand a response (confirmation?) from the tutor, while THINK expresses a modal assessment via a subjective metaphor, rather than a more direct modal verb or adjunct, thus requesting that the tutor respond to the student's mental state. Further research will be needed to examine this interpretation more closely.

As opposed to hedging, students do express affect to machines, though far less often than to humans. The real difference is in the *kind* of affect expressed, though—students do not apologize to computers, nor do they thank them or give them direct feedback; they do, however, express confusion and frustration. Together with our results on hedging, this leads us to suspect that the fact that students know they are interacting with a computer changes their attitude towards the conversation, contra Reeves and Nass (1996), and they are less concerned with helping to keep the flow going than they are in 'normal' conversation (Sacks et al. 1974).

In future work, we will look at hedging and affect in more human tutoring sessions. We wonder if the fact that Michael and Rovick practice the motivational techniques described by Lepper et al. (1993) influences the fact that they receive more positive affective input. This will help us to better understand how tutor style might encourage more useful hedging and expression of affect. Currently, we are concentrating on investigating the responses made by human tutors to student expressions of distress, in order to develop rules to make CIRCSIM-Tutor more friendly and responsive.

Abstract

This paper discusses Betty's Brain, a teachable agent in the domain of ecosystems that combines learning by teaching with self-regulation mentoring to promote deep learning and understanding. Two studies demonstrate the effectiveness of this system. The first study focused on components that define student-teacher interactions in the learning by teaching task. The second study examined the value of adding meta-cognitive strategies that governed Betty's behavior and self-regulation hints provided by a mentor agent. The study compared three versions: an intelligent tutoring version, a learning by teaching version, and a learning by teaching plus self-regulation strategies. Results indicate that the addition of the self-regulation mentor better prepared students to learn new concepts later, even when they no longer had access to the self-regulation environment.

Introduction

The recent proliferation in computer-based learning environments has produced a number of tutoring systems (Wenger, 1987) and pedagogical agents (Johnson, et al., 2000). The typical intelligent tutoring system curriculum is problem-driven. The system selects problems for the user to solve, and provides feedback on the solutions generated. The tutoring paradigm has been very successful. At the same time, it often emphasizes localized feedback, and does not always help students practice higher-order cognitive skills especially in complex domains (e.g., picking what questions to ask or how to examine resources for learning). Problem solving in complex domains requires active decision-making by learners in terms of setting learning goals and applying strategies for achieving these goals. The current paper examines ways to address these latter goals using an "intelligent" learning environment.

Our goal has been to introduce effective learning paradigms that advance the state of the art in computer-based learning systems and support students' abilities to learn, even after they leave the computer environment. Our approach has been to create environments where students teach computer agents. This paper reports the results of two studies. One study explored different features of a specific learning by teaching environment, Betty's Brain. The second study manipulated the metacognitive support students received when teaching "Betty" and measured its effects on the students' abilities to subsequently learn new content several weeks later.

The cognitive science and education research literature supports the idea that teaching others is a powerful way to learn. Research in reciprocal teaching, peer-assisted tutoring, programming, small-group interaction, and self-explanation hint at the potential of *learning by teaching* (Palinscar & Brown, 1984; Cohen, et al. 1982; Papert, 1993; Chi, et al., 1994). Bargh and Schul (1980) found that people who prepared to teach others to take a quiz on a passage learned better than those who prepared to take the quiz themselves. The literature on tutoring has shown that tutors benefit as much from tutoring as their tutees (Chi, et al., 2001; Graesser, et al., 1995). Biswas et al. (2001) report that students preparing to teach made statements about how the responsibility to teach forced them to gain deeper understanding of the materials. Other students focused on the importance of having a clear conceptual organization of the materials. Additionally, teachers can provide explanations and demonstrations during teaching and receive questions and feedback from students. These activities seem significant from the standpoint of their cognitive consequences in improving understanding of complex concepts.

A key benefit of the learning by teaching process focuses on the need to structure knowledge in a compact and communicable format. This requires a level of abstraction that may help the teacher develop important explanatory structures for the domain. For example, many people find that preparing a conference presentation helps them decide which concepts deserve the "high level" status of introductory framing. The need to structure ideas not only occurs in preparation for teaching, but can also occur when teaching. Good learners bring structure to a domain by asking the right questions to develop a systematic flow for their reasoning. Good teachers build on the learners' knowledge to organize information, and in the process, they find new knowledge organizations, and better ways for interpreting and using these organizations in problem solving tasks.

Despite its potential benefits, learning-by-teaching can initially seem inefficient. For example, students may need to learn the right way to teach, which can slow down their learning of the subject matter in the short run. At the same time, learning-by-teaching may have long-term benefits in

that it helps students appreciate what a complete and communicable answer needs to look like, and they may learn how to consult resources to understand deeply enough that they can teach well. In this case, it seems important to evaluate not only how well students learn the target knowledge of the teaching episode, but also how well they are prepared to learn in the future as a result of learning-by-teaching (Bransford & Schwartz, 1999).

We have adopted a new approach to designing learning-by-teaching environments that ideally supports the learning outcomes described above, provide tools that enable users to visually organize and reason about their domain knowledge as they teach a computer agent, and include feedback to promote better self-regulation during the learning and teaching processes. A key challenge to the learning-by-teaching approach is that students are usually novices with regard to domain content and teaching tasks. To help with the domain content, our design includes content-integrated instruction that encourages students to access and think about resources, and check their reasoning during the teaching (and learning) process by interacting with the teachable agent and assessing its performance. To help with the teaching and learning aspects, we have made the computer agent more participatory in the learning process, and developed a Mentor agent that acts as a "meta-cognitive" coach, and provides strategy and content feedback about teaching with understanding, while avoiding the very specific localized feedback that is characteristic of many tutoring systems. Ideally the combination of the two can help students not only learn the content of a specific lesson, but also prepare students to learn in the future when they no longer have access to the system.

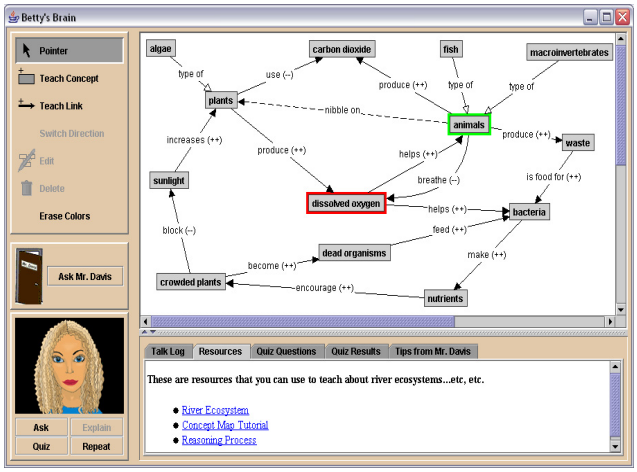
Implementing Learning by Teaching Systems

Our teachable agents (TAs) provide important structures to help shape the thinking of the *learner-as-teacher*. Each agent manifests a visual structure that is tailored to a specific form of knowledge organization and inference. In general, our agents try to embody four principles of design:

- Teach through visual representations that organize the reasoning structures of the domain (e.g., directed graphs and matrices).
- Build on well-known teaching interactions to organize student activity (e.g., teaching by "laying out," teaching by example, teaching by telling, teaching by modeling).
- Ensure the agents have independent performances that provide feedback on how well they have been taught (each agent uses a distinct AI reasoning technique, such as qualitative reasoning, logic, and genetic algorithms).
- Keep the start-up costs of teaching the agent very low (as compared to programming). This occurs by only implementing one modeling structure with its associated reasoning mechanisms.

Betty's Brain makes her qualitative reasoning visible through a dynamic, directed graph called a *concept map* (Novak, 1996). The fact that TAs represent knowledge structures rather than the referent domain is a departure from many simulation-based learning environments. Simulations often show the behavior of a physical system, for example, how an algal bloom increases the death of fish. On the other hand, TAs simulate the behavior of a person's thoughts about a system. Learning empirical facts is important, but learning to use the expert structure that organizes those facts is equally important. Therefore, we have structured the agents to simulate particular forms of thought that may help teacher-students structure their thinking about a domain.

Fig. 1 illustrates the interface of Betty's Brain. Students explicitly teach Betty using a graphical drag and drop interface to create and modify their concept maps in the top pane of the window. They use the *Teach Concept* button to create new concepts, and the *Teach Link* button to create relations between concepts. When teaching the agent about relationships, students use a popup template to specify the name (e.g., *breathe*, *produce*, *helps*) and type of relationship *(causal*, *type of*, and *descriptive*). For causal relations, students indicate whether the relation implies an *increase* (++) or *decrease* (–-). For example, in the map in Fig.1, the concept map implies an increase in *fish* will result in a decrease in *dissolved oxygen*. Note that the student generates all concept and relationship names. They are not chosen from a menu.



Once taught, Betty reasons with her knowledge and answers questions. Users can formulate their own queries using the *Ask* button, and observe the effects of their teaching by analyzing Betty's responses. Templates are provided to ask Betty two kinds of questions: (i) *If <concept A> increases (decreases) what happens to <concept B>?* and (ii) *Tell me all you know about <concept A>*. For the latter question, Betty enumerates all the concepts that are directly linked to *<concept A>*. For the former question, Betty uses qualitative reasoning methods to derive her answers to question through a chain of causal inferences. For example, using the concept map in Fig. 1, Betty can conclude that an increase in *algae* will cause *fish* to increase.

Betty also provides explanations for how she derives her answers by depicting the derivation process using multiple modalities: text, animation, and speech. Details of the rea-

soning and explanation mechanisms in Betty's Brain are presented elsewhere (Leelawong, et al., 2001).

We should clarify that Betty does not use machine learning algorithms to achieve automated learning from examples, explanations, and induction. Our focus is on the well-defined schemes associated with teaching that support a process of instruction, assessment, and remediation. These schemas help organize student interaction with the computer, much as people's well-defined schemas for spatial organizations helped to create the desktop metaphor for windows-based computer systems.

The system also includes sets of teacher-generated quiz questions. Betty can take the quiz, and students see how she performs and receive the correct answer. The quiz questions are structured to provide students cues on concepts and relations that are important in the domain of study. Examples of some quiz questions are shown in Fig. 2.

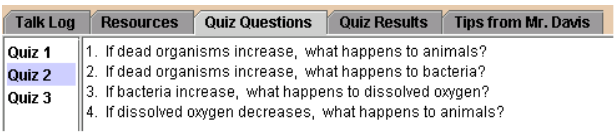


Figure 2: Quiz Questions

A Prior Study without a Self-Regulation Mentor

To study the effectiveness of Betty's Brain we conducted an experiment on 50 high-achieving fifth grade students from a science class in an urban public school located in a southeastern US city. The students were asked to teach Betty about river ecosystems. We examined the effects of the interactive features of the teachable agent environment using a 2×2 between-subjects design. One group of students could submit their agent to take a Quiz (and receive feedback on the correct answer). A second group could Query their agent by generating their own questions and seeing how Betty chains through her map to reach the answer (there was no expert feedback on the answer). The third condition, which could neither Query nor Quiz the agent, was basically using a graphing package. Students who had both Query and Quiz features could ask Betty questions and see her performance on the quiz questions. Students were given instructions on how to use the system, and then they used the software for 3 one-hour sessions. To help students learn what to teach, reference materials were made available during and in between their teaching sessions with Betty.

We hypothesized that having the query feature would help students debug their own thinking and reasoning in the problem domain, and this would result in maps with more inter-linked concepts. Betty's answers and her explanations would make explicit the process of reasoning across chains of links in a concept map. For the Quiz condition, we expected that students would map backward from the quiz questions and use the feedback they received about her answers to produce more accurate concept maps.

Analysis of the scope of students' maps and the types and accuracy of links contained therein are presented in (Leelawong, et al., 2002). On the positive side, students who used the Query and/or Quiz mechanisms understood causal relations better than the students who did not. This was reflected in their concept maps, which had a larger proportion of causal links than the No Quiz and No Query group. As predicted, students who had access to the Query feature had the most inter-linked maps and most elaborate reasoning chains. The Quiz feature was effective in helping students decide the important domain concepts and types of relationships to teach Betty.

We also noted some negative aspects to our system. Our observations of students during the study suggested that students who had the quiz feature were too focused on *"getting the quiz questions correct"* rather than *"making sure that Betty (and they themselves) understood the information"* (Davis, et al., 2003). The activity logs of the students who used the quiz showed a pattern of quick one-link corrections followed by a retake of the quiz. The query mechanism and resources were used sparsely, and it is unlikely they gained a deep understanding of causal structures. On the other hand, the Query-only group spent more time with Betty's explanations and reading resources. Surprisingly, students who had the query feature without the benefit of quiz feedback produced as many valid relevant causal links as the conditions with the quiz and quiz and query feature. This demonstrated the value of explicitly illustrating the reasoning process (by having Betty explain her answers) so that students understand causal structures.

Reflections on these results made us rethink our design and implementation of TA environments. A primary concern was the student's focus on getting quiz questions right without trying to gain an understanding of interdependence and balance in river ecosystems. We realized that interactions between the student-as-teacher, Betty, and the quiz feature had to be improved to facilitate better learning. Further, in exit interviews, students emphasized that they would have liked Betty to be more active and exhibit characteristics of a good student during the teaching phase (Davis, et al., 2003). Several students suggested that we should "*do some sort of game or something and make the system more interactive,*" and "*Betty should react to what she was being taught, and take the initiative and ask more questions on her own.*" Consistent with this feedback, we noted that the first version of Betty was passive and only responded when asked questions. We believed that to create a true learning by teaching environment, Betty needed to better demonstrate qualities of human students. A tutor gains deeper understanding from interactions with a tutee (Chi, et al., 2001) that includes answering the tutee's questions, explaining materials, and discovering misconceptions. Betty should be designed to benefit her users in the same way.

Self-Regulated Learning and Betty's Brain

As mentioned earlier, an important realization from this first study was that we were dealing with young children who were novices in teaching practice and in domain knowledge content. To accommodate this, the

learning environment was redesigned to provide appropriate scaffolds and proper feedback mechanisms to help students overcome their initial difficulties in learning and teaching about a complex domain. The scaffolds took on three primary forms. First, we made improvements in the online resources available for learning about river ecosystems. We reorganized the resources to emphasize the concepts of interdependence and balance. This changed the partitioning of the resources to the three primary cycles that govern ecosystem behavior: (i) the oxygen/carbon dioxide cycle, (ii) the food chain, and (iii) the decomposition cycle. A hypertext implementation allowed direct access to sections and subsections. An advanced keyword search technique provided access to information using keywords. (Students in the study below found the resources to be much more useful, and used them extensively while teaching Betty.)

The second change is that we redesigned the quiz so that the questions would support users in systematically building their knowledge about river eco-systems. The questions were no longer randomly sampled from the full domain, but they gradually introduced more complex questions. Furthermore, the first item in each quiz was a comprehensive question that covered all of the domain concepts and relations associated with a particular cycle. This prevented students from taking a sequential approach of building the concept map to answer one question at a time. We also improved the feedback the students received.

These two changes were important, but we doubted they would be sufficient in supporting users in becoming better learners and teachers, nor did they address our users requests for a more *"life like"* Betty. Therefore, our third change, and most relevant to the study below, was to make Betty more reactive to what she was being taught, as well as to use self-regulation strategies in her interactions with her student-teacher. Along with this, we added a mentor agent to the system to help users observe and develop metacognitive and self-regulation strategies to support active and independent learning. Self-regulated learning should be an effective framework for providing feedback because it promotes the development of higher-order cognitive skills (Corno & Mandinach, 1983), and it is critical to the development of problem solving ability (Pintrich & DeGroot, 1990).

Our new design adopted some aspects of the framework of *self-regulated learning,* described by Zimmerman (1989) as situations where students are "*metacognitively, motivationally, and behaviorally participants in their own learning process.*" Self-regulated learning strategies involve actions and processes that can help one to acquire knowledge and develop problem solving skills (Pintrich & DeGroot, 1990). Zimmerman describes a number of self-regulated learning skills that include goal setting and planning, seeking and organizing information, keeping records and monitoring, and self-evaluation. We developed mechanisms by which Betty forced the student to conform to the self-regulation strategies. In parallel, the Mentor agent included resources that helped students develop these skills during their learning and teaching.

This resulted in a number of changes to Betty's Brain. For example, when a student begins the teach phase by constructing the initial concept map, both the Mentor and Betty make suggestions that the student *set goals* about what to teach, and make efforts to gain the relevant knowledge by studying the river ecosystem resources. The Mentor continues to emphasize the reading and understanding of resources, whenever the student has questions on *how to improve their learning*. The user is given the opportunity to *evaluate her knowledge* while studying. If she is not satisfied with her understanding, she may *seek further information* by asking the Mentor for additional help. While teaching, the student as teacher can interact with Betty in many ways, such as asking her questions (*querying*), and getting her to take *quizzes* to evaluate her performance. Users are given a chance to predict how Betty will answer a question so they can check what Betty learned against what they were trying to teach.

Some of the self-regulation strategies manifest through Betty's persona. These strategies make Betty more involved during the teach phase, and drive her interactions and dialog with the student. For example, during concept map creation, Betty spontaneously tries to demonstrate *chains of reasoning*, and the conclusions she draws from this reasoning process. She may query the user, and sometimes remark (right or wrong) that an answer she is deriving does not seem to make sense. This is likely to make users reflect on what they are teaching, and perhaps, like good teachers they will assess Betty's learning progress more often. At other times, Betty will prompt the user to *formulate queries* to check if her reasoning with the concept map produces correct results. There are situations when Betty emphatically refuses to take a quiz because she feels that she has *not been taught enough*, or that the student has not given her *sufficient practice by asking queries* before making her take a quiz.

After Betty takes a quiz offered by the Mentor agent, she discusses the results with the user. Betty reports: (i) her view of her performance on the particular quiz, and if her performance has improved or deteriorated from the last time she took the quiz, and (ii) the Mentor's comments on Betty's performance in the quiz, such as: "*Hi, I'm back. I'm feeling bad because I could not answer some questions in the quiz. Mr. Davis said that you can ask him if you need more information about river ecosystems.*") The Mentor agent's initial comments are general, but they become more specific if errors persist, or if the student seeks further help (*"You may want to study the role of bacteria in the river"*).

In addition to self-regulation advice that included information on how to be a better learner and better teacher, the domain content feedback from the Mentor agent was directed to make the student think more about interdependence among concepts. Students seeking specific help were first directed to relevant sections in the resources for further study and reflection, rather than being told what was wrong in their concept maps. When the Mentor provided specific feedback, it was about *chains of events* to help students better understand

chains of events to help students better understand Betty's reasoning processes.

Overall, we believe that the introduction of self-regulation strategies provides useful scaffolds to help students learn about a complex domain, while also developing metacognitive strategies that promote deep understanding and abilities to learn in the future. One of the achievements of the new system is that students retain control rather than being told what to do (e.g., they need to request help from the mentor and they teach Betty). Only when the student seems to be hopelessly stuck, does the Mentor spontaneously intervene to help students advance in their learning (and teaching) task.

A Study of the Added-Value of Self-Regulation

A new experiment with fifth graders was designed to compare the Teachable Agent system with the self regulation mentor (SRL) against two other approaches: (i) A learning by teaching (LBT) version that was similar to the Query & Quiz version before, and (ii) An externally-guided learning system (ITS) designed with a pedagogical agent. In the ITS version, the pedagogical agent asked students to create concept maps that could answer a set of quiz questions (therefore, there was no *teaching* component), and the agent would provide feedback on how to correct their map when their quiz answers had errors. All three groups had access to identical resources on river ecosystems and the same query and quiz features. To evaluate student learning, we examined pre-posttest scores, how they used the system, the quality of their final maps, and their ability to reproduce the maps subsequently. Importantly, several weeks later, we asked the students to learn about the Nitrogen cycle, which had not been covered during the initial instruction. This permitted us to determine which group had been better prepared to learn, once they no longer could rely on the scaffolds of their respective version. Our expectation was that the SRL students would do better on this latter measure of preparation for future learning (Bransford & Schwartz, 1999), because they had learned how to "take charge" of their own learning.

Experimental Procedure

A fifth grade classroom was divided into three equal groups of 15 students each using a stratified sampling method based on standard achievement scores in mathematics and language. The students worked on a pretest with twelve questions before they were separately introduced to their particular versions of the system. The three groups worked for six 45-minute sessions over a period of three weeks to create their concept maps. All groups had access to the online resources while they worked on the system.

All three conditions had the same quiz questions while working with the system, and they had access to the query feature and Mentor agent (Mr. Davis), though he appeared with different capacities. The task given to the ITS group was to create concept maps that correctly answered the 16 questions that were divided up into three quizzes. They had the same interface to create and modify their concept maps as the other groups, but Betty did not exist in the ITS system. The ITS feedback came from the Mentor, who told students if their map held the correct answers to the quiz questions and provided hints on how the students could correct their maps. The two other groups, LBT and SRL, were told to teach Betty and help her pass a test so she could become a member of the school Science club. Both of these groups had access to the three quizzes. The LBT group only received mentor feedback about the quality of Betty's specific answers to the quiz. The SRL group received more extensive feedback from the Mentor, but only when they queried him. Coupled with the Mentor, the SRL Betty was also endowed with self-regulation strategies that governed her behavior. Therefore, the SRL condition was set up to develop more active learners by promoting the use of self-regulation strategies.

At the end of the six sessions, every student took a post-test that was identical to the pretest. Two other delayed post-tests were conducted about seven weeks after the initial experiment: (i) a *memory test*, where students were asked to recreate their ecosystem concept maps from memory (there was no help or intervention when performing this task), and (ii) a *preparation for future learning transfer test*, where they were asked to construct a concept map using on-line resources and answer questions about the land-based nitrogen cycle. Students had not been taught about the nitrogen cycle, so they would have to learn from resources during the transfer phase. (All three conditions simply used the concept mapping interface, resources, and "correct/incorrect" feedback from the mentor on several quiz questions.)

For learning about river ecosystems, students in all conditions improved from pre- to posttest on their

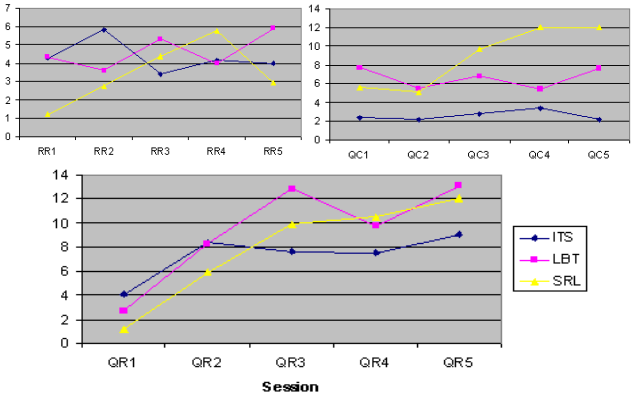

Figure 3: Resource Requests (RR), Queries Composed (QC), & Quizzes Requested QR) per session.

knowledge of interdependence (p's<.01, paired T-tests), but not ecosystem balance. There were few differences between conditions in terms of the quality of their maps. However, there were notable differences in their use of the system during the initial learning phase. Fig. 3 shows

the average number of resource, query, and quiz requests per session by the three groups. It is clear from the plots that the SRL group made a slow start as compared to the other two groups. This can primarily be attributed to the nature of the feedback; i.e., the ITS and LBT groups received specific content feedback after a quiz, whereas the SRL group tended to receive more generic feedback that focused on self-regulation strategies. Moreover, in the SRL condition, Betty would refuse to take a quiz unless she felt the user had taught her enough, and prepared her for the quiz by asking questions. After a couple of sessions the SRL group showed a surge in map creation and map analysis activities, and their final concept maps and quiz performance were comparable to the other groups. It seems the SRL group spent their first few sessions in learning self-regulation strategies, but once they learned them their performance improved significantly.

For the delayed memory test, the table below presents the mean number of expert causal links and concepts in the student maps. Results of ANOVAs using Tukey's LSD to make pairwise comparisons showed that the SRL group recalled significantly more links that were also in the expert map (which nobody actually saw).

Student Map Included:	SRL Mean (se)	LBT Mean (se)	ITS Mean (se)
Expert Concepts	6.7 (.6)	6.4 (.5)	5.8 (.6)
Expert Causal Links	3.3[a] (.6)	1.7 (.6)	2.0 (.6)

[a] Significantly greater than LBT, $p < .05$

We thought that the effect of SRL would not be to improve memory, but rather to provide students with more skills for learning subsequently. When one looks at the results of the test of preparation for future learning, the differences between the SRL group and the other two groups are significant. The table below summarizes the results of the transfer test, where students read resources and created a concept map for the land-based nitrogen cycle. There are significant differences in the number of expert concepts in the SRL versus ITS group maps, and the SRL group had significantly more expert causal links than the LBT and ITS groups. When learning about the river ecology, the SRL students had received some guidance in how to use resources productively and how to think about the quality of their map. This guidance transferred to learning about the nitrogen cycle.

Student Map Included:	SRL Mean (sd)	LBT Mean (sd)	ITS Mean (sd)
Expert Concepts	6.1[a] (.6)	5.2 (.5)	4.1 (.6)
Expert Causal Links	1.1[ab] (.3)	0.1 (.3)	0.2 (.3)

[a] Significantly greater than ITS, $p < .05$;
[b] Significantly greater than LBT, $p < .05$

Conclusions

The results demonstrate the significant positive effects of SRL strategies in understanding and transfer in a learning by teaching environment. Students in all three groups demonstrated the same learning performance in traditional learning tasks, but the SRL group outperformed the other two in the far transfer test. We believe that the differences between the SRL and the other two groups would have been more pronounced if the transfer test study had been conducted over a longer period of time. Lastly, we believe that the concept map and reasoning schemes have to be extended to include temporal reasoning and cycles of behavior to facilitate students' learning about the concept of balance in ecosystems.

Error-Reduction and Simplicity: Opposing Goals in Classification Learning

Mark Blair (mrblair@indiana.edu)
Indiana University, Department of Psychology
1101 E. Tenth Street, Bloomington, IN 47405 USA

Abstract

Studies of real world experts show that they use different and subtler regularities than novices to make effective classifications. In laboratory studies of learning however, participants have a strong preference for simple cue sets, even at the expense of accuracy. The present experiments investigate participants' ability to use subtle stimulus dimensions in order to eliminate category exceptions. Results show that some participants were able to use the optimal 3-cue set, but many could not. When there were two optimal cue sets, one with 2 dimensions and one with 3, participants favored the simpler set, even though it meant ignoring an obvious and diagnostic cue. Overall there were wide individual differences, with almost every cue set adopted by some participants. Current theories of attention that posit rapid shifts of learned attention offer promise in accounting for the results.

For any organism to adapt successfully it must become sensitive to meaningful regularities in the environment. Humans have developed flexible learning systems, allowing them to rapidly adjust to changing environments. Learning concepts, representations of classes of stimuli that 4require an equivalent response, conserves resources by reducing the amount of information that needs to be processed from the environment, and also allows for generalization to related, novel circumstances. Representing a complex environment, with abundant interdependencies and subtle regularities requires a rich set of concepts.

To perform this function, the human perceptual system can attend selectively, become sensitized to highly complex stimulus dimensions, and even create novel functional features. These processes affect the perception of a stimulus and therefore alter the representation of that stimulus. Differences in cue use and representation across experts and novices appear in many areas such as biology (Boster & Johnson, 1989), physics (Chi, Feltovich, & Glaser, 1981), computer programming (Davies, 1994), wine tasting (Solomon, 1997), bird identification (Johnson & Mervis, 1997) and pocket billiards (Blair & McBeath, 2001). Despite an abundance of differences between expert and novice differences in cue use, laboratory studies of learning (specifically "knowledge restructuring") have shown that participants have had a strong resistance to using new information and more complicated cue sets, even though they would afford better performance (Lewandowsky, Kalish & Griffiths, 2000).

To the extent that learning is error driven, exceptions in the cue set provide a powerful motivator to incorporate new dimensions, however, there is also a pressure toward simplicity. Additional dimensions, which may a space in which the categories separate, can be expensive to represent. Completely altering the dimensions used for categorization can require more energy than using unique stimulus-level elements to classify exceptions. This leads to the memorization of exceptions, rather than a refining of the cue set. It is clear that category learning is influenced by opposing forces; one to enlarge, and one to reduce the dimensionality of the cue set.

The present research examines the complementary processes of the expansion and reduction of the cue set toward effective and efficient representation. The goal of the present study is to verify that participants can and do optimize their cue sets using both expansion and reduction when learning categories with subtle dimensions. Previous research has demonstrated these complimentary processes by manipulating the stimulus set to provide a new dimension (Blair & Homa, 2003b). These studies produced wide individual differences, with many participants incorporating new dimensions to eliminate category exceptions, and many others choosing to rely on simple cue sets which result in many exceptions and significant error. The Blair and Homa (2003b) studies also showed that participants can shift to optimal spaces if they are less complex. Overall, in these studies participants demonstrated both the flexibility found in studies of expertise and the insistence on simplicity found in studies of knowledge restructuring.

Many real world category learning problems do not involve learning new information never experienced before, but rather involve learning to be sensitive to stimulus features that have existed all along, but may have been overlooked for more salient dimensions. For example in bird identification, color is an obvious perceptual cue, used by experts and novices alike. To tell the difference between a Hepatic Tanager and a Summer Tanager, both of which are predominantly red, one must notice the color of the bill and whether the bird has a gray ear patch or not. These are features that novices are prone to miss. The present studies use two obvious dimensions as well as a subtle third dimension as a direct analogy to those cases.

Experiment 1

In Experiment 1, a sequential presentation same-different task was employed to examine the discriminability of the three dimensions used in the remaining experiments, and an additional dimension (color) used in a related set of studies (Blair & Homa, 2003b). If the stimuli are to be used in later experiments, they should be of roughly equal discriminability, with the exception of tail bumpiness, which should be significantly less discriminable than the other three dimensions.

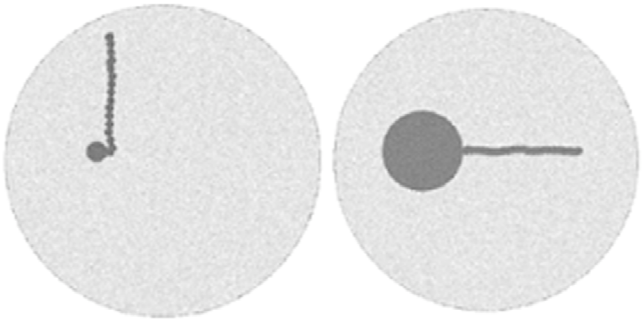

Figure 1: Two Example Stimuli. Tail angle, head diameter, and bumpiness of the tail are the three primary dimensions of variation. Stimuli could take on any one of 11 values on or between the two extremes shown here.

Method

Participants Participants were 26 undergraduates from Arizona State University who participated for course credit. All participants were naïve as to the purpose of the test.

Stimuli Examples of the stimuli are shown in Figure 1. These stimuli were created in the graphics program Adobe Photoshop. Designed to look like something seen under a microscope, these fictitious microorganisms offer a ready analogy to expertise domains such as medical diagnostics. Stimuli varied in one of four different dimensions: head diameter, tail angle, color, and tail bumpiness. Head diameter varied from 25 to 100 pixels. Tail angle varied from 0 to 90 degrees. Color, in RGB values, ranged from 65-75-230 to 139-75-30. These colors were set so that they were of equivalent luminosity, that is, they look the same shade of gray if viewed as a black and white image. The tail bumpiness was created by using brushes with "spacing" set from 60 to 90. The full range of the variation was broken up into 11 equal sized steps, thus dimensions were always one of those 11 values. In addition to possible variations in the four principle dimensions, the tail of each microorganism was hand drawn on top of a line of the correct angle and thus represented a source of stimulus-specific variation. A Gaussian noise filter (30-unit) was also applied to each stimulus. Afterward, a "crystallization" filter (3-pixel) was applied to the stimulus area around, but not including, the microorganism.

Procedure The entire experimental task, including instructions, was displayed on computer. The experimental task was a sequential same-different task in which participants were shown two stimuli, one at a time, and asked to judge whether they were the same or different. Participants were shown two example stimuli and the four main dimensions of variation were indicated. Participants were instructed that only variations on the four consequential dimensions should elicit a 'different' response, any other variations were to be ignored. On each trial, the first stimulus was shown for 2000 msec, and then the screen went blank for 1000 msec. Finally, the second stimulus appeared, and remained on screen until the participant responded. There were 144 trials and of the 144 stimulus pairs, 72 were 'same' pairs and 72 were 'different'. Of the 72 'same' trials, 36 were pairs showing exactly the same stimulus and 36 were pairs of stimuli that had the same values on the consequential dimensions, but were created separately. Of the 72 'different' pairs, there were three stimuli from each of three levels of variation (1, 2 and 4 units) from each of the four main dimensions (head diameter, tail angle, color, and tail bumpiness). The lower, upper and middle parts of the range of variation were used for each trio of stimuli associated with a level of variation. For example, for 1 unit variations on head diameter, the three stimulus pairs might include a pair with 25 and 32-pixel heads, a pair with 93 and 86-pixel heads and a pair with 48 and 54-pixel heads. The values of the remaining three dimensions, which did not vary between members of a stimulus pair, were randomly assigned. They were approximately equally distributed across the possible range of values.

Results and Discussion

To establish that the three primary dimensions are of roughly equal discriminability and that they are all more discriminable than the subtle dimension, a single-factor repeated measures ANOVA was run, using change type (diameter, angle, color, bumpiness, values and same). Results, depicted in Figure 2, showed a significant main effect of change type, $F(5,120)=104.80$, $p<.0001$. Scheffe post-hoc tests revealed that color was not significantly different from either angle or diameter, but that performance on differences in angle were detected significantly more often than differences in diameter, showing that these three dimensions are roughly, but not perfectly equal. The

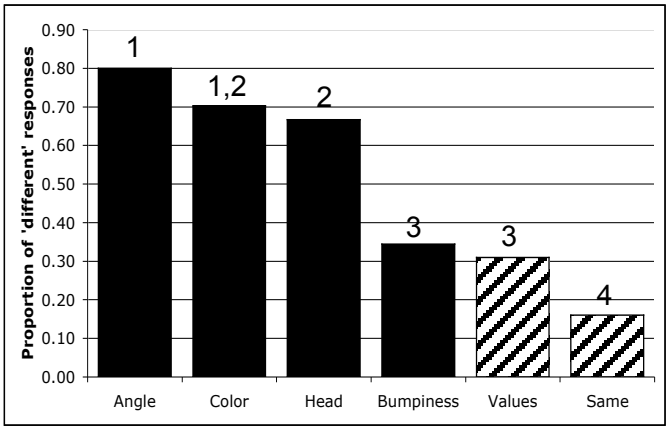

Figure 2: Data from Experiment 1. Groups with different numbers above the bar are significantly different from one another. The striped bars indicate trial blocks where a 'different' was incorrect.

proportions of 'different' responses for each of these three dimensions were significantly higher than for 'same' trials, establishing that participants have the ability to detect these changes. Performance on these three dimensions was also significantly better than on bumpiness, thus, supporting its classification as a subtle dimension. Despite worse performance on the subtle dimension, participants responded 'different' significantly more frequently on trials with changes on this dimension, than on 'same' trials. Finally, performance on 'bumpiness' trials did not differ significantly from performance on 'values' trials, where changes in the way the stimuli were drawn preserved the values of the four key dimensions. Because participants were instructed to ignore the kinds of changes that occur on 'values' trials, they were likely responding without being aware of what kind of changes they saw. The equivalence of performance on these two trial types suggests that participants may be responding with an equivalent lack of awareness on 'bumpiness' trials. This further supports the classification of the bumpiness dimension as subtle.

Experiment 2

Experiment 2 used the subtle dimension of tail bumpiness. This procedure makes this experiment an apt analog to real world categories that experts must master. The effect of pointing out the subtle dimension to participants was investigated using three between-subjects conditions: Help, No-Help (NH) and No-Help/Help (NH-H). In the Help condition participants were told in the instructions at the beginning of the experiment that tail bumpiness is an important cue in helping to classify the stimuli correctly. In the NH condition, participants were never told about tail bumpiness. In the NH-H condition, participants were given this information at the beginning of Stage 2.

Method

Participants Participants were 83 Arizona State University undergraduates enrolled in an introductory psychology course. They participated for course credit. They were randomly assigned to one of three conditions: Help (n=33), NH (n=24), NH-H (n=26).

Stimuli The stimuli had three principal dimensions of variation: head size, tail angle and tail bumpiness as described in Experiment 1.

Structure The two categories used were linearly separable only in three dimensions; therefore the best lower dimensional bounds always had exceptions. The best two-dimensional linear decision boundary left 14% of the exemplars as exceptions and the best single dimension linear decision boundary left 30% as exceptions. Figure 3 shows the training stimuli plotted in the angle/diameter space and also bumpiness/angle/diameter space.

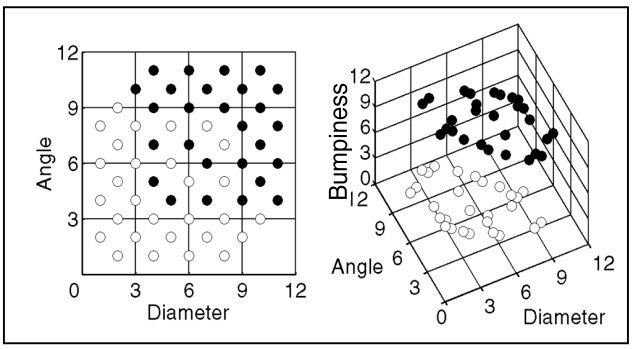

Figure 3: The stimulus space used in Experiment 2, plotted for stimuli with and without the subtle bumpiness dimension.

Procedure The experiment had two stages with each stage consisting of a learning phase and a transfer phase. The learning phase included four blocks of 56 trials. Within a trial block every stimulus in the learning set was presented once. The presentation order was randomized for each trial block, and for each participant. On each trial, the participant was shown a stimulus and asked to classify it as 'normal' or 'deviant'. Once the participants indicated their choice by pressing the appropriate key ('n' or 'd') on the keyboard, the correct answer was presented next to the stimulus for 2000 msec. If the participant answered incorrectly, the feedback was red instead of black. After the learning phase, participants performed a transfer task in which they classified two cycles of 16 novel stimuli. The transfer set presented after the three-dimensional stimulus set consisted of 8 stimuli on either side of the best three-dimensional linear decision boundary at a range of values. These values were such that if participants were using the best combination of angle and diameter dimensions, or any one of the three dimensions alone, they would achieve 50% correct. Participants were not given feedback during the transfer task. Stage 2 was a repetition of Stage 1, except for the instructions, as determined by the condition. For all conditions, the instructions encouraged participants to achieve perfect classification for both Stage 1 and Stage 2.

Results and Discussion

Overall performance was equally good whether or not participants were told about the usefulness of the subtle dimension (Help, M=87%; NH, M=88%; NH-H, M=88%). The dimension of primary interest is tail bumpiness. Single group t-tests against zero revealed that NH-H condition showed significant increase in the use of tail bumpiness in the second stage, $t(25)=2.34$, $p<.05$, but the other conditions showed no significant change in tail bumpiness from Stage 1 to Stage 2. The instructions clearly increased the use of tail bumpiness. The NH group had the lowest use of tail bumpiness, with the NH-H group significantly increasing their use of tail bumpiness, after being instructed to do so.

Table 1: Percentages of participants for which each cue set accounts for most of the transfer test responses from Experiment 2.

Condition	Stage	Bump	Angle	Diam	D/A	B/D/A
NH	1	36%	11%	18%	29%	7%
NH-H	1	29%	14%	14%	32%	11%
H	1	43%	14%	6%	26%	11%
NH	2	16%	32%	13%	26%	13%
NH-H	2	56%	11%	11%	4%	19%
H	2	32%	22%	7%	15%	24%

Individual differences in the adoption of the various cue sets were assessed by the transfer test. Participants were sorted according to the cue set that best matched their responses. Because all dimensions were present in the transfer stimuli, it was possible for a participant's responses to fit two different cue sets equally well. In such cases both cue sets were counted and the percentage reported was calculated across all preferences not all participants. That said, the large majority of participants preferred only one cue set. The percentages of preferences for each cue set are reported in Table 1.

Overall, many participants seemed to make use of the subtle dimension of tail bumpiness early in training; even without having it brought to their attention. Use of the subtle dimension was increased by instructions however, and though participants in the NH condition showed no performance deficit by the end of Stage 2, the transfer test reveals that they used tail bumpiness least. The general findings of this experiment mirror the Blair & Homa (2003b) studies using an obvious 3rd dimension, instead of the subtle one, namely some participants incorporated the 3rd dimension while others stuck with one or two sub-optimal dimensions. One question still open is whether or not more participants would adopt a cue set which separates the categories if it had fewer dimensions. This question is addressed in Experiment 3.

Experiment 3

In Experiment 2, it was shown that many participants rapidly detected and used diagnostic information, even though it was subtle. Some participants can readily use a three-dimensional cue set if the categories are made separable. For Experiment 3, a new stimulus space was created by changing the values on the subtle dimension. Like the space in Experiment 2, this space was not linearly separable using the two regular dimensions (head diameter and tail angle) but was separable by also considering the subtle dimension (tail bumpiness). Unlike the space for Experiment 2, this space was also separable when considering only head diameter and tail bumpiness. The separable 2-D and 3-D spaces are shown in Figure 4. These categories allow participants to collapse their cue set to only two dimensions with no loss of accuracy. The primary objective of this experiment was to assess the degree to which participants are able find the most efficient cue set if it required using fewer dimensions.

The instruction manipulation was dropped for this experiment; all participants were in the equivalent of the NH condition. Also, individual differences in this experiment were expected to be more important because there were multiple effective strategies. Accordingly, a larger number of participants were tested.

Method

Participants Participants were 96 Arizona State University undergraduates enrolled in an introductory psychology course. They participated in the experiment to fulfill a course requirement.

Structure In order to detect the use of the various possible 2-D spaces during transfer, the stimulus values for the training and transfer stimulus spaces were altered from Experiment 2. As in the Experiment 2 space, individually, diameter and angle were 70% predictive. The bumpiness dimension was 73% predictive. In 2-D space (head diameter and tail angle) this stimulus space is identical to the Experiment 2 space, that is, 8 of the 56 stimuli (14%) were exceptions. In 3-D space, the two categories were linearly separable. Also, in the 2-D space defined by head diameter and tail bumpiness the categories were linearly separable. The two spaces where the categories are linearly separable are shown in Figure 4. The category structure (mean within-category distance divided by mean between-category distance) was .60 for the categories represented in the diameter/bumpiness space and .66 for the categories when represented in the 3-D space.

Procedure The procedure was identical to Experiment 2 except the transfer tasks, which involved 2 cycles through a transfer set with 12 stimuli.

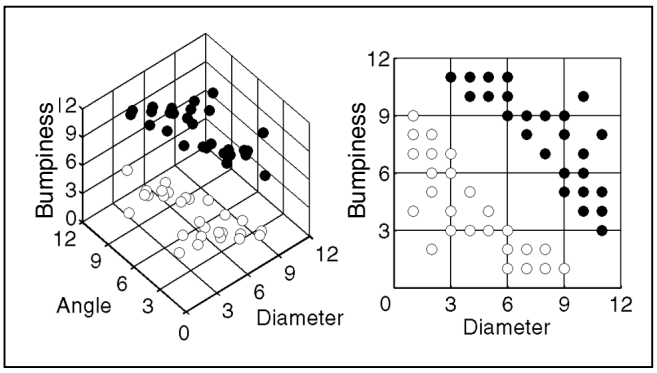

Figure 4: This stimulus space used for Experiment 3. This space was modified from the space for Experiment 2 so that the categories are separable in both the B/A/D space (plotted on the left) and the B/D space (plotted on the right).

Results and Discussion

Overall, performance improved across trial blocks and participants averaged 83% correct on the final trial block. In the transfer task, the measures of the three single dimension cues (bumpiness, angle and head diameter) and three two dimension cue sets (bumpiness/angle, bumpiness/diameter and diameter/angle) are not independent and require some explanation. Dimension use, as in Experiment 2, is measured as the proportion of trials that would be supported by that dimension or pair of dimensions. For each of the six cues, 8 of the 12 transfer trials present a stimulus on which the values of the cues suggest one category over another, and 4 of the 12 transfer trials present a stimulus for which the cue is neutral. Each single dimension and its dual-dimension opposite (e.g., diameter and bumpiness/angle) use the identical eight trials, and so are perfectly negatively correlated. This means that if a participant chose according to the value of tail bumpiness on .88 proportion of the trials, then they must also have chosen according to head/angle on the remaining .12 proportion of the trials. The other cues are only partially correlated. The overall attention use is forced to sum to 1.5 for the three single dimension cues and to 3.0 for all six dimensions. As an example, a participant might have a balanced attentional profile, equally distributing attention to all dimensions in combination (the 3-D solution). This profile would conform to each cue set on .50 proportion of the trials. A different participant might not use the subtle tail bumpiness cue at all. This profile would yield a 1.0 proportion for D/A (and 0 for bumpiness) and, assuming equal weight to the remaining dimensions, .25 for B/A and B/D (and therefore .75 for diameter and angle individually).

In the first transfer task, the use of the head dimension is consistent with the highest proportion of trials (.63) with D/A (.61) and B/D (.52) the next two highest. The emphasis on these three dimensions increased after the second stage of training (.70, .62 and .58 respectively). Both the increase in head and the increase in B/D (or, alternatively, the decrease in use of angle) were significantly different than chance, $t(95)=2.89$, $p<.01$ and $t(95)=3.20$, $p<.01$. Participants seem to increasingly ignore the information given by angle in favor of reliance on head diameter, even though angle provides easier discriminations (Experiment 1).

As in Experiment 2, a table summarizing individual data was created. The number of participants for which a cue or cue set received the highest use during the final transfer test was recorded. Twelve participants had equal endorsement for two different cue sets. In these cases, each cue was given credit, so the total number of endorsements is 108, even though there were only 96 participants. The percentage of the total number of preferences is shown for each cue in Table 2.

Table 2: Percentages of participants for which each cue set accounts for most of the transfer test responses from Experiment 3.

Stage	Bump	Angle	Diam	D/A	B/D	B/A	B/D/A
1	6%	16%	29%	24%	17%	4%	5%
2	1%	6%	38%	23%	23%	1%	8%

This tabulation reveals that 30% of the participants used a space in which the categories were separable, with nearly three times as many preferring the simpler B/D space to the B/D/A space by the end of training. This more than the 13% in the equivalent condition from Experiment 2. The reduction in angle use that is equivalent to the adoption of the B/D cue set is made more dramatic in that the angle dimension yielded the most accurate discriminations in Experiment 1. Further, both tail angle and tail bumpiness are features of the same component of the stimulus. On the other hand, there were still two thirds of the participants who used only obvious dimensions and failed to adopt a cue set which separates the categories. The preference for simplicity may extend to the discriminability of the cues as well as their number.

General Discussion

The experiments reported here investigated participants' ability to use subtle perceptual cues to disambiguate overlapping categories. In Experiment 1, it was established that the primary dimensions of variation, head diameter and tail angle, were roughly equated for discriminability, and the subtle dimension of tail bumpiness was much less discriminable. Experiment 2 demonstrated that some, but not all participants were able to use the subtle dimension in conjunction with the other dimensions to eliminate exceptions to the obvious dimensions. Experiment 3 showed that participants favored using a 2-cue optimal cue set over a 3-cue one.

There are two aspects of the present data that are challenging from a modeling perspective. The first is the widespread disregard for diagnostic cues. In some participants, this shows up as an inability to use the bumpiness cue or perhaps even a total reliance on just one obvious cue. These expedient cue sets could not yield enough information to result in perfect performance without additional memorization of exceptions. Even for participants who chose one of the cue sets that separated the categories, there was a strong preference for the simpler (2-d) set. Use of the angle dimension, which was part of the optimal 3d cue set, and which was independently diagnostic, decreased with training. The second aspect of the data that is challenging is the broad individual differences. Nearly every possible cue set was used in all phases of the reported experiments. Category learning models which adjust attention weights based on gradient descent on error (i.e., the backprop algorithm) will tend to converge on a set of optimal weights, rather than showing dramatic differences in predicted performance (see discussion in Kruschke, 2001). These optimal weights will also be positive for any informative dimensions. More recent models of attention in associative learning that incorporate rapid shifts of attention

in conjunction with annealed learning rates show more promise of fitting our data. The rapid shifts of attention can lead to shifts away from dimensions before associations can form, and the annealed learning results in a progressive discounting of error, leading to participants getting frozen in a sub-optimal space. Kruschke and Johansen's (1999) RASHNL model has fit similar data in probabilistic category learning task.

The present study is related to recent work on human concept learning that is based on a simplicity principle (Feldman, 2003). This principle suggests that the ease with which categories can be learned is related to how incompressible or complex the categories are, that is, the length of its minimum description. Maximally complex categories, for example one consisting of a mailman, a speedboat, and a jelly doughnut, have no regularities at all, and the minimum description is simply a list of its members. Simpler categories, for example: big blue triangle, big red circle, and big yellow square, can be compressed down to exclude some of the data from the examples, leaving a smaller description, in this case "big" things. In the context of the current work, it could be said that incorporating the information from the bumpiness dimension, while increasing the number of dimensions, decreases the overall category description length, because the exceptions do not have to be explicitly encoded. Participants in Experiment 2, some of who showed increasing use of the bumpiness dimension, but also decreasing use of the angle dimension, also seemed to use a simplicity principle. Angle use decreased not because it was uninformative, but because it was not part of the minimal description. In addition to reworking their description of their overall category regularities, participants can and do augment their category representation by identifying and memorizing specific exception stimuli. In other words, simply adding any exceptions to the representation they have already formed. Several results, including the present data, suggest that this strategy is not uncommon in some typical category learning paradigms (Blair & Homa, 2001). This focus on individuals rather than on category level regularities seems to occur even in some separable categories if they are small and weakly structured (Blair & Homa, 2003). These results highlight the potential disparity between mathematical complexity and psychological complexity, and emphasize the importance of understanding how the cognitive system implements complexity minimization. A precise account of the relative costs of adding or shifting dimensions versus memorizing exceptions will certainly involve a better understanding of how attentional, perceptual, and memorial processes interact as classification expertise develops.

Acknowledgments

This work was completed in partial fulfillment of the Ph.D. requirements in psychology at Arizona State University. I would like to thank Steve Goldinger, Mike McBeath and Sue Somerville who comprised my excellent dissertation committee, and especially Don Homa, my mentor and committee chair. I would also like to thank Jacqueline Blair for helpful comments on an earlier draft of this paper and Chris Summers for help in conducting these experiments.

The Effect of Temporal Delay on the Interpretation of Probability

Amber N. Bloomfield (a-bloomfield@northwestern.edu)
Department of Psychology, 2029 Sheridan Road
Evanston, IL 60208 USA

Abstract

The studies reported here investigate the interaction between probability and delay. In the first study, the fits of a range of high and low probability words were calculated for numerical probabilities presented with either a short or long delay. Results show that participants in the long delay condition felt that high probability words fit small numerical probabilities better and that low probability words fit large numerical probabilities better than did participants in the short delay condition. In a second study, participants were presented with money offers that were both delayed and risky. Findings indicate that delay is given less weight at low probabilities, and probability is given less weight at large delays when probabilities are mid-range. Combined, these data suggest that a trade-off occurs between giving attention to delay and giving attention to probability in judgments. One component of this arises from long time delays "dampening down" the influence of probability level, but the complete nature of the interaction between probability and delay remains to be explored.

Introduction

In everyday decision making, individuals must determine the value that various outcomes have for them. Often, even if people have a clear idea of the value that an outcome has for them in general (such as a week in Paris), they must assess its value in terms of different types of uncertainty associated with the outcome. One type of uncertainty arises from the outcome having a less than 100% likelihood of occurring (i.e., it is probabilistic). This type of uncertainty is normatively applied by translating an outcome into its *expected value* (EV): multiplying the value of the outcome by its probability of occurring. Another type of uncertainty associated with outcomes is temporal delay. Adjustment of an outcome due to temporal delay is referred to as *temporal discounting.*

Choice involving risk (i.e., probabilistic outcomes) and intertemporal choice have several parallel anomalies (Prelec & Loewenstein, 1991). These anomalies include common difference and ratio effects, immediacy and certainty effects, magnitude effects and sign effects. Common difference effect occurs when a pair of delayed outcomes which an individual is indifferent between produce a decisive preference for him or her when a common delay is added to both. For instance, a person might be indifferent between $25 now and $40 is one week, but may express a preference for the $40 if a one-week delay is added to both options. Similarly, common ratio effect occurs when two probabilistic options which a person is indifferent between produce a solid preference when their probabilities are multiplied by a common probability. A person might be indifferent between a 5% chance of $10 and 2% chance of $15, but prefer the $15 option if both probabilities are multiplied by 50%. Immediacy and certainty effects involve the overweighting of immediate outcomes in intertemporal choice and the overweighting of certain outcomes in risky choice. Magnitude effects occur when large amounts are discounted to a lesser (temporal discounting) or greater (discounting for risk) degree than are small amounts. Sign effects involve a tendency towards risk-aversion for gains and risk-seeking for losses in risky choice, and a steeper discounting of gains than losses in intertemporal choice.

Given these parallels, it is not surprising that some researchers have suggested that discounting for risk and discounting for delay arise from the same source. For instance, Benzion, Rapoport and Yagil (1989) argue that, in addition to the time value of money (characterized as the accepted interest rate) delay introduces a *risk premium*, which arises from the implicit risk associated with delay. By this interpretation, the temporal discounting stems from implicit risk combined with the rational time value of money. Alternatively, Rachlin and Raineri (1992) argue that probability can be expressed as waiting time, by estimating the number of trials until a win (60% chance ≈ 6 out of 10 trials are wins), and adding together the amount of time between each trial preceding the first win to calculate overall waiting time. These two ideas both argue for a fundamental source of uncertainty (either risk or delay) that leads to both types of discounting.

It is likely that because of the focus on equating probability and delay little attention has been paid to how they affect each other, both in determining the value of outcomes and directly. Only a few studies have actually presented participants with outcomes that are both delayed and probabilistic. Keren and Roelofsma (1995) argue for two different types of uncertainty present in intertemporal choice: internal (involving doubts about one's ability to predict future tastes/needs) and external (concerning doubts about whether promised future payments will be honored). Internal uncertainty is the type of uncertainty typically associated with intertemporal choice. External uncertainty is probabilistic uncertainty, which they argue is also a component of any temporal delay. They found that the immediacy effect could be derailed by making the options probabilistic (the immediate option was no longer over-weighted), and that adding a delay to a certain option weakened the certainty effect (the certain option was no longer as over-weighted, and more people preferred a risky

option that had a higher payoff). Keren and Roelofsma did not find a significant interaction of delay and probability, and suggested that the two factors are additive. However, they used only two levels of probability in their experiment examining the immediacy effect, and only one level of temporal delay when examining the certainty effect.

Keren and Roelofsma's (1995) description of the external uncertainty component of delay does suggest that the subjective interpretation of a given probability when a delay is introduced should be lower, because the uncertainty associated with a delay should make the relevant outcome seem even less likely to be received. While Keren and Roelofsma only used delay and probability to make qualitative departures from certainty and immediacy, respectively, a more continuous effect of delay on probability should be evident if external uncertainty increases with delay.

In the following studies, the effect of delay on the interpretation of probability is explored. In the first study, a range of probabilities are paired with one of two levels of delay for all participants, and 10 probability words are rated as to their fit of each of the numerical probabilities. In the second study, multiple levels of probability and delay are combined to examine their effects on the value of two different monetary outcomes.

Study 1

In Study 1, a direct method of examining the influence of delay on probability was employed. This design was based on past work by Budescu, Karelitz and Wallsten (2003) examining how numerical probabilities are mapped on to linguistic probability words/phrases. The method of presentation was reversed, so that participants were asked to rate degree of fit of 10 probability words for each of 10 numerical probabilities. It was predicted that, if there is an external uncertainty component of delay, this would lead to numerical probabilities presented with the longer temporal delay to elicit higher fit ratings for the low probability words and lower fit ratings for the high probability words.

Methods

Materials

Instructions Participants were asked to respond to each numerical probability item by rating each probability word for that numerical probability on a scale from 1 to 8, with 1 indicating that the word fit the numerical probability "not at all" and 8 indicating that the word "absolutely" fit the numerical probability.

Stimuli Participants were randomly assigned to receive all numerical probability statements with either a short (6 months) or long (3 years) delay. Participants were presented with 10 numerical probabilities (5% - 95% in steps of 10%) embedded in the following statement: "If someone told you 'you have a _% chance of winning $9,864 in 6 months/3 years,' to what degree do you feel each of the following words fits the probability this person stated?" For each statement, participants rated 10 probability words on the basis of their fit. The probability words, (from lowest to highest probability-mapping, according to Budescu, et al., 2003) were: Impossible, Improbable, Unlikely, Doubtful, Toss-up, Possible, Probable, Good chance, Likely and Certain. The numerical probabilities were presented in a different randomized order for each participant.

Procedure Participants received the instructions for the task and responded to the test items via computer. During the task, participants were presented with each numerical probability statement followed by the 10 probability words. Participants typed in their rating for each word on the keyboard. After responding to all 10 numerical probability statements, participants were presented with the debriefing.

Participants Participants were 32 Northwestern undergraduates who participated to fulfill partial course requirement (17 in the 6 month delay condition, 15 in the 3 year delay condition).

Results

The mean rating of each probability word for each numerical probability in the two conditions was translated into proportion of total fit (by dividing the mean score by eight). These proportions were then collapsed across the three low probability words, not including impossibility (Improbable, Unlikely, and Doubtful) and the three high probability words, not including certainty (Probable, Good chance and Likely) to create a composite Overall-Low and Overall-High fit for each numerical probability.

A regression performed on the Overall-Low composite fits revealed a significant effect of probability ($t(19) = -24.94$, $B = -.979$, $p<.001$), a marginally significant effect of condition ($t(19) = 2.05$, $B = .080$, $p = .058$) and a significant interaction between probability and condition ($t(19) = 2.51$, $B = .099$, $p<.05$). Figure 1 displays the Overall-Low fits for the 6 month and 3 year conditions across numerical probabilities.

Overall-Low fits decreased as probability increased (as

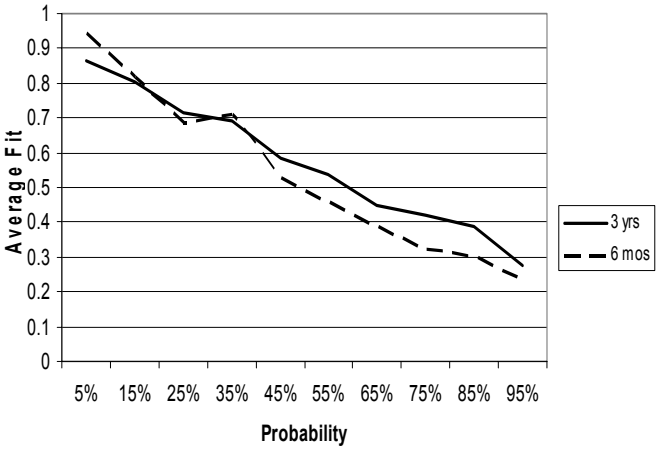

Figure 1: Overall-Low Proportions Across Probabilities

would be expected), and were higher for the 3-year delay condition (as was predicted). However, the interaction between condition and probability reveals a more complicated picture: While participants in the 3 year delay condition have higher Overall-Low fits for the higher numerical probabilities than do participants in the 6 month delay condition, there is also a tendency for these participants to rate the fit of low probability words as *lower* for the smaller numerical probabilities.

A regression performed on the Overall-High composite fits revealed a significant effect of probability ($t(19) = 25.47$, $B = .981$, $p<.001$) and a significant interaction between probability and condition ($t(19) = -2.90$, $B = -.111$, $p<.05$). Figure 2 presents the Overall-High fits across probabilities for both conditions. For the Overall-High ratings, the nature of the interaction between condition and probability is more pronounced. Participants in the 3-year condition provided lower fit ratings of the high probability words for the higher numerical probabilities *and* higher fit ratings for the lower numerical probabilities.

The findings of Study 1 suggest that delay does not have a uniform effect on the interpretation of probabilities. Rather, the effect of delay is determined by both the level of the numerical probability and the "level" of the probability word. The longer delay increases the fit of the low probability words to the numerical probabilities, as predicted, but only for those probabilities in the mid-range or higher. For smaller numerical probabilities, the longer delay *decreases* the participants' ratings of low probability words. Similarly, the longer delay decreases participants' ratings of high probability words for probabilities in the mid-range or higher, as predicted, but *increases* these ratings for the lower numerical probabilities. It seems that a longer delay decreases the "positive-ness" of the high probabilities but also the "negative-ness" of the low probabilities. At long delay, participants do not seem to uniformly interpret probabilities as lower, but do seem to uniformly interpret probabilities as less extreme.

Given the findings of Study 1, it is apparent that delay does influence how numerical probabilities are understood, and the direction of this effect depends on the level of the numerical probability. Because this interaction exists, it is important to look at how probability and delay combine in determining the value of outcomes that are both delayed and probabilistic. In Study 2, the effects of delay and probability, and the interaction between the two, on the value of monetary outcomes are investigated.

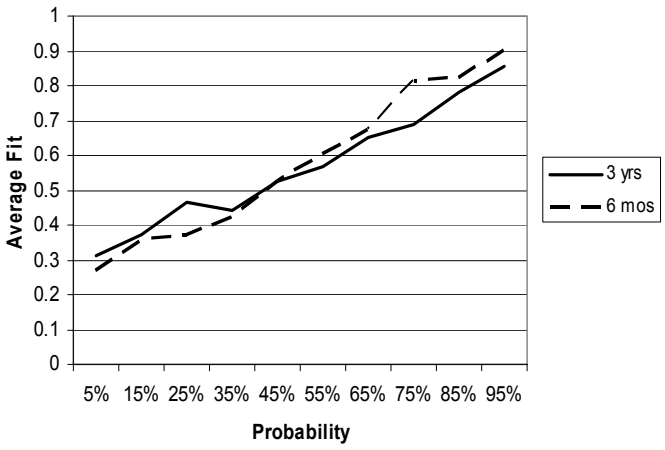

Figure 2: Overall-High Proportions Across Probabilities

Study 2

Methods

Materials

Instructions Participants were instructed to respond to each item by providing a *certainty equivalent* (CE) for the money offer. A certainty equivalent is an amount that will be received immediately and for certain, such that participants feel they would be indifferent between this amount and the presented money offer.

Stimuli Participants responded to a total of 70 money offers. For each of two payoff amounts ($10,000 and $1 million) participants responded to five gambles with one of five probabilities (5%, 30%, 55%, 80% or 95%), five delayed payments with one of five time delays (6 months, 1 year, 3 years, 5 years or 10 years) and 25 *delayed gambles*, combining each probability level with each delay level once. Gambles, delayed payments and delayed gambles for both payoffs were presented in a different random order for each participant.

Procedure Participants received the instructions for the task and responded to the test items via computer. During the task, participants were presented with each money offer and typed in a certainty equivalent using the keyboard. Participants were not given any feedback on their performance. At the end of the 70 money offers, participants were read debriefing information by the experimenter.

Participants Participants were 18 Northwestern undergraduates who participated to fulfill partial course requirement. The data from two additional participants was excluded due to a failure to follow directions (more than ¼ of their responses were greater than the payoff of the money offer or they responded "0" to one or more items).

Results

Because several participants had one or two responses that were greater than the payoff amount (errors occurring from accidentally typing an extra "0" into the computer), all analyses were performed on median responses as opposed to mean responses.

Weighting and Discounting Factors Using the responses to the delayed payments, it was possible to calculate the temporal discounting factor (k) for each participant. This factor represents the extent to which, for each day of delay, an individual devalued the payoff amount. The formula for k

is derived from the formula for temporal discounting developed by Mazur (1987): k = (V/dv)-(1/d), where V is the undiscounted value of the outcome, d is the delay in days and v is the provided subjective value of the outcome. A k of 0 implies no discounting of the outcome for delay. For each participant, the median k across all delayed payments was obtained.

There was a significant effect of amount on the median k values: participants tended to have larger ks for payoffs of $10,000 than for payoffs of $1 million ($t(17) = 2.85$, $p < .05$). The mean k for the $10,000 delayed payments was .0005, while that for the $1 million delayed payments was .0002. Larger ks imply greater temporal discounting, and greater discounting of smaller payoffs is consistent with the magnitude effect discussed in Prelec and Loewenstein (1991). Although the difference between the k factors for the two amounts seems quite small, such a difference would result in an 8% decrease in value for $10,000 delayed by 6 months compared to only a 4% decrease for $1 million delayed by 6 months.

Using the responses to the gambles, the probability weighting factor (h) was calculated for each participant. This factor represents the extent to which an individual's weighting of probabilities in their responses corresponds to expected value (h = 1 means responses are perfectly in line with expected value). An h greater than 1 demonstrates risk-aversion (the certainty equivalent is less than the expected value of the gamble), while an h between 0 and 1 shows risk-seeking (the CE is more than the gamble's expected value). The formula used to calculate h was derived from the probability weighting formula provided by Rachlin and Raineri (1991): h = pV/v(1-p) – p/(1-p). Here, p is the probability of acquiring the outcome amount V, and v is the provided subjective value of the outcome. For each participant, a median h was obtained.

There was no significant effect of amount on h, ($t(17) = 1.51$, $p > .05$). The mean h for $10,000 gambles was 1.66, and 5.62 for the $1 million gambles. The large difference is due to one participants' extremely risk-averse responses for the $1 million gambles (median h for $10,000 = 1; for $1 million, median h = 1.11). This is consistent with Green, Myerson and Ostaszewski (1999), who found that magnitude effects in probability discounting are often small or non-existent. However, it is worth mentioning that, of the 14 participants that had different probability weighting factors for the $10,000 and $1 million gambles, 10 had larger h values for the $1 million gambles, which is consistent with the discussion of Prelec and Loewenstein (1991).

Overall Analyses for Delayed Gambles Participants' certainty equivalents were transformed to proportion of payoff amount (e.g., $5000 for a $10,000 payoff was .50) for overall data analyses. Again, the median rather than the mean of these proportions was used for analyses to control for extreme responses. A regression with amount, probability and delay as predictors revealed significant effects of probability ($t(49) = 23.15$, $B = .95$, $p<.001$) and delay ($t(49) = -2.97$, $B = -.12$, $p<.01$), and a marginally significant interaction between probability and delay ($t(49) = -1.88$, $B = -.08$, $p = .068$), on the median proportion CE. The effect of probability on response was as expected (greater CEs provided for larger probabilities), although participants over-weighted 5% to a far greater degree than has been found in past studies. Delay also had the predicted effect, with smaller CEs provided for larger delays. Figure 3 displays the overall findings of proportion CE for the five delays and the five probabilities. Because amount had no significant influence on proportion CEs, they are collapsed across amount.

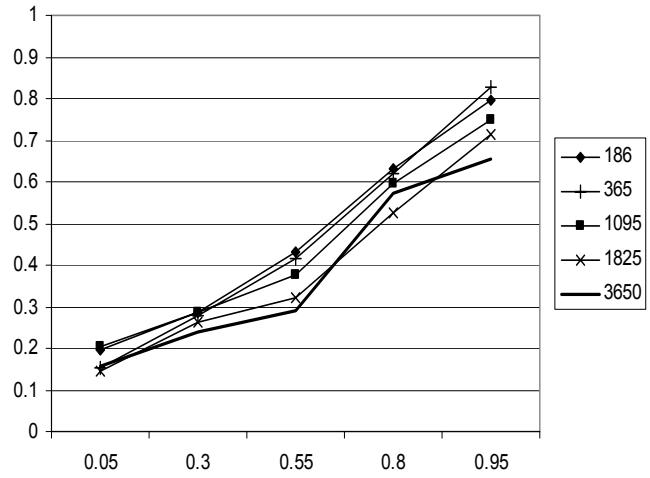

Figure 3: Proportion Certainty Equivalents by Delay and Probability

The delay by probability interaction is most apparent for the two longest delays (5 and 10 years). Participants show little increase in proportion CE with the increase from 30% to 55% probability for delayed gambles at a 5 or 10 year delay. In addition, participants show little sensitivity to delay at the two smallest probabilities.

These findings suggest an interaction between probability and delay of the type found in Study 1. Probability appears to be given less weight at longer delays. While the lines representing gambles at 5 and 10 year delays show no increase in CEs between 30% and 55%, the lines for gambles at 6 month, 1 year and 3 year delays show a relatively constant increase with probability. The influence of delay on probability is not evident until delay reaches high levels.

The findings of Study 2 are not so one-sided, however. In deciding the value of delayed and probabilistic outcomes, participants seem to be dividing their attention between probability and delay. It is not simply that probability is given less weight when longer delays are present: probability levels are given less weight at long delays when probabilities are *small*. Further, as is evident from examining the points at 5% and 30%, little attention is given

to delay at the two smallest probability levels (it is not until a 55% probability of winning that participants really begin to differentiate between the delay levels in their responses). This interpretation does not necessarily require that long delays induce smaller subjective probabilities. Rather, in the influence of delay on probability, at long delays participants could simply be using probability less in determining their responses. This idea of trading off attention between option components is supported by analyses performed for the $10,000 and $1 million gambles separately: delay was not a significant predictor for the $1 million gambles ($t(24) = -1.61$, $B = -.09$, $p > .10$, but was significant for the $10,000 gambles ($t(24) = -2.67$, $B = -.15$, $p < .05$). This could indicate that, when outcome amount was large, participants devoted attention to the amount and the probability level in their figuring of a certainty equivalent, leaving no attention for delay.

The present interaction demonstrates that probability is weighted less when a long delay is associated with the gamble, and that delay is weighted less when probability of winning is low. Study 2 provides evidence that probability and delay influence each other in determining the value of payoffs.

Discussion

Study 1's findings indicate that delay influences the interpretation of probability, such that low probabilities are interpreted as less *unlikely*, *improbable* and *doubtful*, and high probabilities are interpreted as less *probable*, representative of a "*good chance*," and *likely*. A large delay seems to take attention away from probability at both high and low levels, suppressing the negative-ness of the low probabilities, and the positive-ness of the high probabilities (in effect, "dampening " the impact of probability).

Study 2's findings support the idea that delay influences the interpretation of probability: Probability (when it is mid-range) is given less weight in participants' judgments when delays are long. However, the relationship between delay and probability seems to be more complicated: delay is also given little weight when probability is very small. This suggests that what may actually be going on in the evaluation of the delayed gambles is a tradeoff between the attention given to probability and the attention given to delay. Thus, when delay is very large, and probability is mid-range, probability is given less attention than at smaller delays. Conversely, when probability is small, delay is given less attention than when probability is higher. The finding that delay is not a significant predictor for $1 million gambles also suggests that when amount is very high, there may not be enough attention left over for delay to figure into participants' responses.

Whether or not the "dampening" effect was present in Study 2 is not completely clear. Although the interaction of delay and probability can be interpreted as less attention given to probability when delay is very long, the effect of probability level on the weight given to delay was unanticipated. Further, if the dampening effect of large delays on probability was present one would have expected to see less weight given to probability, not just for the mid-range probabilities, but for the higher probabilities as well. However, if the interaction of delay and probability arises largely from the influence of delay on probability, it would be extremely difficult to see in the data from Study 2. As was pointed out above, probability had a *much* greater impact on responses than either delay or the interaction of delay and probability. In fact, it was not unusual for participants to show no sensitivity to delay at all in responding to the delayed gambles, but rather simply respond in accordance with expected value.

Past studies have demonstrated that outcome amount and probability have a dominant/subordinate relationship, with outcome amount taking precedence (Liberman & Trope, 1998; Sagristano, Trope, & Liberman, 2002). Although Study 2 did not provide any way of looking at that particular relationship, its findings do suggest that a similar relationship may exist between probability and delay. Probability accounted for most of the variance across both outcome amounts, and was significant within both outcome amounts. Delay, on the other hand, accounted for a small amount of variance across amounts, and ceased to be a significant predictor when only the $1 million gambles were considered. This makes sense if payoff is more important to participants than probability, which is more important than delay. The possibility of a dominant/subordinate relationship between probability and delay should be more directly examined in future studies using a method similar to that used by Liberman and Trope (1998).

If probability is indeed more important to participants making decisions about delayed gambles than is delay, techniques to highlight delay could be used. In Study 2, for all delayed gambles, participants were given the probability information first. This could have decreased the role of delay in participants' responses. Further, payoff amounts were expressed as round numbers ($10,000 and $1 million) for which it would be relatively easy to calculate expected value. A current study is investigating the influence between delay and probability when items are counterbalanced as to which information is presented first, and when payoffs are not round (e.g., $10,135). It is hoped that this study will produce responses that are more sensitive to delay, and allow a clearer picture of the interaction between delay and probability.

Another question that remains unanswered is the manner in which probability level influences the interpretation of a given delay. Study 2's findings suggest that the effect of delay may be dampened by the presence of a small probability. If the external uncertainty portion of the temporal delay affects probability interpretations, perhaps the external uncertainty associated with risk changes the interpretation of delays, by highlighting the delay's external uncertainty. Although it is difficult to find a factor to pair with delay that will parallel the relationship between numerical probabilities and probability words, one could be constructed presenting linguistic descriptions of durations

(e.g., "brief time" or "very long wait") to examine the influence of small and large probability levels on the interpretation of delays associated with monetary outcomes. It is possible that for a very small probability people will not differentiate as much between different levels of delays as they do with a large probability.

A final area yet to be examined is that the two uncertainty components of delay (internal and external) mentioned in Keren and Roelofsma (1995) may be able to be separately manipulated. For instance, it is easy to imagine situations where a delay could imply greater external uncertainty (e.g., a promise from an unreliable source), but not necessarily greater internal uncertainty. Conversely, while a spring vacation in Cancun might seem very valuable to me now, I have good reason to believe that it will have less value for me when I am ten years older, though I have no reason to think that I am less likely to receive that trip in ten years as opposed to a trip to Spain. Looking at how delay influences the value of different outcomes which emphasize or increase its internal or external uncertainty component is necessary to fully understand why delay decreases value.

Conclusion

The present studies demonstrate that there is an effect of delay on the interpretation of probabilities and an interaction between delay and probability on the value of monetary outcomes. When delay is longer, probabilities are interpreted as less extreme, at both higher and lower levels. Further, mid-range probabilities are weighted less at longer delays when valuing monetary outcomes, and delay is weighted very little when probabilities are small, suggesting that attention is traded off between delay and probability, depending on the levels of each. Because choices in life often involve delays and likelihoods less that 100%, it is worthwhile to explore the way people combine these two types of uncertainty and, especially for temporal delay, to gain a better understanding of the roots of delay's influence on value.

Enhancing Simulation-Based Learning through Active External Integration of Representations

Daniel Bodemer (d.bodemer@iwm-kmrc.de)
Knowledge Media Research Center, Konrad-Adenauer-Str. 40
72072 Tuebingen, Germany

Abstract

Discovery learning with computer simulations is a demanding task for many learners. Frequently, even fostering systematic and goal-oriented learning behavior does not lead to better learning outcomes. This can be due to missing prerequisites such as the coherent mental integration of different types of representations comprised in the simulations and in the surrounding learning environment. Prior studies indicated that learning performances can be enhanced by encouraging learners to interactively and externally relate different static sources of information to each other before exploring dynamic and interactive visualizations. In an experimental study addressing the domain of mechanics it was largely confirmed that the active external integration of representations can improve simulation-based learning outcomes.

Introduction

Computer-based learning environments increasingly comprise simulations in terms of dynamic and interactive visualizations to illustrate complex processes and abstract concepts. These simulations may be highly interactive in that they allow learners to change input variables by entering data or by manipulating visual objects and to observe the consequences of these changes in the dynamic visualizations as well as in additional representations such as numeric displays, formulas or text labels.

The conceptual model underlying the simulations has frequently to be inferred by the learners in processes of discovery learning, which correspond to the steps of scientific reasoning: defining a problem, stating a hypothesis about the problem, designing an experiment to test the hypothesis, carrying out the experiment and collecting data, evaluating the data, and (re-)formulate a hypothesis. The use of simulations frequently aims at inducing active learner behavior and constructive learning processes (e.g., de Jong & van Joolingen, 1998; Rieber, Tzeng & Tribble, in press). Learners have to self-regulate their learning behavior in order to discover the underlying conceptual model, which is assumed to lead to the acquisition of deeper domain knowledge (e.g., Schnotz, Boeckheler, & Grzondziel, 1999). However, it has shown that learners encounter difficulties in all phases of the discovery learning process. For example, learners have problems formulating useful hypotheses, designing appropriate experiments, and evaluating the output variables adequately (e.g., de Jong & van Joolingen, 1998; Njoo & de Jong, 1993; Reigeluth & Schwartz, 1989; Reimann, 1991). Moreover, many learners have difficulties in planning their experiments in a systematic and goal-oriented way and therefore interact with the simulations rather randomly (e.g., de Jong & van Joolingen, 1998; Schauble, Glaser, Raghavan, & Reiner, 1991).

Additional problems may be caused by the dynamic visualization of the simulated concepts. On the one hand the externalization of dynamic processes may prevent learners from performing cognitive processes relevant to learning on their own (e.g., Schnotz et al., 1999). On the other hand dynamic visualizations may overburden the learners' cognitive capabilities due to large amounts of continuously changing information, particularly if the output variables are represented as non-interactive animations that do not provide learners with the possibility to adjust the playback speed or to watch single frames (e.g., Lowe, 1999). In order to cope with these requirements, learners frequently make use of a strategy that limits their processing to selected aspects of a dynamic visualization, which are often not the most relevant aspects of the visualization, but rather those that are most perceptually compelling (cf. Lowe, 2003).

In order to support simulation-based discovery learning it has been suggested to structure the learners' interactions with the learning environment (e.g., van Joolingen & de Jong, 1991). Typically, these support methods guide learners to focus on specific variables of the underlying model, to generate hypotheses about relationships between these variables, to conduct experiments in order to test the hypotheses, and to evaluate the hypotheses in light of the observed results. Furthermore, various instructional support methods have been developed to facilitate specific processes of discovery learning, such as offering predefined hypotheses or providing experimentation hints (e.g., Leutner, 1993; Njoo & de Jong, 1993; Swaak, van Joolingen & de Jong, 1998). However, empirical results regarding these methods of instructional guidance are ambiguous (cf. de Jong & van Joolingen, 1998). Learners frequently did not make sufficient use of the instructional support to increase their learning outcomes.

One way to explain these findings is that learners lack prior knowledge necessary to benefit from complex visualizations. Learners who do not know enough about the domain of the visualized and simulated concept have problems processing complex dynamic visualizations and to interact with them in a goal-oriented way, even if they have enough information about useful learning behavior (cf. Leutner, 1993; Lowe, 1999; Schauble et al., 1991). Another reason – which is not independent from prior knowledge – is the difficulty of interconnecting multiple representations. Usually, simulations are embedded in multimedia learning

environments and presented in combination with symbolic external representations such as text and formulas. These different kinds of representations may complement each other, resulting in a more complete representation of the illustrated concept (e.g., Ainsworth, 1999; Larkin & Simon, 1987). Both Mayer (1997, 2001) in his theory of multimedia learning and Schnotz and Bannert (1999, 2003) in their integrative model of text and picture comprehension place emphasis on the importance of integrating textual and pictorial information into coherent mental representations during multimedia learning. However, learners are frequently not able to systematically relate multiple external representations to each other. As a consequence, these learners fail to integrate the different external representations into coherent mental representations, resulting in fragmentary and disjointed knowledge structures (e.g., Ainsworth, Bibby, & Wood, 2002; Seufert, 2003). Accordingly, to facilitate simulation-based learning it seems to be important not only to support learners in dealing with the dynamics and the interactivity of the simulations, but also to help them in relating the dynamically visualized information to corresponding information of other external representations.

To facilitate learning with multiple external representations it has been repeatedly suggested to present textual and pictorial information in a spatially integrated format instead of presenting them separately from each other in a "split-source" format (e.g., Chandler & Sweller, 1991, 1992; Mayer, 1997, 2001; Tarmizi & Sweller, 1988). According to cognitive load theory (Sweller, 1988; Sweller, van Merriënboer, & Paas, 1998) this can reduce unnecessary visual search resulting in a decrease of cognitive load and thus better learning. Another suggested method to support learners in making connections between different sources of information is to link the features of multiple representations by various symbolic conventions such as using the same color for corresponding entities in different representations (e.g., Kalyuga, Chandler, & Sweller, 1999; Kozma, 2003; Kozma, Russell, Jones, Marx, & Davis, 1996). While these instructional suggestions have the potential to reduce cognitive load, they do not directly support learners in constructing meaningful knowledge. Learners may nevertheless remain rather passive, concentrating on surface features of the visualizations and they may still be unable to mentally process and integrate the represented information in an adequate way (cf. Ploetzner, Bodemer & Feuerlein, 2001; Seufert, 2003).

Bodemer, Ploetzner, Feuerlein & Spada (in press) tried to initiate more active processes of coherence formation by encouraging learners to systematically and interactively integrate different multiple representations in the external environment. Learners were provided with spatially separated pictorial and symbolic representations on the screen and were asked to relate components of familiar representations to components of unfamiliar representations by dragging the symbolic represented elements and dropping them within the visualizations (see Figure 1).

This external process corresponds largely to the mental process of structure mapping as described by Gentner (1983; Gentner & Markman, 1997) and Schnotz and Bannert (1999). While (inter-)actively relating different sources of information is intended to directly support coherence formation, the simultaneous construction of an integrated format is supposed to gradually reduce unnecessary cognitive load (e.g., Chandler & Sweller, 1991, 1992). Bodemer et al. (in press) were able to demonstrate that – compared to the presentation of information in a pre-integrated or in a split-source format – learning outcomes can be improved significantly when learners actively integrate static information before interacting with dynamic visualizations

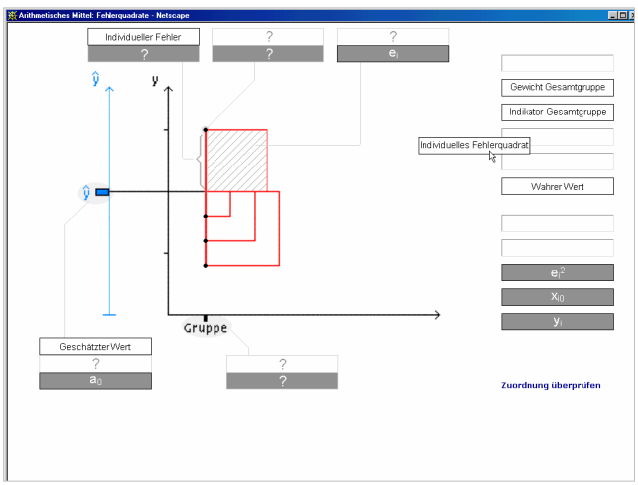

Figure 1: Active integration of information while learning statistics (cf. Bodemer et al., in press).

Bodemer et al. (in press) found the largest benefit of active integration when teaching extremely complex statistics concepts. In this paper an experimental study will be described which investigates possible benefits of active integration in another application domain with a slightly lower degree of complexity. It is hypothesized that also in less complex domains learners who actively integrate multiple representations will outperform those learning with a pre-integrated format. However, the advantage of active integration should rise with the degree of complexity of the learning material.

In order to avoid influences of assessment on the processes of discovery learning, Bodemer and his colleagues assessed the learning outcomes only after the learners had interacted with the dynamic visualizations. Thus they could not identify if knowledge has been acquired already during the process of active integration or afterwards during the process of discovery learning or both. In the study described below the learners' knowledge has been assessed both after integrating static representations and after interacting with dynamic visualizations. It is hypothesized that already the active integration of static representations can lead to better

learning outcomes. Additionally, learners who integrate multiple representations actively should improve comparatively more during simulation-based discovery learning.

Method

In this experimental study the participants learned various mechanics concepts in two consecutive learning phases. In the first learning phase they were provided with symbolic representations and static versions of dynamic and interactive visualizations. In the second learning phase they explored dynamic and interactive visualizations in a self-guided way.

Design

The experiment used a 2 x 2 factorial design with repeated measures on the second factor. The first factor addressed two levels of *information integration*, which was varied in learning phase 1: (1) presentation of the information in a pre-integrated format and (2) active integration of information. In the first condition the learners had to deal with visualizations that were already labeled while in the second condition the learners had to establish a relationship between the symbolic representation and the visualizations by dragging and dropping the symbolic representations onto the visualizations. The within-subjects factor was time of assessment: After the integration of multiple representations (test 1) and after the exploration of dynamic and interactive visualizations (test 2).

Participants

Forty-eight students (22 males and 26 females, aged 19 to 31) of the University of Tuebingen were randomly assigned to each of the two experimental conditions. They were paid for their participation. To prevent a high level of prior knowledge students of Mathematics and Physics were excluded as participants.

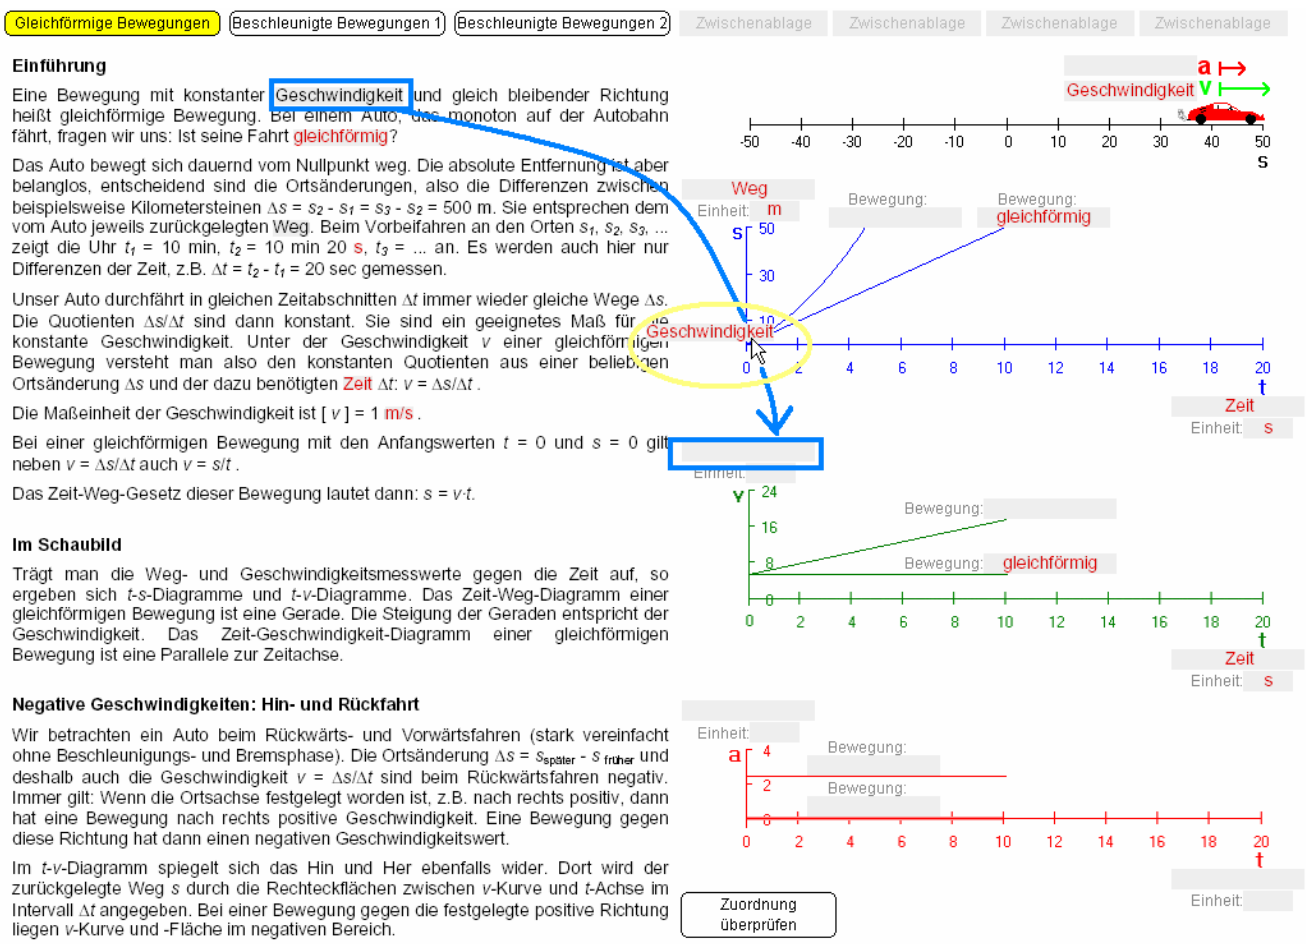

Figure 2: Active integration of information about mechanics concepts (learning phase 1).

Material

The *application domain* was comprised of various mechanics concepts, such as uniform and accelerated motion in one dimension. The *instructional material* consisted of two parts corresponding to the two learning phases:

(1) an instructional text accompanied by static visualizations, presented in the first learning phase on a computer (cf. Figure 2). The instructional text covered the left side of the screen and comprised three pages between which the learners could switch back and forth. The right half of the screen showed static versions of dynamic and interactive visualizations comprising the sketch of a moving car with corresponding velocity and acceleration vectors, a position-time graph, a velocity-time graph, and an acceleration-time graph. The presentation differed according to the two experimental groups of the first factor. In the group with *pre-integrated information* components of the visualizations were labeled with textual and algebraic information; whereas in the *active integration* group the learners interactively related the textual and algebraical information from the instructional text to the visualizations and thus created an integrated format on their own.

(2) dynamic and interactive visualizations, which were presented in the second learning phase (cf. Fig. 4). The visualizations were taken from the interactive learning environment PAKMA (Blaschke & Heuer, 2000). They correspond to the graphs of learning phase 1 with the addition that they could be modified by interactively changing variables and by running animated motion sequences.

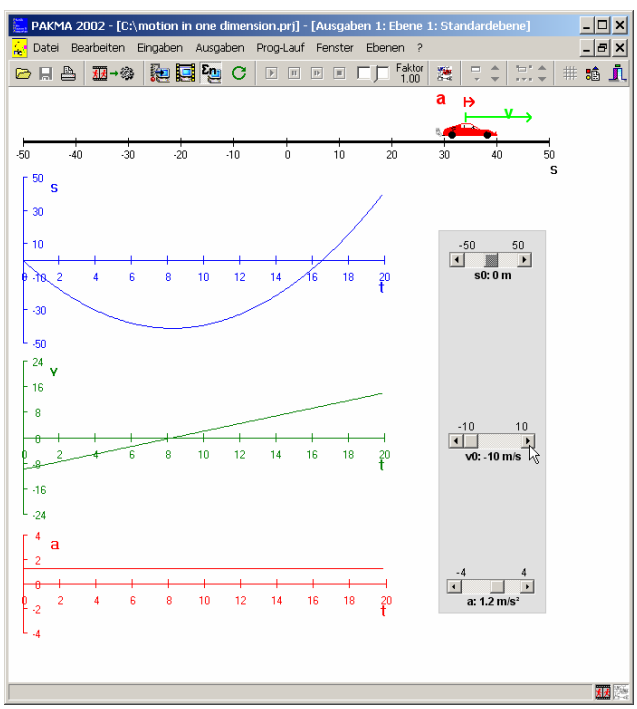

Figure 3: Dynamic simulation displaying motion in one dimension (learning phase 2).

The *test material* consisted of a knowledge test, given to the learners prior to the first learning phase, and two tests, which assessed the knowledge after each of the two learning phases. The tests were made up of different types of questions, which all required reasoning and transfer, and contained graphical elements in either the question or the answer or both: (1) questions which addressed transformations from textual to graphical representations, (2) questions which addressed transformations from graphical to textual representations, and (3) questions which addressed transformations within graphical representations. The pre-test and the first post-test consisted of six questions (two of each type); the second post-test consisted of 12 questions (four of each type). The participants' answers were scored by two independent raters.

Procedure

At the beginning of the experiment, all participants took the pre-test (20 minutes). Thereafter, learners of the condition *active integration of information* could train dragging and dropping of objects in a neutral domain (2 minutes). In learning phase 1 the participants were provided with the static versions of the dynamic and interactive visualizations accompanied by the instructional text (30 minutes). The information was either provided in a pre-integrated format or required learners to actively integrate it on their own. Then the learners took post-test 1 (20 minutes), followed by learning phase 2, in which the participants explored the dynamic and interactive visualizations without instructional guidance (15 minutes). Finally, the learners took post-test 2 (40 minutes). All participants had to spend the same time on the tasks.

Results

With regard to the pre-test there were no statistically significant differences between the groups for any of the test categories. The results of the post-tests are presented in the following. Table 1 shows the means and the standard deviations for the three types of questions: textual-graphical, graphical-textual, and graphical-graphical. Table 2 shows the results of a multivariate (Wilks-Lambda) and univariate two-way analyses of variance with repeated measures on the factor *time of assessment*.

The analyses of variance revealed a significant effect of *information integration* for those test questions which addressed transformations from graphical to textual representations. Learners with active integration performed better than with pre-integrated information in all categories of both tests; however, with regard to the two other types of questions the comparisons failed to reach statistical significance. The factor *time of assessment* had a significant effect on the test categories graphical-textual and graphical-graphical as well as across all types of questions. However, there were no interaction effects indicating that learners of both groups improved their knowledge during the exploration of the dynamic and interactive visualizations to approximately the same degree.

Additionally performed *t*-tests revealed that, on average, learners with active integration already achieved better learning outcomes after the first learning phase. Against the expectations, these differences between the groups slightly diminished in the second assessment after learning phase 2.

Table 1: Relative solution frequencies and standard deviations in both post-tests for the different questions.

Information integration		**textual-graphical**		**graphical-textual**		**graphical-graphic.**	
		Test 1	Test 2	Test 1	Test 2	Test 1	Test 2
Pre-integrated	M	.74	.71	.21	.40	.55	.66
	SD	.26	.28	.28	.26	.26	.28
Actively integrated	M	.84	.78	.37	.52	.67	.69
	SD	.24	.26	.26	.23	.29	.22
Overall	M	.79	.74	.29	.46	.61	.67
	SD	.25	.27	.28	.25	.28	.25

Table 2: The results of the multivariate and univariate two-way analyses of variance.

Source of variance	**Dependent variable**	**df**	**F**
	Between subjects		
Information integration	Across all types of questions	3, 44	1.48
	textual-graphical	1, 46	1.83
	graphical-textual	1, 46	4.32*

Discussion

This paper investigated the benefit of an instructional support method to support learning with dynamic simulations in multimedia learning environments. Learners were encouraged to interactively and externally relate different static sources of information to each other before exploring dynamic simulations. In an experimental study the active integration of multiple representations was compared to the presentation of information in a pre-integrated format as suggested by Chandler and Sweller (1991, 1992) and Mayer (1997, 2001). The application domain was mechanics. It was hypothesized that learners who initially integrate multiple representations actively achieve better learning outcomes as found by Bodemer et al. (in press) for the domain of statistics.

The results largely confirmed that encouraging learners to actively integrate symbolic and static representations during multimedia learning can improve learning. Moreover, it shows that active integration of information – compared to the presentation of information in a pre-integrated format – can lead to the acquisition of knowledge already during learning with static symbolic and pictorial representations, and not only in combination with dynamic and interactive visualizations.

Contrary to expectations learners who actively integrated different representations were not able to improve comparatively more during simulation-based discovery learning. This may be due to the relatively low amount of additional information provided by the dynamic and interactive visualizations compared to their static versions. The static graphs already contained dynamic information by representing time on one axis. Ainsworth and van Labeke (2003) state that dynamic representations that express the relation between a variable and time do not contain more information than the same representation in a static form. Except for the illustration of the car with the corresponding velocity and acceleration vectors this applies to the dynamics of the simulation used in this study. However, the simulations contained additional information by providing the possibility to change variables interactively. But the number of changing options was very limited compared to the dynamic and interactive visualizations used by Bodemer et al. (in press).

The results differed with respect to the codalities of the test items. It appeared, that not only the retrieval cue codalities have to be considered (cf. Brünken, Steinbacher, Schnotz & Leutner, 2001); but also the codality of the learners' response effects the test result. Active integration of information was particularly helpful for answering questions that required transformations from graphical to textual representations.

Future research should consider the different codalities of test items as well as differences of visualizations and simulations with respect to the dynamics and the interactivity. Moreover, the learners' prior knowledge and the complexity of the learning task have to be accurately analyzed in further studies because they seem to significantly affect the use of actively integrating multiple representations.

Abstract

The present research aims to investigate the distinction between simple and complex communicative acts in the context of extralinguistic communication. We propose that, within the same pragmatic phenomena studied - which are standard communicative acts, deceit and irony - a simple communicative act is easier to comprehend than a complex one. Our proposal is based on the different complexity of inferential processes involved in comprehending communicative acts. We provide empirical evidence in support to our hypothesis with an experiment on children aged 5;5 to 8;6 years. We consider our results as favoring a unitary model of communication, where 'linguistic' and 'extralinguistic' are similar expressive channels underlying the same cognitive faculty.

Introduction

Philosopher John Searle (1975) introduced the classical distinction between direct and indirect speech acts. A direct speech act consists of a sentence where a speaker means exactly and literally what she is saying, for instance [1] 'Please pass me the salt', proffered by the speaker to obtain the salt, located on the table, from her table-companion. On the contrary, an indirect speech act consists of a sentence by which the speaker communicates to the hearer more than what she is actually saying. For instance [2] 'Do you mind passing me the salt?' or [3] 'My soup is lacking in salt', proffered by a speaker in order to obtain the same goal as in the previous example.

Searle claims that the primary illocutionary force of an indirect speech act is derived from the literal meaning *via* a series of inferential steps. The hearer's inferential process is triggered by the assumption that the speaker is following the Principle of Cooperation (Grice, 1975), together with the evidence of an inconsistency between the utterance and the context of enunciation. According to Searle, the hearer tries first to interpret the utterance literally, and only after the failure of this attempt, due to the irrelevance of the literal meaning, does he look for a different one, which conveys the primary illocutionary force. In this view, an indirect speech act is intrinsically harder to comprehend than a direct one. Indeed, understanding a direct speech act such as [1] is straightforward, that is, it does not require inferences, while understanding indirect speech acts, such as [2] and [3] relies on some kind of common knowledge. However, the length of the inferential path is not the same for each indirect speech act. For instance [3], an example of non conventional indirect speech act, requires a greater number of inferences than [2], an example of conventional direct speech act.

Some authors have criticized this position for different reasons (Clark, 1979; Sperber & Wilson, 1986; Recanati, 1995). In particular, Gibbs (1986; 1994) shows that a speaker can use an indirect act when she thinks that there might be obstacles against the request she intends to formulate: for example, when the speaker does not know whether the hearer owns the object she desires, he can use a conventional indirect request. The context specifies the necessity of using a conventional indirect and thus helps the hearer to understand the intended meaning more quickly. Gibbs suggests that, in such a circumstance, the partner infers the meaning of a conventional indirect speech act *via* an habitual shortcut that facilitates its comprehension.

In addition, Bara and Bucciarelli (1998) point out that for 2;6-3 year old children conventional indirects, such as 'Would you like to sit down?', compared to direct speech acts, such as 'What is your name?', are equally easy to comprehend. On the contrary, the same children have difficulties with non-conventional indirects: for instance they find it hard to understand that the answer 'It's raining' to the proposal 'Let's go out and play' corresponds to a refusal.

On the basis of the Cognitive Pragmatics theory, by Airenti, Bara and Colombetti (1993a), Bara, Bosco and Bucciarelli (1999) advanced an alternative explanation that constitutes the theoretical basis for the present research. The authors propose to abandon the distinction between direct and indirect speech acts and to adopt a new one between simple and complex speech acts, based on the increasing complexity of the inferential processes underlying their comprehension. This distinction has the distinct advantage of applying not only to standard speech acts, but also to non standard ones, like irony and deceit.

The aim of the present research is to extend the distinction between simple and complex speech acts to extralinguistic communication, and to provide empirical evidence in support of our hypothesis.

Cognitive Pragmatics theory

Airenti et al. (1993a) have presented the bases for a theory of the cognitive processes underlying human communication that holds for both linguistic and extra-linguistic communication. A major assumption of Cognitive Pragmatics is that intentional communication requires behavioral cooperation between two agents; this means that when two agents communicate they are acting on the basis of a plan that is at least partially shared. The authors call this plan a *behavior game*. The behavior game is a social structure mutually shared by the participants of the dialogue. Each communicative action performed by the agents realizes the moves of the behavior game they are playing. The meaning of a communicative act (either linguistic or extralinguistic or a mix of the two) is fully understood only when it is clear what move of what behavior game it realizes. Consider for example the following communicative exchange:

[4] Susan: "Do you have 10 dollars?"
Mark: "Oh, I forgot my wallet"

Mark understands that Susan is asking him to lend her some money on the basis of the behavior game they are mutually sharing:

[5] [LEND-MONEY]:
• A gives money to B;
• B returns money to A.

A game provides a context for the assignment of meaning to a communicative action (Bosco, Bucciarelli & Bara, 2004). It is the sharedness of these knowledge structures that allows them to maintain conversational cooperation in spite of Mark's refusal to cooperate on the behavior level.

Simple and complex standard speech acts

The comprehension of any kind of speech act depends on the comprehension of the behavioral game bid by the actor[1]. Unless a communicative failure occurs, each participant in a dialogue interprets the utterances of the interlocutor on the ground she gives as shared between them. According to such a perspective, the difficulty in comprehension of different types of speech acts depends on the chain of inferences required to pass from the utterance to the game it refers to. Direct and conventional indirect speech acts do immediately make reference to the game, and thus they are defined as *simple speech acts*. On the contrary, non conventional indirect speech acts can be referred to as *complex speech acts* in that they require a chain of inferential steps, since the specific behavior game of which they are a move is not immediately identifiable (Bara & Bucciarelli, 1998). For example, to understand [1] and [2] it is sufficient for the partner to refer to the game [ASK-FOR-OBJECT]. In order to understand [3], a more complex inferential process is necessary: the partner needs to share with the speaker the belief that if the soup is lacking salt it is not good to eat and that if there is some salt on the table and somebody proffers [3] she probably wants it. Only then, can the partner attribute to the utterance the value of a move of the game [ASK-FOR-OBJECT].

In other words, if the problem is how to access the game, the distinction between direct and indirect speech acts is irrelevant. The comprehension of a speech act requires the comprehension of the game of which it is part: in order to understand the actor's communicative intentions, the partner has to find a meaningful connection between the actor's utterance and the behavioral game they are playing. In the case of simple speech acts there is an immediate correspondence between the utterance and the game, that is the utterance straightforwardly refers to the game. On the contrary, in the case of complex speech acts the comprehension of the link between the speech act and the game requires the partner to make longer inferential processes. The bigger the distance between the utterance and the communicative context shared by actor and partner, the more difficult the comprehension of the utterance itself. In sum, the difference in the difficulty of comprehension between simple and complex acts depends on the steps needed to refer the utterance to the game bid by the actor or already shared by the participants.

We find the notion of simple and complex speech act more useful rather than the one of direct and indirect speech act because, as Bara et al. (1999) propose, it can be extended to other non standard pragmatic phenomena, in particular irony and deceit.

Simple and complex deceits and ironies

A deceit occurs when the mental states that the actor entertains are covertly different from those she communicates. Bara et al. (1999) propose that the difficulty in its comprehension can vary depending on the complexity of the inferential chain necessary to refer the utterance to the behavioral game. Consider the following example:

[6] *Andrew is eating some biscuits from a plate in front of him. He hears Julia arriving, and then he pushes away the empty plate in front of him. Julia sees the empty plate and asks:* "Who has finished my biscuits?". *Andrew answers…*
(a) Simple: "I don't have the slightest idea"
(b) Complex: "I'm on a diet"

In our example, the deceitful speech act [6a] is simple because it consists in an utterance which denies the actor's private (and true) belief *(not-p)*, that would allow the partner to immediately refer to the game [BISCUIT-STEALING] that the actor wishes to conceal from the partner. Instead, a complex deceitful speech act, such as [6b], consists in an utterance which leads to the inference: if he is on a diet, he cannot eat biscuits, that is inconsistent with the game [BISCUIT-STEALING] that the actor wishes to deny. Thus,

[1] Since the theory holds both for linguistic and extralinguistic communication, we prefer to use the terms actor and partner instead the classical speaker and hearer.

to comprehend a complex deceit, an agent needs a longer inferential chain.

Cognitive Pragmatics theory claims that irony can be understood when compared with the belief provided by the behavior game shared between actor and partner (Airenti, Bara & Colombetti, 1993b; Bara, in press). According to Bara et al. (1999), bearing in mind the complexity of the inferential chain necessary to refer the utterance to the game bid by the interlocutors, it is possible to distinguish two kinds of irony, simple and complex. Consider the following example:

[7] *Alex takes out from a toaster two completely burned pieces of toast. Mary arrives and Alex asks with a puzzled expression*: "Am I a good cook?" Mary *answers*…

(a) Simple *:* "The best cook in the world!"

(b) Complex: "I'll hire you in my restaurant"

A simple ironic speech act, such as [7a], corresponds to the antiphrastic theory of irony (Grice, 1989): an actor expresses *p* to mean *not-p*. Thus, a simple irony immediately contrasts with a belief shared between the agents, in our example that Alex is not a good cook. On the contrary, a complex ironic speech act requires a series of inferences in order to detect its contrast with the belief shared by the agents. Consider our example, by producing the complex irony [7b], an actor proffers an utterance which implies the belief *p* (to employ someone in a restaurant, s/he has to be a good cook), contrasting with the belief *not-p* (the guy is not a good cook), shared between the two agents. Thus, a person needs a longer inferential chain to comprehend a complex deceit rather than a simple one.

Bosco and Bucciarelli (submitted) empirically supported the distinction between simple and complex speech acts: children aged from 6;7 to 10 years, find it easier to comprehend simple speech acts, rather than complex ones, within the same pragmatic phenomena investigated, i.e. standard speech acts, deceits and ironies.

The present research focuses on the difference of the inferential processes between communicative acts pertaining to the same pragmatic category and it did not analyze the difference among inferential processes existent among various kind of pragmatic phenomena. Details about how different types of mental representations underlie the comprehension of standard communicative acts, deceits and ironies can be found elsewhere, e.g. Bucciarelli, Colle and Bara (2003): such a work focuses on the *type of inference* underlying specific kinds of pragmatic phenomena; for instance, understanding an ironic act requires the detection of a contrast between the speech act and the background knowledge shared by the interlocutors. The present research deals instead with the *length of the inferential* processes underlying the comprehension of communicative acts within the same pragmatic phenomenon, i.e. simple vs. complex standard acts, simple vs. complex deceits, simple vs. complex ironies.

Experiment: simple vs. complex extralinguistic communication

As we have shown in the previous paragraphs, the difference between simple and complex acts has been demonstrated in the context of linguistic communication. Let us now focus on extralinguistic communication. By extralinguistic communication we refer to actions such as facial expressions, hand gestures and body movements when they are intentionally performed to share a communicative meaning. These means of expression are of special importance in that communication, in the first phases of life, heavily relies on such kinds of actions. Also, persons who have lost the ability to communicate through language, e.g. patients with aphasia, have to resort to extralinguistic means. Not to mention the various kinds of situations in which normal adults need to communicate but are forced not to use speech. For all these sort of reasons, we conducted a study in the context of extralinguistic communication. In particular, our aim is to analyze whether the distinction between simple and complex acts holds also in such a context: if language and gestures are comparable ways of communication, we should expect that the distinctions made in linguistic contexts holds also for extralinguistic communication.

According to Cognitive Pragmatics theory, communication is indeed a unitary cognitive faculty aimed at modifying and sharing mental states, while 'linguistic' and 'extralinguistic' are means of expression that an agent may use indifferently in order manifest to and share her communicative intentions. For instance, waving a hand or saying 'Hello' are two ways of greeting that are only superficially different; at a deeper level, they can be seen as two different realizations of a greeting act. Thus, as Bara and Tirassa (1999; 2000) propose, the difference between 'linguistic' and 'extralinguistic' communicative acts turns out to be a matter of cognitive processing rather than of intrinsic nature. Within such a perspective Bucciarelli et al. (2003) assume that the construction of the meaning of a communicative act is independent of the input modalities[2]. Empirically, they tested the prediction that a communicative act has in principle the same difficulty of comprehension, whether performed through speech or gestures. Their results show that children of different age groups comprehend each pragmatic phenomenon (simple and complex standard communicative acts, simple deceits and simple ironies) equally well in the two modalities.

The present experiment investigates the comprehension of different extralinguistic communicative acts. It consists of two experimental conditions: simple and complex. In both conditions, participants have to attribute communicative

[2] Note that on the bases of other theoretical approaches (Burling, 1993; Chomsky, 1987), nonverbal and verbal communication do have separate roots in phylogenies; on such basis, the prediction that what holds for linguistic communication holds also for extralinguistic communication would be false.

intentions to actors in videotaped stories. Our analysis focuses on a perspective of a third person who observes an actor and a partner in a communicative interaction. We now report one example for each of the investigated pragmatic phenomena. They are all extracted from our experimental protocol.

Standard extralinguistic communication
[8] *Ann has just finished preparing dinner and walks out of the kitchen holding a dish of pasta. In order to call Bob, who is listening to loud music, Ann moves her head as if to say 'Come on! Dinner's ready'.*
In the simple version of the task, Bob [8a] nods to show that he is coming. In the complex version of the task, Bob [8b] places his hand on his stomach as if to say 'I'm hungry'. The request of coming for dinner is part of the behavior game [FAMILY-DINNER], in which Ann prepares dinner, calls Bob when dinner is ready, and B answers. Bob's [8a] nodding is a simple standard communicative act because it is a straightforward answer to Ann's question and, thus, immediately relies on the game shared between the two agents. On the contrary, to understand that the complex standard gesture [8b] for 'I'm hungry' implies an acceptance, a person has to assume that if one is hungry then he wants to eat and that if one wants to eat then he has the intention of coming to dinner.

Extralinguistic deceit
[9] *Bill and his brother are playing with cushions in their room, when a lamp falls down and breaks into pieces. Mum comes into the room and, standing with her hands on her hips, she assumes a severe and questioning look as if to ask 'Who broke the lamp?'.*
In the simple version of the task, Bill [9a] opens his arms in order to state his innocence. In the complex version of the task, Bill [9b] takes a book and shows it to Mum in order to convince her he was reading. Bill's [9a] gesture is a simple deceit because it immediately denies the actor's private belief, allowing the partner to refer to the game [DOMESTIC-MISDEED]. On the contrary, [9b] is a complex deceit because it implies a belief (if one is reading a book he is not moving, then he cannot cause any damage) that is inconsistent with the game [DOMESTIC-MISDEED]. Thus, in order to understand this sort of deceit one needs to make a more complex inferential chain.

Extralinguistic irony
[10] *Alice pours some soup into her and Ben's plates and both assume a disgusted look. Alice looks at Ben as if she is waiting for a comment.*
In the simple version of the task, Ben, with an ironic expression [10a] licks his lips as if to say 'It's delicious!'. In the complex version of the task, Ben with an ironic expression, [10b] gives his plate to Alice as to ask to have some more soup. Ben's [10a] gesture is a simple irony because it immediately contrasts with the belief (the soup is not good) which is part of the game [HOME-COOKING] shared between Alice and Ben. On the contrary, the complex irony [10b] implies a belief (if one asks for more food, it is because the food is good) that contrasts with the belief 'the soup is not good' shared between the two agents.

In conclusion, within the same pragmatic category, comprehending a simple communicative act requires an easier inferential chain than that required for a complex act. Indeed, simple acts immediately refer to the behavior game shared by actor and partner, while complex acts do not. Thus, for each of the investigated pragmatic phenomena, we predict that simple communicative acts are easier to comprehend than complex communicative acts.

Our study was conducted on children of different age groups. Indeed, adult subjects possess a fully developed cognitive system and communicative competence, and thus should not show any interesting errors in comprehending the different kinds of pragmatic tasks. On the contrary, within a developmental perspective, we expect that the ability to comprehend each kind of communicative act improves with children's age.

Material and Procedures

The experimental material comprised 12 videotaped scenes, each lasting 20-25 seconds and showing two characters engaged in a communicative interaction. All communicative acts were completely extralinguistic, performed only through gestures. Of these 12 scenes, 4 represented standard communicative acts, 4 deceiving acts and 4 ironic acts. Each scene has been recorded in two versions, one simple and one complex (see the examples described in the previous paragraph). Thus we devised two experimental protocols, A and B. Each protocol contains only one version for each scene. In each protocol the scenes are represented in a different random order. Half of the participants dealt with protocol A, while the other half dealt with protocol B. Each child was randomly assigned to protocol A or B. Every child saw 4 scenes representing a standard communicative act (2 simple + 2 complex), 4 scenes representing a deceiving communicative act (2 simple + 2 complex) and 4 scenes representing an ironic act (2 simple + 2 complex).

At the end of each scene, children had to show that they had understood the communicative interaction by explaining to the examiner what had happened and what the actor's communicative intention was. Participants' responses were rated by 2 independent judges. For each item, judges assigned a score of Ø (completely wrong answer), 1 (only partially correct answer) or 2 (correct answer).

Participants

The protocol was administered individually to 300 children, divided into three age groups: 100 children ranging from 5 to 5;6 (mean age = 5;3 years), 100 children ranging from 6;6 to 7 (mean age = 6;9 years), and 100 children ranging from 8 to 8;6 (mean age = 8;2). Within each age group, there were 50 males and 50 females. Children came from nursery and primary schools of Turin.

Results

Our hypotheses were globally confirmed. Figure 1 shows the mean percentages of the correct responses over all children to the simple and complex items: in every type of investigated phenomena (standards, deceits and ironies), subjects understand the simple communicative acts better than the complex ones. More in detail, overall children understand simple standard communicative acts more easily than the complex ones (T Test: $t = 5.55$; $p < .0001$).

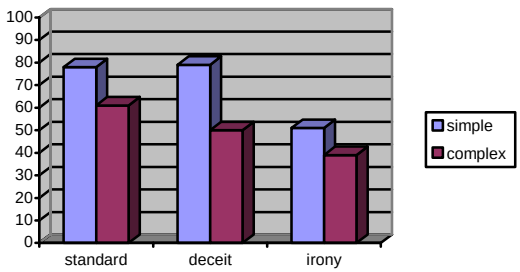

Figure 1: Histogram of the mean percentages of correct responses over all children.

As shown in Table 1, the same result holds for 5-year-olds (T Test: $t = 3.20$; $p < .002$), for 6-year-olds (T Test: $t = 2.67$; $p < .009$) and for 8-year-olds (T Test: $t = 3.76$; $p < .0001$). The same pattern of results holds also for simple and complex deceits. Simple deceits are easier, both overall subjects (T Test: $t = 10.19$; $p < .0001$), and within the various groups: for 5-year-olds (T Test: $t = 5.63$; $p < .0001$), for 6-year-olds (T Test: $t = 5.98$; $p < .0001$) and for 8-year-olds (T Test: $t = 6.15$; $p < .0001$). Finally, for ironic acts, simple ones are easier than complex ones over all subjects (T Test: $t = 3.26$; $p < .001$), for 6-year-olds (T Test: $t = 2.24$; $p < .03$) and for 8-year-olds (T Test: $t = 3.11$; $p < .003$), whereas there is no significant difference for 5-year-olds (T Test: $t = 0.65$; $p < .52$).

Table 1**:** Mean percentages of correct responses over all children and for single age groups.

Age groups	Standard		Deceit		Irony	
	Simple	Complex	Simple	Complex	Simple	Complex
5-5;6	67	50	70	42	37	34
6;6-7	79	65	83	53	56	39
8-8;6	86	68	83	56	64	46
Global	78	61	79	50	51	39

We also found significant data concerning children's performance improvement, in understanding every kind of task, in accordance with the increase of their age. Differences in performance among the three groups have resulted in both simple and complex standard speech acts (Anova: F ranging from 6.53 to 10.36; p ranging from .002 to .0001). Also the performances in comprehension of deceit improve as the age of the subjects increase, both for simple and complex deceits (Anova: F ranging from 3.32 to 6.44; p ranging from .002 to .03). The same result holds for simple ironies (Anova: $F = 13.23$; $p < .0001$) and for complex ironies (Anova: $F = 3.1$; $p < 0.05$).

Conclusions

In the present study we aimed to extend the analysis on simple vs. complex communicative acts to the domain of extralinguistic communication. The results globally confirm our predictions. Simple communicative acts are easier to comprehend than complex ones in all pragmatic phenomena investigated. This is true of all subjects, even within age groups. We explain such data considering the cognitive processes underlying the comprehension of the investigated tasks: in order to be understood complex communicative acts involve a higher inferential load than simple ones. Furthermore, as predicted, children's improve their performance in all investigated tasks, in accordance with the increase of their age.

Only in one case our data are not in line with our expectations: we did not detect significant differences in the comprehension of simple vs. complex ironies in the youngest group of 5-year-olds. A possible explanation is that irony is a too difficult pragmatic phenomenon to be fully understood by children of that age. For this reason irony comprehension results difficult in both cases (simple and complex): children gave such a few correct answers, that no significant difference emerged. This interpretation is consistent with results in literature which showed that only 6 year-old-children seem to fully grasp the intentions of ironic exchanges (Lucariello & Mindolovich, 1995). In line with such data Bucciarelli et al. (2003) found that irony – expressed both by linguistic speech acts and by gestures – is the most difficult pragmatic phenomena to comprehend, in comparison to standard communicative acts and deceits, for children aged 2;6 to 7 years. In addition, though still in line with our results, the authors found that only a small percentage (38%) of the 4;6-5;6 children in their study understood ironic gestures in an experimental setting.

Our results on children's ability to interpret extralinguistic gesture with a deceitful intent are in line with other experimental studies. For example Shulz and Cloghesy (1981) showed that only from 5 years of age children start to interpret pointing gestures with a deceitful intent, and that such an ability improves with the age. A related task has been studied by Call and Tomasello (1999). The authors investigated children's ability to deal with deceits - with the classic false belief task - in an extralinguistic form. The results are consistent with the verbal version of the task: only a few 4 year olds are able to complete the task, whereas most 5 year olds succeed.

Let us now consider our results in a wider perspective. Our main prediction was to detect an increasing difficulty in comprehension between simple and complex extra-

linguistic communicative acts in different pragmatic tasks. Such a prediction was grounded on the assumption that comprehension of simple and complex communicative acts can be explained by the complexity of the inferential chain involved in each of them, despite the communicative channel used to express them, i.e. linguistic or extralinguistic. Our results confirm such a perspective: we find the same trend of difficulty between simple and complex communicative acts that other studies underlined in linguistic comprehension (see Bucciarelli et al., 2003; Bosco & Bucciarelli, submitted). These similarities between linguistic and extralinguistic comprehension, which we found in each of the investigated pragmatic phenomenon, confirm that speech acts and extralinguistic communicative acts share the most relevant mental processes. Opposing viewpoints (e.g. Chomsky, 1987; Burling, 1993) consider linguistic and extralinguistic communication as two distinct phenomena, different in their intrinsic nature, and having separate roots in phylogenies. According to such a view, language is a complex module, independently evolved due to a non-finalized, genetic mutation. Our data seem to falsify the hypothesis of a separated line of development of language and communication, in favor of a unified theoretical framework in which linguistic and extralinguistic communication develop in parallel as different aspects of a unique communicative competence (Bara, in press).

Similarity and Categorisation: Getting Dissociations in Perspective

Nick Braisby (N.R.Braisby@open.ac.uk)
Department of Psychology, The Open University, Walton Hall,
Milton Keynes, MK7 6AA, UK

Abstract

Dissociations between similarity and categorization have constituted critical counter-evidence to the view that categorization is similarity-based. However, there have been difficulties in replicating such dissociations. This paper reports three experiments. The first provides evidence of a double dissociation between similarity and categorization. The second and third show that by asking participants to make their judgments from particular perspectives, this dissociation disappears or is much reduced. It is argued that these data support a perspectival view of concepts, in which categorization is similarity-based, but where the dimensions used to make similarity and categorization judgments are partially fixed by perspective.

Introduction

Explanations of categorisation have undergone a number of theoretical shifts (Medin, 1989), from classical to prototype models, and from prototype to theory-based models (e.g., Murphy & Medin, 1985). One of the key pieces of evidence against similarity-based models has been the finding that similarity and categorisation judgments can dissociate. For example, Rips (1989) found that participants judged an unknown item more similar to a coin yet more likely to be a pizza; and a bird transformed to look like an insect as more similar to an insect, yet more likely to be a bird.

Dissociations between similarity and categorization judgments appear directly to undermine similarity-based models of categorization. Prototype models, for example, assume that categorisation involves a similarity comparison between an object and a prototype in memory (e.g., Hampton, 1995). Exemplar-based models assume that a similarity comparison is made between an object and sets of exemplars in memory. In both kinds of model, categorization is taken to be a monotonic increasing function of similarity. That is, according to similarity-based models, it should not be possible for categorization to increase without a corresponding increase in similarity. These models thus deny the possibility of two kinds of change: i) a decrease in categorization accompanied by an increase in similarity; and ii) a decrease in categorization accompanied by no change in similarity.

In spite of the evidence and arguments in support of similarity-categorisation dissociations (henceforth, SCD), similarity-based models have maintained their appeal. Some of this can be attributed to the apparent success of similarity-based models in explaining much categorization data (cf. Hampton, 1998) even if SCDs remain as recalcitrant cases. But similarity-based models have also retained their appeal because the existence of SCDs has been questioned (despite other apparent demonstrations – e.g., Kroska & Goldstone, 1996; Roberson, Davidoff & Braisby, 1999). Smith & Sloman (1994), in seeking to replicate Rips' results, were able only to produce a SCD when participants were required to operate in a reflective, rule-based mode, by giving a concurrent verbal protocol. Similarly, Estes & Hampton (2002) only obtained a SCD when using a within-participants design; a between-participants design failed to show a dissociation. In contrast, Thibaut, Dupont & Anselme (2002) obtained SCDs in two experiments. Their participants were required to learn two artificial categories, exemplars of which were novel shapes. They found that participants tended to judge category membership according to the presence of a necessary feature, but similarity according to the presence of a salient characteristic feature.

Thibaut et al.'s results show that SCDs can arise without participants entering a reflective mode of categorization. However, they do not demonstrate that natural (as opposed to artificial) categories give rise to SCDs. That is, they have shown that participants can learn and use non-similarity-based categories, but not that natural categories are not similarity-based.

This paper seeks to add to this debate concerning SCDs and, more widely, similarity-based models of concepts by i) attempting to demonstrate a double similarity-categorisation dissociation; and ii) showing that such dissociations can be eliminated or diminished when judgments are given in context or perspective.

Previous work (e.g., Thibaut et al.) has shown that stimuli defined by the presence of both necessary and characteristic features may be categorized according to the necessary feature, and rated for similarity according to the characteristic feature. Of course, such work also implies the existence of two kinds of (potentially) borderline case: (a) an exemplar possessing the necessary but not the characteristic feature (N+C−); and (b) an exemplar possessing the characteristic but not the necessary feature (N−C+). According to the rationale extended by Thibaut et al., exemplar (a) should receive

a high categorisation but low similarity rating, and (b) should receive a low categorization but high similarity rating. Together these borderline cases could provide a double dissociation, and potentially more robust evidence of SCDs.

This paper also seeks to establish whether SCDs are context-sensitive. That is, it is possible that in context, categorization judgments are similarity-based, but that dissociations arise when categorization and similarity judgments are elicited in the absence of any specific context. If so, then the mixed evidence reported in the literature may stem from minor variations in task presentation, and it might be possible to retain a similarity-based model in which the weighting of features varies with context.

Experiment 1

This experiment sought to establish whether similarity and categorization judgments for biological categories dissociate for two kinds of borderline case: Appearance+Genetics− and Appearance−Genetics+.

Design

Task (Typicality, Categorisation), Appearance (A+,A−) and Genetics (G+,G−) were within-participants factors.

Method

Participants 40 undergraduate psychology students attending an Open University residential school volunteered to participate.

Materials Four food categories were chosen based on previous work (Braisby, 2001): salmon, apple, potato and chicken. Sixteen scenarios were constructed, as described below, so that there were four exemplars per category defined by the presence or absence of appearance and genetic properties: A+G+; A+G−; A−G+; and A−G−. The following shows how scenarios were constructed for the category 'apple'; the first set of brackets indicates wordings for G+ and G− conditions, and the second set indicates the A+ and A− wordings.

"You have just bought an apple from a reputable retailer. On examining its packaging closely, you find that it has been genetically modified [but it retains ALL/so that it has NONE] of the genetic properties specific to apples. On closer examination, you find that it [looks, feels, smells and even tastes JUST/does NOT look, feel, smell or even taste] like an apple."

Procedure All scenarios were presented and responses recorded using E-prime (Schneider, Eschman & Zuccolotto, 2002). Participants were given a practice example, and then asked to read the 16 scenarios. After each, participants first judged the category membership of the exemplar given the category label (e.g., apple), choosing either a Yes or No judgment. They then rated the exemplar for typicality on a 7-point scale relative to the category label. The typicality question is taken to be an index of similarity (cf. Hampton, 1998). Order of presentation of scenarios was random.

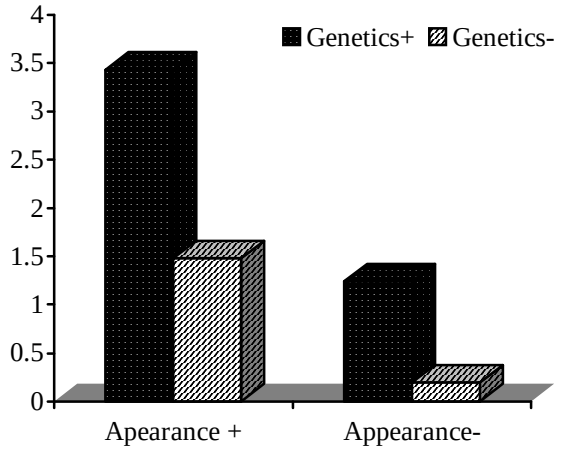

Figure 1. Overall ratings by Appearance and Genetics.

Results

Responses to the categorization question were summed over the four categories, yielding a scale of 0 to 4; the typicality question was transformed to the same scale (high scores imply high typicality and high categorization probability). Both typicality and categorization scores were analysed using ANOVA with Task (Typicality, Categorisation), Appearance (+,−) and Genetics (+,−) all within-participant factors.

There was no effect of Task ($p = 0.61$), but main effects of Appearance [$F(1,39) = 149.29$, $p < 0.001$; $\eta^2 = 0.79$] and Genetics [$F(1,39) = 109.59$, $p < 0.001$; $\eta^2 = 0.74$], interactions between Task and Appearance [$F(1,39) = 14.30$, $p < 0.01$; $\eta^2 = 0.27$], Task and Genetics [$F(1,39) = 11.63$, $p < 0.01$; $\eta^2 = 0.23$], Appearance and Genetics [$F(1,39) = 21.17$, $p < 0.001$; $\eta^2 = 0.35$], all subsumed by a marginal three-way interaction between Task, Appearance and Genetics [$F(1,39) = 3.88$, $p = 0.06$; $\eta^2 = 0.09$]. The key interactions between Appearance and Genetics, and between Task, Appearance and Genetics, are shown in Figures 1, and 2 and 3 respectively.

Pair-wise comparisons were conducted to examine the locus of the three-way interaction between Task, Appearance and Genetics. There was no effect of Task for either of the clear cases, i.e., either the A−G− or the A+G+ cases. However, there was an effect of Task, though in opposite directions, for the two borderlines. For the A+G− case, Typicality scores were markedly higher than Categorisation scores (Typicality = 1.93, categorization = 1.03, $t(39) = 3.21$, $p < 0.01$) while for the A−G+ case, Typicality scores were markedly lower

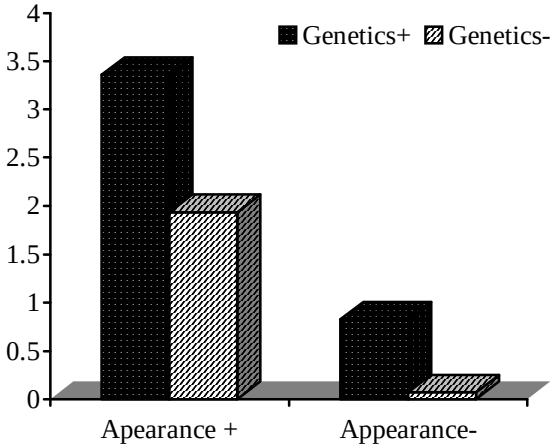

Figure 2. Typicality ratings by Appearance and Genetics.

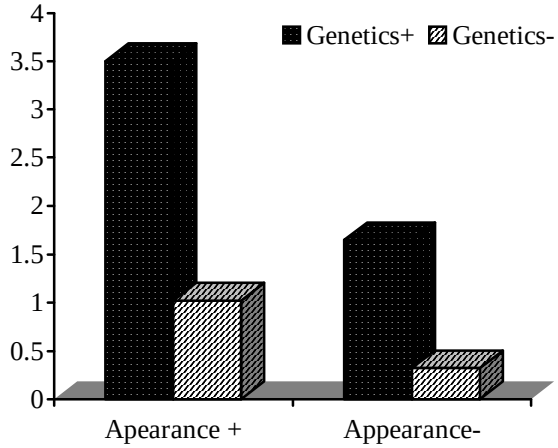

Figure 3. Categorisation ratings by Appearance and Genetics.

than Categorisation scores (Typicality = 0.83, categorisation = 1.65, $t(39) = 2.69$, $p < 0.05$).

Both Thibaut et al. and Estes & Hampton found that SCDs were due to only a subset of participants dissociatin their judgments. To examine this possibility, the number of times each participant gave dissociated pairs of judgments for the borderline items was calculated. A dissociated pair of judgments was defined in terms of differences between typicality and categorization responses for two borderline items within the same category, where the differences in the scores have different sign. For example, a participant might rate an A+G− as more typical than an A−G+, but categorise the former negatively and the latter positively. Though the difference in typicality scores is positive, the difference in categorization will be negative. Dissociations were also defined to include cases where participants gave differing categorization responses to the two borderlines within the same category, but gave the same typicality judgments. Each of these types of dissociation undermines the suggestion that categorization is a function of similarity.

Of the 40 participants, 25 (63%) gave no dissociated pair of judgments to the four pairs of borderlines with which they were presented; however, 5 (13%) gave dissociated judgments to all four pairs of borderlines.

Discussion of Experiment 1

Although previous research has claimed evidence of such dissociations, largely these have been single dissociations, i.e., items for which categorization points to category A and similarity to category B. In contrast, the present research dissociates these judgments in two ways. First, for A+G− items, typicality scores are higher than their corresponding categorization scores. For A−G+ items, typicality scores are lower than the corresponding categorization scores. Moreover, A+G− items are judged more typical than A−G+ items (1.93 and 0.83 respectively, $t(39) = 3.94$, $p < 0.001$); yet A+G− items are judged less likely to be in the category than A−G+ items (1.03 and 1.65 respectively, $t(39) = 1.73$, $p = 0.09$). Taken together, these findings present a challenge for similarity-based models, for it should not be possible for an item A to be more typical than item B and yet less likely to be a category member than item B.

It should also be noted that these materials do not present participants with fantastical transformations or discoveries. Nor do they tap artificial categories. Moreover, these data do not provide support for the idea that dissociations arise only under an especially reflective mode of categorisation. Response times were collected for both typicality and categorisation judgments. Typicality is often taken to be an index of an initial similarity computation, which can be over-ridden by a subsequent reflective categorisation. However, the response times in this experiment provide no support for this thesis: typicality response times averaged 5.13 seconds (including the time taken to read each scenario), yet categorisation averaged 3.86 seconds (again including reading time), a statistically significant difference [$t(39) = 5.40$, $p < 0.001$].

Lastly, though, it should be noted that the dissociations arise because of a subset of the participants, corroborating the findings of Estes & Hampton, and Thibaut et al.

In spite of not supporting similarity-based models, there is the possibility that categorisation and similarity judgments may align in context. That is, when in a specific context, it may be that participants make similarity-based categorisations, and dissociations arise only because these judgments are elicited out of context. The next two experiments sought to investigate this possibility by eliciting judgments in contexts

thought to emphasise either appearance or genetic properties. Both require participants to adopt a perspective in making their categorisation and typicality judgments (cf. Barsalou & Sewell, 1984)

Experiment 2

This experiment sought to establish whether similarity and categorization judgments dissociate for the two kinds of borderline, A+G− and A−G+, when participants are asked to adopt a perspective that emphasizes appearance properties.

Design

Task (Typicality, Categorisation), Appearance (A+,A−) and Genetics (G+,G−) were within-participants factors.

Participants 33 undergraduate psychology students attending an Open University residential school volunteered to participate.

Materials The same categories in experiment 1 were used. Scenarios were as in experiment 1, but were prefaced by the clause "Imagine that you are a Sculptor…". It was assumed, based on previous work, that participants would take this profession to signal the enhanced relevance of appearance properties.

Procedure An identical procedure to experiment 1 was followed. However, categorization and typicality questions were prefaced by the clause "Imagining yourself to be a sculptor…".

Results

Responses to the categorization and typicality questions (transformed as before) were analysed using ANOVA with Task (Typicality, Categorisation), Appearance (+,−) and Genetics (+,−) as within-subject factors.

There was no effect of Task ($p = 0.96$), but main effects of Appearance [$F(1,32) = 325.18$, $p < 0.001$; $\eta^2 = 0.91$] and Genetics [$F(1,32) = 35.30$, $p < 0.001$; $\eta^2 = 0.53$], interactions between Task and Genetics [$F1,32) = 6.82$, $p < 0.05$; $\eta^2 = 0.18$] and between Appearance and Genetics [$F(1,32) = 4.23$, $p < 0.05$; $\eta^2 = 0.12$]. However, there was no three-way interaction between Task, Appearance and Genetics ($p = 0.20$). The interaction between Appearance and Genetics is shown in Figure 4.

Although no three-way interaction was found, pair-wise comparisons were performed to examine the possibility that there might be differences between the Tasks for the two borderline items (since these were the source of the three-way interaction in experiment 1). Unlike experiment 1, there was no effect of Task for the A−G+ borderline, though there was a marginal effect for the A+G− borderline (Categorisation = 2.64, typicality = 3.17, $t(32) = 2.03$, $p = 0.05$).

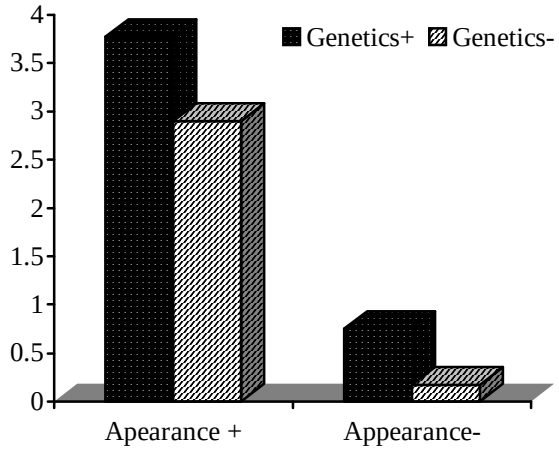

Figure 4. Overall ratings by Appearance and Genetics under a 'Sculptor' perspective.

As before, the response patterns of individual participants were examined to see how many gave dissociated judgments. Of the 33 participants, 23 (70%) gave no dissociated pair of judgments to the four pairs of borderlines with which they were presented; no participants gave dissociated judgments to all four pairs of borderlines.

Discussion of Experiment 2

Unlike experiment 1, these results provide no evidence of a dissociation between categorisation and similarity judgments. That is, the dissociation appears to have been eliminated by ensuring participants give their judgments from a specific perspective or context. The pairwise comparisons support this interpretation. Critically, the typicality and categorization scores do not violate the assumptions of similarity-based models: both A+G− and A−G+ cases differ in categorisation (2.64 and 0.94 respectively, $t(32) = 4.29$, $p < 0.001$) but also in typicality (3.17 and 0.56 respectively, $t(32) = 10.12$, $p < 0.001$). Hence the borderlines here do not provide evidence of dissociation – the increase in categorization is matched by an increase in typicality.

Experiment 3 seeks to establish whether the salience of genetic properties can be enhanced sufficiently to eliminate the dissociation in experiment 1.

Experiment 3

This experiment sought to establish whether similarity and categorization judgments dissociate for the two kinds of borderline, A+G− and A−G+, when participants are asked to make adopt a perspective that emphasizes genetic or biological properties.

Design

Task (Typicality, Categorisation), Appearance (A+,A−) and Genetics (G+,G−) were within-participants factors.

Participants 35 undergraduate psychology students attending an Open University residential school volunteered to participate.

Materials The same categories in experiment 1 were used. Scenarios were as in experiment 1, but were prefaced by the clause "Imagine that you are a Biologist…". It was assumed, based on previous work, that participants would take this profession to signal the enhanced relevance of biological properties.

Procedure An identical procedure to experiment 1 was followed. However, categorization and typicality questions were prefaced by the clause "Imagining yourself to be a biologist…".

Results

Responses to the categorization and typicality questions (transformed as before) were analysed using ANOVA with Task (Typicality, Categorisation), Appearance (+,−) and Genetics (+,−) as within-subject factors.

The pattern of results from the ANOVA exactly replicates that of experiment 2. There was no effect of Task ($p = 0.53$), but main effects of Appearance [$F(1,33) = 84.28$, $p < 0.001$; $\eta^2 = 0.72$] and Genetics [$F(1,33) = 125.02$, $p < 0.001$; $\eta^2 = 0.79$], an interaction between Task and Genetics [$F(1,33) = 13.93$, $p < 0.01$; $\eta^2 = 0.30$] and between Appearance and Genetics [$F(1,33) = 7.86$, $p < 0.01$; $\eta^2 = 0.19$]. As in experiment 2, there was no three-way interaction between Task, Appearance and Genetics. The interaction between Appearance and Genetics is shown in Figure 5.

As in experiment 2, although no three-way interaction was found, pair-wise comparisons were performed to examine the possibility that there might be differences between the Tasks for the two borderline items. As before, there was no effect of Task for the A−G+ borderline, but an effect of Task for the A+G− borderline (Categorisation = 1.03, typicality = 1.72, $t(34) = 2.51$, $p < 0.05$).

19 participants (54%) gave no dissociated pair of judgments to the four pairs of borderlines with which they were presented; only 1 (3%) participant gave dissociated judgments to all four pairs of borderlines.

Discussion of Experiment 3

As in experiment 2, this experiment suggests that the dissociation between categorization and similarity judgments reported in experiment 1 can be eliminated when judgments are given under a specific perspective.

While the pairwise comparisons support this interpretation, other comparisons suggest that the perspective has not exerted such a strong influence in this experiment as in experiment 2. Overall, the typicality scores do not differ significantly for the two borderlines cases, A+G− and A−G+ (1.72 and 1.71 respectively, $p = 0.96$); however, the two borderlines do differ in their categorization scores: 1.03 and 2.09 respectively, $t(34) = 2.55$, $p < 0.05$). Hence the borderlines in this experiment provide evidence contrary to similarity-based models, i.e., an increase in categorization is not matched by an increase in similarity. Nevertheless, relative to experiment 1, the perspective has served to eliminate the differences in typicality between the borderlines, even though differences in categorization remain.

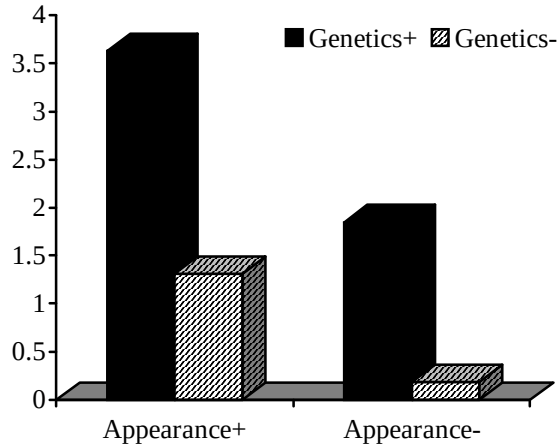

Figure 5. Overall ratings by Appearance and Genetics under a 'Biologist' perspective.

General Discussion

This paper provides evidence to support two main claims. The first is that similarity and categorization judgments dissociate for natural categories. The second is that such dissociations are perspective-dependent.

The data in experiment 1 reflect a double dissociation between similarity and categorization judgments, and serve to undermine similarity-based models of categorization. Though previous research has also uncovered dissociations, these have been single dissociations, and there have been difficulties in replicating those findings. Indeed, suggestions have been made that such dissociations arise only when categorization is highly reflective, only when designs are within-participant, and only for certain participants.

The data reported here contradict the first of these claims. That is, the categorization judgments obtained in these experiments have not been sought under a reflective mode – indeed response times show that participants take considerably less time to make these judgments than they do the corresponding typicality judgments. So, there is little evidence for these categorization judgments being particularly reflective.

These data confirm previous findings that dissociations arise because of a minority of participants.

The data do not speak to the claim that dissociations only arise in within-participant designs, although Thibaut et al.'s evidence contradicts such a claim. However, Thibaut et al.'s study arguably shows only that people can learn artificial categories for which similarity and categorization dissociations arise, not that these arise also for natural categories. This study appears to provide strong evidence that even for everyday, natural kind categories such dissociations arise. Moreover, the work presented here does not rely on identifying features that could be considered necessary or characteristic, a problem Thibaut et al. identify in previous work – indeed, the stimuli used here are defined without reference to particular features.

The second main claim is that by fixing perspective, dissociations between similarity and categorization judgments are reduced or eliminated. In experiment 2, making judgments from a 'sculptor' perspective eliminated the dissociation, whereas it was reduced in experiment 3.

How might these findings of perspective-dependence be explained? One possibility is that similarity-based models should be seen as models of categorization-in-context. Categorization and typicality judgments are often elicited out of context. Without the constraint of context, participants may call on different kinds of information to make the two kinds of judgment. In other words, models of categorization should first seek to model categorization-in-context and then attempt to explicate context-free categorization judgments. One possibility for such a perspectival account of concepts allows that categorization is similarity-based, but that the current perspective fixes the relevant dimensions to be used in the similarity computation (Braisby, 1998).

Another possible explanation is that in experiments 2 and 3, dissociations do not appear because the instructions used for categorization and similarity do not elicit those judgments. For example, it could be that both sets of instructions actually elicit a categorization judgment, and participants respond in the typicality task as best they can given that their judgment reflects a categorization, rather than an overt judgment of typicality. However, such an explanation is fraught with problems – for example, if conventional instructions do not determine the kind of judgment people make, then there is no obvious basis for deciding whether any previous research has really elicited categorization or typicality judgments.

In conclusion, the data reported here suggest that a simple similarity-based view of categorization is not right. However, when context is fixed, then the similarity-based models may fare much better. What is needed to augment such models is a mechanism by which the current perspective or context fixes the relevant dimensions on which categorizations and similarity judgments are made.

A New Theory of the Representational Base of Consciousness

Andrew Brook {abrook@ccs.carleton.ca}
Paul Raymont {praymont@ccs.carleton.ca}
Cognitive Science
Carleton University
Ottawa, ON Canada

Abstract

Though we take mainly a philosophical approach, we hope that the results of our work will be useful to researchers on consciousness who take other approaches. Everyone agrees, no matter what their point of view on consciousness, that consciousness has a representational base. However, there have been relatively few well-worked-out attempts to say what this base might be like. The two best developed are perhaps the higher-order thought (HOT) and the transparency approaches. Both are lacking. Starting from the notion of a self-presenting representation, we develop an alternative view. In our view, a representation, a completely normal representation, is the representational base for not just for consciousness of its object (if it has one), but also itself and oneself as its subject. The unified picture of consciousness that results should assist research on consciousness.

Introduction

Though we take mainly a philosophical approach, we hope that the results of our work will be useful to researchers on consciousness using other approaches. Current views on consciousness can be divided by whether the theorist accepts or rejects cognitivism about consciousness. Cognitivism is the view that consciousness is just a form of representation or a property of information-processing systems that have representations (e.g., focussed attention). Anti-cognitivists deny this, claiming that inverted spectrum and zombie thought experiments show that consciousness could change while everything cognitive or representational stays the same. Whatever, researchers on both sides of this fence agrees that consciousness has a *representational base.* Whether or not consciousness *simply is* representational or cognitive, it at least *requires* representation and cognition.

However, there have been few well-worked out attempts to say what this representational base might be like. The two best developed are perhaps the higher-order thought (HOT) approach, in which the representational base of consciousness is a thought directed at one's own psychological state(s), and the transparency theory, in which one's conscious states are said to be, not objects of representation, but things that one knows about by inference from consciousness of the world around one, one's body, and so on.

As we will see, both approaches are lacking. We then introduce a notion of a self-presenting representation and attempt to build a better alternative around this notion. On our view, representations are self-presenting but more than that. A single representation is the basis not just of consciousness of the world and itself but also of oneself as its subject. This notion leads to a unified picture of consciousness.

The standard picture of representation

Many consciousness researchers accept the following as a principle of representation:

> RP: Representations represent something other than themselves and only something other than themselves.

If RP is right, our view is wrong and something like a HOT model or transparency model has to be right.

There are a host of problems facing HOT models (see Raymont, forthcoming). Perhaps the most serious arises from its separation of the representing state that confers consciousness from the state on which consciousness is conferred. The problem is that a representation can exist in the absence of its object. If so, a HOT that represents pain should be able to make things seem subjectively just as they would if one really were in pain – with no real pain. Rosenthal (1997, p. 744) at least bites this bullet but it is a pretty tough chew. Moreover, since in this case what is represented is not real, it is the representing state that has to be the conscious state. If so, there is nothing higher-order about consciousness. Indeed, the resulting conscious state would look remarkably like our self-presenting state.

So what about the transparency alternative? The basic idea behind transparency theory is that one is directly conscious only of what a representation represents and not the representation itself. We are conscious *via* representations, not *of* representations. Representations are transparent to us.

If so, consciousness of representing is an inference from the fact that we are conscious of what is represented. As Dretske puts it,

> You cannot represent something as F without, necessarily, occupying a state that carries the information that it is F (not G or H) that you are representing something as. [1995, p. 56]

All we know about our representing is what we can infer from how represented items appear. Dretske (p. 40) calls the resulting consciousness of our representing states *displaced perception*. The perception of an object is displaced by an inference onto the perception itself.

The transparency thesis faces some problems. First problem: when one is conscious of something by means of a given representation, one is thereby conscious of that repre-

sentation's content, i.e., of how that thing is represented by one's representation (visually, aurally, and so on). It is a *very* small step from this to consciousness *of* the representation. To take this step, various things may be needed but an inference from *what* one is representing does not seem to be one of them. One is conscious of not only *what* is represented but also *how* it's represented. The latter is an aspect of the representation itself.

Second problem: when one is conscious of *how* one is representing given contents (seeing them, imagining them, doubting them, remembering them), even Dretske allows that this knowledge does not come by way of an inference from representing something (1995, p. 57-8), though he does not say where it does come from. If transparency is not the case here, why anywhere?

Third problem: itches, pains and other bodily sensations. On the transparency view, feeling a pain, hurting, has to be nothing more than an inference from what the pain represents – some bodily damage or whatever. This is extremely implausible. (Dretske recognizes that he has a problem about pains, etc.: "this is a topic that I have neither the time nor (I admit) the resources to effectively pursue" [1995, p. 103].) All who accept RP face this problem.

Indeed, about the only phenomenon for which a transparency claim seems at all plausible is perception, especially vision, though even here transparency might have trouble with the difference between, say, seeing a corner and feeling it, in general with situations in which there is one content, two or more modes of representation. Put bluntly, the transparency thesis seems simply to be false, at least for most of consciousness.

As we said, if RP is right, something like a HOT model or transparency model are the only alternatives. If accepting RP leads to such problems, what happens if we deny it? It is not obviously true. Think again of pains and itches and other bodily sensations, not to mention feelings of tension and tiredness, mood states such as aimless anxiety or euphoria, and so on. What (other than themselves) are states like these about? Then there are altered states of consciousness. When consciousness is altered, what it is like to have those states certainly changes but there is no obvious candidate, other than the conscious states themselves, for what they are about.

There are two ways to reject RP. One would be to say that pains, etc., are not representations at all. This move is hopeless. In having pains (and mood states, altered states of consciousness, and so on), one is clearly aware *of something*, something about which a pain, for example, carries information. These are marks of representing. But what one becomes aware *of* in having a pain, what this state carries information *about*, is *itself*. Pains are representational by being *self*-representational; the qualities of which one becomes conscious by having these states are mainly qualities of the states themselves. So the other way of rejecting RP is to say that some representations at least are self-presenting.

Not only do we think that RP is false but our version of the opposing idea that representations can be self-presenting is fairly radical. Here is how our story goes.

Self-presenting Representations: The Representational Base of Consciousness

On our view, having a representation is all the representation that one needs to become conscious not only of what the representation is about and the representation itself, the standard view of self-presenting representations, but something more.[1] Consider the following sentence as uttered by MM:

1. I am reading the words on the screen in front of me.

Having the representation expressed by (1) can make MM conscious of the words on the screen, obviously. It can also make her conscious of the representation itself, that the words are being seen (not heard, imagined, touched, and so on). In addition, having this representation can make MM conscious of who is seeing the words, namely, herself. An ordinary single representation is all the representation that one needs to become conscious of that representation and also oneself as the subject of it. Let us call such a representation the *representational base* of becoming conscious of these items.

> **Representational base –** an act of representing that is all the representation that one needs to be conscious of it and of oneself as its subject

Almost any representation will do.

Imagining something unreal such as Pegasus will do just as well as perceiving an external object such as a computer screen. Indeed, even a representational state that had no object, and therefore could not make us conscious of anything other than itself, could still be the basis of becoming conscious of that state and of oneself. Moreover, a representation need not itself actually be recognized in order to provide a representational base for self-consciousness. Just recognizing what is represented in it would be an adequate representational base for one to be conscious of oneself (as conscious of that object).

Note carefully the term representational *base.* We are not saying that to have a representation is *to be* conscious of it. That would be a crazy view to hold. What we are saying is that having a representation provides everything *representational* needed to become conscious of having it and of oneself. Other things may be needed, too, shift of attention for example, or the conceptual resources to go from consciousness of something to consciousness of representing it.

Lest it be thought that the idea of a self-presenting representations is exotic, note that something as lowly as a bar code can be run quite a long way as an analogy. A bar code contains information about what it is 'about', usually the item's nature and price. But it also contains information about itself – a few of the bars are an integrity check on the

[1.] Among others, James held the standard view, as more recently have Kriegel (2003) and Tye (2003).

bar code itself. And it contains information about the thing that has it – it is physically mounted on the thing that has it. How far the analogy can be run does not matter here. What matters is that even a representation as simple as a bar code can be self-presenting.

Another homely example, a gauge, shows how our story goes.[2] A gauge presents information about something other than itself, namely, whatever it has the function of indicating information about. For example, an altimeter presents information about the distance to the earth's surface. However, an altimeter also presents information about itself, how far it is from earth, for example. And it is the gauge that presents this information about the gauge, not some higher-order gauge pointed at it! This is how we see conscious states. To be conscious of having a representation, all the representation that one needs is the state itself.

For the analogy of the gauge to be complete, the gauge would have to have one more function, It would have to represent the system that has it. Not a problem. Suppose that to provide information about altitude and itself, an altimeter has to port itself to a system. And suppose that to do so correctly, it has to recognize what sort of system it has been installed in. ('Ah, this is a Cessna Skylane.') Now we have at least a rough analogue of a representation presenting not just its object and itself but also its subject, the person who has it.

We don't have room to mount the full case for our notion of the representational base of consciousness but notice, if it is right, it would do some real work for us.

- It would entail that RP is false.
- It would entail that the idea behind transparency and displaced perception, the idea that we are not conscious of our own conscious states, is false and that the displaced perception move is unnecessary – the consciousness one has of one's own representations by having them is as direct and non-inferential as any consciousness of anything.

And,

- It would show that the HOT move is unnecessary. If a representation itself is all the representation we need to become conscious of that representation, there is no need for a higher-order representation of any kind.

Global Representation

Our notion of the representational base gives a single, unified account of the basis of three forms of consciousness – consciousness of the world, consciousness of one's own states, and consciousness of oneself. This nicely unified account is progress. Progress – but not the whole story.

So far we have talked exclusively about individual representations as understood by the tradition. As Kant already knew, however, the representations that serve as the representational base of consciousness are usually much 'bigger' than individual representations traditionally conceived. Indeed, in complex beings like us, we do not believe that there are any individual representations as traditionally conceived; but we will not go into that here.

The representations serving as the representational base of consciousness usually have multiple objects and encompass multiple representations (as traditionally conceived). Let us call such a representation a *global representation.* In a global representation, one is conscious of many objects and/or many representations as traditionally conceived, and one is conscious of them as a single complex object and/or a single complex representation.

> **Global representation** – representing many objects and/or many representations as traditionally conceived as a single complex object and/or a single representation.

Our points about the representational base can now be made using this notion. A global representation is all the representation that one needs to be conscious not just of its complex object, if it has one[3], but also of the representation itself, and of oneself as the 'the single common subject' of the elements of this representation (Kant, 1781/7, A350).

The structure of a global representation is complicated. Suppose that at the same time as one has the representation expressed by (1),

1. I am reading the words on the screen in front of me,

one also has representations expressed by,

2. I am puzzled by your comments
3. I am enjoying the music I hear outside
4. I believe our agreement was to meet at 6:00
5. Yesterday I thought I understood Kant's notion of the object
6. I wish the world were a fairer place

There are three elements of (1)-(6) that could be united in a single global representation.

- One could be conscious of the various represented objects here as a single complex object.
- One could be conscious of the various ways in which these objects are being represented as a single complex representation.

And,

- One could be conscious of oneself, the subject, as the single common subject of the whole business.

The next question is, How does a global representation serve as the representational base of consciousness of its complex object, itself, and its subject, the person who has it?

Joint Consciousness

Central to a global representation of objects is what we will

---

2. A gauge is one of Dretske's favourite examples.

3. Must global representations have objects (other than themselves)? Nice question; but not one for us here.

call *joint consciousness:*

> **Joint consciousness –** to be conscious of any of the objects of a global representation is to be conscious of other such objects.

It seems obvious that joint consciousness is a distinctive feature of a global representation. The notion of joint consciousness just stated clearly applies to consciousness of the world (plus such things as one's own bodily states), more exactly, to consciousness of intentional objects. What about consciousness of one's global representation and of oneself as its subject?

When one is conscious of representing in a global representation, here too there will be joint consciousness – to be conscious of some representings is to be conscious of others. And conscious of self? Here the idea that is plausible is a bit different. When one is conscious of oneself as subject of one bit of representing, one will usually be conscious of oneself as the subject of other representings, as their 'single, common subject', to use Kant's words again.

The next question. How could a global representation serve as the representational base of *joint* consciousness of representings and of oneself as their *common* subject? It seems plausible to hold that only certain elements of a global representation are needed for one to have an adequate representational base for consciousness of a single representing and of oneself as its subject. One will be conscious of doing an act of seeing by doing that act of seeing, whatever the rest of one's current global representation is like. And one will conscious of oneself *seeing*, which makes it likely that the act of seeing is the basis of this consciousness of oneself. If so, what is the representational base of *joint* consciousness of objects, of being *jointly* conscious of various representings, of being conscious of oneself as the *common* subject of a number of acts of representing?

Here we can only sketch what would have to happen for these forms of joint consciousness to occur. In the same way as an act of representing is the representational base for consciousness of that act and of oneself, it will have to be the representational base for consciousness of doing *other* acts of representing and of oneself as their *common* subject.

Moreover, the relationship will be symmetrical. One is not 'located' at any given representing. When consciousness of a representing carries one to consciousness of other representings, one has all the representings concerned equally. So it would be better to say that representings in general are the base for consciousness of representings in general. It is not any given representing that is the base of consciousness of oneself as common subject but representings in general.

Thinking of representations in the traditional way, it is hard to make sense of what we just said. But that may be the fault of the traditional conception. There is another way to think about representation within which what we just said makes fine sense.

Structure of a Global Representation

Instead of trying to make sense of the base of joint consciousness of representing and of oneself as subject in terms of relations *among* representations, let us try out the idea that these forms of consciousness are something that obtains *within* a single complex representation.

Our test case will be a person seeing something, hearing something, and tasting something, all parts of a global representation and global object, where the person is jointly conscious of the objects, the representings, and herself as subject. To be the base for such consciousness, how are the three acts of representing brought together in a global representation? Here are three possibilities:

1. The three acts and their objects become the object of a fourth, higher-order representation.

2. The three acts and their objects become parts of a single subsuming representation.

3. While their contents are taken up in a global representation, the three acts of representing do not survive even as parts of this state, though their objects remain distinct. They become three (for the moment let us call them) *modalities* of a single representation.

How might (3) work?

Consider what happens if one goes from a situation, at time *t*, that has objects *o*1 and *o*2 to a situation that has *o*1 but not *o*2. We could try to capture the change in two ways. We could say that where once there were two representations, r(*o*1) and r(*o*2), which were bundled in a mental structure of some kind, [r(*o*1) & r(*o*2)], we now have only the one representation, r(*o*1); one representation has been dropped from the bundle that existed at *t*. Or we could say that there was just one representation, r(*o*1 & *o*2), at *t* and it has been replaced by another single representation, r(*o*1).

The second view is simpler, since it does not involve postulating representations as parts of an encompassing representation. According to it, at *t* there was one representation that had a complex content. The content was complex because it had multiple contents, *o*1 and *o*2, as its parts. If it were a conscious representation, what would make it one representation is that to be conscious of any of its objects by means of it is to be conscious of other of its objects, too. Here, the part-whole relation obtains among objects, but there is no parallel multiplicity of representational states. On this approach, unlike the first, the representing state does not have 'smaller' or less complex representing states as parts.[4]

On this picture, globality obtains *within* a representation but not *among* representations. It does obtain among objects. Returning to the joint consciousness condition, where to be conscious of one thing is to be conscious of others, on our picture joint consciousness of objects can be present or absent but it is trivially present in a global representation,

---

[4.] If the representing state is a brain state, then it will have parts, but these parts will not be representing states.

simply because a global representation is a single representing state, r(o1 & o2). For conscious representing states of of this form, to be conscious of o1 by means of this state is also, by that very same act, to be conscious of o2. One representational state-token provides consciousness of both o1 and o2.

Consider an act of reference as an analogy. Suppose I refer to Toronto. Scarborough is part of that city; it is a part of the thing to which I referred. It does not follow that my act of referring to Toronto contains a numerically distinct reference to Scarborough. It was of course *possible* for me to refer simply to Scarborough, and thus to refer to part of the thing to which I actually referred, but it does not follow that I actually did so. The mere fact that Scarborough is part of the thing to which I referred does not entail that a reference to that borough figures as part of my act of referring. Similarly, the mere fact that o1 is part of (o1 & o2) does not entail that a distinct representation of o1 must figure as part of my act of representing (o1 & o2).

It may be objected that in advancing these observations and contrary to our intentions, we actually *provide the resources* for showing that a subject's global representation will contain parts that are themselves representations. Didn't we ourselves just say that representations are individuated by their objects? This suggests that for each object that we can individuate, including objects that are parts of a global object, there will be a corresponding representation individuated by that object.

This objection does not work. If we have relied on a claim that each representation is individuated by an object, we have not said how objects individuate a representation. What if only some objects individuate a representation? Let us introduce the idea of a *global object.*

> **Global object –** a group of represented objects that is the single complex object of a global representation

If we now say that only a global object individuates at least a conscious representation, we are clear of the objection.

To capture these claims about singularity of representation, let us generalize (3),

> 3. While their contents are taken up in a global representation, the three acts of representing [viz., seeing something, hearing something, and tasting something] do not survive even as parts of this state, though their objects remain distinct. They become three modalities of a single representation.

into (3′),

> 3′. A global representation at a given moment is a single representation not made up of multiple distinct representations and it has a complex object.[5]

Now that we have said what we mean by (3) and (3′), what about (1) and (2)? Though most philosophers hold to (1) or (2), they do so uncritically and seldom offer any support for the views. We do not know of any good argument for either one of them. To see where those adopting (1) or (2) might go wrong, recall the representation, r(o1 & o2).

Suppose that this representation occurs at t. Supporters of (1) and/or (2) may confuse the *untokened* (at t) representational type that would take part of r(o1 & o2)'s object (*viz.* o1) as its object, with a representational token, r(o1), held to be *part* of r(o1 & o2) and to have one of the latter state's objects as its sole object. There is no reason to suppose that there actually is such a distinct representational state nestled within r(o1 & o2). There could have been such a token at t, but the mere fact that we can entertain such a possibility – that is, the mere fact that we can think of an instantiation at t of that type – is no reason to conclude that there actually exists a token of that type at t.

Conclusion: (3′), the idea that at a given moment a global representation is not a group of representations but a single representation with a complex object, is a perfectly coherent point of view, one well supported by examples and analogies. Before we leave it, however, there are some objections that we need to answer. One of them is so obvious that it has probably occurred to most readers already.

Single Representation View: Objections

The obvious objection is this. In a global representation, we are conscious, within a single unified representation, of several sensory modalities. The phenomenal field is polymodal: it involves tactual data, visual data, auditory data, and so on.

(1) or (2) would try to account for the contributions of the different modalities to consciousness by saying that there are several distinct representations here – visual representations, auditory representations, and so on – that come together as parts of an encompassing global representation. On this view, the cognitive system constructs a variety of representations in different modalities. These representations are not simply superseded by a global state that combines their informational contributions in one representation. Instead, they are preserved as distinct representations within it. The polymodal complexity of the resulting global state is due to the presence in it of this range of representations.

Against this, we offer the following picture: we do not have several visual, aural, etc. representations, not conscious ones anyway. Rather, the information we represent is *formatted* visually, aurally, etc. The cognitive system receives some information in a visual format (reflecting, perhaps, the wave length of incoming energy) or tagged as visual, some formatted or tagged as aural, and so on. When this information appears in a global representation, its modality appears with it. But there is just one representation, the global representation. In this one state, diverse bits of information are formatted in a variety of modalities.

This view has the twin virtues of adequacy and parsimony. The onus rests with proponents of the more complicated view, in which a global representation is held to be an assemblage of other representations, to show that our account has failed to account for something. It is difficult to

[5] James (1890, vol. 1, pp. 145-61) held something like this view.

see what that could be.

Suppose that one is consciously representing things both visually and aurally. What accounts for something there being aural? This question must be answered either in terms of *how* the representation represents or in terms of *what* it represents. There are no other ways to specify the modality of a representation. But a global representation can incorporate either of these ways. There can be a diversity in what it represents; it can represent many things having many properties. And it can represent these contents in a variety of ways, visually, aurally, and so on.

In support of this contention, note that we are *compelled* to postulate a plurality of representations only when there is a particularly strong sort of incompatibility in how or what a cognitive system represents, that is, only when the system represents in ways that exclude one another. For example, theorists tend to attribute distinct representations (not all of which are held to be conscious) to a system in such cases as binocular rivalry, or to explain the fact that consciously seeing the Necker Cube in one way precludes consciously seeing it in the alternative way.

These cases and all others that we've been able to think of are not problems for us. To be a counter-example to our single representation/complex object picture, the elements would have to be: all conscious, and all available simultaneously to one conscious subject. The cases we've just considered do not meet these conditions.

In the Necker cube case, the conflicting representations are successive. In binocular rivalry, the representations may be simultaneous but one is not simultaneously conscious of them (Baars 1988, pp. 82-3; see p. 126). So even when we are driven to multiply representations in a subject at a time, the results are not a problem for our view.

Notice that cases such as binocular rivalry and the Necker cube arise *within* a modality. It is not clear that there are any strong incompatibilities across modalities. Certainly there aren't many. In the absence of strong incompatibilities, nothing compels us to posit *more than one* representation to make a place for different perceptual modalities.

Second objection. Think of a picture of a car in front of a house. It is plausible to say that this picture includes a picture of the car and a picture of the house, that the bigger picture of the car and house together contains little pictures of the car and of the house.

Is it so clear, though, that the picture of house and car together literally contains several distinct *pictures*, one for each item depicted? The belief that it does threatens to introduce an implausible multiplication of pictures. If one can discern ten thousand blades of grass in front of the house, then there would have to be ten thousand pictures in the larger picture. Clearly, at some level of decomposition, we stop positing a distinct picture for each part of the content that we are able to distinguish. Why not stop at the whole picture and say that it is the only picture, with no smaller pictures in it?

Third objection: If conscious representation consists of one big, non-compositional representation, how are acts of judging particular bits of content, forming beliefs about things based on particular bits of content, possible? Response: In the same way as information in the complex global object of a global representation can come 'marked' with various modalities (aural, visual, etc.), particular bits of the information in a complex global object can enter into particular information-processing activities: judging, remembering, and so on. These *activities* do not need to merge into a single representation and they can pick and choose information to work on *ad libitum*.

Even after responding to these objections, the support we have offered for (3´) is not decisive. It is strong, however, certainly strong enough to justify acceptance of the view.

Our theory that a single global representation is the representational base of consciousness has real potential. As we have seen, it provides a unified account of three major kinds of consciousness, consciousness of world, one's own representations, and oneself as subject. Though we can't show this here, it also opens the way to a nice account of: the unity of consciousness; the special features of consciousness of self; and the subject of consciousness (Brook and Raymont, forthcoming).

Abstract

When decision makers perceive all issues related to a decision as being consistent with their choice, they achieve *coherence*. Participants rated their agreement with different views of various issues related to a couple's relationship. Those who later decided whether the couple would get engaged or break up subsequently reinterpreted the issues to be consistent with their decision. Increasing the importance of the decision, highlighting coherent perspectives, or giving participants a prior preference did not strengthen the coherence shift, but coherence shifts did not occur without the chance to decide, suggesting that they occur in an all or nothing fashion. Individuals with higher need for cognition (Cacioppo & Petty, 1982) achieved a greater degree of coherence among facts associated with the relationship but not among more general beliefs about relationships.

Introduction

Early social psychologists attempted to develop a general model of cognitive functioning based on consistency maintenance (Festinger, 1957; Heider, 1946; Osgood & Tannenbaum, 1955; Newcomb, 1953). Those theories shared the assumption that cognition involves the interaction among elements, and that those elements tend to settle into stable states characterized by some type of *good form*, in which similar elements are interconnected and segregated from dissimilar elements. However, early consistency theories narrowly focused on small sets of two (Festinger, 1957) or three (Heider, 1946) elements at a time, and so were unable to represent the larger, more complex situations that people often encounter in their daily lives.

More recently, computer based models of multiple constraint satisfaction systems have begun to provide a mechanism for simulating maintenance of consistency throughout large, complex systems (Holyoak & Simon, 1999; Read, Vanman, & Miller, 1997; Simon, Snow, & Read, in press). In these models, units represent cognitive elements and links between units represent relations between elements, with excitatory links representing consistent relations and inhibitory links representing inconsistent relations. Dynamic processing is simulated by allowing units connected by excitatory links to increase each other's activation and units connected by inhibitory links to decrease each other's activation until the system settles in to a stable state of *coherence*, a kind of good form in which a subset of mutually consistent elements are highly activated.

Drawing on constraint satisfaction systems, researchers have begun to show that cognition involves imposing consistency on related concepts. Simon and colleagues (Holyoak & Simon, 1999; Simon, Pham, Le, & Holyoak, 2001; Simon, Snow, & Read, in press) developed a paradigm showing how, when people think about the issues related to a legal case and then render a verdict, their perceptions of the issues shift to become consistent with their eventual verdict, thereby achieving a coherent understanding of the whole case.

The finding that perceptions of issues shift to become consistent with an emerging decision violates two important assumptions of algebraic models of information integration, such as Bayes theorem and Anderson's (1962) Information Integration Theory. Those models assume that (1) the value of one element is not affected by the values of other elements and that (2) the value of an element is not changed when it is integrated with other elements to arrive at a conclusion. Nevertheless, Simon and colleagues found that during decision making, evaluations of issues related to a legal case shift to become consistent with the emerging decision and with each other.

The present research adapts Simon and colleagues' paradigm to test for coherence outside the legal context. In the first phase (pretest) participants read vignettes describing different couples and ambiguous events in their relationships, and then rated their agreement with statements giving different interpretations of the events. Some of the statements were *factual* items that involved interpreting the meaning of an event and others were *belief* items that involved interpreting the general implications of an event. For example, one vignette described how Eric and Daniella spent a day with Daniella's aunt Rachel, enabling her to observe the couple's interactions and subsequently report that she thought their relationship was going well. A factual item related to that vignette asks participants to rate the extent to which they think Aunt Rachel's optimistic impression was correct and a belief item asks them to rate the extent to which they think that, in general, it is possible to get a good sense of a couple's relationship by observing them for a day.

In the second phase participants read a longer story about a couple, Jenny and Mark, that combined all of the issues

raised separately in the pretest. For example, one part of the story involved Jenny and Mark spending a day with Jenny's aunt Rose, so that the aunt formed an impression that the relationship was going well. In the third phase (posttest) participants decided whether Jenny and Mark would get engaged or break up and then rated their agreement with the different interpretations of the issues, now that they were all embedded in the context of a single story. For example, on the posttest a factual item asked participants to rate the extent to which they thought Aunt Rose's optimistic impression of Jenny and Mark's relationship was correct and a belief item asked them to rate the extent to which they think it is possible to get a good sense of a couple's relationship by observing them for a day.

We predicted a *coherence shift*, so that from pretest to posttest interpretations of ambiguous issues would shift to become consistent with the decision. Thus, we expected participants who decided that Jenny and Mark would get engaged to be increasingly likely to interpret issues in a manner suggesting that they would stay together, and we expected participants who decided that they would break up to be increasingly likely to interpret issues in a manner suggesting that they would not stay together.

Simon, Snow, & Read (in press) tested several variations on their paradigm in a legal context, but could not affect the strength of the coherence shift, so in the present research we introduced four manipulations designed to moderate the strength of the coherence shift. First, we tried to increase the strength of the coherence shift by increasing the perceived importance of the decision. In a *decision* (control) condition, participants simply read about Jenny and Mark's relationship and indicated whether they thought the couple would get engaged or break up. To increase the perceived importance of the decision, we asked participants in a *gift* condition to decide not simply whether they thought the couple would get engaged or break up, but whether they would spend a substantial amount of money to buy an engagement present. We predicted that the added importance associated with the decision would induce participants to think about the choice more extensively, leading to stronger coherence shifts than in the control condition.

The second way we tried to increase the strength of the coherence shift was by outlining the two coherent perspectives on the story. As in the control condition, participants were asked to decide whether they thought the couple would get engaged or break up, but in an *outline* condition they were also asked to imagine that they had talked to two friends who gave their perspectives on the couple's relationship. The friends' perspectives were presented in two lists, with one interpreting each of the ambiguous issues as suggesting that the couple would get engaged and the other interpreting each issue as suggesting that they would break up. We predicted that outlining the two coherent perspectives would help participants reach their own coherent perspective more quickly and proceed to achieve more extensive coherence shifts than participants in the control condition.

The third way we tried to increase the coherence shift was by giving participants a prior preference for one of the alternatives. Russo, Medvec, and Meloy (1996) gave participants an extraneous reason to prefer one of a pair of alternatives (called an "endowment") and then presented information on the alternatives one attribute at a time, asking participants to rate the extent to which it favored one alternative or the other, until they were ready to choose one. Russo, Medvec, and Meloy found that participants "distorted" the attribute information so that it favored the endowed alternative, thereby further increasing their preference for it until they chose it. We thought that if decision makers distort information to favor a prior preference within the pre-decision phase, their attitudes might also start shifting to become consistent with a prior preference within the pre-decision phase, producing a stronger coherence shift by the time they reach the post-decision phase. Therefore, we introduced two new conditions in which participants were given a prior preference for one alternative. As in the control condition, participants were asked to decide whether they thought the couple would get engaged or break up, but in an *endowment-engage* condition they were also asked to imagine that they knew Jenny and Mark and thought they *should* stay together, while in an *endowment-breakup* condition they were asked to assume that they thought Jenny and Mark *should* break up. We predicted that, compared to participants in the control condition, participants in the endowment-engage condition would be more likely to decide that the couple would in fact get engaged, participants in the endowment-breakup condition would be more likely to decide that the couple would break up, and that participants in both endowment conditions would report stronger coherence shifts.

A fourth manipulation was designed to decrease the strength of the coherence shift. We thought that, just as the degree of importance of a decision may affect the amount of processing, the degree of involvement in a decision task may also affect the amount of processing and the strength of the coherence shift. Therefore, we predicted that decreasing participants' involvement in the decision task would decrease the strength of the coherence shift. In a pair of *assigned decision* conditions participants were asked to think about whether to buy an engagement present (as in the gift condition), but they were not allowed to make their own choices; instead, participants in an *assigned-buy* condition were asked to assume that they had decided to buy the necklace and participants in an *assigned-not-buy* condition were asked to assume that they had decided not to buy the necklace. We predicted that depriving participants of the ability to reach their own decisions would decrease their involvement and amount of processing, leading to weaker coherence shifts in the assigned decision conditions than in the gift condition.

We also tested whether two personality dimensions moderate the strength of the coherence shift. First, need for cognition (NFC; Cacioppo & Petty, 1982) involves individual differences in the "tendency to engage in and

enjoy thinking" (p. 116). We thought that participants with greater NFC would think about the experimental materials more extensively, leading them to report stronger coherence shifts than participants with lower NFC. Second, personal need for structure (PNS; Neuberg & Newsom. 1993) may involve individual differences in desire for simple structure. We thought that participants with greater NFS would be more likely to impose a coherent good form on the information given to them, thereby achieving greater coherence than participants with lower NFS.

Methods

Participants and Design

This experiment ran on the Internet. Participants were recruited by e-mailing notices to people who asked to be notified of new experiments and giving each participant an entry in a lottery for a cash prize. Participants were randomly assigned to the decision (n = 134 usable data sets), gift (108), outline (118), assigned-buy (105), assigned-not-buy (132), endowment-engaged (110), and endowment-breakup (98) conditions.

Materials and Procedure

The pre-test had 12 vignettes, including seven that involved romantic relationships and five that involved legal cases (distracters). The seven relationship vignettes concerned (1) a woman (Michelle) who had broken off several previous relationships and may appear to have "a problem with commitment," (2) a woman (Joanne) who declined to talk to her boyfriend about the future of their relationship, (3) a woman (Aunt Rachel) who spent a day with her niece and her niece's boyfriend and thought that their relationship was going well, (4) a woman (Lisa) who was two hours late for a date with her current boyfriend because she was consoling a previous boyfriend who was upset about his mother's illness, (5) a woman (Suzy) who was too busy at work to join her boyfriend and his parents for dinner, (6) a woman (Candice) who joined a gym after her boyfriend disparaged people who don't exercise, and (7) a woman (Rona) who brought her boyfriend to a family party.

After each vignette, there were 1 to 4 statements interpreting the facts in the vignette or expressing related beliefs. Some of the statements expressed attitudes consistent with the view that the couple in the vignette would stay together (e.g. *Aunt Rachel's favorable view of the relationship was correct*) and other statements expressed attitudes consistent with the view that they would break up (e.g. *Aunt Rachel's favorable view of the relationship was influenced by the fact that on that day Daniella displayed particular affection towards Eric*). Participants rated the extent to which they agreed with each statement on an 11-point scale ranging from -5 (strongly disagree) to 0 (neutral) to 5 (strongly agree).

The next page presented a set of analogy word games (distracter task) and the following page introduced the experimental manipulations. In the decision condition, participants were asked to imagine that "Mark and Jenny live in your town and are pretty close friends of yours. They have been involved in a relationship for over a year…." Participants were also informed that "after reading some information about the relationship, you will be asked to decide whether you think Jenny and Mark will get engaged or break up, and then to make some evaluations about the relationship…." Participants then read the story of Jenny and Mark, which combined the seven issues that had been raised in separate vignettes in the pretest. For example, the story described one incident when Jenny was too busy at work to join Mark and his parents for dinner and another incident when she brought him to a family party. After reading the story participants indicated whether they thought Jenny and Mark would get engaged or break up (by clicking on one of two radio buttons) and rated their confidence that they had made the best possible decision (5-point scale). The posttest appeared next; participants were asked to give their "impressions of the issues in Jenny and Mark's relationship" and then there was a list of statements interpreting the facts in the story or expressing related beliefs. Some of the statements expressed attitudes consistent with the view that Jenny and Mark would stay together (e.g. *Aunt Rose's favorable view of the relationship was correct*) and other statements expressed attitudes consistent with the view that they would break up (e.g. *Aunt Rose's favorable view of the relationship was influenced by the fact that on that day Jenny displayed particular affection towards Mark*). Participants rated the extent to which they agreed with each statement on an 11-point scale. The order of items in the posttest was counterbalanced between participants. The posttest was followed by self-report measures of NFC (Cacioppo & Petty, 1982) and NFS (Neuberg & Newsom, 1993), and demographic questions.

The outline condition was the same as the decision condition, except that after reading the story participants were asked to imagine that, "you have talked to two other mutual friends and found that they have very different views on Jenny and Mark's relationship." The instructions continued, "Caitlin doesn't think Jenny and Mark will get engaged. When you talked to Caitlin, she explained why she thinks Jenny and Mark are headed for a breakup" and then there was a bullet-list of statements interpreting the seven issues in a manner suggesting that the couple would break up. The instructions then continued, "Unlike Caitlin, Brian thinks Jenny and Mark will get engaged. When you talked to Brian, he explained why he thinks they will get engaged," and then there was a list of statements interpreting the seven issues as suggesting that the couple would stay together. After reading the lists, participants made their decisions, confidence ratings, posttest ratings, and personality ratings.

The endowment conditions were the same as the decision condition, except that before reading the story participants were told that "we're going to ask you to get more 'involved' with the story, by imagining that you know the people and playing a small role yourself." Participants in the endowment-engage condition were told that "although they have had some problems (as most couples do), you think they are good for each other and you hope they work things

out," while participants in the endowment-breakup condition were told that "although they have been fairy happy together until now, you think that they may be growing apart and it wouldn't be a good idea for them to rush into a commitment." After reading the story participants in the endowment-engaged condition were reminded, "you don't know whether Jenny and Mark will get engaged or break up, but you think they are good for each other and you'd like to see their relationship work out" while participants in the endowment-breakup condition were reminded, "you don't know whether Jenny and Mark will get engaged or break up, but you think that they are growing apart and shouldn't rush into a commitment." Participants in both conditions then went on to make their decisions, confidence ratings, posttest ratings, and personality ratings.

In the gift condition, participants were told that Jenny loved *Zapotec* jewelry, which was available in Cancun, where the participant was vacationing, so the decision was framed in terms of whether to buy a $150 Zapotec necklace as an engagement present for Jenny; since "the necklace cannot be returned and you cannot think of anything else to do with it," the participant should only buy the necklace if an engagement seemed likely. After reading the story, participants were reminded of their dilemma – whether the probability of an engagement was high enough to justify buying an expensive necklace as an engagement present for Jenny – and then they indicated whether they would buy the necklace. After that, participants made their confidence ratings, posttest ratings, and personality ratings.

The assigned decision conditions were the same as the gift condition, except that before reading the story, participants were asked to "get more 'involved' with the story, by imagining that you know the people and playing a small role yourself" and were instructed, "while you're reading, think about your character's dilemma – whether to buy the necklace for Jenny. At the end of the story we'll tell you what your character decided." After reading the story, participants were reminded of their character's dilemma and those in the assigned-buy condition were asked to imagine that "you finally decided to go ahead and buy the necklace…. your sense was that they probably will get engaged, so it was worth it to buy Jenny an engagement gift you know she'll love" while those in the assigned-not-buy condition were asked to imagine that "you finally decided against buying the necklace… your sense was that they probably won't get engaged, so it wasn't worth it to spend so much money on a necklace you have no use for." Participants in both conditions then completed the posttest and personality measures.

Results and Discussion

Collapsing across all conditions (excluding the assigned decision conditions), participants were evenly split between deciding that Jenny and Mark would get engaged (49.5%) or that they would break up (49.8%), suggesting that the story was highly ambiguous. Average confidence ratings were fairly high among participants who decided that the couple would get engaged (3.52) and those who decided they would break up (3.77). High confidence in a decision about an ambiguous situation is consistent with constraint satisfaction models, in which activation spreads until the system reaches a stable state of coherence.

In the control condition participants were evenly split between the alternatives (50.7% chose the *engaged* alternative). In the outline condition there was a tendency to favor *engaged* (61.0%) but the change from the control condition was not significant. Participants in the gift condition were significantly less likely to choose *engaged* (36.1%) than participants in the control condition, X^2 (1, 239) = 4.90, p < .03, suggesting that people become more cautious when a decision has financial implications. Participants who were given an endowment favoring engagement were more likely to choose *engaged* (65.4%) than participants who were given an endowment favoring breakup (40.8%), X^2 (1, 207) = 4.72, p < .04, suggesting that the endowment manipulation was effective, though the probability of choosing *engaged* was not significantly different in the endowment conditions than in the control condition. Scores on the NFC, p = .55, and PNS, p = .98, were not significantly correlated with decisions.

We first tested for an overall coherence shift by running a 2(pretest, posttest, within Ss) by 2(engagement, breakup items, within Ss) by 2(engage, breakup decision, between Ss) ANOVA, collapsing across the experimental conditions. We found a significant three-way interaction, $F(1, 799) = 84.51$, $p < .001$, suggesting that after participants decided whether they thought Jenny and Mark would get engaged or break up, their attitudes shifted to be more consistent with their decision. As shown in Figure 1, among participants who decided that the couple would get engaged, agreement with statements suggesting that the couple would get engaged increased from pretest to posttest, $t(385) = 3.94$, $p < .001$, and agreement with statements suggesting they would break up decreased, $t(385) = 4.46$, $p < .001$. In contrast, among participants who decided that the couple would break up, agreement with engagement statements decreased, $t(414) = 6.47$, $p < .001$, and agreement with breakup statements increased, $t(414) = 5.86$, $p < .001$.

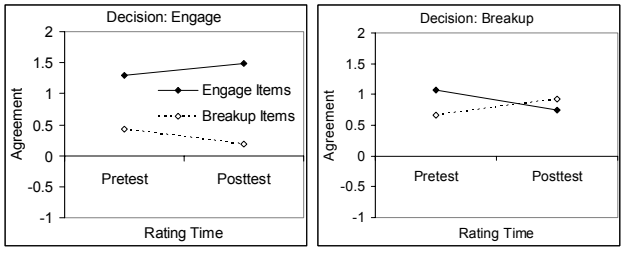

Figure 1: Agreement with Engage and Breakup items at Pretest and Posttest among participants who decided Engage (left) and participants who decided Breakup (right).

This pattern of results suggests that as participants thought about the story and made their decisions, their attitudes about the issues shifted to become more consistent

with their emerging decision and with each other. This would not have been predicted by algebraic information integration models (e.g. Anderson, 1962; Bayes' theorem), which assume that the value of an element is not affected by the values of other elements and does not change when it is integrated with other elements.

We then ran the analysis separately for items relating to facts and items relating to beliefs. For facts the three-way interaction was significant, $F(1, 799) = 73.75$, $p < .001$, and the pattern was similar to the overall analysis (Figure 2). Agreement with engagement items was initially higher than agreement with breakup items among participants who chose *engage*, $t(385) = 15.80$, $p < .001$, and among participants who chose *breakup*, $t(414) = 9.75$, $p < .001$, but among participants who chose *engage* agreement with the two types of items spread apart from pretest to posttest, while among participants who chose *breakup* agreement with the two types of items converged.

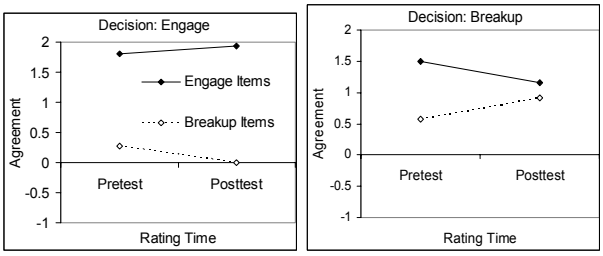

Figure 2: Agreement with Engage and Breakup fact items at Pretest and Posttest among participants who decided Engage (left) and participants who decided Breakup (right).

For beliefs the three-way interaction was significant, $F(1, 797) = 30.97$, $p < .001$, indicating the predicted coherence shift, but the pattern was somewhat different than for the facts (Figure 3). Agreement with engagement items was initially lower than agreement with breakup items among participants who chose engage, $t(385) = 6.60$, $p < .001$, and among participants who chose breakup, $t(414) = 6.72$, $p < .001$. Among participants who chose *engage* agreement with the two types of items converged, while among participants who chose *breakup* agreement with the two types of items spread apart.

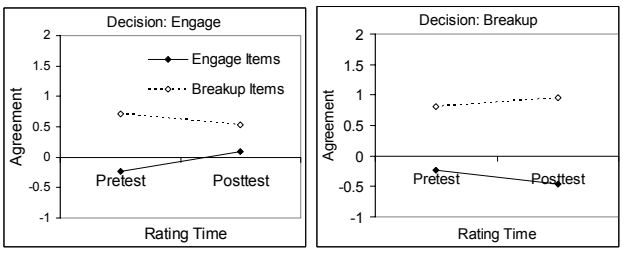

Figure 3: Agreement with Engage and Breakup belief items at Pretest and Posttest among participants who decided Engage (left) and participants who decided Breakup (right).

The unexpected difference in the patterns of results for facts and beliefs reveals that when people consider the facts of a specific couple's relationship they are initially optimistic about their future together, and those who go on to decide that the couple will get engaged become increasingly optimistic, but those who decide that the couple will break up become less optimistic. However, when it comes to abstract beliefs about relationships in general, people are initially pessimistic, and if they decide that a specific couple is likely to break up their beliefs become even more pessimistic, but if they decide that they are likely to get engaged their pessimism decreases. These data suggest that people are initially pessimistic about relationships in general but initially assume an optimistic outlook on specific cases. The data also suggest that regardless of initial attitude, when people reach a decision about a specific case their attitudes toward facts related to the case as well as their general beliefs about relationships shift in a coherent manner.

To test whether the experimental manipulations affected the strength of the coherence shift, we added a variable representing experimental condition, but did not find that it moderated the three-way interaction. We found three-way interactions of similar magnitude within the control, $F(1, 131) = 47.44$, $p < .001$, gift, $F(1, 104) = 23.98$, $p < .001$, and outline conditions, $F(1, 116) = 18.83$, $p < .001$, suggesting that increasing the material importance of a decision or outlining the coherent perspectives does not increase the strength of the coherence shift. The three-way interaction was significant in the endowment-engage, $F(1, 108) = 9.29$, $p > .01$, and endowment-breakup, $F(1, 95) = 14.45$, $p < .001$ conditions, suggesting that giving participants a prior preference within the pre-decision phase did not increase the strength of the coherence shift. The finding that introducing a prior preference within the pre-decision phase did not increase coherence shifts suggests that coherence seeking may generally operate within the pre-decision phase, even when there is no prior preference. Indeed, Simon and colleagues have found coherence shifts among participants who had not yet reached decisions (Holyoak & Simon, 1999; Simon et al., 2001; Simon, Snow, & Read, in press).

When we analyzed data from the two assigned decision conditions the three-way interaction was not significant, $p = .45$. The task in the assigned decision conditions was intended to minimize participants' involvement in the task, since they were simply waiting to be told what their character had decided. Thus, unlike Simon and colleagues' previous research on coherence shifts, in which participants expected to make a decision or had a memorization or communication goal (Simon et al., 2001), participants in the assigned decision conditions of the present research had no active processing goal. Our finding that participants in the assigned decision conditions were less likely to show coherence shifts, then, suggests that under minimal conditions, where participants think about a complex situation without any active processing goal, they may not achieve coherence.

Considering the results of the present research with those of previous research using the same type of paradigm in a legal context (Holyoak & Simon, 1999; Simon et al., 2001; Simon, Snow, & Read, in press) suggests that coherence shifts may occur in an all or nothing fashion. When participants think about a situation without an active processing goal (as in the forced decision conditions of the present research) they may not achieve coherence. However, if they do have an active processing goal (involving memorization, communication, or decision making) they are likely to report coherence shifts, and increasing the importance of the decision, outlining coherent perspectives, giving them a prior preference (as in the present research) or manipulating other aspects of the context (as in previous research) does not substantially affect the strength of the coherence shift. It appears, then, that whenever there is an active processing goal coherence shifts occur and that it may not be possible to further adjust their strength.

To test whether personality moderated the strength of the coherence shift, we added a variable representing personality measure. We found that PNS did not moderate the three-way interaction, $p < .5$, but NFC had a marginal effect overall, $F(1, 794) = 3.41$, $p < .07$, and a significant effect on fact items, $F(1, 794) = 4.39$, $p < .04$. Inspecting the means revealed that among participants who chose *engage*, those with higher NFC scores rated engagement facts higher at posttest than at pretest, $t(188) = 2.19$, $p < .04$, but those with lower NFC did not, $p < .3$. This finding suggests that people who have a greater "tendency to engage in and enjoy thinking" (Cacioppo & Petty, 1982, p. 116) may achieve a greater degree of coherence, though increased thought may only affect coherence among the facts of the issue currently being considered and may not affect more general beliefs.

Summary and Conclusions

We extended Simon et al.'s (2001; Simon, Snow, & Read, in press) paradigm to test for coherence shifts in perceptions of a romantic relationship. When participants thought about a couple's future and decided whether they would get engaged or break up, their attitudes about facts in the relationship and their general beliefs about relationships shifted to become coherent with their decision. When participants were not able to make their own decisions coherence shifts did not occur, suggesting that an active processing goal may be necessary to activate coherence mechanisms. Increasing the importance of the decision, increasing the ease of perceiving coherent perspectives, and introducing a prior preference within the pre-decision phase did not increase the strength of coherence shifts, suggesting that once there is an active processing goal and coherence mechanisms are activated it may not be possible to alter their intensity. Together with previous research in legal contexts (Holyoak & Simon, 1999; Simon et al.; Simon, Snow, & Read, in press), these findings suggest that coherence seeking mechanisms operate within the pre-decision phase in an all or nothing fashion, being activated any time there is an active processing goal. Finally, we found that individuals with higher need for cognition, who chronically engage in more cognitive processing, reported stronger coherence shifts in attitudes about facts of the current case, suggesting that individuals with higher NFC may achieve a greater degree of coherence across a broad range of situations in their daily lives.

Abstract

Spatial prepositions work as pointers to localize objects in space. For instance "The book is over the table" indicates that the located object (LO) is somewhere "over" the reference object (RO). To understand where the LO is people need to assign direction to space (selecting a reference frame). Three experiments are reported which investigated the reference frame conflict between LO and RO. We found that when the LO was not vertically aligned, the appropriateness for a given spatial preposition (*above, below, over* and *under*) changes. In general scenes with the LO pointing at the RO were judged less acceptable than scenes with the LO vertically oriented. These results suggest that reference frames for both LO and RO are accessed before direction can be assigned for spatial prepositions. Modifications to Multiple Frame Activation theory (Carlson-Radvansky & Irwin, 1994) are discussed.

Introduction

Spatial language forms an essential part of the lexicon for a competent speaker of a language. In English, spatial prepositions work as pointers to localize objects in space. For instance "The book is over the table" indicates that the located object ("the book") is somewhere "over" the reference object ("the table"). Prepositions like "over" and "behind" (the so-called projective prepositions) are particularly interesting as they require the selection of a reference frame before the assignment of a direction to space specified by the preposition can be established. Levinson (1996) distinguishes between the intrinsic (object-centred), relative (or viewer-centred/deictic), or absolute (environment-centred/extrinsic) reference frames. For example, "the car is behind the house" used intrinsically locates the car in relation to the opposite wall from where the salient front of the house is (which is where the back door is). The relative use of the same expression locates the car directly behind the opposite wall to where the speaker and hearer are standing. The absolute frame locates an object with respect to a salient feature of the environment, such as the gravitational plane or cardinal directions (e.g., North, South, etc.).

Carlson-Radvansky and Logan (1997) have argued that spatial apprehension occurs in a series of stages as follows; (1) identify the reference object (e.g., the house), (2) superimpose multiple reference frames (relative and intrinsic), (3) construct spatial templates and align them to the relevant reference frames, (4) select a reference frame, (5) combine templates into a composite template, (6) search the composite template that fits best with the located object for each position within the template, (7) calculate whether the goodness of fit measure for the located object is high (good or acceptable region) or low (bad region). In this paper we focus on the process underlying the orientation of space and the consequent reference frames selection.

Experimental evidence has demonstrated that by rotating the reference object by 90º (noncanonical orientation), acceptability ratings for *above* mirror the new spatial template that is the sum of all the reference frames active in that moment (Carlson-Radvansky & Irwin, 1994). The acceptability for the given spatial preposition varies as a function of the reference frame activated. Consider the scenes in Figure 1. In the canonical orientation the absolute, relative and intrinsic reference frames overlap. In the noncanonical orientation the absolute reference frame is dissociated from the intrinsic. This produces a lower acceptability for the given spatial preposition because a conflict emerges between all the reference frames activated in that moment (Carlson-Radvansky & Irwin, 1994; Carlson, 1999).

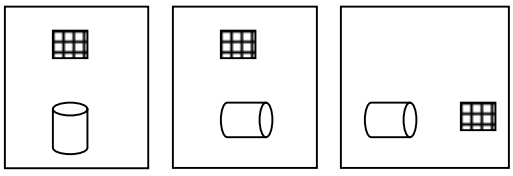

Figure 1: Canonical absolute/intrinsic "above" (left picture), noncanonical absolute "above" (middle picture) and noncanonical intrinsic "above" (right picture).

Although there is evidence that reference frame activation is important, to date studies have only focused on the reference frame generated from the reference object (Carlson & Logan, 2001; Carlson, 1999; Carlson-Radvansky & Logan, 1997). Furthermore, theories of spatial

language largely assume that the assignment of direction is generated from the reference object to the located object. For example, in the Attentional Vector-Sum model (Regier & Carlson, 2001) the direction indicated by a spatial relation is defined as a sum over a population of vectors that are weighted by attention. An attentional beam is focused on the reference object (at the point that is vertically aligned with the closest part of the located object) and separated in a population of vectors pointing toward the located object. But other experiments suggest that both objects (even distractors or those not relevant for the task) require allocation of attention to be processed (Lavie, 1995; Lavie & Cox, 1997). This suggests that both objects could play a role in the spatial apprehension process.

There is much evidence indicating that the LO is important in establishing the acceptability of a range of spatial prepositions (see Coventry & Garrod, 2004 for a review). For example, Coventry, Prat-Sala and Richards (2001) found that the appropriateness of a spatial preposition is correlated with the functional relation between located and reference object. For example, an umbrella is regarded as being more *over* a person if it is shown to protect that person from rain than when the rain is shown to hit the person. Furthermore, Coventry et al. found that the acceptability ratings for *over* and *under* were more influenced by the function of the object than by the relative positions of LO and RO, while conversely *above* and *below* were more influenced by geometry than function. Additionally, in a study which manipulated reference frame conflicts with function present (e.g., the man holding the umbrella in the gravitational plane was either upright, lying down, or upside down), Coventry et al. found that reference frame conflicts influenced the acceptability of *above* and *below* more than *over* and *under*.

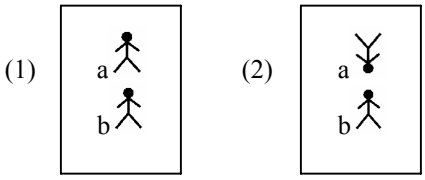

Figure 2: Reference frame conflicts between LO and RO.

However, although there is much evidence that the located object does influence the acceptability of a range of prepositions, no studies to date have examined whether the located object contributes to reference frame assignment, and hence the assignment of direction to space. This paper reports three experiments employing an acceptability rating task where possible reference frame conflicts for both the located object and reference object are manipulated. For example, consider the scene in Figure 2, and the acceptability of man [a] is above man [b]. In (1), the reference frame of man in location [a] is aligned with the reference frame of man [b] (the reference object), but not in (2) where their intrinsic reference frames are in conflict. We predicted that rotating the LO in this way would influence the appropriateness of *over, under, above* and *below*

Experiment 1

In this experiment we tested the hypothesis that the reference frame(s) associated with the located object would affect acceptability of *over, under, above* and *below* to describe the position of the LO in relation to a RO.

Method

Participants & Procedure

Twenty-three undergraduate students from the University of Plymouth participated in this investigation for course credit. All the participants were English native speakers. Participants had to judge the appropriateness of a spatial preposition (*above, below, over* or *under*) to describe pictures using a scale from 1 to 9 (where 1 = not at all acceptable and 9 = perfectly acceptable). All trials showed the located object in a "good" or "acceptable" location, never in a "bad" location (following Carlson-Radvansky and Logan's definitions, 1997).

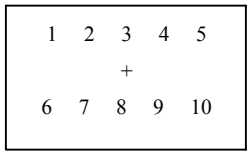

Figure 3: Location for the located object with respect to the reference object (indicated here with a "plus").

The located object could appear in 10 different locations around the reference object (see Figure 3). The sentences were shown before the scene and in this form; <The "located object" is PREPOSITION the "reference object">. The prepositions tested were *above, below, under* or *over*. Two orientations for the located object were used: "vertical" and "pointing at". In the "pointing at" condition the axis of the located object was pointing exactly towards the center-of-mass of the reference object.

Materials

The materials consisted of three stimuli; a circle, an hourglass and a stickman. These objects were selected as the circle does not have an oriented axis, while the hourglass has a salient axis but not an intrinsic top and bottom, and the stickman has a salient axis and an intrinsic top and bottom. We will use the following labels to classify the objects; "no axis" (circle), "ambiguous axis" (hourglass) and "intrinsic axis" (stickman). All the objects employed were presented at the same size and distance from the reference object regardless of the orientation. This is because it has been found that proximity, center-of-mass orientation and distance affect the appropriateness of spatial preposition (Regier & Carlson, 2001).The objects could appear as reference objects or as located objects, but the same object was never shown as LO and RO at the same time.

Design
The experiment consisted of 480 trials constructed from the following variables: 4 spatial prepositions X 10 locations X 3 objects X 2 orientations ("vertical" and "pointing at"). The locations were collapsed in two factors; high vs. low location (2 levels) and proximity (3 levels) as follows; far misaligned (locations 1, 6 and 5, 10) versus near misaligned (locations 2 and 4) versus aligned (central location). All the trials were presented in a randomized order.

Results
A 4-way within subjects ANOVA was performed on the rating data. The variables included in the analysis were; 2 located objects (hourglass versus stickman) x 2 preposition set (above-below vs. over-under) x 2 superior versus inferior prepositions (above-over vs. below- under) x 2 orientations of LO (vertical and pointing at). The division between spatial prepositions has been employed following the Coventry et al. findings summarized above (Coventry, Prat-Sala and Richards, 2001).

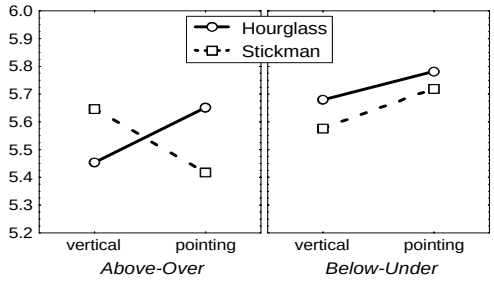

Figure 4: 3-way interaction between superior versus inferior prepositions (above/below vs. over/under), located object and orientation of LO (collapsed over locations).

Trials with the circle as the located object were excluded from the analysis since this kind of object does not have an axis. Furthermore we analyzed only the trials with a circle as the reference object because it has no axis. A main effect of preposition set (above-below vs. over-under) was found, [$F_{(1, 22)} = 7.21$, $p < .05$]. Higher ratings were given for Above-Below ($M = 6.526$) than for Over-Under ($M = 5.192$). This is unsurprising as it known that these spatial prepositions have larger areas of acceptability. No other significant main effects were found. There was a significant 3-way interaction between superior versus inferior spatial prepositions, located object and orientation of LO [$F_{(1, 22)} = 6.694$, $p < .05$], displayed in Figure 4. It is interesting to note that objects with a top/bottom orientation such as a stickman are rated less acceptable when pointing ($M = 5.42$) than when vertical ($M = 5.65$) for trials with above-over, although this was not the case for below-under ($M_{vertical} = 5.58$; $M_{pointing} = 5.72$). None of the other interactions were significant.

Discussion

An interesting difference was found between trials with the stickman and trials with the hourglass as LOs. The stickman trials generate a reference frame conflict in the pointing condition but the hourglass did not. This could be explained by a preferential assignation of a top/bottom orientation based on the vertical plane. In other words an hourglass could not be seen as upside down but always as pointing away from the reference object.

Acceptability rating showed that for inferior spatial prepositions (below-under) the pointing condition was more acceptable than the vertical one. All these results can be explained by the activation of an intrinsic reference frame on the located object that in the case of under-below produces facilitation and with above-below produces conflict. Therefore the results seem to suggest that the orientation of the located object is important in establishing the appropriateness of projective prepositions. However, this experiment only used two located objects (an hourglass and a stickman), so there is an issue regarding the extent to which the results can be generalized. For this reason the aim of the next experiment is to try to replicate the effect of the orientation of the LO using a wider range of LOs and orientations of LO.

Experiment 2

The second experiment utilized the same design and procedure as the first experiment, except that more materials and orientations of LO were included.

Method

Participants & Procedure
Twenty-nine undergraduate students from the University of Plymouth participated in this investigation for course credit. All the participants were English native speakers and none of them took part in the previous experiment. The procedure was the same procedure used for the previous experiment based on the acceptability rating task of the given spatial prepositions; *above, below, over* and *under*.

Materials
This experiment involved a wider number of located objects and two more orientations; "pointing away" from the reference object and "upside down". The reference object in this experiment was always a picture of a football. The located objects were picked from two sets; the first consisted of objects with a distinctive top-bottom (8 new objects "with an intrinsic axis") and the second one of objects with "an ambiguous axis" (7 new objects plus the hourglass). All the stimuli were hand-drawn and transformed to electronic format by a computer scanner.

Design
There were 384 trials constructed from the following variables: 8 located objects X 3 locations (collapsed over side) X 4 spatial preposition X 4 orientations ("vertical", "upside down", "pointing at" and "pointing away"). All the trials were presented in a randomized order. We added 192 distractors where the LOs were objects without salient axes, meaning that a total of 576 trials were presented.

Results

A full factorial ANOVA was chosen to analyze the data. In this analysis we focus on trials where the LO had an intrinsic axis (following the results of Experiment 1). A significant main effect was found for preposition type (above-below vs. over-under), [$F_{(1,28)} = 15.44$, $p < .001$], for superior versus inferior prepositions, [$F_{(1,28)} = 10.72$, $p < .005$], for location [$F_{(1,28)} = 80.17$ $p < .0001$] and for direction [$F_{(1,84)} = 3.35$, $p < .05$]. Objects vertically oriented ($M = 5.75$) were judged more acceptable than the other levels of orientation. In particular the "upside down" ($M = 5.6$) and "pointing at" ($M = 5.55$) orientations produced the lowest ratings (and indeed generated the highest reference frame conflict). The analysis also revealed significant 2-way interactions between preposition set and location [$F_{(1,28)} = 10.96$, $p < .005$], between preposition set and direction [$F_{(1,84)} = 3.23$. $p < .05$] and between superior versus inferior prepositions and direction [$F_{(1,84)} = 2.82$, $p < .05$].

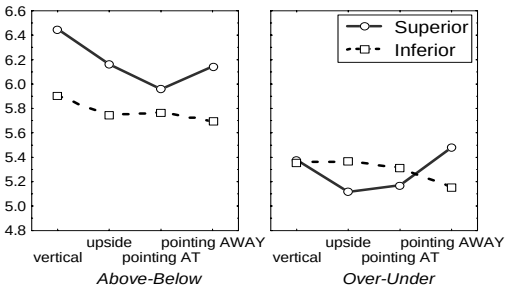

Figure 5. 3-way interaction between orientation of LO, superior-inferior prepositions and preposition set.

Finally, there was also a significant 3-way interaction between superior-inferior prepositions, preposition set and location, [$F_{(1,28)} = 5.45$, $p < .05$], and between preposition set, superior-inferior preposition and direction [$F_{(1,84)} = 3.99$, $p < .01$]. This interaction is displayed in Figure 5. As can be seen in Figure 5, the results of the orientation of LO are clearest for *above*, which exhibited a reliable difference between the vertical orientation of LO and all the other levels of LO. For *over*, pointing away from the RO is also associated with higher acceptability ratings. The results are less clear for inferior prepositions.

Discussion

The pattern of results in this second experiment confirms the hypothesis that the orientation of the located object influences acceptability ratings, although there are clear differences between prepositions. However, in the first two experiments the reference objects were objects without a salient axis. It is therefore possible that the activation of the located object reference frame could depend on the features of the reference object. The next experiment tested whether the effects of the orientation of LO were present across a wider range of ROs.

Experiment 3

This experiment used the same basic methodology as before, but this time with a range of reference objects including ROs without a salient axis, with an ambiguous axis, and with an intrinsic axis.

Method

Participants& procedure

Twenty-three undergraduate students from the University of Plymouth participated in this investigation for course credit. All the participants were English native speakers and they did not take part in any of the previous experiments. The procedure was the same as that used in Experiments 1 and 2.

Materials

For this experiment we used a set of 24 objects (8 "without a salient axis", 8 "with an ambiguous axis" and 8 "with an intrinsic axis"). The objects "with an ambiguous axis" and "with an intrinsic axis" were the same as those used in Experiment 2. We drew 8 new objects "without a salient axis". Thus we were able to study the effect of the reference frame activation on the located object in scenes with different kinds of reference object.

Design

The experiment was composed of 576 trials with the following factors: 8 located objects with an intrinsic axis (treated as random factor), X 3 reference objects (picked up from a set of 24 objects, 8 with no axis, 8 with an ambiguous axis, and 8 with an intrinsic axis; within subjects factor), X 2 prepositions set (between subjects factor), X 2 superior-inferior preposition (within subjects), X 3 locations for the probe (within subjects) and 4 directions for the located object (within subjects). This time preposition set was between subjects; half the participants received *above* and *below* and the other half received *over* and *under*.

Results

We performed two analyses; one by subjects (F^1) and one by materials (F^2). The results were similar for both analyses, so here we report the F^1 analyses alone. The means for all the conditions can be found in Table 1. Significant main effects were found for superior-inferior prepositions [$F_{(1,22)} = 18.74$, $p < .001$], for location [$F_{(1,22)} = 69.14$, $p < .0001$] and for orientation of LO [$F_{(1,44)} = 5.25$, $p < .005$]. Furthermore we found several significant 2-way interactions; between preposition set and RO [$F_{(1,44)} = 3.61$, $p < .05$], between location and RO [$F_{(1,44)} = 4.45$, $p < .05$], between superior-inferior prepositions and orientation of LO [$F_{(1,66)} = 4.93$, $p < .005$] and between location and orientation of LO [$F_{(1,66)} = 3.12$, $p < .05$].

Located Object (intrinsic)		*Reference Object*		
		No axis	Ambig.	Intrin.
Above	vertical	6.281	6.307	6.375
	inverted	5.560	5.542	5.490
	point at	5.524	5.670	5.644
	point away	6.047	6.026	5.974
Below	vertical	5.797	6.036	6.167
	inverted	5.411	5.604	5.453
	point at	5.786	5.823	5.754
	point away	5.387	5.536	5.578
Over	vertical	5.419	5.084	5.479
	inverted	5.047	4.823	5.220
	point at	5.182	5.115	5.188
	point away	5.785	5.366	5.335
Under	vertical	5.131	5.058	5.162
	inverted	4.691	4.901	4.889
	point at	5.335	5.073	5.156
	point away	4.698	4.693	4.901

Table 1. Means for conditions across the four spatial prepositions (*above, below, over and under*).

A 3-way interaction was also significant between superior-inferior prepositions, location and orientation of LO [$F_{(1,66)} = 3.93$, $p < .05$] and a 4-way interaction between superior-inferior prepositions, location, RO and orientation of LO [$F_{(1,132)} = 2.74$, $p < .05$]. Follow-up analysis revealed significant differences in orientation between prepositions and locations, but the effects of orientation were present at all levels of RO.

Discussion

The outcome from this experiment supports the idea that the orientation of the located object affects acceptability ratings even when the reference object has an intrinsic orientation. The results for this experiment mirror the results of the previous experiment, but extend the results to show that the activation of reference frame for the LO is not restricted to cases where the RO does not provide sufficient information to cue a reference frame.

General Discussion

The series of experiments explored the hypothesis that the spatial apprehension process computes a composite template for a given spatial preposition making use of the located object reference frame as well as the reference object reference frame. The results of the experiments confirmed this hypothesis showing that the orientation of the located object affects acceptability ratings for projective prepositions.

The results suggest necessary extensions to the idea of Multiple Frame Activation (Carlson-Radvansky & Irwin, 1994) where it is suggested that in comprehending a scene multiple frames are available. However, we found that an additional reference frame is generated from the located object as well as from the reference object and the final template generated is influenced by its orientation.

In addition to the reliable effects of the orientation of LO for intrinsic objects, the results of Experiment 1 showed some interesting differences between intrinsic objects and objects such as an hourglass with a salient axis, but without an intrinsic axis. For the objects like an hourglass, the "pointing at" condition was considered more acceptable than the vertical condition. A possible explanation is that people assign a subjective top/bottom orientation to "ambiguous" objects. Thus the hourglass in trials with above-over should be seen as pointing away from the reference object instead of pointing at the RO.

The last experiment provided evidence that the conflict among reference frames emerges across a range of reference objects, including those that are more "real" with a top/bottom orientation. So the effect of the located object is not exclusive for circle-like reference objects but it is part of a more general process.

But why should we activate the located object reference frame when the reference frame of the RO should be sufficient to localize the objects in the scene? An explanation is that objects not vertically oriented suggest that there is something implausible in the scene. A cat upside down is not a "plausible" stereotypical mental representation. Thus the knowledge revision function (Holland, Holyoak, Nisbett & Thagard, 1986, Wason, 1960) should look for an explanation; this activates the located object reference frame to process every possible orientation that fits with the whole scene. Another possible explanation is based on the concept of direction of potential motion (Regier, 1996). People perceive objects rotated away from the gravitational plane as falling. So a located object oriented at 90º may be perceived as moving downwards on a path to the left of/right of and away from the reference object.

Implication for existing models

The results found suggest a review of the key characteristics of the spatial apprehension process Carlson-Radvansky & Irwin, 1994; Carlson & Logan, 2001; Hayward & Tarr, 1995; Logan & Sadler, 1996). We found evidence of an involvement of the located object reference frame in the process of assigning direction to space. Therefore evaluating the process of goodness of fit of the spatial preposition involves the located object as well and future studies should take this into account. The finding that the located object interacts with the spatial apprehension process has some repercussions for models of spatial language as well. Models such as the Attentional-Vector-Sum model (Regier & Carlson, 2001) simulate attentional processes, but thus far does not deal with attentional processing of the LO (but see Regier, Carlson & Corrigan, 2004, for a modification of AVS to deal with processing of function). It may be possible to develop the AVS model to deal with the projection of vectors from the LO to the RO as well as the

other way round (see Coventry and Garrod, 2004, for a discussion).

Limitations and future developments

This investigation brings experimental evidence in support of the hypothesis that the located object, in a scene with two objects, takes part in the spatial apprehension process. Future investigations should attempt to ascertain the degree to which features of the LO influence the spatial apprehension process further. For example, in some contexts the LO may be more important than the RO, and vice versa for other contexts. In addition, the present experiments do not tell us anything about the time course of processing of LO reference frames. Studies underway are testing the conflict among reference frames using a reaction time paradigm. Finally, we should consider how these findings can be implemented within frameworks such as the AVS model.

Multiple Session Masked Priming: Individual differences in orthographic neighbourhood effects

Abstract

Multiple Session Masked Priming was used to investigate differences between individuals in the fine-tuning of their lexical representations. The form-priming effects were determined separately for each of the 50 participants, from the patterning of masked priming effects over three neighbourhood (N) levels. At each N level, primes varied in their orthographic similarity to the target - Identity, One-Letter-Different and All-Letters-Different. An analysis of the pooled data showed patterns of masked priming consistent with other group studies, but considered separately, an array of individual differences in the tuning of lexical representations was observed.

Inconsistent findings and conflicting evidence characterise much of the word recognition literature, and have lead to a plethora of theories on many aspects of word recognition. One explanation for the conflicting evidence regarding theories of word recognition, is the possibility that it reflects individual differences. The problem here lies in the fact that support for one model or another has generally been drawn from standard group studies, where outcomes are averaged over the sample of participants. Averaged outcomes may show what is generally true for that sample, but fail to capture the critical variations between individuals.

In order to study individual differences a task must be found that will provide reliable data concerning the processing capacities of each participant. There are two issues here. First, the task used must reflect the automatic processes of lexical access, and second, the task must generate sufficient data on each participant to enable stable conclusions to be drawn about their individual performance; that is, we need to be able to generate reliable individual profiles of lexical processing.

Although there is some debate (e.g. Bodner & Masson, 1997; Bodner & Masson, 2001), Forster and Davis' (1984) Masked Priming paradigm is widely considered to be an ideal tool for examining automatic lexical processing. In masked priming, a prime word/nonword is presented very briefly (50-60ms), forward masked (for 500ms) by a row of hash marks (######) and backward masked by an upper case target (500ms), to which a timed lexical decision response is made. The relationship between prime and target is manipulated in some way and if performance on the target is enhanced by a particular prime-target relationship, relative to a control condition, this relationship is taken to reflect the properties of written words important for lexical access. Masked priming has been argued to enable the investigation of lexical access processes free from any influence of more central and strategic processes (e.g. Forster, 1998). This is achieved in the way the prime is presented, making it typically unavailable for conscious report by participants. Critically, while the masked prime is not available for conscious report, a variety of priming effects are consistently observed. Such facilitatory priming effects include repetition-priming (e.g. Forster & Davis, 1984) where prime and target are the same word (e.g. farm – FARM) and form-priming (e.g. Forster, Davis, Schocknect & Carter, 1987; Forster & Veres, 1998) where the prime is of similar orthographic form (e.g. firm – FARM). The absence of both expectancy effects (e.g. Forster, 1998) and priming for nonwords (e.g. Forster & Davis, 1984; Forster et al., 1987; cf. Bodner & Masson, 1997), in addition to the existence of semantic- (e.g. Perea & Gotor, 1997) and cross-language translation-priming (e.g. Kim & Davis, 2003) indicate that masked priming effects reflect lexical level processing.

While the masked priming task provides a means of examining the automatic processes of lexical access, a new variant of this task was required to enable the collection of sufficient data from each participant that they could stand as an experiment in their own right. The Multiple Session Masked Priming paradigm (e.g. Byrne, Yelland, Johnston & Pratt, 2000; Yelland & Byrne, 2001) achieves this by repeatedly testing each participant on the same experiment. Since participants are unaware of the primes, the prime-target relationship cannot be realised, even over repeated test sessions. Thus, in the Multiple Session Masked Priming paradigm, the participant's experience is simply one of repeated exposure to the target items.

Used previously to reveal marked individual variation in the use of orthographic and phonological input codes for lexical access (e.g. Byrne, Yelland, Johnston & Pratt, 2000; Yelland & Byrne, 2001), the Multiple Session Masked Priming paradigm has proved useful for investigating individual differences in lexical processing. This study aims to look at the use of this new technique in other areas of the word recognition literature, namely orthographic neighbourhood effects.

The neighbourhood effect was first investigated by Coltheart, Davelaar, Jonasson and Besner (1977), who coined the term neighbourhood (N) density. A word's N density is simply the number of words that can be made from it by changing one letter. For instance, a high N word like *torn* has many neighbours – *corn, born, turn, town, tore* etc. In this way, N provides a rough index of a word's similarity to other words. The effects of such orthographic similarity have been used by researchers to model constraints on, and organisation of, the internal word-recognition system. Previous experiments looking at the effects of N density have shown form-priming effects when using word or nonword primes that are one-letter-different from their word targets, however, such effects are present for low N density words only, not high N (e.g. Forster et al., 1987). The form-priming effects seen at the low N density are reported consistently, albeit are smaller in magnitude than those observed in repetition-priming (e.g. Andrews, 1997). The lack of form-priming effects in high N words is usually described as an increased tuning of these lexical representations. Forster et al. (1987) first proposed a now commonly used explanation for this change in tuning, whereby a word's lexical representation becomes more finely tuned in response to increasing N density. A word with many neighbours needs to ensure only exact matches can activate its representation, otherwise a large number of these neighbours will need to be considered and errors in activation are more likely. In contrast, a word with only few neighbours can afford to be less stringent (i.e. it can be activated by a one-letter-different neighbour) as there are only a small number of possible lexical candidates. A range of word recognition theories and models have been provided for these results. Such accounts, however, will only prove useful if either, all readers show the same pattern of priming effects as a function of N density, or they are able to account for individual variation in sensitivity to N levels . The question addressed in this study is whether there are individual differences in the priming effects for similar form, indicating differences in the fine-tuning of lexical representations.

Method

Participants

Seventy-one undergraduates, graduates and staff from Monash University, Australia, volunteered to complete the experiment. All were aged between 18 and 33 years with normal or corrected-to-normal vision and were paid a token amount for their participation.

Seventeen participants chose not to complete all 12 sessions, and were therefore excluded from the analyses. In addition, a further four participants were excluded (three on the basis of overall error rates exceeding 20%, and one who was found to be a non-native speaker of English). In all, 50 participants contribute to the final analyses.

Materials and Design

One hundred and eight 4-letter words were used as targets. All were monosyllabic content words with a mean frequency of occurrence of 85.2 (SD=162.9) tokens per million in text (Kucera & Francis, 1967). The target words were selected from three (n=36) N levels (i.e. Low, Medium and High), with written frequency matched across these conditions. In addition, targets were chosen to ensure they did not belong in another target's neighbourhood. For each target word, primes of three types were constructed: (a) an All-Letters-Different (ALD) prime, a nonword which differed at each letter position from the target, to be used as a baseline control; (b) an Identity (ID) prime, which was the exact same word as the target, to measure the maximum priming effect; and (c) a One-Letter-Different (1-LD) prime, a nonword which differed from the target in one letter position, to examine any form-priming effects. The letter position at which the 1-LD prime differed from the target was varied evenly within the three N levels. Primes were matched to targets on N and consonant-vowel patterns within neighbourhood conditions.

An equivalent set of nonword items was constructed to act as foils in the lexical decision task. All matching procedures undertaken for the selection of word targets and primes was repeated for the nonword items, with the exception of written frequency matching. Some characteristics of the target items are shown in Table 1, while example items are shown in Table 2.

Table 1: Characteristics of the Masked Priming Target Items

	N		Frequency
	Range	Mean (SD)	Mean (SD)
Words			
Low N	1 - 3	2.1 (0.8)	84.3 (153.7)
Med N	6 - 7	6.5 (0.5)	85.3 (173.0)
High N	12 -15	13.9 (1.1)	85.9 (165.9)
Nonwords			
Low N	1 - 3	2.3 (0.8)	N/A
Med N	6 - 7	6.5 (0.5)	N/A
High N	10 -15	11.9 (1.5)	N/A

Note. N = Neighbourhood size

Table 2: Example Targets and Primes

	Target	ID Prime	1-LD Prime	ALD Prime
Words				
Low N	FREE	Free	frue	merp
Med N	HELP	Help	hulp	vand
High N	WIDE	Wide	kide	barp
Nonwords				
Low N	NORL	Norl	norf	vube
Med N	PALD	Pald	peld	bist
High N	BAFE	Bafe	bape	fook

Note. N = Neighbourhood size; ID = Identity; 1-LD = One-Letter-Different; ALD = All-Letters-Different

All targets were presented as UPPER CASE letter strings, while primes were presented in lower case. This reduced the possibility that any observed priming effects could be the result of priming by virtue of visual features rather than orthographic form. Three different, counterbalanced versions of the experiment were constructed so that all targets appeared with each of their primes, but only once in each version. Practice items (one exemplar of each word and nonword condition) were constructed and placed at the beginning of each version.

Procedure

For each of the 12 masked priming sessions, participants were seated in a sound attenuated booth where items were displayed on a 15" flat screen, fast decay monitor, controlled by an IBM compatible computer operating DMDX presentation software (developed at Monash University and at the University of Arizona by K.I. Forster and J.C. Forster). Participants began the experiment by pressing a foot pedal, which initiated the presentation of the instructions in the centre of the screen. The practice items were then shown, followed by the experimental items. Progress through the experiment was self-paced with a press of the foot pedal initiating each item. Participants took approximately 10 minutes to complete each session.

Each item was presented in the centre of the screen in the following sequence. First, the forward mask, a row of six hash marks (e.g. ######) was presented for 500ms. This was replaced by the 54ms presentation of the lower case prime, which was in turn replaced by the upper case target for 500ms. Participants made a timed lexical decision response to each target, pressing a blue button with their preferred hand if the target was a word of English and a red button with their other hand if it was not. Participants received response time (RT) and accuracy feedback after each response. RT was measured from the onset of the target display to the button-press response. Both response latencies and errors were recorded for each item by the computer.

Participants were asked to complete 12 masked priming sessions to ensure that each prime-target pair were tested enough to gain sufficient data for every item. Therefore, the three counterbalanced versions were completed four times each. The participants completed the sessions on a roughly daily basis, according to their availability.

Results and Discussion

In order to determine whether the group study approach was masking quite disparate patterns of individual difference amongst participants, analysis of the patterning of the group data was needed to provide a baseline against which the individual differences could be examined.

Group Analyses

The data entered into the group analyses were the condition means for both session and item based data for each of the 50 participants. Analyses of the data from word targets comprised three planned comparison ANOVAs at each of the three N levels, conducted over both participant (F_1) and item (F_2) based data. The first compared the ID and ALD prime conditions, to confirm the existence of a repetition-priming effect. The subsequent analyses looked for orthographic form-priming (1-LD vs ALD) and whether form-priming was equal in magnitude to the repetition-priming effect (ID vs 1-LD)[1]. In the interests of brevity, only the significance level of F_1 and F_2 will be reported. The group mean RTs and error data obtained from participant-based data for word targets are shown in Table 3.

Table 3: Group mean response time (RT), percentage error rate (+/- SE) and priming effects (Δ), as a function of prime type and neighbourhood (N) level for word targets.

N level	Prime	RT (ms)	Δ	% Error	Δ
Low	ID	418 (7.1)	56	3.0 (0.02)	6.8
	1-LD	448 (8.1)	26	7.4 (0.52)	2.4
	ALD	474 (7.3)	-	9.8 (0.40)	-
Medium	ID	419 (7.5)	52	3.9 (0.35)	5.6
	1-LD	449 (8.3)	22	7.7 (0.46)	1.8
	ALD	471 (7.8)	-	9.5 (0.55)	-
High	ID	432 (7.4)	41	6.2 (0.66)	5.7
	1-LD	469 (8.9)	4	12.6 (1.02)	-0.7
	ALD	473 (7.6)	-	11.9 (1.00)	-

Note. ID = Identity; 1-LD = One-Letter-Different; ALD = All-Letters-Different

As can be seen in the summary of RT data (Table 3), participants responded more rapidly to word targets preceded by their ID prime than their ALD prime, yielding significant repetition-priming effects at each of the N levels [F_1 & F_2, $p < 0.01$]. Repetition effects were found in the error data also [F_1 & F_2, $p < 0.01$]. These results indicate that the ID primes facilitate faster and more accurate lexical access for their targets at each N level.

A comparison between the mean RT for the 1-LD and ALD prime conditions showed significant orthographic form-priming effects at the Low and Medium N levels [F_1 & F_2, $p < 0.01$], while at the High N level this comparison was not significant [F_1 & F_2, $p > 0.05$]. This pattern was mirrored in the error data, with a significant decrease in errors for 1-LD primes over ALD primes for Low and Medium N targets [F_1 & F_2, $p < 0.01$], but not for High N targets [F_1 & F_2, $p > 0.05$].

As expected for masked priming studies with group data, the orthographic form-priming effects, seen in the Medium and Low N conditions, were significantly reduced in magnitude relative to those seen with repetition-priming, for both RT [F_1 & F_2, $p < 0.01$] and accuracy [F_1 & F_2, $p < 0.01$] (i.e. ID vs 1-LD). For the High N targets, this

[1] While not orthogonal, these comparisons are meaningful, an attribute Keppel (1991) believes is more important than a set of purely orthogonal comparisons without such meaning.

comparison was also significant [F_1 & F_2, $p < 0.01$], however, this was in the absence of a 1-LD prime advantage.

Overall, the group analyses for the word targets provide results which are comparable with other masked priming studies in this area. It would seem from these results that, on average, only words with High N density become finely tuned, while words without such neighbourhoods (i.e. Low and Medium) are open to activation by close relatives.

In order to complete the traditional group analyses, an investigation of nonword effects was undertaken. An omnibus analysis of the group nonword data revealed significant main effects of N Level [F_1 & F_2, $p < 0.01$] and Prime Type [F_1 & F_2, $p < 0.01$] but no interaction between them [F_1 & F_2, $p > 0.05$]. Subanalyses were then conducted to examine the within factor effects, separately for N level and Prime Type. The group mean RTs and error data, obtained from participant-based analyses of the nonwords, are shown in Table 4 for the three N levels (collapsed over prime type) and the three prime types (collapsed over N level).

Table 4: Group mean response time (RT) and percentage error rate (+/- SE) by prime type and neighbourhood (N) level for nonword targets.

	RT (ms)	% Error
N Level		
Low	471 (8.4)	4.2 (0.42)
Medium	493 (10.1)	9.5 (0.52)
High	500 (11.7)	9.7 (0.78)
Prime Type		
ID	483 (10.9)	7.9 (0.95)
1-LD	486 (10.4)	7.5 (0.93)
ALD	495 (10.7)	8.0 (1.00)

Note. ID = Identity; 1-LD = One-Letter-Different; ALD = All-Letters-Different

As seen in Table 4, the Low N nonword targets were responded to significantly faster and more accurately than both the High N [RT: F_1 & F_2, $p < 0.01$; % Error: F_1 & F_2, $p < 0.01$] and Medium N targets [RT: F_1 & F_2, $p < 0.01$; % Error: F_1 & F_2, $p < 0.01$]. This difference was also evident between the Low and Medium N targets [RT F_1 & F_2, $p < 0.01$; % Error: F_1 & F_2, $p < 0.01$]. However, no such differences were found between the Medium and High N targets [RT: F_1, $p < 0.05$, F_2, $p > 0.05$; % Error: F_1 & F_2, $p > 0.05$]. These results show that only the Low N words had an RT and accuracy advantage, an expected effect in nonwords, as a nonword with more neighbours has a larger number of words to eliminate before concluding that the target is in fact not a word.

Somewhat surprising were nonword priming effects in the group RT data. From Table 4 it can be seen that the ID primed target has a small, but secure, 12ms facilitation relative to the ALD baseline [F_1 & F_2, $p < 0.01$]. A similar sized (9ms) significant facilitation effect was afforded the 1-LD over ALD primes [F_1 & F_2, $p < 0.01$]. Indeed, the 3ms advantage ID primes have over 1-LD primes proved to be significant [F_1 & F_2, $p < 0.01$]. Nonword effects of these magnitudes are not uncommon in group studies; however, they rarely prove significant (Forster, 1998). They do so here due to the power afforded the group analyses with 7,200 data points per condition. Although the absence of nonword effects is usually taken to indicate that masked priming effects for words are showing lexical level processes, the nonword priming effects found here do not contradict this conclusion. As only a lexical representation can be tuned by its N density, the modulation of priming effects by N density shown for words, but not nonwords, would indicate that the word priming effects are lexical in nature. In additon, the large reduction in magnitude of the nonword priming, compared to the word priming, would also indicate different mechanisms were involved in priming for these targets. Taken together, these findings suggest that the priming effects seen for word targets can still be considered lexical in nature, but may contain a small pre-lexical, graphemic priming component.

The critical issue, however, is whether these patterns of outcomes for the group data are an accurate characterisation of the lexical processes of all skilled readers, or the average of individual differences in the nature of lexical tuning across skilled readers.

Individual Analyses

The Multiple Session Masked Priming procedure yields sufficient data for each participant to be considered an experiment in their own right. That is, each of the 50 participants were the equivalent of an experiment, where test sessions replace participants. This gives a fully repeated measures design that provides 2,592 points of data for every individual (12 sessions over 18 conditions of 12 items each). Critically, this provides sufficient data for any one person, that the analyses of the type performed on the group data can be carried out for each participant separately. From this, reliable statements can be made for *each* participant about changes in orthographic form-priming as a function of N level.

Words

Each participant's data were analysed in the same way as the group data. A true appreciation of the subtleties of individual differences found within the data would require consideration of the priming outcomes at each N level, separately for each of the 50 participants. Unfortunately, space does not permit this. Instead, participants were classified according to their pattern of significant priming effects, as a function of N level. Priming effects fell into four categories. Three represent different patterns of priming effects between the ID, 1-LD and ALD conditions that are statistically distinguishable, (a) ALD>1-LD=ID, significant orthographic form-priming of the same magnitude as the repetition-priming effect; (b) ALD>1-LD>ID, orthographic form-priming which was significantly

greater than the baseline, but significantly less than the repetition-priming effect; and (c) ALD=1-LD>ID, no orthographic form-priming, in the presence of secure repetition-priming. These patterns of secure priming effects are illustrated in Figure 1. The fourth category contained cases where the pattern of priming effects was not secure. Each was of the form of (a), (b) or (c) but variability in the participants was such that the pattern of effects could not be statistically distinguished. This fourth group will not be reported on any further here.

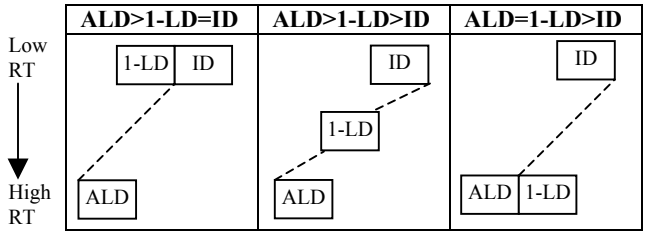

Figure 1: Depiction of the three secure priming patterns found within the data. Dashed lines indicate significant differences in response time (RT) between prime conditions.

Table 5 reports the number of participants displaying each particular priming pattern as a function of N level. The obvious feature of this data is that at Low and Medium N, participants are showing distinctly different patterns of performance; that is, the individual data differs from the grouped data.

Table 5: Number of participants as a function of priming pattern and neighbourhood (N) level.

Priming Pattern	Low N	Med N	High N
ALD>1-LD=ID	3	4	0
ALD>1-LD>ID	28	21	1
ALD=1-LD>ID	14	22	39

Note. ID = Identity; 1-LD = One-Letter-Different; ALD = All-Letters-different

At Low N, a small number of participants displayed a pattern of priming that would indicate their lexical entries for these words were poorly tuned (i.e. ALD>1-LD=ID). For these participants, the priming effects of the 1-LD and ID primes were of the same magnitude, indicating that these words were able to be accessed equally as well by a neighbour as the word itself. The majority of participants showed the priming pattern commonly found in group studies at similar N densities (i.e. ALD>1-LD>ID) (e.g. Andrews, 1997). These participants have slightly better lexical tuning than the former group, with lexical entries showing sharper but not perfect tuning for the target word. In contrast, 14 of the participants at this N level showed a finely tuned processor, which would only activate entries for an exact word match. Here the pattern shows no form-priming, even though repetition-priming was still present (i.e. ALD=1-LD>ID).

For Medium N level words there was a small shift towards increased specificity of lexical tuning, with an increase in the number of participants showing the highest level of tuning (i.e. ALD=1-LD>ID). More importantly though, there were still considerable differences between participants in the specificity of their lexical processes. This changed for High N words, with almost all the participants displaying finely tuned lexical entries for these targets (i.e. ALD=1-LD>ID).

Overall, the results shown in Table 5 indicate a general shift towards more finely tuned lexical processing with increasing N densities; a result which ties in with previous research (e.g. Forster, 1987). More importantly, however, these results demonstrate the variability between subjects in their tuning level, especially at the Low and Medium N densities; illustrated by the variation in priming patterns at these levels.

In addition to demonstrating an overall shift to fine tuning as N increases, the data obtained in this study allowed for investigation into the nature of this shift within each participant, by looking at their individual patterns of effects across N levels. Although space does not permit a full account of this data, three groups accounted for the majority of participants. The largest of these (n=16) followed the priming pattern shown in the overall group analyses. That is, these participants showed finely tuned entries for High N level targets (i.e. ALD=1-LD>ID) but slightly less tuned entries for Medium and Low N words (i.e. ALD>1-LD>ID). The second largest group (n=10) showed fine tuning (i.e. ALD=1-LD>ID) which was unaffected by changes in N level, while the third (n=6) differed from this only by having less tuning for entries at Low N densities (i.e. ALD>1-LD>ID). The remaining participants showed variations upon these themes.

Nonwords

Each participant's nonword data was analysed in the same manner as the group data, beginning with a single omnibus analysis. As with the group analyses; none of the 50 participants showed an interaction between the N Level and Prime Type factors, which was expected given that N density only tunes *lexical* representations. Forty-six participants showed a main effect of N Level and 30 showed a main effect of Prime Type. Again these effects were investigated with separate subsequent analyses.

Forty of the participants' N level effects followed the same pattern as seen in the group analyses, that is, RTs to Low N targets were significantly faster than those of the Medium or High N targets. However, there seemed to be at least some variation being masked by the group study approach. One participant's Low *and* Medium N nonword targets showed a response time advantage over High N targets, while two further participants showed RT differences between each N level (i.e. RTs increasing with N level). In addition, two participants had non-secure N level effects. Each of these variations of N level effects could be explained by the fact that with increasing N density, lexical processes have more competing entries to

eliminate before concluding a nonword. Perhaps the individual pattern variation could be accounted for by variations in sensitivity to these competitors.

Half of the participants with Prime Type effects showed a similar pattern to that seen with the group analyses; that is, an equivalent RT advantage for both the 1-LD and ID conditions. Three participants showed an RT advantage for the ID condition only, while a further 12 had non-secure effects. For these 30 participants, differences between the repetition-priming effects for nonwords overall and words at each N level were calculated (Low: M=41, SE=3.3; Medium: M=36, SE=3.2; High: M=27, SE=3.4). Consistent with the group analyses, these mean differences indicate large reductions in the magnitude of nonword priming effects, compared to word priming, for these participants. It would seem that individual differences in performance are not restricted to lexical processing, but also extend to the level of graphemic priming induced by orthographically related prime-target pairs.

Conclusions

Although space constraints precluded the reporting and interpretation of the full data from this study, one major conclusion can be drawn. Although the group data were consistent with previous studies of neighbourhood density, the Multiple Session Masked Priming results revealed the group approach was masking an array of individual differences in lexical tuning. Indeed, individual variation was also evident in the existence of pre-lexical, graphemic processing.

A simple explanation of the source of such variation may be that the internal coding of representations are handled differently between the lexical processors of individuals. This may be due to some predisposition and/or individualised set of experiences, but at this stage far more would need to be known about individual differences in other aspects of written word recognition in order to make a more specific claim.

The results of this study suggest that future research should consider the Multiple Session Masked Priming paradigm and look more carefully at other fundamental claims about lexical processing drawing solely on group outcomes, in the hope of developing more sensitive models of lexical access and written word recognition.

Acknowledgments

The authors wish to thank the reviewers of this paper for their comments. Special thanks also to Ken Forster for his invaluable suggestions.

Abstract

This paper introduces a new algorithm for calculating semantic similarity within and between texts. We refer to this algorithm as NLS, for Non-Latent Similarity. This algorithm makes use of a second-order similarity matrix (SOM) based on the cosine of the vectors from a first-order (non-latent) matrix. This first-order matrix (FOM) could be generated in any number of ways; here we used a method modified from Lin (1998). Our question regarded the ability of NLS to predict word associations. We compared NLS to both Latent Semantic Analysis (LSA) and the FOM. Across two sets of norms, we found that LSA, NLS, and FOM were equally predictive of associates to modifiers and verbs. However, the NLS and FOM algorithms better predicted associates to nouns than did LSA.

Introduction

Computationally determining the semantic similarity between textual units (words, sentences, chapters, etc.) has become essential in a variety of applications, including web searches and question answering systems. One specific example is AutoTutor, an intelligent tutoring system in which the meaning of a student answer is compared with the meaning of an expert answer (Graesser, P. Wiemer-Hastings, K. Wiemer-Hastings, Harter, Person, & the TRG, 2000). In another application, called Coh-Metrix, semantic similarity is used to calculate the cohesion in text by determining the extent of overlap between sentences and paragraphs (Graesser, McNamara, Louwerse & Cai, in press; McNamara, Louwerse, & Graesser, 2002).

Semantic similarity measures can be classified into Boolean systems, vector space models, and probabilistic models (Baeza-Yates & Ribeiro-Neto, 1999; Manning & Schütze, 2002). This paper focuses on vector space models. Our specific goal is to compare Latent Semantic Analysis (LSA, Landauer & Dumais, 1997) to an alternative algorithm called Non-Latent Similarity (NLS). This NLS algorithm makes use of a second-order similarity matrix (SOM). Essentially, a SOM is created using the cosine of the vectors from a first-order (non-latent) matrix. This first-order matrix (FOM) could be generated in any number of ways. However, here we used a method modified from Lin (1998). In the following sections, we describe the general concept behind vector space models, describe the differences between the metrics examined, and present an evaluation of these metrics' ability to predict word associates.

Vector Space Models

The basic assumption behind vector space models is that words that share similar contexts will have similar vector representations. Since texts consist of words, similar words will form similar texts. Therefore, the meaning of a text is represented by the sum of the vectors corresponding to the words that form the text. Furthermore, the similarity of two texts can be measured by the cosine of the angle between two vectors representing the two texts (see Figure 1).

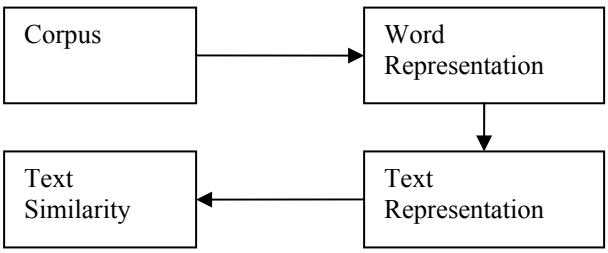

Figure 1. From Corpus to Text Similarity.

The four items of Figure 1 can be described as follows. First, the corpus is the collection of words comprising the target texts. Second, word representation is a matrix G used to represent all words. Each word is represented by a row vector g of the matrix G. Each column of G is considered a "feature". However, it is not always clear what these features are. Third, text representation is the vector $v = G^{T}a$ representing a given text, where each entry of a is the number of occurrences of the corresponding word in the text. Fourth, text similarity is represented by a cosine value between two vectors.

More specifically, Equation 1 can be used to measure the similarity between two texts represented by a and b,

respectively. For reasons of clarity, we do not include word weighting in this formula.

$$sim(a,b) = \frac{a^T GG^T b}{\sqrt{a^T GG^T a}\sqrt{b^T GG^T b}} \quad (1)$$

Latent Semantic Analysis (LSA)

LSA is one type of vector-space model that is used to represent world knowledge (Landauer & Dumais, 1997). LSA extracts quantitative information about the co-occurrences of words in documents (paragraphs and sentences) and translates this into an *N*-dimensional space. The input of LSA is a large co-occurrence matrix that specifies the frequency of each word in a document. Using singular value decomposition (SVD), LSA maps each document and word into a lower dimensional space. In this way, the extremely large co-occurrence matrix is typically reduced to about 300 dimensions. Each word then becomes a weighted vector on *K* dimensions. The semantic relationship between words can be estimated by taking the cosine between two vectors. This algorithm can be briefly described as follows.

(1) Find the word-document occurrence matrix *A* from a corpus[1].
(2) Apply SVD: $A = U\Sigma V^T$.
(3) Take the row vectors of the matrix *U* as the vector representations of words.

Non-Latent Similarity (NLS) Model

NLS is proposed here as an alternative to latent similarity models such as LSA. NLS relies on a first order, non-latent matrix that represents the non-latent associations between words. The similarity between words (and documents) is calculated based on a second-order matrix. The second order matrix is created from the cosines between the vectors for each word drawn from the FOM. Hence, for NLS, the cosines are calculated based on the non-latent similarities between the words, whereas for LSA, the similarities are based on the cosines between the latent vector representations of the words. The following section describes the components and algorithms used in NLS.

Lin's (1998) Algorithm Our starting point for NLS is Lin's (1998) algorithm for extracting the similarity of words. Similarity is based upon the syntactic roles words play in the corpus. A syntactic role is designated here as a feature. For example, "the Modifier of the NP *man*" is a feature. A word has this feature if and only if it is used as the modifier of *man* when *man* is part of an NP in the corpus. For example, if the corpus contains the phrase *the rich man*, then *rich* has the (adjectival) feature of modifying *man.* Each feature is assigned a weight to indicate the feature's importance. This algorithm is briefly described as follows.

(1) For each word base, form a feature vector.
(2) For each pair of word bases, find the similarity of two word bases from the corresponding two feature vectors.

In Lin's algorithm, the similarity is calculated according to Equation 2.

$$sim(w_1, w_2) = \frac{2 \times I(F(w_1) \cap F(w_2))}{I(F(w_1)) + I(F(w_2))} \quad (2)$$

$F(w)$ is the set of features possessed by the word w and $I(F)$ is the "information" contained in the feature set F: $I(F) = \sum_{f \in F} u(f)$. u is the weight function of the feature f.

First-Order Matrix LSA is referred to as latent because the content is not explicit or extractable after SVD. Thus, the features that two similar words share are "latent." In contrast, every feature is explicit and directly extractable from the matrix using Lin's (1998) algorithm. Hence, it is non-latent, and can be used as a first-order similarity matrix (FOM).

We created the FOM using a modification of Lin's algorithm with cosines rather than proportions. First, we parsed all of the sentences (about 2 million) in the TASA corpus using Lin's MINIPAR parser (Lin, 1998). This provided about 9 million word-relation-word triplets. Table 1 shows the triplets extracted for the sentence *People did live in Asia, however*.

Table 1: An example with word-relation-word triplets.

Word1	Relation	Word2
Live	V:s:N	people
Live	V:aux:Aux	do
Live	V:mod:Prep	in
In	Prep:pcomp-n:N	Asia
Live	V:mod:A	however

A "feature" consists of a word (e.g., Word1 or Word2) and a relation that contains a verb (V), noun (N), or modifier (A). For example, the association between the word *live* and its relation to *people*, which is "V:s:N", comprises two features (*live* - V:s:N; *people* - V:s:N). About 400,000 such features were obtained. Each feature was assigned a weight, using Lin's formula. We adopted an occurrence frequency threshold, which yielded 10363 nouns (occurrence > 50), 5687 verbs (occurrence > 5), and 6890 modifiers (occurrence > 10). For each of the selected words, a feature vector was formed according to the features it involved.

We modified Lin's method in the last step. Specifically, rather than applying Equation 2 to the feature vectors, the cosine between any two feature vectors was calculated. This provided a FOM containing the similarity between all word pairs. In addition, the FOM guarantees a property called "decomposability", which will be addressed in the next section.

[1] Hu et al. (2003, theorem 2) proved that the LSA similarity measure is a special case of (1)

Non-Latent Similarity (NLS) Algorithm The logic behind the use of a second order matrix to represent textual similarity relies on a reformulation of the algorithm used in general vector models. Specifically, Equation 1 can be rewritten as Equation 3.

$$sim(a,b) = \frac{a^T Sb}{\sqrt{a^T Sa}\sqrt{b^T Sb}} \quad (3)$$

When the columns of G are normalized to be unit vectors, S becomes a word-similarity matrix [2]. In other words, each entry of $S, s_{ij} = g_i g_j^T$, is the similarity of two words represented by row vectors g_i and g_j, respectively. Essentially, a word-similarity matrix (S) is used rather than word representation vectors (G).

From Equation 3 we can see that the similarity of two texts is determined by two factors: the word occurrences in each text and the similarity between words. Since we can do little to the occurrence vectors (other than applying word weighting), the word similarity matrix will determine the validity of the measure of text similarity. In other words, Equation 3 provides a good measure if and only if similar words have similar vector representations. If similar words have dissimilar vector representations or dissimilar words have similar representations, then the measure provided by Equation 3 is unreliable. Therefore, the verification of the validity of the word representation, at least in terms of text similarity comparison, is equivalent to the verification of the validity of the word similarity matrix (or FOM in this case).

While it is not possible to directly judge the quality of a vector representation, it is possible to judge the validity of word similarity. Provisions for such a judgment will be made in the next section of this paper.

Equation 3 raises an important question: Instead of creating the similarity matrix S by the word representation matrix G, can we find the similarity matrix by any other method that provides a better word similarity measure? One of the conditions under which this question may be answered is that the similarity matrix S, no matter how it is created, must be decomposable. That is, there exists a matrix G (we do not have to find it) such that $S = GG^T$. This condition is necessary to guarantee that the value calculated from Equation 3 ranges from -1 to 1.

The FOM that we generated by the modified Lin's method is decomposable and can therefore be used in Equation 3 for text comparison. However, that matrix is high-dimensional (N by N, where N is the total number of words). This will cause some computational complexity. To reduce the number of dimensions, we kept only the 400 largest similarity values for each word and set the other smaller values to be zero. Thus, the similarity matrix became sparse and the computational complexity was reduced. However, this made the similarity matrix un-decomposable and invalid for Equation 3.

[2] The normalization guarantees that the similarity between any two words will not exceed the similarity of a word to itself and that the values are in a known range [-1,1].

The decomposability therefore raises a new question: Is there a straightforward way to guarantee both decomposability and validity of the similarity matrix S? An easy way of guaranteeing these criteria is by using a word similarity matrix to act as a word representation matrix.

Suppose S is a word similarity matrix regardless of its creation method. Then each column vector in S contains the similarities of a particular word to all other words. Therefore, each column vector can represent the corresponding word.

Table 2. A small section of a first order matrix.

	chair	table	strength
desk	0.16	0.17	0
bed	0.14	0.13	0
speed	0	0	0.14
success	0	0	0.11

Table 2 is a small section of our FOM. It can be seen that the column vectors for *chair* and *table* are very similar to each other, but quite different from that of "strength". In the complete matrix, *desk* is the 4th nearest neighbor of (i.e., most similar to) *chair* and the 1st nearest neighbor of *table*. In addition, *bed* is the 2nd nearest neighbor of *chair* and the 5th nearest neighbor of *table* (see http://cohmetrix.memphis.edu/wordsim/wf1.aspx).

If we believe that similar words should share most nearest neighbors (a group of words that are most similar to a given word), then similar words should have similar column vectors in S. Therefore, we can create a new word similarity matrix by the cosine between the column vectors of S, $\tilde{S} = D^T S^T SD$, where D is a diagonal matrix formed by the reciprocal of the norms of the column vectors of S. We call $\tilde{S}$ the second-order word similarity matrix (SOM) and S the first-order similarity matrix (FOM). This new matrix $\tilde{S}$ is obviously decomposable and should maintain the validity of the original word similarity matrix.

If the SOM is valid, then we can form a measure based on the FOM:

$$sim(a,b) = \frac{a^T D^T S^T SDb}{\sqrt{a^T D^T S^T SDa}\sqrt{b^T D^T S^T SDb}} \quad (4)$$

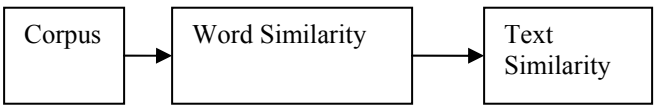

Figure 2. From Corpus to Text Similarity (SOM).

Equation 4 provides a new algorithm for text comparison, which relies solely on the similarity matrix. We call this algorithm the Non-Latent Similarity (NLS) algorithm, assuming that the FOM is non-latent. Figure 2 shows the difference between NLS and the general vector-space model. When compared with Figure 1, we can see that the "representations" are replaced by the similarity matrix.

Evaluation

In this section, we compare NLS to LSA to examine the differences between the latent analytic method exemplified by LSA and the non-latent method of NLS. We examine the validity of these two methods by examining their ability to predict word associates obtained from two sources of free association norms. We also examine the ability of the FOM to predict these word associates. The ability of FOM and NLS to predict word associates should be reflective of the overall validity of NLS to predict similarity of text corpora, which is crucial to our new algorithm shown in Equation 4.

We have two concerns. First, is our FOM valid? Second, if our FOM is valid, then will the second order similarity matrix (SOM) be valid as well? To answer these questions, we compared the validity of the following three similarity matrices generated by three different methods.

- *LSA*: The similarity matrix created from TASA corpus by LSA.
- *FOM*: The similarity matrix created from TASA corpus using the modified version of Lin's method.
- *NLS*: The second order similarity matrix based on the above *FOM*.

Our overall question addressed the ability of the three similarity metrics (LSA, FOM, and NLS) to correctly list word associates. We were also interested in examining how this ability varied as a function of several variables. First, we were interested in whether the results remained stable across norming databases. We chose to use two sets of free association norms: the Edinburgh Associative Thesaurus (EAT; Kiss, Armstrong, Milroy, & Piper, 1973) and the University of South Florida Free Association Norms (USFFAN; Nelson, McEvoy, & Schreiber, 1998).

We were also interested in how the results differed across word types (i.e., nouns, verbs, vs. adjectival/adverbial modifiers). One difference between the three classes of words is the amount of semantic contextualization. Specifically, the meaning of verbs and modifiers is usually context dependent, whereas the meaning of nouns is less dependent on the context (e. g., Graesser, Hopkinson & Schmid, 1987). For example, in the phrase *a big house*, the size of the adjectival modifier *big* depends on the noun *house*. It could be argued, moreover, that words that are more concrete are less context-dependent. Adjectives are less concrete than nouns so they would be more context-dependent. A similar argument could be made for verbs, which are more context dependent than nouns.

We expected the context-dependency factor to most affect the performance of LSA, because the success of LSA relies heavily on the occurrence of words in similar contexts, and essentially taps into that factor to assess word similarity. The basic assumption behind LSA is that words used in similar context have similar representations. Thus, if a word is less context-dependent, LSA may be less able to tap into associations.

While NLS similarly uses semantic context to compute similarity, it also uses syntactic context. The word similarities are extracted not only from the similar semantic context but also from the similar syntactic roles that the words play. That is, the FOM includes syntactic relations as features, whereas word order and the relations between words are ignored in LSA. Thus, we expected LSA to be less successful in identifying the associates of nouns as compared to modifiers and verbs. We did not expect this factor to affect the performance of NLS. We expected that FOM and NLS would be sensitive to both context based and non-context based associations.

To examine these factors, we randomly selected 135 common words, composed of 45 modifiers (including adjectives and adverbs), 45 nouns, and 45 verbs. We then determined the first most commonly listed and the second most commonly listed associate to those words, based on the association norms provided by EAT and the USFFAN. Finally, we determined whether each of the three similarity metrics listed the first and second most commonly listed associate from the respective norm database. A criterion was set in the following analyses: A metric identifies an associate of a word if, according to the metric, the associate is among the top five nearest neighbors of the word. While not extremely strict, the cutoff was intended to be relatively conservative compared to setting the cutoff at 20 words.

Results

Table 3 shows the proportion associates identified by each metric. A 3 x 2 x 2 analysis of variance (ANOVA) was conducted that included the between-words variable of word type (noun, verb, adjectival/adverbial modifier) and the within-words variables of associate (first, second) and database (EAT, USFFAN).

Table 3: Proportion of correctly identified associates listed in the top five nearest neighbors provided by LSA, FOM, and NLS as a function of the free association norms and word types.

	EAT			USFFAN		
	Mod	Noun	Verb	Mod	Noun	Verb
Associate 1						
LSA	0.40	0.11	0.16	0.31	0.07	0.13
FOM	0.40	0.36	0.13	0.31	0.31	0.16
NLS	0.38	0.36	0.11	0.27	0.36	0.13
Associate 2						
LSA	0.07	0.04	0.09	0.13	0.04	0.18
FOM	0.18	0.11	0.11	0.16	0.16	0.11
NLS	0.16	0.11	0.11	0.13	0.13	0.16

There was a main effect of word type, $F(2, 132) = 3.4$, $MSE = .471$, $p < .05$. Bonferroni Means tests indicated that the proportion of associates identified for modifiers ($M = .243$) was significantly greater than for verbs ($M = .122$), but not significantly greater than for nouns ($M = .187$). There was an effect of associate, $F(1, 131) = 19.5$, $MSE = .330$, $p<.001$, reflecting a greater proportion of first

associates identified (M = .250) than second associates (M = 0.120). There was also an interaction between word type and associate, $F(2, 131) = 4.2$, $p < .05$. This interaction reflected an effect of word type for first associates, $F(2,132) = 5.5$, $MSE = .533$, $p<.01$ ($M_{modifier} = .34$ $M_{noun} = .26$ $M_{verb} = .14$), compared to no differences between word types for second associates, $F<1$, ($M_{modifier} = .14$, $M_{noun} = .11$, $M_{verb} = .12$). Thus, the metrics were unable to identify the second associates, regardless of word type.

Finally, there was significant effect of similarity metric, $F(2,264) = 4.6$, $MSE = .139$, $p < .05$, and an interaction between metric and word type, $F(4,264) = 4.1$, $p<.01$. This interaction is depicted in Figure 3. The interaction reflects the finding that the three metrics were equally successful in identifying the associates to modifiers and verbs, whereas FOM and NLS were significantly more successful in identifying the associates to nouns than was LSA, $F(2,88)= 4.1$, $MSE = .052$, $p < .05$.

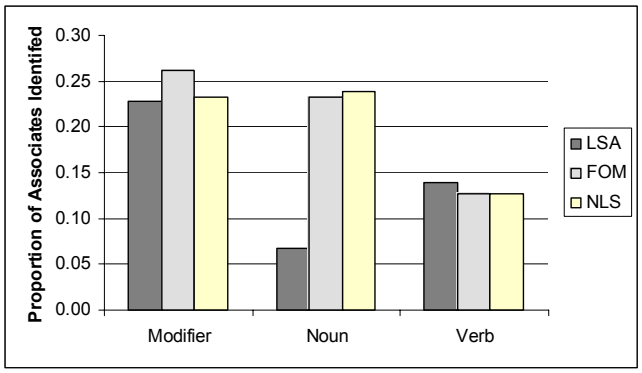

Figure 3. Proportion of associates identified (in the top 5 of the list) by the three similarity metrics.

These results did not depend on where the cutoff was drawn, (e.g., top 5 vs. top 20). Of course, the means increased with a more lax cutoff. For example, the overall accuracy of associate identification for LSA increased from 20% to 28% when the cutoff was set at 20 (i.e., when 20 of the words output by LSA were considered). Similarly, the overall accuracy for NLS increased from 27% to 42% when the cutoff was set at 20 words. Thus, there was a 140% and 157% increase respectively for LSA and NLS. The results also remained the same when word frequency was entered as a covariate. Essentially, these trends emerged regardless of how we examined the data.

There were no differences as a function of norming database. This indicates that the results we have reported should remain stable across norming databases.

Conclusions

In summary, we have provided an alternative algorithm, NLS, which makes it possible to use any non-latent similarity matrix to compare text similarity. This algorithm uses a second-order similarity matrix (SOM) that is created using the cosine of the vectors from a first-order (non-latent) matrix. This FOM could be generated in any number of ways. We used a modified form of Lin's (1998) algorithm to extract non-latent word similarity from corpora. Our evaluation of NLS compared its ability to predict word associates to the predictions made by the FOM and LSA. The critical difference between the algorithms addressed the latency of the word representations. The use of SVD results in latent word representations in LSA, whereas the use of the syntax parser in NLS results in a non-latent representation. We found that NLS, using the similarity matrix that we generated, identified the associates to modifiers and nouns relatively well. Both LSA and NLS were equally able to identify the associations to the modifiers. In contrast, none of the metrics successfully identified the associates to the verbs.

FOM versus NLS

There were two motivations for examining the results from the FOM as well as NLS. The first was to examine the validity of using a FOM. The second was to examine the correspondence in results between FOM and NLS. That is, if the FOM is valid, is the SOM valid as well? We found that NLS and FOM were equally successful in identifying all types of associations. This result indicates that SOM maintains the validity of FOM. The result supports the validity of using the NLS algorithm.

One consideration is that the second order similarity matrix may reveal new similarity relations which do not exist or are weak in the FOM. It is not hard to imagine that two words that have weak similarity in FOM may share some nearest neighbors and thus reveal a stronger relation between the two words in SOM. Nonetheless, we found here that the second-order matrix maintains the validity of FOM as much as possible, assuming the FOM is valid. When the FOM is decomposable, it can be directly used in NLS. The SOM is used when FOM is computationally heavy or is not decomposable. Our future investigations will work toward a better understanding of the situations that require a SOM as opposed to a FOM, or vice versa.

LSA versus NLS and FOM

We confirmed our predicted results that LSA would be less accurate in identifying the associates to context-independent nouns than to adjectival or adverbial modifiers, which have greater context dependency. We further predicted that this difference would not occur for NLS and the FOM. Indeed, NLS and FOM were equally predictive of noun and modifier associates. Thus, one advantage of NLS is that it makes use of both semantic and syntactic information within the text corpora. Specifically, the FOM includes both syntactic and semantic relations as features. Here, we have documented this advantage solely with respect to word similarities. However, we expect that this advantage will also improve the detection of similarity across larger bodies of text.

Verbs versus Nouns and Modifiers

One result that has baffled us is why NLS and LSA are both unable to pick up on the associates to the verbs. We

considered several explanations. First, one might think that the number of forms of the word would be a factor to consider. Since verbs tend to have more forms than do modifiers (e.g., *add* has four forms: *add, added, adding, adds*), a typical vector space model would contain relatively less information about any one form of the verb. This factor may explain the inability of LSA to identify the associates to verbs. However, it cannot do so for NLS because we used the word base, not the word itself, when forming the matrix.

We further considered that humans may have produced a greater variety of associates to verbs than to nouns or modifiers. If so, then across the two databases (i.e., EAT and USFFAN), the match between the associates in one database to another should vary as a function of word type. However, this was not the case. The two databases matched the first associate for 69% of the words, with no differences across word types. There was lower agreement (40%) and greater variance for the second associate, but not in the expected direction.

An alternative explanation regards the contextualization of verbs as compared to nouns. As we stated earlier, the meaning of verbs is more dependent on semantic context than are nouns. In addition, verbs seem to be used in a wider variety of contexts. Whereas a person can do only so much with a *chair*, the person can *sit* just about anywhere and anyhow. One can imagine eating, walking, and thinking in any number of contexts, whereas the contexts for chairs and cars are more constrained. Hence, semantic context is more variable for verbs than for nouns. This variability may render models such as NLS or LSA unable to determine the 'meaning' of verbs.

This idea is in line with notions of how verbs are represented with semantic representations. Generally, verbs are treated as the links between the concepts. Verbs constitute the relations or links between nodes. Essentially, we see here that vector space models are less able to abstract meanings of relations than the meanings of concepts.

This notion gains clarity when we examine the associates to verbs that were provided by LSA and NLS. The EAT associates to *try* are *attempt* and *again*. LSA's top five predictions were *do*, *if, you*, *can*, and *wa*y. FOM's predictions were *think*, *say*, *go*, *know*, and *ask*. We can provide many examples such as these where the associates produced by the metric make little sense. The associations predicted for nouns and modifiers, in contrast, showed obvious relationships to the target word. This observation leads us to conclude that these metrics are not able to use contextual information of verbs, perhaps because that information is not available.

Abstract

Do the languages that we speak affect how we experience the world? This question was taken up in a linguistic survey and two non-linguistic psychophysical experiments conducted in native speakers of English, Indonesian, Greek, and Spanish. All four of these languages use spatial metaphors to talk about time, but the particular metaphoric mappings between time and space vary across languages. A linguistic corpus study revealed that English and Indonesian tend to map duration onto linear distance (e.g., a *long* time), whereas Greek and Spanish preferentially map duration onto quantity (e.g., *much* time). Two psychophysical time estimation experiments were conducted to determine whether this cross-linguistic difference has implications for speakers' temporal thinking. Performance on the psychophysical tasks reflected the relative frequencies of the 'time as distance' and 'time as quantity' metaphors in English, Indonesian, Greek, and Spanish. This was true despite the fact that the tasks used entirely non-linguistic stimuli and responses. Results suggest that: (1.) The spatial metaphors in our native language may profoundly influence the way we mentally represent time. (2.) Language can shape even primitive, low-level mental processes such as estimating brief durations – an ability we share with babies and non-human animals.

Introduction

"Are our own concepts of 'time,' 'space,' and 'matter' given in substantially the same form by experience to all men, or are they in part conditioned by the structure of particular languages?" (Whorf, 1939/2000, pg. 138.) This question, posed by Benjamin Whorf over half a century ago, is currently the subject of renewed interest and debate. Does language shape thought? The answer *yes* would call for a reexamination of some foundational theories that have guided Cognitive Science for decades, which assume both the universality and the primacy of non-linguistic concepts (Chomsky, 1975; Fodor, 1975). Yet despite unreserved belief among the general public that people who talk differently also think differently (ask anyone about the Eskimos' words for snow), it has remained widely agreed among linguists and psychologists that they do not.

Skepticism about some Whorfian claims has been well founded. Two crucial kinds of evidence have been missing from many previous inquiries into relations between language and thought: objectively evaluable linguistic data, and language-independent psychological data. A notorious fallacy, attributable in part to Whorf, illustrates the need for methodological rigor. Whorf (1939) argued that Eskimos must conceive of snow differently than English speakers because the Eskimo lexicon contains multiple words that distinguish different types of snow, whereas English has only one word to describe all types. The exact number of snow words the Eskimos were purported to have is not clear. (This number has now been inflated by the popular press to as many as two-hundred.) According to a Western Greenlandic Eskimo dictionary published in Whorf's time, however, Eskimos may have had as few as two distinct words for snow (Pullum, 1991).

Setting aside Whorf's imprecision and the media's exaggeration, there remain two problems with Whorf's argument, which are evident in much subsequent 'Language and Thought' research, as well. First, although Whorf asserted an objective difference between Eskimo and English snow vocabularies, his comparative linguistic data were subjective and unfalsifiable: it is a matter of opinion whether any cross-linguistic difference in the number of snow words existed. As Geoffrey Pullum (1991) points out, English could also be argued to have multiple terms for snow in its various manifestations: *slush, sleet, powder, granular*, *blizzard, drift, etc*. The problem of unfalsifiability would be addressed if cross-linguistic differences could be demonstrated empirically, and ideally, if the magnitude of the differences could be quantified.

A second problem with Whorf's argument (and others like it in the contemporary Cognitive Linguistics literature) is that it uses purely linguistic data to motivate inferences about non-linguistic thinking. Steven Pinker illustrates the resulting circularity of Whorf's claim in this parody of his reasoning: "[Eskimos] speak differently so they must think differently. How do we know that they think differently? Just listen to the way they speak!" (Pinker, 1994, pg. 61). This circularity would be escaped if non-linguistic evidence could be produced to show that two groups of speakers who talk differently also think differently in corresponding ways.

[†]Corresponding author: Daniel Casasanto (djc@mit.edu)

But what counts as 'non-linguistic' evidence? Recent studies have tested predictions derived from cross-linguistic differences using behavioral measures such as accuracy and reaction time. Oh (2003) investigated whether Korean and English speakers would remember motion events differently, consistent with the way motion is habitually encoded in their native languages (i.e., in terms of 'path' or 'manner' of motion). Participants described videos of motion events, and then took a surprise memory test probing small details of the videos. Oh found that, as expected, English speakers used more manner-of-motion verbs in their video descriptions than Korean speakers. English speakers also performed better than Koreans on the manner-relevant portion of the memory test. Oh refers to the memory task as 'non-linguistic,' yet the questions were posed using motion language, and participants may have recalled their own verbal descriptions of the videos while responding.

Boroditsky (2001) investigated whether speakers of English and Mandarin think differently about time. English typically describes time as horizontal, while Mandarin commonly uses vertical spatiotemporal metaphors. Boroditsky found that English speakers were faster to judge sentences about temporal succession (e.g., *March comes earlier than April*) when primed with a horizontal spatial event, but Mandarin speakers were faster to judge the same sentences when primed with a vertical spatial stimulus. This was true despite the fact that all of the sentences were presented in English.

These studies by Oh and Boroditsky support a version of the Whorfian hypothesis which Slobin (1986) has termed *thinking for speaking*: language can affect thought when we are thinking with the intent to use language, plausibly by directing attention to elements of our experience that are ordinarily encoded in the language we speak. For instance, because English tends to encode information about manner of motion more often than Korean does, Oh's English subjects may have automatically attended to the manner information in the videos more than her Korean subjects did. Some researchers have characterized the effects of thinking for speaking as uninterestingly weak (Pinker, 1994; Papafragou, Massey, & Gleitman, 2002). Results such as Oh's and Boroditsky's suggest otherwise: at minimum, thinking for speaking appears to influence ubiquitous cognitive processes such as attention and memory, and is capable of changing the nature of our abstract mental representations. Furthermore, habits formed while thinking for speaking are likely to be practiced even when people are not explicitly encoding information for language. We never know when we might want to talk about an event at some later point, so it is in our best interest to encode language-relevant details as a matter of policy.

Can the influence of language on thought go beyond thinking for speaking? Much of our mental life is unutterable: what words can capture the sound of a clarinet, or explain the color *red* to a blind person (Locke, 1689/1995; Wittgenstein, 1953)? Can peculiarities of our native language shape even the deep, primitive kinds of representations that we share with pre-linguistic infants and non-human animals? Previous research suggests that language can affect our high-level linguistic and symbolic representations in the abstract domain of time (Boroditsky, 2001). The goal of the present study was to find out whether language can also shape our low-level, non-linguistic, non-symbolic temporal representations. A linguistic study was conducted to investigate a previously unexplored pattern in spatiotemporal metaphors, and to quantify cross-linguistic differences in the way these metaphors are used by speakers of English, Indonesian, Greek, and Spanish (Experiment 1). To determine whether these cross-linguistic differences have consequences for speakers' non-linguistic time representations, the results of the linguistic study were used to predict performance on a pair of psychophysical time estimation tasks, with entirely non-linguistic stimuli and responses (Experiments 2 and 3).

Experiment 1:
Time in a Bottle or Time on the Line?

Linguists have noted that spatial metaphors are often used to talk about non-spatial phenomena -- in particular abstract phenomena such as social rank (e.g., a *high* position), mathematics (e.g., a *low* number), and time (e.g., a *long* vacation) (Clark, 1973; Gibbs, 1994; Jackendoff, 1983; Lakoff & Johnson, 1980). Recently, psychologists have begun to explore the proposal that these metaphors in language provide a window on our underlying mental representations in abstract domains, using the domain of time as a testbed (Boroditsky, 2000, 2001; Boroditsky & Ramscar, 2002; Casasanto & Boroditsky, 2003; Gentner, 2001). In general, this work has focused on how time can be expressed (and by hypothesis conceptualized) in terms of linear space. Linear spatiotemporal metaphors are pervasive in English, and are used to talk about various aspects of time, including succession (e.g., Monday comes *before* Tuesday), motion through time (e.g., Let's move the meeting *forward*), and duration (e.g., a *short* intermission). But is time necessarily conceptualized in terms of uni-dimensional space? English speakers also talk about *oceans of time, saving time in a bottle*, and compare epochs to *sand through the hourglass*, apparently mapping time onto volume.

Experiment 1 compared the use of 'time as distance' and 'time as quantity' metaphors across languages. Every language examined so far uses both distance and quantity metaphors, but their relative prevalence and productivity appear to vary markedly. In English, it is natural to talk about *a long time*, borrowing the structure and vocabulary of a spatial expression like *a long rope.* Yet in Spanish, the direct translation of 'long time', *largo tiempo*, sounds awkward to speakers of most dialects. *Mucho tiempo*, which means 'much time', is preferred.

In Greek, the words *makris* and *kontos* are the literal equivalents of the English spatial terms *long* and *short*. They can be used in spatial contexts much the way *long* and *short* are used in English (e.g., *ena <u>makry</u> skoini* means 'a

long rope'). In temporal contexts, however, *makris* and *kontos* are dispreferred in instances where *long* and *short* would be used naturally in English. It would be unnatural to translate *a long meeting* literally as *mia makria synantisi*. Rather than using distance terms, Greek speakers typically indicate that an event lasted a long time using *megalos*, which in spatial contexts means physically 'large' (e.g., a big building), or using *poli*, which in spatial contexts means 'much' in physical quantity (e.g., much water). Compare how English and Greek typically modify the duration of the following the events (literal translations in parentheses):

1e. long night
1g. megali nychta (*big night*)
2e. long relationship
2g. megali schesi (*big relationship*)
3e. long party
3g. parti pou kratise poli (*party that lasts much*)
4e. long meeting
4g. synantisi pou diekese poli (*meeting that lasts much*)

In examples 1g. and 2g., the literal translations might surprise an English speaker, for whom *big night* is likely to mean 'an exciting night', and *big relationship* 'an important relationship'. For Greek speakers, however, these phrases communicate duration, expressing time not in terms of uni-dimensional space, but rather in terms of physical quantity (i.e., three-dimensional space).

For Experiment 1, the most natural phrases expressing the ideas 'a long time' and 'much time' were elicited from native speakers of English, Indonesian, Greek, and Spanish (see table 1). The frequencies of these expressions were compared in a very large multilingual text corpus: www.google.com. Each expression in table 1 was entered as a search term. Google's language tools were used to find exact matches for each expression, and to restrict the search to web pages written only in the appropriate languages.

Table 1: Distance and quantity metaphors for duration.

	Distance	Quantity
English	long time	much time
Indonesian	waktu panjang	waktu banyak
Greek	makry kroniko diatstima	poli ora
Spanish	largo tiempo	mucho tiempo

Results The number of google 'hits' for each expression was tabulated, and the percentage of distance hits and quantity hits was calculated for each pair of expressions, as a measure of their relative frequency (see figure 1). Results showed that in English and Indonesian, distance metaphors were more frequent than quantity metaphors. The opposite pattern was found in Greek and Spanish. A Chi-Square test showed that the relationship between distance and quantity metaphors varied significantly across languages (X^2=8.5x10^5,df=3, p<0.0001). These findings corroborate native speakers' intuitions for each language. Additional quantitative studies are in progress to validate these results.

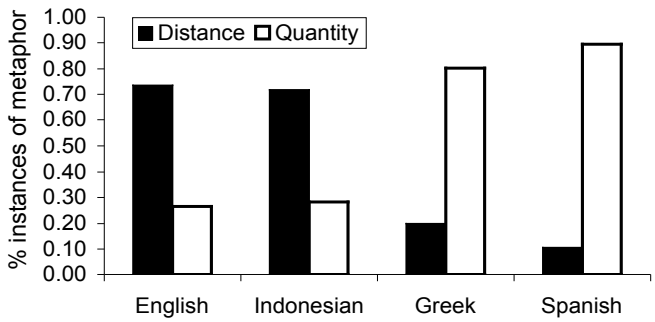

Figure 1: Corpus search results. Black bars indicate the percentage of distance metaphors and white bars the percentage of quantity metaphors found for each language.

Experiments 2 & 3:

Do People Who Talk Differently Think Differently?

How might this difference in the way English, Indonesian, Greek, and Spanish speakers talk about time affect the way they think about it? Linguists and psychologists have argued that our conception of time is intimately dependent on our knowledge of space, noting that in many languages, people can hardly avoid using spatial words when they talk about time (Clark, 1973; Gibbs, 1994; Jackendoff, 1983; Lakoff & Johnson, 1980). Behavioral studies show that changing someone's immediate spatial environment or frame of reference can dramatically change the way they interpret temporal language (Boroditsky, 2000; Boroditsky & Ramscar, 2002). But does space influence our temporal thinking even when we are not *thinking for speaking*?

A recent study by Casasanto & Boroditsky (2003) shows that space influences even our low-level, non-linguistic, non-symbolic representations of time. English speakers watched lines 'growing' across a computer screen, one pixel at a time, and estimated either how far they grew or how much time they remained on the screen. Estimates were made by clicking the mouse to indicate the beginning and end of each spatial or temporal interval. Line distances and durations were varied orthogonally, so there was no correlation between the spatial and temporal components of the stimuli. As such, one stimulus dimension served as a distr actor for the other: an irrelevant piece of information that could potentially interfere with task performance. Patterns of cross-dimensional interference were analyzed to reveal relationships between subjects' representations of space and time. Results showed that subjects were unable to ignore irrelevant spatial information when estimating time (even when they were encouraged to do so). Line stimuli of the same average duration were judged to take a longer time when they grew a longer distance, and a shorter time when they grew a shorter distance. In contrast, line duration did not affect subjects' distance estimates. This asymmetric relation between space and time was predicted based on patterns in language: we talk about time in terms of space more than we talk about space in terms of time (Lakoff & Johnson, 1980).

These findings suggest that the metaphoric relationship between time and space is not just linguistic, it is also conceptual. Not only do people talk about time in terms of space, they also think about time using spatial representations. However, the experiments reported in Casasanto & Boroditsky (2003) leave the Whorfian question unanswered: do metaphors in language merely reflect underlying conceptual structures, or might the metaphors we use also play some role in constructing concepts, or establishing their interrelations?

In the present study speakers of four different languages performed the same pair of non-linguistic psychophysical tasks, which required them to estimate time while overcoming spatial interference. It was reasoned that if people's concepts of time and space are substantially the same universally, irrespective of the languages they speak, then performance on these tasks should not differ between language groups. If, on the other hand, the spatiotemporal metaphors people use affect how they represent time and space non-linguistically, then performance should vary in ways predicted by participants' language-particular metaphors.

For Experiment 2, subjects performed a 'growing line' task similar to the task described above. It was reasoned that the English participants in our previous study may have suffered interference of distance on duration estimation, in part, because these notions are conflated in the English language. It is hard to imagine expressing the idea 'a long time' in English without using an adjective that can also indicate spatial extent. Piaget (1927) made a similar suggestion when he observed that young French speaking children often mistook distance for duration, noting that both of these concepts are commonly described in French using the adjective *longue*. We predicted that speakers of 'Distance Languages' (i.e., English and Indonesian) would show a considerable effect of distance on time estimation when performing the growing line task.

If conflations in language contribute to confusions in thought, can distinctions in language help speakers distinguish closely related concepts? We reasoned that speakers of languages that do not ordinarily express duration in terms of distance might have an easier time distinguishing the spatial and temporal information conveyed in our growing line stimuli. We predicted that speakers of 'Quantity Languages' (i.e., Greek and Spanish) would show only a mild effect of distance on time estimation when performing the growing line task.

For Experiment 3, a task complementary to the growing line task was developed. Subjects watched a schematically drawn container of water filling up, one row of pixels at a time, and estimated either how full it became or how much time it remained on the computer screen, using mouse clicks. We predicted the converse pattern of behavioral results for the filling container task as for the growing line task: speakers of Quantity Languages would show a considerable influence of 'fullness' on time estimation, whereas speakers of Distance Languages would show a milder effect.

Methods for Experiment 2: Growing Lines

Subjects A total of 65 subjects participated in exchange for payment. Native English and Spanish speaking participants were recruited from the Greater Boston community, and were tested on MIT campus. Native Indonesian speakers were recruited from the Jakarta community, and were tested at the Cognation Outpost in the Jakarta Field Station of the Max Planck Center for Evolutionary Anthropology. Native Greek speakers were recruited from the Thessaloniki community, and tested at the Aristotle University of Thessaloniki.

Materials Lines of varying lengths were presented on a computer monitor (resolution=1024x768 pixels, dpi=72), for varying durations. Durations ranged from 1000 milliseconds to 5000 milliseconds in 500 millisecond increments. Displacements ranged from 100 to 500 pixels in 50 pixel increments. Nine durations were fully crossed with nine displacements to produce 81 distinct line types. Lines started as a single point and 'grew' horizontally across the screen one pixel at a time, from left to right along the vertical midline. Each line remained on the screen until its maximum displacement was reached.

Written instructions were given prior to the start of the task, in the native language of the participant. Care was taken to avoid using distance metaphors for time. The task itself was entirely non-linguistic, consisting of lines (stimuli) and mouse clicks (responses).

Procedure Participants viewed 162 growing lines, one line at a time. Immediately before each trial, a prompt appeared indicating that the subject should attend either to the line's duration or to its spatial displacement. Space trials and time trials were randomly intermixed.

To estimate displacement, subjects clicked the mouse once on the center of an 'X' icon, moved the mouse to the right in a straight line, and clicked the mouse a second time to indicate they had moved a distance equal to the maximum displacement of the stimulus. To estimate duration, subjects clicked the mouse once on the center of an 'hourglass' icon, waited the appropriate amount of time, and clicked again in the same spot, to indicate the time it took for the stimulus to reach its maximum displacement.

All responses were self-paced. Importantly, for a given trial, subjects reproduced either the displacement or the duration of the stimulus, never both. Response data were collected for both the trial-relevant and the trial-irrelevant stimulus dimension, to ensure that subjects were following instructions.

Methods for Experiment 3: Filling Containers

Subjects A total of 74 subjects participated in exchange for payment. Subjects were recruited at the same time as those who participated in Experiment 2, from the same populations.

Materials and procedure The filling container task was closely analogous to the growing line task (Experiment 2). Participants viewed 162 containers, and were asked to imagine that each was a tank filling with water. Containers were simple line drawings, 600 pixels high and 500 pixels wide. Empty containers filled gradually, one row of pixels at a time, for varying durations and 'volumes,' and they disappeared when they reached their maximum fullness. Nine durations were fully crossed with nine volumes to produce 81 distinct trial types. For each trial, participants estimated either the amount of water in the container (by clicking the mouse once at the bottom of the container and a second time at the appropriate 'water level'), or they estimated the amount of time that the container took to fill (by clicking the hourglass icon, waiting the appropriate time, and clicking it again, as in Experiment 2). Durations ranged from 1000 milliseconds to 5000 milliseconds in 500 millisecond increments. Water levels ranged from 100 to 500 pixels, in 50 pixel increments.

As before, written instructions were given prior to the start of the task, in the native language of the participant. Care was taken to avoid using quantity metaphors for time. The task itself was entirely non-linguistic, consisting of containers (stimuli) and mouse clicks (responses).

Results for Experiments 2 and 3

Both time estimates and space estimates were collected for each subject, but since our present hypothesis concerns effects of language and space on time estimation, only data for the time estimation trials are reported here. (See Casasanto & Boroditsky, 2003 for a discussion of subjects' space estimation in a related task.)

Time estimation, within-domain effects Overall, for both Experiments 2 and 3 subjects' time estimates were highly accurate across all language groups, as indicated by the strong correlations between the actual stimulus duration and subjects' estimated stimulus duration. These correlations did not differ significantly between groups or between tasks (see table 2).

Table 2: Time estimation results for Experiments 2 and 3. Slope and r-square values for the correlation between actual stimulus duration and subjects' grand averaged estimates of stimulus duration. (Perfect performance would be indicated by a slope of 1.00 and r^2 of 1.00.)

	Growing Lines		Filling Containers	
	Slope	r2	Slope	r2
English	0.75	0.999	0.76	0.999
Indonesian	0.71	0.996	0.68	0.997
Greek	0.74	0.995	0.77	0.996
Spanish	0.72	0.996	0.71	0.995

Time estimation, cross-domain effects The within-domain results reported in table 2 are important to establish that subjects were able to estimate time well, and importantly, that subjects estimated time about equally well in all groups, and on both tasks. Of principal interest, however, are the cross-domain effects (i.e., effects of actual distance and actual quantity on estimated time), which are summarized in figure 2.

To investigate the effect of spatial interference on time estimation, grand averaged time estimates in milliseconds were plotted as a function of actual stimulus displacement in pixels (i.e., line length or water level). A line of best fit was computed, and the slope was used as an index of effect strength. In our previous experience with similar tasks, we found the strongest linear effects on the dependent variable (i.e., estimated time) near the middle of the range of the independent variable (i.e., actual stimulus displacement), possibly due to 'endpoint effects' commonly observed in magnitude estimation tasks. For the analyses reported here, the outer points were removed, and the middle five points of the correlations were analyzed.

Cross-domain effects varied markedly across language groups. For the growing line task, English and Indonesian speakers showed a strong effect of distance on time estimation (English: Slope=1.49, r^2=0.98; t=8.5; df=3; $p<0.001$; Indonesian: Slope=1.40, r^2=0.80; t=3.4; df=3; $p<0.01$). By contrast, Greek and Spanish speakers showed weak, non-significant effects of distance on time estimation (Greek: Slope=0.47, r^2=0.33; t=1.2; df=3; *ns*; Spanish: Slope=0.20, r^2=0.13; t=0.7; df=3; *ns*).

For the filling container task, the opposite pattern of results was found. English and Indonesian speakers showed a weak, non-significant effect of volume on time estimation (English: Slope=0.18, r^2=0.12; t=0.6; df=3; *ns*; Indonesian: Slope=0.13, r^2=0.51; t=1.7; df=3; *ns*), whereas Greek and Spanish speakers showed strong effects of volume on time estimation (Greek: Slope=1.24, r^2=0.95; t=6.9; df=3; $p<0.001$; Spanish: Slope=1.16, r^2=0.97; t=8.5; df=3; $p<0.001$).

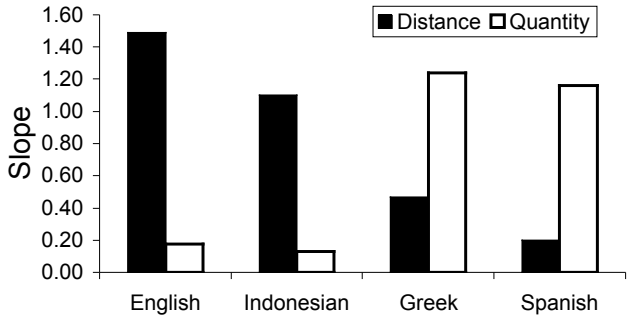

Figure 2: Effects of distance and quantity interference on time estimation.

A 4 x 2 factorial ANOVA with Language and Task as between-subject factors revealed a highly significant Language by Task interaction ($F(3,139) = 5.25$, $p<0.002$), with no main effects, signaling a true crossover interaction.

Linear regression analysis revealed a highly significant positive relation between the frequency of Distance and Quantity metaphors in each language (as measured in Experiment 1) and the amount of Distance and Quantity interference on time estimation (as measured in Experiments 2 and 3) (Slope=1.62, r^2=0.84; t=5.6; df=6; $p<0.001$).

General Discussion and Conclusions

Do people who talk differently also think differently? Performance on a pair of psychophysical time estimation tasks differed dramatically for speakers of different languages, in ways predicted by their language-particular spatiotemporal metaphors. The effects of distance interference and quantity interference on time estimation in speakers of English, Indonesian, Greek, and Spanish corresponded strikingly to the relative prevalence of distance metaphors and quantity metaphors found in these languages (compare figures 1 and 2). This was true despite the fact that the behavioral tasks comprised entirely non-linguistic stimuli and responses.

Returning to the question of Whorf's posed in the introduction, it is possible that our concepts of time and space are "given in substantially the same form by experience" to all of us, *and also* that they are "in part conditioned by the structure of particular languages." Perhaps people learn associations between time and space via physical experience (e.g., by observing moving objects and changing quantities). Since presumably the laws of physics are the same in all language communities, pre-linguistic children's conceptual mappings between time, distance, and quantity could be the same universally. When children acquire language, these mappings could be adjusted, plausibly by a process analogous to Hebbian learning: each time we use a linguistic metaphor, we may invoke the corresponding conceptual mapping. Speakers of Distance Languages then would invoke the time-distance mapping frequently, eventually strengthening it at the expense of the time-quantity mapping (and vice-versa for speakers of Quantity Languages). Alternatively, experience may not teach us to map time onto space. It could be language that causes us to notice structural parallels between these domains, in the first place. On this possibility, language would be responsible for establishing the time-distance and time-quantity conceptual mappings evident in our adult subjects, not just for modifying these mappings. Studies are in progress on young learners of Distance and Quantity languages to explore these possibilities.

The findings we present here are difficult to reconcile with a 'universalist' view of language-thought relations according to which language calls upon pre-formed, antecedently available non-linguistic concepts, which are presumed to be "universal" (Pinker, 1994, pg. 82) and "immutable" (Papafragou, Massey, & Gleitman, 2002, pg. 216). Rather, these results support what we might call a *deep* version of the linguistic relativity hypothesis (to distinguish it from the so-called *weak* version which posits that language affects 'thinking for speaking,' and from *strong* linguistic determinism). The particular languages that we speak can influence not only the representations we build for the purpose of speaking, but also the non-linguistic representations we build for remembering, acting on, and perhaps even perceiving the world around us.

Grammatical Processing Using the Mechanisms of Physical Inference

Abstract

Although there is considerable evidence that humans use the same mechanisms for linguistic and nonlinguistic cognition, the thesis of linguistic modularity will remain plausible so long as well-established formal properties of syntax remain unexplained in terms of domain-general cognitive mechanisms. This paper presents several dualities between the formal structure of syntax and cognitive structures used to represent the physical world. These dualities are used to construct a cognitive model of syntactic parsing that uses only the mechanisms required for infant physical reasoning. The model demonstrates how a formal syntactic constraint, the c-command condition on binding, can be explained by a cognitive process used in physical reasoning. Several consequences for language development and the doctrine of linguistic modularity are considered.

Introduction

Although there is extensive evidence that humans use the same or similar mechanisms for linguistic and nonlinguistic cognition, the precise manner in which nonlinguistic cognitive processes are related to the formal properties of human grammar have yet to be determined.

In the field of linguistic semantics, several researchers have noticed extensive parallels between physical and abstract semantic fields. For example, Jackendoff (1990) has formalized the semantics of many verbs with primitive conceptual structures such as *GO*, *TO*, *FROM*, *PATH*, etc. Leonard Talmy (1985) has shown that semantic fields for psychological, social, argumentative and many other domains involve notions of force dynamics that underlie semantic fields for physical domains. Cognitive psychologists (e.g, Boroditsky, 2001; Spelke & Tsivkin, 2001) have found that the way in which language represents a concept can influence cognition using that concept. Clark's (1996) work culminates a long tradition beginning in the philosophy of language that analyzes language use as a species of social interaction. Bloom (2000) presents evidence that children use cognitive abilities that exist for nonlinguistic purposes to learn the meaning of words.

Some researchers (e.g., Langacker, 1999) have explored the interaction of grammar and nonlinguistic cognition by advancing a "cognitive grammar" research program that views the grammatical structure of sentences as the result of the process which maps linear sequences of words into nonlinear cognitive structures. Although the research has explained many linguistic phenomena, it has not shown in detail how this transformation explains specific syntactic constraints such as the empty-category principle, subjacency and the anaphoric binding principles that occur in some form in most mature formal theories of human syntax. Until these apparently peculiar formal properties are accounted for using general cognitive mechanisms, the thesis that humans use different mechanisms for syntactic and nonlinguistic processing remain plausible.

This paper outlines a mapping of structures in formal grammar to cognitive structures used to represent physical events, shows how to use this mapping to construct a model of human syntactic parsing that uses only the mechanisms of a model of infant physical reasoning and demonstrates how this model explains a universal, putatively innate and language-specific grammatical constraint in terms of domain-general cognitive mechanisms.

Grammatical Structure	Cognitive structure
Word, phrase, sentence	Event
Constituency	Meronomy
Phrase structure constraints	Constraints among (parts of) events
Word/phrase category	Event category
Word/phrase order	Temporal order
Phrase attachment	Event identity
Coreference/binding	Object identity
Traces	Object permanence
Short- and long-distance dependencies	Apparent motion and long paths.

Table 1. Dualities between elements of physical and grammatical structure.

Structural Dualities

The structures of grammar and of naïve physics appear more similar when a verbal utterance is conceived as an event that is composed of a sequence of word utterance subevents. Like physical events, verbal events belong to categories, combine to form larger verbal events and are ordered in relation to other verbal events according to lawful regularities. This section examines these dualities in detail, and shows that many grammatical structures have analogues to nonlinguistic cognitive structures. These dualities are summarized in Table 1.

Notation

In order to explain the mapping between syntactic structure and cognitive structures used to represent the physical world, it will be helpful to use a formal notation for representing physical events. This paper uses a notion based on the notation Cassimatis (2002) uses to present

problems to his model of physical reasoning. Although there is no claim that the notation resembles the mind's representations for syntactic or physical structure, the next section will show how to use this formalism to present sentences to a model physical reasoning so that the model can use its own representations and processes to infer the syntactic structure of sentences.

In this formalism, events, objects and places have names. Predicates describe attributes on and relations among named entities. For example, an event in which an object, `x`, moves from `p1` to `p2` during the temporal interval, `t`, is indicated with the following propositions: `Category(e, MotionEvent)`, `Agent(e, x)`, `Origin(e, p1)`, `Destination(e, p2)`, `Occurs(e, t)`. Intervals are ordered using Allan's (1983) temporal relations. For example, `Before(t1,t2)` indicates that `t1` finishes before `t2` begins and `Meets(t1, t2)` indicates that `t1` ends precisely when `t2` begins. Category hierarchies are described using subcategory relationships, e.g., `Subcateogry(Fly, MotionEvent)`. `PartOf(e1,e2)` indicates that event `e1` is part of event `e2`. That two names for events, objects or places refer to the same object is indicated using an identity relationship. For example, `Same(o1,o2)` indicates that "`o1`" and "`o2`" name the same object. Finally, regularities between physical events can be expressed using material implication. For example, that an unsupported object falls is indicated:

```
Location(o,p1,t1) + Below(p2,p1) +
Empty(p2,t1)
→
Category(e,MotionEvent) + Origin(e,p1)
+ Destination(e,p2) + Occurs(e,t2) +
Meets(t1,t2).
```

With this background, it is now possible to describe several dualities between syntactic and physical structure.

Physical and verbal event perception both have a linear order.

Although human vision has two-dimensional access to a three-dimensional physical world, there is a linear order to human perception. People can attend to only one region of space at a time. Large, complicated and/or spatially distributed visual scenes must be perceived through a series of attentional foci. For example, a person standing between two houses, A and B, can perceive that A is to the left of B by turning to the left, focusing on house A, turning to the right and focusing on house B. Likewise we perceive verbal utterances as a linear sequence of word utterance events.

Further, such multidimensionality as there is in the visual system is not unique to it. Spoken phonemes have a multidimensional character. In most phonological theories phonemes are points in a multi-dimensional vector space with dimensions such as "voiced" or "nasal".

Thus, both perceiving physical scenarios and perceiving spoken utterances involve a linear sequence of foci that each integrate multiple dimensions of information.

Utterances are events.

The philosophical tradition of "speech act theory", (which is psycholinguistically implemented by Clark (1996)), holds that linguistic utterances are actions used to achieve goals. In this way, words are similar to other nonlinguistic actions such as gesturing or tool use. Other people's actions are events we must perceive in order to interpret their intent. Both verbal and nonverbal events occur over temporal intervals. Like nonverbal events, verbal utterances can be executed with various manners (hastily, carefully, loudly, softly).

Thus, the same concepts used to describe physical events can be used to describe verbal utterances. For example, using the present notation, the utterance of the word "dog" at time, `t`, may be represented, `Category(e, dog-utterance)`, `Occurs(e, t)`.

Word order is temporal order.

The temporal order of a set of physical events has important consequences for their ultimate result. For example, pulling a gun's trigger *before* loading it results in a much different event from the pulling its trigger *after* loading it. This is also a fundamental feature of grammar: the result (in terms of its effect on the listener) of uttering "The dog", uttering "bit" and then uttering "John" is much different from the result of uttering "John", "bit" and then "the dog". In our notation, "John bit the dog" is represented as sequence of utterance events:

```
1. Category(e1, JohnUtterance)
   Occurs(e1, t1)
2. Category(e2, BitUtterance)
   Occurs(e2, t2)
   Meets(t1, t2)
```

Etc.

Physical and linguistic events both belong to categories, which exist in hierarchies.

Word and phrase categories are an important component of almost every serious syntactic theory and especially important in some (e.g., Pollard & Sag, 1994). Categories are also an essential part of most every other domain of cognition. The previous subsection demonstrated that the same `Category` predicate that represents the category of a physical event can represent the category of a word or phrase utterance. Likewise, just as physical categories exist in hierarchies (e.g., `Subcategory( RunningEvent, MotionEvent)`, so do verbal and phrasal categories (e.g., `Subcategory(CommonNoun, Noun)` and `Subcategory( TransitiveVerbPhrase, VerbPhrase)`).

Just as the category of a physical event determines which other events it occurs with (e.g., a gun-firing event tends to be preceded by a trigger-pulling event), so does the category of a word or phrase determine the distribution of words and phrases (e.g., transitive verbs are often followed by noun phrases).

Constituency is a meronomic relationship.

Physical events combine into larger events, which themselves can combine into even larger events. Word utterance events combine into phrase utterance events which combine into larger phrase utterance events. Meronomy[1] is thus a feature of both physical and verbal events. Predicates for representing physical event meronomy can capture phrasal constituency. For example, the noun phrase "the dog" can be represented thus:, `Category(e, CommonNounPhrase)`, `Category(e1, Determiner)`, `Occurs(e1, t1)`, `Category(e2, CommonNoun)`, `Occurs(e2, t2)`, `PartOf(e1,e)`, `PartOf(e2,e)`, `Meets(e1,e2)`.

The same notation for expressing physical regularities can be used to represent phrase structure rules and constraints. For example, a rule for a transitive verb's arguments can be expressed thus:

```
Category(verb, TransitiveVerb) +
Occurs(verb, t-verb)
→
Exists(object) + Category(object,
NounPhrase) + Occurs(object, t-object)
+ Before(t-verb, t-object).
```

Coreference and binding are object-identity relationships.

Coreference and binding are perhaps the most obvious identity relationships in language. Consider the following sentence, where "the dog" refers to an object, `d`, "the cat" refers to an object, `c`, and "it" refers to an object, `i`:

The dog chased the cat through the park where it lives.

"it"'s reference is ambiguous. It can refer to the dog (`Same(i,d)`), to the cat (`Same(i,c)`) or to some other object in the conversation or the environment (`Same(i,?)`). In each case, the coreference is just a special kind of identity relationship.

Identity is an extremely widespread and important relationship in everyday physical reasoning. When we lose visual contact with an object because we turn our gaze or because it is occluded and then see a similar object, we must decide whether the sightings are of the same object. Many infant reasoning experiments test for sensitivity to a physical constraint (e.g., continuity (Kestenbaum et al., 1987) or category persistence (Xu & Carey, 1999)) by testing whether infants are surprised by identities that violate those constraints.

Phrase attachment is an event identity relationship.

The occurrence of a physical event often implies the occurrence of another physical event. For example, when an object resting on shelf falls to the floor (event `f`), there must have been an event (`p`) which pushed the object off the shelf. One can infer the pushing event from the falling event even if the pushing event is not visible. Later, after observing marks left by a cat's claws on the shelf, we can infer a cat walking event (`w`). If this cat walking event occurred near the original location of the object that fell, then the cat walking event might be *identical* to the pushing event, i.e., `Same(p,w)`.

Event identity is an important feature of grammar as well. For example, the existence of a prepositional phrase utterance within a sentence utterance implies the existence of a noun or verb utterance that the prepositional phrase is an argument or adjunct of. For example, in the sentence "John saw the man with the telescope", the "with the telescope" utterance event implies the existence of an utterance event, `pp-head`, which takes "with the telescope" as an argument or adjunct. In this case, `pp-head` might be the "John" or "man" utterance event. More formally, either one of the following propositions might be true: `Same("John",pp-head)` or `Same("the man", pp-head)`. Thus phrase attachment and attachment ambiguity are instances of event identity and uncertainty about event identity.

Traces and Object Permanence

In many clauses, the arguments of a word are spoken. For example, in (1), the subject and object phrases of "eats" are spoken directly before and after it:

(1) [The man] eats [steak].

In some cases, however, the argument of a word is not spoken near it. For example, in (2), the subject noun phrase of "eats" is not adjacent to it. Sentence (3) show this distance is not an obstacle to "eats" requiring its subject to be third-person singular.

(2) The man John said [_ eats [steak]] was wearing a hat.
(3) *The men John said [_ eats [steak]] was wearing a hat.

Thus, even though the subject of "eats" is a "long distance" from it, that subject's character is constrained by or "depends" on "eats". Such relationships are often called "long-distance dependencies". Some grammatical theories posit the existence of a "trace" that is the subject of "eats"

[1] Meronomy is the study of the relationships of an entity with its parts.

and is left when "the man" is "moved" out of that subject position to another part of the sentence.

Invisible events such as traces and long-distance dependencies are common features of physical inference. For example, if a ball is rolled behind a screen on a flat table and fails to roll out from the other end of the screen, one can posit the existence of a second object behind the screen blocking the first object and make inferences about it (for example, that it is large and massive enough to stop the rolling ball) without ever perceiving the obstacle itself. Thus just as understanding language (depending on one's favorite syntactic theory) requires reasoning about phonetically unrealized phrases, physical event understanding often requires one to reason about events that are not "visually realized", i.e., perceived.

Long-distance dependencies and apparent motion

It was just noted that in (2), the number of the phrase "The man" is constrained by "eats", which is grammatically distant from it. Characterizing and inferring these long-distance dependencies has been a difficult problem for linguistic theorists and designers of sentence parsers for most of modern linguistic history. This contrasts with "short-distance" dependencies which are much simpler. Notice that the subject of "eats" is much closer to and more obvious in (4) than it is in (2).

(2) The man John said [_ eats [steak]] was wearing a hat.
(4) The steak John said [the man eats _] was tender.

A rough way of characterizing the difference between the two sentences is that the immediate proximity of "eats" to its subject makes their relationship much more obvious.

In the case of physical inference, the phenomenon of object permanence is an example of proximity (in space and time) making an identity relationship much more obvious than the identity of two objects perceived over a long-distance. When people see an object at a particular place and time and then in a fraction of a second see an object with a similar appearance, the two object sightings are perceived as the "apparent motion" of a single object. When the distance between the two objects in space and time is much larger, the identity is no longer obvious. For example, when a red Toyota drives into a crowded parking deck and a red Toyota emerges an hour later, the two car sightings might or might not be of the same car. The identity is not so obvious. Thus, long-distance dependencies and the problems they pose are a common feature of linguistic as well as physical events.

Infant physical reasoning mechanisms are sufficient to infer grammatical structure.

The dualities between physical and grammatical structure suggest that mechanisms for inferring the physical structure of the world might be useful for inferring the grammatical structure of an utterance. This section presents a model of syntactic understanding that is based on Cassimatis' (2002) model of infant physical reasoning. The model accounts for a wide variety of syntactic phenomena, including gapped constructions, long-distance dependencies and binding principles, using only the mechanisms included in the physical reasoning model.

Since the central argument of this paper is that human physical reasoning mechanisms, whatever they are ultimately found to be, are sufficient to parse syntactic structure, this paper has only discussed how to formulate parsing problems as physical reasoning problems and does not discuss in any detail the mechanisms of the physical reasoning model.

Polyscheme contains several modules, called *specialists*, for representing aspects of the physical world. Grammatical knowledge was added to Polyscheme using the representations of these specialists. For example, the category hierarchy (strictly speaking, a multi-tree) of Polyscheme's category specialist was used to represent lexical and phrasal category relationships; its temporal specialist was used to represent word order; its meronomic specialist was used to represent phrasal constituency and Polyscheme's physical constraint specialist was used to represent phrase structure constraints. No modifications of Polyscheme representations were needed to represent grammatical knowledge.

Physical problems are presented to Polyscheme using the formal language outlined in the last section. The structural dualities described in that section enable sentences to be presented to Polyscheme so that it can use its physical reasoning mechanisms to parse them. For example, the sentence, "The dog John bought bit him", is represented by a series of propositions, `Category(w1, TheUtterance) Occurs(w1, t1), Category(w2, DogUtterance) Occurs(w2, t2), Meets(t1,t2),` etc.

Upon receiving sentences in this format Polyscheme (using its mechanisms for resolving uncertainties) infers that the event `w2` is a `NounUtteranceEvent` and that it should be preceded by an event, `dogDeterminer`, that is a `DeterminerUtterance` event. Polyscheme's inference that "the" is the determiner of "dog" is represented by the proposition: `Same(w1,dogDeterminer)`, which indicates that the determiner event implied by "dog" is "the". Polyscheme's parse of an utterance is represented by a set of such propositions. They represent the identity of heads, arguments and adjuncts implied by words and phrases in the utterance (e.g., `dogDeterminer`) to the actual spoken words or phrases perceived (e.g., "the"). These propositions constitute a complete description of the syntactic structure of a sentence. Figure 1 illustrates the parse of the sentence, "The dog John bought bit him".

The crucial point is that once a sentence is represented in Polyscheme's input format, *only the mechanisms needed for physical inference are necessary to infer the grammatical structure of the sentence.*

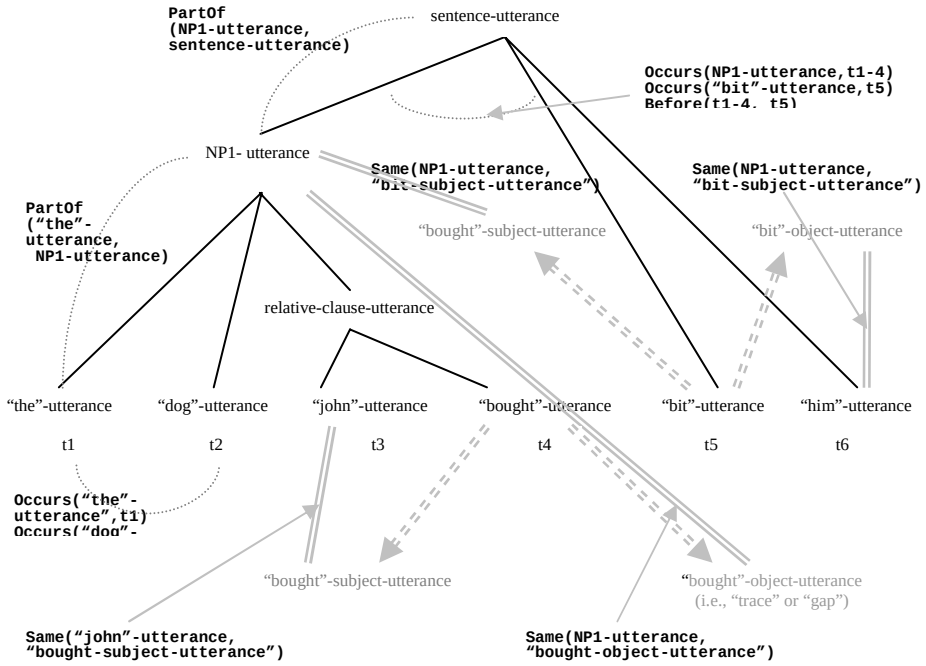

Figure 1. The syntactic structure of a sentence represented using concepts from infant physical reasoning.

Domain-general cognitive processes can enforce grammatical constraints.

The existence of several language universal constraints on syntactic structure is perhaps the most apparently unique feature of syntactic theory. Since they appear so peculiar to language, these constraints lend creditability to the thesis of linguistic modularity. This section argues that a supposed language-specific constraint, the c-command condition on binding, can be represented using the same cognitive structures used to represent physical events and that the cognitive processes used in the Polyscheme physical reasoning model from the last section explain how parsing obeys such constraints.

Radford (1997) formulates the c-command condition on binding thus: *A bound constituent must be c-commanded by an appropriate antecedent*. He defines c-command by stating that *A node X c-commands Y if the mother of X dominates Y, X ≠ Y and neither dominates the other*.

C-command is a constituency relationship and can therefore be reformulated using the notation of section 2:

> *X* ***c-commands*** *Y if* `PartOf(X,Z)` *and there is no* `X'` *such that* `PartOf(X,X')` *and* `PartOf(X',Z)` (i.e.,"Z is the mother of X")*;* `PartOf(Y,Z)` ("Z dominates Y")*;* `Same(X,Y)` *is false* ("X≠Y")*; and* `PartOf(X,Y)` *and* `PartOf(Y,X)` *are both false* ("neither dominates the other").

Having thus reformulated c-command as a meronomic relationship, it is possible explain how a cognitive process called *part inhibition*, which Polyscheme uses for physical reasoning, forces Polyscheme to observe the c-command condition on binding when parsing sentences.

In most physical interactions, a moving object "stays together". The parts of the object move together with the rest of the whole object. Spelke (1990) has termed this the "Cohesion Principle". This principle implies that people tracking the motion of an object composed of many smaller objects need only track the compound object. Its component objects will be wherever the whole object is. This makes, for example, the task of tracking one object composed of seven smaller objects generally much less than seven times more difficult than tracking one simple object. Thus, the Cohesion Principle supports the practice of paying more attention to a whole objects than to its parts. Markman (1989) found evidence that children do this when learning words. In Polyscheme, this attention preference can be implemented with "part inhibition":

> *When entities* $e_1, \ldots, e_n$*, are learned to be part of a larger entity*, E*, inhibit each of the* e_i.

When active during syntactic parsing in Polyscheme, part inhibition suppresses the activation of phrases that are forbidden antecedents under the c-command condition of binding. This is illustrated for the sentence, "The doctor Mary met at Bill's house likes herself". Notice that by the time processing reaches "herself", the model will have inferred that several noun phrases are constituents (directly or indirectly) of other noun phrases. In particular:

- `PartOf("house", "Bill's house").`
- `PartOf("Bill's house", "The doctor Mary met at Bill's house").`
- `PartOf("Mary", "The doctor Mary met at Bill's house").`

Part inhibition will therefore inhibit (and hence make them less likely binding targets) "house", "Bill's house" and "Mary" because they are each part of at least one larger utterance event. The following rewrite of the sentence shows these inhibited noun phrases in light gray:

[The doctor [Mary] met at [[Bill]'s house]] likes herself.

This example demonstrates that a single cognitive process (meronomic inhibition) can help syntactic inference conform to a grammatical constraint (on anaphoric binding) and on a physical constraint (on object motion). Although this is only one of many language-universal syntactic constraints, it raises the possibility that other constraints can be so treated.

Conclusions and future directions

Considerable work remains to establish that the mechanisms underlying physical reasoning also support syntactic parsing and that the model this paper presents is on the right track. The model must be extended to account for more languages and more grammatical phenomena, especially accounts of other universal syntactic constraints. The influence of mechanisms such as part inhibition on the observance of syntactic constraints must also be empirically confirmed. To the extent that the proposed dualities between cognitive structures and processes involved in inferring the structure of physical events and the syntactic structure of sentences are real, several important consequences follow.

First, the ability of a cognitive process such as part inhibition on help inference conform both to syntactic binding conditions and to the cohesion constraint on object motion is relevant to arguments for the existence of innate linguistic knowledge. These arguments (e.g., Chomsky, 1975) assert that children's early linguistic experience is too poor for them to learn these grammatical constraints and conclude that the constraints must therefore be part of some innate linguistic knowledge. This paper raises the possibility that these constraints are the linguistic manifestations of cognitive processes involved in cognition generally. These processes themselves may be innate or children may develop them as they learn to interact with their physical environment. In either case, since children's physical experience is so much richer than their early linguistic experience, this and many issues surrounding a putatively innate language faculty cannot therefore be resolved through *a priori* learnability arguments alone.

Finally, this work raises two methodological opportunities. First, since many other arguments in developmental psychology are also of the form, "behavior B implies knowledge or mechanism X", cognitive models which display B without X can potentially falsify those claims. Second, if the same mechanisms underlie physical reasoning and syntactic parsing, then corresponding to each language universal syntactic constraint should be a cognitive mechanism that supports the observance of this constraint in the same way that supports binding constraints. This suggests the potential for the theoretical posits of syntactic theory to be used as clues for the discovery of cognitive processes and *visa versa*.

Reactive Agents Learn to Add Epistemic Structures to the World

Sanjay Chandrasekharan (schandra@sce.carleton.ca)
Terry Stewart (tcstewar@connect.carleton.ca)
Institute of Cognitive Science, Carleton University,
Ottawa, Canada, K1S 5B6

Abstract

We provide a computationally tractable model of how organisms can learn to add structures to the world to reduce cognitive complexity. This model is then implemented using two techniques: first using a genetic algorithm, and then using the Q-learning algorithm. The results clearly show that organisms with only reactive behavior can learn to systematically add structures to the world to reduce their cognitive load. We show that such learning can happen in both evolutionary time and within an agent's lifetime. An extension of this model (currently being implemented) is then illustrated, where organisms with just reactive behavior learn to systematically generate and use internal structures akin to representations.

Many organisms generate stable structures in the world to reduce cognitive complexity (minimize search or inference), for themselves, for others, or both. Wood mice (*Apodemus sylvaticus*) distribute small objects, such as leaves or twigs, as points of reference while foraging. They do this even under laboratory conditions, using plastic discs. Such 'way-marking' diminishes the likelihood of losing interesting locations during foraging (Stopka & MacDonald, 2003). Red foxes (*Vulpes vulpes*) use urine to mark food caches they have emptied. This marking acts as a memory aid and helps them avoid unnecessary search (Henry, 1977, reported in Stopka & MacDonald, 2003). The male bower bird builds colorful bowers (nest-like structures), which are used by females to make mating decisions (Zahavi & Zahavi, 1997). Ants drop pheromones to trace a path to a food source. Many mammals mark their territories.

At the most basic level, cells in the immune system use antibodies that bind to attacking microbes, thereby 'marking' them. Macrophages use this 'marking' to identify and destroy invading microbes. Bacterial colonies use a strategy called 'quorum sensing' to know that they have reached critical mass (to attack, to emit light, etc.). This strategy involves individual bacteria secreting molecules known as auto-inducers into the environment. The auto-inducers accumulate in the environment, and when it reaches a threshold, the colony moves into action (Silberman, 2003).

Such 'doping' of the world is commonly seen in lower animals. Most large animals (large body & brain size) do not exploit this strategy. Humans, however, do so to a tremendous degree. Markers, color-codes, page numbers, credit-ratings, badges, shelf-talkers, speed bugs, road signs, post-it notes, the list of epistemic structures used by humans is almost endless. Humans also add structures to the world to reduce cognitive complexity for artifacts. Examples include bar codes (makes check-out machines' decisions easier), content-based tags in web pages (makes Web agents' decisions easier), sensors on roads (helps the traffic light program's decision-making), etc.

The pervasiveness of such structures across species indicates that adding structure to the world is a fundamental cognitive strategy (Kirsh, 1996). Note that these structures predominantly serve a task-smoothening function – they make tasks easier for agents. Some of these structures have referential properties, but they do not exist for the purpose of reference. From here onwards, we will term such stable structures that provide "cognitive congeniality" (Kirsh, 1996), *epistemic structures*. The term is derived from a distinction between epistemic and pragmatic action made by Kirsh (1994).

How do organisms generate and use such structures? Can this generation of structures be captured computationally? These are the questions we address in this paper.

A Taxonomy and a Property

Most of the literature on epistemic structures is by David Kirsh, and from the field of Distributed Cognition in general. Kirsh's work explores the structural and computational properties of such structures, and how they function. We are interested in the other half of the problem, i.e., how such structures are generated and used. We use Kirsh's model to develop a situated cognition model of how such structures are generated. We then outline two simulations we implemented to test this model. An extension of this model (currently in progress) is then described.

Epistemic structures can be classified into three types, based on whom they are generated for. (examples of each in brackets).

1. Structures generated for oneself (Cache marking, bookmarks)
2. Structures generated for oneself and others (Pheromones, color codes)
3. Structures generated exclusively for others (Warning smells, badges)

A central feature of such structures is their task-specificity (more broadly, function/goal-orientedness). To illustrate this concept, consider the following example. Think of a

major soccer match in a large city, and thousands of fans arriving in the city to watch. The organizers put up large soccer balls on the streets and junctions leading up to the venue. Fans would then simply follow the balls to the game venue. Obviously, the ball reduces the fans' cognitive load, but how? To see how, we have to examine the condition where big soccer balls don't exist to guide the fans.

Imagine a soccer fan walking from his hotel to the game venue. She makes iterated queries to the world to find out her world state (What street is this? Which direction am I going?), and then does some internal processing on the information gained through the queries. After every few set of iterated queries and internal processing, she updates her world state and mental state, and this continues until she reaches her destination.

What changes when the ball is put up? The existence of the big soccer ball cuts out the iterated queries and internal processing. These are replaced by a single query for the ball, and its confirmation. The agent just queries for the ball, and once a confirmation of its presence comes in, she updates her world state and internal state. The ball allows the agent to perform in a reactive, or almost-reactive mode, i.e., move from perception to action directly. The key advantage is that almost no (or significantly less) inference or search is required.

This happens because the ball is a task-specific structure; it exists to direct soccer fans to the game venue. Other structures, like street names and landmarks in a city, are function-neutral or task-neutral structures. The fans have to access these task-neutral structures and synthesize them to get the task-specific output they want. Once the huge ball, a task-specific structure, exists in the world, they can use this structure directly, and cut out all the synthesizing. How the soccer fans manage to discover the ball's task-specificity is a separate and relevant issue, but we will not address it here. Task-specificity is a property of all epistemic structures found in nature, including pheromones and markers.

Kirsh's model of "changing the world instead of oneself" (Kirsh, 1996), postulates that such generation of structures involve task-external actions, and these structures work by deforming the state space, so that paths in a task environment are shortened. Such structures also allow new paths to be formed in the task environment. Kirsh's model tackles only physical structures generated by organisms, like tools. He does not consider structures generated for cognitive congeniality.

The Tiredness Model

How are task-specific structures that lower cognitive complexity generated? In this paper we consider the case of non-human organisms like ants, wood mice and red foxes. We will make two reasonable assumptions here. One, organisms sometimes generate random structures in the environment (pheromones, urine, leaf piles) as part of their everyday activity. Two, organisms can track their physical or cognitive effort (i.e., they get 'tired'), and they have a built-in tendency to reduce tiredness.

Now, some of the randomly generated structures are encountered while executing tasks like foraging and cache retrieval. In some random cases, these structures make the task easier for the organisms (following pheromones reduces travel time, avoiding urine makes cache retrieval faster, avoiding leaf-piles reduce foraging effort). In other words, they shorten paths in the task environment. Given the postulated bias to avoid tiredness, these paths get preference, and they are reinforced. Since more structure generation leads to more of these paths, structure generation behavior is also reinforced.

This theoretical framework gives us the basis for building artificial agents who also display the ability to learn to systematically generate useful structures in their environment.

The Simulation

To test and investigate the above model of epistemic structure generation, we have developed a computational model, where simple agents in a simple world, given feedback only in terms of their 'tiredness' (i.e., the effort required to perform their task), learn to systematically add structures to their environment.

The task we have chosen is analogous to foraging behavior, i.e., navigating from a home location to a target location and back again. Our environment consists of a 30x30 toroidal grid-world, with one 3x3 square patch representing the agent's home, and another representing the target. This 'target' can be thought of as a food source, to fit with our analogy to foraging behavior.

Agent Actions

At any given time, an agent can do one of five possible actions. The first and most basic of these is 'moving randomly'. This consists of going straight forward, or turning to the left or right by 45 degrees and then going forward. The agent does not pick which of these three possibilities occurs (there is a 1/3 chance of each).

In deciding the actions available to the agent, we needed to postulate some basic facilities within each agent. In our case, we felt it was reasonable to assume that the agents could distinguish between their home and their target. To do this, we added two more actions to the agents' repertoire. These are exactly like the first action, but instead of moving randomly, the agent would move towards whichever square is sensed to be the most 'home-like' (or the most 'target-like'). Initially, the only things in the environment that are 'home-like' or 'target-like' are the home and the target themselves.

One way to think about these actions is to consider the pheromone-following ability of ants. Common models of ant foraging (e.g. Bonabeau et al, 1999) consist of the automatic release of two pheromones: a 'home' pheromone and a 'food' pheromone. The ants go towards the 'home' pheromone when they are searching for their home, and they go towards the 'food' pheromone when foraging for food. This exactly matches these two actions in our agents.

The 'home' pheromone would be an example of a 'home-like' structure in the ant environment.

The fourth and fifth possible actions provide for the ability to generate these 'home-like' and 'target-like' structures. In the standard ant models, this could be thought of as the releasing of pheromones. However, our simulation has an important and very key distinction. Here, this ability to modify the environment is something the agents can do *instead* of moving around. That is, this generation process requires time and effort. The best way to envisage this is to think of an action that a creature might do which inadvertently modifies its environment in some way. Examples include standing in one spot and perspiring, or urinating, or rubbing up against a tree. These are all actions which modify the environment in ways that might have some future effect, but do not provide any sort of immediate reward for the agent. Kirsh (1996) terms these 'task-external actions'.

It must be stressed here that we are not presuming any sort of long-term planning on the part of the agents. We are simply specifying a collection of actions available to them, and they will choose these actions in a purely reactive manner (i.e., based entirely on their current sensory state). It may also be noted that our 'actions' are considered at a slightly higher level than is common in agent models. Our agents are not reacting by 'turning left' or 'going forward'; they are reacting by 'following target-like things' or 'moving randomly'. Furthermore, they do not initially have any sort of association between the action of making 'home-like' structures and the action of moving towards 'home-like' things. Any such association must be learned (either via evolution, or via some other learning rule).

Also, our agents are not designed to form structures automatically as they wander around (as is the case in standard ant models). In our simulation, a creature must expend extra effort to systematically generate these structures in the world. An agent that does this will be efficient only if the effort spent in generating these structures is more than compensated for by the effort saved in having them. Moreover, these are not permanent structures. The agents' world is dynamic and the structures do not persist forever. The 'home-likeness' or 'target-likeness' of the grid squares decrease exponentially over time. Furthermore, these structures also spread out over time. A 'home-like' square will make its neighboring squares slightly more 'home-like'. This can be considered similar to ant pheromones dispersing and evaporating, or leaf/twig piles being knocked over and blown around by wind or other passing creatures.

Agent Sensing

Since our agents are reactive creatures and thus do no long-term planning, they require a reasonably rich set of sensors. We have given them four sensors, two external and two internal, to detect their current situation. The two external sensors sense how 'home-like' and how 'target-like' the current location is (digitized to 4 different levels). The internal sensors are two simple bits of memory. One indicates whether the agent has been to the target yet, and the other indicates how long it has been since the agent generated a structure in its environment (up to a maximum of 5 time units). This is all that the agents can use to determine which action to perform.

This configuration gives each agent 192 (4 x 4 x 6 x 2) possible different sensory states.

The Learning Rules

For a purely reactive agent, we need some way of determining which action the agent will perform in each of these 192 states. We investigated two different methods for matching sensory states to actions: a Genetic Algorithm, and Q-Learning.

Stage 1: The Genetic Algorithm

For our first model, we used a genetic algorithm to determine which action to take in each situation. The genome consisted of a simple list of actions, one to perform in each state. To evaluate a particular genome, we started 10 agents in the home location and ran the simulation for 1000 time steps. The evolutionary fitness was the agents' average tiredness (i.e., how long it took each agent to make it back home from the target).

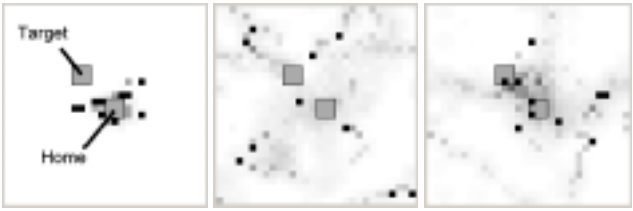

Figure 1: The computer model at 10, 100, and 300 time steps. Black dots are the agents. The shading is darker the more 'home-like' or 'target-like' a particular square is. This run shows typical agent behaviour after 300 generations.

Result: Initially, the agents behaved randomly. Starting at the 'home', they would wander about and might, by chance, find the target and then, if they were very lucky, their home. Indeed, most agents did not find the target and make it back within the 1000 time steps. On average, we found that each agent was completing 0.07 foraging trips every 100 time steps. After a few hundred generations, the agents were soon completing an average of 1.9 trips in that same period of time. In other words, the agents were able to, on an evolutionary time scale, learn to make use of their ability to sense and generate structures in the world. Furthermore, this ability provided a very large advantage over completely random behaviour.

This result confirmed that it is possible for agents to learn to systematically generate and use structures in the world in an evolutionary time scale. It also showed that we had not

chosen an impossible task for the agents to learn. However, for our purposes, we were much more interested in an individual agent learning to generate epistemic structures within that agent's lifetime. To investigate this, we turned to the Q-Learning algorithm.

Stage 2: Q-Learning

The heart of our investigation was to determine whether a simple, general learning algorithm would allow our agents to discover and make use of the strategy of systematically adding structures to the world. In keeping with our 'tiredness' theory, the only feedback the learning mechanism had was an indication of the exertion or effort. The delayed-reinforcement learning rule known as Q-Learning (Watkins, 1989) seemed best suited for this task. (Other similar algorithms will be investigated in future work). The Q-Learning algorithm[1] develops an estimate of the eventual outcome of performing a given action in a given situation. The agent then performs the action with the highest expected payoff.

Using the Q-Learning algorithm, we again ran 10 agents for 1000 time steps. To indicate 'tiredness', we gave them a reinforcement value of -1 all the time (indicating a constant 'punishment' for expending any effort). When they returned home after finding the target, they were given a reinforcement of 0, and they were then sent back out again for another trip. Each agent independently used the Q-Learning algorithm, and there was no communication between the agents.

Result: The dark line in figure 2 shows the results averaged over 100 separate trials. We can clearly see that the agents are improving over time (i.e., they are spending less time to perform their foraging task).

Stage 3: Confirmation

Although we have observed improvement over time, we still need to show that it is the agents' ability to systematically add structures to the world that is causing this effect. To prove this, we re-ran the experiment, this time removing the agents' ability to generate structures in the world. No other changes were made.

Result: We found that when the agents were unable to generate structures in the world, Q-Learning did not provide as much improvement[2]. This result is shown in the lighter line in Figure 2. There is still a small improvement given by Q-Learning, but we are able to conclude that the significant improvement seen in the previous experiment is due to the agents' ability to modify their environment.

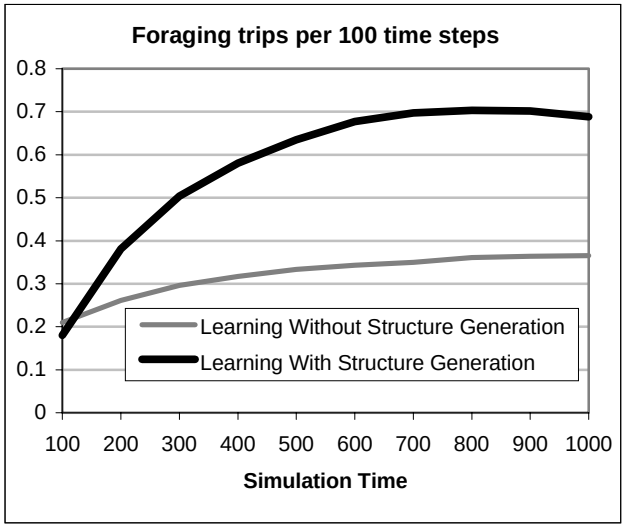

Figure 2: The effect of epistemic structure generation. The foraging rate is measured in trips per 100 time steps. A foraging rate of 0.5 means that trips require an average of 200 time steps to complete.

We can also see from Figure 2 that having these extra actions available does incur some cost in the early stages. Initially, the agents perform slightly worse. However, the advantage of being able to form epistemic structures quickly improves the agents' performance. By the end of the simulation, agents require only around 150 time steps to make a complete trip (a foraging rate of 0.66 trips in 100 time steps). This is twice as quick as agents without the structure-forming ability.

Table 1: Time spent performing various actions.

Action	With Structure Generation	Without Structure Generation
Move randomly	10%	32%
Toward 'home-like'	19%	36%
Toward 'target-like'	13%	32%
Make 'home-like'	35%	
Make 'target-like'	23%	

When we analyzed the actions of the agents, we found that they actually spent 58% of their time generating structures. This is striking, since time spent generating these structures means less time for wandering around trying to find the target or their home. Table 1 gives the breakdown of how time was allocated to different actions. The data indicates that epistemic structure generation allowed the agents to go from spending 300 time steps down to 150 time steps to complete their foraging task, even

[1] The estimated reward for performing action a in state s is $Q(s,a)$. This is increased by $\alpha(r+\gamma\max(Q(s',b))-Q(s,a))$, where r is the immediate reward/punishment, s' is the resulting state, γ is the future discounting rate (set to 0.5), and α in the learning rate (0.2). We used an ε-choice rule with ε set to 0.1, so the agents choose the action with the highest expected reward 90% of the time, and the other 10% they perform an action at random.

[2] Q-Learning also did not provide significant improvement if the agents were only able to generate one type of structure, or if any of the agent's sensors were removed.

though over half of those 150 time steps are spent standing still. There is clearly a large efficiency advantage to making use of these structures.

There are many Reinforcement Learning algorithms available other than Q-Learning, and any one of them could be used in this sort of model. As we investigate other, more complex situations, we will try using these alternatives to Q-Learning, such as actor-critic methods. All of these models learn in a similar way, but with rather different details, and so the resulting high-level behaviour may be different.

Conclusions

The Q-Learning system is a concrete implementation of our model: a simple learning mechanism that allows agents with purely reactive behavior to systematically add structures to the world to lower search.

The 'tiredness'-based learning model implemented in this simulation can explain the generation of task-specific structure in cases 1 and 2 (structures for oneself and structures for oneself & others). Case 2 (structures generated for oneself & others) is explained by appealing to the similarity of systems – if a structure provides congeniality for me, it will provide congeniality for other systems like me. In our computer model, the agents ended up forming structures that were useful for everyone, even though they were just concerned about reducing their own tiredness. This was possible only because the agents were similar to each other. This is similar to how paths are formed in fields: one person cuts across the field to reduce his physical effort, others, sharing the same system and wanting to reduce their effort, find the route optimal. As more people follow the route, a stable path is formed.

For case 3, (structures generated exclusively for others), the 'tiredness' model explains only some cases. For instance, it could explain the generation of warning smells and colors exclusively for others, because the effect of such structures could be formulated in terms of tiredness (the release of some chemical ends up cautioning predators, which reduces the number of fleeing responses the organism makes, thus reducing tiredness, which, when fed back, reinforces the initial action). However, this model, as it stands, cannot explain the generation of structures like the bower or the peacock's tail, which do not seem to provide any tiredness benefit for the generator.

Other Models

It is worth noting that our model presents a novel simulation of ant behaviour. The closest existing models are those in (Bonabeau et al, 1999) which use the 'home-pheromone' and the 'food-pheromone'. This is in contrast to such models as (Nakamura & Kurumatani, 1996), where a land-based and an airborne pheromone are used, or any models of the Cataglyphis species of ant, which uses a complex landmark-navigation scheme which allows it to return directly to the nest (Miller & Wehner, 1988).

That said, all of these other models assume both that pheromones are continually being released while the ant forages, and that there is no learning happening during the foraging behaviour. Our Q-Learning model does not make either of these assumptions.

We were unable to find references indicating that real ants might, in fact, learn to use pheromones, or any research that indicates that the effort required to produce these pheromones might interfere with foraging behaviour. So our model may not be a good one for understanding ants. However, the fact that our agents are able to learn to reflexively generate these cognitively beneficial structures in the absence of any immediate feedback to their benefit, indicates a simpler way to model more complex creatures that exhibit such behaviour.

Future Work

Our current simulation implements a learning process based on the feedback of tiredness. It leads to organisms generating task-specific *external* structures in the world. These are structures that lower cognitive load, accessed by organisms at run-time, while they execute tasks.

Interestingly, the same model can explain generation and tracking of *internal* structures in organisms. The actions which generated structure in our simulation were actions that affected the environment. But this does not have to be the case. Just as we had both internal and external sensors, we can have actions which affect either the state of the world *or* the state of the agent itself. In other words, we can use this model to investigate the generation of *internal* structure (i.e., representations).

As an example, consider foraging bees. Suppose that, just as our agents left traces in the world of their activity via their structure-generating actions, we have the bees leave a sequence of internal memory traces corresponding to landmarks (say a tall tree, a lake, a garden) as a result of their everyday foraging activity. In some foraging trips of some bees, the trace sequences match to some degree the external structures they perceive. Such trips involve less search, because they lead to food more directly, i.e., they form shorter paths in the task environment. Over time, using the exact same learning mechanisms that apply in the external case, the bias against tiredness leads to such paths being used more, and so they are reinforced. This leads to landmark-based navigation, which, in fact, exists in bees (Gould, 1990). As in the case of external structures, the generation of such memory traces is reinforced because more traces lead to more such shorter paths in the task environment. We are currently working on a computational model of this example. Interestingly, recent research shows homing pigeons using human-generated environment structure in a similar fashion to reduce cognitive load. They follow highways and railways systematically to reach their destination (Guilford, 2004).

The above framework presents a situated cognition model of how memory structures come to be used as task-specific structures, and why such internal structures are

systematically generated. If such task-specific memory structures are considered to be representations (that is, they stand for something specific in the world), then the model explains, in a computationally tractable manner, how organisms with just reactive behavior can learn to generate and use representations.

The model also explains what such 'primitive' representations are: they are the internal traces of the world that allow the agent to shorten paths in a task environment. Roughly, they are computation-reducing structures (and equivalently, energy-saving structures). They are internal 'stepping stones' that allow organisms to efficiently negotiate the ocean of stimuli they encounter. This means the traditional cognitive science view, that thinking is computations happening over representations, presents a secondary process – it describes a privileged path in the task environment. In the stepping stone view, representations are crucial for organisms, but they are just useful, incidental entities, not fundamental entities by themselves. We are exploring the philosophical implications of this view.

Abstract

We present a computational model of how partial comprehension of utterances in context may drive the acquisition of children's earliest grammatical constructions. The model aims to satisfy convergent constraints from cognitive linguistics and crosslinguistic developmental evidence within a statistically driven computational framework. We examine how the tight coupling between contextually grounded language comprehension and learning processes can be exploited to improve the model's ability to search the space of possible constructions. In particular, previously learned constructions may not fully account for all contextually perceived mappings between forms and meanings. In the model, these incomplete analyses directly prompt the formation of new relational mappings that bridge the gap. We describe an experiiment applying the model to the acquisition of English verb island constructions and discuss how the model handles more complex examples involving Russian morphological constructions. Together these demonstrate the viability of the overall approach and representational potential of the model.

Beyond single words

How do children make the leap from single words to complex combinations? The simple act of putting one word in front of another to indicate some relation between their meanings is widely considered the defining characteristic of linguistic competence and the key to unlocking the combinatorial and expressive power of language. A viable account of the acquisition of these combinatorial patterns, or *grammatical constructions*, would thus have significant implications for any theory of language that aspires to cognitive plausibility.

As with most issues impinging on the nature of grammar, linguistic and developmental inquiries into the source of combinatorial constructions have bifurcated along theoretical lines. These reflect divergent assumptions about, among other things, what kind of learning bias children bring to the task, how the target linguistic knowledge should be represented, what kind of data should be considered part of the training input, and how (if at all) language learning interacts with other linguistic and cognitive processes. Theoreticians within the formalist "learnability" paradigm, for example, have generally restricted their attention to the form domain, taking the input for learning to be a set of surface strings (each a sequence of surface forms) and positing relatively abstract structures that govern the combination of linguistic units.

This paper takes as starting point the hypothesis that the learning problem at hand may encompass a broader subset of the child's experience, centrally including meaning as it is communicated in context. We assume along with many theories of language that the basic unit of linguistic knowledge, for both lexical items and larger phrasal and clausal units, is a symbolic pairing of form and meaning, or *construction* (Langacker, 1987; Goldberg, 1995; Fillmore and Kay, 1999). Since the target of learning is rooted in both form and meaning domains, the learner should exploit information from both domains during learning.

Most importantly, we view linguistic constructions as inherently dependent on and supportive of dynamic processes of language *use*, anchored in a communicative context. A crucial but often neglected source of bias in learning constructions must therefore be how much they help the child meet her communicative goals.

This paper presents a computational model of construction learning consistent with these principles, focusing on how language understanding drives language learning. We describe a statistically driven machine learning framework that takes as input a sequence of child-directed utterances paired with their associated situational context, along with the current grammar, or set of constructions; this grammar is initially restricted to lexical items. The utterances are passed to a language understanding system (Bryant, 2003) that produces a partial interpretation, which provides the basis for the learning model to form new constructions. We present results showing how the model acquires simple English "verb island" constructions (Tomasello, 1992), and discuss how the same mechanisms handle the more complex constructions involved in Russian nominal case marking. These studies lend support for the larger program of integrating cognitive and constructional approaches to linguistics, crosslinguistic developmental evidence, and machine learning techniques to address the puzzles of language acquisition.

The Construction Learning model

We briefly describe the construction learning model in terms of (1) the target representation of learning, (2) assumptions about the child language learning scenario, and (3) the computational learning framework; see (Chang, 2004; Chang and Maia, 2001) for more details.

Target representation: embodied constructions

Embodied Construction Grammar (Bergen and Chang, in press; Chang et al., 2002) is a computationally explicit formalism for capturing insights from the construction grammar and cognitive linguistics literature. ECG supports an approach to language understanding based on two linked

processes: **analysis** determines what constructions and schematic meanings are present in an utterance, resulting in a *semantic specification* (or *semspec*); the semspec serves to parameterize a **simulation** using active representations (or *embodied schemas*) to produce context-sensitive inferences.

Semantic representations in ECG are richly detailed and cognitively motivated, incorporating image schemas, motor schemas, force-dynamic schemas, and fine-grained representations of event and participant structure. But for ease of exposition, we omit most of this detail in our simple examples below, since it is not crucial for our current focus on the acquisition of the earliest constructions with constituent structure.[1]

We highlight a few aspects of the formalism relevant for the learning model discussion to follow, exemplified by the lexically specific clausal THROW-TRANSITIVE construction shown in Figure 1. The formalism draws from both object-oriented programming languages and constraint-based grammars, including notations for expressing features, inheritance, typing, and unification/coindexation.

construction THROW-TRANSITIVE
constituents
t1 : REFERRING-EXPRESSION
t2 : THROW
t3 : REFERRING-EXPRESSION
form
$t1_f$ `before` $t2_f$
$t2_f$ `before` $t3_f$
meaning
$t2_m$.thrower $\longleftrightarrow$ $t1_m$
$t2_m$.throwee $\longleftrightarrow$ $t3_m$

Figure 1: Representation of a lexically specific THROW-TRANSITIVE construction, licensing expressions like *You throw the ball*, with separate blocks listing constituent constructions (t1, t2, t3), form constraints (e.g., the word order relation `before`) and meaning constraints (e.g., the identification binding $\longleftrightarrow$).

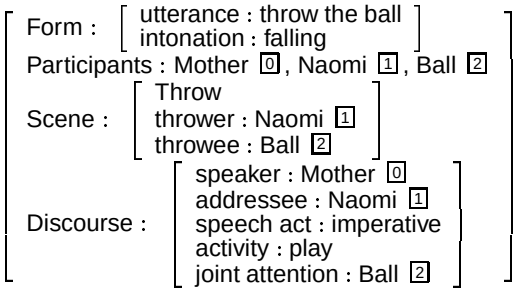
All constructions have **form** and **meaning** blocks, but the **constituents** block appears only in the complex constructions that are the target of the present learning enterprise. These constituents may be typed as instances of particular constructions, and their form and meaning components (or *poles*) may be referred to (shown with a subscripted f or m) by the constraints listed in the form and meaning blocks. Form constraints are used to capture (partial) word order and other relations between form segments. In the meaning domain, the primary relation is *identification*, or unification, between two meaning entities. In particular, we will focus on role-filler bindings, in which a role (or feature) of one constituent is identified with another constituent. The example construction involves three constituents – two referring expressions and the verb THROW. Their form poles are constrained to come in a specified order, and the meaning poles of the two referring expressions fill the specified roles (thrower and throwee) of the verbal constituent's meaning pole.

[1]These features play a key role in the acquisition of argument structure and grammatical markers; we return to this issue later.

Input: modeling the child learning scenario

Children entering the two-word stage (typically toward the end of the second year) are relatively savvy event participants, having developed a wealth of structured knowledge about the participant roles involved in different events and the kinds of entities likely to fill them (Nelson, 1996; Tomasello, 1992). Their single-word vocabularies typically include names for familiar people and objects, as well as some words for actions. They make use of pragmatic knowledge and joint attention to infer both communicative intentions (Tomasello, 1995) and subtle lexical distinctions (Bloom, 2000), and often respond appropriately to multi-word comments and queries from their parents even in the single-word stage (Bloom, 1973). That is, children can robustly interpret utterances beyond their productive abilities, using (incomplete) lingustic knowledge and relatively sophisticated inference abilities.

These findings suggest that grammar learning may, rather than suffer from the poverty of the stimulus, instead capitalize on the opulence of the substrate. Our learning model thus assumes an ontology of known concepts and an initial lexicon of constructions, represented in ECG. Input data reflects the child's ability to perceive an utterance with a particular intonational contour and segment it into a sequence of word forms, and to pragmatically infer the relevant participants and events in the accompanying situation, as shown in the example input below, where boxed index numbers indicate identification links between participants:



The example input represents a discourse event in which the mother says "throw the ball" with falling intonation to the child (Naomi). We assume the child can infer (using pragmatic cues) that the corresponding main scene concerns a throwing event to be performed by the child on a particular ball attended to in context. Note here that the action is the inferred intent of the mother, and may or may not be carried out by the child. But the (intended) role-filler structure is assumed in our model to be inferrable in context and thus available to the learning mechanism.

Besides these assumptions, the learning model also draws on findings about the developmental course of construction learning. Early word combinations appear to be lexically specific, with a gradual transition to more general constructions (Tomasello, 1992); crosslinguistically they tend to relate to a small set of basic scenes (Slobin, 1985); and acquisition phe-

nomena are sensitive to a number of usage-based considerations (Tomasello, 2003; Clark, 2003) such as the frequency with which a construction is encountered, the simplicity of its form and meaning, and how easily a particular utterance can be analyzed into its component constructions.

In sum, the model incorporates strong assumptions about the child's conceptual and lexical knowledge and pragmatic abilities, based on developmental evidence. Relatively weak assumptions are made about innate syntactic biases: the ECG formalism allows word order as a possible form constraint. Thus most of the learning bias comes from the meaning domain, and the constructional assumption that forms and meanings are linked.

Computational learning framework

We now describe a computational model of how constructions can be learned from experience. The input is a sequence of utterances paired with their meanings in context, as described in the last section. The learner has access to a language analysis process like that described earlier, which produces a (partial) interpretation of the input utterances based on the current (potentially incomplete) set of constructions. The learning task is then modeled as an incremental search through the space of possible grammars, where the learner adds new constructions on the basis of encountered data. As in the child learning situation, the goal of learning is to converge on an optimal set of constructions, i.e., a grammar that is both general enough to encompass significant novel data and specific enough to accurately predict previously seen data.

A suitable overarching computational framework for guiding the search is provided by the minimum description length (MDL) heuristic (Rissanen, 1978), which is used to find the optimal analysis of data in terms of (a) a compact representation of the data; and (b) a compact means of describing the original data in terms of the compressed representation. The MDL heuristic exploits a tradeoff between competing preferences for smaller grammars (encouraging generalization) and for simpler analyses of the data (encouraging the retention of specific/frequent constructions). This is an approximation of the same tradeoff exploited in previous work applying Bayesian model merging to learning verbs (Bailey, 1997) and context-free grammars (Stolcke, 1994). We extend these approaches to handle the relational structures of the ECG formalism and the process-based assumptions of the model.

Learning strategies. The model may acquire new constructional mappings in two ways:

relational mapping New relational map(s) are formed to account for form-meaning mappings present in the input but unexplained by the current grammar.

reorganization Regularities across known constructions are exploited, either to merge two similar constructions into a more general construction, or to compose two constructions that cooccur frequently into a single construction.

Each construction is also associated with a weight that is incremented as a result of its successful use in analysis.

Algorithms for these operations are given elsewhere (Chang and Maia, 2001; Chang, 2004); relational mapping plays the most crucial role in proposing new relational constraints among constituents and will be illustrated in more detail in the next section.

Evaluating grammar cost. The strategies above provide means for updating the current grammar; the model must then determine which update is optimal at any point in learning, according to some length-based evaluation criterion. We use an approximation of the Bayesian posterior probability of the grammar G given the data D that we call the *cost* of G:

$$\begin{aligned}
\text{cost}(G|D) &= m \cdot \text{size}(G) + n \cdot \text{cost}(D|G) \\
\text{size}(G) &= \sum_{c \in G} \text{size}(c) \\
\text{size}(c) &= n_c + r_c + \sum_{e \in c} \text{length}(e) \\
\text{cost}(D|G) &= \sum_{d \in D} \text{score}(d) \\
\text{score}(d) &= \sum_{x \in d} (\text{weight}_x + p \cdot \sum_{t \in x} |\text{type}_t|) \\
&\quad + \text{height}_d + \text{semfit}_d
\end{aligned}$$

where m and n are learning parameters that control the relative bias toward model simplicity and data compactness. The size(G) is the sum over the size of each construction c in the grammar (n_c is the number of constituents in c, r_c is the number of constraints in c, and each element reference e in c has a length, measured as slot chain length). The cost (complexity) of the data D given G is the sum of the analysis scores of each input token d using G. This score sums over the constructions x in the analysis of d, where weight_x reflects relative (in)frequency, $|\text{type}_t|$ (where t ranges over the constituents of x) denotes the number of ontology items of type t (i.e., the number of alternative fillers for the constituent), summed over all the constituents in the analysis and discounted by parameter p. The score also includes terms for the height of the derivation graph and the semantic fit provided by the analyzer as a measure of semantic coherence.

These criteria favor constructions that are simply described (relative to the available meaning representations and the current set of constructions), frequently useful in analysis, and specific to the data encountered.

Learning from meaning in context

This section describes in greater detail the integration of the learning model with an implemented construction analyzer (Bryant, 2003). We illustrate the analyzer-learner interaction with an example based on the input data shown earlier.

Constructional analysis. On encountering new data, the learner first calls a construction analyzer designed to perform the analysis process described earlier (Bryant, 2003).

The analyzer consists of a set of *construction recognizers* that recognize the input forms of each construction and check whether the relevant semantic constraints are satisfied. The analyzer draws on partial parsing techniques so that utterances not fully covered by known constructions can nevertheless yield partially filled in semantic specifications. Moreover, unknown forms in the input can be skipped, allowing quite simple constructions to provide at least skeletal interpretations of more complex utterances.

In the example, we assume the current grammar includes lexical constructions for *throw* and *ball*, but no word combinations or construction for the article *the*. The utterance "throw the ball" at this stage produces a semspec containing two schemas, corresponding to the meanings of the two recognized constructions, but no associations between them:

```
SCHEMA13 (Ball)
SCHEMA3 (Throw)
    thrower: SCHEMA4 (Human)
    throwee: SCHEMA8 (Physical-Object)
```

Here, SCHEMA13 corresponds to the meaning pole of the BALL construction, and SCHEMA3 corresponds to the meaning pole of the THROW construction.

Resolution. We extended the existing analyzer with a resolution procedure that matches the output semspec against the input context. Like other resolution (e.g. reference resolution) procedures, it relies on category/type constraints and (provisional) identification bindings. The resolution procedure attempts to unify each schema and constraint appearing in the semspec with some type-compatible entity or relation in the context. In the example, SCHEMA13 resolves by this process to the salient Ball in the input, and SCHEMA3 resolves to the Throw action in context.

Relational mapping. At this point the learner has a partial semspec that through resolution accounts for a subset of the information available in the input context description (namely, the presence of a throwing event and a ball). The learner now searches for a candidate relational mapping present in the input context but not accounted for by the semspec – that is, a form relation that is unused in the current analysis, paired with a meaning relation that is unaccounted for in the semspec. These relations must be structurally isomorphic, that is, their arguments must involve form and meaning poles of the same constituent constructions. In the example, the input includes a number of unexplained meaning relations – for example, the identity of the speaker and addressee, and both Throw schema roles. But only one of these – the binding between the throwee role and the ball – involves meanings that are also accounted for in the input, and for which there is a corresponding form relation over the form poles of the relevant constructions (i.e., an ordering relation between *throw* and *ball*).

The situation is depicted in Figure 2, where the input utterance-context pair are shown as form and meaning schemas and relations on either side of the figure. Constructions found by the analyzer are shown in the center, accounting for the form and meaning schemas drawn with solid heavy lines (i.e., the recognized input and produced semspec). The discovery of structurally isomorphic relations over the form and meaning poles of the two recognized constructions leads to the hypothesis of the new lexically specific THROW-BALL construction shown in the figure (with heavy dotted lines) and formally in Figure 3.

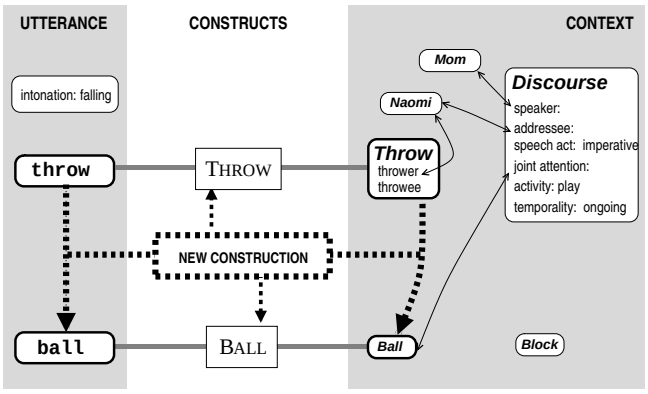


Figure 2: Relational mapping in the learning model for the utterance *throw (the) ball*. Heavy solid lines indicate structures matched during analysis; heavy dotted lines indicate the newly hypothesized mapping.

construction THROW-BALL
constituents
t1 : THROW
t2 : BALL

$t1_f$ before $t2_f$
meaning
$t1_m$.throwee $\longleftrightarrow$ $t2_m$

Figure 3: Example learned construction: THROW-BALL learned from the utterance-context pair in Figure 2.

This example illustrates the simplest relational mapping strategy; the requirement of strictly isomorphic form and meaning relations can also be relaxed to allow more complex relational correspondences (expressed using longer constraints). All such mapping strategies are designed to discover how known constructions may fit together in larger structures, thus giving rise to constituent structure.

Once these structured (but lexically specific) constructions are learned, they are subject to reorganization, such that multiple constructions involving *throw* and a specific thrown object may be merged into a generalized *throw*-Object construction (contingent on the MDL learning criteria). We now explore how the model can learn patterns of this kind from a corpus of child-directed utterances.

Experiment: English verb island constructions

The construction learning model was tested in an experiment targeting the acquisition of lexically specific, or item-

based, constructions; we focus on patterns centering on specific verbs. This task is of cognitive interest, since "verb island" constructions appear to be learned on independent trajectories (i.e., each verb forms its own "island" of organization (Tomasello, 1992; Tomasello, 2003)).

Input data. The training corpus for the experiment is a subset of the Sachs corpus of the CHILDES database of parent-child transcripts (Sachs, 1983; MacWhinney, 1991) annotated as part of a study of motion utterances (Dan I. Slobin, p.c.). The transcript data consists of parent and child utterances occurring during a joint background activity (e.g., a meal or play). All motion expressions were annotated with descriptions of the inferred speaker meaning and the surrounding discourse and situational context. We used a subset of this corpus containing 829 labeled motion-related child-directed utterances spanning the child's development from 1;3 through 2;6, during which the child makes the transition from the single-word stage. Parental utterances were extracted into input data of the form shown above.

Evaluation criteria. The goal of language learning in our framework is to improve language understanding. We thus defined a quantitative measure intended to gauge how new constructions incrementally improve the model's comprehensive capacity. We defined a grammar G's *coverage* of data D as the percentage of total bindings b in the data (i.e., role-filler bindings relevant to the verb) included in its interpretation (semspec), and measured coverage at each stage of learning. The *throw* subset, for example, contains 45 bindings to the roles of the Throw schema (thrower, throwee, and goal location). At the start of learning, the model has no combinatorial constructions and can account for none of these, but as learning progresses, the model should learn constructions that allow it to cover increasingly more of these bindings.

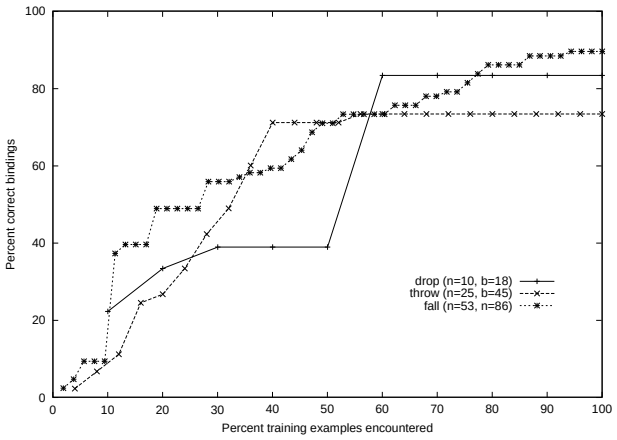

Figure 4: Incremental coverage for three verb islands. (Graphs are scaled relative to subcorpus size.)

Results. Figure 4 shows results for three verb islands: *drop* (n=10 examples), *throw* (n=25), and *fall* (n=50); other verbs followed similar patterns. In all cases coverage gradually improved over the course of learning, as expected, and the model was able to account for a majority of the bindings in the data relatively quickly. But as shown by these examples, the particular learning trajectories were distinct: *throw* constructions show a gradual build-up before plateauing; *fall* has a more fitful climb that seems to converge at an upper bound; and *drop* has an even more jagged rise. A possible explanation for some of these differences may lie in pragmatic differences: *throw* has a much higher percentage of imperative utterances than *fall* (since throwing is pragmatically more likely to be done on command). The relational mapping strategy used in the experiment misses the association of an imperative speech-act with unexpressed agent, which has a more pronounced effect on the learning of *throw* constructions.

Also as expected, the earliest constructions are combinations of specific words (e.g, *throw-ball*, *throw-frisbee*, *you-throw*), giving rise later in learning to more general constructions (e.g., *throw*-Object and Agent-*throw*). Figure 5 shows the number of each type learned.

	lexical	general	total
drop	5	1	6
throw	11	4	15
fall	21	9	30

Figure 5: Number of constructions learned for each verb, including both fully lexically specific constructions and verb island constructions with at least one generalized argument.

Discussion. Despite the small corpus sizes, the results are indicative of the model's ability to acquire useful verb-based constructions. Differences in verb learning lend support to the verb island hypothesis and illustrate how the particular semantic, pragmatic and statistical properties of different verbs can affect their learning course.

Case study: Russian

The verb island experiment demonstrates the model's ability to acquire constituent structure, an essential step in moving beyond lexical items. But the child's learning scenario may be significantly more complicated. We briefly consider some problems that arise for learners of comparable Russian constructions and how the model addresses them.

In Russian, casemarkers suffixed on nouns indicate the participant role played by their associated referents. Word order is thus highly variable: *malchik brosaet devochk-e myach* (boy-NOM throw-3s girl-DAT ball-ACC) and *devochk-e brosaet myach malchik* (girl-DAT throw-3s ball-ACC boy-NOM) have the same participant structure, glossed as 'boy throws ball to girl'. Moreover, the same marker may be ambiguous over multiple class/case combinations (e.g., *-a* indicates either Feminine-I/NOM or Masculine-Animate/ACC).

Flexible word order does not in itself pose an obstacle to the model. Deferring nominal morphology for the moment (see below), the first multi-word constructions learned by the

model (via relational mapping) are, like their English equivalents, both verb-specific and fixed-order (e.g., one for each of the examples above). During construction reorganization, the model seeks candidates for merging that are similar in both meaning and form; separate fixed-order constructions involving the same constituents with equivalent participant structures are prime candidates. Generalizing over these constructions leads to a new construction that contains all the shared structure of the original constructions, omitting in this case the order constraints.

Morphological constructions are similar to word combinations in involving constituency, though word-internal. The main difference is that casemarkers do not occur independently of their nominal contexts, and are first learned as part of an unstructured larger unit. Thus the relational mapping strategy for learning constituent structure cannot apply directly. We assume, however, that over time the child is able to segment words into stems and endings, based on general pattern-detection mechanisms (Peters, 1985). Then the model can merge multiple constructions with the same stem and different endings (e.g., merging *devochk-e* (girl-DAT) and *devochk-a* (girl-NOM) yields a stem *devochk-* with no participant role specified). Similarly, a particular casemarker occurring on different stems (but the same verbal context) can be merged to yield a suffix construction whose meaning pole is associated with a specific participant role (or multiple roles, since polysemous markers are allowed). The resulting stem and casemarker constructions may then serve as constituents for larger morphological constructions.

Conclusion

The work described in this paper are best characterized as first steps toward concrete computational validation of our broad research paradigm. The model is intended to offer a detailed picture of the pivotal role meaning in context plays in the acquisition of grammar. It draws on evidence from across the cognitive spectrum arguing for a construction-based grammar formalism, extensive prior knowledge, and a data-driven, incremental learning course.

We have concentrated on the acquisition of constituent structure, as demonstrated by the verb island learning experiment. Note that we have not addressed how the model learns constructions that depend on more general semantic categories; these include both general argument structure constructions corresponding to basic scenes (caused motion, manipulative activity, etc.), and casemarking constructions that generalize across verbs. These categories are not assumed to be universal, but rather must be learned based on the fine-grained semantic structure available in the ECG representation. In ongoing work we are investigating the conditions and assumptions that allow such constructions to emerge. We are also exploring the relative rates of acquisitions of different classes of verbs and continuing to test the robustness of the model to crosslinguistic data.

Abstract

One approach to conceptual change suggests that ontological barriers may impose beliefs that contribute to learners' misconceptions and misunderstanding of many science concepts. Overcoming this hurdle requires ontological training, which we argue may be possible using concepts and behaviors related to the discipline of complexity. We investigated the difficulties related to learning complex systems concepts, specifically systems exhibiting emergent causal processes. Results showed that all students acquired the following three concepts: Multiple Levels of Organization, Local Interactions, and Probabilistic Behavior. However, all but one student remained unable to develop and use a sophisticated understanding of the concepts of Nonlinearity and Randomness. This suggests that these latter concepts may be the most deeply rooted and robust of the ontologically based misconceptions. Further research is required to investigate if this tendency toward "causal determinacy" may be modified using other types of interventions.

Introduction

Beliefs are thought to have substantial affects on how we interact with and interpret the world. Recent studies in fields such as theories of self (Dweck, 1999) and epistemological beliefs (Hofer & Pintrich, 2002) suggest that these ways of thinking also may affect learners' ability to perform certain tasks or construct certain types of knowledge. It is therefore reasonable to propose that ontological beliefs may play a significant role in learners' misunderstanding of concepts whose mechanisms are unfamiliar or completely unknown.

Chi, Slotta and deLeeuw (1994) put forward the argument that robust misconceptions associated with the learning of certain key science concepts[1] may be the result of assigning these concepts to incorrect ontological categories. It is possible also that lacking knowledge of a specific ontological category limits learners' ability to construct explanatory frameworks for a certain class of science concept.

The ontological category at the heart of this inquiry is that of emergent causal processes. It describes the behavior of phenomenon that rely on the interactions of multiple agents, all operating under the same constraints, without centralized control, influenced by flows of information with feedback loops and selection mechanisms, which generate multiple levels of organization within a system. The nonlinear and probabilistic nature of these complex systems is responsible for the seemingly magical transformations that occur between levels of the system. Put simply, emergence is characterized as the higher-level system's behavior, which arises, but cannot be predicted, from the behavior of individual lower-level entities in the system.

Conceptual Challenges of Emergence

Although we know a lot about emergent causal processes, we continue to be challenged by why these concepts pose obstacles to learners. Duit, Roth, Komorek and Wilbers (1998), and Penner (2000), among others, have studied what students learn about complex systems when provided with different types of models. From their work we know that it is possible to learn some aspects of emergent behaviors, but these studies have not articulated the dimensions nor have they looked at the potential for transfer of this explanatory framework to achieve conceptual change.

Although students may be exposed to the behaviors and functioning of complex systems in general course work (e.g., diffusion of gases), it appears that many do not understand the concepts deeply; and they do not transfer these explanations to other instances of emergence (Jacobson, 2000). In fact, Jacobson's work shows that novice learners do not correctly attribute emergent causation to explain the behavior of complex systems whereas experts in fields such as biology and economics do so readily. Therefore we know that it is possible to use this as a generic framework as a generic to explain novel emergent phenomena. Additionally, Jacobson's results provide evidence to support the claim that expertise in certain fields may be built on a deep understanding of this emergent ontological category.

[1] Conceptual change difficulties reported in learning some important science concepts such as electricity in physics (Chi, Feltovich, & Glaser, 1981; White, 1993), gas laws and equilibrium in chemistry (Wilson, 1998), and in the biological sciences such concepts as diffusion, osmosis (Odom, 1995; Settlage, 1994), and evolution (Anderson & Bishop 1986; Brumby, 1984; Jacobson & Archodidou, 2000).

Lastly, there are powerful computer models to facilitate the acquisition of complex systems, however, the literature tells us that certain beliefs appear to limit how readily learners "see" and correctly explain the model's behaviors (e.g., Resnick & Wilensky, 1997). For instance, Resnick (1994) identifies the tendency to attribute centralized control to self-organizing behaviors of multi-agent computer models in StarLogo™. But we do not know the impact of simulations and modeling of different types of complex systems on understanding of emergent behaviors. Nor do we know if all aspects of emergence as demonstrated by these models of complex systems are equally challenging to novice learners.

Our interest in this paper is to take a modest step toward addressing some of these gaps in understanding how knowledge of emergent causal processes, as demonstrated in multi-agent simulations, may affect learning of certain science concepts. More specifically, we seek to identify and describe which emergent behaviors can be learned through simple simulations and modeling of emergent systems and which are more problematic for learners.

In the following sections we will describe the mixed method longitudinal case study of nine science students who participated in five, one-on-one, one-hour long inquiry-based sessions using simulations designed with StarLogo™. We will also describe the coding taxonomy (Complex System's Taxonomy – CST) which we developed to analyze the transcribed audio data collected.

Material and Methods

Sample

We recruited science students, between the ages of 17 and 18, in their freshmen year at a pre-university English college in Quebec (equivalent to grade 12). From this cohort we selected nine case studies using a purposeful sampling strategy (Creswell 2002). A major criterion for selection was the students' level of motivation and persistence[2].

The students' ages and academic experiences guaranteed that their formal knowledge of complex systems and emergent processes was limited or non-existent. However, we administered a pre-test to establish a baseline of their entry-level knowledge of these concepts (these data are not discussed in this paper).

Instruction

The treatment consisted of five, 60 minute one-on-one inquiry-based sessions. Each session was comprised of two major components: (a) StarLogo computer simulations, and (b) cognitive scaffold in the form of coach/interviewer. The simulations were selected based on the ratings of four subject matter experts. The criteria were that the simulations should demonstrate emergent causal processes, and may in fact exhibit other behaviors of complex dynamic systems. The resulting treatment consisting of three simulations, and one tutorial, (Slime - session 1; FreeGas – session 2; StarLogo programming tutorial – session 3; no simulation – session 4; Wolf-Sheep – session 5) selected from a bank of over 12 other existing StarLogo simulations that also were judged appropriate for grade 12 science students. The simulations finally selected also have a prior history of providing learners with opportunities to learn about concepts of complexity (e.g., Resnick & Wilensky, 1997). This should not suggest that each simulation presented the same level of affordance for learning complexity concepts, however, they all held the potential to demonstrate some level of the more anticipated behaviors (i.e., non-isomorphic multiple levels of organization, decentralized control, randomness, nonlinearity, probabilistic behavior, and dynamic homeostatic behaviors). A question of interest that emerged from the observations was the differential effects of the different types of complexity represented in the simulations (i.e., the tightly coupled organization modeled in Slime simulation, versus the dissipative systems of FreeGas, and the somewhat in-between system modeled in Wolf-Sheep). Lastly, we also did not know the impact of presentation sequence but decided to keep this constant across learners to reduce the variability among cases although it prevented us from learning more about this question.

Procedure

Over the period of five one-hour sessions, spanning a 7-week period each of the nine learners met individually with the coach in a research lab and worked with the simulation assigned for the session (see above). As they explored the assigned simulation, learners were asked to describe their observations related to the behaviors of the agents (i.e., slime mould, gas molecule, turtle, wolf-sheep) and construct and articulate possible explanations for these behaviors. The literature suggests that these causal explanations would reveal the underlying component beliefs/mental models (deterministic "clockwork" component beliefs used by novice learners versus nondeterministic "emergent" component beliefs used by experts) used to interpret these phenomena (e.g., Chi, et al, 1994; Jacobson, 2000). These statements could then be coded and triangulated with data collected relating to shifts in component ontological beliefs that forms part of a larger study (Charles, 2003).

Based on the literature (e.g., Resnick, 1994) we anticipated that learners would be able to identify and describe behaviors common to complex dynamic systems during their sessions. Therefore the ability to

[2] Learning Approach Questionnaire (LAQ) created by Donn (1989) was used to assess motivation. We selected participants with high internal motivation to ensure persistence with the task over course of this longitudinal study.

comply a list of the structural similarities between the simulations was viewed as the high level objective of this experience. At the conclusion of each session learners were asked to attempt to produce a list of behaviors exhibited by the simulation. If necessary they were reminded of the list complied from their previous sessions. Lastly, they were provided with a list of concepts, which may be related to either complex or simple systems and asked to construct a concept map. These data are not described in this paper.

Data collection, coding, and analysis

We collected direct observational data (audio and video tapes of the instructional activities), written documents (students' responses at the pretest and posttest), and interview data. A coding scheme entitled Complex Systems Taxonomy (CST) was developed to determine students' conceptual understanding of the various aspects of complex systems. Adapted from Jacobson (2000), it reflects concepts presented by Holland (1995), Bar-Yam (1997), and others. This "fine grain" overly represented coding scheme was used purposefully to ensure that all articulated observations of systems' behaviors could be coded (see Appendix for complete CST). Post analysis results allowed for narrowing of the taxonomy for future use.

Results

One of the major themes constructed from the categories to emerge from the interviews was that the different simulations facilitated the acquisition of different aspects of complex systems. The results in Table 1 represent the total responses aggregated across students. It displays the percentage of responses within each complex systems component.

Table 1: Distribution of responses (percentages) within Complex Systems Taxonomy (CST) for each simulation.

To answer the question *what difficulties might students experience with learning the concepts involved with emergent causal processes* we analyzed the data both at the level of students and at the level of emergent causal process concepts. Thereby producing the two levels of analysis reported below.

Student level analysis

Figure 1 illustrates the combined scores on the CST for each student across all sessions. On this basis students could be classified into four groups:

- *Sophisticated Emergent Causal Processes (ECP) Identifier* (CST score > 75). This describes Greg who is considered an outlier at the high end.
- *High Moderate Emergent Causal Processes (ECP) Identifier* (CST score between 60 and 70). This describes Mitch, Sidney and Sam.
- *Moderate Emergent Causal Processes (ECP) Identifier* (CST score between 40 and 50). This describes Walter and Norman.
- *Novice Emergent Causal Processes (ECP) Identifier* (CST score between 30 and 40). This describes Emilie, Penny, and Monique (an outlier at the low end).

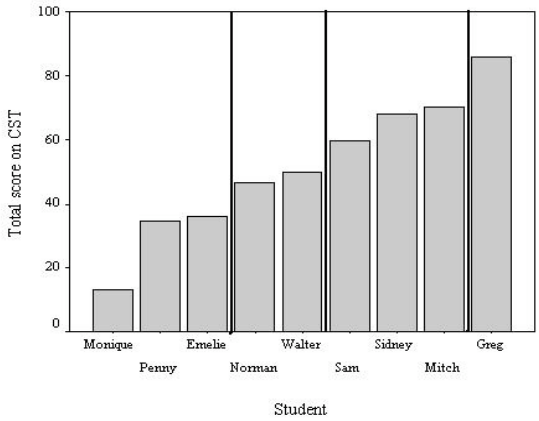

Figure 1: Student's understanding of Complex Systems concepts over three simulations.

Concepts level analysis

The results of Table 2 show the number of statements (relative to each student's total number of statements) that were coded (using the CST) into each Complex Systems concept. Thus, it allows us to make a provisional decision on whether each student observed and therefore discussed the Complex Systems concepts. If one arbitrarily, takes a value of 1 as the cutoff point, we can provisionally conclude that all students including the three Novice ECP Identifiers (Monique, Emilie, and Penny) observed and discussed the

concepts of "multiple levels of organization", "local interactions", and "probabilistic causes". All the other students also observed and discussed the concept of "random behavior". The major difference between the Moderate ECP Identifiers (Norman and Walter) and the High ECP Identifiers (Sam, Sidney, and Mitch) was in the general strength of their responses. On the other hand, the Sophisticated ECP Identifier (Greg) not only had a greater response to the latter concepts, he also observed and discussed more concepts, namely "flows" and "dynamic equilibrium"

Table 2: Relative number of statements made by each student coded into Complex Systems concepts over three simulations.

CST Concepts	Novice ECP			Moderate ECP		High-Moderate ECP			Sophisticated ECP

ML is Multiple Levels of Organization, LI is Local Interactions, OS is Open Systems, PR is Probabilistic Behavior, RB is Random Behavior, TA is Tags, FL is Flows, DE is Dynamic Equilibrium, SR is Simple Rules, DC is Decentralized Control, DI is Diversity, NL is Nonlinear, PA is Pattern Recognition

The interpretation that concepts, which had low counts on the CST scheme (e.g., random behavior, nonlinear effect, decentralized control, dynamic equilibrium), suggests that students did not observe them is not the only conclusion to be drawn from these data. It may indicate that learners readily recognized the behavior described by the concept and chose to focus instead on other concepts that were more challenging or interesting. It may also indicate that the simulation did not offer sufficient affordances for learning that concept.

Discussion

Chi and colleagues (e.g., Chi et al., 1994; Chi 2000) have long proposed that ontological training will remove ontological barriers, which they speculate create the misunderstandings observed when learning certain scientific concepts. Our study shows that not all of these identified barriers are equally daunting. In fact, our study confirmed that using the selected intervention, it was possible to hurdle two of the barriers (Multiple Levels and Local Interactions) identified as problematic by Chi (2000). Our results also suggest that two (Nonlinearity and Random Behaviors) of a possible six complex systems concepts are either not affected by this intervention with its relative affordances for learning complex systems concepts (i.e., non-isomorphic multiple levels of organization, decentralized control, probabilistic behavior, and dynamic homeostatic); or, that these concepts represent a deeper level of entrenched beliefs and require some other type of intervention or condition before substantial change will be observed. The more important of these two is randomness because it is an addition to the list of barriers identified by Chi (2000).

Adding to the list of Ontological Barriers - "Causal Determinacy"

One of the ontological barriers not identified by Chi (2000) is the attribution of causal determinacy (i.e., difficulty in acquiring the concept of random actions). This current study shows that, possibly because of weak affordances of the simulations, students experienced difficulty with the notion of randomness. Klopfer and Um (2000) in a study of fifth and seventh grade students using StarLogo in a scaffolded learning environment called "Adventures in Modeling" also demonstrated that students experienced difficulties with learning the concept of random events; although in the latter portion of their 14 sessions intervention, students were able to grasp this concept.

The evidence from the study reported here and from the larger study (Charles, 2003) is that all the learners at some level were challenged by randomness. In fact, it was the main stumbling block for Greg who otherwise acquired an understanding of all the emergent causal processes without exceptional cognitive struggle. For example, Greg when provided with an ontological prompt during session 1, answered with an explicit statement describing the Slime mould model as being deterministic. His view was that the computer program limited the options and therefore the outcome was determined a priori, therefore predictable.

> Greg: Yeah, I think it's more of a deterministic system. Because like even looking at the way that this is set up there was a minimum number of turtles that you could have and I think it starts off as a system that has a plan and that all the other variables just act on whether like it's your plan ... so you have a deterministic system.

What this suggests perhaps is that even though learners accept the randomness of some happenings, as indicated in their answers to the question about ants foraging, at a deeper level they struggle to accept the lack of some means of predicting future outcomes (even by infinitesimally small or remote means). This deep level understanding is further confounded by the limitations of the programmed environment of the simulations, which indeed may confirm beliefs that there is some level of predictability because random number generations machines are behind these calculations. This is the level of discussion that Greg, Mitch and Sidney all at some point conducted with the coach.

How then did any of the learners show signs of acquiring a deeper level understanding of this concept? The evidence suggests that Greg was the only case to describe random actions at the deeper level of understanding as an element of true causal indeterminacy and "noise". He appeared to accomplish this as a consequence of both cognitive scaffolding and his domain knowledge. During the final interview session, one year after the intervention, Greg was asked to explain his concept map. In this discussion, he elaborated on the role played by random actions in the behavior of systems. This required him to reflect and in doing so he referenced his course work from biology and how the "noise" of random events creates the "possibilities" of the future states.

> Greg: ...so that creates um, randomness, and that creates possibilities, also. That if there were no random events, then you wouldn't have those possibilities. Um, but all these chance events, they, when they get absorbed into the complex system, they have very little effect. It's like throwing a pebble into a river. Sure, you might course the river in a one in billion chance or something, but chances are it does nothing. It's not going to affect the flow of the river in any way. Uh, so, what that means is that complex systems, they follow more rules of probability, and they, they... so nothing is for sure I guess, there is always the element of chance involved. But they're [complex systems] by and large more predictable than simple systems.

The attribution of causal determinacy is a key obstacle to understanding emergent causal process for most learners. This arises either because of the learners' component beliefs, as in the instantiation of the case study Norman, or because of the confounding of concept and programming limitations as demonstrated by Sidney, Mitch and overcome by Greg. The contention may come as no surprise to those investigating the cognitive processes involved in reasoning about uncertainty (e.g., Shauhnessy, 1992). Metz (1998) points to the spurious causal attributions that result from misunderstanding of randomness and probability. What is surprising is that this same barrier also may account for a major difficulty in learning emergent causal processes such as evolution. This contention is supported by research from Zaïm-Idrissi, Désautels, and Larochelle (1993). In their study working with 15 biology students (master's level) they concluded that the majority of the sample held deterministic forms of reasoning about the topic of evolution. Furthermore, they uncovered several inconsistencies in the belief systems of the study's participants, primarily, the conflict between deterministic and probabilistic reasoning.

Therefore, it is possible that this causal determinacy attribution may be one of the most widely interconnected beliefs that affect other related beliefs such as probabilistic causes, and even decentralized control. It may well fit Chinn and Brewer's (1993) description of the evidentiary supporting schema. They state: "It appears, then, that well-developed schemas are not necessarily entrenched. The key is whether the schema is also embedded in evidentiary support and is used to support a wide range of other theories and observations that the person believes" (p. 17). Future research is required to try and untangle the possible confounding of the simulations' weak affordances and the students' ontological belief about randomness.

Conclusions

Using the complex systems' taxonomy, the results of this inquiry show that all nine case study students had little difficulty developing an understanding of three emergent causal processes: Multiple Levels of Organization, Local Interactions and Probabilistic Behavior. However, the emergent component concepts of Nonlinearity and Randomness were challenging for all. In fact, only one student, Greg, was capable of demonstrating a deep conceptual understanding of these concepts. Furthermore, his understanding grew with maturation over time, with experience from complementary content areas, and cognitive scaffolding from the coach/interviewer. Greg's persistent attempts to reason with these concepts and explain phenomena using these notions (e.g., explaining evolution of a species as dependent upon random events) may also account for his ability to acquire this knowledge.

The results of our study also show that the affordances for learning aspects of emergent causal processes, and concepts of complexity, offered by multi-agent simulations and modeling are highly related to the type of complex system represented and also to the students' background understanding of science. In particular more learners had difficulty learning with representations (simulations) of dissipative system complexity (FreeGas) compared to those using

representations of tightly coupled organization models of complexity (Slime).

In summary, this investigation provides evidence that it is possible, using simple simulations and scaffolding, to facilitate the learning of some aspects of an emergent causal explanatory framework. However, other components of emergence, which are linked to non-deterministic (i.e., randomness) and nonlinear conceptions are not easily acquired and may represent the more deeply entrenched ontological beliefs. Further research is needed to examine these specific aspects of emergent causal frameworks and the effectiveness of other types of instructional simulations and tools.

Abstract

This study explored the statistical patterns of English and Mandarin Chinese sound sequences, by comparing their learning in a simple recurrent network. Experiment 1 showed that vivid syllable structure emerged from the sound sequence of Mandarin Chinese. Experiment 2 further demonstrated that the emerged syllable structure of Mandarin Chinese is considerably more salient than that of English. We claim that the more salient syllable structure in Mandarin Chinese inputs is one reason why syllable units are particularly emphasized in its processing in comparison to English.

Introduction

According to linguistic theory, the sound patterns of all languages are hierarchical. Segmental speech sounds (or phonemes) are concatenated into syllabic constituents (onset, rhyme), which join to form syllables, which, in turn, are the constituents of larger units such as feet and words. In psycholinguistic theories of production, each kind of unit plays a part, but some units are more salient than others. For example, standard theory (e.g. Levelt, Roelofs, & Meyer, 1999) holds that lexical items are stored as sequences of segments. The organization of these sounds into syllables, however, is not stored, but rather is computed during production. Evidence against stored syllables comes from two principal sources:

(1) *The absence of syllabic speech errors.* For example, exchanges of non-morphemic syllables are very rare. You would never hear "napkin" spoken as "kinnap."

(2) *The absence of syllabic priming effects that cannot be attributed to segmental units*. For example, naming a word is speeded when a masked orthographic prime syllable that matches the initial sounds of the word precedes it. In many such studies, this priming is unaffected by whether or not the prime syllable corresponds to a whole syllable in the target word (e.g. Schiller, 2000).

The conclusion that syllables are not units of storage has been based on studies of Germanic languages such as English and Dutch. Our own production research has demonstrated that this conclusion is not warranted for all languages. Here, we briefly review our studies of production in Mandarin Chinese, which show that the syllable is far more unitary than has been found in English and Dutch. Then, we present two computational studies involving the learning of Mandarin and English sound sequences. These studies suggest that cross-linguistic differences in the salience of the syllable in production emerge from the statistics of the sequences.

Speech Error Data Psycholinguists believe that the commonness of slips of units such as segments or words provides evidence that these units are psychologically real. Research has shown that whole syllables, in contrast, rarely move, at least in English and in related languages, and the few apparent cases can be otherwise explained as morphemic or segmental slips (Chen, 2000). However, this is not the case for Mandarin Chinese. Chen (2000) demonstrated that syllable movement errors indeed happen in the natural speech of Mandarin Chinese at a rate of 10,000 times greater than would be expected if these errors were the result of independent segmental slips. Importantly, these syllable errors "strand" tone; only the segmental part of the syllable moves. One such example is that the word [ching1zhuo2du4] (清濁度 'clarity') slipped to [ching1du2du4], an anticipation of the third syllable [du]. This stranding of tone rules out the explanation that these are slips of morphemes or characters.

Masked Priming Data Studies of masked priming of word naming in Mandarin Chinese also point to the syllable as a unit. Chen, Lin, and Ferrand (2003) found that when the segmental overlap between the target word to be produced and a preceding character prime constituted a complete syllable, the response time was faster than when it did not. This result was obtained for both CVC and CV-glide syllables (Lin & Chen, 2003).

Implicit Priming Data The implicit priming paradigm is a production task that is useful for discovering relevant phonological units. Participants learn several cue-target word pairs, and later must say the target member of the pair as quickly and correctly as possible upon seeing its paired cue word. Using this task in Dutch, Meyer (1991) showed that when target words in a set shared their initial portions,

responses were faster than when they did not. Moreover, when the shared initial portions did not constitute a syllable, priming was still observed and correlated positively with the number of shared segments. Hence, the observed priming effects seem to derive from shared segments. Implicit priming in Mandarin Chinese was quite different from that in Dutch (Chen, Chen, & Dell, 2002). Crucially, priming was only found when target words shared the segments of entire first syllable, or the segments and the tone together. Accordingly, the priming effects in Mandarin Chinese derive from syllable rather than segment sized units.

Why are Mandarin Chinese speakers more sensitive to syllable units than other speakers?

We believe that the production system reflects the language. Relative to English, Mandarin Chinese has few syllable types. English has more than 10,000 syllables, and Mandarin only around 400 (without counting the tone) or 1,200 (when tones are considered). In addition, re-syllabification commonly occurs in English speech, e.g. 'demand it' becomes 'de-man-dit', but not in Mandarin (Kuo, 1994). Moreover, English, but not Mandarin, involves ambisyllabicity, the apparent membership of a consonant in more than one syllable e.g. 'hap-py'. These properties make the syllable a more efficient planning unit for Mandarin Chinese. In this paper, we explore the hypothesis that these properties lead to sound sequences whose statistical structure favors syllabic, as opposed to word and segmental, units. More generally, we claim that the relative importance of various unit types is a product of experience and test this claim by adopting the computational approach of Elman (1990) to phonological sequences.

Analysis of Sequences by Simple Recurrent Network

The Simple Recurrent Network (Elman, 1990)

A simple recurrent network (see Figure 1) is a three-layer feedforward network, in which input, hidden and output layers are linked by forward trainable connections in a distributed fashion, i.e. fully connected. Crucially, the network includes another input layer, the context layer, which serves as the dynamic memory of the network. The connections from context layer to hidden layer are trainable and distributed, but the recurrent connections from hidden layer to context have fixed weights of 1.0 and are one-to-one. Functionally, the recurrent connections behave much like a copier, which duplicate the activation pattern of hidden layer at a particular time step on the context layer. Hence, output at any given time step is shaped by the network's previous internal state together with its current input. These properties make simple recurrent networks useful models of how people implicitly learn the structure of sequences.

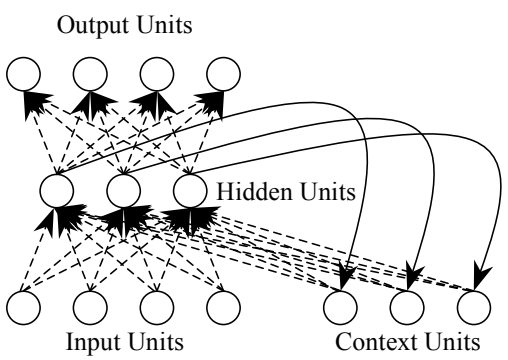

Figure 1. Elman's (1990) simple recurrent network, in which activations are copied from hidden layer to context layer on a one-for-one basis, with fixed weight of 1.0. Dotted lines represent trainable connections.

Word Structure in a Letter Sequence

Elman (1990) examined the statistical structure of English letter sequences by having the simple recurrent network predict the letter that follows the current input letter. Trainable weights were changed to the extent that the prediction was incorrect. The degree of prediction error was highly correlated with word boundaries. Error tended to spike up for word-initial letters, and declined as a function of the serial position for letters within words (see Figure 2). Hence, the relatively higher error for word-initial letters successfully demonstrated that the simple recurrent network discerns the word structure in the letter sequence without providing it with any word boundary cue during training. It appears that the word is the dominant unit, at least in English letter sequences. Next, we perform the same analysis on spoken Mandarin Chinese input.

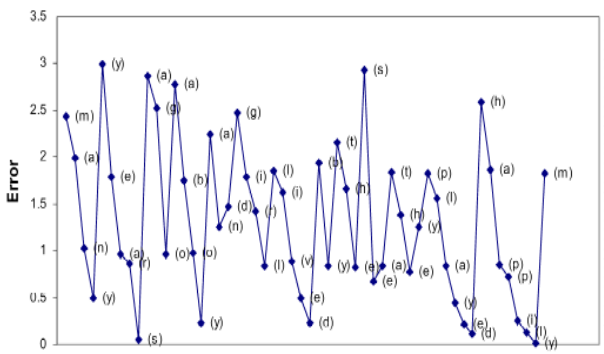

Figure 2. Graph of root mean squared error plotted over time in the letter prediction task (Elman, 1990, Figure 6). The letter to be predicted each time is shown in parenthesis.

Experiment 1: Exploring the Syllable Structure in Mandarin Chinese Inputs

In this experiment, Mandarin Chinese input was assessed by inspecting the relative performance of the network on predicting (1) word-initial sounds, (2) syllable-initial sounds that are not also word initial, and (3) the sounds within the syllable (hereafter, within-syllable sounds). If predicting syllable-initial sounds is harder than predicting within-syllable sounds, syllable boundaries will be protruded, that

is, syllable units will show up. Besides, if predicting the syllable-initial sound is as difficult as predicting the word-initial sound, it suggests that the syllable is the sole emergent unit. This is because word-initial sounds themselves are also syllable-initial, and the syllable unit alone could explain the pattern without postulating a word level.

Method

Simulation Materials and Sound Representation The simulation material came from a 30-minute stretch of a children's radio broadcast program (for ages 6 and upward) downloaded from the "National Education Radio" website at **http://www.ner.gov.tw.** It contained 5,394 sounds (sounds differing only in nasal features were regarded as different sounds), comprising 2,072 syllables and 1,300 words. For the simulation, each sound was represented as a 52-bit binary vector, 47-bit for the segment (because 47 different segments were involved) and 5-bit for the tone (because there are five lexical tones in Mandarin Chinese).

Simulation Design and Network Training The performance of the network on predicting the word-initial, syllable-initial, and within-syllable sounds was examined under 18 conditions created by crossing three factors: (1) tonal information (Syllable condition: tone distributed to each sound of the syllable; Rhyme condition: tone only distributed to sounds of the rhyme; Without condition: no tonal information), (2) the number of training epochs (20, 40), (3) the number of hidden units (25, 100, 200). Performance of the network was evaluated by two kinds of scores: (1) the Error Rate, calculated by regarding the output vector incorrect if the proposed target vector was not its closest vector, and (2) the Euclidian Distance between the actual output vector and its target vector. For both ways of scoring, the larger scores index greater unpredictability and, hence, a more salient boundary.

Before training, the connection weights were initialized randomly in the range of ±0.5. Training began with presenting the network a sequence of input vectors one at a time, and having the network learn to predict the next by adjusting the connection weights with the backpropagation algorithm. Leaning rate and momentum were set to 0.3 and 0.9 respectively.

Results and Discussion

Throughout the study, the Error Rate and Euclidian Distance displayed the same pattern. We present only the latter measure in Figure 3, which illustrates the results of single, but typical, condition. Sounds at word and syllable boundaries were much more difficult to predict than within-syllable sounds. The difficulty of predicting the syllable-initial sounds, however, was quite similar to that of the word-initial sounds. This pattern held no matter how many hidden units the network was equipped with, how many epochs of training had passed, and how (or even whether) the tone was represented. These findings strongly suggest that the syllable is functioning as a unit. Predictability is very high within the syllable, and the word boundary does little to increase uncertainty beyond that associated with the syllable boundary. Whether *any* word structure exists will be statistically examined in Experiment 2 when we directly compare Mandarin Chinese with English.

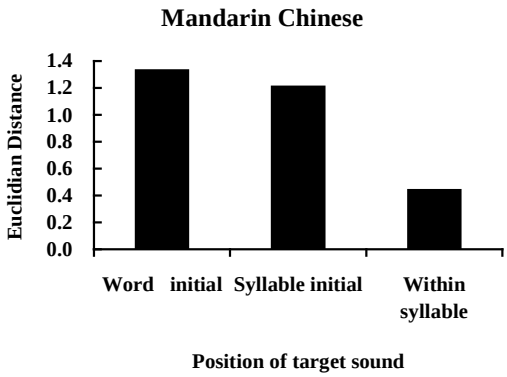

Figure 3. Average Euclidian Distance for predicting sounds in different positions. (Simulation condition: 100 hidden units, 20 epochs, tone was distributed to each sound of the syllable)

An important side result of this experiment is that the pattern shown in Figure 3 was, for the most part, independent of how we represented tone, or even whether we represented it at all. For example, if tone was not represented, the condition corresponding to the one illustrated in Figure 3 led to distances of 1.00, 0.94, and 0.56 for word-initial, syllable-initial, and within-syllable sounds, respectively. Thus, the segmental pattern alone is more than enough to motivate dominant syllable-sized units. In fact, the speech error study of Chen (2000), the implicit priming study of Chen, Chen, and Dell (2002), and the masked priming study of Chen, Lin and Ferrand (2003) all suggested that tone-less or segmental syllables as well as syllables with tone function as important production units in Mandarin. The findings of Experiment 1 are quite consistent with these data.

Experiment 2: Comparing Sound Patterns in English and Mandarin Chinese

The second experiment compared the sound distributions in English and Mandarin Chinese inputs directly. This was achieved by replicating the prior experiment using English and Mandarin Chinese versions of comparable simulation materials. The experiment also manipulated the nature of the representation of diphthongs, that is, whether they are considered to be one or two sounds. Because the prior experiment had shown that the supra-segmental (tone) information, the number of the hidden units, and the number of training epochs did not matter, the present experiment was conducted without supra-segmental information (tone or stress), and with a constant 100 hidden-unit network trained for 20 epochs.

Method

Simulation Materials The simulation materials consisted of 10 short English-Mandarin Chinese bilingual children's stories, downloaded from the "Mandarin Daily News" website at **http://www.mdnkids.org.tw/**. The English versions contained a total of 6,511 sounds when diphthongs were counted as two sounds and 6,243 sounds when diphthongs were counted as one sound, 2,482 syllables and 1,949 words. The Mandarin Chinese versions contained 7,116 sounds when diphthongs were counted as two sounds and 6,472 sounds when diphthongs were counted as one sound, 2,743 syllables and 1,860 words. The principle of representing the sounds for simulation was identical to the prior experiment.

Simulation Design Four conditions were created by crossing two factors: (1) the number of sounds that diphthongs denote (one, two), and (2) languages (English, Mandarin Chinese). Aside from the Error Rate and Euclidian Distance, another score, Syllabic Saliency, was created for representing the degree of saliency of syllable structure. It was defined as where, in percentage terms, the performance of predicting the syllable-initial sound locates on a scale that is maximal at the performance of predicting the word-initial sound and minimal at the performance of predicting the within-syllable sound.

Results

The results with Euclidian Distance and Error Rate were statistically indistinguishable and so we continue to report only the distance measure. The main finding from the experiment was that, as expected, Mandarin Chinese differed considerable from English. Treating the 10 stories as "subjects" in an analysis of variance with language, type of boundary, and diphthong representation as independent variables yielded a strong interaction between language and boundary type, $F(1,18) = 197.2$, $p < .0001$. Figure 4 shows the findings from the diphthong-as-two-sounds condition. In Mandarin the predictability at syllable and word boundaries was nearly identical. The Syllable Saliency here was 96%, that is, predicting sounds at syllable boundaries was almost as inaccurate as predicting them at word boundaries. For English, the Syllable Salience in this condition was 35%, much lower than in Mandarin, $F(1,9) = 25.9$, $p < .001$. In fact, for English, syllable-initial prediction accuracy was actually closer to within-syllable than word-initial accuracy. The results were similar, but less dramatic, when the diphthong was treated as a single sound. The Syllable Saliencies for Mandarin and English were 88% and 43%, respectively, $F(1,9) = 19.4$, $p < .002$. Pooling across the diphthong treatment yielded a strong effect of language on this measure, $F(1,9) = 24.6$, $p < .001$.

Clearly, in Mandarin, the predictability was close for word-initial and syllable-initial sounds. Were word-initial sounds any less predictable than syllable-initial ones? For English, they definitely were, $F(1,9) = 28.7$, $p < .001$. For Mandarin, the very small effect was not significant in the diphthong-as-two-sounds condition, but it was in the diphthong -as-one-sound condition, $F(1,9) = 4.4$, $p < .03$.

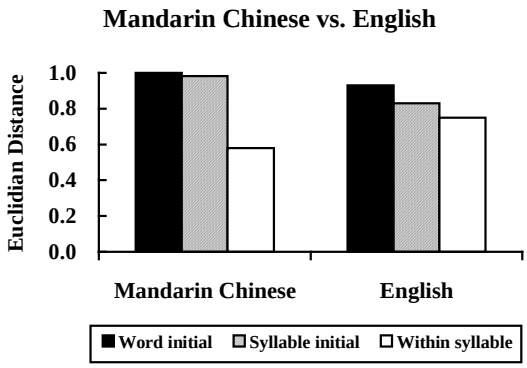

Figure 4. Average Euclidian Distance for predicting sounds in different positions in Mandarin Chinese and English (Simulation condition: diphthong as 2 sounds, 100 hidden units, 20 training epochs, without tonal information)

Discussion

To summarize, three major findings were obtained. First, vivid syllable structure emerged from the sound sequence of Mandarin Chinese. Second, the emerged syllable structure is more salient in Mandarin Chinese than in English. Third, equivalent syllable structure was found even when supra-segmental information was removed from the sound sequence. Implications of these results are discussed below.

As described in the introduction, psycholinguistic studies demonstrated that the role of the syllable is not equally emphasized in the production of English and Mandarin Chinese, a finding that hints that the sound patterns the language presents should reflect such difference. This is exactly what we demonstrated in this experiment. In Mandarin, the predictability of a sound was almost entirely determined by whether or not it is at a syllable boundary. In English, word structure was more salient, and the predictability within a syllable was not that much greater than that at syllable boundaries that are not word boundaries.

A stronger, but more speculative, interpretation of our findings makes reference to the particular kind of model that we used to assess predictability, the simple recurrent network. This network architecture has been offered as an account of phonological retrieval in production (e.g. Dell, Juliano, & Govindjee, 1993). One of the advantages of such an account is that one does not need to explicitly include or exclude particular kinds of units. Rather, the weights acquired through learning lead to activation states with greater or lesser correspondence to discrete units at several levels. Hence, the learner is not faced with the all-or-none decision as to whether to have a syllable level in the system. To the extent that different languages possess gradations in the salience of units such as the syllable, this connectionist approach may help explain the cross-linguistic variation

Another finding of note was that a strong syllable structure emerged in Mandarin Chinese even when supra-segmental (tone) information was not considered. This suggests that the segmental syllable, i.e. the syllable without the tone, has statistical support in the input, and may function as a processing unit. Psycholinguistic studies of Mandarin support this hypothesis. For instance, analysis of natural speech errors indicated that sometimes a syllable moves to a new location, leaving its tone behind (Chen, 2000). That is, the slipping unit was a segmental syllable. Pan, Chen, and Chen (1999) demonstrated this effect with experimentally generated slips. Furthermore, implicit priming and masked priming findings are robust both for syllables with tones and for segmental syllables (Chen, Chen & Dell, 2002; Chen, Lin & Ferrand, 2003).

Toward a Model of Comparison-Induced Density Effects

Jessica M. Choplin (jchoplin@depaul.edu)
DePaul University Department of Psychology
2219 North Kenmore Avenue
Chicago, IL 60614-3504

Abstract

A model of the effects of distribution density on evaluations of attribute values is proposed in which biases created by language-expressible magnitude comparisons (e.g., "I waited longer for the bus today than I did yesterday") serve as the mediating mechanism. The biases created by comparisons as well as the mechanisms by which comparison-induced biases could produce density effects are described. Simulation data demonstrate signature characteristics of comparison-induced density effects. An experiment found preliminary evidence in support of the view that some density effects might be comparison-induced.

Density Effects

Evaluations of attribute values such as grades (Wedell, Parducci, & Roman, 1989), taste (Riskey, Parducci, & Beauchamp, 1979), visual velocity (Sokolov, Pavlova, & Ehrenstein, 2000), prices (Niedrich, Sharma, & Wedell, 2001), income (Hagerty, 2000) and so forth often depend upon the density—or frequency—of the distribution from which judged values are drawn (Krumhansl, 1978; Parducci, 1965, 1995). In particular, evaluation functions are typically concave (downward) for positively skewed distributions and convex (concave upward) for negatively skewed distributions. Values drawn from positively skewed distributions are also often judged larger than are values drawn from negatively skewed distributions.

Several explanations for these effects have been proposed. Parducci's (1965) Range-Frequency Theory assumes that people are aware of and use percentile rank information to evaluate attribute values. Range-Frequency Theory explains the finding that evaluation functions are often concave for positively skewed distributions, because the density at the lower end of positively skewed distributions gives low values larger percentile rank scores than they would have had otherwise. The slope of the function becomes shallow at the sparse upper end of the distribution where percentile rank scores increase at a slower rate. The reverse pattern of changes in percentile rank scores in negatively skewed distributions explains the finding that evaluation functions are often convex for negatively skewed distributions.

Haubensak (1992) suggested an alternative explanation for density effects on evaluations of sequentially presented values. He argued that since people do not know the distribution density and range in advance, they tend to assume that early values are typical or average and assign them intermediate verbal labels or category ratings. After these initial labels or category ratings have been assigned, people are obliged to use them consistently. Since early values are most likely to come from the dense portion of skewed distributions, the portion of the range at the dense end of these distributions will be smaller than the portion of the range at the sparse end. To cover the entire range of values the remaining verbal labels or category ratings would have to be assigned asymmetrically.

In this paper, I propose yet another possible explanation for density effects. Namely, that some density effects might be comparison-induced (Choplin & Hummel, 2002). Verbal comparisons will tend to bias values apart in dense regions making the slope of the evaluation function steep and bias values together in sparse regions making the slope of the evaluation function shallow. These biases would make evaluation functions concave for positively skewed distributions and convex for negatively skewed distributions. The assignment of verbal labels or category ratings to these biased values might explain why values drawn from positively skewed distributions are often judged larger than are values drawn from negatively skewed distributions.

I start by reviewing the basic tenets of Comparison-Induced Distortion Theory (Choplin & Hummel, 2002) and describing how comparisons could produce density effects. I present simulation data to demonstrate signature characteristics of comparison-induced density effects and how they differ from density effects produced by other mechanisms. I then describe an experiment in which I found preliminary support for the view that some density effects might be comparison-induced.

Comparison-Induced Distortion Theory

The basic idea behind Comparison-Induced Distortion Theory (Choplin & Hummel, 2002) is that language-expressible magnitude comparisons suggest quantitative values. To investigate the meanings of English age comparisons Rusiecki (1985) gave his participants sentences such as "Mary is older than Jane" and "Martin's wife is older than Ken's wife" and asked them to report the ages they imagined. Rusiecki found considerable agreement in the values imagined by his participants. In response to the comparison "Mary is older than Jane" participants imagined Mary to be 20.2 years on average and Jane to be 17.9 years on average. In response to the comparison "Martin's wife is older than Ken's wife" participants imagined Martin's wife to be 37.2 years on average and Ken's wife to be 33.0 years on average.

Of particular interest to the current discussion, the age differences imagined by Rusiecki's (1985) participants were remarkably similar. Regardless of the particular ages they imagined, participants imagined a difference between the ages of approximately 2 to 5 years (slightly larger for larger values)—not 1 month or 30 years. Inspired by these results, Rusiecki argued that comparisons suggest quantitative differences between compared values. I will henceforth call

these quantitative differences "comparison-suggested differences," because they are the differences suggested by comparisons. In the case of age comparisons, for example, Rusiecki's results demonstrate that comparison-suggested differences are approximately 2 to 5 years (for ease of discussion I operationally define the comparison-suggested difference implied by age comparisons to be 3.5 years).

Choplin and Hummel (2002) proposed a model of attribute evaluation in which magnitude comparisons (like those investigated by Rusiecki, 1985) bias evaluations of magnitude values. In particular, they suggested that evaluations of magnitude values might be vulnerable to bias whenever values differ from the values suggested by comparisons. For example, if the actual age difference between two people were 1.5 years (i.e., less than the comparison-suggested difference of 3.5 years), then a comparison would tend to bias evaluations of their ages apart—toward a difference of 3.5 years. The younger person would be evaluated younger than she or he would have been evaluated otherwise and the older person would be evaluated older than she or he would have been evaluated otherwise. If the actual age difference between two people were 5.5 years (i.e., more than the comparison-suggested difference of 3.5 years), then a comparison would tend to bias evaluations of their ages together—again toward a difference of 3.5 years. The younger person would be evaluated older than she or he would have been evaluated otherwise and the older person would be evaluated younger than she or he would have been evaluated otherwise.

Formally, the comparison-suggested value of the smaller of two compared values (E_S; E for Expected) and the comparison-suggested value of the larger of two compared values (E_L) can be calculated from the comparison-suggested difference, D:

$$E_S = S_L - D \quad (1a)$$

$$E_L = S_S + D \quad (1b)$$

where S_L and S_S (S for Stimulus values) are the values of the larger and smaller values unbiased by comparisons respectively. Represented values are assumed to be a weighted mean of the values unbiased by comparisons and the comparison-suggested values:

$$R_S = wE_S + (1\text{-}w)S_S \quad (2a)$$

$$R_L = wE_L + (1\text{-}w)S_L \quad (2b)$$

where w is the relative weights of the two values, is bound between 0 and 1, and is constrained so as to prevent impossible values (e.g., negative years or sizes of geometric figures) from being represented. For example, assuming a comparison-suggested difference, D, of 3.5 years, a comparison between a 22-year old and a 28-year old would bias evaluations of their ages toward each other. If the weight given to comparison-suggested values were .2, then the represented age of the 22-year old would be 22.5 years and the represented age of the 28-year old would be 27.5 years. That is, the age of the 22 year old would be evaluated, i.e., treated, as if it were half a year older and the age of the 28 year old would be evaluated as if it were half a year younger.

Comparisons Might Create Density Effects

Comparison-induced biases like those just described might produce density effects. Consider, for example, the positively skewed distribution of ages presented in Figure 1 which might be approximately representative of the ages of students in a typical undergraduate classroom. Filled-in arrows represent biases created by comparisons between values that are closer together than the comparison-suggested difference and that are, therefore, biased apart by comparisons. Outlined arrows represent biases created by comparisons between values that are farther apart than the comparison-suggested difference and that are, therefore, biased together by comparisons. Values in dense regions (i.e., 18 – 22 years in Figure 1) are more likely to be closer together than the comparison-suggested difference and as a result comparisons will more likely bias evaluations apart. Values in sparse regions (i.e., 22 – 28 years) are more likely to be farther apart than the comparison-suggested difference and as a result comparisons will more likely bias evaluations together. I propose that this difference in the effects of comparisons within dense regions versus the effects of comparisons within sparse regions might produce comparison-induced density effects.

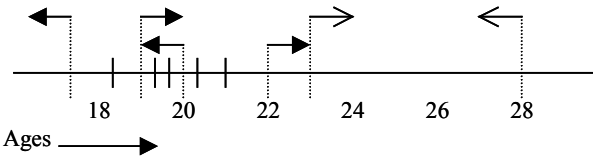

Figure 1: Comparison-induced biases that might occur in a positively skewed distribution of ages.

Modeling Density Effects

To model comparison-induced density effects, Comparison-Induced Distortion Theory requires several assumptions. First, an operational definition of the comparison-suggested difference (D) is required. In the preceding sections, for example, an adequate operational definition of the difference suggested by age comparisons was obtained from Rusiecki's (1985) study in which he queried his participants as to the differences they imagined. Alternatively, an adequate operational definition might be obtained from common real-world differences.

Second, because the number of comparisons people could hypothetically articulate as well as the sequences in which they could hypothetically articulate them is—in most cases—indefinite, assumptions about which comparisons get articulated are required. Almost any comparison scheme would produce density effects. Comparing each value to the value presented one item back, for example, would produce density effects. In the modeling presented below, I assumed that the to-be-judged item is only compared to one other item. Additionally, I assumed two constraints on the selection of this comparison item: the similarity between the to-be-judged item and candidate comparison items and the sequence in which values were presented. Although these assumptions were optional, I utilized them because they are

psychologically realistic and they have a long history in models of categorization and the psychology of judgment (see, for example, Haubensak, 1992; Nosofsky & Palmeri, 1997; Smith & Zarate, 1992).

To model the constraint of similarity on the selection of comparison items, I (along with Shepard, 1987) assumed that similarity is an exponentially decreasing function of the distance between item values. For every recently presented item j, it's similarity to i, the to-be-judged item, (η_{ij}) is calculated as:

$$\eta_{ij} = e^{-cd_{ij}} \quad (3)$$

where c is a sensitivity parameter and d_{ij} is the weighted distance between i and j in similarity space across all relevant dimensions weighted by the importance of each dimension (see, for example, Nosofsky & Palmeri, 1997).

To model the constraint provided by the sequence in which items are presented, I calculated the activation (a_{ij}) of each candidate comparison item j as:

$$a_{ij} = M_j \eta_{ij} \quad (4)$$

where M is the memory strength of exemplar j and is given by: $M_j = \alpha^{t(i) - t(j)}$ where α represents the memory decay on each trial and is bound between 0 and 1 and where t(i) and t(j) are the trials on which i and j were presented respectively (see Nosofsky & Palmeri, 1997). Selection of the item to which the to-be-judged item is compared could be accomplished a number of different ways. The choice axiom might be used to make selection stochastic. In the simulations below, maximum activation (a_{ij}) was used to make selection deterministic.

Simulation Using Artificial Values

The purpose of this simulation was to demonstrate how the model proposed above might create density effects and to point out signature characteristics of comparison-induced density effects that differentiate them from density effects created by other mechanisms. To demonstrate how the model presented above would create density effects, a computer-generated sequence of 500 values drawn from a log-normal distribution was created from equations 5 and 6.

$$V_{normal} = \sqrt{-2 \log R_1} \sin(2\pi R_2) \quad (5)$$

$$V_{\log - normal} = e^{\sigma V_{normal}} \quad (6)$$

where R_1 and R_2 are random, computer-generated values between 0 and 1. Equation 5 produced a normally distributed sequence and Equation 6 changed that sequence into a log-normally distributed sequence. To skew the log-normal distribution, σ was set at .9.

To model recall of the item to which the to-be-judged item was compared, the parameter α, representing memory decay, was arbitrarily set at .985 thereby minimizing memory losses. The parameter c, representing sensitivity to differences, was set at 0.3. Within the sequence, the second value was compared to the first value; the third value was compared to whichever of the first or the second value had the highest activation (a; see Equation 4); the fourth value was compared to whichever of the first, second, or third value had the highest activation, and so forth. In these simulations, only the most recent 7 values were candidates for comparison. Recalled values were biased by the comparison on the trial on which they were judged, but were not biased further by subsequent comparisons.

To model comparison-induced distortions, the comparison-suggested difference, D, was set at 0.38 and the weight given the comparison-suggested values, w, was .5. As suggested in Figure 1, values from the dense region were more likely to be compared to values that were less than a comparison-suggested difference away than were values from the sparse region. The values that were smaller than 1.5 (the dense lower region) were most similar to a value that was less than a comparison-suggested difference away 86.1% of the time (329/382). By contrast, the values that were larger than 1.5 (the sparse upper region) were most similar to a value that was less than a comparison-suggested difference away 40.2% of the time (47/117).

The results are presented in Figure 2. Generated values are plotted along the horizontal axis. The value of each item is plotted on the vertical axis. The filled-in squares represent comparison-biased values and the outlined circles represent unbiased values.

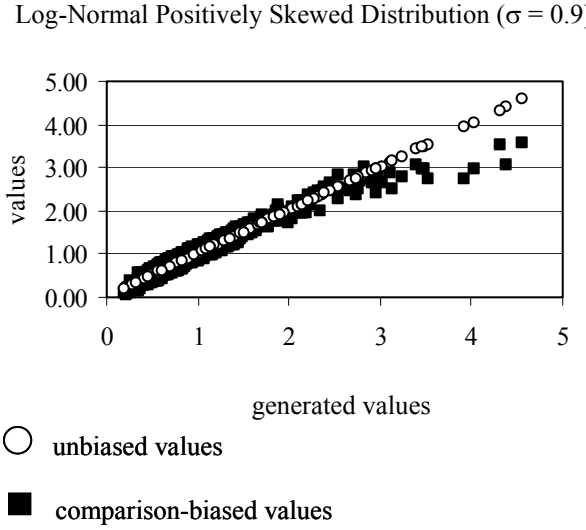

Figure 2: Simulation Results.

As shown in Figure 2, comparisons between each value and the most recent similar value created biases. Consistent with previous research using category ratings as the dependent measure, these biases produced a concave evaluation function. Seemingly contrary to previous research, however, comparisons had a tendency to bias values downward instead of upward.

This seeming contradiction can be reconciled by noting that category ratings depend not only upon representations of values but also upon the function mapping representations to category ratings. A number of functions could produce high category ratings. For example, if people were to use the range of values to make category ratings as proposed by Volkmann (1951), then even if comparisons biased representations in one direction (perhaps, as

measured by reproduction), category ratings could be biased in the other direction (see Biernat, Manis, & Kobrynowicz, 1997).

To demonstrate this possibility, range scores (i.e., [value on trial t minus smallest value up to trial t] divided by [largest value up to trial t minus smallest value up to trial t]) were calculated from the comparison-biased values. The results—after the initial 35 trials in which the range was established—are plotted in Figure 3. Filled-in squares represent comparison-biased range scores. The range transformation makes comparison-biased values comparable to the predictions of Range-Frequency Theory and so range-frequency compromise values (with the weight given to frequency set at .35) are also plotted in Figure 3 and represented as outlined triangles (see Parducci, 1965). The comparison-biased range scores mirrored the unbiased range-frequency compromise scores, suggesting that in some cases the effects of density on people's category ratings might be comparison-induced.

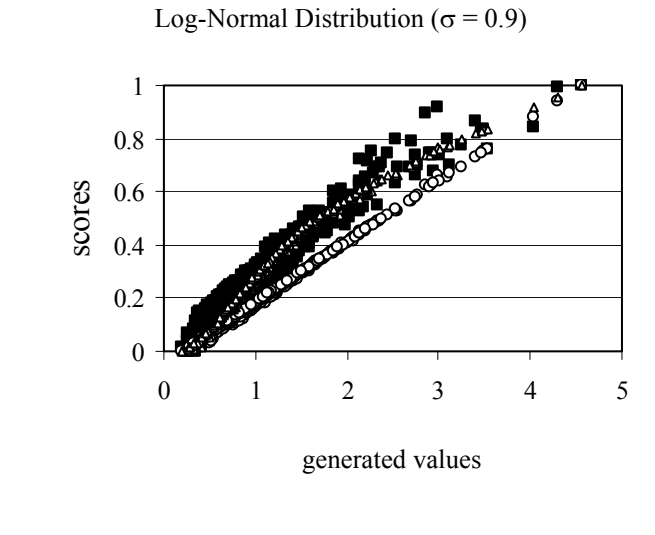

Figure 3: Simulation Data. Range scores on comparison-biased values mirror Parducci's (1965) range-frequency compromise scores.

Mirroring range-frequency compromise scores, the generated values in this simulation had comparison-biased range scores that were larger than their unbiased range scores 97.4% (487/500) of the time. I have successfully fit the model of comparison-induced density effects presented here to the results of several published density effect studies (e.g., Riskey et al., 1979) under the assumption that the comparison-biased represented values are mapped to category ratings using Volkmann's (1951) range function.

This modeling points out several signature characteristics of comparison-induced density effects that differentiate them from density effects produced by other mechanisms (e.g., range-frequency compromise). The comparison-induced biases in this simulation depended solely upon the model's knowledge of the comparison-suggested difference (D), the importance of the comparison (w), and the value retrieved for comparison. The model has no knowledge of the density of the distribution or of the percentile ranks of values and so the percentile ranks of values do not affect the model's judgments on individual trials. Rather, density affects aggregate data, because values in dense regions are more likely to be compared to values that differ from them by less than a comparison-suggested difference (and less likely to be compared to values that differ from them by more than a comparison-suggested difference) than are values in sparse regions. By contrast, Range-Frequency Theory assumes that people have implicit knowledge of percentile rank information and use that knowledge in making judgments on individual trials. Due to this difference, Range-Frequency Theory predicts that density effects ought to be observable on individual trials and Comparison-Induced Distortion Theory predicts that they ought not to be.

Experiment

The purpose of this experiment was to investigate whether the signature characteristics of comparison-induced density effects demonstrated in the modeling presented above could be observed empirically. Participants imagined that they were spending 25 days in rural Minnesota during the middle of winter and had to rely upon public transportation. The length of time they had to wait for the bus varied each simulated day and they indicated how aversive the wait would be. Half of the participants judged wait times drawn from a negatively skewed distribution and the other half judged wait times drawn from a positively skewed distribution.

Method

Participants. Seventy-three people volunteered to participate after being approached by the experimenter on the University of California, Los Angeles campus or in the surrounding community (36 in the positively skewed condition and 37 in the negatively skewed condition).

Materials and Procedure. A random sequence of 10 wait times drawn from a negatively skewed (7, 10, 13, 16, 16, 16, 19, 19, 19, and 19 minutes) or a positively skewed (7, 7, 7, 7, 10, 10, 10, 13, 16, and 19 minutes) distribution was created for each participant. Each participant's sequence was presented twice. An initial sequence of 5 days was inserted at the start of the sequence to control for primacy effects, introduce participants to the range of values they would see in the experiment, and to measure participants' baseline evaluations prior to being exposed to the density manipulation. The wait times on these 5 days were 7, 19,

13, 19, and 7 respectively and were the same for all participants. On each simulated day (simulated within a single session), the experimenter verbally told participants how long the fictitious wait for the bus was that day. Participants indicated how aversive they imagined that wait would be using a line-analogue measure in which they placed a tick at the spot along the line that was analogous to how aversive the wait was (see Schifferstein & Frijters, 1992). A stop mark on the left-hand side of the line was labeled 0=not bad and a stop mark on the right-hand side of the line was labeled 10=extremely bad. The 25 lines were presented on a single, one-page experimental handout and labeled Day 1 through Day 25.

Results and Discussion

To reduce variance caused by idiosyncratic reactions to wait times, participants' judgments during the initial sequence were used as a baseline. Each participant's judgments on trials 6 through 25 were divided by the average of her or his judgments on trials 4, 5, and 6.

Distribution density effects were revealed by differences between judgments in sparse regions versus differences between judgments in dense regions. Among participants whose wait times were drawn from the negatively skewed distribution, the difference between judgments of 7-minute wait times and judgments of 13-minute wait times (i.e., the sparse region) was reliably smaller than the difference between judgments of 13-minute wait times and judgments of 19-minute wait times (i.e., the dense region), $t(36) = 3.99$, $p < .01$. Among participants whose wait times were drawn from the positively skewed distribution, the difference between judgments of 7-minute wait times and judgments of 13-minute wait times (i.e., the sparse region) was approximately the same size as the difference between judgments of 13-minute wait times and judgments of 19-minute wait times (i.e., the dense region), $t < 1$. A 2 (distribution) x 2 (region) Mixed-Factors ANOVA found that this interaction was significant [$F(1,71) = 6.11$, $MSE = 0.22$, $p = .01$].

Because the initial sequence of 5 days inserted at the start of the experiment introduced participants to the entire range of wait times and was the same for all participants, Haubensak's (1992) model is not a viable model of the observed density effects (but note that the density effects observed in this experiment were smaller than the density effects often observed). Range-Frequency Theory and Comparison-Induced Distortion Theory remain as viable models of the observed density effects.

Range-Frequency Theory assumes that people have implicit knowledge about the percentile ranks of stimulus values and use that knowledge to judge stimulus values on particular trials. It, therefore, predicts density effects on individual trials. By contrast, Comparison-Induced Distortion Theory assumes that comparisons produce the same biases regardless of the type of distribution from which values are drawn (as long as D, w, and the values to which they are compared remain constant). It predicts density effects not on individual trials, but rather only in the aggregate and it does so only because the values to which judged values are compared differ across distributions.

The predictions of Range-Frequency Theory and Comparison-Induced Distortion Theory were tested by concentrating on differences between successive wait times of 3 minutes. At 3-minute differences the stimulus one back will likely be the most similar recent value, although occasionally the identical value 2 trials back may be the most similar recent value. To-be judged values drawn from the negatively skewed distribution were preceded by a value that was 3 minutes away 41.5% of the time (292/703). Of these to-be-judged values, 69.9% (204/292) were larger than 13, i.e., were in the dense region, and 14.7% (43/292) were smaller than 13, i.e., were in the sparse region. The to-be-judged values drawn from the positively skewed distribution were preceded by a value that was 3 minutes away 40.6% of the time (278/684). Of these to-be-judged values, 72.7% (202/278) were smaller than 13, i.e., were in the dense region, and 12.2% (34/278) were larger than 13, i.e., were in the sparse region.

Contrary to the predictions of Range-Frequency Theory and consistent with the predictions of Comparison-Induced Distortion Theory, differences between successive judgments (when actual differences were 3 minutes) were not correlated with differences in percentile rank. These correlations were not significant for descending ($r = .065$, $F < 1$) or ascending ($r = -.030$, $F < 1$) pairs from the positively skewed distribution or for descending ($r = -.047$, $F < 1$) or ascending ($r = -.050$, $F < 1$) pairs from the negatively skewed distribution.

Consistent with the predictions of Comparison-Induced Distortion Theory and not predicted by Range-Frequency Theory, the differences between judgments of successive wait times that were different by 3 minutes were biased apart, i.e., larger than their rightful proportion of 25% of the range (using participants' responses on trials 4, the large end of the range, and 5, the small end of the range, as the baseline). The differences between judgments of values that differed by 3 minutes were 33.2% of the range on average (SD = 25.1%) in the positively skewed distribution [which was significantly larger than their rightful proportion of 25%, $t(277) = 5.46$, $p < .01$] and were 44.6% of the range on average (SD = 49.6%) in the positively skewed distribution [which was also significantly larger than their rightful proportion of 25%, $t(291) = 6.77$, $p < .01$]. Further analyses did not find differences between the two distributions or between regions within the two distributions, or interactions between them. The differences between judgments of values that differed by 6, 9, and 12 minutes did not differ from their rightful proportions of the range (all t's < 1), perhaps because more similar recent items were recalled instead.

General Discussion

A model of distribution density effects in which verbal comparisons such as "I waited longer for the bus today than I did yesterday" create the observed biases was proposed.

Modeling demonstrated that comparisons might produce density effects. An experiment found preliminary empirical support for this proposal.

Future research will investigate density effects using reproduction dependent measures and investigate the predicted disassociation between representations of values (perhaps as measured by reproduction, see Figure 2) and category ratings (see Figure 3, Biernat et al., 1997). Future work will also investigate effects of distribution density on recall of values from memory. Comparison-Induced Distortion Theory predicts density effects on recall of values from memory and Range-Frequency Theory does not (see Choplin & Hummel, 2002, for a discussion).

Although in my view many density effects are likely to be comparison-induced, I do not assume that all density effects are comparison-induced. Density effects observed when all values are presented simultaneously in ascending or descending order (e.g., Wedell et al., 1989) strike me as cases where density effects are particularly likely to be categorization-induced as Parducci (1965) suggested. Additionally, even if density effects are found to be comparison-induced, the equations used to formalize Range-Frequency Theory will likely still provide a useful heuristic for predicting effects of density on judgment.

Conclusions

Some density effects might be comparison-induced. Comparisons of values in dense regions will tend to bias values away from each other, while comparisons of values in sparse regions will tend to bias values toward each other. These biases could produce density effects.

Acknowledgments

I thank Allen Parducci, Doug Wedell, and Gordon Logan for helpful conversations and Deborah Moradi for running the experiment.

Visual Cues to Reduce Errors in a Routine Procedural Task

Abstract

This paper reports an experiment designed to evaluate the efficacy of visual cues as error "interventions" in computer-based routine procedural tasks. Using two separate tasks with a well-documented error prone step, the effects of several visual cues were compared. The findings provide support for goal selection driven by environmental cues in routine procedural tasks. The importance of cue timing and movement and meaningfulness characteristics, particularly in dynamic tasks with external pressures, is demonstrated.

Introduction

History and Motivation

With the introduction of automation and computers, an outstanding arena for human error has been established. Subsequently, much effort has been given to categorize errors occurring in such situations, yet for the most part understanding of this very human phenomenon remains fairly nebulous. As John and Kieras (1996) stated in the 90s, "No methodology for predicting when and what errors users will make as a function of interface design has yet been developed and recognized as satisfactory…even the theoretical analysis of human error is still in its infancy."

Over the years, several elaborate models and taxonomies of human error have been developed for the purpose of qualitative diagnosis (e.g., Reason, 1990). Although useful for post hoc explanations, the predictive power of these is quite limited. Results from controlled studies with various error "interventions" may extend our understanding of why such cognitive errors arise, helping us not only evaluate (post hoc) but also design (predict) safer machines. Application areas to benefit abound, from aerospace to medicine.

Postcompletion Errors

Noting the general lack of specificity in the existing theories of human error, Byrne and Bovair (1997) moved to develop a computational theory for one widely cited (e.g., Rasmussen, 1982; Young, 1994) omission error, postcompletion error. Postcompletion errors can be broadly defined as errors that occur when the task structure demands "that some action…is required after the main goal of the task…has been satisfied or completed," (Byrne & Bovair, 1997, p. 32). With this particular class of error, the actor possesses the correct knowledge necessary to execute the task, usually performed frequently and correctly. Yet, for even operators highly familiar with the task, the isolation of a postcompletion step within the task structure makes omissions there not unlikely. This is particularly true when the actor is further affected by external factors such as a working memory load and/or fatigue, as well as internal tendencies such as hillclimbing (Gray, 2000; Polson & Lewis, 1990).

Some commonplace examples include forgetting to remove the original after making a photocopy, leaving a card in the ATM after withdrawing cash, and failing to replace the gas cap after filling up a car. Byrne and Bovair (1997) hypothesized that these errors were due to excessive working memory load leading to goal loss, or an omission of a step from the task at hand. Since with postcompletion errors the actor omits a specific subgoal rather than forgetting what to do altogether (the overlying main task goal), the source of the error was thought to more likely be working memory than long-term memory. A more recent study by Reason (2002) examined the photocopy example in detail, finding postcompletion errors to be the most common type of omission in that task (Figure 1).

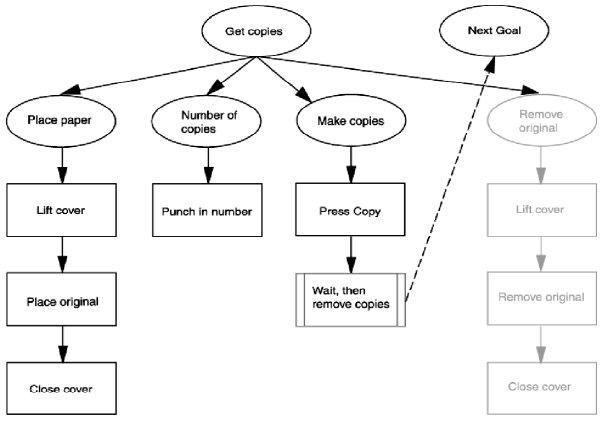

Figure 1: Photocopy task structure.

Three high-level explanatory observations were provided:

1. The emergence of the last copy generates a strong but *false completion signal* since the main goal of copying is achieved before all necessary steps (subgoals) are complete.

2. The proximity of this false signal to the end of the main task allows for the *attention to be increasingly diverted* to the subsequent task.
3. The emergence of the last copy indicates that it is no longer necessary to put in another original leaving it *functionally isolated*.

Hierarchical Control Structures and Goal Management

Many of the assumptions behind the current theory of postcompletion error reside on the foundational concept of hierarchical control structures and their retention by skilled operators. In previous studies by Byrne and Bovair (1997) and Serig (2001), participants reliably generated errors at the postcompletion steps both within subtasks as well as within the larger task, in keeping with the idea of a hierarchical task structure. Cognitive modeling work by Kieras, Wood, and Meyer (1997) has also provided strong evidence to suggest that even well practiced experts, such as telephone assistance operators, do not abandon such task hierarchies.

As Altmann and Trafton (1999) propose, the ability to break down complex tasks and problems into hierarchies and subgoals, "may be to complex cognition what the opposable thumb is to complex action." Traditionally, these types of goal-based processing strategies have relied solely on a "task-goal" stack that essentially predicts perfect memory for old goals. However, their activation-based model of memory for goals (MAGS) offers an alternative account to this approach that provides a more straightforward account for the types of errors found in human behavior.

In essence memory and the environment (i.e., dual-space, Rieman & Young, 1996; internal and external representations, Zhang & Norman, 1994) are substituted for a goal stack, and task goals are considered as ordinary memory elements with encoding and retrieval processes that must overcome noise and decay. Retrieval cues from the environment dictate the reactivation of suspended goals (e.g., Figure 1, in grey) with perceptual heuristics acting as a substitute for the stack-native last in, first out rule. This model makes several predictions about postcompletion errors and the characteristics of a successful cue:

1. Any *salient* cue (e.g., a loud beep) should be sufficient to prime a postcompletion action (suspended goal).
2. It should *not* be necessary to put the postcompletion action on the critical path.
3. Reminders at the start will *not* help a PCE at the end (masked by other goals).
4. Just-in-time priming from environmental cues are the *only* reliable reminder.

Previous Study

A previous experiment (Chung, 2004) examined the effects of a simple visual cue (red singleton onset) and a downstream error cost (in the form of a resultant mode error) on postcompletion error commission. Although neither was found to cause significant change in reaction times or error commission at the postcompletion step, the results did generate some valuable implications. First, the fact that the visual cue did not significantly reduce the number of postcompletion errors committed by the participants suggested that the cue lacked sufficient salience to prime the suspended postcompletion goal. While the sudden onset of a large red dot (against a black and white console) next to the button that needed to be pressed seemed informative enough, omissions were made regardless. Undoubtedly, participants had sufficient understanding of the task and scenario, since they could not proceed to testing without completing extensive training.

Neither did the downstream error cost (resulting in a mode error) bring about a significant change in behavior at the postcompletion step for participants. While it was expected that the visual cue would be more effective between the two treatments, it was also hypothesized that the downstream error cost would cause a change in behavior. However, the number of postcompletion errors in this condition was not significantly different from the control group, suggesting that it did not provide any significant advantage (or disadvantage) for participants. This perhaps follows findings by Serig (2001) that demonstrated error commission to be relatively independent of negative or positive feedback.

Experiment

Two tasks

Along with the original Tactical task introduced in the study by Byrne and Bovair (1997), a separate Medical task was added to distinguish the effects of the interventions. The task also included a potential postcompletion step (determined via task analysis) where the interventions could be implemented, as with the Tactical task.

Intervention Implementation

Two different interventions were introduced in this experiment: an enhanced visual cue (see Figure 2) and a mode indicator (Figure 3). These were developed specifically to address issues brought up by the findings in previous work (Chung, 2004), help pinpoint the characteristics of a successful intervention, and evaluate the predictions of MAGS (Altmann & Trafton, 1999), should one or both have a significant effect.

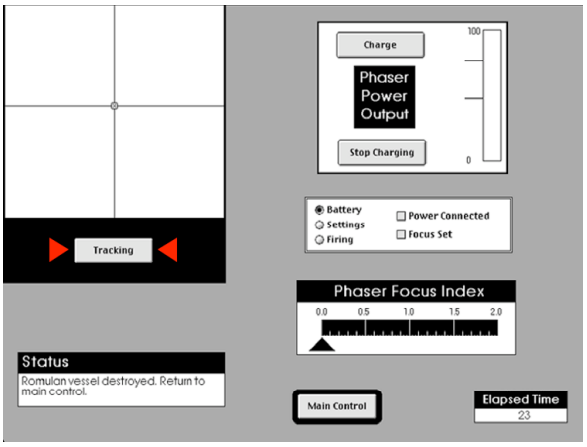

Figure 2: Tactical interface with cue (two arrows).

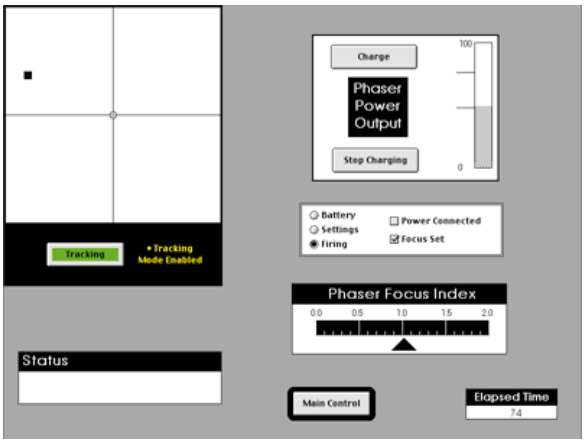

Figure 3: Mode indicator (highlighting on "Tracking" and "Tracking Mode Enabled" message).

Intervention Attributes

In a study by Monk (1986), auditory cues were employed to drastically reduce the occurrence of mode errors. Monk (1986) notes that display changes are similarly effective when the person is required to look at the relevant parts of the display at the appropriate moment in the dialogue. The related automatic processing of novel peripheral cues regardless of whether or not they are informative has been well documented (e.g., Remington, Johnston, & Yantis, 1992). Colorful visual cues are known to be effective and necessary in guiding individuals to select points of activity, such as the push plate on a door (Norman, 1988).

Research (Sutcliffe, 1995) and real-world practice indicates that the visual attributes most effective for attracting attention (warnings and indicators) on a computer interface, in order, are as follows: movement (blinking or change of position), shape and size (character font, shape of symbols, text size, size of symbols), color, brightness, shading and texture (different texture or pattern), and surroundings (borders, background color). Sutcliffe (1995) advises that these should be applied sparingly, however, as the presence of many conflicting stimuli can essentially dull their individual effectiveness. Red, green, and yellow are recommended as the optimal colors for status indicators, each corresponding to its meaning on a traffic light. To draw attention, white, yellow, and red are most effective, although yellow offers the best visibility.

Based on these recommendations and the characteristics of the failed cue from previous work (Chung, 2004), alternating red and yellow blinking arrows (Figure 2) were used for the visual cue. As per the Altmann and Trafton's (1999) predictions, the cue appeared "just-in-time" at the postcompletion step. In contrast, the mode indicator consisted of green and yellow highlighting on the "Tracking" button along with other contextual indication appearing *before* the postcompletion step. When combined with the given if-then rule at training (i.e., "If you see a mode indicator light and message, the system is on"), the mode indicator was expected to prime the corresponding goal (the postcompletion step) of turning off the Tracking system. Once the participant finishes the intermediate steps and hits the "Tracking" button a second time, the indicator disappears to indicate that the Tracking mode has ended. Exact placement of the interventions was determined through pilot studies.

Method

Participants

Ninety-one undergraduate and graduate students from Rice University aged 18 to 35 participated for course credit in a psychology course and additional cash prizes ranging from $10 to $40.

Materials

Materials consisted of a short paper-based quiz, paper-based instruction manuals for each of the four tasks (Tactical, Medical, and two filler tasks), Apple iMac computers running the Tactical and Medical applications written in Macintosh Common Lisp, stereo headphones, and a web-based general questionnaire for demographic information.

Design

This study used a two-factor between participants design with two independent variables, task and intervention. Task consisted of two conditions (Tactical and Medical) to compare the effectiveness of the interventions across task and interface. Intervention consisted of three conditions: control (no intervention), visual cue (alternating red and yellow blinking arrows), and mode indicator (mode indication for the system state change). Participants were randomly assigned to one of the six groups.

The primary dependent measure was the number of postcompletion errors made during the Tactical and Medical tasks. Other dependent measures of interest included the overall number of errors per task and performance on a

concurrent working memory task (described in Byrne & Bovair, 1997).

Procedure

Participants were run in two sessions spaced two days apart. The first session served as a training session using written documentation for each of the tasks. The major steps of the two target tasks (Tactical or Medical) are outlined in Table 1 and essentially consist of a series of key presses and mouse clicks and movements. Order of training and group assignment were randomized for every participant. Once participants successfully completed the training trial with the manual and logged three subsequent error-free trials, they were allowed to move on to the next task.

Table 1: Steps in each task.

Tactical	Medical
Charge Phaser (5 substeps)	Insert Cassette (1 substep)
Set Focus (3 substeps)	Program Rate (2 substeps)
Track Target (3 substeps)	Program Vol (2 substeps)
Fire Phaser (4 substeps)	Start Flow (2 substeps)
Return to Main Control (1 substep)	

Errors resulted in warning beeps and messages and participants were returned to the main control to restart the task. This was to prevent participants from completing training without having gone through each of the tasks at least four times with all steps done correctly and completely. When training was complete, they were reminded that they would compete for prizes in two days and given a short quiz to ensure that they had accurate working knowledge of the tasks.

The second session consisted of the test trials for both the Tactical and Medical tasks. In random order, participants completed seventeen trials of their assigned postcompletion task (Tactical or Medical) and eleven trials for each of the two filler tasks, for a total of thirty-nine trials on the test day. At testing, the experiment program emitted beeps on error commission to warn individuals but did not immediately return them to the main control or provide warning messages, as in training. Participants were encouraged to work both accurately and quickly by means of a scoring system, prizes, and an onscreen timer. A three-letter span auditory working memory task was introduced in all task conditions at testing.

Results

Data from 82 of the original 91 participants was used in the final analysis. The primary reason for the loss of data was participant failure to show up at their assigned testing date. Only one participant was removed as an outlier (Medical, cue condition). Groups broke down as shown in Table 2 below.

Table 2: Participants per group.

Condition	Control	Cue	Mode
Tactical	14	16	13
Medical	14	12	13

Postcompletion Error Frequency

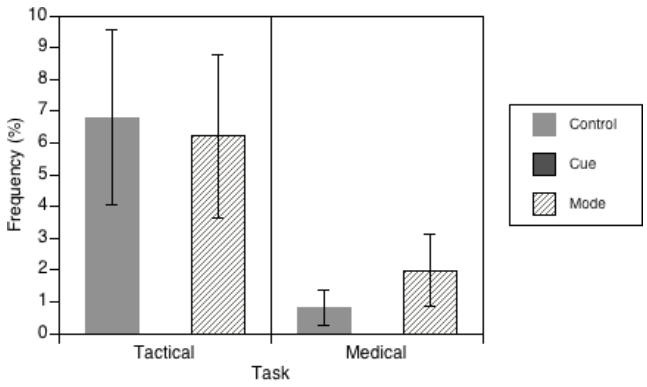

Figure 4: Postcompletion error frequency (std. error bars). Cue condition is 0% for both Tactical and Medical tasks.

Our primary measure of interest was the frequency of errors at the postcompletion step (out of seventeen trials) in both tasks. This is the step immediately following completion of the main task goal. For the Tactical task, mean postcompletion error frequencies were 6.81%, 0%, and 6.21% for the control, cued, and mode indicator conditions, respectively (Figure 4).

Analysis of variance showed the effect of intervention to be reliable, $F(2, 76) = 4.061$, $p = .021$, but not the interaction of intervention by task, $F(2, 76) = 1.86$, $p = .162$. Planned comparisons confirmed our hypothesis, as participants made significantly less errors in the cued condition versus the control, $t(76) = 3.14$, $p = .002$, and even versus the mode indicator group, $t(76) = 2.81$, $p = .006$. In comparison, the mode indicator failed to produce reliable differences with the control group, $t(76) = .263$, $p = .793$.

In the simpler Medical task, mean errors at the postcompletion step were very low: 0.82%, 0%, and 1.99% for the control, cue and mode indicator conditions, respectively. Again, none of the twelve participants in the Medical cued condition made a single postcompletion error in all seventeen of their trials. The same planned comparisons done on the Tactical task revealed no reliable differences across intervention and task.

Total Errors

The average number of total errors (out of all possible steps) was found to be higher for the Tactical task than the

Medical: 0.67 in the Tactical versus 0.28 in the simpler Medical task, $F(1, 76) = 14.60$, $p < .001$. Differences across intervention were not reliable, $F(2, 76) = 2.24$, $p = .113$, although it should be noted that the total number of errors was slightly higher for both the cue and mode indicator conditions in both tasks.

Working Memory Task

Participants showed no reliable differences in working memory task performance regardless of task $F(1, 76) = 3.47$, $p = .07$ or intervention, $F(2, 76) = 1.09$, $p = .342$.

Discussion

Our findings generally corroborate our hypothesis for the visual cue. As reported, all sixteen participants in the just-in-time cue condition of the Tactical task exhibited error-free performance at the postcompletion step on all seventeen of their trials. In contrast, the control and mode indicator groups showed mean postcompletion error frequencies between six and seven percent. Given the lack of reliable differences across intervention for overall error rates and performance on the working memory task, there seems to be no reason not to attribute the difference in postcompletion error frequency to the success of the intervention.

Nevertheless, our expectations for the mode indicator were not met. While the just-in-time cue reduced the postcompletion error mean to nil, the mode indicator had hardly any effect relative to the control. This was despite the fact that all participants were given equal training and the mode indicator was made as large, if not larger, than the flashing arrows in the cued condition. With the additional novel appearance of the crosshairs (Tactical) and display information (Medical), the state change should have been noticeable. Thus, its failure does not seem attributable to a lack of knowledge or relative visibility.

The Medical task was ineffective as a parallel of the Tactical task, perhaps primarily due to its substantially shorter length (see Table 1). It took participants nearly one quarter of the time taken to finish the Tactical task and simply failed to generate sufficient error rates to prove useful for comparing the effects of the interventions. However, it is notable that the visual cue also completely eliminated postcompletion errors in the Medical task as in the Tactical task.

Validation of MAGS

Our findings generally fell in line with the predictions of Altmann and Trafton (1999), given that the cue in the previous experiment (Chung, 2004) failed from a lack of salience. As claimed, the new ("just-in-time") cue was sufficient to prime the postcompletion step, making it unnecessary to place the postcompletion action on the critical path. Moreover, the mode indicator (a state change "at the start") did not sufficiently prime the postcompletion step that followed. It was likely "masked" by the intermediate steps or goals, as they explained.

These results support the idea of goal selection in tasks as a product of environmental cues. Hence, it follows that postcompletion errors are often generated by "false completion signals" (Reason, 2002), such as the emergence of the copy in the photocopy task. Likewise, the visual cue implemented here, in the form of two blinking arrows, was able to prime the postcompletion goal sufficiently to be correctly retrieved.

Conclusion

Several guidelines for the design of safe interfaces used in routine procedural tasks can be gleaned from this work. Interventions should be made to appear "just-in-time," as to reduce demands on memory. Asynchronous cues like the mode indicator place their own demands on memory, since there are steps intermediate to the step they are meant to prime. Even negative feedback (*after* the postcompletion step), as a downstream error cost (Chung, 2004) or as a reprimand from an "overseer" (Serig, 2001), has demonstrated no reliable reduction in the frequency of errors. Postcompletion errors cannot simply be willed away.

Also, it seems that movement and/or shape (meaning) are strong determinates of whether or not a cue is attended to (Sutcliffe, 1995). A cue (a simple red singleton) used in previous work (Chung, 2004) appeared at the same exact location as the just-in-time cue in this experiment, yet generated no significant reduction in error frequency. The mode indicator, which relied on static contextual cues, also had no reliable effect. It was made static (as in most real-world applications) since the nature of such cues is that there are intermediate steps between their onset and the step they are meant to prime. Blinking would unnecessarily attract visual attention to an inactive control.

Implementing a successful error intervention may not, however, be so simple as merely adding visual cues with these properties to the interface. Differences in task (e.g., length) and interface (e.g., background color) characteristics also attenuate the effectiveness of these cues, as demonstrated by the Medical task. Additionally, the fact that our participants had explicit training on the meaning of the cue must be considered. Simply placing blinking arrows or other novel cues on the interface would affect naïve users differently from those who had been trained.

The failure of a singleton onset (Chung, 2004) and subsequent success of two blinking arrows in this experiment may at least partially be explained by the speed at which our visual attention shifts in procedural tasks with medium to high level of skill and external pressures. Hence, while the cue used in the previous experiment also appeared in temporal conjunction with the completion of the previous step and in spatial proximity to the targeting window, it was overlooked. In contrast, the successful blinking cue continued to generate attention-capturing movement until the postcompletion step was satisfied. Moreover, it offered immediate information (arrows pointing to the correct button) about its meaning.

Hence, these findings come as further empirical evidence for cue-driven goal selection in procedural tasks. More specifically, they highlight the importance of cue timing and the visual properties of movement and meaningfulness. Follow up inquiry is underway to determine the individual strengths of these properties. Such data will be vital for any truly predictive theory of human error.

Imagistic Processes in Analogical Reasoning: Conserving Transformations and Dual Simulations

John J. Clement (clement@srri.umass.edu)

Abstract

The classical theory of analogical reasoning focuses on mappings between discrete symbols as the mechanism of analogy evaluation and transfer. This paper introduces several other analogy evaluation strategies discovered in expert reasoning protocols: bridging analogies, conserving transformations, dual simulations used to detect perceptual-motor similarity, and overlay simulations. These findings provide evidence for the hypothesis that certain analogical reasoning processes can be imagery based.

Earlier work on higher order reasoning has indicated that expert subjects use various methods to generate analogies spontaneously when solving difficult problems (Clement, 1988), and that evaluating the validity of such analogies is essential to using them (Clement, 1989). That is, even if one has generated a confidently understood analogous case, one must evaluate one's confidence in the validity of the analogy relation to have confidence in transferring results to the target. The classical theory of analogical reasoning (Gentner, 1983; Holyoke and Thagard, 1989; Forbus, et al, 1997) focuses on mappings between discrete symbols as the mechanism of analogy evaluation and transfer. This paper examines several other analogy evaluation strategies observed in expert think aloud protocols. The data base for the study comes from professors and advanced graduate students in scientific fields who were asked to think aloud about a variety of problems. This paper focuses on two mathematicians solving physics problems they found difficult. By focusing on problems with which they were unfamiliar (i.e., a problem on the frontier of their own personal knowledge). it is plausible that the thought processes analyzed will share some characteristics with hypothesis formation and model construction processes used on the frontiers of science.

An example of a problem where analogy evaluation is important is the "Sisyphus problem" in Figure 1A: "You are given the task of rolling a heavy wheel up a hill. Does it take more, less, or the same amount of force to roll the wheel when you push at x, rather than at y? Assume that you apply a force parallel to the slope at one of the two points shown, and that there are no problems with positioning or gripping the wheel. Assume that the wheel can be rolled without slipping by pushing it at either point."

One expert subject proposed the analogy that the wheel acts like a heavy lever perpendicular to the slope, with its fulcrum at the point of contact. Intuitively, the lever would be easier to move by pushing at X, suggesting that the same would be true for the wheel. But in the wheel the point of contact is moving, and ordinarily lever fulcrums do not move. In addition some subjects assume that the fulcrum should instead be at the wheel's center. Therefore the evaluation of the validity of the analogy relation (shown as the dotted line between A and B in Figure 1) was in question. This is distinguished from the subject's confidence in his understanding of the analogous case B itself, which was quite high in this case.

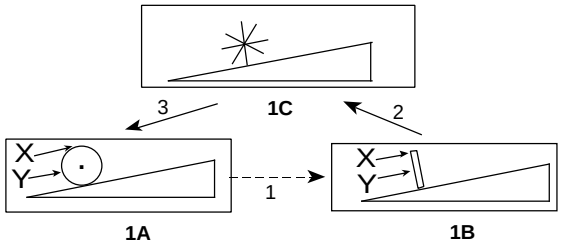

Figure 1: S2's lever analogy for the wheel

Bridging Analogies

One method for evaluating this analogy used by this subject was the bridging analogy shown in Figure 1C of a spoked wheel without a rim. By breaking the problem of confirming a "farther" analogy into the problem of confirming two "closer" analogies. such a bridge can make it easier to develop confidence that the wheel does work like the lever in Figure 1B (a correct analysis). Bridging analogies are defined as occurring when the subject finds or generates an intermediate case which shares features with both the target and source analog. Their value has been documented previously in a number of expert problem contexts and in instructional applications (Clement, 1986). While it can be very helpful to subjects, bridging in itself is an incomplete strategy for analogy evaluation, since each half of the bridge must itself be evaluated. Therefore bridging is most useful in conjunction with other evaluation methods and it adds to, rather than reduces, the number of tasks to be performed.

This raises the problem of why experts bother to consider bridging cases at all, since they seem to create more work.

Conserving Transformations

In this section I present examples of a second evaluation strategy called conserving transformations and argue that it is distinctly different from the commonly cited method of matching discrete features for evaluating an analogical relationship. A paradigmatic case of a conserving transformation (although he did not identify it as such) is Wertheimer's method for determining the area of a parallelogram by cutting one end off and moving it to the other end to form a rectangle. A transformation is an action that changes a system 1 to system 2. If 2 is the same as 1 with respect to a feature or relationship R, then the transformation conserves R. An example of a conserving transformation in the Sisyphus problem occurred when subject S7 changed the problem to an analogous one involving an almost-vertical cliff with gear teeth:

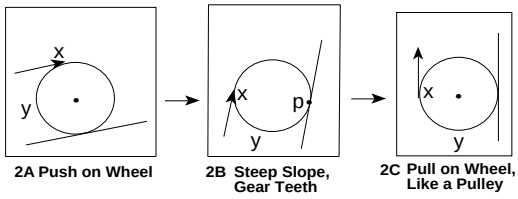

Figure 2: Wheel analogy series of S7

(Brackets in transcripts denote interpretations from viewing tape, while parentheses denote observed actions.)

01 S: "Suppose it were tilted steeply and you did that; so steep as to be almost vertical. (Draws Figure 2B). It seems like it [the wheel] would skid out from under you the other way [down along the cliff]. This (moves hands as if turning an object clockwise) would get away from you here [at point p]. Let's assume it's gear toothed [gear teeth on the wheel and the cliff] and that it won't slip. "

The change from situation A to B in Figure 2 appears to be a double transformation consisting of: the change of slope, and the addition of gear teeth. One can define the "targeted relationship" as the one for which an explanation or prediction is sought in the target situation (e.g. the relation between the force required and its location on the wheel). In his further work on the problem S7 never questions the validity of these transformations, and assumes that the targeted relationship in the problem situation is not affected by them. One can surmise that this occurs because the gear teeth transformation is a standardized one in physics and both are intuited to be irrelevant to the relationship of interest in the problem, i.e. they are conserving transformations. The origins of this kind of intuition have been studied since Piaget's early conservation experiments but are still poorly understood. (Case 2C will be discussed later.)

The hand motions over the drawing here provide one source of evidence on the use of dynamic imagery. Although the drawing can be an external support for a static visual representation, it does not depict movements, so it is reasonable to hypothesize that the subject is performing a mental imagistic simulation of the wheel slipping down on the cliff. The change in slope simplifies the problem by changing it to one in which forces act mostly along only one dimension.: upward and downward. Since the problem already specified no slipping, the gear teeth do not add new information but may help in imagistically simulating what will happen in the analogous case. Thus they may be an example of what I have called an "imagery enhancement" strategy (Clement, 1994, 2003).

The transformations appear in this case to be a means of both generating and evaluating the new analogy. Clement (1988) found that of a collection of 31 spontaneous analogies generated by ten experts, a greater number of analogies were generated via such transformations than those generated via an association to another case already in memory. However, the present paper focuses on the possible analogy evaluation function of transformations rather than on their analogy generation function.

Spring problem. A more substantial transformation is illustrated by the passage below from S2's solution to the following spring problem: "A weight is hung on a spring. The original spring is replaced with a spring made of the same kind of wire, with the same number of coils, but with coils that are twice as wide in diameter. Will the spring stretch from its natural length more, less, or the same amount under the same weight? (Assume the mass of the spring is negligible.) Why do you think so?" Earlier this subject has considered long and short horizontal bending rods made of the same wire as the spring and bent by hanging the same amount of weight on one end as an analogy for the spring problem (Figure 3B). Knowing that the longer rod will bend more suggests to him that the wider spring stretches more. In the following passage he evaluates that analogy by speaking of rolling up the bending rod into a spring (Figure 3C is discussed later):

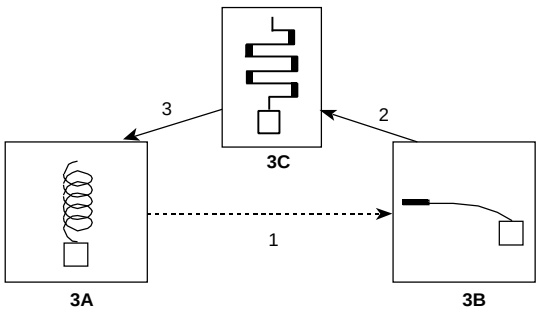

Figure 3: Rod analogy and zigzag bridge of S2

102 S: "You can imagine a spring...and you know...there's no difference between the top and the bottom. It's a symmetric situation…

105 S: You take your [straight, horizontal] wire, you say 'OK, you think it's the bending that does it. Well, then

let's bend it [by pulling down on one end of the straight wire]. And then let's roll it up [around a vertical axis] to make the spring. And you get a spring which stretches more and more at the bottom. The loops are wider apart!

107 S: Stretch it [a normal spring]: you don't get this increase of the distance between the loops toward the bottom. You just get a uniform stretching. And therefore the stretched spring cannot be understood as a rolled up bent spring."

This argues against bending as the source of stretching. Here the subject describes a very explicit spatial transformation between the spring and the rod. The sequence is: he generates the rod analogy; he simulates bending in the rod; he evaluates the analogy by transforming it back into a spring; there is a conflict with a known property of the spring, and he discounts the rod analogy. This evaluation is extremely valuable in that it gives him information arguing that the conjectured mechanism of bending is invalid. (In fact springs stretch primarily via twisting in the wire, not bending.) Note the imagery report in line 102. These passages suggest the attempt to use a visual transformation to evaluate the validity of a tentative analogy. The evaluation is influential in that it leads to discounting the validity of the analogy. Griffith, Nersessian, and A. Goel (2000) have also designed and investigated a computer program which successfully accounts for a number of features of this protocol and others collected for the spring problem. Transformations played an important role in modifying and improving faulty analogies or models in their program. However, they did not examine the role of conserving transformations as a means for analogy evaluation.

Prior to these sequences the subject had generated not only the analogous rod case, but what appeared to be a complete mapping of symbolic features between the rod case and the spring case. Bending, length, and slope, in the rod were mapped onto stretching, width, and slope in the spring. The relation of <greater length causes greater bending in the rod> had been mapped to the sought-after relation of <greater width causes greater stretch in the spring>. Therefore the transformations above do not appear to be adding any new elements to the mappings. Rather, they seem to be increasing the subject's confidence that he has found an important visual mismatch in the slope feature. They are new ways to *arrive at* the same mappings. That is, the transformations are a *means* to determining a match or a mismatch as the outcome, not just the notation for a mismatch as read off from two different lists. The notion that the transformation should be conserving is quite plausible. If the main mechanism is bending, this "winding up" transformation is locally perpendicular to the bending, therefore it could very well be a conserving transformation. Instead of transferring the "result" from the base to the target by using an explicit set of correspondences, in the present model this can be simply "read off" from an image derived from the imagistic results simulated in the base being transformed back to the target. Thus the conserving transformation strategy is a process that can work independently from an explicit feature matching process.

A traditional approach to analogy evaluation focuses on determining that multiple similarities between the base and target are sufficiently important. In contrast, a conserving transformation strategy need only focus on determining that a single transformation from base to target is sufficiently unimportant (irrelevant to the targeted relationship). This may mean that confirmation of an analogy via a conserving transformation can require considerably less work than confirmation via mapping.

Dual Simulation

Case 1. There is evidence in the protocols for a very direct strategy for analogy relation evaluation termed "dual simulation". A brief example that hints at this possibility follows where S2 says:

(Line 23) "Surely you could coil a spring in squares, let's say, and it would behave more or less the same".

There is not very much data in this statement, but it is plausible that the subject created an image of a square spring, simulated the effect of hanging a weight on it, and found this to be similar to the image of hanging a weight on a normal spring. However, the resolution of the perceived similarity appears to be at a low level of detail.

It is doubtful that his conclusion here is from "looking up a fact in memory", because of the novelty of the square case. (Later simulations by S2 with the square coil lead to imagining one side acting like a wrench to twist the next side. This produces an Aha episode with the insight that torsion is a major mechanism of stretching in the spring, and predicts correctly that the wider spring will stretch more, but that is the topic of another study (Clement, 1989)).

Dual simulation depends upon the process of **imagistic simulation** discussed in Clement (2003). That article found evidence for such an internal process from several observation categories for external behavior: **personal action projections** (spontaneously redescribing a system action in terms of a human action, consistent with the use of kinesthetic imagery), **depictive hand motions**, and **imagery reports**. The latter occurs when a subject spontaneously uses terms like "imagining," "picturing," a situation, or "feeling what it's like to manipulate" a situation. In several of the present cases one sees **dynamic imagery reports** (involving movement or forces). None of these observations are infallible indicators on their own, but as multiple instances accumulate, they can be taken as evidence for imagery. Taken together with the subject's new predictions, the observations above can be explained via *imagistic simulations* wherein a somewhat general perceptual motor schema assimilates the image of a particular object and produces expectations about its behavior in a subsequent dynamic image, or simulation.

The process of **dual simulation** can be summarized as follows. Imagistic simulations of the target and the analogous case are each run in as much detail as possible. The dynamic images of the behavior of each system are then

compared; and they may be inspected for certain aspects. If their behavior "appears" to be the same, the analogy relation receives some support, depending on the level of certainty in the comparison.

Case 2. More data is present in the following episode of an analogy to a two-dimensional spring made of zig-zagging wire that lies in a single vertical plane, shown in Figure 3C.

> 23 S2: "I wonder if I can make the spring..which is a 2 dimensional spring..but where the action ..isn't at the angles...it's distributed along the length… I have a visualization... Here's a .. a bendable bar, and then we have a rigid connector...(draws more bars connected in a zig zag, two dimensional shape). And when we do this what bends...is the bendable bars...and that would behave like a spring. I can imagine that it would.... it would stretch, and you let it go and it bounces up and down. It does all the things."

Here the conjunction of the dynamic imagery reports and the comparison of the two systems gives more support to the hypothesis that a dual simulation is occurring to compare the target and the zig zag cases. The dual simulation appears to establish the analogous case as being relevant and plausibly analogous in that its behavior is similar, at least at a gross level of qualitative behavior, to the target. But this does not tell the subject whether the two systems exhibit the same relationship between width and stretch. Thus in the above cases dual simulation appeared to serve only as a check on the initial plausibility of the analogy.

One then needs to be clear that dual simulation as an analogy evaluation strategy does not necessarily mean confidently simulating the targeted relationship in both base and target. In that case there would be no need for an analogy because the target could have been directly simulated on its own. However, the examples presented indicate that dual simulation can still help one determine whether the target and base are similar with respect to other important behaviors, thereby increasing one's confidence that the analogy is sound (or eliminating the analogy from consideration).

Overlay Simulation

Lever case: There is evidence for the existence of a more precise type of dual simulation that I term "overlay simulation" where the image of one simulation takes place "on top of" a second image. Although I have separated them in Figure 1 for clarity, S2 actually drew his lever analogy (Figure 1B) directly on top of the wheel (Figure 1A) and compared the movement of the wheel and the lever. This meant that the arrow symbolizing the application of a force by pointing to the top of the wheel was also pointing to the top of the lever. When two separate systems are represented as overlapping in the same external diagram with salient features aligned I term this an *overlay diagram*. This supports the interpretation that internal dynamic images of the two systems and their actions were overlapping in the same way. I call this hypothesized internal aspect here an *overlay simulation* as a special type of dual simulation. Presumably the alignment of key features made it easier for him to compare the expected movements and resistances of the wheel and the lever as he simulated each of them.

Spokes case: Overlay simulation may also be responsible for the power of S2's "spoked wheel without a rim" bridging analogy shown in Figure 1C. For the spoke that is touching the ground, the spoke can be seen as a lever with its fulcrum at the ground. This means that the entire wheel of spokes can be seen at any one time as equivalent to a single lever, supporting the analogy on the right hand side of the bridge BC in Figure 1. This subject spoke of a tireless, rimless wheel. Again this is shown separately in figure 1C for clarity, but in fact the spokes were inscribed within the rim of a circular wheel in the subject's drawing. So on the other side of the bridge AC, the spokes are envisioned at the same size as the original wheel, and this may make it easy to sense via dual simulation that they behave in the same way as the wheel when a force is applied. In particular, the way the rimless spoked wheel "rocks" on each spoke over a short distance can be seen as similar to the way the original wheel rolls. That is, it appears, especially with many spokes, to have the same kind of motion in a mental simulation and therefore be amenable to the same type of analysis with respect to the causes of motion. Although such arguments must be bolstered mathematically to make them rigorous, as a form of heuristic reasoning, this type of qualitative argument can be quite compelling.

Pulley case: As a third example the case of the pulley analogy in Figure 2C was also used by S7 in the Sisyphus problem. He believes that perhaps the push needed at X on the wheel is smaller than at Y, similar to a pulley where the force applied to the end of the rope need only be half of the weight of the wheel. As part of an attempt to evaluate that analogy, S7 speaks and gestures as if alternating between seeing the same drawing (Figure 2C) as a wheel and a pulley, referring to it differently as one or the other in alternate fashion. Continuing from segment 01 above:

> 05 S7: What it feels like is the weight of it [wheel in Figure 2B]-; is pretty close to parallel with what you've got if you go roll it with a complete vertical. It now begins to feel like a pulley...(Draws Figure 2C) What the vertical is over here no longer matters perhaps but we'll say it's er, gear toothed again.
>
> 06 S: ...And you're over here pulling like this [at x]. That feels like you're on the outside of a pulley pulling up.
>
> 07 S: And since you say it doesn't slip, then this thing over here (points to line in upper right of Figure 2C and adds upward pointing arrowhead to it) must be providing the other half of it, something it feels, in which case it's a classic pulley; no, it can't be classic pulley. But it's, like a classic pulley in which now you only need half of the force. If the weight of the thing is 10 lbs. here, it feels like 5 would work here (writes 5 on upper left of C) and 5

over here (writes 5 on upper right) as though it were a pulley… So let's imagine it is a pulley.

08 S: [In] this new point of view, it feels like working at X [on the edge of the wheel] is better [than at the center].

The personal action projections and alternating references to both the wheel and the pulley systems while staring at the same diagram 2C provide initial evidence for an overlay simulation here that compares the system of rolling the wheel straight up a vertical cliff to the pulley system. Presumably it is easy in an overlay simulation to switch rapidly between simulations of the two cases, (which happens at least five times above). Again, although the imagery is probably assisted in this case by the drawings, the drawing cannot be providing perceptions of forces or motions involved, and so I hypothesize that these are imagined via imagistic simulations. Some evidence for kinesthetic imagery is indicated by personal action projection phrases like "feels like you're on the outside of a pulley pulling up" and "you're over here pulling" in the transcript, and such imagery is clearly not already enacted in the static drawings.

Later he expresses some reservations about the pulley analogy however: "This rope wrapping around here..doesn't feel to me necessarily like...pushing (moves hand . to r.) on the outside of a wheel." But in the passage below he appears to reevaluate the analogy positively by (1) generating a bridging analogy; and (2) using overlay simulations by simulating different systems in alternating fashion using the original wheel drawing. Therefore this final example is more complicated because it combines these two strategies.

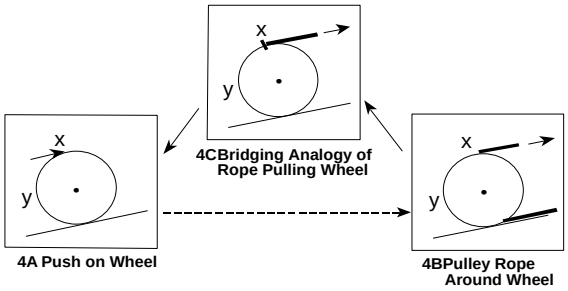

Figure 4: Second analogy series of S7

162 S7: (Looking at Figure 4A) I've got my full (holds both hands out as if pulling a rope and shakes them slightly) power available- and where would I apply that? My instinct tells me [it is easier to apply force at] X again but that er, but again it's in terms of a pull and not a push. I'd have to get a grip.(closes eyes) Assuming that's not a problem, then pulling should be the same as pushing.. Seems clear that- (silently holds both hands out as if pulling a rope for 4 sec.)...So we attach a rope to one of the teeth [as in 4C but staring at the same Figure 4A], now it becomes more like the pulley problem (holds r. hand out as if pulling a rope for 3 sec)…the teeth at the bottom are playing the role of-; the pulley doesn't look so bad after all. And you hang on for all you're worth up there, to keep it from rolling; to keep it balanced.

Figure 4C shows how a rope attached to the edge of the wheel at X can be seen as an intermediate bridging case between the original problem and the pulley case in 4B. Although I have drawn three cases in Figure 4 for clarity, in fact S7 used only Figure 4A while talking about the three cases: the pushed wheel, the pulley, and the rope attached to the tooth at X on the wheel. One can hypothesize that the internal overlay simulations create a context whereby the alignment between trajectories and forces in imagistic simulations of different cases, as well as the evaluation of the validity of the analogies between the cases, can be more easily made.

163 S7: Seems a lot easier than getting down here behind it [at "Y" in Figure 4A] and pushing. Why? because of that coupling pulley effect. It seems like it would be a lot easier to hold it here [at "X"] for a few minutes (Holds hands in "pulling" position) than it would be to get behind it… yeah, my confidence here is much higher now, that it's right… [easier to push at X] And so the pull--it just felt right with the pulley feeling. Now pushing (lays extended finger on paper pointing up slope at X in Figure 4A and moves it toward X) uh,.. it's got to be the same problem…

178 I: Do you have a sense of where your increased confidence is coming from?

179 S: It's the pulley analogy starting to feel right.

The subject's thinking here appears to determine whether the forces on the edge of the wheel and on the rope from the pulley "feel" the same as he performs an imagistic simulation of each case. The bridging case in Figure 4C of a rope tied to the wheel at point X appears to serve the purpose of setting up two pairs of cases (base:bridge B:C and bridge:target C:A) that are "closer" to each other than AB. In other words the bridging case creates two analogy pairs that are more perceptually similar. This may be an important advantage if the evaluation of each pair is being done via a dual simulation of the cases. This provides one answer to the earlier question of why bridging can be useful to a subject even though it seems to add more work in creating additional analogy relations.

In fact the underlined references to feeling forces, personal action projections, and hand motions in the above passages provide evidence for the involvement of kinesthetic imagery and for dual imagistic simulations when he is comparing two cases. One can hypothesize that Figure 4A is acting as an overlay diagram for an overlay simulation. The use of an overlay diagram and references that the wheel problem solution "felt right with the pulley feeling." supports the hypothesis that dual simulations are being used to evaluate these analogies. Thus this last example illustrates the combined use of overlay simulation (as a special kind of dual simulation) and bridging as analogy evaluation strategies.

Conclusion

In summary, rather than a single process for mapping elements in a discrete symbolic representation, a number of

additional processes for evaluating an analogy relation have been identified, namely: bridging analogies, conserving transformations, dual simulations to detect dynamic similarity, and overlay simulations. Roughly, conserving transformations work by allowing the subject to detect the causal, perceptual motor irrelevance to a targeted relationship, of making a transformation on a case. Dual simulations work by allowing the subject to detect a causal, perceptual motor similarity between base and target. Overlay simulations are a special type of dual simulation in which the image of one case is overlaid and aligned on top of the other case to make comparisons more precise. An intermediate bridging case is a higher order strategy that can facilitate making one of the above processes easier to perform. The relationship of these strategies to discrete feature mappings is still unclear, but when subjects can articulate such mappings, that may add another important kind of precision to the process of analogy evaluation.

Implications. These findings add to previous evidence (Casakin and Goldschmidt 1999; Clement 1994, 2003: Craig, Nersessian and Catrambone, 2002; Croft and Thagard, 2002; Trickett and Trafton, 2002) for formulating the general hypothesis that many analogical reasoning processes can be imagery based. Also, the wheel problem transcript provides evidence that imagery and runnability are transferred from base to target. Clement (2003) extended this theme by examining evidence for the transfer of imagery and runnability from source analogues to explanatory models and hypothesized that this may be an important source of model flexibility, providing an argument for the importance of such processes. The importance of bridging analogies as an instructional technique has been documented previously (Clement, 1989), and the same may very well be true for conserving transformations (Wertheimer, 1959), and overlay simulations/animations. Thus much work remains to be done in this area.

Abstract

There is an ongoing debate on the nature of the processes and knowledge involved in learning language. On one side of the debate, people argue that children learn words through deliberative processes that use propositional conceptual knowledge; on the opposing side, people argue that children learn words through automatic processes and knowledge based on learned associations among perceptual features. In this paper we concentrate on the Animate/Inanimate distinction as evidenced in children's novel noun generalizations. The results of two experiments with 3-year-olds and adults suggest that 1) automatic processing guides children's generalizations of novel nouns and 2) "conceptual" knowledge may be formed as a web of learned correlations.

Background

The nature of the processes and knowledge involved in children's learning of new nouns is a highly contentious issue. Children generalize names for things in appropriate ways depending on the kind of thing being named. For example they generalize names for artifacts by their shape; names for non-solid substances by their material; and names for animates by their shape and texture. The debate centers on the nature of the processes and knowledge involved in this behavior. On one side of the debate, people argue that children reason about category membership using slow, deliberative, conscious processes and propositional beliefs about categories and category structure (Gelman & Markman, 1987; Keil, 1994; Kemler-Nelson, Russell, Duke & Jones, 2000). On the opposite side, people support fast, unconscious, automatic processes and knowledge in the form of correlations among perceptual features (Smith, 1995; Smith, 2000; Smith, Colunga & Yoshida, 2003). Sometimes this debate has been framed in terms of whether children's early word learning is "smart" (reflective, conceptual) or "dumb" (built from more basic general and automatic processes). In this paper we concentrate on the Animate/Inanimate distinction as shown in children's novel noun generalizations. We show evidence that automatic processing guides children's generalizations of novel nouns, and suggest that the "conceptual" knowledge that enters word learning, even in adults, may be me made out of correlations of perceptual features.

One widely used task to study children's word learning biases is the novel noun generalization task. In this generalization task, children are shown an exemplar like those in Figure 1. They are told its name, and then asked what other things have the same name. When shown an exemplar like that in Figure 1a, with cues indicating it is a depiction of an animate thing, children systematically generalize its name only to new instances that match in both shape and texture, but not to things that match in shape only or texture only. When shown an entity without such features, children systematically generalize the name to new instances that match in shape, whether they match in other properties or not, as shown in Figure 1b. Jones & Smith, (1991) and others have suggested that children learn correlations between features and category structure -- between having eyes and being in a category organized by shape and texture, and between being angular (and without animacy features) and being in a category organized by shape. Consistent with theories and evidence on attentional learning, they suggest that in the novel noun generalization task, these features automatically increase attention to relevant properties, enabling children to attend to the right similarities according to the kind of the object at hand. This correlational learning account has been supported by showing that the requisite correlations between features and category organization exist across the first 300 nouns that children learn (Samuelson & Smith, 1999).

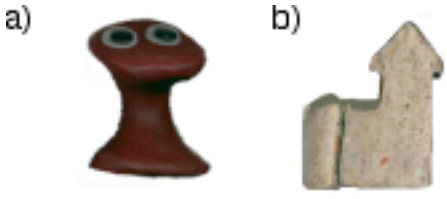

Figure 1. Examples of an exemplar with cues indicating it is a depiction of an animate thing, and an exemplar with artifact cues.

Recently, Booth and Waxman (2002) provided support for the alternative "smart" interpretation of children's performance in this task. Booth and Waxman presented exemplars in a context that construed them as animate or inanimate. The disambiguating context consisted of brief stories in which the experimenter gave the child information about the exemplar. For example, in the animate condition,

the experimenter introduced an exemplar as a Teema and explained that the Teema has a mommy and a daddy that love it very much and gave it hugs and kisses. Similarly, in the inanimate condition, the experimenters showed the same exemplar but this time introduced it as a Teema which is used by astronauts in their trips and will be replaced if it breaks. Their results showed that 3-year-olds can use the information in the stories to guide their generalizations of the novel noun – in the Animate condition, children generalized the novel name for the exemplar to other objects matching in shape and texture, but in the Artifact condition they generalized the novel name to any object that matched the exemplar on shape. Booth and Waxman take this result to mean that children word learning is "smart", a result of deliberative processes operating on conceptual knowledge in the form of an unitary concept of animacy. Their account is illustrated in Figure 2a.

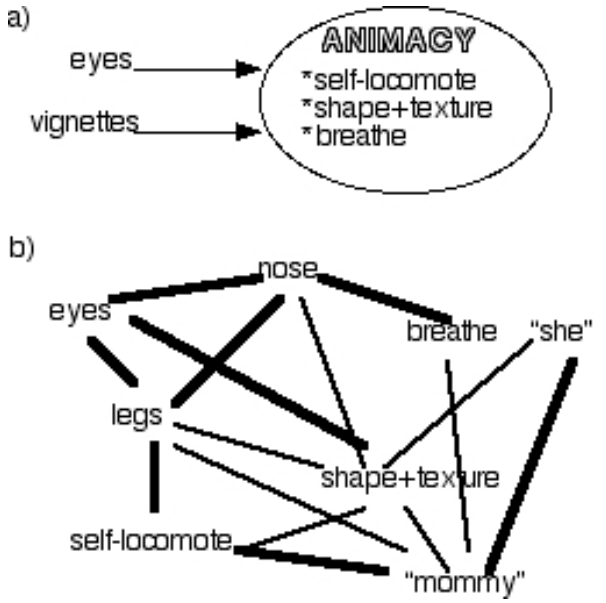

Figure 2. In Booth & Waxman's account, eyes, like vignettes, serve as a gateways to children's concept of animacy. In the correlational learning account, eyes and words like "she" or "mommy" are part of a web of correlations that is learned from the regularities that exist in animate categories in the world.

According to Booth and Waxman, the stories affect children's extension of novel nouns because they provide conceptual information relevant to the exemplar's ontological kind. That is, the Animate story identifies the exemplar as an animate, and the Artifact story identifies the exemplar as an artifact. Once children know the ontological kind of the exemplar, they have access to all the knowledge regarding that ontological kind, including the fact that shape and texture are central features for Animates and shape is the central feature for Artifacts.

The correlational learning account can also explain Booth and Waxman's findings. Novel nouns are extended on the basis of learned correlations among perceptible properties. Having eyes correlates with having a mouth, correlates with being called "he" or "she", correlates with animate-like motion patterns, correlates with attention to shape and texture. This web of correlations is the "knowledge" used in the novel noun generalization task through automatic processes, rather than through deliberative reasoning. Importantly, by this account any one cue can activate any other part of the web, *depending on the degree to which they have been correlated in the learner's experience*. Under this view, Booth and Waxman's results can be explained as a consequence of learned correlations among perceptible properties, including words. The vignettes shift children's attention because they are made out of words – words that correlate with categories of animates that are organized by shape and texture (like zebra, or snake) and words that correlate with categories of artifacts that are organized by shape (like hammer, or cup).

If the correlational story is correct, these words should cue attention to shape and texture in the Animate condition and attention to shape in the Artifact condition automatically, and without being strung together to form a coherent story *about* the exemplar. A strong test of this prediction would be to prime the children with animate-correlating or artifact-correlating words presented merely as a list and measure how this affects their performance in the novel noun generalization task. Under Booth and Waxman's explanation, reading children these words in a list should not have an effect since they are not put together into a coherent story that presents conceptual information regarding ontological status, nor are they presented as referring in any way to the exemplar. Thus, if children's novel noun generalizations are shifted by this priming, this attentional shift will not be attributable to any kind of deliberative process that reasons about the ontological status of the exemplar using the information given by the experimenter. Experiment 1 tests this prediction.

Experiment 1

Methods

Participants. 24 3-year-old children with a mean age of 42.6 months (range: 38.4-45-5 months) participated.

Materials. The stimuli consisted of two sets of eight abstract objects that could be construed as either animate or inanimate. Each set consisted of an exemplar object and 7 test objects that matched the exemplar in none, one, or more features of shape, texture or color. Figure 3 shows the diagnostic items, the ID test object matched the exemplar in all shape, color and texture features (but was different in size), there were also test objects that matched the exemplar in shape only, color only, texture only, shape + texture, shape + color, color + texture, and none of these features.

Two lists of words, one of animate-correlating words, the other of artifact-correlating words, were selected from the Animate and Artifact vignettes in Booth and Waxman (2002). Table 1 shows the words used.

Table 1: List of animate-correlating and artifact-correlating words selected from Booth & Waxman (2002).

Animate	Artifact
mommy	take
daddy	worn
love	break
sleep	make
hugs	bought
kisses	use
hungry	
walking	
gobbled	
happy	

Procedure. Children were randomly assigned to either the Animate or Artifact condition. During the Priming Phase, the child and the parent were asked to repeat the words said by the experimenter. The experimenter then went through the corresponding list saying each word once and letting parent and child repeat it. None of the test objects or exemplars were in view during the Priming phase. The Priming Phase was followed by the Testing Phase. The list of words was put away and children were informed that now they were going to play a different game and they were introduced to one of the exemplars "This is a Teema." and then asked for each of the test objects in that set "Is this a Teema?". Each of the test objects were presented twice in one of two previously generated random orders. Then the second set was presented, preceded by a second Priming Phase, for a total of 28 trials. The order of the sets was counterbalanced across conditions.

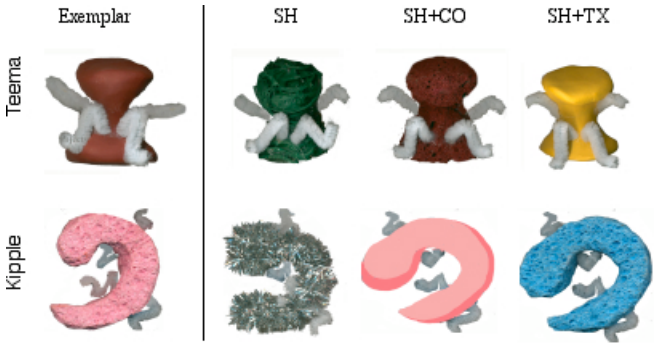

Figure 3. The two exemplars and some of their corresponding test items.

Results

The number of "yes" responses (the name applies) was submitted to a 2(Priming List)x7(Test Item) repeated measures ANOVA. The analysis revealed a main effect of Priming List ($F_{(1,22)}$ = 5.38, P < .05). That is, children overall said "yes" more when primed with the Artifact list of words than when primed with the Animate list. There was also a main effect of Test Item ($F_{(1,22)}$ = 37.21, P < .001). No interactions were significant.

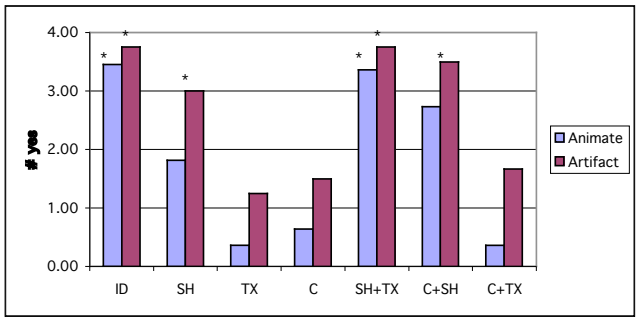

Figure 4. Results for Experiment 1.

Furthermore, post-hoc analysis revealed different patterns of noun extension in the two conditions. As shown in Figure 4, children in the Animate condition extend the name to the ID test object and to the shape+texture match, whereas children in the Artifact condition extend the name to the ID test object, the shape-only, the shape+texture and the shape+color matches. We counted the number of children who said "yes" more than expected by chance on each condition. On the critical test item, the shape-only match, there was a significant difference on the number of children who said "yes" more than expected by chance in the Animate versus the Artifact condition ($\chi^2(1,N=24)$ = 4.19, P <0.05). That is, children in the Artifact condition extended the name of the exemplar to all the test objects that matched it in shape, regardless of their size, color or texture, but children in the Animate condition extended the name of the exemplar more conservatively, only to those test objects that matched it in both shape and texture.

Discussion

At the very least, the results of Experiment 1 showed where the Animacy/Artifact information in Booth and Waxman's vignettes comes from. Just hearing these words, without weaving them into a coherent story, was enough to shift children's attention to features typical of animate vs. artifact categories – shape only for artifacts, shape+texture for animates. But more importantly, children's novel noun generalizations were influenced by these words in a priming paradigm, without these words being heard at the same time that the exemplar or test objects were present. Apparently, these words automatically activate the attentional biases with which they are associated, a fact consistent with well-supported ideas about memory processes (). The result thus supports the idea that children's novel noun generalizations depend on automatic processes that operate on learned correlations.

But is it possible that the concept of animacy is nothing but learned correlations of perceptible features? At least intuitively, it would seem that adults have a concept of animacy that corresponds to the kind of conceptual knowledge Booth and Waxman are talking about. Certainly, adults know the word "animate" and understand the words "living thing". Do these concepts enter into their generalizations of novel nouns? Will adults differentially

generalize names for ambiguous stimuli if told the exemplar represents an animate entity vs. an artifact? One reason to believe they may not is that "animate" – the word – as such, is probably not very correlated with perceptual category formation, that is, with deciding the range of instances that go in a category. If the knowledge used in this task comes from learned correlations, the word "animate" in and of itself may not be potent enough to activate attention to shape and texture. A better cue would be one that is strongly associated with perceptual category decision and category name extensions.

In contrast, by Booth and Waxman's account, the word "animate" should directly activate adults' concept of animacy, indeed, and should therefore direct adults to the relevant knowledge within that concept, enabling them to reason that the relevant properties for categorization are shape and texture.

Experiment 2 tests these ideas using two experimental conditions. In one, adults were told the exemplar is an animate or an artifact; in the other, they were given additional perceptual cues (motion) correlated with animates or artifacts.

Experiment 2

Methods

Participants. 40 undergraduate students participated in this experiment.

Stimuli. The two sets of objects used in Experiment 1 were used in this experiment.

Procedure. Participants were randomly assigned to one of 4 conditions: WordOnly-Animate, WordOnly-Artifact, Word+motion-Animate, and Word+motion-Artifact. Participants were introduced to the exemplar of a set and told "This is a Teema. It is an animate. It is a living thing" in the WordOnly-Animate condition; "This is a Teema. It is an artifact. It was made in a factory" in the WordOnly-Artifact condition. In the Word+motion condition, the exemplar was presented with the corresponding phrases but they were also moved in a walking or slithering motion in the Animate condition or in a rolling or hammering motion in the Artifact condition. Each participant saw both sets and the order of the sets was counterbalanced across conditions. As in Experiment 1, each participant was queried on each of the 7 test-objects twice, for a total of 28 trials.

Results.

We first consider performance in the WordOnly conditions (Figure 5). The number of "yes" responses was submitted to a 2(Kind) x 7(TestItem) repeated measures ANOVA. The analysis revealed a main effect of TestItem ($F_{(1,18)}$ = 41.763, $P < 0.001$) and no other main effects or interactions. There was no significant effect of Kind, that is of hearing Animate versus Artifact instructions ($F_{(1,18)}$ = 1.153, $P > 0.2$). Post-hoc analysis on the critical test item, the shape-only match, also yielded no significant difference between conditions ($\chi^2(1,N=20)$ = .2197, $P > 0.05$). In short, when the ontological kind information consisted solely of words like "animate" and "artifact", attention was not shifted consistently with ontological kind.

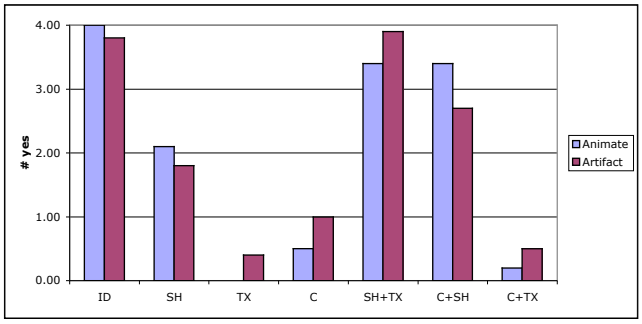

Figure 5. Results for the Word Only condition in Experiment 2.

Figure 6 shows adults' performance in the Word+motion conditions. Again, the number of "yes" responses was submitted to a 2(Kind) x 7(TestItem) repeated measures ANOVA. The analysis revealed a main effect of TestItem ($F_{(1,18)}$ = 26.543, $P < 0.001$) and a significant interaction between Kind and TestItem ($F_{(2,18)}$ = 3.024, $P < 0.01$). Post-hoc analysis confirmed a different pattern of responses in the Animate and Artifact conditions for the shape match. There was a significant difference on the number of adults who said "yes" more than expected by chance on the shape-only match in the Animate versus the Artifact condition ($\chi^2(1,N=20)$ = 5.4945, $P <0.025$). As predicted, participants were more likely to accept the shape only match in the Artifact than in the Animate condition. Thus, adult's novel noun generalizations, when given additional perceptual cues highly correlated with ontological status, did generalize names according to kind – by shape and texture for Animates and by shape for Artifacts.

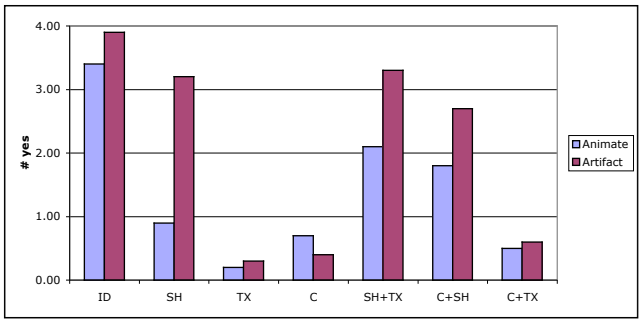

Figure 6. Results for the Word + motion condition in Experiment 2.

Discussion

As expected from the correlational learning account, adults do not show evidence of the animate/artifact distinction in their novel noun generalizations when the only

information they get about the kind of the exemplar is in the form of phrases like "is an animate" and "is a living thing". They do, however, show differing patterns of generalizations when perceptual correlations, in the form of motion cues, are added. This result suggests that, although adults most likely understand what the word "animate" and what the phrase "living thing" mean, this may not be the kind of information that enters in generalizing a novel noun. It also suggests that reasoning about the implication of the ontological status of the exemplar is not the kind of process that primarily guides the extension of novel nouns. Instead, this result suggests that the knowledge that constrains novel noun generalizations is formed by learned correlations of perceptual features and category structure.

General Discussion

Put together, the results of the two experiments support the idea that automatic processes operating on learned correlations of perceptual information can guide word learning. The results of Experiment 1 showed that just listening to a list of words correlated with animates (or a list of words correlated with artifacts) is enough to shift children's attention to the features that typically organize categories of animates (or artifacts). The fact that the lists of words -- without forming complete sentences, without referring to the exemplar, without even co-occurring with the exemplar – can shift attention in kind-specific ways suggests an explanation to Booth and Waxman's results that does not need to appeal to any form of deliberative reasoning on the party of the child. It could be, however, that when given complete sentences forming coherent stories, children do take advantage of that information and more deliberative processes that work on this more propositional information are invoked, but the results in Booth and Waxman (2002) and the results in Experiment 1 can be explained as simple priming, operating on previously learned associations. Further experiments are necessary to determine when this more "conceptual" knowledge is used in extending a novel noun.

Furthermore, the results of Experiment 2 suggest that what we think of as more "conceptual" knowledge may be, at the end, nothing more than a web of correlations, including perceptual features, words, category structure, contexts, and so on. The adults in this experiment failed to shift their attention when explicitly told that the exemplar was animate or artifact, but had no problem doing so when given further correlational support, like watching the to-be-construed-as-animate exemplar "walk" or used as a hammer. Clearly, adults do have highly abstract knowledge about animates and artifacts, and in a different task they might show this. For example, if the task were to make inferences about the exemplar, being told that it is to be construed as an animate might lead to more sound reasoning than watching it "slither". However, it seems that when it comes to extending a novel noun, adults, like children, rely on automatic processes guided by learned correlations.

Conclusion

Extending a novel noun in ways consistent with the ontological kind of its referent is certainly a "smart" thing to do – it allows word learning to proceed quickly and carves the world into useful partitions. However, this "smartness" may be the product of rather "dumb" processes such as associative learning and generalization by similarity. Through the application of these dumb mechanisms in a world that presents regularities we may create smart concepts.

Making the Implausible Plausible

Louise Connell (louise.connell@ucd.ie)
Department of Computer Science, University College Dublin
Belfield, Dublin 4, Ireland

Abstract

Whenever we must evaluate a theory, consider an excuse, or appraise a situation, we must judge how plausible things appear to us. In short, plausibility judgement occupies a central position in human cognitive life. Recently, it has been shown that the plausibility of a scenario depends on how its events can be connected (Connell & Keane, in press). In this paper, two experiments examine how a normally implausible scenario can be made to seem plausible by forcing a connection between its events. Results show that people's perceptions of a scenario's plausibility can be manipulated by encouraging them to represent events in a causal chain or temporal sequence.

Introduction

Every day, in many different situations, we judge plausibility. Whether evaluating a theory, considering the plot quality of a movie, or listening to child explain how a dish came to be broken, we are assessing how plausible a scenario seems to us.

Across the cognitive science and cognitive psychology literature, plausibility judgement has been shown to be useful in a diverse range of cognitive tasks. People often use plausibility judgements in place of costly retrieval from long-term memory, especially when verbatim memory has faded (Lemaire & Fayol, 1995; Reder, 1982; Reder, Wible & Martin, 1986). Plausibility is also used as a kind of cognitive shortcut in reading, to speed parsing and resolve ambiguities (Pickering & Traxler, 1998; Speer & Clifton, 1998). In everyday thinking, plausible reasoning that uses prior knowledge appears to be commonplace (Collins & Michalski, 1989), and can even aid people in making inductive inferences about familiar topics (Smith, Shafir & Osherson, 1993). It has also been argued that plausibility plays a fundamental role in understanding novel word combinations by helping to constrain the interpretations produced (Costello & Keane, 2000; Lynott, Tagalakis & Keane, in press). Yet, despite its apparent usefulness in cognitive life, the study of plausibility judgement in its own right has been neglected in cognitive science until recently.

The Knowledge-Fitting Theory of Plausibility

Recently, Connell and Keane have proposed the Knowledge-Fitting Theory of Plausibility (2003a, 2003b, in prep; Connell, 2004) to rectify this oversight. According to the Knowledge-Fitting Theory, a plausible scenario is one that fits well with our knowledge of the world. In other words, a plausible scenario has good *concept-coherence*. A concept-coherence view of plausibility suggests that when people make a plausibility judgement, they relate the current scenario to their prior experience, and in some way assess whether it fits in with what they have experienced in the past. For example, take the scenario "*The bottle rolled off the shelf and smashed on the floor.*" People might understand this scenario by drawing a causal inference between the events – that is, the bottle falling *caused* it to smash on the floor. This might lead them to judge this scenario as being highly plausible because prior experience tells them that fragile things often break when they fall on hard surfaces. Put simply, the scenario has a certain concept-coherence. In contrast, if the scenario was "*The bottle rolled off the shelf and melted on the floor*", people might consider it less plausible because they cannot connect the events, as their past experience has few examples of falling fragile objects melting on contact with floors. In other words, this scenario lacks a certain concept-coherence.

The Knowledge-Fitting Theory is supported by a number of empirical findings. For example, Black, Freeman and Johnson-Laird (1986) disrupted the sequence of events in short stories and found that people's plausibility ratings were sensitive to the degree to which the overall concept-coherence of the story had been altered; when people could no longer infer connections between events, they no longer considered the stories plausible. Connell and Keane (in press; Connell, 2004) investigated this issue further, and found that the plausibility of a scenario is not only affected by *whether* the events can be connected, but also by *how* the events are connected. For example, events linked by causal inferences (i.e., *X* was caused by *Y*) were judged to be more plausible than events linked by temporal inferences (i.e., *X* happens after *Y*). These types of scenario were both considered more plausible than scenarios where the events could not be connected at all (i.e., unrelated events). Connell and Keane (2003a, 2003b, in prep.) suggest that causal connections have better concept-coherence than temporal connections because they fit more closely with prior experience, and this makes causal scenarios seem more plausible.

The Current Study

When we judge the plausibility of some scenario in everyday life, it is often with the objective of accepting or rejecting the presented scenario. For example, we may choose to accept or reject an excuse based on whether we find it plausible or not. However, plausibility is not always a binary variable (i.e., a choice between plausible and implausible) (e.g., Black et al., 1986; Connell & Keane, in press). Rather, it may sometimes be considered as a sliding scale between plausibility and implausibility, and we may judge a particular scenario as lying somewhere along this scale. In addition, the plausibility of a particular scenario may not have a constant value: for example, temporal scenarios can be made to seem less plausible when attention is drawn to their non-causal nature (Keane, Connell & O'Donoghue, in prep.).

This paper investigates whether an implausible scenario can be made seem plausible by forcing a particular connection between its events. The Knowledge-Fitting Theory holds that if we cannot connect the events in scenario, we will find it implausible. However, it is possible that if we manage to connect unrelated events in some way, then the plausibility of the scenario might increase. For example, the scenario "*The bottle rolled off the shelf and melted on the floor*" seems generally implausible, but it is possible to construct some set of circumstances that makes it appear more plausible (e.g., the bottle melted because the floor was very hot, because the house was on fire). This suggests that the concept-coherence and plausibility of a normally implausible scenario could be manipulated by encouraging people to make particular connections between events. Therefore, the first experiment asks people to make specific causal or temporal connections between unrelated events, and examines how this influences their decision to accept or reject the scenario. In the second experiment, the same manipulation is used to show how different connections also influence people's plausibility ratings. These results are then related back to the Knowledge-Fitting Theory, and are used to examine what kind of relationship exists between binary and scale plausibility judgements.

Experiment 1

In Experiment 1, participants are presented with implausible scenarios and are asked to judge whether each scenario is plausible or not. Connell and Keane (in press) show that scenarios with no connection between events are considered implausible, while those with causal and temporal connections are considered plausible. This experiment leads people to think about how the events in a scenario may be causally or temporally connected, and examines how these different connections can make people accept as plausible a scenario that would normally be rejected as implausible. For example, take this scenario: "*The teacher misspelled a word. The vase smashed.*" If people are encouraged to represent this normally implausible scenario with a causal or temporal connection between events, then this may lead them to perceive the scenario as plausible. For example, if this scenario was represented within a specific temporal frame (e.g., the vase smashed a second or two after the teacher misspelled a word), then it may have sufficient concept-coherence to appear plausible to some people. Alternatively, if this scenario was represented with a causal chain between events (e.g., the vase smashed because the teacher bumped against it when taking a step back to examine the misspelled word), then it may have sufficient concept-coherence to appear plausible to many people.

This experiment uses different types of question to encourage people to make particular connections between events. In the no-connection control condition, participants judged the plausibility of the scenario directly after reading it, and were not asked to connect the events in any particular way. In the other conditions, participants had to answer a question that encouraged them to represent the scenario in a particular way before judging its plausibility; the causal condition required participants to connect the events as cause and effect, while the temporal condition required participants to connect the events as a temporal sequence. In short, people are expected to find few scenarios plausible in the no-connection condition (poor concept-coherence), more scenarios plausible in the temporal condition (better concept-coherence), and most scenarios plausible in the causal condition (best concept-coherence).

Method

Materials & Design. Materials consisted of twenty "implausible" scenarios, each consisting of two sentences describing unrelated events. The materials were constructed by creating twenty causal scenarios (e.g., "*The surgeon performed the operation. The patient recovered.*") and then randomizing the combinations of first and second sentences (e.g., "*The surgeon performed the operation. The candle flickered.*"). Thus, each scenario contained two events where the cause (Event A) was followed by a different, unrelated effect (Event B). The experimental design was a single between-participants factor (connection type), with three conditions (causal, temporal, no-connection). A between-participants design was chosen to avoid possible confounds (e.g., participants forming a causal connections in all presented scenarios).

Participants. Thirty-six student volunteers from University College Dublin participated in this experiment.

Procedure. Participants were randomly assigned, in equal numbers, to one of the conditions in the experiment.

Instructions stated that each scenario was taken from a story and consisted of two events: Event A and Event B. An example not used in the materials was given:

Event A: *The boy kicked the football.*

Event B: *The branch snapped.*

In the causal condition, participants were asked to write down their answer to the question "Why do you think Event B happened?" and were presented with a sample answer "The branch snapped because the football hit it hard, because the boy was aiming at the tree." In the temporal condition, participants were asked to write down their answer to the question "How long after Event A do you think Event B happened?" and were presented with a sample answer "The branch snapped 2 or 3 seconds later." In all conditions, participants were then given a forced-choice plausibility judgement "Do you find this scenario plausible?" and asked to circle "Yes" if they would accept the scenario as plausible, and to circle "No' if they would reject the scenario as implausible. The scenarios were presented on separate pages in random order, resampled for each participant.

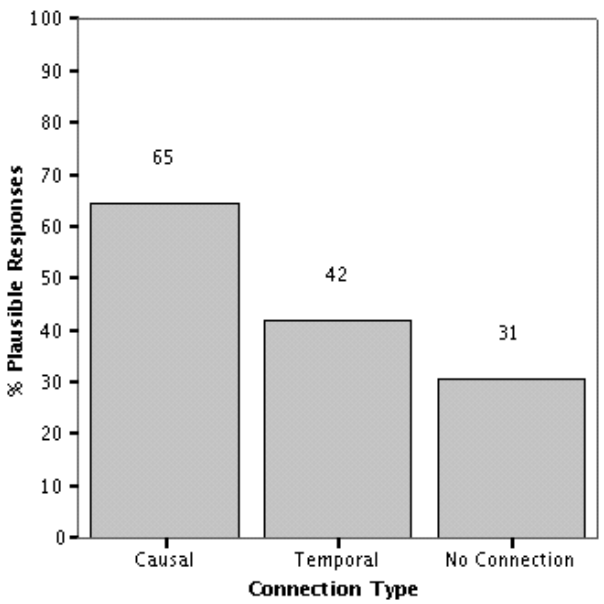

Figure 1: Percentage of scenarios accepted as plausible for each connection type in Experiment 1.

Results & Discussion

The results were in line with predictions, and are shown in Figure 1. Three scenarios were considered plausible by more than 80% of participants in the no-connection control condition, and these were excluded from the analysis in all conditions. While this paper lacks sufficient space to discuss participants' answers in detail, people reported little difficulty in making the connections in the temporal condition, and only occasional difficulty in the causal condition.

People's willingness to accept the scenarios as plausible was influenced by how they had been encouraged to represent the connections between events, as shown by chi-squared analysis, $\chi^2 = 47.74$, $df = 2$, $p < 0.0001$. When asked to represent the events as a specific temporal sequence, people accepted significantly more scenarios as plausible (42%, compared to 31% control), $\chi^2 = 5.31$, $df = 1$, $p < 0.05$. However, the greatest change occurred when people were asked to represent a causal chain between the events, with over twice the number of scenarios being perceived as plausible (65%, compared to 31% control), $\chi^2 = 45.77$, $df = 1$, $p < 0.0001$. In this way, causal connections were reliably better than temporal connections at making scenarios appear plausible (65% compared to 42%), $\chi^2 = 20.71$, $df = 1$, $p < 0.0001$.

So what makes implausible scenarios suddenly appear plausible? Why do people perceive the plausibility of a scenario differently when they are asked why or when events happened? After all, the actual connection made between unrelated events is arbitrary: people are free to come up with any explanation or time frame they choose to connect the events. There is nothing stopping people from causally connecting the events in the no-connection control condition, nor is anything stopping them from causally representing the scenario when answering the temporal question. Indeed, it could be argued that the 31% plausible responses in the no-connection control condition result from the times that people managed to make a causal connection between events without any guidance. In effect, the pattern of results suggests that a kind of "cognitive laziness" is at play, and that people do not put any more effort into representing the scenarios than is absolutely necessary. In the no-connection control condition, most scenarios are judged as implausible because no obvious connection between the events comes to mind. However, in order to be able to answer the temporal question, a certain amount of extra effort must go into connecting the events. If the resulting representation has sufficient concept-coherence, the scenario then seems plausible. Lastly, answering the causal question requires quite a lot of effort, as people must explicitly lay out the circumstances that brought about the second event. The resulting causal representation is likely to have good concept-coherence, and so the scenario is likely to appear plausible. This "cognitive laziness" view is consistent with other studies that have demonstrated people's reluctance to infer causal relations unless prompted to do so (e.g., Keane, 1997; McKoon & Ratcliff, 1992).

This experiment shows that people will accept an implausible scenario as plausible if they are encouraged to connect events in a certain way. However, it is also possible to elicit a more fine-grained judgement of plausibility. When people accept a scenario, is it because they judge it to be very plausible or just moderately plausible? This question is addressed in the next experiment.

Experiment 2

Experiment 2 is identical to Experiment 1, except participants are asked to rate the plausibility of scenarios on a scale from 0-10 instead of simply choosing whether the scenario seems plausible or implausible. In other words, participants are presented with implausible scenarios and are asked to judge how plausible they find each scenario. As with Experiment 1, scenarios in the causal and temporal conditions are expected to be rated as more plausible than those in the no-connection control condition because of their greater concept-coherence. However, there are two possibilities for how the causal and temporal conditions may be distinguished.

The first possibility is that when people in the causal condition accept a scenario as plausible, they actually consider it to be *highly* plausible. This means that causal connections between unrelated events would be considered to have very good concept-coherence; indeed, just as good as for more straightforward causal scenarios. If this were the case, the results would mirror those of Connell and Keane (in press, experiment 1), where causal scenarios were rated as highly plausible (7.8 out of 10) and temporal scenarios were rated as only moderately plausible (4.2 out of 10).

The second possibility is that, although implausible scenarios may become acceptably plausible in the causal condition, they will never seem *highly* plausible. This means that people will perceive causal connections between unrelated events to be of a lower quality (i.e., have poorer concept-coherence) than more straightforward causal scenarios (as in Connell and Keane's study). If this were the case, then ratings in the causal and temporal conditions would be expected to be capped at a level of moderate plausibility.

Method

Materials & Design. The materials and design were the same as in Experiment 1.

Participants. Thirty-six student volunteers from University College Dublin, who had not taken part in Experiment 1, participated in this experiment.

Procedure. The procedure was the same as in Experiment 1, except that participants were asked for a plausibility rating rather than a forced choice judgement. In all conditions, participants were asked "How plausible do you find this scenario?" and asked to circle a rating on a scale from 0 – 10. A rating of 0 was described as meaning the scenario was "not at all plausible", while 5 meant "moderately plausible" and 10 meant "completely plausible".

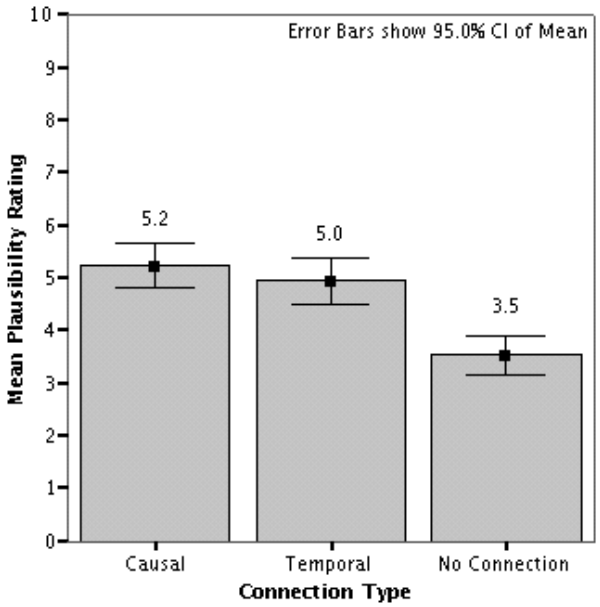

Figure 2: Mean scenario plausibility ratings for each connection type in Experiment 2.

Results & Discussion

The results were in line with predictions, and are shown in Figure 2. As before, three scenarios that were considered plausible by more than 80% of participants in Experiment 1's no-connection control condition were excluded from the analysis in all conditions. Analyses of variance are performed by-participants (F_1) and by-items (F_2), treating participants and items as random factors, respectively.

People's plausibility ratings were influenced by how they had been encouraged to represent the connections between events, as shown by the main effect of connection type, $F_1(2, 33) = 6.30$, $p < 0.005$; $F_2(2, 32) = 31.36$, $p < 0.0001$. Planned comparisons showed that, when asked to represent the events as a specific temporal sequence, people judged the scenarios to be significantly more plausible (5.0, compared to 3.5 control), $F_1(1, 22) = 9.53$, $p < 0.005$; $F_2(1, 16) = 50.58$, $p < 0.0001$. Similarly, when people were asked to represent a causal chain between the events, they perceived the scenarios as being significantly more plausible (5.2, compared to 3.5 control), $F_1(1, 22) = 11.74$, $p < 0.005$; $F_2(1, 16) = 53.23$, $p < 0.0001$. However, there was no difference between the temporal and causal conditions; people did not consider causal

connections between events to be any more plausible than temporal connections, $F_1 < 1$; $F_2(1, 16) = 1.30$, $p > 0.25$.

This experiment shows that, although implausible scenarios may become acceptably plausible in the causal condition, they can never seem *highly* plausible. In other words, while unrelated events can be causally connected, they do not fit with prior knowledge quite as well as more obvious causal connections. For example, we may causally connect the events in the scenario "*The teacher misspelled a word. The vase smashed.*" by assuming that the vase smashed because the teacher bumped against it when taking a step back to examine the misspelled word. While this scenario may just about seem acceptably plausible, it does not seem highly plausible. It certainly does not seem as plausible as a more straightforward causal scenario like "*The cat knocked over a vase. The vase smashed.*" Similarly, for the temporal condition, the results show that connecting events in a specific time frame (e.g., the vase smashed seconds after the teacher misspelled a word) makes a scenario seem somewhat plausible. However, temporal scenarios are considered only moderately plausible at best (Connell & Keane, in press), which suggests that a temporal connection between unrelated events fits with prior knowledge about as well as any other temporal connection. In short, the concept-coherence and plausibility of a normally implausible scenario can be manipulated by encouraging people to make particular connections between events, but the scenario will generally not be judged more than moderately plausible.

So what is the relationship between judging *whether* a scenario is plausible and judging *how* plausible it is? In Experiment 1, we saw that 65% of scenarios in the causal condition were considered acceptably plausible, but yet in Experiment 2, these same scenarios received a plausibility rating of only 5.2 / 10. Similarly, 42% of scenarios in the temporal condition were considered acceptably plausible, and yet were also rated at 5.0 / 10. Analysis of the percentage of plausible responses in Experiments 1 and the mean plausibility ratings in Experiment 2, for each scenario in each condition, shows a direct linear relationship between a scenario's plausibility rating and its acceptability (see Figure 3). This relationship has a significant correlation of $r = 0.88$, $N = 60$, $p < 0.0001$. In short, scenarios with a high plausibility rating will be accepted by most people, while scenarios with a low plausibility rating will be rejected by most people. This suggests that there is no absolute plausibility threshold, above which a scenario will be accepted by everyone as completely plausible. Rather, it depends on what level of acceptability is desired. For example, if we wish 90% of people to accept a scenario, then it should have a mean plausibility rating of approximately 7 out of 10.

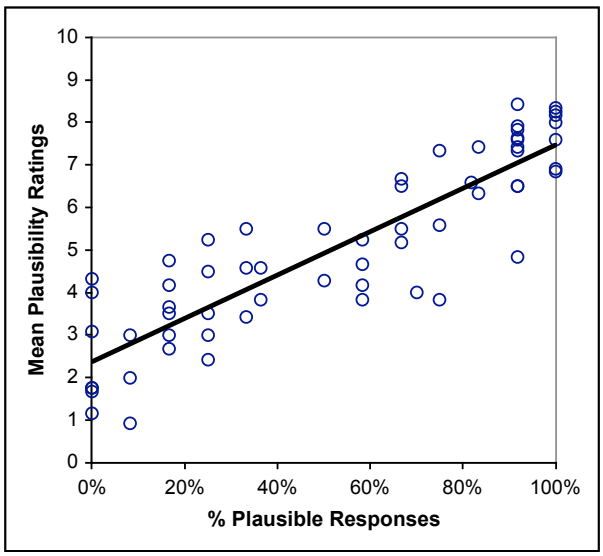

Figure 3: Relationship between scenarios' plausibility ratings and their frequency of acceptance.

General Discussion

This paper shows that an implausible scenario can be made seem plausible by forcing a particular connection between its events. Encouraging people to represent events in a causal chain or temporal sequence, without specifying what the connection should be, alters their perceptions of a scenario's plausibility. In Experiment 1, people are shown to accept 65% of scenarios as plausible once they had explicitly noted a possible causal chain, and 42% of scenarios once they had explicitly noted a possible temporal frame for the events. This compares to a low rate of acceptance for the same scenarios when people are free to make any connections they choose. In Experiment 2, people are shown to consider scenarios as moderately plausible when they are guided into connecting events causally or temporally. In contrast, the same scenarios receive low plausibility ratings when people are free to make any connections they choose. Thus, the novel empirical work reported here demonstrates how people's perceptions of plausibility can be influenced by the circumstances surrounding the task. These findings have implications for any research making use of plausibility judgements, in fields including memory, discourse comprehension, reasoning and conceptual combination.

According to the Knowledge-Fitting Theory of Plausibility (Connell & Keane, 2003a, 2003b, in prep; Connell, 2004), plausibility judgement is about assessing concept-coherence. This view holds that when people make a plausibility judgement, they relate the current scenario to their prior experience, and in some way assess whether it fits in with what they have experienced in the past. Depending on how we

represent a scenario in the first place (i.e., how we connect its events) will therefore determine how well it fits with our prior knowledge. What this paper demonstrates is that the representation of a scenario varies according to how we are encouraged to connect the events. In other words, the concept-coherence and plausibility of a scenario can be manipulated by guiding people towards certain kinds of representation.

The results reported here suggest that people judge plausibility with a certain "cognitive laziness". This means that they do not put any more effort into representing the scenarios than is absolutely necessary. When presented with a scenario, if a possible connection between events does not immediately leap out, then people do not take the trouble to connect the events and instead dismiss the scenario as implausible. However, if circumstances require, people are perfectly capable of connecting even the most disparate events in a coherent manner. For example, the scenario "*The teacher misspelled a word. The vase smashed.*" contains events that are quite difficult to connect. However, people were well able to connect these unrelated events in the causal condition of both experiments, as evinced by the wide and creative variety of causal chains given – e.g., the vase smashed because the teacher bumped against it when stepping back from the blackboard, or because the teacher smashed it in a temper after realising the mistake, or because it was knocked over by a student eager to correct the teacher's error. It is only when circumstances demand it that people overcome their cognitive laziness and take the trouble to reason out a possible connection between events. Indeed, this "cognitive laziness" view is not without its advantages. As well as allowing people to judge plausibility with the least amount of computational expense, it is also tends towards false negatives rather than false positives. This makes it quite a sound approach, as it is safer to reject a scenario that later proves viable than to accept one that later proves unviable.

Abstract

Falsification may demarcate science from non-science as the *rational* way to test the truth of hypotheses. But experimental evidence from studies of reasoning shows that people often find falsification difficult. We suggest that domain expertise may facilitate falsification. We consider new experimental data about chess experts' hypothesis testing. The results show that chess masters were readily able to falsify their plans. They generated move sequences that falsified their plans more readily than novice players, who tended to confirm their plans. The finding that experts in a domain are more likely to falsify their hypotheses has important implications for the debate about human rationality.

Hypothesis Testing

People understand everyday and scientific phenomena by generating hypotheses to explain them. They achieve a true understanding only by *testing* hypotheses by searching for proof. There are two main ways people can test the truth of their hypotheses. They can either seek *confirmation*: evidence that is consistent with a hypothesis, or *falsification*: evidence that is inconsistent with a hypothesis. Falsification is generally considered better than confirmation: no matter how much evidence is gathered to confirm a hypothesis, there remains the possibility of refutation later (Popper, 1959). Confirmation could lead to the endorsement of untrue ideas and so if people are rational, they should attempt to falsify their hypotheses. Many cognitive scientists have interpreted experimental findings on hypothesis testing within the framework of falsification (e.g., Wason, 1960). The conclusion has sometimes been reached that when people fail to attempt to falsify, they fail to think rationally.

Early research on hypothesis testing found that people were prone to a *confirmation bias*: they tended to search for confirming evidence and avoid falsifying evidence (e.g., Wason, 1960). Confirmation bias has sometimes been viewed as evidence of human irrationality, for example, it may lead people to form prejudiced beliefs (e.g., Aronson, 1995). But the idea that human hypothesis testing is irrational presents a paradox: How can it be flawed given that it has led to important civil, technological and scientific discoveries? There are two possible answers: one possibility is that testing hypotheses through confirmation is more useful than indicated by a Popperian analysis, and a second possibility is that people are more capable of falsification than experimental evidence has revealed so far. We will first outline the view that confirmation is a useful strategy to test hypotheses and the view that falsification may be conceptually impossible (e.g., Poletiek, 1996). Then we will show that falsification is in fact possible in a domain that has been a trusted test-bed for theories of cognition for almost forty years: chess problem solving. We will consider experimental results that testify to high levels of falsification in the hypothesis testing of chess masters (Cowley & Byrne, 2004).

Confirmation: Vice or Virtue?

Irrational hypothesis testing in the form of confirmation bias was first reported in the 2-4-6 task (Wason, 1960). Participants in this task are required to discover the rule to which the number triple 2-4-6 conforms. The participants are analogous to scientists and the rule is analogous to a law of nature to be discovered. Participants test their hypotheses by generating other number triples and they are told by the experimenter whether each triple conforms to the rule or not. The rule in the 2-4-6 task is the deliberately general rule of 'any ascending numbers'. The salient features of the 2-4-6 triple tend to induce incorrect hypotheses, for example, participants tend to focus on its properties of even numbers and numbers ascending in twos. Participants who generate these hypotheses, 'ascending even numbers' or 'numbers ascending in twos' can discover the real rule 'any ascending numbers' in only one way: by generating triples that falsify their hypothesis. For example, a participant could try to falsify the 'ascending even numbers' hypothesis by generating the triple '3-5-7'. They would discover their hypothesis is false when the experimenter tells them that '3-5-7' is consistent with the real rule. But participants overwhelmingly generated confirming triples such as '10-12-14'. The triple confirms their hypothesis and it is also consistent with the real rule and so the experimenter tells them '10-12-14' is consistent. They announce their incorrect hypothesis as the rule and fail to solve the task correctly.

Confirmation bias has been demonstrated many times in the 2-4-6 task and in other related laboratory tasks, for example, in a task in which participants are required to discover the law governing the motion of particles in an artificial universe displayed on a computer screen (e.g., Mynatt, Doherty, & Tweney, 1978).

But do people confirm their hypotheses only in artificial laboratory tasks? Perhaps they are better able to falsify in real world contexts where they can access their knowledge about the task? In fact, the tendency to confirm has been observed in NASA Apollo mission scientists (Mitroff, 1974), and in the notes of scientists such as Alexander Graham Bell (Gorman, 1995). It is possible that confirmation is useful. For example, the participants who successfully discovered the rule in the complex artificial universe task tended to be those who confirmed their hypotheses in the early stages of their attempted discovery of the rule, and then tried to falsify when they had a well-corroborated hypothesis (Mynatt et al., 1978). Perhaps it is only when a hypothesis worth testing has been established that it is necessary to attempt to falsify it. Confirmation and falsification may be complementary strategies for successful hypothesis testing.

But it is also possible that people do not falsify because they cannot (Poletiek, 1996). According to this view when people generate a hypothesis it is their *best guess* about the truth, and it does not make sense for them to try to show that their best guess is wrong. In a version of the 2-4-6 task, participants were encouraged to generate their best guess about what the rule might be and then they were instructed to perform falsifying tests on it. The instruction to falsify decreased the number of positive triples, such as '10-12-14', which is consistent with the best guess 'even ascending numbers'. The instruction to falsify also increased the generation of negative test triples, such as '3-5-7' which is inconsistent with the best guess 'even ascending numbers'. However, this test is only a falsifying one if the participant expects the experimenter to say that the triple is consistent with the real rule (and then the participant would know that the hypothesis 'even ascending numbers' was wrong because ascending odd numbers are consistent too). But if the participant generates the inconsistent '3-5-7' triple and expects the experimenter to say that it is *not* consistent with the real rule, then they have attempted to confirm their hypothesis (albeit with a negative triple). In fact, participants generated triples that were inconsistent with their hypothesis (negative triples) *but* they expected them to be inconsistent with the experimenter's rule. The participants could not seem to make sense of the instruction to falsify. The instruction to falsify may be impossible to carry out (Poletiek, 1996).

Given the ideas that confirmation is useful and falsification is impossible, does it follow that the normative prescription of falsification is flawed, rather than human rationality? Perhaps, not. Even when a hypothesis is the best guess it is not necessarily an accurate representation of the truth. We turn to the case for falsification next.

Falsification and the Path to Truth

Consider the following example:

> *You are a scientist and your job is to identify the cause of a dangerous new disease. You identify a previously unrecognized virus in tissue samples of symptomatic patients and your hypothesis is that this 'new virus' is the cause of the disease. However, other scientists have identified two viruses, including your new virus in their tissue samples. They hypothesize that it is the 'other virus' and not the new virus that is the cause. Both hypotheses have confirming evidence. A case is reported where the new virus is present and the other virus is absent. What should you conclude?*

A situation similar to this one faced scientists working on the cause of the SARS epidemic. They concluded that the 'new virus' hypothesis was correct. The case where the 'other virus' was absent falsified the 'other virus' hypothesis and corroborated the 'new virus' hypothesis. The example illustrates how important falsification can be.

There are many situations in which it is helpful to anticipate the ways in which a hypothesis or plan could go wrong. For example, it may be helpful to falsify in interactions with a collaborator or opponent, whether in contexts such as political or social engagement, or in games such as tic-tac-toe or poker. The importance of considering what might go wrong is observed in cases of military strategy, for example, in Northern Ireland (Mallie, 2001). Attempts to falsify hypotheses, particularly plans of action, could help reduce costly mistakes.

The merits of falsification are not lost on experts, as the SARS example illustrates. It may even be the case that the ability to falsify is part of what makes an expert (Cowley & Byrne, 2004). The competitive nature of science may ensure that different groups of scientists attempt to falsify their opponent's theories even if they only attempt to confirm their own. The refutation of a theory is often discovered by someone who did not invent the theory (Kuhn, 1996). Hypothesis testing in scientific discovery may benefit from a strategy of attempting to confirm a hypothesis until there is sufficient corroboration for it to be considered seriously, and then attempting to falsify it, just as in the 'artificial universe' task (Mynatt et al., 1978). Perhaps more importantly, experts may generate high quality hypotheses from the outset. An exceptional scientist such as Alexander Graham Bell may have tended to confirm rather than falsify his hypotheses because his expertise ensured that his hypotheses were exceptionally good (and there is a smaller potential set of falsifying evidence for a good quality hypothesis than for a poor one).

As these observations suggest, a more systematic study of expert hypothesis testing is warranted. We chose the game of chess as our expert domain because it meets the essential criteria: it is possible to identify a large sample of experts whose expertise is objectively defined and categorised relative to each other, and it is a task that draws directly on participants' expert knowledge and experience.

Chess and Hypothesis Testing

Studies of chess have contributed substantially to understanding cognition, including problem solving (Newell & Simon, 1972), chunking in working memory (Chase & Simon, 1973), and expertise (De Groot, 1965). Findings from research on chess have successfully explained expertise in non-game domains such as physics (e.g., Larkin, McDermott, Simon, & Simon, 1980). Chess offers great potential for an investigation of expert hypothesis

testing. Of course, choosing a move in chess may depend on a variety of processes including accessing a large repository of chunked domain knowledge about possible opponent moves (e.g., Chase & Simon, 1973; Gobet, 1998a). Our suggestion is that hypothesis testing may be one of several important processes for selecting a move in chess. We expect that expert master players will be better than novices at falsifying their planned moves by thinking about opponent moves that could ruin their plan (for details see Cowley & Byrne, 2004).

Our key research question is, do experts and novices differ in their ability to find refutations to lines of play in chess? We conceptualize hypothesis falsification in chess as finding opponent moves that refute the moves a player examines for play. The opponent moves could ruin the player's plan and worsen the player's position. We address an important aspect of choosing a move that has never been systematically investigated: the evaluation of move sequences.

Hypothesis Testing in Chess

The overall goal of chess is to checkmate the opponent by attacking the opponent king and eliminating all the possible ways the opponent king can escape the attack. Chess thinking may consist of exploring different alternative paths in a 'problem space' (Newell and Simon, 1972). The problem space consists of the initial problem state, that is, the start of the game, intermediate problem states, for example, capturing an opponent piece, and the end state (checkmate). Progress from state to state is achieved through *operators*, that is, in chess the way chess pieces are allowed to move. For example, a bishop operates diagonally backwards and forwards and captures on the square it lands on for any one move.

At the beginning of a game of chess the two players have equal numbers of pieces and theoretically equal chances of securing a win, loss or draw. To secure the best possible result the players must play moves they hypothesize to be so good that they cannot be refuted (Saariluoma, 1995). Refutation (that is, hypothesis falsification) occurs when the opponent plays a move that results in a worsening of the player's position. For example, a player may play a move that he or she plans to be a good move, but the opponent replies with a move that stops the player's plan. The opponent's play worsens the player's position and reduces the player's chance of a win.

There may be three major processes in the choice of a chess move: exploration, elaboration and proof (DeGroot, 1965). Evidence of hypothesis testing is available in the proof process. A chess player tests how good a move is by mentally generating move sequences following on from that move. For example, a move sequence might be: "If I move my knight to that square, you might move your pawn to attack my knight, and then I will have to retreat, and that is really bad for me…". In this example, the move sequence is evaluated as leading to a negative outcome: a falsification has been found for the knight move. Move sequences can be evaluated as leading to either a positive, negative or neutral outcome for a chess position. We conceptualize move sequences that are judged to lead to a positive outcome as akin to evidence confirming that a particular move is a good move. Move sequences evaluated as leading to a negative outcome are akin to evidence falsifying a move that was thought initially to be a good move. Move sequences evaluated as leading to a neutral outcome are neutral evidence.

Accessing Hypothesis Testing in Chess

We carried out an experiment on hypothesis testing in chess players (see Cowley & Byrne, 2004, for details). The 20 participants (19 men and 1 woman) were registered members of the Irish Chess Union. The participants were classified according to the Elo system, which calculates expected playing strength value on the basis of tournament and league results, and the value varies from approximately 1000 for an absolute novice and over 2800 for the world champion. We tested *experienced* novices (mean rating of 1509) and experts (mean rating 2240). The expert group included experts from different Elo categories of expertise, including one grandmaster (Irish Elo >2500) two international masters (Irish Elo > 2300), three Fide masters (Irish Elo > 2200, i.e. International Chess Federation masters), and four initial category experts (Irish Elo > 2000). All international class masters living in Ireland at the time participated in the study (for further information on participant details see Cowley & Byrne, 2004).

We presented the participants with six board positions, three normal and three random (as well as an initial practice position). The board positions were chosen from games in chess periodicals. They were middle game positions with 22-26 pieces to ensure complexity and to rule out the chances that the masters' had seen them before. Importantly, they were 'equality outcome' positions, where there were equal chances with best play for both black and white pieces. This constraint ensured that there would be no obvious confirming or falsifying move sequences. The positions were chosen with the assistance of a chess expert (who was not a participant in the study). See figure 1 for an example of a chess position used.

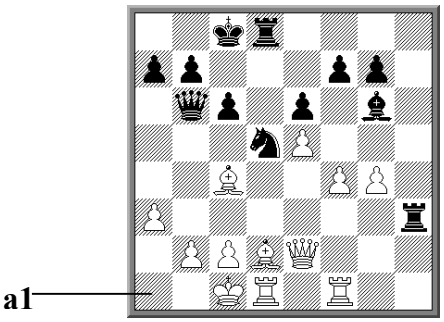

Figure 1: Position 1 with white to play (and the co-ordinate a1 is also illustrated in this diagram).

The participants' task was to, "choose a move you would play in the way you are used to going about choosing a move in a real game". They were given instructions to think aloud, and their verbalizations were recorded by dictaphone. It is instructive to focus on the master level players (for

comparison with masters studied in the chess literature previously) and to this end we selected the think-aloud protocols of five *master level* players (i.e. 1 Grandmaster, 2 International Masters, and 2 Fide International Chess Federation Masters), and compared them to the think-aloud protocols of five novice chess players, chosen at random from the full sample of novices (for other analyses see Cowley & Byrne, 2004).

Moves examined by the player during think-aloud are verbalized using algebraic chess notation, for example a sequence of moves verbalized was: f5 exf5 gxf5 Bh5 Qg2 Rh4. This notation describes each piece and the location of the square it will go to on the chess board. Each square on a board has a location name called an algebraic coordinate. The letters a-h are horizontally along the bottom of the board. The numbers 1-8 are vertically up the board. Each type of piece is given a letter in upper case format. Each coordinate is given a letter in lower case format alongside a number. So for example, the move 'Ra1' refers to a rook piece (R) moving to the a1 square. Or, the rook could go to the b1 square to the right of a1 (Rb1). A sequence of such moves is a move sequence. All of the players were sufficiently fluent with algebraic notation to be able to 'think aloud' using it. Three minutes thinking time was allotted for choosing a move as it is just over the average time per move in tournament play. Exposure for each board position was timed using a standard tournament chess clock, each clock was set at three minutes and when the clock's flag fell participants were told that their time was up.

To accurately access hypothesis testing we also needed participants to provide us with an evaluation of each move sequence that they examined. However, spontaneous evaluation in chess has a low probability of verbalization (Newell & Simon, 1972). Accordingly we used a combined methodology of think-aloud followed by retrospective evaluation. Verbalized move sequences were recorded not only by dictaphone but also by the experimenter (the first author) in algebraic notation concurrent with think-aloud. The experimenter asked the participants for their evaluation of each move sequence, by first saying back the move sequence immediately after each chess problem to reduce retrospective error and interference (Ericsson & Simon, 1993). The participants were then asked to evaluate each move sequence as having lead to a positive, negative or neutral outcome for their positions.

Scoring confirming and falsifying hypothesis tests

The transcribed think-aloud protocols for the responses to the normal board positions were segmented into episodes, move by move. We constructed 'problem behavior graphs' (using Newell and Simon's guidelines) for the responses to the three normal board positions for each of the ten selected participants (thirty problem behavior graphs in total). These graphs plot each move sequence and its corresponding retrospective evaluation. To illustrate we present in Figure 2 a small fragment of a master's problem behaviour graph for one board position.

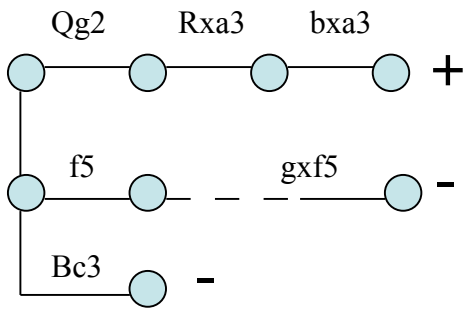

Figure 2: A fragment of a problem behaviour graph constructed from a chess master's protocol.

Each line across represents a move sequence. The order of search is from left to right, then down. Each circle (i.e. node) represents a new position following a move made in the problem space. For example, Qg2 means the player thought aloud about the possibility of moving his queen to the g2 square. Next the player thought aloud about a possible reply from his opponent to his Qg2 move, that is, the move Rxa3 where the opponent moves their rook to the a3 square, and the x indicates that the rook captures a piece, in this case a pawn. Next the player thought aloud about his reply to this opponent's move, that is, bxa3 where he would move his pawn on the b file to a3 (pawn moves do not have a P in front of them), and capture the opponent's rook. The plus sign shows that the player evaluated this move sequence as positive for him. The next line sequence begins with the player thinking about f5, that is, a pawn moves to the f5 square. The next utterance the player makes is gxf5, that is, the pawn on the g file of the board captures a pawn on the square f5. This move is only possible for the player and not his opponent. The player has generated a move sequence that mentions only his own moves and does not mention opponent moves. The dashed line captures these *skipped* moves. The minus shows a negative evaluation. Each problem behavior graph incorporates the think-aloud move sequences with the retrospective evaluation (positive, negative, or neutral).

We used *Fritz 8* (one of the most powerful current chess programs) to obtain an objective evaluation of the chess position that occurs at the final move of each sequence (i.e. terminal node). For readers familiar with *Fritz 8*, we used the infinite analysis module, in which each move sequence is evaluated at least from 11ply from the terminal node (see Chabris & Hearst, 2003). The evaluations provided by *Fritz 8* enable us to identify move sequences that would genuinely be positive or negative for a player. We could distinguish between the move sequences that a player indicated as leading to a positive outcome for their position and that the program established would lead to a positive outcome if played, from the move sequences that a player identified as positive, but that the program established would in fact lead to a negative outcome. We conceptualize confirmation bias as a move sequence that a player evaluates as leading to a positive outcome for them, when in

fact it leads to a negative outcome. Likewise, we were able to distinguish the move sequences that a player identified as leading to a negative outcome and that the program established would be negative if played, from move sequences that the player identified as negative, but that the program established were in fact positive for them. We conceptualize falsification as a move sequence that a player evaluates as leading to a negative outcome for them, when in fact it leads to a negative outcome.

Hypotheses Testing in Chess Masters' Thinking

Masters tended to think about 8 move sequences on average for each board position, and experienced novices tended to think about 6 move sequences. A total of 218 move sequences were generated by the 10 players for the three normal board positions (N = 122, M = 8.1 for each board position for the masters, N= 96, M = 6.4 for novices).

Four types of move sequences were identified from the problem behaviour graphs. (1) 50% were *complete move sequences* where every move for the player and his or her opponent was articulated along the move sequence. (2) 25% were *skipped move sequences* where an essential move was not mentioned somewhere in the move sequence. (3) 19% were *base skip sequences* where the first move or 'base move' of the sequence was not mentioned. (4) 6% were *ambiguous move sequences* where the move sequence could not be interpreted. Only the complete move sequences lend themselves to objective evaluation by *Fritz 8*, so we concentrate our analysis here on these hypothesis tests (see Cowley & Byrne, 2004 for further details).

A complete move sequence is scored using the following criteria: (a) whether it is predicted by the player to lead to a positive, negative, or neutral outcome, and (b) whether it is evaluated objectively by *Fritz 8* as leading to a positive, negative or neutral outcome. Thus there are nine possible hypothesis tests for complete move sequences, as Table 1 illustrates. Confirmation bias corresponds to the '+/-' cell in Table 1, and falsification corresponds to the '-/-' cell. These two types of evaluation accounted for 42% of all evaluations.

Table 1: Objective and subjective evaluations of move sequences ('+' refers to a positive evaluation, '-' to a negative one, '=' to a neutral one; '+/-' means the player's evaluation was positive and the program's evaluation was negative).

	Fritz 8's evaluations		
	Positive	negative	neutral
Player's evaluations			
Positive	+/+	+/-	+/=
Negative	-/+	-/-	-/=
Neutral	=/+	=/-	=/=

Falsification In three of the cells of Table 1 (the three on the diagonal from upper left to lower right), the subjective evaluation of the player matches the objective evaluation of the computer program. One of these matching cells is particularly important for our prediction that experts falsify more than novices: genuine falsification occurs in the situation captured by the '-/-' cell in Table 1, in which the player and the program both evaluated the outcome of the move sequence as negative. Chess masters generated more of these falsifying move sequences than novices (M = 3.2 for masters, M = 1.2 for novices) and this difference was reliable (t (8) =2.02, p = .039).

The result indicates that chess masters are capable of falsifying their plans by identifying opponent moves that would worsen the master's position. People are able to falsify (pace Poletiek, 2000). Domain expertise may facilitate this falsification. Moreover, the moves chosen by chess masters for play at the end of each of the three board positions were evaluated by *Fritz 8* as objectively better moves than novices (the quality of moves is measured in terms of 'pawn advantage' or 'pawn disadvantage', and it was +0.309 pawn advantage for masters compared to –1.2 pawn disadvantage for experienced novices). The result is consistent with the idea that the ability to falsify may contribute to making better moves in chess.

Confirmation Bias Confirmation bias occurs when a move sequence is evaluated subjectively by the participant as leading to a positive outcome, but evaluated objectively by the computer program as leading to a negative outcome (the **'+/-'** cell in Table 1). The results show that novices produced somewhat more instances of confirmation bias than masters (M = 2.6 for novices and M = 1.6 for masters). Although the difference was in the predicted direction it was not reliable (t (8) = 1.443, p = .094).

Positive and Negative Testing The nine test types in Table 1 can be categorized into three groups: (1) Objective tests: the player's positive, negative and neutral evaluations matched *Fritz 8*'s evaluations (the three cells on the diagonal from upper left to lower right mentioned earlier), and this category includes the falsification tests. (2) Positive bias tests: the player's evaluation was more positive than *Fritz 8*'s. The three cells in this category include the second and third cells in the first row (**'+/-'**, **'+/='**), and the middle cell in the third row (**'=/-'**), and this category includes the confirmation bias tests. (3) Negative bias tests: the player's evaluation was more negative than *Fritz 8*'s. The three cells in this category include the second and third cells in the first column (**'-/+'**, **'=/+'**), and the middle cell in the third column (**'-/='**).

Chess masters generated reliably more objective tests than novices (M = 6.6 for masters and M = 2.4 for novices). Novices generated somewhat more positive bias tests than the masters (M = 5 for novices and M = 3.4 for masters), but the difference was not reliable. They generated a similar amount of negative bias tests (M = 1.8 for masters, M = 1.2 for novices), as Figure 3 shows.

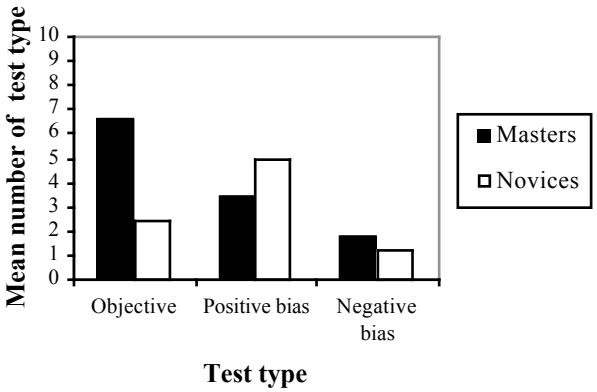

Figure 3: The mean number of objective tests, positive bias tests and negative bias tests generated by masters and novices. (Instances of falsification and confirmation bias are included in these categories).

Conclusions

People are capable of falsifying their hypotheses. Our experimental results show that chess masters falsified their hypotheses: they thought about how their opponent might refute their plan in their move sequences. Chess masters tended to evaluate their moves as good or bad for them more realistically than experienced novices: their judgments matched the objective evaluations of one of the most highly advanced chess computer programs, *Fritz 8*. Experienced novices exhibited something of a confirmation bias: they tended to think about how their opponent would play moves that fit in with their plan, somewhat more than chess masters did. Novices, somewhat more than masters, tended to evaluate their moves as better for them than they were objectively. The evidence that chess masters can falsify suggests that it may be premature to conclude that the normative prescription of falsification is flawed. In this case falsification can be considered a useful and rational strategy.

Hypothesis testing may be influenced by domain expertise. How does domain knowledge affect the ability to falsify by chess experts? We plan to explore this question by examining how masters test their hypotheses for random board positions compared to novices. If falsification relies on domain knowledge, then masters should tend not to falsify their hypotheses about move sequences in the random board positions as often as they do in the normal board positions. Nonetheless, they may attempt to falsify more than experienced novices, if their expertise has helped them to develop a strategy of falsification in this domain.

Synchronization Among Speakers Reduces Macroscopic Temporal Variability

Fred Cummins (fred.cummins@ucd.ie)

Abstract

A recent method for restricting inessential variation in speech is presented. Synchronous Speech is obtained by having two subjects read a prepared text in synchrony. Past results demonstrate that this is easy for subjects to do, and that some prosodic variability is greatly reduced when reading synchronously. Particular advantage has been found in the analysis of pauses and fundamental frequency variation, where synchronous speech has been demonstrated to exhibit markedly less inessential variability, thus furthering analysis and modeling. Here, duration ratios within a phrase are compared across synchronous and solo conditions. Variables associated with global timing and with the relationships between phrases are shown to be more consistent in the synchronous condition, while smaller units are not noticeably affected by the speaking condition. No systematic artifacts are found to be introduced by asking subjects to read in synchrony.

A Method for Restricting Variability

Synchronous Speech is obtained with the simple expedient of having two subjects read a prepared text together, with the minimal instruction to attempt to maintain synchrony (Cummins, 2002). The reason for constraining subjects in this manner is perhaps best appreciated by analogy with the difficult task of attempting to reconstruct a musical score, based only on a recording of a specific musician (Heijink et al., 2000). This task is interestingly similar to the work of the theoretically minded phonetician who attempts to uncover control and timing information, along with combinatorial units, from the continuous stream of speech.

If one were faced with this task, it is worth considering which musician would give one more tractable data: the soloist, or the 14th violin player in the string section. Neither will reproduce the durations (or pitches) specified in their score exactly, of course, due to the inherent underspecification of the score. Both players will overlay some inherent biophysical noise, along with conventional timing variability, such as the predictable decellerando at the end of a phrase. The soloist will add additional complexity, however, in keeping with her role as the expressive focus in performance, making the inverse mapping from the recording to the score considerably more difficult.

Now return to the position of the laboratory phonologist (or theoretical phonetician). An overarching goal is to deduce the units of control which relate to the linguistic message being uttered, and to uncover their mutual relations. This is not so different in kind from the above musical analog, though additional levels of complexity undoubtedly arise. Signal variability which is related to the linguistic content is relevant, while (for many purposes) one might like to find a way to reduce or exclude variability of para- or non-linguistic origin. The approach which I and colleagues have recently been following is to constrain the speaker to speak in time with another co-speaker. For this purpose, speakers read through a given text silently to familiarize themselves with it, and then commence reading together on a signal from the investigator. For many purposes, recording using near field head-mounted microphones onto the left and right channels of a single stereo file is sufficient to separate the two speakers while preserving the relative temporal alignment of speech events.

We call speech collected in this manner Synchronous Speech, and both the task and the product have provided us with much food for thought (Cummins, 2001; Cummins, 2002; Cummins and Roy, 2001; Cummins, 2003). In this paper, I will summarize those findings which have best revealed the advantages of this novel method, then provide some new results which examine the variability of intervals below the whole phrase, and finally provide pointers to areas I believe might benefit from adoption of the method.

Properties of Synchronous Speech

Synchronizing with a co-speaker, without extensive practice, turns out to be simple for subjects to do (Cummins, 2002; Cummins, 2003). After reading through a simple text once, and being given a start signal, subjects typically manage to keep inter-speaker lags to average values of around 60 ms at phrase onsets, and 40 ms or less after the first syllable or so. Rather surprisingly, extensive practice at the task does not improve the degree of synchrony significantly (Cummins, 2003), although with repeated readings of the same text, and with the same co-speaker, a slight improvement may be detected. Visual contact with the co-speaker does seem to have a small beneficial effect on synchrony, even though subjects are typically attending to a read text in front of them (Cummins, 2003).

In experiments done to date, speakers have not been carefully matched for familiarity, intrinsic speaking rate

or volume. Among the heterogeneous pairs of speakers we have studied to date, most appear to be collaborating, producing speech at a relatively slow rate (but faster than some of the slowest speakers' natural reading rate). We have not yet (in over 60 pairs of speakers) found a speaking pair in which one speaker consistently lagged behind the other. Rather, they seem to genuinely speak together, with a high degree of synchrony.

Phrasing and Pauses

One of the first properties of Synchronous Speech we noticed, was that phrasing, i.e. the division of a long stretch of speech into intonational units separated by pauses, appeared to be much more consistent in Synchronous Speech than in control readings done alone. In an initial pilot with 4 speakers, we found that in 48 'solo' readings, pauses occurred at points other than major expected phrase breaks 48 times (Cummins, 2002). By contrast, in Synchronous Speech, there were only 4 such idiosyncratic pauses in 24 paired readings.

These findings have been extended in the studies of pauses in Synchronous Speech (Zvonik and Cummins, 2002; Zvonik and Cummins, 2003), who found that inter-speaker variability in pause duration was greatly reduced in Synchronous Speech, compared with 'solo' speech. The reduced variability allowed the identification of a quantitative relationship between pause duration and the length (in syllables) of the preceding phrase—a relationship which was obscured in the rather more variable solo data. Specifically, we found a restricted distribution of clauses of less than 300 ms length. These pauses were far more likely to occur when the preceding phrase was relatively short (less than 11 syllables long)[1]. We examined pause duration in readings by 6 speakers (3 pairs) of 19 short texts (13 distinct authors). Table 1 shows the proportion of pauses in each environment (preceding phrase long or short, following phrase long or short) which were below 300 ms. The preponderance of short pauses in an environment following a short phrase is clear.

Table 1: Number of pauses of duration less than 300 ms as a function of the length of the surrounding Intonational Phrases. For IPs, 'short' is here taken to mean less than or equal to 10 syllables. Reproduced from Zvonik (2004, unpublished PhD thesis).

Preceding IP	Following IP	Proportion of Short pauses
short	long	0.32
short	short	0.39
long	short	0.11
long	long	0.06

[1]An earlier observation in Zvonick and Cummins (2003) that a similar relationship obtained between pauses and *following* phrases is probably an artifact of the idiosyncratic text used in that study

Fundamental Frequency Variability

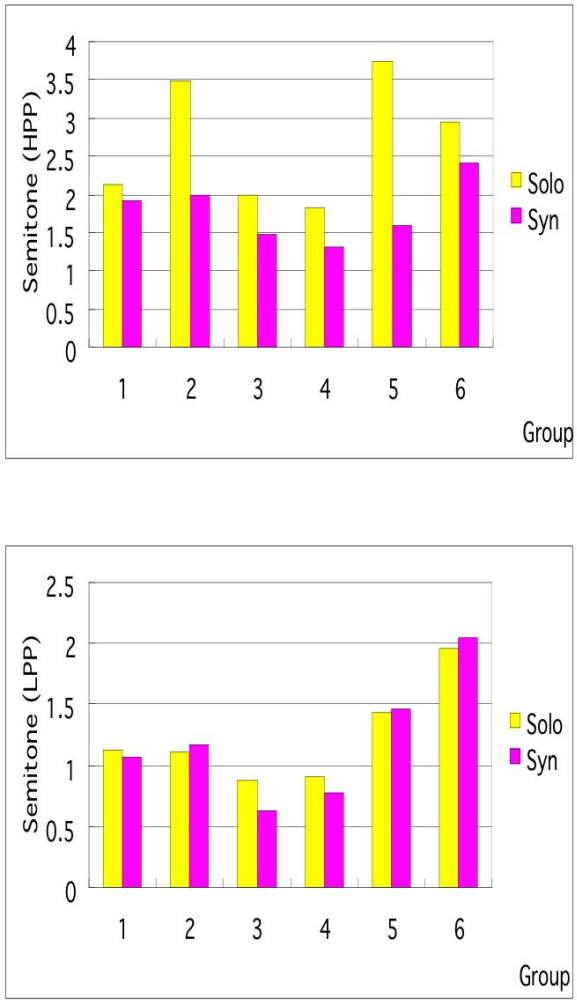

Figure 1: Difference in F0 peaks (HPP, top) and valleys (LPP, bottom) between speakers in a pair in solo and synchronous readings. All F0 values converted to semitones before analysis.

Given the above findings on phrasing and pauses, it seemed natural to examine the effect of speaking synchronously on other prosodic variables. To this end, we recorded six pairs of female speakers reading simple fairy tales (Wang and Cummins, 2003). We identified peaks and valleys in the intonation contour (HPP: High Point of Pitch, LPP: Low Point of Pitch), and looked to see whether these variables were affected by speaking synchronously. We found that the peaks were considerably more highly correlated across speakers within a pair in the synchronous condition (mean $r = 0.72$, s.d = 0.08) than in the solo condition (mean $r = 0.59$, s.d.=0.07). This did not hold for valleys (Synchronous: mean $r = 0.43$, s.d.=0.08; Solo: mean $r = 0.30$, s.d.=0.17). Figure 1 shows the differences in pitch between speakers of a

pair for both conditions. From the peaks (top panel), it can clearly be seen that there is a substantial reduction in inter-speaker differences in the synchronous condition, while the difference is slight or nonexistent for the valleys. This suggests that there might be a difference in the amount of free variability which speakers may employ in the absolute placement of H and L tones, a possibility which has been suggested independently elsewhere (Liberman and Pierrehumbert, 1984).

On Synchronization

How do speakers manage to synchronize so efficiently? One possibility which can be discounted already is that one speaker provides the lead, and the other follows. As mentioned above, we have yet to find a dyad in which a single leader could be identified. The very short lags between speakers also seem to preclude an explanation along these lines, as the typical lag of 40 ms is simply too short to allow perceptually guided correction while speaking.

Most mathematical models we have of synchronization are based on populations of oscillators (Glass and Mackey, 1988; Strogatz and Stewart, 1993). The mathematics of coupling among periodic sources is complex, but by and large tractable. Powerful predictive models have been constructed of such phenomena as juggling (Beek and Lewbel, 1995), heart cells (Mirollo and Strogatz, 1990), etc. Some have chosen to restrict the term 'synchronization' to the "adjustment of rhythms of oscillating objects due to their weak interaction" (Pikovsky et al., 2001, p. 8). Certainly, speech production is not oscillatory or periodic in anything but the loosest sense, and so the known mechanisms of entrainment among periodic sources can not be invoked here.

The answer, it seems to us, must lie in the shared knowledge speakers have of what is essential and what is redundant, or optional, in the modulation of the speech organs. Speakers of the same dialect must have control structures in common that govern the production of, and temporal relations among, the discrete units of speech. Little has yet been ascertained about the degree to which these putative control structures must coincide among such speakers. Certainly, many of the processes of diachronic change in language which have been described suggest that differences among speakers are not particularly rare, e.g. the age-related differences observed among speakers of Brazilian Portuguese by Major (1981). Nonetheless, the efficiency of communication dictates that most such structures must be shared among speakers. Although we do not have privileged access to the units and processes of speech production, speakers do seem to be able to modify their speech in direct response to the task demands, suggesting that the method of synchronous speech elicitation is a promising technique for tapping speakers' unconscious knowledge of the process of speaking.

An acknowledged limitation of the present is that much of the prosodic richness of spontaneous speech, specifically that associated with information management, speaker's attitudes, etc, is clearly not present in Synchronous Speech. The method requires the reading of a prepared text, and the additional constraint of synchrony places strict limits on the degree of personal interpretation and expression which a speaker can employ. Some of what is shorn away can correctly be considered to be meaningful prosodic structure. This limitation has an upside, however, as the timing which remains is still an immensely rich object of study, and those aspects of speech timing which are preserved (very many!) can be seen more clearly in the absence of the other additional sources of variation in speech.

The closest parallels to the demands of the Synchronous Speech task appear to be met in studies of synchronization among ensemble musicians (Rasch, 1979; Rasch, 1988), and the largely unstudied process of synchronization among dancers. In studying ensemble playing, Rasch (1979; 1988) used the standard deviation of differences in onset time of simultaneous notes in many voices as an index of asynchrony and noted typical values of 30 to 50 ms. The more direct measure of mean lag used in our studies of two voices at a time have provided values of approximately 40 ms.

Effect of Synchronization on Proportional Durations

An important question about the process of synchronization is whether it introduces artifacts into the temporal structure of speech, or conversely, whether it merely serves to reduce variability and reveal a shared understanding of temporal structure among speakers. Artifacts might be revealed in the systematic alteration of proportional durations, as would be the case if, e.g., unstressed syllables were found to be less reduced, and hence longer compared with stressed syllables. Any such systematic alteration of the durational properties of speech would severely limit the potential of Synchronous Speech to inform researchers about the properties of speech in the more general case.

As one way to investigate this, we here examine means and variances of a variety of interval ratios. By looking at ratios rather than durations, we better capture the relational properties of speech, and simultaneously avoid the difficult issue of rate normalization.

Methods

Readings of the first paragraph of the Rainbow Text were obtained from 27 pairs of speakers, as described in Cummins (2003). Each subject provided one reading alone and one with a co-speaker, obtained during a larger corpus collection exercise. The second sentence of the passage was chosen for detailed analysis. It reads "The rainbow is a division of white light into many beautiful colors". Reliably identifiable points in the waveform were chosen for measurement (stop releases, V-nasal transitions, etc). Figure 2 illustrates a representative set of measurement points for one recording.

Each variable studied was a ratio of two intervals, and comparisons were made of both mean values (using t-tests) and variability (F-test, one-sided, with the hypothesis of reduced variability in Synchronous Speech). Each

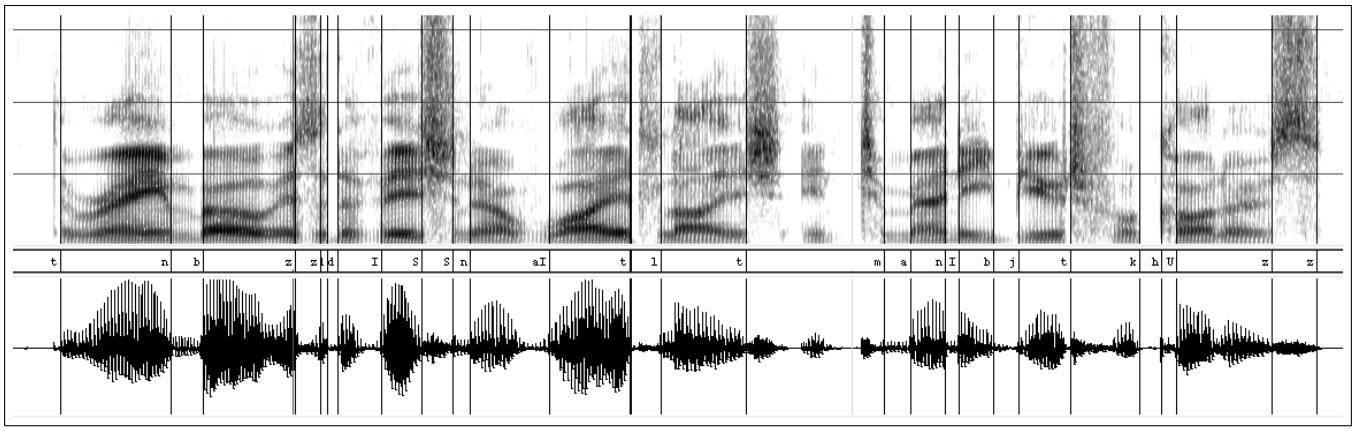

Figure 2: Measurement points for a single recording.

Table 2: Comparison of interval ratios in Synchronous Speech and Solo Speech. Intervals are taken from the sentence "The rainbow is a division of white light into many beautiful colors". Segments at measurement points are capitalized and intervals used are in bold face.

No.	Variable Type	Interval 1	Interval 2	t (df)	$p(t)$	F (df)	$p(F)$
1	juncture/phrase	ligh**T into M**any	rai**Nbow...ighT**	0.15 (93)	n.s.	1.67 (50,45)	< 0.05
2	juncture/phrase[1]	ligh**T into M**any	**Many...colorS**	0.36 (90)	n.s.	2.0 (50,45)	< 0.01
3	phrase/phrase	**Many...colorS**	rai**Nbow...ighT**	-0.27 (89)	n.s.	2.16 (50,45)	< 0.01
4	unstressed/stressed syllables	**NY**	**MA**	1.66 (92)	n.s.	1.06 (47,45)	n.s.
5	onset segment/word	**C**olors	**ColorS**	0.7 (94)	n.s.	1.04 (50,45)	n.s.
6	stressed vowel/word	div**I**sion	**DivisioN**	-0.56 (79)	n.s.	0.56 (43,42)	n.s.

ratio was expressed as the smaller value divided by the larger, and distributions were checked visually for approximate normality. Adjustment to degrees of freedom as appropriate for distributions of unequal variance was made using the Welch approximation.

Previous results had demonstrated that macroscopic phrasing (the division of an utterance into intonation phrases, the placement and duration of pauses) was significantly less variable in Synchronous Speech. No analysis of the durations of shorter intervals had yet been done. The possibility that duration ratios might be significantly different in Synchronous Speech was of interest, as this would suggest that the process of synchronization introduces artifacts into speech timing, and speech so obtained cannot be considered as unproblematically related to conventional speech. On the other hand, it was of interest to see whether the previous indications of reduced inter-speaker variability would be found with shorter, intra-phrasal, units also.

Results

Major Syntactic Juncture: The sentence studied contains one major syntactic juncture, between "white light" and "into many". The most reliably measurable interval spanning this juncture was delimited by the obstruent occlusion at the end of "light" and the first nasal onset of "many". We examined the ratio of this interval to the duration of each of the surrounding phrases (From the onset of "many" to the fricative onset in "colors" and from the nasal of the initial "rainbow" to the obstruent closure in "light"). Rows 1 and 2 of Table 2 show that the relative duration of the interval spanning the juncture is similar across conditions, whether one takes the preceding or the following phrase as a referent, but the variability of this ratio is substantially reduced in Synchronous Speech.

Phrase Length: The durations of the two major phrases ("The rainbow is a division of white light" and "into many beautiful colors") were compared. No difference in the ratios was discernible, but the variability of the ratio was greatly reduced in Synchronous Speech (Row 3, Table 2). This result may be attributable to a greater constancy of speaking rate in the synchronous condition.

Stressed and Unstressed Syllables: The word "many" provides unambiguous measurement points which make a comparison of the duration ratio of an unstressed to a stressed syllable within the same word possible. Row 4 of Table 2 provides the results of the analysis in which no significant differences in either ratios or ratio variability was found across conditions.

Segment 1: Onset. The length of the initial consonant (closure to voicing onset) in "colors" as a propor-

tion of the word length (/k/ closure to /z/ onset) was examined. Row 5 in Table 2 shows that mean ratio was not different across conditions, nor was ratio variability different in Synchronous Speech.

Segment 2: Vowel: The length of the stressed vowel /I/ in "division", expressed as a proportion of the word duration (stop closure to nasal release) was also studied. Again, neither ratio means nor variability was significantly different across conditions.

Discussion

The variables examined in the present study spanned a range of temporal scales and phonological structures. Those variables which were most directly related to macroscopic temporal structure (i.e. phrasing) all showed significant reduction in Synchronous Speech without any discernible change in mean values. The variables which describe smaller intervals showed no effects. In none of these cases was the proportional duration indexed by the ratio found to differ in its mean value between Synchronous Speech and solo speech, nor was the variability affected by speaking condition.

These results accord well with previous findings on Synchronous Speech and suggest areas for further study. No evidence has yet been found that speaking synchronously produced durational artifacts. The only properties of Synchronous Speech which have been reliably identified to date are a demonstrable increase in the consistency of global timing and phrasing (including intonation) across speakers. Those variables which exhibit substantially reduced variability in the Synchronous Speech condition are those most closely tied to timing at a global level, in which whole phrases are coordinated with respect to one another. Neither the unstressed/stressed syllable comparison, nor the segmental variables exhibited any difference in mean value or variability, suggesting that at a finer timescale there is little if any change to speakers' timing when speaking in synchrony with another person.

Some of the reduction in variability which is observed may be due to the forced maintenance of a constant speech rate. The indexing of speech rate is a notoriously difficult problem. Crude indices such as articulation rate, measured in number of syllables or segments per second, do little to match speakers' intuitions of a continuous abstract 'rate' of speaking. The constraint of speaking together with another speaker places severe limits on the freedom of the speaker to continuously modulate this abstract speaking rate, as any modification must be predictable for the co-speaker also.

[2]Alone among the distributions used herein, the ratios of the juncture to the second phrase were not normally distributed in the solo condition, but were skewed right. A Wilcox rank sum test substantiated the findings of the parametric test.

Further Exploitation of Synchronous Speech

The earlier examples of studies of pauses and intonation illustrate two different ways in which Synchronous Speech offers a novel approach to the analysis of variability in speech. In the former case, Synchronous Speech provided cleaner data than solo read speech, allowing the identification of temporal regularities which would otherwise be obscured. Synchronization among speakers is a simple and effective way of obtaining high-quality spoken data which is stripped of inessential sources of variability. This interpretation of the character of Synchronous Speech is supported by the durational measurements reported here for the first time. No difference in the fine structure of speech was observed, but variability associated with macroscopic timing was reduced. Future work should also examine finer gradations in the prosodic hierarchy: are there changes at levels between the intonational phrase and the syllable?

In the intonation study, the difference between solo speech and Synchronous Speech was itself a source of information about essential variability. By comparing Synchronous Speech with solo speech, we obtain a partition of variability into essential and inessential parts. It is tempting to associate the essential variability, preserved in Synchronous Speech, with linguistic sources, and inessential variability, absent in Synchronous Speech, with para- and non-linguistic sources, but this step is probably premature at this stage. To gauge the reliability of this attribution of the source of variation to linguistic or nonlinguistic origins will require further targeted research. However, the prospect of obtaining this partition potentially opens up new avenues of exploration for both kinds of variation.

Important information about the quality of Synchronous Speech will come from testing to see if subjects can perceive artifacts in Synchronous Speech, or indeed distinguish it from normal speech in perception tests. This work is ongoing.

One tantalizing possibility is the identification of parameters of free variability which might be exploited in the synthesis of expressive or characterful voices. Synthetic voices are bland, while carefully tailored voices which convey some sense of personality (emotion, expression) are laborious to construct. Adding random variation to synthesis parameters does nothing but reduce intelligibility. However an analysis of the properties of Synchronous Speech and a comparison with solo speech may inform voice designers about those parameters which they are relatively free to vary for expressive purposes. For example, the above study on intonation strongly suggested that an excitable voice might result from an expanded dynamic range of intonation in which the high targets are modified, but not the low targets.

Obtaining synchronous speech is not difficult. All studies of the properties of Synchronous Speech to date have suggested that the principal effect of the constraint of speaking together is to reduce idiosyncratic variability, leaving the essential quality of the speech untouched. This seems to offer two things to the experimental pho-

netician. Firstly, it provides an easy route to cleaner (less variable) data, for studies in which non-linguistic variability is unwanted. Secondly, it may provide a principled manner of partitioning variability, so that intrinsic variability which cannot be voluntarily avoided is retained, while superfluous variability is removed, thus allowing the differentiation of two kinds of variability in speech.

Active and Passive Statistical Learning: Exploring the Role of Feedback in Artificial Grammar Learning and Language

Rick Dale (rad28@cornell.edu) **Morten H. Christiansen (mhc27@cornell.edu)**

Department of Psychology, Cornell University
Ithaca, NY 14853 USA

Abstract

Language is immersed in a rich and active environment. One general dimension of that environment, feedback, may contribute greatly to learning language structure. Artificial-grammar learning offers an experimental means of exploring different kinds of potential feedback. In this paper, two experiments sought to investigate the role of feedback in an artificial-grammar learning task designed to resemble some aspects of language acquisition. An artificial language composed of auditory nonsense syllables and an accompanying visual semantics were created. Participants faced the task of mapping a sample sentence to a visual semantic scene. Results indicated that feedback is highly useful, allows participants to reach a high level of competence in the language, and also helps the acquisition of detailed aspects of the artificial grammar. Implications for language acquisition are discussed, and future directions considered.

Introduction

That humans can learn without any direct feedback has been well established for decades. From basic information extraction in perceptual processes (Gibson & Gibson, 1955), to social facilitation of a choice task (Bandura & Mischel, 1965), it seems that learning can occur passively and observationally across multiple levels of cognitive complexity.

One particular area of research with similar findings has been that of implicit learning or artificial grammar learning (AGL; Reber, 1967), in which subjects become sensitive to the regularities of a simple artificial grammar through passive exposure to sample sentences. A considerable amount of this research has been directed towards uncovering the mechanisms of this learning (e.g., Reber, 1967; Reber & Lewis, 1977; Vokey & Brooks, 1992; Redington & Chater, 1996; Cleeremans, Destrebecqz, & Boyer, 1998; Pathos & Bailey, 2000).

Learning through passive exposure to these grammars, however, is usually defined as performance at above-chance levels. Therefore, to gain further insight into language acquisition, theoretical and empirical bridges are needed between what may be called *passive structural learning* in these cases and the natural world, in which a learner acquires a firm competence with sequential structures in a meaningful, interactive context (e.g., see Berry, 1991, for an investigation of action in learning a probabilistic system). In pursuit of this, some research has been guided by questions about the possible connections between this kind of learning and real-world tasks, in particular language acquisition (e.g., Saffran, Aslin & Newport, 1996; Christiansen & Ellefson, 2002; Lupyan, 2002; Saffran, 2003). AGL can be used for studying the kinds of structural regularities that children discover while learning language (Saffran, 2003). The goal of this work has mostly involved exploring learning under passive observational exposure. Indeed, these experiments have demonstrated the richness of statistical learning under such circumstances.

However, language acquisition does not take place in a social vacuum. Instead, children are acquiring their native language while interacting with both people and things in the environment (e.g., Snow, 1999; Chouinard & Clark, 2003; Moerk, 1992; and even before two-word production; see Tomasello, 2003, for a review). In this context, and others in the natural world, relevant sequential behavioral structure *has a function* or *serves a purpose*, socially or otherwise, and its acquisition is immersed in this interactive context. What kind of information in the environment, and possible mechanisms in the learner, can supplement passive exposure to sequential structure in order to obtain a competence over what is to be learned? This paper presents a first step toward identifying one such dimension of learning. By using an AGL procedure, we explore the role of one kind of feedback that may be present in language acquisition.

We first offer a brief summary and review of this source of feedback in language acquisition. The potential for exploring this dimension is then presented in two experiments, demonstrating how an interactive task can bring a learner to a strong level of competence. In addition, we demonstrate that detailed aspects of an artificial grammar can be acquired in the context of feedback. We end with a discussion of implications, especially in view of language acquisition, and future directions this research may take.

Feedback in Language and AGL

Although the child may not be told explicitly that a given utterance or word is incorrect (also referred to as the lack of "negative feedback"; Saxton, 1997), the child does get other types of evidence or feedback.[1] For example, a mother may

[1] For simplicity, we do not consider the difference between negative feedback and negative evidence, though the distinction is important and may be explored by the experimental means presented here. See Saxton, 1997, for further discussion.

ask her child to pick up a particular toy, say a little plastic pig, from among several other toys. When the child successfully picks up the right toy, the mother may emphatically repeat the name of the target object: *The pig! Yes, that's the pig*. Once the child chooses the right toy, the mother repeats the label (e.g., *the pig*) and thus provides positive feedback on the child's correct mapping of the linguistic label to the appropriate object. Although there is considerable and continuing debate on the cultural variability of such practices (see Lieven, 1994, for a review and discussion), it is nevertheless possible that feedback of this nature may be present and useful in language acquisition (e.g., see Peters and Boggs, 1986, for a discussion of interactional routines across cultures).

Here we take a first step toward assessing the potential usefulness of such feedback in an AGL task meant to model the learning of sequential structure and how it maps to the non-linguistic world – a task not unlike what the child faces.

It should be noted that the role of feedback in language acquisition is highly controversial (see, for example, Morgan, Bonamo & Travis, 1995; Valian, 1999; Moerk, 2000; Saxton, 1997, 2000). It has perhaps for this reason not been extensively investigated in AGL research, where the focus has been on training techniques that largely parallel the kind of passive input considered central during language acquisition. Nevertheless, the role of feedback is widely acknowledged in such areas as skill acquisition (Moerk, 1992), learning theory (Rescorla, 1968), and reinforcement-learning models (Sutton & Barto, 1998).

There are therefore two primary objectives of the following experiments. A basic empirical objective is to consider the influence of feedback on AGL in a training procedure that resembles a natural-world context. To meet this goal, an experimental paradigm has been designed to resemble a kind of task faced by the child during language acquisition, adapted from Lupyan (2002; also, see Billman, 1989 and Morgan, Meier & Newport, 1987 for similar techniques).

Another objective is primarily theoretical: How does learning sequential structure get immersed in an interactive context and lead to competence? These experiments approach one aspect of an answer by considering how interactive feedback in a sequential learning task might bring the learner to a competent level of performance.

Experiment 1

This experiment is a first demonstration of the influence of feedback on learning an artificial grammar. The conditions in this experiment focus on the consistency of forms of feedback, and the extent to which the feedback is a salient, meaningful aspect of the learning task.

Method

Participants 51 college students were recruited for extra credit. Participation required approximately 20 minutes.

Materials A simple artificial grammar was created for the experiment, illustrated in Figure 1. Each category (e.g., N, *noun*) was instantiated by a set of nonsense syllables (e.g., *voop* or *jux;* see Table 1).

$$S \rightarrow N_1 \quad VP$$

$$VP \rightarrow \left\{ \begin{array}{l} \text{intransitive-V} \\ N_2 \quad \text{transitive-V} \\ N_2 \quad N_3 \quad \text{ditransitive-V} \end{array} \right\}$$

Figure 1: The artificial grammar

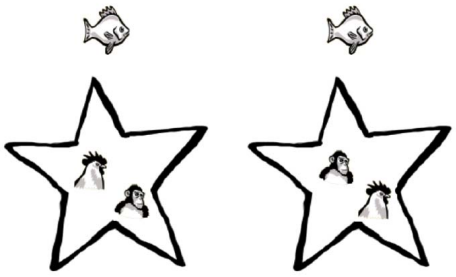

Figure 2: An example stimulus from one trial

An elementary visual "semantics" was created for this language. Each noun was randomly assigned an animal referent, and each verb had as its "meaning" a simple shape. Each nonsense syllable in the language had a referent of this kind in the visual semantics (Fig. 2).

Although the extent to which the visual scene contains a "subject" or "object" or "verb" is abstract, the language and its semantics are meant to capture structure-world correspondences not entirely unlike what might be seen in natural language structure.

Fifty random sentences were constructed for the experiment, and an incorrect visual semantic scene for each sentence was created (see Figs. 3 and 4). This incorrect scene was paired, as a foil, with the correct scene in training, as described below.

Table 1: Classes and assigned syllables

class	sounds	class	sounds
N	*kav*	Intran V	*voop*
	jux		*poox*
	ruj	Tran V	*sook*
	hep		*lem*
	pel	Ditran V	*rud*
	hes		*jove*

Procedure In every trial, participants saw two visual semantic scenes side by side then heard a sample sentence from the grammar. Their task was to select the appropriate visual semantics for the sentence heard. The task therefore involved learning the sequential structure of the grammar, and learning to map each sound to its semantic animal or shape.

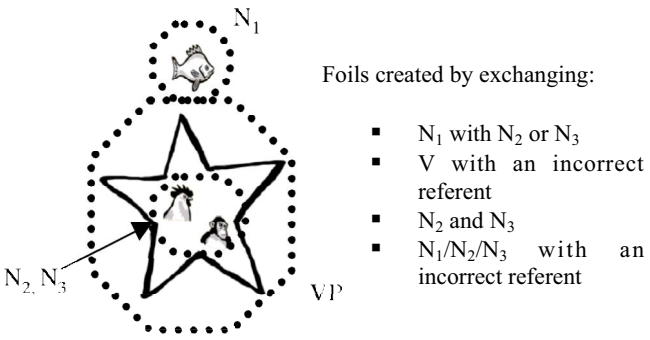

Figure 3: The structure of the visual scene and foils

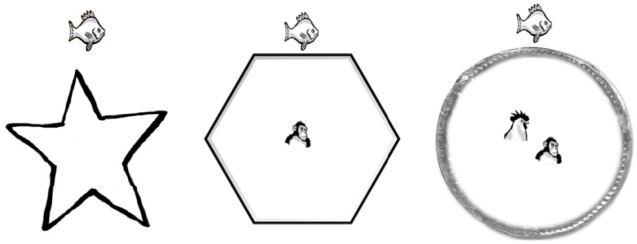

Figure 4: Example sentences

A *positive feedback event* was defined as a repetition of the sentence when the participants selected the appropriate visual semantic scene.

Two feedback conditions were investigated. Some subjects received *only* consistent feedback, occurring with 50% probability on any *correct* trial. Other subjects received 40% *random* repetitions, not contingent on the correctness of their selection (these probabilities were chosen so that all participants heard approximately the same number of repetitions).

Two further conditions were defined in terms of the kinds of instructions provided to subjects. In one condition, subjects were not informed about the meaningfulness of the repetitions (as positive feedback); in a second condition, subjects were explicitly informed that feedback would occur.

Out of the four possible subject groups, three were used in the experiment. One group received no instruction about the feedback but received it consistently. A second received no instruction, but the feedback occurred randomly. A third group of subjects received both consistent feedback and instructions about the presence of feedback during training.

Performance on the final 10 items of training served as the measure of learning. These items were new to the subjects. This permitted observation of performance in a continuous learning task without interruption. There was therefore no distinction between training and testing.

Results

No main effect for condition was found (corrected $F(2, 50) = 1.65$, $p = .21$). However, due to the probabilistic nature of the training phase, an additional planned regression analysis on each condition was conducted (because, by chance, some subjects may experience less consistent positive feedback than others). This was meant to investigate the number of actual feedback events experienced during the first 40 trials of training, and how it might predict performance on the final 10 items.

The only condition that produced a reliable predictive relationship was that in which subjects received information about the presence of feedback ($r = .65$, $p < .05$). Although the consistent feedback without instruction condition had a positive slope, the coefficient was not significant ($r = .28$, $p = .26$).

Discussion

This preliminary experiment offers some important observations. First, inconsistent feedback present in training did indeed stultify learning, even when the subjects were not certain about the significance of the sentence repetitions. We may tentatively contend that even contingent events in

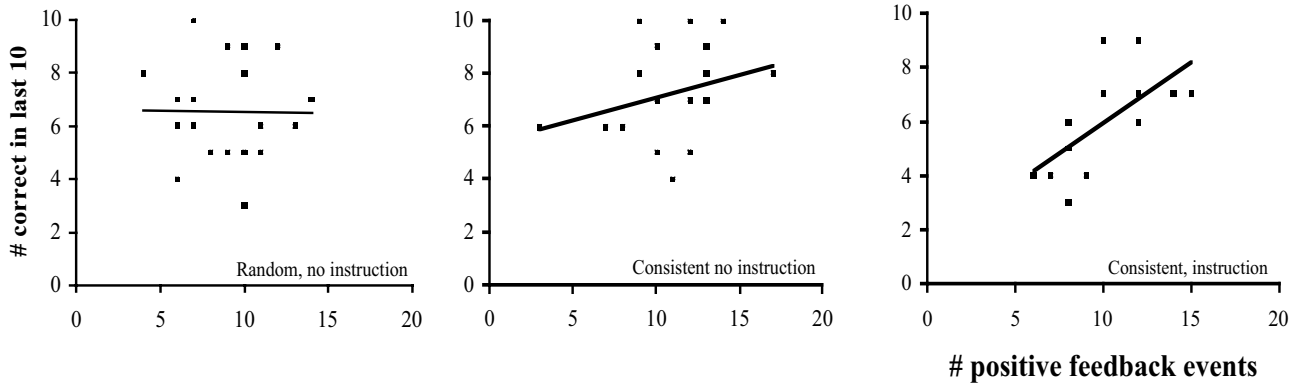

Figure 5: Regression analyses of different conditions. Each point represents a subject.

the learning environment can help or hinder learning sequential structure. It was *not* the case that learners simply ignored the repetitions and extracted the sequential invariants across the training trials.

Second, when participants were informed about the presence of feedback, the repetitions served as *significant* elements of acquiring the structure. It appears that subject performance became highly reliant upon even occasional, contingent repetitions of sentences as positive feedback, especially when the feedback was made meaningful to subjects. There is evidence that perceiving the import of such events may have an important influence on language acquisition (Saxton, 1997; Tomasello, 2003).

Despite these positive results, the learning that took place in the experiment hardly exhibits competence of the kind described in the introductory discussion. We therefore conducted a second experiment to address this and other questions. First, we enhanced the salience of the feedback event by changing the training environment. Second, we devised a separate test phase to explore the learning of specific kinds of structures in the grammar. Finally, we tracked learning of the grammar over time to observe the effect of feedback across training.

Experiment 2

Experiment 2 changed the nature of the feedback event to render it more salient. This involved not merely repeating the sentence, but also changing the visual environment selected by the participants. In addition, we explored how participants learned different aspects of the grammar, such as the abstract verb-argument structure.

Method

Participants 34 college-age participants were recruited for extra credit. Participation required approximately 20 minutes.

Materials The artificial grammar used was the same as in the first experiment. We created an additional 30 sentences to be used in a test phase without feedback. The paired incorrect visual scenes in these test items were constructed so as to sample across all possible grammatical errors. These included exchanging nominal shapes with an incorrect shape, inverting nominal shapes, and exchanging verbal shapes with incorrect shapes (see Fig. 3 for the kinds of foils used).

Once again, 50 sentences were presented randomly in a training phase. Feedback again was defined as a repetition of the spoken sentence.

Procedure Similarly to the first experiment, participants selected one of two visual scenes in response to a heard sentence of the grammar. This training once again consisted of 50 trials. Half the subjects received 60% feedback consistently, the other half hearing random feedback with 50% probability (these were selected once again so that all subjects heard approximately the same number of repetitions).

Given the results of the first experiment, it seems that salience of such feedback is a crucial property of using it in the task. To enhance this effect, we added a feature to the feedback event: When a correct visual scene was selected, the incorrect scene would be removed *and* the sentence would be repeated to the participant. This served to make these events as informative as possible to the participants. Also, this event may bear some resemblance to social interaction between the child and caregiver. When the child correctly interprets a lexical item, the caregiver may emphasize its referent object, thereby focusing the child's attention on it.

Following this training procedure, 30 trials were presented to participants *without* feedback in either condition. Performance on these 30 items served as the basic comparison between groups (consistent vs. random feedback), and item analyses allow us to investigate the role of feedback in acquiring more detailed aspects of the grammar (e.g., verb argument structure).

An additional control condition was conducted in which participants only experienced the test phase of the experiment.

Results

A main effect of condition (positive feedback, random feedback, control) was found ($F(2, 31) = 7.1$, $p < .01$). Subsequent comparisons among the groups indicated that only the positive feedback condition differed significantly from the random feedback and control groups ($p < .05$ in both cases; see Fig. 6). In fact, participants in the random feedback condition did not differ significantly from the control group ($p = .28$).

We further conducted item analyses within the positive and random feedback conditions to find wherein their performance differences lie (see Table 2). A repeated-measures ANOVA was conducted over the different kinds of items within subjects, and found that the primary differences in performance were in verb exchanges, the "subject" shape being exchanged, and a marginally significant result for identifying inversions in the argument structure of the verbal shapes.

By looking at the overall performance of participants, graphed over time, we get an interesting illustration of learning under the condition of consistent feedback (Fig. 7). The final 4 points include performance during the training stage.

Table 2: Number correct on different foils, and significance of the comparisons

Type of error in scene	Pos	Ran	Out of	p
Verbs different	5.2	3.8	6	< .05
Nouns different	3.8	3.8	5	.88
Sub exchanged w/ obj	12	8.8	14	< .01
Objects exchanged	3.2	2.4	5	.07

Discussion

These results further indicate that the salience of positive feedback in a sequential learning task of this kind can strongly influence performance. Participants in this task were performing almost perfectly in the positive feedback condition, even in the test phase, during which feedback was no longer issued.

Moreover, item analyses indicated that even subtle structure-world correspondences as the idealized "verb argument" structure in this artificial grammar was being learned more effectively under the condition of feedback.

General Discussion

Although we feel the current experiments hold considerable promise, they do have limitations. First, although they more closely resemble natural-world contexts than previous research, they are still quite simple. Future experiments will address this issue by incorporating an even more interactive experimental task. Second, the grammar itself is quite simple, and *mere* passive exposure may be sufficient to learn it. Experiments are currently being conducted that directly compare passive exposure to scene-sentence pairs and the active selection task used here.

These limitations notwithstanding, the experiments have provided a first step towards investigating how feedback in an interactive task can bring performance in AGL to a more competent level than typically observed. The language acquisition literature itself has been deeply involved in debate for decades about the nature of feedback and evidence to children. For example, one may argue that the issue of positive and negative feedback has been resolved since Brown and Hanlon (1970), who demonstrated quite clearly that commonplace conceptions of feedback to a language learner are incorrect. Nevertheless, many continue to tease apart the negative and positive function of different types of input to children (e.g., Saxton, 1997; Saxton, 2000; Chouinard & Clark, 2003).

The experiments here can contribute to this endeavor. They may offer empirical means by which different kinds of feedback and their effects can be investigated experimentally, albeit here in college-aged subjects. The technique could be modified for children, and many of its dimensions explored in experiments with both children and adults. Some have pursued similar techniques such as "human simulations" (e.g., Gillette, Gleitman, Gleitman & Lederer 1999; Snedecker, Gleitman & Brent, 1999). For example, Snedecker et al. (1999) used college-aged subjects to explore the role of ambient social and environmental input to support a noun bias during language acquisition. This idea is not unlike what is being argued here (see Snedecker et al. for an interesting exploration and discussion of feedback in word learning).

More importantly, these experiments are intended to support a perspective in "ecological" sequential learning, and particularly language learning, that sees the task facing a learner as an active and interactive one. We would contend that such learning cannot *only* involve passively extracting statistical regularities from different modalities. Instead, sequential structure in the natural world, linguistic or otherwise, is *used* in an *interactive* environment – these uses generate consequences in the environment that impinge upon a learner's expectations and help carry the learner into a world of meaningful sequential structure.

Semantic Inhibition due to Short-Term Retention of Prime Words: The Prime-Retention Effect and a Controlled Center-Surround Hypothesis

Eddy J. Davelaar (e.davelaar@bbk.ac.uk)

Abstract

The semantic priming effect is shown to be modulated by the instruction to maintain the prime word while conducting a lexical decision to the target. Specifically, the priming effect is absent in situations of prime-retention. An extended version of Dagenbach and Carr's (1994) Center-Surround hypothesis is proposed, in which the prime-retention effect, the absence of priming under prime-retention, can be accommodated. This extended hypothesis suggests that under prime-retention, activation remains centered on the prime, preventing unwanted spread of activation. This impact of the on-center-off-surround mechanism increases over time, making it sensitive to manipulations of stimulus duration.

Introduction

In the field of memory, semantic priming is a basic paradigm used to investigate the processes that inter-relate conceptual representations in long-term memory. The basic result is reduced lexical decision times or naming latencies and improved accuracy to words (i.e., targets), when they are preceded by a related word (i.e., the prime) relative to control. The semantic priming effect is such a robust phenomenon that even the absence of priming is theoretically relevant, as can be seen by the large literature on the prime-task effect (the absence of priming when attention is allocated away from the semantic level, but is still within the verbal domain) (see for a review, Maxfield, 1997). The implied assumption in the priming literature seems to be that the more attention the prime word receives, the more priming is expected. This paper focuses on the counterintuitive observation that the semantic priming effect is absent when in a standard priming paradigm the prime has to be reported *after* making a lexical decision to a target. This observation will be referred to as the *prime-retention effect*, as it is the active retention of the prime in short-term memory that modulates the priming effect.

Controlled Center-Surround Hypothesis

There are a number of theories and models of priming, but for the present purposes the spreading-activation view of semantic priming will be addressed to highlight the need for auxiliary mechanisms to accommodate the to-be-presented data. In the standard spreading-activation theory, concepts in semantic memory are linked together to form a semantic network, with the strength of the connection between two concepts representing the strength of association. Extensive investigations into the nature of the semantic priming effect has led to the view that the semantic priming effect is due to a fast-acting automatic process and a slow-acting controlled process (Neely, 1976, 1977, 1991). By varying the stimulus-onset-asynchrony (SOA) between the prime and the target, the relative contributions of these processes can be modulated. It is therefore assumed that with short SOAs the priming effect is predominantly due to automatic processes. However, this assumption has been challenged by behavioural and neuroimaging studies that show context effects at short SOAs (e.g., Mummery, Shallice & Price, 1999; Smith, Besner & Miyoshi, 1994).

One theory that specifically addresses the possibility of controlling the spread of activation is the Center-Surround hypothesis by Dagenbach and Carr (1994). In a nutshell, the hypothesis states that there exists a mechanism that facilitates "the semantic code on which it is focused or *centered* while inhibiting *surrounding* codes, codes that are similar to but different from the desired code and are competing with it for retrieval" (p.328, italicised words were between quotes in original). Dagenbach and Carr's work was mainly focused on priming effects found at the threshold of subjective and objective awareness and was applied quite successfully in a model of negative priming (Houghton & Tipper, 1994). However, in the standard supra-threshold priming paradigm, the data does not seem to demand such on-center-off-surround mechanism. This may be because the prime word does not have to be actively maintained. An on-center-off-surround mechanism would be necessary under conditions of prime-retention. For example, when a task requires focusing on a particular word, the increased activation to that word would lead to more spread of activation, which would in turn compromise the attentional focus on the word, due to the now-activated distractors. Intuitively, we are able to focus on the word 'doctor' for several seconds without strongly activating related concepts like 'nurse', 'patient', 'hospital', 'medicine' and so on. Besides preventing a situation where the whole lexicon becomes activated, inhibitory mechanisms seem particularly relevant in situations of short-term retention where a robust focus is necessary (e.g., Grossberg, 1978).

The view that will be pursued here is that there exists a trade-off between prime-activation and activation-spread, of which the balance depends on the task requirements. This hypothesis will be referred to as the Controlled Center-Surround hypothesis, implying that a controlled effort (i.e., deliberate active maintenance) needs to be made in order to observe the on-center-off-surround mechanism at supra-

threshold SOAs. In the prime-retention paradigm used here, the participant is presented with the prime and has to maintain it while making a lexical decision to a target. The Controlled Center-Surround hypothesis would predict that normal priming effects are found when the prime need not be retained (as the on-center-off-surround mechanism is not fully operational), while in the retention condition the off-surround component nullifies (or even reverses) the priming effect.

Before presenting the experiments that were designed to address the Controlled Center-Surround hypothesis, the next section will highlight two earlier reports that presented hints of a *prime-retention effect*.

Earlier reports

A *prime-retention effect*, the absence of a priming effect when the prime is actively maintained during lexical decision, can be observed in reports from at least two research groups (Fischler & Goodman, 1978; Henik, Friedrich, Tzelgov & Tramer, 1994). In a study by Fischler and Goodman (1978), participants were tested on a masked priming paradigm in which the prime was presented very briefly (50 ms) with a visual mask preceding and succeeding it. They asked participants to report the prime word after making a lexical decision to the target string. Participants were able to report the prime in about 50 % of the trials. Semantic priming was only found when the prime could *not* be reported; the priming effect was absent when participants could correctly report the prime word. A second example of the *prime-retention effect* can be found in one of the conditions in a study by Henik, Friedrich, Tzelgov and Tramer (1994). These authors were interested in the time-course of the prime-task effect (the finding that the priming effect is eliminated when the prime word is processed on a non-semantic level). Participants had to read the prime out loud and make a lexical decision to a target word. In one particular condition (in their experiment 3), the SOA was relatively short (240 ms) and therefore participants had to report the prime word *after* the lexical decision was made, thus actively maintaining it during the lexical decision. No priming effect was found in this condition. Henik et. al. (1994) explained the lack of priming in terms of the prime being processed at a shallow (e.g., phonological) level and thereby preventing resources to be allocated to the semantic level. However, this idea was not elaborated further.

The results by Fischler and Goodman (1978) and Henik, et. al. (1994) suggest at the very least that maintaining the prime modulates the priming effect and that the underlying mechanism may be inhibitory in nature. However, the results indicating this were tangential to the main focus of their investigations and did not receive enough attention. Therefore it is possible that their results, indicating a *prime-retention effect*, may have been a chance-finding. For example, in Fischler and Goodman's (1978) study, the results strongly depended on the erroneous recall performance of the participants (50 % error rate), making the data sensitive to participants' idiosyncratic biases (see for discussion, Holender, 1986). In addition, the results obtained by Henik, et. al. (1994) were not replicated without participants completing several other experimental conditions, which could have led to carry-over effects.

Experiments

Here, three experiments are reported that were specifically designed to address the *prime-retention effect*. The experiments involved two blocks of prime-target pairs in a standard lexical decision paradigm. The first block was always the control condition, in which participants did not need to maintain the prime word. In the second block, participants were required to maintain the prime and give a verbal report (in Experiment 1) or recognise it from four alternatives (in Experiment 2 and 3) after the lexical decision. In order to assess whether the prime has been processed on the semantic level, the association strength between prime and target was taken into account in the analyses. Any modulation with associative strength would counter an explanation based purely on shallow non-semantic processing.

According to the Controlled Center-Surround hypothesis, in the control condition, normal priming effects are expected for strongly and weakly related targets at both short and long SOAs, as the activation of the prime is allowed to decay after presentation. However, in the retention condition, it is expected that only strongly related targets show priming effects at both SOAs (controlled on-center), but that weakly related targets show less or even no priming effect (controlled off-surround).

Experiment 1

Participants. Twenty volunteers from the University of London participated in the experiment in exchange for £5. All participants had English as their first language, were right-handed and had normal or corrected-to-normal vision.

Design. The experiment conformed to a 3 x 2 within-subject design, with Relatedness (unrelated, low-related, high-related) and Retention as independent variables. Lexical decision times and accuracy were measured.

Materials. Eighty-four word pairs were selected from the MRC Psycholinguistic Database (Coltheart, 1981). The word pairs had a word frequency ranging from 10 to 660 per million (Kucera & Francis, 1967). The association strengths between the prime and target word ranged from 12.5 to 73.8 (M=34.5; Moss & Older, 1996). A median split divided the targets in the high and low association trials. All words and pseudohomophones were one syllable long. Unrelated trials were formed by rearranging the related pairs. Each participant saw each word only once, but target words rotated across participants in all conditions.

Apparatus. The experiment was run on an IBM-compatible PC using Micro Experimental Laboratory (MEL) Professional software (Schneider, 1995). Letter size was approximately 0.5 cm and average viewing distance was about 50 cm.

Procedure. Participants were given the instructions on the screen as well as verbally by the experimenter. The experiment had a total of 168 trials grouped into two blocks; the 'no retention' block was always followed by the retention block. After the instructions for each block, subjects practised 8 trials. On each trial, a fixation stimulus was presented for one second in the center of a computer screen, followed by a word in lowercase white letters that remained for one second. After a 250 ms interval (blank screen) a target was presented (in uppercase yellow letters) that remained on the screen until a lexical decision was made. In the control condition, the next trial started after a 500 ms delay, whereas in the retention condition a question mark prompted the participant to recall the prime word. The experimenter recorded the recall. Participants got feedback whenever an error was made.

Results and discussion

The mean median reaction times and error rates for all conditions are presented in Table 1. Performance on naming the prime was at ceiling (100% correct), discounting an explanation based on some form of speed-accuracy trade-off. Because of the large differences in standard deviations between the control and the retention condition, log-transformed RTs were used in the analyses with the Retention-variable, while untransformed RTs were used in the pairwise within-block comparisons.

An overall ANOVA on the lexical decision times revealed a main effect of Retention [$F(1,19)=40.35$, $MSe=0.04$, $p<.001$] and a marginal effect of Relatedness [$F(2,38)=2.55$, $MSe=0.02$, $p=.091$]. The interaction did not reach significance. A similar ANOVA on the response accuracy only revealed a marginal effect of Relatedness [$F(2,38)=2.64$, $MSe=0.001$, $p=.084$].

Pairwise comparisons were conducted to specifically address the predictions made by the Controlled Center-Surround hypothesis. This analysis revealed that priming effects were only obtained for the strongly related prime-target pairs in the no-retention control condition both for RTs [$t(19)=2.48$, $p<.05$] and error rates [$t(19)=2.42$, $p<.05$].

Experiment 1 replicates the failure to obtain a priming effect when the prime word needs to be retained. Although several methodology-related explanations could be given for the absence of priming, the mere observation of a lack of priming due to an experimental manipulation begs further inquiry. One possibility for the lack of priming in the retention condition could be that participants were preparing the articulatory response while making the lexical decision. This could lead to a form of response interference, where both verbal and manual responses are prepared and executed. Therefore, Experiments 2 and 3 employed a recognition task on the prime word instead of a verbal response. It was hoped that this would 'clean up' the processes during the lexical decision.

Experiment 2

Participants. Twenty-four volunteers from the University of London participated in the experiment. All participants had English as their first language, were right-handed and had normal or corrected-to-normal vision.

Design. The experiment conformed to a 3 x 2 within-subject design, with Relatedness (unrelated, low-related, high-related) and Retention as independent variables. Lexical decision times and accuracy were measured.

Materials. 112 word pairs were selected from the MRC Psycholinguistic Database (Coltheart, 1981). The word pairs had a word frequency ranging from 10 to 660 per million (Kucera & Francis, 1967). The association strengths between the prime and target word ranged from 5.4 to 66.7 ($M=34.5$; Moss & Older, 1996). A median split divided the words in high and low association-trials. All words and pseudohomophones were one syllable long. Unrelated trials were formed by rearranging the related pairs. Each participant saw each word only once, but target words rotated across participants in all conditions.

Apparatus. The apparatus as in Experiment 1 was used.

Procedure. Participants were given the instructions on the screen as well as verbally by the experimenter. The experiment had a total of 224 trials grouped into two blocks; the 'no retention' block was always followed by the retention block. After the instructions for each block, subjects practised 8 trials. On each trial, a fixation stimulus was presented for one second in the centre of a computer screen, followed by a word in lowercase white letters that remained for one second. After a 250 ms interval (blank screen) a target was presented (in uppercase yellow letters) that remained on the screen until a lexical decision was made. In the control condition, the next trial started after a 500 ms delay, whereas in the retention condition a list of four words appeared (the prime and three distractors) and the participant had to indicate by pressing one of four keys which one was the prime word. Participants got feedback whenever an error was made.

Results and discussion

The mean median reaction times and error rates for all conditions are presented in Table 1. Performance on recognising the prime was at ceiling (99% correct) and did not show an effect of Relatedness.

An overall ANOVA on the (log-transformed) lexical decision times revealed a main effect of Retention [$F(1,23)=43.34$, $MSe=0.0056$, $p<.001$] and a main effect of Relatedness [$F(2,46)=11.61$, $MSe=0.004$, $p<.001$]. The interaction did not reach significance. A similar ANOVA on the response accuracy only revealed a main effect of Relatedness [$F(2,46)=3.97$, $MSe=0.001$, $p<.05$] and a marginal Retention x Relatedness interaction [$F(2,46)=2.59$, $MSe=0.001$, $p=.086$].

Pairwise comparisons revealed that priming effects were only obtained for the strongly related prime-target pairs in the no-retention control condition for RTs [$t(23)=3.90$, $p=.001$]. Priming effects in the error rates were

found for strongly related prime-target pairs in both Retention conditions [control: $t(23)=2.10$, $p<.05$; retention: $t(23)=2.40$, $p<.05$] and for weakly related prime-target pairs in the retention condition [$t(23)=2.81$, $p=.01$].

Experiment 2 replicates the findings of Experiment 1 in showing priming effects only in the control condition and only for the strongly related prime-target pairs. A between-experiment analysis further revealed that the reaction times between the two groups did not differ (all $ps>.15$), suggesting that the type of memory task did not have a noticeable impact on performance.

Given the possibility that the amount of priming is affected by the increased attentional focus, a Controlled Center-Surround hypothesis would have to predict that the off-surround component exerts more influence the more attention is paid to the prime word. It is therefore expected that at shorter SOAs, priming will be observed in the retention condition, even when the prime can be reported after the lexical decision. Experiment 3 tests this assumption.

Experiment 3

Thirty-two volunteers from the University of London participated in the experiment. All participants had English as their first language, were right-handed and had normal or corrected-to-normal vision. The design, materials and procedure were the same as in experiment 2, with the difference that the prime was presented for 250 ms and was immediately followed by the target.

Results and discussion

The mean median reaction times and error rates for both conditions are presented in Table 1. Performance on recognising the prime was at ceiling (98% correct) and did not show an effect of Relatedness. The data from one participant were excluded from the analysis due to extreme long RTs.

An overall ANOVA on the (log-transformed) lexical decision times revealed a main effect of Retention [$F(1,30)=75.14$, $MSe=0.06$, $p<.001$] and a main effect of Relatedness [$F(2,60)=8.15$, $MSe=0.005$, $p=.001$]. The interaction did not reach significance. A similar ANOVA on the response accuracy also revealed a marginal effect of Retention [$F(1,30)=3.51$, $MSe=0.002$, $p=.071$] and a marginal effect of Relatedness [$F(2,60)=2.62$, $MSe=0.001$, $p=.081$].

Pairwise comparisons revealed that, for RTs, priming effects were obtained for the strongly related prime-target pairs in both the control [$t(30)=3.46$, $p<.005$] and the retention [$t(30)=2.20$, $p<.05$] condition. Weakly related prime-target pairs showed a priming effect only in the retention condition [$t(30)=2.15$, $p<.05$]. Priming effects in the error rates were found only for strongly related prime-target pairs in the no-retention control condition [$t(30)=2.43$, $p<.05$].

Experiment 3 confirms the assumption that the mechanism responsible for the absence of priming in Experiments 1 and 2 develops over time. Interestingly, in contrast to the findings with long SOA, with short SOA, the numerical values of the RT-priming effect are larger in the retention than in the control condition.

Table 1: Results of Experiments 1, 2 and 3. RTs in ms and proportion correct within brackets.

	Unrelated	Weak-related	Strong-related
Experiment 1 (N=20): recall + long SOA			
Control	606 (.95)	587 (.98)	576 (.98)
Retention	759 (.96)	769 (.98)	736 (.96)
Experiment 2 (N=24): recognition + long SOA			
Control	633 (.96)	631 (.99)	597 (1.0)
Retention	816 (.98)	828 (1.0)	788 (1.0)
Experiment 3 (N=31): recognition + short SOA			
Control	755 (.97)	741 (.96)	722 (.99)
Retention	1070 (.98)	1015 (.98)	1012 (.99)

General Discussion

The three experiments provided further insight into the observation that priming effects are absent when the prime word is actively maintained during lexical decision to the target. In all three experiments, reaction times in the retention condition were slower than in the standard control condition, which merely reflects the increase in cognitive demand in this dual-task situation. The effect of relatedness was only significant in Experiments 2 and 3, which employed a recognition task on the prime word. Although the interaction between Retention and Relatedness was not significant in any of the experiments, based on previous reports, pilot studies and the predictions from the Controlled Center-Surround hypothesis, pairwise comparisons revealed an interesting picture. With long SOA (1250ms), priming was only found for strongly related targets and only in the control condition, the *prime-retention effect*. With short SOA (250 ms), priming was found for weakly and strongly related targets in the retention condition and for strongly related targets in the control condition.

Although further studies are required to investigate this pattern in more depth, the present set of experiments already rules out two alternative explanations for the absence of a priming effect in the retention condition. First, in Fischler and Goodman (1978), Henik et. al. (1994) and Experiment 1, a verbal report had to be given after the lexical decision task. It is possible that the absence of semantic priming does not originate at a memory level, but instead may be due to some form of interference between executing the lexical decision and preparing the articulatory response for reporting the prime. However, the fact that the main results did not change when a recognition task was used instead of

a recall task, suggest that the *retention* of the prime and not the articulatory preparation of the prime was crucial. Second, Henik, et. al. (1994) suggested that the absence of priming in their experiment was due to the prime word being held at a shallow level of processing (e.g., phonological code) preventing "the needed attentional resources from being allocated at the semantic level" (p. 165). However, in the experiments reported here, the strength of the prime-target association modulated the effect. This also indicates that the *prime-retention effect* and the *prime-task effect* are different phenomena. The former requires full processing and active maintenance of the prime word, whereas the latter requires allocating attention away from the semantic level (but remaining within the same processing domain; Chiappe, Smith & Besner, 1996).

In awaiting more conclusive evidence, the current results support the proposal that the center-surround mechanism, which is assumed to be a structural component of the semantic memory system, dominates when more attention is directed to the prime word. In such situations prime-activation and activation-spread may trade off. To illustrate the Controlled Center-Surround hypothesis, consider Figure 1. In this figure, the strength of association between prime and target are set on the abscissa with the weakest strength to the right. On the ordinate the priming effect (RTunrelated – RTrelated) is set out for the long SOA (averaged over Experiments 1 and 2) and for the control and retention condition. The 'priming effect' for the 'prime' is a linear extrapolation of the values for the strong and weak associates. This figure makes two points. First, it makes the intuitive prediction that when the prime is in short-term memory, a decision on the prime itself is speeded up. Second, the overall pattern resembles the textbook example of an attentional on-center-off-surround 'Mexican hat' receptive field in the visual domain.

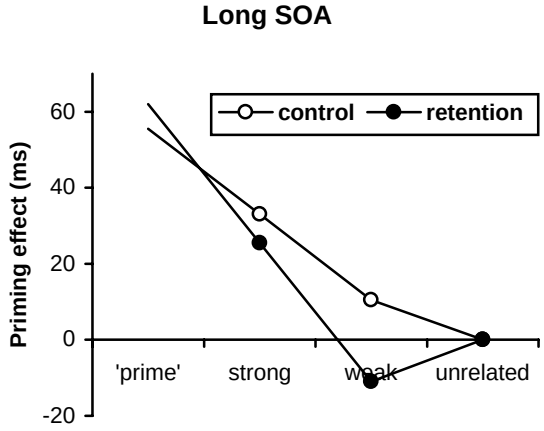

Figure 1: Priming effect as function of the strength of the prime-target association for *long* SOA. The values for the 'prime' are linear extrapolations from the values at strong and weak strength.

The figure for the short SOA is more complex (see Figure 2). The same prediction for identity priming is made, with larger 'priming' in the retention condition compared to control. However, the priming effect at short SOA seems larger in the retention condition than in the control condition. This pattern was replicated in a follow-up study (not reported here) and if this holds true in future studies, it would mirror the two-stage activation process proposed in the literature using homographs (words that have multiple meanings). In this two-stage process, an initial (automatic) activation of all meanings of a word is followed by a stage in which non-dominant or incongruent meanings are suppressed (Simpson & Burgess, 1985; Simpson & Kang, 1994). According to the hypothesis proposed here, the suppression in the second stage is a result of biased competition, where a deliberate directed attention to relevant word meanings makes them win this competition.

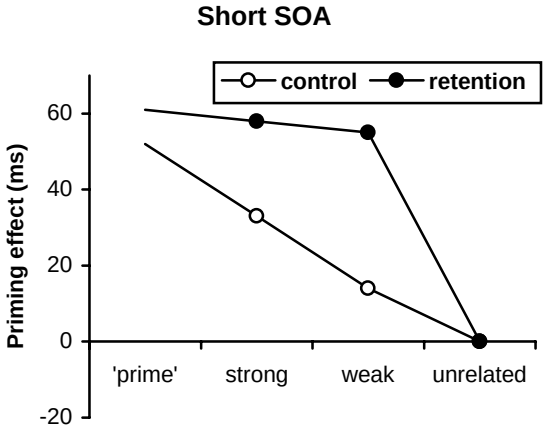

Figure 2: Priming effect as function of the strength of the prime-target association for *short* SOA. The values for the 'prime' are linear extrapolations from the values at strong and weak strength.

Although not predicted initially, the numerically larger priming effect with short SOA is not inconsistent with the Controlled Center-Surround hypothesis. The initial activation of the prime facilitates strong and weak related targets, but the inhibitory influence is only felt after the prime has received a large amount of activation (as is the case with long SOA). When the prime needs to be retained, the prime is activated very strongly, leading to larger priming effects for both weak- and strong-related targets at short SOA, but at long SOAs the off-surround component depresses both targets below the point where priming effects are obtained (or even a trend for a negative priming is observed). This attentional tuning on semantic concepts is only suggested by the presented dataset. A series of experiments are being prepared to address other methodological and theoretical issues. Nevertheless, the mere observation that the priming effect is modulated by short-term retention of the prime word poses interesting

constraints on existing and future computational models of priming.

The finding of a *prime-retention effect* motivates taking a closer look at the structure of semantic memory and the influence of controlled attention on its internal dynamics. Understanding these characteristics may provide valuable contributions to debates on the automaticity assumption of the spread of activation and resource limitations in language/cognitive processing. For example, an initial step in modelling the prime-retention effect (Davelaar, 2004), suggests ways to account for a variety of empirical findings on the interaction between attention and memory, such as hyperpriming in thought-disordered schizophrenic patients (e.g., Spitzer, et. al., 1993), individual differences in negative priming and presentation rate effects in false memory (McDermott & Watson, 2001).

Dagenbach and Carr (1994) proposed the Center-Surround hypothesis to account for the strategic carry-over effects in masked priming experiments. Here, the *prime-retention effect* suggests that (1) the center-surround mechanism can be observed in the behavioural data when attention is allocated to parts of the semantic system and (2) has a specific time-course. Future research, using the prime-retention paradigm, could provide detailed information on the structure of semantic memory and the temporal dynamics of the processes that control the spread of activation.

Abstract

A recent line of research suggests that an event's temporal distance from the present has an effect on the way in which it is likely to be construed. Specifically, more distant events are proposed to be represented primarily in terms of abstract, decontextualized information, while events in the near future tend to produce relatively more concrete, situation-specific construals. In the current study, we examine the extent to which this sort of effect can differentially emphasize *commonalities* between two events. Similarity ratings were collected for pairs of events sharing either high-level or low-level commonalities, and described as occurring in either the near or distant future. Consistent with predictions, an interaction was observed between temporal distance and commonality level. Broader implications for cognitive processing are discussed.

Introduction

One of the remarkable strengths of the human cognitive system is its flexibility. Not only are we able to store vast amounts of information about our world, organized into categories, scripts and schemas, we also seem particularly proficient at tailoring that information to fit the current demands of our environment. In particular, we seem capable of representing the same entity or event in a wide variety of ways. In addition to taxonomic organizations that can differentially emphasize various aspects of the same individual (e.g., *animal* / *mammal* / *dog* / *collie* / *Rover*), we appear to fluently cross-classify things based on goals, scripts, and evaluations (Barsalou, 1983, 1985; Ross & Murphy, 1999). Further, activation and retrieval of specific information can be highly subject to effects of general context (e.g., Tulving, 1972; Godden & Baddeley, 1975). Similarly, contextual or top-down effects may have a substantial impact on how new experiences are perceived and encoded (Bower, Black, & Turner, 1979; Bransford & Johnson, 1972). An important implication of this variation in representation concerns the impact that it may have on the processes that operate this activated information.

An intriguing recent body of research demonstrates an additional factor which may broadly affect event representations: temporal distance. Given the importance of our perceptions of the future for our ability to plan, to set and pursue goals, and to generally make long-term judgments, predictions, and choices, these effects have received surprisingly little attention in cognitive science on the whole. In the current paper, we examine the impact of such temporally-based construals on the ubiquitous process of similarity judgment. A demonstration that these construal effects may influence similarity—which is widely implicated in such fundamental cognitive processes as retrieval, categorization and inference—could serve to emphasize the expansive role that this kind of context-based effect plays throughout cognition.

Temporal Construal Theory

A recent set of studies in the judgment and decision making literature suggests that the way a person construes an event can be influenced by the temporal context in which that event takes place. According to Temporal Construal Theory (TCT) (Liberman & Trope, 1998; Sagristano, Trope, & Liberman, 2002; Trope & Liberman, 2000), events in the near future are likely to be represented largely in terms of concrete, circumstantial, and goal-irrelevant features, while the representations of events in the distant future tend to emphasize features that are more abstract, central, and goal-relevant. Trope and Liberman refer to these sparser, less contextualized representations characteristic of the distant future as *high-level* construals, and to the more enriched and highly contextualized representations more common in near future events as *low-level* construals.

These differences in representation can have behavioral consequences. For instance, one might agree to give a talk at a conference on some date in the distant future, perhaps focusing almost exclusively on the event's abstract, positive aspects: the opportunity to receive feedback on one's work, the opportunity for public exposure, and so on. As the date of the conference approaches, however, one's focus may begin to shift to some of the contextualized details that were absent in the initial representation. For instance, the time demands one faces in preparing for the presentation might become more salient, making the whole experience seem more effortful. The net effect, in this case, would be that the presentation loses some of the positive valence it once had.

These proposed differences in event representations can lead to changes in preference, depending on whether an event is described as being in the near or distant future. In one set of studies (Liberman & Trope, 1998), participants were given descriptions of events which, like the conference example, had opposite evaluative valences for high- versus low-level construals. For instance, one set of participants was asked to judge their likelihood of attending a lecture that was described as relevant and interesting but scheduled at an inconvenient time of day, while another set considered the case of a less interesting lecture, but one which was scheduled for a more convenient time. In the first group, the high-level construal was assumed to be positive

(relevant, pleasant experience) and the low-level construal negative (the logistics of fitting it into one's schedule). The second group was expected to have the opposite pattern of appraisal: a more negative impression of the abstract details of the situation, but a more positive sense of the low-level procedures involved in participating. While participants were more likely to attend the interesting lecture overall, this difference was more pronounced when the lecture was described as taking place a year from now rather than tomorrow. In other words, the decision pertaining to the near future seemed to give significantly more weight to the concrete, contextual aspects of the situation. The overall preference for the interesting lecture is also relevant, since it is consistent with the theory's suggestion that more proximal events are represented by some combination of contextual and abstract information, while distant events are primarily abstractly represented.

Note, however, that in these studies, the focus is on shifts in preference; representation is just a tool for the demonstrations. As such, this and all of their evidence concerning how we represent events is second-order, in that we have to infer differences in event representation from people's choices, or from people's preferred descriptions of events (see Liberman & Trope, 1998). One purpose of the present study was to seek more direct evidence for differences in event representation as a function of temporal context.

Similarity and Representational Level

Similarity is widely held to be one of the most critical concepts in cognition, and there are few aspects of mental life that do not seem to depend on it in one way or another. Similarity is seen as playing a vital role in recall through reminding (Hintzman, 1984; Ross, 1984); most theories of categorization rely heavily on the concept of similarity to determine category membership of a new item (Hintzman, 1986; Medin & Schaffer, 1978; Nosofsky, 1984); similarity is proposed to be fundamental in making generalizations, inferences and knowledge transfer (e.g., Novick, 1988; Osherson, et al, 1990; Ross, 1984).

It has been demonstrated that judgments of similarity are not simply a function of low-level featural overlap, but also depend on structural relationships between representations (Gentner & Markman, 1997; Markman & Gentner, 1993). This is true not only in terms of the impact of commonalities in the relations and relational systems themselves, but also in the way that attributes in corresponding roles that are defined by those structures are emphasized.

These "deeper" commonalities of relational systems are extraordinarily useful for generating new knowledge and for applying existing knowledge to new situations. For example, recognition of a common causal structure in two ostensibly different systems may lead to a deeper understanding of one system via analogical inferences from the other (*see* Gentner, 1983; Hummel & Holyoak, 1997).

Thus, the similarity rating task seems particularly apt in the current context, first because it acts as a connection to deeper aspects of cognition in general, and also because it may provide added insight into situations in which high-level, relational commonalities may be highlighted in comparison.

Experiment

The primary goal of this study was to determine whether temporal distance could affect event representations in such a way as to alter the perceived similarity between events. There are two significant motivations for this approach. First, it would provide a fairly direct way of assessing representation that would not need to rely on complex secondary tasks. Second, and perhaps more important, it would provide a bridge linking temporal effects such as these to a much broader set of cognitive issues. The critical role that similarity is proposed to play in so many mental activities suggests that observed systematic changes in similarity should have a relevant and far-reaching impact on cognition generally.

Just as any entity or event may be represented in a wide variety of ways, so may any pair of things share a great number of commonalities. Some have gone so far as to suggest that this robs similarity of any explanatory power (Goodman, 1972), since all pairs of items are potentially infinitely similar to one another (*e.g*., two things may both have mass, may both be smaller than the sun, etc.). A more measured and practical approach has been to emphasize the relative salience of the various pieces of information in each entity's representation. This salience could vary as a function of things such as prior knowledge, recent exposure or priming, and even the nature of the comparison context itself (Medin, Goldstone, & Gentner, 1993; Tversky, 1977; Gentner & Markman, 1997; Gentner, Rattermann & Forbus, 1993). Information that is more salient in a representation is assumed to be given more weight in judgments of similarity. Importantly, as previously noted, the properties that contribute to similarity judgments are not limited to concrete perceptual features, but also include the more abstract, relational concepts that structure and bind those features together (Gentner & Markman, 1997).

The predictions for the current study are straightforward. If the representations of two events are composed primarily of high-level, abstract descriptions of those events, then commonalities (or lack of commonalities) at that level of analysis should play a major role in their perceived similarity. That is, we would expect similarity ratings to be driven significantly by abstract, structuring information such as goals, causes and relationships. If, on the other hand, the representations also contain information involving low-level concrete and perceptual aspects of the situations, an impact of the commonalities at that situation-specific level should also be observed.

Consider for a moment your representation of visiting a dentist's office. This representation could include fairly high-level information pertaining to conscientiousness and long-term health benefits, as well as more concrete situational information about the particular setting and sensations involved. Now consider two different events to which this situation could be compared: the act of joining a health club, or the act of getting a tattoo. The health club event seems to share a number of abstract characteristics with the dentist visit (the goal of health benefits, etc.), but

appears quite different in terms of the situation-specific details. The tattoo, on the other hand, shares a surprising number of low-level, concrete features (reclining chair, needles, physical pain), but little in the way of high-level commonalities. The important outcome of this is that the abstraction level at which the dentist event is construed should have significant (and opposite) effects on the outcomes of these two comparisons.

This is exactly the situation that we created in our study. Participants were asked to give similarity ratings for pairs of events that shared primarily either high-level or low-level commonalities. Further, these events could be described as taking place in either the near future or the distant future. If, in fact, the temporal relationship of the events to the present time has an impact on their level of construal, then we should expect to see an interaction between temporal distance and level of commonality, such that pairs with high-level commonalities should be perceived as *more* similar in the distant than the near future, while pairs sharing low-level features should become *less* similar in the distant future relative to the near future.

Participants

Twenty-three Northwestern University undergraduates participated in this study for partial course credit.

Materials and Procedure

The materials for this experiment consisted of sentence pairs describing two events that a fictitious character was planning to undertake in the future. Each test item included a *standard* sentence, and one of two *comparison* sentences. These comparison sentences were constructed to share either high-level or low-level commonalities with the standard, but not both. In addition to these test items, the material set included several filler sentence pairs, which were either *literally similar*, sharing both high- and low-level features, or *non-similar*, sharing neither.

Additionally, these events were described as taking place either in the near future ("this week") or the distance future ("next year"). This distinction acted as a between-subjects factor, with all events for a particular participant being described at the same temporal distance. Commonality level served as a within-subjects factor, with half of the standards randomly being paired with high-level comparison sentences and the other half with low. Thus, the experiment was a 2 (temporal distance: near vs. distant future) × 2 (commonality level: high vs. low pairing) mixed design.

In total, 10 test items (five at each commonality level) and 13 filler items were presented in a completely randomized order (different for each participant), with the exception that all participants were given the same two initial items (one literally similar, and one non-similar) to help "anchor" their rating range and reduce variability. Within each item, sentence order was randomized, with the standard appearing first in approximately half of the pairs. A typical test item might read as follows: "Tomorrow, Karen will go to the dentist. Tomorrow she also will join a health club." Sample materials are given in Table 1.

The experiment was implemented as a computer-based task. After instructions, the first sentence pair appeared on the screen, followed by the prompt "How similar do you think these activities are to each other?" Beneath this prompt was a horizontal bar, with endpoints labeled "very dissimilar" and "very similar". Participants were instructed to click a location on this bar to indicate their perception of the similarity of the two events. This response was normalized to a value between 0 and 1, for the "dissimilar" and "similar" endpoints, respectively. To ensure that participants were attending to the task, response latencies of less than 3 seconds for any item resulted in the warning "Too Fast" appearing on the screen, followed by a delay of several seconds before proceeding to the subsequent item.

Table 1. Sample events. Low-level comparison sentences were designed to share concrete features and procedures with the standard, while High-level comparisons share more abstract commonalities.

Event Standard	Low-level comparison	High-level comparison
Reading and coding completed research questionnaires	Doing taxes	Conducting telephone surveys
Going door-to-door distributing leaflets about the environment	Going trick-or-treating with daughter	Writing letters to congressmen and local council members
Going to the dentist	Getting a tattoo	Joining a health club
Buying diamond necklace for wife	Buying expensive watch for self	Taking wife out for gourmet meal
Calling colleges requesting information packets	Calling hotels to arrange Summer trip to Mexico	Taking the SAT

Results

Consistent with predictions, a 2 × 2 ANOVA revealed an interaction between temporal distance and commonality level, F (1, 21) = 8.60, $p < .01$. Participants rated high-level pairs as more similar in the distant future condition (M = 0.63, SD = 0.11) than in the near future condition (M = 0.58, SD = 0.10). Conversely, low-level pairs were rated as more similar in the near future condition (M = 0.54, SD = 0.10) than in the distant future condition (M = 0.40, SD = 0.09).

A main effect of commonality level was also observed. Participants rated high-level pairs as more similar (M = 0.60, SD = 0.11) than low-level pairs (M = 0.47, SD = 0.12) overall, F (1, 21) = 18.84, $p < .001$. Additionally, there was a marginal trend for participants to rate near future events as more similar than distant future events (p = .092). This latter effect is more pronounced in the across-item analyses: a 2 × 2 ANOVA run across items revealed the same interaction between temporal distance and commonality level, F (1, 18) = 7.77, p = .012, the same main effect of commonality level, F (1, 18) = 9.96, p = .005, and a significant effect of temporal distance, F (1, 18) = 4.73, $p <$ .05. This final effect reflects the fact that the low-level comparisons showed a more dramatic decrease with temporal distance than the corresponding increase in the high-level comparisons. In fact, post-hoc t-tests indicated that only the low-level comparisons changed significantly across distances (t (1,22) = 3.67, $p < .01$) (see discussion below).

Discussion

The primary predictions of the experiment were confirmed. Participants judged event pairs with abstract, high-level commonalities to be more similar in the distant future than the near future, while pairs sharing more concrete and low-level procedural features showed the opposite pattern. This supports the proposal that temporal distance is in fact influencing the level at which events are construed, and that these representational differences are stable enough to be reflected in perceived similarity.

The two observed main effects, while not predicted, are in retrospect completely consistent with the assumptions of temporal construal theory. While distant events are assumed to be represented primarily in terms of their abstract characteristics, proximal events are suggested to have more "enriched" representations that combine some contextual and some abstract information. Consistent with this characterization, the greatest observed effect was the drop in the similarity of low-level pairs between close and distant conditions, contributing to both of these additional effects. As noted above, although both low- and high-level comparisons changed in the predicted direction with temporal distance, this change was only statistically significant for the low-level pairs.

The second main effect—the overall preference for high-level commonalities—has been replicated in more recent pilot data, and is consistent with prior research showing a preference for relational over attributional similarity (Gentner & Clement, 1988; Goldstone, Medin, & Gentner, 1991).

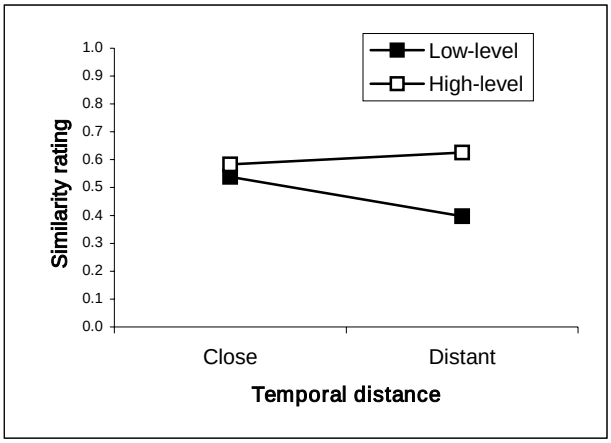

Figure 1. Interaction between commonality level and temporal distance.

The most immediate implication of these findings is that this sort of temporally-based context effect should now be predicted to influence many of the other cognitive processes in which similarity participates. For instance, it is possible that categorization of events and entities considered as being in the distant future may be based on somewhat more abstract dimensions than those considered in the immediate present. This categorization would in turn affect the inferences that an individual is likely to make in the absence of explicit knowledge, and their confidence in the accuracy of those inferences. One interesting prediction is that these perceived similarities may influence the extent to which knowledge is successfully transferred from one domain to another. Moreover, this knowledge transfer—which is seen as relying on the mapping of structural commonalities—might benefit more generally from the abstract representations characteristic of temporal distance.

Preliminary pilot data collected by the authors suggest that temporal context may have an effect on cued retrieval. That is, the perceived increase in similarity associated with an "appropriate" encoding situation (temporally close for low-level commonalities, temporally distant for high-level commonalities) may improve the probability of retrieving an event from memory when cued with the previously compared event.

The results suggest a number of avenues for future research. One important direction would involve varying the kind of high-level commonalities involved in the comparisons to include abstract characteristics other than those emphasizing individual plans and goals. While this proved to be a useful way of describing future events for our experimental purposes, it could potentially lead to confounds such as attribution of particular personality traits to the characters (e.g., planning to do x is consistent with planning to do y), and the use of a broader set of abstract event commonalities would help to address this.

Another interesting approach would be the examination of temporal distance in the opposite direction, seeing whether similar results could be obtained with events that occurred

in the recent or distant past. Taking this a step further, it may be the case that the important dimension in these effects is *psychological distance* rather than simply temporal distance. If this were the case, we might expect to find similar effects by varying dimensions such as similarity of the character to the participant, or the probability of a future event occurring.

Conclusions

We spend a great deal of time thinking about the future. In fact, this capacity seems to be a defining and distinctive characteristic of human cognition. We consider possible outcomes, evaluate potential alternatives, and pursue distant goals that may take years or even decades to achieve. Because our mental focus is so often situated in the future, it seems particularly relevant to consider the influence of temporal distance on cognition. The current study, though modest, highlights just how far-reaching these effects may be.

Abstract

In Dutch matrix clauses the verb is not in its base position, but has been moved from the end of the clause to second position. Three Cross-Modal Priming experiments showed that the on-line activation pattern for moved verbs in Dutch differs significantly from the pattern for moved nouns in English. Whereas in *wh*-movement reactivation of moved nouns is found at their base position, the current results suggest that moved verbs are maintained active during the entire clause. The results are discussed in light of a gap-filling account, and three proposals are given to explain the long-lasting activation of the verb.

Introduction

Cross-Modal Priming (CMP) studies (e.g. Love & Swinney, 1996; Swinney, Ford, Bresnan, & Frauenfelder, 1988) have shown that in complex sentences where the object is not in its base position the meaning of this moved constituent is reactivated at its original position, directly after the verb. Swinney et al. (1988) tested reactivation of moved *wh*-phrases in sentences such as:

(1) The cop saw the boy_i who_i the crowd at the party accused t_i of the crime.[1]

Since *boy* is the direct object of *accused* in base structure[2], and English is an SVO language, the base position of *boy* is to the right of the verb *accused*. Therefore, it is assumed that a trace (or gap) is postulated after *accused*. Using the CMP task[3] priming effects were found for probes related to the antecedent *boy* when presented at the gap position (directly after the verb). Importantly, no priming was found at a control position before the verb. In other words, it appears that listeners *re*activate the meaning of the moved constituent when they encounter the gap. This finding has been replicated many times (for an overview see Featherston, 2001; Love & Swinney, 1996).

Several explanations have been given for this phenomenon. Swinney and colleagues (1988) provide a structural account: the meaning of the moved object is recovered in its base position to regain the canonical sentence structure. This would suggest a close correspondence between linguistic theory (or at least the generative approach) and psychological reality (the functioning of the human parser). Others (e.g. Pickering & Barry, 1991) came up with a verb-centered, semantic, account: the meaning of the moved object is reactivated because after processing the verb a dependency relation is established between the verb and its dependents, that is, its arguments (see also Nicol, 1993).

The current paper is an attempt to broaden this research area by extending the topic of research to the activation

[1] Following the traditions in processing research, the *t* refers to the gap position (*trace)* and co-indexation indicates the relationship between filler and gap.

[2] Strictly speaking, 'who' is the direct object of 'accused' and not 'boy', but it is assumed that 'who', because of its coreference with 'boy', has inherited the semantic characteristics of 'boy'.

[3] The CMP task is a dual task in which participants listen to sentences and make a lexical decision to a visual probe presented at a particular point during each sentence. Faster reaction times to a probe that is associatively related to a particular word in the sentence as compared to reaction times to a probe that is unrelated (but otherwise comparable to the related probe) is attributed to priming effects. If priming is found at a certain point during the sentence, this is taken as evidence that the meaning of the relevant word in the sentence is activated.

pattern of verbs. It is unknown whether *verbs* that are not in their base position are reactivated at this position. If moved verbs show reactivation at their base position, then a strong case can be made for the possibility that listeners attempt to recover base word order whenever they encounter a structure that is non-canonical. However, some characteristics of verbs suggest that moved verbs might behave differently from moved noun constituents.

Linguistic Background

Whereas in *wh*- and NP-movement whole sentence constituents (XPs) are moved, in verb movement it is only the verb itself (the head, X^0) that moves. Linguists (e.g. Chomsky, 1995) stress that movement of syntactic heads is radically different from movement of syntactic phrases, having for example no effect on interpretation.

In English, the language in which most studies on gap-filling have been performed, verb movement only occurs in negative inversion structures and in questions, where the auxiliary moves. In Dutch, however, verb movement is an omnipresent phenomenon. Dutch is generally agreed to be an SOV language (Koster, 1975, but see Zwart, 1997), but in a matrix clause the finite verb moves from its basic, clause-final, position to the second position in the clause (Verb Second or V2).

Psycholinguistic Background

Verbs play a central and binding role in the sentence: they not only determine the event of the sentence, but they are also linked to all other main constituents of the sentence (the arguments) and assign thematic roles to these constituents. Psycholinguistic studies suggest that these differences between nouns and verbs may matter in sentence processing: influences of argument structure have been found at different levels of sentence processing (for interference effects see Shapiro, Zurif, & Grimshaw, 1987; for syntactic priming effects, see Trueswell & Kim, 1998).

It is unknown what role the characteristics of verbs play in on-line processing of moved verbs, although two unpublished studies suggest that the patterns for verb movement might differ from those found in *wh*-movement. Muckel, Urban and Heartl (p.c.) examined split particle verbs in German SVO sentences in which the matrix verb had been moved to V2 and the particle remained in the base position of the verb (German is an SOV language). Responses to identical probes were faster than responses to control probes at the control probe point (which was placed in front of the word preceding the particle, so two words before the gap) as well as at the experimental probe point. No interaction between probe point and probe type was found, so no evidence was found for *re*activation.

Basilico, Piñar and Antón-Méndez (1995) ran a CMP-study that focused on moved verbs in Spanish. They used declarative sentences with two different word orders (VSO and VOS) and concluded that in the sentences where the verb was moved (VSO) the verb was activated at the gap. Conclusions about *re*activation cannot be drawn, however, because no pre-gap control probe-point was included in the design.

Experiment 1 & 2

In two consecutive CMP experiments, the question was addressed whether or not verb movement has processing consequences similar to *wh*-movement. The experimental sentences in these experiments are Dutch matrix clauses in which the verb has been moved from its base clause-final position to V2 position, leaving behind a gap. If verb movement and *wh*-movement are processed similarly, we expect to find activation of the verb directly after the verb (direct priming), deactivation of the verb in between the overt verb position and the gap, and finally reactivation at the gap (gap-filling).

Method

Participants 44 Participants were tested in experiment 1 and 60 in experiment 2.

Materials Sentences consisting of a matrix clause (SVO) followed by an embedded clause were auditorily presented. In both experiments the matrix clause ended after the direct object. In experiment 1 the direct object occurred directly after the verb (see example sentence 2), in experiment 2 an adjunct preceded the direct object (see example sentence 3).

(2) De kleine jongens imiteren$_i$ [1] hun fanatieke [2] rood-aangelopen voetbaltrainer t_i, omdat [3] ze later allemaal profvoetballer willen worden.
The little boys imitate$_i$ [1] their fanatical [2] red-faced soccer coach t_i, because [3] they all want to be professional soccer players when they grow up

(3) De trouwe volgelingen wijzigen$_i$ [1] eens in de zoveel tijd hun altijd [2] controversiële mening t_i [3], want [4] hun leider is een wispelturig man.
The faithful followers change$_i$ [1] once in a while their always [2] controversial opinion t_i [3], because [4] their leader is a rather fickle man.

The probes that were presented during the experimental sentences were verbs that were either associatively related to the finite verb or unrelated but matched to the related probe for baseline lexical decision time, frequency, length and argument structure. Both probe types were pre-tested off-line for any possible inadvertent source of priming. The same prime - unrelated probe - related probe triads were used in both experiments.[4]
Probes were presented at four different positions (see example sentences 2 and 3):

1. *verb* probe point: indicated as [1], placed directly after the verb

[4] Two triads were excluded in experiment 2 for counterbalancing reasons (we used 4 probe points instead of 3, so the number of experimental sentences had to be dividable by 4).

2. *control* probe point: indicated as [2], presented at 700 ms after [1] in experiment 1 and at 1500 ms after [1] in experiment 2
3. *end-of-clause* probe point: measured in experiment 2 only and indicated as [3], presented at the end of the clause (offset object head noun)
4. *conjunction* probe point: indicated as [3] in experiment 1 and as [4] in experiment 2, presented at the offset of the conjunction.

In experiment 1 42 experimental sentences were used, in experiment 2 there were 40 experimental sentences. In each experiment, an equal number of pseudo-experimental sentences (sentences with the same structure as the experimental sentences) were added and combined with non-words, to prevent any correlation between sentence type and response type. In addition, 20 filler sentences of different structures (10 words, 10 non-words) and 15 yes/no comprehension questions were added (to encourage participants to pay attention to the spoken sentences).

Probe point and probe type were both within-participants factors. All sentences were ordered pseudo-randomly. A completely counterbalanced design was created to assure that all participants saw both related and control probes, and saw probes at all three probe points. Each participant was tested twice, on the same list, but with related and control probes shifted.

Procedures The participants were tested individually in a sound-proof room with no visual distractors. The sentences were presented over headphones with an interval of 1500 ms. The probes were presented on a standard computer screen. The experimental software Tempo (designed at the University of California, San Diego, for running CMP-studies), combined with a response box with two buttons, was used to present the items and register the accuracy and RTs of the responses. Each probe was presented for 300 ms and a response could be given within a 2000 ms interval from stimulus onset. Importantly, the sentences continued without interruption during visual presentation of the probe.

Participants were instructed to listen carefully to the sentences and to expect comprehension questions about some sentences, but only about the sentence immediately prior to the question. Questions were answered and lexical decisions were made by pressing the left button on the button box for *no* and *non-word* and the right button for *yes* and *word*. Participants were instructed to answer as quickly and accurately as possible.

Results

Participants were excluded from further analysis 1) if their error score on the lexical decision task was greater than 10%, 2) if their mean or SD RT deviated from the overall mean or SD by more than 2.5 SD, or 3) if less than 67% of the comprehension questions were answered correctly. Data from three participants were excluded in both experiments.

Error rates were low (1.4% and 1.8%, respectively) and equally distributed across related and control probes and across probe points. The exclusion of errors and outliers (all values deviating from the participants and item mean for the particular data point with more than 2.5 SD were excluded) resulted in 2.7 and 3.1 percent data loss, respectively.

The mean RTs for all probe points and probe types are presented in Table 1 (the values that are presented here and in the following tables are derived from the subject-analyses; the item-analysis revealed very similar data).

The subject-based ANOVAs revealed a significant main effect of probe type in both experiments; overall, the related probes generated shorter RTs than the control probes (exp 1: F1 (1,40) = 7.91, p = .008; exp 2: F1 (1,56) = 4.61, p = .036). The item-based ANOVA was marginally significant in experiment 1 (F2 (1,41) = 3.43, p = .07), but did not reach significance in experiment 2 (F2 (1,39) = .98, p > .3).

Paired t-tests showed significant[5] faster responses to related than to control probes (priming) at the *verb* probe point in experiment 1 (t1 (40) = 2.53, p = .008; t2 (41) = 1.75, p = .044), but not in experiment 2 (t1(56) = .15, p > .4; t2 (39) = .29, p > .3). At the *control* probe point priming was found in both experiments (this effect was significant in the subject analysis (exp 1: t1 (40) = 2.64, p = .006; exp 2: t1 (56) = 2.49, p = .008), but in the item-analysis only a trend was found (exp 1: t2 (41) = 1.40, p = .085; exp 2: t2 (39) = 1.37, p = .09). Furthermore, priming was found at the *end-of-clause* probe point in experiment 2 (t1 (56) = 2.08, p = .021; t2 (39) = 1.76, p = .043). Neither of the experiments, however, showed a priming effect at the *conjunction* probe point (exp 1: t1 (40) = .81 p > .2; t2 (41) = .82, p > .2; exp 2: t1 (56) = -.98, p > .15; t2 (39) = -.95, p > .15).

Table 1: Mean RTs (and SDs) to probe type as a function of probe position in experiment 1 and 2.

probe type	verb	control	end-of-clause	conjunction
Experiment 1				
control	633 (68)	635 (61)	-	626 (72)
related	617 (65)	621 (66)	-	620 (73)
difference	*16 (41)*	*14 (33)*	-	*6 (47)*
Experiment 2				
control	663 (94)	671 (99)	668 (95)	666 (88)
related	662 (91)	657 (84)	654 (101)	672 (103)
difference	*1 (49)*	*15 (45)*	*14 (51)*	*-6 (42)*

Conclusion and Discussion

These experiments did not provide evidence for *re*activation of the verb at its base position. Both experiments converge on a pattern of activation of the verb at the *control* probe points (700 and 1500 ms after the actual occurrence of the verb in the sentence) and deactivation of the verb immediately following the conjunction linking the matrix to the second clause. The second experiment further shows that the verb is active at the *end of the clause*. The results for the

[5] As no inhibition effects were expected all t-tests are 1-tailed.

verb probe point, where priming of the verb was expected directly after its occurrence, are less clear. Although significant facilitation of the related probe compared to the control probe was found in experiment 1, experiment 2 surprisingly showed a null-effect at this probe position. [6]

An important question that remains to be answered after these experiments is: Why do verbs remain active for such an extended period of time? One possible reason is that verbs stay active to 'find' their arguments in order to theta-mark them (Argument Structure Hypothesis).[7] According to this hypothesis continued activation is predicted up to the final argument. As all verbs that were used in the current experiments were two-place verbs, the final argument was always the direct object, which occurred at the end of the matrix clause in both experiments.

Experiment 3

To test the Argument Structure Hypothesis, an experiment was run that employed an adjunct immediately after the second argument. This allowed investigation of whether saturation of the argument structure of the verb is the basis for discontinued activation of the verb, or whether the verb always remains active up till the end of the clause.

Method

Materials The same primes, related probe and control probes were used in experiment 3, but the sentences were slightly altered. The experimental sentences still consisted of a matrix clause followed by an embedded clause, but after the Object Noun Phrase an adjunct was inserted (4). The adjuncts that were used were Adverbial Phrases of Time.

(4) De domme gedetineerden beroven [1] vijftien rijke bejaarden tijdens hun [2] eerste proefverlof [3], dus vrijlating zit er voorlopig niet in.
The stupid detainees rob [1] fifteen rich seniors during their [2] first parole [3], so release seems to be out of the question for now.

The *verb* probe point (see [1]) was presented slightly later than in experiment 1 and 2: at the onset of the first word following the verb, and if this point could not be measured adequately, at the onset of the first vowel of this word. The *control* probe point [2] was now at 700 ms after the onset of the adjunct. The final probe point was at the *end of the clause*, directly at the offset of the final word of the adjunct [3].

[6] Phonological assimilation made it impossible to place all probe points exactly at the onset of the next word. Post hoc analyses showed that probes that were placed too early had a low probability to show faster RTs to related probes than to control probes, whereas the majority of probes that were presented exactly at the onset of the word following the verb showed facilitation for the related probe (χ^2 (1) = 17.4, p < .001). Part of the third experiment focuses on this observation.

[7] More accounts will be discussed in the General Discussion.

Participants and Procedures 48 Participants were tested following the same procedure as in experiment 1 and 2.

Results

The data were handled in the same way as in experiment 1 and 2. Three participants were excluded from further analysis and exclusion of errors and outliers resulted in 3.0 percent data loss.

The RTs for this experiment are presented in table 2 and show faster responses to related probes than control probes at all probe points (F1 (1,44) = 24.35, p < .001; F2 (1,41) = 6.38, p = .016). So, first of all, directly after the *verb*, a significant priming effect is obtained again, which indicates that a small adaptation in probe placement (consistently at the onset of the first word following the verb or slightly later) resulted in stable priming effects at this probe point (t1 (44) = 3.08, p = .002; t2 (41) = 1.75, p = .044). But more interestingly, activation of the verb was still evident after all arguments were processed, 700 ms into the adjunct (t1 (44) = 2.35, p = .012; t2 (41) = 2.39, p = .011), as well as at the end of the clause (t1 (44) = 2.59, p = .007; t2 (41) = 1.77, p = .042).

Table 2: Mean RTs (and SDs) to probe type as a function of probe position in experiment 3.

probe type	verb	control	end-of-clause	conjunction
control	721 (86)	723 (95)	712 (89)	-
related	697 (89)	706 (96)	693 (88)	-
difference	*24 (53)*	*17 (48)*	*19 (48)*	-

Conclusion

The current experiment shows that verbs in Dutch declarative matrix clauses are maintained active throughout their entire clause, even after all arguments have been encountered.

General Discussion

The aim of the first two experiments was to evaluate whether moved verbs (in Dutch) behave similarly to moved nouns, which show reactivation of the moved constituent at the location of the gap. The results show that, at least in Dutch, processing of moved verbs is different from that of moved noun constituents in English. No evidence was provided for *re*activation of the verb at its base (clause-final) position. Instead, the experiments demonstrated that the verb remains active from the point where it is first encountered up to the offset of the object head noun, clause-finally. So even though activation of the verb at the site of the gap was found in the second experiment, the verb was also active at the control probe points, unlike in the gap-filling studies in English (Love & Swinney, 1996).

The question whether verb movement is reflected in psychological reality cannot be answered on the basis of these data. Although we did not find evidence for reactivation, a syntactically based *Gap-Filling Account* can

still hold for the data; the verb was indeed active at the gap. It is possible that, instead of being reactivated, verbs are maintained active until the gap (and because of the gap).

The studies by Basilico et al. (1995) and Muckel et al. (p.c.) show that the present results do not stand alone. The results from both studies can be interpreted in different ways, but their findings might well be in line with ours. Muckel et al. found activation of a split particle verb at a control probe point and at the particle. Since they did not test for priming directly after the verb and do not present baseline reaction times for the two probe types the results are suggestive of either continued activation of the verb or no activation at all[8]. Basilico et al. found activation of the verb at the site of the assumed gap (VS*O) in Spanish sentences with non-basic word order. However, they did not test directly after the verb, neither did they use a control probe point to check whether the activation of the verb had faded in between. It is possible, therefore, that a moved verb in Spanish also remains active.

As far as the third experiment is concerned, current linguistics theories disagree about the position of adjuncts and therefore it remains unclear whether the base position of the verb should be postulated at the end of the clause (after the adjunct) or after the direct object (in front of the adjunct). If the verb gap is posited in front of the adjunct in sentences like the ones used in experiment 3, the results of this particular experiment show activation of the verb even after the gap and thus provide evidence against the Gap-Filling Account as an explanation for our data.

It is not inconceivable that movement of verbs is not reflected in psychological reality. In *wh*-extraction, all linguistic theories accept some kind of relation between the *wh*-constituent and the verb later in the sentence. In movement of noun constituents, gap-filling is necessary to assign thematic roles to constituents that are detached from their subcategorizer. In contrast, the assumption of verb movement is very theory-internal to generative linguistics (Chomsky, 1995). Also, where verb movement is concerned, gap-filling is not necessary for sentence interpretation but only for structural, syntactic reasons: to fulfill requirements formulated by formal syntactic theory.

The Gap-Filling Account can definitely be rejected if non-moved verbs are also found to remain active in English. A study in English will be performed by Lewis Shapiro and David Swinney. In this study sentences similar to the ones used in the present experiments will be used. In English, the finite verb is in base position, and there is no gap at the end of the clause. If the verb does not remain active in English, the present results are most likely to be due to restoration of the base word order (gap-filling). If, however, the results for the study on English are similar to the results of the experiments discussed in this paper, other accounts will gain in credibility.

[8] In this case, the priming effects can be explained by the materials: identical probes are generally more 'sensitive to priming' than associatively related primes.

Three possible alternative accounts will be discussed in the final section of this paper.[9] The first account is the *Argument Structure Account* which was tested in experiment 3. According to this explanation, verbs remain active to be able to assign theta roles to their arguments. This hypothesis was falsified in experiment 3 where activation of the verb was found during an adjunct phrase placed after the final argument.

An alternative syntactic explanation for the present data is the *VP-shell Theory* (Larson, 1988). According to the variant of Van Zonneveld & Bastiaanse (2000), both arguments and adjuncts are in SpecVP positions. This is only possible when the VP is recursive: it takes a VP as a complement. The VP-shell theory thus predicts a sentence structure with as many VPs as there are specifiers (arguments and adjuncts). The VP-shell in itself is a complement of IP. An example of sentences as used in experiment 2 can illustrate this (figure 1).

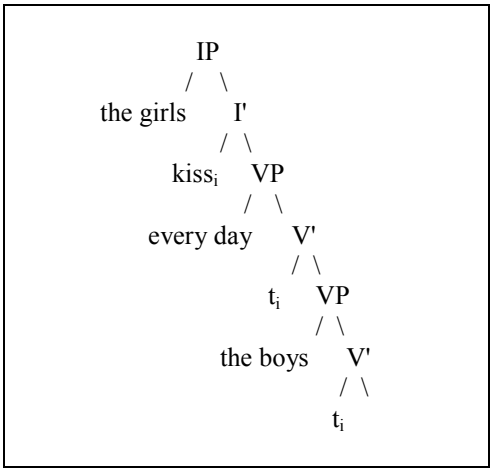

Figure 1: Syntactic representation for Dutch, according to VP-shell theory (simplified version of an experimental sentence from experiment 2).

As this figure shows, there is an empty V^0 position in the first and second VP. According to Van Zonneveld & Bastiaanse (2000) the verb is not 'moved' to the head of I', but it is 'lexicalized' or 'activated' again in each head position of V'. This means that the verb is active during the entire clause and, unlike nouns, does not need to be *re*activated at the gap position.

[9] These accounts are all based on the assumption that only verbs show long-lasting activation. Although no continued activation for *wh*-constituents was found in CMP experiments within the standard *wh*-movement paradigms, Nicol (1993) could not exclude a pattern of maintained activation of PPs in sentences with ditransitive verbs, where the PP was fronted, and of subjects in S - relative clause - V - O sentences, where priming of the subject was found after the verb. Nevertheless, other explanations could apply to these data as well (or even better), suggesting that detailed studies on the activation pattern of nouns need to be done as well. We are currently preparing a study on the activation pattern of nouns.

The verb thus remains active within its own clause boundary. Only when a new CP or IP is encountered, with a new VP-shell structure as its complement, the activation of the verb is no longer necessary and will therefore disappear. This is exactly what was found in the present experiments. Interestingly, unlike the Gap-filling Account, VP-shell theory predicts similar verb-activation patterns for both English and Dutch matrix clauses, because in both cases the verb c-commands the entire VP-shell.

A third theory (*Semantic Account)* is deduced from studies that show that verbs are more polysemous than nouns (Fellbaum, 1993; Gentner & France, 1988) and are more adjustable and mutable. In a paper-and-pencil task, Gentner & France (1988) found that if the meaning of a verb does not fit with the noun that it co-occurs with, participants are more eager to change the meaning of the verb than the meaning of the noun. Interestingly, these mutability effects are seen in on-line processing as well: an eye-tracking study by Pickering and Frisson (Pickering & Frisson, 2001) showed that lexical ambiguity resolution for verbs is delayed compared to nouns. The suggestion of these authors is that the interpretation of a verb is highly dependent on the arguments with which it combines in a particular sentence. Interestingly, this is also the case for non-ambiguous verbs that have multiple senses. To understand the full meaning of, for example, the verb *open*, one needs to know whether it concerns *opening a door*, or *a file*. According to the "underspecification model" (Frisson & Pickering, 1999) "the processor activates a single underspecified meaning for a verb with multiple senses and uses evidence from context to home in on the appropriate sense" (Pickering & Frisson, 2001, p. 564). Therefore, also in the case of unambiguous verbs, delaying the interpretation process until the arguments are processed seems to make sense.

Although Pickering and Frisson focus on the role of arguments, it is possible that adjuncts play a role in the interpretation of the verb, too. Actually, one should notice that verb-interpretation and sentence-interpretation are intermingled and can be seen as ongoing processes, which possibly only stop at clause boundaries. This also suggests that the VP-shell Account and the Semantic Account might be difficult to tease apart and should perhaps be interpreted as accounts that explain the same phenomena, but do so at a different linguistic level.

Acknowledgments

The first author is funded by the Dutch Organization for Scientific Research (NWO) under grant #360-70-091. Edwin Maas has been of invaluable help in setting up the first experiment. We are grateful to John Hoeks, Roel Jonkers and three anonymous reviewers for their helpful comments on earlier versions of this paper.

Smarter and Richer?: Executive Processing and the Monty Hall Dilemma

Wim De Neys (Wim.Deneys@psy.kuleuven.ac.be)
Department of Psychology, K.U.Leuven, Tiensestraat 102
B-3000 Leuven, Belgium

Abstract

The Monty Hall Dilemma (MHD) is a striking example of the human tendency to base probability judgment on intuitive, erroneous heuristics instead of an analytic, normative reasoning process. Two experiments tested the claim (e.g., Stanovich & West, 2000) that correct, normative reasoning draws on executive, working memory resources (WM) whereas heuristic reasoning would be purely automatic. Experiment 1A examined the link between MHD-reasoning and WM-capacity. Participants that solved the MHD correctly had a significantly higher WM-capacity. Experiment 1B presents a new approach to test the role of the WM-resources experimentally. Participants solved the MHD while WM-resources were burdened by a secondary task. Correct responses decreased under load. The results provide new evidence for the differential role of executive resources in heuristic and analytic reasoning.

Introduction

A main theme of cognitive reasoning research over the last decades is that human judgment frequently violates traditional normative standards. In a wide range of reasoning tasks most people do not give the answer that is correct according to logic or probability theory. The discrepancy between normative models and peoples actual performance has been labeled the "normative/descriptive gap" (Stanovich, 1999). The present study focuses on one of the most striking examples of this discrepancy: The Monty Hall Dilemma.

The notorious, counterintuitive Monty Hall Dilemma was adapted from a popular TV game show (Friedman, 1998). Host Monty Hall asks his final guest to choose one of three doors. One of the doors conceals a valuable prize and the other two contain worthless prizes such as goats or a bunch of toilet paper. After the guest makes a selection, the host, who knows where the prize is, opens one of the non-chosen doors to show that it contains a dud. The guests are then asked if they want to stay with their first choice or switch to the other unopened door.

Most people have the strong intuition that whether they switch or not the probability of winning remains 50% either way. However, from a normative point of view, the best strategy is to switch to the other door. Indeed, switching yields a 2/3 chance of winning. The solution hinges on the crucial fact that the host will never open the door concealing the prize, and obviously, he will not open the guest's door either. Taking into account that two thirds of the times the prize will be in one of the non-chosen doors, the non-chosen door that is still closed will hide the prize in two thirds of the trials (Tubau & Alonso, 2003).

Empirical studies of the Monty Hall Dilemma consistently showed that the vast majority of college students fails to give the correct response (switching rates ranging from 9% to 21%, e.g., Burns & Wieth, 2000, 2003; Friedman, 1998; Granberg & Brown, 1995; Krauss & Wang, 2003; Tubau & Alonso, 2003). Likewise, vos Savant (1997) reports that after she discussed the problem in a weekly magazine column she received up to 10,000 letters in response. Ninety-two percent of the writers from the general public disagreed with the switching answer. To paraphrase Friedman (1998), it seems that because of peoples poor MHD reasoning "millions of dollars were left on Monty's table".

Research indicates that the typical MHD response can be attributed to the operation of erroneous but very powerful intuitions or heuristics. For example, Shimojo and Ichikawa (1989) found that most people base their answer on the so called number-of-cases heuristic ("if the number of alternatives is N, then the probability of each one is 1/N"). Thus, since only two doors remain people will automatically assign a 50% chance to each door and fail to take the "knowledgeable host" information into account. Similar claims can be found in Falk (1992) and Johnson-Laird, Legrenzi, Girotto, Legrenzi, and Caverni (1999).

It has been argued that human thinking in general typically relies on the operation of intuitive, prepotent heuristics instead of a deliberate, controlled reasoning process. The primacy of these heuristics has been called the fundamental computational bias in human cognition (Stanovich, 1999). Whereas the fast and undemanding heuristics provide us with useful responses in many situations they can bias reasoning in tasks that require more elaborate, analytic processing (e.g., Evans & Over, 1996; Kahneman, Slovic, & Tversky, 1982;. Sloman, 1996; Stanovich, 1999; Stanovich & West, 2000; Tversky & Kahneman, 1983).

Stanovich and West (e.g., 2000) stressed that although the modal response is often erroneous in many reasoning tasks, a small proportion of

the participants does give responses that are in line with the normative standards. Their research on individual differences showed that participants that gave the normative response on classic reasoning tasks such as the conjunction fallacy (Tversky & Kahneman, 1983) and the Wason (1966) selection task were disproportionally those highest in cognitive (working memory) capacity. According to Stanovich and West's dual process framework (see also Evans & Over, 1996; Sloman, 1996) correct normative responding requires that an analytic, controlled reasoning process overrides the prepotent heuristics. The inhibition of the heuristic system and the computations of the analytic system would draw on limited, executive working memory resources. The more resources that are available, the more likely that the analytic system will be successfully engaged and the correct response calculated.

The Stanovich and West (2000) findings suggest that a possible antidote to erroneous MHD reasoning might be a high working memory span. If correct normative reasoning requires executive working memory (WM) resources, then participants with a higher WM-span should be more likely to select the switching response. Bluntly put, the guests that win the prize in the game show will not only be richer but also "smarter"[1]. The link between MHD-reasoning and WM-capacity was examined in Experiment 1A.

The Stanovich and West framework and related dual process theories have been severely criticized (e.g., Stanovich & West, 2000). One important issue concerns the central assumption about the role of controlled, executive resources. Both the claim that correct, normative reasoning depends on the executive system and the characterization of the heuristic system as automatic and independent from executive control have been questioned (e.g., Handley, Feeney, Harper, 2002; Klaczynski, 2000, 2001; Osman, 2002)

Experiment 1B presents a new approach in the dual process field. The experiment adopted secondary task methodology to burden the executive WM-resources while participants were solving the MHD. If correct responding in the MHD draws on WM-resources, performance should decrease under load since less resources will be available for inhibition of the prepotent "50%-heuristic" and subsequent analytic computations. On the other hand, if the heuristic processing would not be automatic and would draw on WM, it will also become harder for people to come up with the "equal probability" answer. The procedure thereby allows a direct, experimental test of the basic executive processing assumptions.

[1] The term « smarter » refers of course to the tight connection between executive WM-capacity and general cognitive ability (e.g., Engle, Tuholski, Laughlin, & Conway, 1999).

Experiment 1A

Method

Participants

A total of 236 first-year psychology students from the Unversity of Leuven, Belgium, participated in return for psychology course credit.

Material

Working memory measure. Participants' working memory capacity was measured using a version of the Operation Span task (Ospan, La Pointe & Engle, 1990) adapted for group testing (Gospan, for details see De Neys, d'Ydewalle, Schaeken, & Vos, 2002). In the Ospan-task participants solve series of simple mathematical operations while attempting to remember a list of unrelated words The main adaptation in the Gospan is that the operation from an operation-word pair is first presented separately on screen (e.g., 'IS (4/2) – 1 = 5 ?'). Participants read the operation silently and press a key to indicate whether the answer is correct or not. Responses and response latencies are recorded. After the participant has typed down the response, the corresponding word (e.g., 'BALL') from the operation-word string is presented for 800 ms. As in the standard Ospan three sets of each length (from two to six operation-word pairs) are tested and set size varies in the same randomly chosen order for each participant. The Gospan-score is the sum of the recalled words for all sets recalled completely and in correct order.

Participants who made more than 15% math errors or whose mean operation response latencies deviated by more than 2.5 standard deviations of the sample mean were discarded (participants already in the bottom quartile of the Gospan-score distribution were not discarded based on the latency criterion). De Neys et al. (2002) reported an internal reliability coefficient alpha of .74 for the Gospan. The corrected correlation between standard Ospan and Gospan-score reached .70.

Monty Hall Dilemma. Participants were presented a standard version of the MHD taken from Krauss and Wang (2003). The formulation tried to avoid possible ambiguities (e.g., the random placement of the prize and duds behind the doors and the knowledge of the host were explicitly mentioned). The text stated (translated from Dutch):

> *Suppose you're on a game show and you're given the choice of three doors. Behind one door*

is the main prize (a car) and behind the other two doors there are dud prizes (a bunch of toilet paper). The car and the dud prizes are placed randomly behind the doors before the show. The rules of the game are as follows: After you have chosen a door, the door remains closed for the time being. The game show host, Monty Hall, who knows what is behind the doors, then opens one of the two remaining doors which always reveals a dud. After he has opened one of the doors with a dud, Monty Hall asks the participant whether he/she wants to stay with his/her first choice or to switch to the last remaining door. Suppose that you chose door 1 and the host opens door 3, which has a dud.

The host now asks you whether you want to switch to door 2. What should you do to have most chance of winning the main prize?

a. Stick with your first choice, door 1.
b. Switch to door 2.
c. It does not matter. Chances are even.

The MHD was presented on computer. Participants were instructed to carefully read the basic problem information (text in italics), first. When they were finished reading they pressed the ENTER-key and then the question and answer-alternatives (underlined text) appeared on the screen (text in italics remained on the screen). Participants typed their response (a, b, or c) on the keyboard. Instructions stated there were no time limits.

Procedure

The experiment was run on computer. Participants were tested in groups of 21 to 48. Participants completed the Gospan and MHD in a one-hour session, in which they also completed some other tasks not part of the present investigation. The MHD was presented after the Gospan task.

Results and discussion

Six participants were discarded because they did not meet the operation correctness or latency requirements of the WM-measure. Mean Gospan-score of the remaining 230 participants was 32.26 (SD = 10.45).

Consistent with previous MHD-studies only a small minority of the participants (5.2%) gave the correct switching answer. The vast majority (85.7%) believed that switching and sticking were equally good strategies. However, the crucial finding is that the participants that did give the correct response had a significantly larger WM-capacity. Mean Gospan-score of the participants that gave the correct response was 38.08 vs. only 31.94 for the incorrect responders, $t(228) = 2$, $n1 = 12$, $n2 = 218$, $p < .05$. In terms of effect sizes, Cohen's d reached .59. Such an effect is classified as "moderate" (Rosenthal & Rosnow, 1991) and corresponds to the effect sizes reported by Stanovich and West (1998a, 1998b) for the impact of executive capacity on the reasoning tasks in their studies.

The present association between MHD-performance and WM-capacity supports Stanovich and West's basic claim concerning the involvement of executive resources in normative reasoning. However, the evidence remains purely correlational. More direct evidence for the mediating role of the executive resources is needed (Klaczynski, 2000). Experiment 1B introduces secondary task methodology to test the basic processing claims experimentally.

Experiment 1B

A major problem for Stanovich and West (2000) and related dual processing frameworks is that the basic processing assumption, the different involvement of controlled, executive resources in heuristic and analytic reasoning, is disputed. On one hand, available (correlational) evidence for the role of executive resources in analytic, normative reasoning has been questioned (e.g., Klaczynski, 2000). On the other hand, the proposed characterization of the heuristic system as automatic and independent from executive control has been challenged (e.g., Handley, Feeney, Harper, 2002; Klaczynski, 2001; Osman, 2002). Experiment 1B presents a new approach to test the basic processing claims.

Participants solved the MHD while they performed a secondary task that burdened the executive WM-resources. If correct responding in the MHD draws on WM-resources, performance should decrease under load since less resources will be available for inhibition of the dominant "50%-heuristic" and subsequent analytic computations. On the other hand, if heuristic processing would not be automatic and would draw on WM, it will also become harder for people to come up with the "equal probability" answer and we would expect a decrease in "50%" responses. In case both the heuristic and normative response would draw on executive resources the computation of any single response should be hindered and we might expect a random guessing pattern under secondary task load.

The secondary task was adopted from Kane and Engle (2000). Participants were requested to continuously tap a novel, complex finger pattern (e.g., index finger/ring finger/ middle finger/ pinkie) with their non-dominant hand while reasoning. The task was selected because previous studies (e.g., Kane & Engle, 2000; Moscovitch, 1994) consistently showed that it put a premium on efficient executive WM-functioning.

Method

Participants
Forty-one first-year psychology students from the Unversity of Leuven, Belgium, participated in return for psychology course credit. None of the participants had participated in Experiment 1A. All participants had taken the Gospan-test prior to Experiment 1B. Between 13 to 46 days intervened between participation in the Gospan-test and Experiment 1B.

Materials
Monty Hall Dilemma. Participants were presented the same version of the MHD as in Experiment 1A.

WM-load task. A program executed by a second computer collected the finger-tapping data. All participants tapped on the "V", "B", "N", and "M" keys on the QUERTY-keyboard of the second computer.

Procedure
All participants were tested individually. Participants were instructed to tap the index-ring-middle-pinkie pattern with their non-dominant hand. The experiment started with five 30s practice tapping trials. Participants always received on-line accuracy feedback: Whenever a wrong finger (key) was tapped the computer emitted a 300 ms, low pitch tone. During the first three practice trials the program also calculated the mean tapping speed for each participant. If any one intertap interval in the subsequent trials was more than 150 ms slower than the established mean, the computer emitted a 600 ms, high pitch tone. The online monitoring served to assure that the tapping task was properly performed.

After the tapping practice, the experimenter explained that the practice tapping speed had to be maintained in the upcoming reasoning task. Participants then read the basic MHD problem information (underlined text) on the screen. When they were finished reading they pressed the ENTER-key and started tapping. Then the question and answer-alternatives (text in bold) were presented and participants continuously tapped the finger pattern (with online response time and accuracy feedback) until they gave their response. Participants said out loud the letter (a, b, or c) corresponding to their answer. Instructions stated there were no time limits.

Results and discussion

Performance of the participants in Experiment 1A was used as a baseline to evaluate the impact of the WM-load. A control analysis established that the WM-capacity of the participants in Experiment 1A (Mean Gospan-score = 32.26, SD = 10.45) and 1B (Mean Gospan-score = 33.1, SD = 10.88) did not differ, $F(1, 269) < 1$.

Burdening the executive resources with the tapping task affected participants' performance. As Table 1 shows the response pattern was clearly not random. The switching rate under the secondary task load decreased to 0%. This decrease in the proportion of correct responses reached marginal significance, p1 = 5.22%, p2 = 0%, n1 = 230, n2 = 41, $t(269) = 1.50$, $p < .07$, one-tailed. The finding supports the claim that correct normative reasoning in the MHD draws on executive WM-resources. Burdening the executive resources did not decrease the rate of "equal probability" answers. Indeed, there was a slight tendency in the opposite direction. This suggests that the central MHD intuition to assign a 50% chance to the two remaining doors is an automatic, heuristic response that does not involve executive processing.

Table 1: Percentage of Different Responses in Experiment 1A and 1B

	Experiment	
Answer	1A: No load	1B: Load
Stick	9.1 (21)	7.3 (3)
Switch	5.2 (12)	0.0 (0)
Equal	85.7 (197)	92.7 (38)

Note. Raw frequencies in parentheses.

General Discussion

The present study focused on the Monty Hall Dilemma because it is one of the most striking examples of the "normative/descriptive" gap in the literature (Friedman, 1998). As in previous MHD studies only a small proportion of participants gave the correct, normative switching response. However, Experiment 1A established that the participants that did give the correct response had a significantly larger working memory capacity. This finding complements the work of Stanovich and West (2000) on individual differences in executive resources with related reasoning tasks.

According to the Stanovich and West (2000) framework and associated dual process theories (e.g., Evans & Over, 1996; Sloman, 1996) correct normative responding requires that an analytic, controlled reasoning process overrides prepotent heuristics. The inhibition of the heuristic system and the computations of the analytic system would draw on limited executive, working memory resources. The more resources that are available, the more likely that the analytic system will be successfully engaged and the correct response calculated. Experiment 1B provided experimental evidence for this view. Burdening the executive resources with a secondary task while participants were solving the MHD tended to decrease the rate of correct,

switching responses: Although the participants in Experiment 1A and 1B had comparable span sizes, non of the participants in Experiment 1B managed to solve the MHD correctly under WM-load. Indeed, more people tended to commit the intuitive tendency to assign a 50% chance to the two remaining doors. These findings support the basic claim of dual process theories concerning the differential involvement of executive resources in analytic and heuristic reasoning.

As in most MHD-studies, the proportion of correct responses under "standard" conditions in the present study was very low. A consequence of this low figure is that the study inevitably suffers from a floor-effect. The decrease in correct performance under executive load in Experiment 1B still reached marginal significance but the decrease could never be large. One possible solution for the floor-effect is adopting some of the manipulations known to increase MHD performance. Previous studies indicated that practice with the task, training procedures and simple clarifications of the causal structure of the task (e.g., Burns & Wieth, 2000, 2003; Krauss & Wang, 2003; Tubau & Alonso, 2003) increase performance. Thus, testing the impact of the WM-load with such modified MHD versions might suffer less from a floor-effect. In addition, it might be especially enlightening to examine how different span groups benefit from the increased performance manipulations.

The present findings indicate that executive resources are *necessary* for correct, normative reasoning. However, by no means this implies that a large resource pool is also *sufficient* for correct reasoning. The relation between WM-capacity and reasoning performance is not absolute. Although participants that solved the MHD correctly in Experiment 1A had a larger WM-span, numerous "high spans" nevertheless answered erroneously. To illustrate this point MHD-performance of participants in the top and bottom quartile of the WM-capacity distribution in Experiment 1A was compared. Consistent with the previous findings high spans gave significantly more switching responses[2]. But even among the 25% most cognitively gifted college students only 10% gave the correct response. Clearly, factors outside the cognitive WM-ability spectrum will also affect performance (e.g., "epistemic thinking dispositions", see Stanovich, 1999). Thus, in pointing out the necessary role of executive, WM-resources for correct reasoning the present study does not minimize the role of other mediating factors.

The present study demonstrated the potential of a dual task approach to test the central processing claims of dual process theories. In principle, future studies could adopt this procedure with all the classic tasks studied in the field (e.g., conjunction fallacy, base-rate neglect, selection task). Of course, the final empirical evaluation of the executive processing claims of dual process theories will depend on the generalization of the present findings.

[2] p1 = 10%, p2 = 1%, n1 =70, n2= 70, $t(138) = 2.21$, $p < .03$.

Abstract

We examined whether individual differences in WM-capacity affected the acceptance of an extended MP problem that explicitly mentioned a possible disabler. The explicit disabler presentation was assumed to stimulate the spontaneous disabler search process. Two experiments showed that the acceptance ratings of the extended MP problems followed a U-shaped, quadratic trend with low and high spans showing the highest MP acceptance. Contrasting performance with extended and standard MP problems indicated that all span groups showed the standard suppression effect. Findings support the claim that high spans manage to inhibit the spontaneous disabler search and underline the generality and robustness of this inhibition phenomenon.

Introduction

Suppose that on a hot, summer day you hear someone claiming "If Jenny turns on the air conditioner, then she will feel cool". Next, you hear that Jenny did turn the air conditioner on. It is likely that you will conclude that Jenny will feel cool. This inference ('If P then Q. P. Therefore, Q') is known as the Modus Ponens (MP). The MP inference is considered valid in standard logic. Now, suppose that you would also have been reminded of the fact that the air conditioner might be broken or that Jenny might have a fever. In this case you would probably have been rather reluctant to accept the standard MP inference that turning on the air conditioner will make Jenny feeling cool. Thereby, the additional information would have tempted you to commit a fallacy.

Cognitive scientists have spent a great deal of research to establish how people reason with 'if, then' sentences or conditionals. One of the main findings is that additional, 'background' knowledge about the conditional relation affects the inferences people are willing to draw (Evans, Newstead, & Byrne, 1993; Manktelow, 1999). The crucial kind of background knowledge for the evaluation of the MP inference is referred to as 'disabling conditions'. A disabling condition (also 'disabler' or 'additional requirement') is a condition that prevents the antecedent specified in the conditional (e.g., turning on the air conditioner or the P part) from bringing about the consequent (e.g., feeling cool or the Q part). In the introductory example a broken air conditioner or Jenny having a fever will both function as disablers.

In a pioneering study Byrne (1989) showed that when a possible disabler was explicitly presented to participants (e.g., If she has an essay to write, then she will study late in the library. If the library is open, then she will study late in the library. She has an essay to write. Thus, she will study late in the library?) the MP inference was less frequently accepted compared to the standard MP condition without presented disabler. Further studies established that during conditional reasoning people spontaneously search their long-term memory for stored disablers. Cummins (1995) used causal conditionals for which a pilot group could retrieve many (e.g., If you put fertilizer on plants, then they grow well) or only few (e.g., If Tom grasps the glass with his bare hands, then his fingerprints are on it) disablers. Cummins reasoned that for conditionals with many (vs. few) disablers spontaneous retrieval of a disabler would be more likely. Although no specific disablers were explicitly presented, the results indeed showed that MP inferences based on conditionals with many disablers were rejected more frequently. Numerous studies confirmed these findings (e.g., Bonnefon & Hilton, 2002; Byrne, Espino, & Santamaria, 1999; Thompson, 1994; De Neys, Schaeken, & d'Ydewalle, 2002; Stevenson & Over, 1995; George, 1997; see Politzer & Bourmaud, 2002 for a review). Thus, it is well established that finding a disabler (either spontaneously or presented by the experimenter) will result in a decreased MP acceptance. This impact of disablers on the MP inference acceptance is known as the suppression effect.

In the present study we present the first experiments that look at individual differences in the suppression impact. More precisely, we will examine whether differences in working memory (WM) capacity affect the acceptance of MP problems when a possible disabler is explicitly presented. Such WM-mediation could be expected on the basis of recent findings pointing to the role of WM in the retrieval and inhibition of stored disablers (e.g., De Neys, Schaeken, & d'Ydewalle, 2003a, 2003b; Markovits, Doyon, & Simoneau,

2002; Simoneau & Markovits, 2003; Verschueren, De Neys, Schaeken, & d'Ydewalle, 2002).

De Neys et al. (2003a) and Verschueren et al. (2002) established that the efficiency of the disabler retrieval process is mediated by WM-capacity. In a task where people were asked to generate disablers for a set of conditionals in limited time, participants higher in WM-capacity retrieved more disablers. Putting a load on WM also reduced the efficiency of the retrieval process. In a further experiment, De Neys et al. (2003b) tested a group of low, medium, and high spans (participants in the bottom, middle and top quintile of first-year psychology students' WM-capacity distribution, respectively) in an everyday conditional reasoning task. Consistent with the more efficient disabler retrieval, medium spans were more likely to reject the MP inference than low spans. On the other hand, despite the intrinsic superior retrieval capacity high spans showed nevertheless higher MP acceptance ratings than the medium spans (see also Markovits et al., 2002).

Based on findings of Stanovich and West (2000), it was assumed that a basic decontextualization ability would allow high spans to put background knowledge aside when it conflicts with the logical standards. Remember that in standard logic MP is a valid inference. Since disabler retrieval will result in the rejection of MP, a basic validity notion will conflict with the disabler retrieval process. De Neys et al. reasoned that high spans would therefore use their WM-resources for an active inhibition of the disabler search.

Simoneau and Markovits (2003) showed that more efficient inhibitory processing (as measured by a negative priming task) was indeed linked with higher MP acceptance. In a related dual-task study De Neys et al. found additional support for the inhibition hypothesis. The basic assumption states that lower spans allocate WM-capacity to the disabler retrieval, while high spans allocate WM-capacity primordially to the retrieval inhibition. Consistent with the hypothesis, the dual-task study showed that a less efficient disabler retrieval under WM-load resulted in higher MP acceptance ratings under load (vs. no load) for low spans, while the less efficient inhibition resulted in lower MP ratings under load (vs. no load) for high spans.

In sum, there is evidence for the claim that high spans are inhibiting the disabler retrieval process during conditional reasoning. Inhibition of cognitive processes deemed inappropriate is indeed one of the key executive working memory functions (e.g., Baddeley, 1996; Levy & Anderson, 2002; Miyake & Shah, 1999).

The present study will allow a further test of the disabler inhibition hypothesis. Presenting extended MP problems where a possible disabler is explicitly mentioned will push the inhibition demands to the limit. The explicit disabler presentation will stimulate the search process. Note that one of the difficulties of retrieving disablers in a reasoning task is that there is no explicit retrieval cue (e.g., Markovits & Barrouillet, 2002; Markovits & Quinn, 2002). The standard MP premises do not tell you what kind of information you should look for. If a possible disabler is added, it will be incorporated in the elementary mental representation of the inference problem. It is assumed that this representation is held in working memory. As suggested by many authors, activation will automatically start to spread from the information stored in WM (or "the focus of attention" see Cowan, 1995) to related long-term memory elements (Anderson, 1993; Cowan, 1995; see also Markovits & Barrouillet, 2002 for an integrated account). Therefore, stored disablers will receive more activation by the explicit presentation of a possible disabler with the MP inference. Consequently, it will be more likely that additional stored disablers will be automatically retrieved.

In Experiment 1 participants were given a measure of WM-capacity and extended MP problems that mentioned a possible disabler. If the high spans still manage to inhibit the stimulated disabler search we expect to see a U-shaped, quadratic trend in the acceptance ratings in function of WM-capacity. Low spans were expected to show high MP acceptance ratings because of the inefficient disabler retrieval. Medium spans should show lower MP ratings because the search will be more efficient. If high spans still manage to inhibit the disabler retrieval, acceptance ratings should increase again for the high spans.

In Experiment 2 we compared the acceptance ratings of standard and extended MP problems for different WM-span groups.

Experiment 1

Method

Participants

A total of 105 first-year psychology students from the University of Leuven (Belgium) participated in the experiment in return for course credit. None of the students had had any training in formal logic.

Material

Working memory task. Participants' working memory capacity was measured using a version of the Operation span task (Ospan, La Pointe & Engle, 1990) adapted for group testing (Gospan, for details see De Neys, d'Ydewalle, Schaeken, & Vos, 2002). In the Ospan-task participants solve series of simple mathematical operations while attempting to remember a list of unrelated words The main adaptation in the Gospan is that the operation from an operation-word pair is first presented separately on screen (e.g., 'IS (4/2) – 1 = 5 ?'). Participants read the operation silently and press a key to indicate whether the answer is correct or not. Responses and

response latencies are recorded. After the participant has typed down the response, the corresponding word (e.g., 'BALL') from the operation-word string is presented for 800 ms. As in the standard Ospan three sets of each length (from two to six operation-word pairs) are tested and set size varies in the same randomly chosen order for each participant. The Gospan-score is the sum of the recalled words for all sets recalled completely and in correct order.

Participants were tested in groups of 21 to 48 at the same time. Participants who made more than 15% math errors or whose mean operation response latencies deviated by more than 2.5 standard deviations of the sample mean were discarded (participants already in the bottom quartile of the Gospan-score distribution were not discarded based on the latency criterion). De Neys, d'Ydewalle et al. (2002) reported an internal reliability coefficient alpha of .74 for the Gospan. The corrected correlation between standard Ospan and Gospan-score reached .70.

Reasoning task. Participants received three extended MP problems. These were Dutch translations of the three Byrne (1989) MP problems (see Dieussaert, Schaeken, Schroyens, & d'Ydewalle, 2000). The following item format was used:

Rule: If she has an essay to write, then she will stay late in the library.
If the library stays open, then she will stay late in the library.
Fact: She has an essay to write
Conclusion: She will stay late in the library.

All three MP problems were presented on a separate page of a booklet together with a 7-point rating scale ranging from 1 (*Very certain that I cannot draw this conclusion*) to 7 (*Very certain that I can draw this conclusion*) with 4 representing *can't tell*. Participants placed a mark on the number of the scale that best reflected their evaluation of the conclusion.

Procedure

Participants were tested in groups of 21 to 42 at the same time in a large computer room with an individual booth for every participant. All participants started with the Gospan task that was run on computer. After all participants of a group had finished the Gospan-task the extended MP evaluation task was presented. The three items were presented on separate pages of a booklet. The first page of the booklet included the task instructions. They showed an example item that explained the specific task format. Participants were told that the task was to decide whether or not they could accept the conclusions. Care was taken to make sure participants understood the precise nature of the rating scale. The task instructions did not mention to accept the premises as true or to endorse conclusions that follow necessarily. Instead participants were told they could evaluate the conclusions by the criteria they personally judged relevant (see Cummins, 1995).

Results and discussion

Rejection probability for all reported statistical analyses was .05. For completeness, we always report the individual estimated p-values.

Three participants were discarded because they did not meet the operation correctness or latency requirements of the WM-task (see De Neys, d'Ydewalle et al., 2002). The remaining 102 participants were split in three span groups of equal n based on the boundaries of the Gospan-score distribution. Mean Gospan-score for the three successive span groups was 23.27 (SD = 4.34, low span), 35.15 (SD = 2.79, medium span), and 45.89 (SD = 4.97, high span).

For every participant we calculated the mean acceptance rating for the three extended MP problems. The means were subjected to an ANOVA with span group as between-subject variable. There was a significant effect of span group, $F(2, 99) = 5.55$, $MSE = 1.23$, $p < .01$. The acceptance rating showed the expected pattern: Medium spans ($M = 3.84$, $SD = 4.67$) showed lower MP acceptance ratings than the low ($M = 4.56$, $SD = 1.11$) and high spans ($M = 4.67$, $SD = .99$). A trend analysis confirmed that there was a significant U-shaped, quadratic trend, $F(1, 99) = 10.85$, $MSE = 1.23$, $p < .005$ without mediation of a linear trend, $F(1, 99) < 1$.

Thus, even when the disabler search was specifically stimulated high spans showed the highest levels of MP acceptance. This is consistent with the claim that high spans are inhibiting the disabler search and underlines the generality and robustness of the inhibition phenomenon.

Experiment 2

The first experiment showed that the acceptance ratings for the extended MP problems differed for participants of different WM-capacity. In Experiment 2 we compare the acceptance ratings of standard vs. extended MP problems in function of WM-span. This allows us to establish the impact of the explicit disabler presentation per se. For the validity of our framework it is crucial that the acceptance ratings decrease when a disabler is explicitly presented.

First, for low spans it is assumed that the disabler search with standard MP problems will not be very successful. Although low spans' limited resources will restrict the impact of the extra search stimulation, the extended disabler manipulation does present low spans a disabler they will probably not retrieve in the standard condition. Therefore, low spans' inference acceptance should decrease for the

extended MP problems. Second, because of the more efficient retrieval, medium spans in the standard condition will probably retrieve the disabler presented in the extended MP condition themselves. Hence, the mere presentation of the disabler should not affect medium spans. Nevertheless, if we are right that the search process is stimulated by the disabler presentation one should expect that additional disablers will be retrieved in the extended condition and this should further decrease the MP acceptance (see De Neys, Schaeken, & d'Ydewalle, 2003c, for a study on the effect of the number of retrieved disablers on MP acceptance). High spans are expected to inhibit the search both for the standard and extended problems. However, it is explicitly assumed that the inhibition is not automatic, but draws on WM-resources. Therefore, the inhibition should be less successful when the process is more demanding. De Neys et al. (2003a) already observed that the increasing inhibition demands caused by an increasing number of available disablers resulted in a less efficient disabler inhibition. Hence, although the high spans should overall show a high MP acceptance, their acceptance level should nevertheless be affected by the stimulated disabler search.

In sum, we expected a standard suppression effect for all span groups: Acceptance ratings should be lower for the extended (vs. standard) MP problems. In addition, overall MP acceptance ratings should be affected by WM-span: Extended and standard MP acceptance in the successive span groups should follow the U-shaped trend observed in Experiment 1.

Method

Design

As standard condition or baseline we used the MP evaluations of the 282 participants in the study of De Neys et al. (2003b). In this study participants were presented a standard conditional inference task with causal conditionals and a measure of WM-capacity. We calculated the mean MP acceptance for different span groups and used this as a baseline to compare the MP acceptance of matched span groups with similar extended causal MP problems.

Participants

All 105 participants of Experiment 1 evaluated the extended MP inferences in the present experiment. The data for the standard MP condition were taken from the study of De Neys et al. (2003b) where 282 first-year psychology students evaluated standard conditional inferences.

Material

Working memory task. All participants' working memory capacity was measured with the Gospan-task (see De Neys, d'Ydewalle et al., 2002).

Reasoning tasks. All conditionals were selected from the generation studies of De Neys et al. (2002) and Verschueren et al. (2002). Eight causal conditionals were used for the standard condition and six causal conditionals for the extended condition. Half of the conditionals in each condition were previously classified as having many possible disablers, while the other half had only few possible disablers. The number of possible alternative causes (see Cummins, 1995) of the selected conditionals with few and many disablers was kept constant. The item format for the extended and standard task was similar to the format used in Experiment 1, except that for the extended items a possible disabler was mentioned. We always presented the disabler that was most frequently generated for that conditional in the generation task (e.g., see De Neys et al., 2002). As in Byrne (1989) the disablers (e.g., engine broken) were always presented as an additional requirement, embedded in a conditional (e.g., If the engine works, then the car starts). This resulted in the following format:

Rule: If the ignition key is turned, then the car starts.
If the engine works, then the car starts.
Fact: The ignition key is turned.
Conclusion: The car starts.

It should be noted that the set of conditionals in the standard and extended condition was not completely similar. Although both conditions used causal conditionals with a comparable number of possible disablers, the standard condition should therefore not be conceived as a control condition per se. Rather, the standard condition serves as a baseline against which the performance of the different WM-span groups can be compared.

Procedure

Participants were tested in groups of 21 to 48 at the same time in a large computer room with an individual booth for every participant. All participants started with the Gospan task that was run on computer. After all participants of the group had finished the Gospan-task the extended MP evaluation task or the standard conditional inference task was presented. The standard task was run on computer. Participants evaluated eight standard MP inferences mixed with other conditional inferences. The six items of the extended MP task were presented on separate pages of a booklet. This booklet was presented before the booklet with the items of Experiment 1. Task instructions for the standard and extended MP task were similar to the instructions given in Experiment 1.

Results and discussion

In order to match the span groups in the extended and standard conditions as closely as possible we decided to split both samples up in five span groups

each, based on the quintile boundaries of the Gospan-score distribution of the 282 participants in the standard condition. A 5 (span group, between-subjects) x 2 (MP task, between-subjects) ANOVA on the Gospan-scores established that there were no WM-capacity differences for participants in both task conditions [effect of MP task, $F(1, 374) < 1$; interaction MP task x Span-group, $F(4, 374) = 1.84$, $MSE = 10.91$].

Each participant evaluated eight or six MP evaluations. The mean of these ratings was calculated and subjected to a 5 (WM-span, between-subjects) x 2 (MP task, between-subjects) ANOVA.

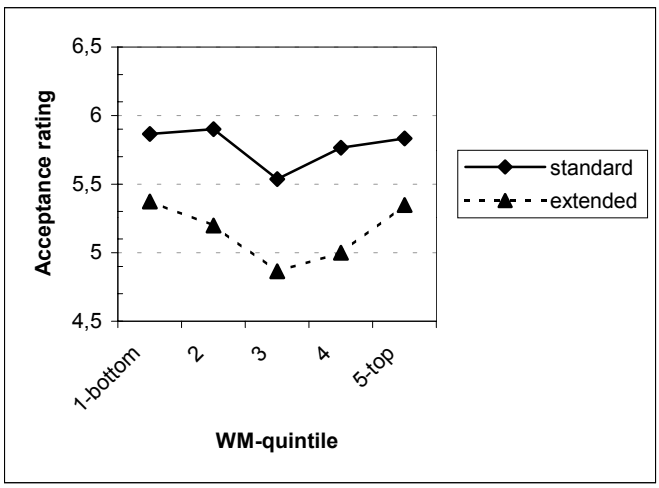

Figure 1. Mean MP acceptance rating in function of WM-capacity with (extended) and without (standard) explicitly presented disabler. The rating scale ranged from 1 (very sure cannot draw this conclusion) to 7 (very sure can draw this conclusion).

Explicitly presenting a disabler clearly decreased the MP acceptance, $F(4, 374) = 37.56$, $MSE = .72$, $p < .0001$. Figure 1 shows that, as expected, this effect was present for all WM-span groups, span group x MP task interaction, $F(4, 374) < 1$. There was also a marginal main effect of WM-span, $F(4, 374) = 2.28$, $MSE = .72$, $p < .06$. As Figure 1 indicates, a trend analysis clearly established that the MP ratings followed a U-shaped, quadratic trend in function of WM-span, $F(1, 374) = 6.77$, $MSE = .72$, $p < .01$. There was no sign of a linear trend, $F(1, 374) < 1$, and the quadratic trend did not differ for the standard and extended MP problems, $F(1, 374) = 1.07$, $MSE = .71$, $p > .35$. Thus, as expected, all span groups showed an impact of the explicit disabler presentation, but both on the standard and extended problems the MP acceptance ratings were affected by WM-capacity.

Finally, one might note that the number of disablers of the adopted conditionals in the present experiment varied systematically (e.g., half of the conditionals had few vs. many possible disablers). We had no specific hypotheses concerning the impact of this factor on the manipulations. For completeness, the variable was entered as a within-subjects factor in the ANOVA. We replicated the traditional (e.g., Cummins, 1995) main effect of the number factor: MP acceptance was always lower for conditionals with many disablers than for conditionals with few disablers, $F(1, 374) = 139.40$, $MSE = .51$, $p < .0001$. However, none of the interactions with the other factors reached significance. Thus, the crucial effects of span group and the explicit disabler presentation were not affected by the number factor.

General Discussion

The two experiments clearly established that even when a disabler is explicitly presented MP acceptance ratings of the successive working memory (WM)-span groups follow a U-shaped trend. Previous studies already suggested that the higher MP acceptance ratings of high vs. medium spans, despite high spans' superior retrieval capacities, result from an active inhibition of the disabler search. The fact that in the present study the same pattern is found under conditions that can be assumed to stimulate the search process points to the robustness and generality of the inhibition phenomenon.

As De Neys et al. (2003a, 2003b) we hypothesized that the disabler inhibition is not occurring in a cognitive vacuum but draws on working memory resources. Therefore, higher inhibition requirements were expected to result in a less efficient inhibition process. The goal of the search stimulation by the explicit disabler presentation was precisely to increase the inhibition demands. Disablers that would be inhibited under less demanding inhibition conditions could 'slip through' the filter and decrease the MP acceptance. Consistent with these hypotheses Experiment 2 clearly showed that even high spans' MP acceptance decreased for the extended MP problems.

The present findings have implications for traditional suppression studies. The results indicate that Byrne's (1989) findings can be generalized over the whole WM-capacity distribution: For all WM-span groups MP acceptance decreased when a possible disabler was explicitly presented. Thus, all WM-span groups show the basic suppression effect. However, it is important to note that the final acceptance level is systematically affected by WM-capacity: Reasoners with an inefficient disabler retrieval and reasoners that inhibit the retrieval show the highest levels of MP acceptance. These people will be typically situated in the bottom and top levels of the WM-capacity distribution, respectively. Reasoner that can allocate sufficient resources to the retrieval and do not inhibit the search process, typically people with medium sized WM-span, will be most likely to reject MP. These findings further

emphasize the role of WM-capacity in the retrieval and inhibition of disablers during conditional reasoning.

Abstract

A computational model of children's semantic memory is built from the Latent Semantic Analysis (LSA) of a multisource child corpus. Three tests of the model are described, simulating a vocabulary test, an association test and a recall task. For each one, results from experiments with children are presented and compared to the model data. Adequacy is correct, which means that this simulation of children's semantic memory can be used to simulate a variety of children's cognitive processes.

Introduction

Models of human language processing are usually based on a layer of basic semantic representations on top of which cognitive processes are described. For instance, the construction-integration model (Kintsch, 1998) describes processes that operate on a network of propositions. These basic representations can just be descriptions of what the human memory looks like, in order for the upper models to be explicitly stated, but they can also be operationalized so that the model can be tested on a computer. In the first case, these representations are usually designed by hand, but this method prevents large-scale simulations.

This was the case with Kintsch's construction-integration model until 1998. Before that, researchers had to code propositions by hand and guess relevant values to code the strength of links between nodes. Then Kintsch (1998) used the Latent Semantic Analysis (LSA) model (Deerwester et al., 1990; Landauer et al., 1998) which provides a way to automatically build these basic representations. This was a major step since the construction-integration processes could then be tested on a large variety of inputs, while being less dependent on idiosyncratic codings. Such a mechanism for automatically constructing basic semantic representations should be carefully designed and tested in order to simulate as good as possible human semantic memory.

LSA is nowadays considered as a good candidate for modeling an adult semantic memory based on a large corpora of representative texts: Bellissens et al. (2002), Kintsch (2000) and Lemaire & Bianco (2003) used it for modeling metaphor comprehension; Pariollaud et al. (2002) used it for modeling the comprehension of idiomatic expressions; Howard & Kahana (2002) relied on it to model free recall and episodic memory retrieval; Laham (1997) did the same for modeling categorization processes; Landauer & Dumais (1997) designed a model of vocabulary acquisition based on LSA; Lemaire & Dessus (2001), Rehder et al. (1998) and Wolfe et al. (1998) used it for modeling knowledge assessment; Quesada et al. (2001) modeled complex problem solving by means of LSA basic representations; Wolfe & Goldman (2003) worked on a model of reasoning about historical accounts based on LSA. However, to our knowledge, no computational basic representations were made that mimic full children's semantic memory.

This paper aims at presenting such a model. First, we present LSA. We then describe our corpus, which is supposed to mimic the kind of texts children are exposed to. Finally, we present three experiments which aim at validating the model.

Latent Semantic Analysis

Basic semantic representations

There are many ways of constructing basic semantic representations that can be processed by a computer. The first one is to build them by hand. Powerful formalisms like description logic (Borgida, 1996) or semantic networks (Sowa, 1991) have been designed to accurately represent concepts, properties and relations. However, in spite of huge efforts (Lenat, 1995), no full set of symbolic representations has been made that can be considered a reasonable model of human semantic memory. Hand-coding semantic information is tedious and, as we mention later, symbolic representations might not be the best formalism for that.

Another strategy is to rely on corpora to get the semantic information. Artificial intelligence researchers have designed sophisticated syntactic processing tools for automatically describing the knowledge using the kind of symbolic formalisms mentioned earlier. They usually refer to them as ontologies or knowledge bases (Vossen, 2003). However, in spite of great strides, this approach still cannot be the means to form the basic semantic representations that cognitive researchers need. First, it cannot be fully automatized, except for specific domains, thus preventing complete descriptions of the language. Second and quite paradoxically, since the descriptions are quite elaborated, it is very hard to design reasoning processes on top of them. For instance, a simple process like estimating the degree of semantic association is very hard to operationalize on complex structures like semantic networks.

Instead of relying on symbolic representations, a third approach consists in (1) analyzing the co-occurrence of words in large corpora in order to draw semantic similarities and (2) relying on very simple structures, namely high-dimensional vectors, to represent meanings. In this approach, the unit is the word. The meaning of a word is not defined per se, but rather determined by its relationships with all others. For instance, instead of defining the meaning of bicycle in an absolute manner (by its properties, function, role, etc.), it is defined by its degree of association to other words (i.e., very close to bike, close to pedals, ride, wheel, but far from duck, eat, etc.). This semantic information can be established from raw texts, provided that enough input is available. This is exactly what human people do: it seems that most of the words we know, we learn by reading (Landauer & Dumais, 1997). The reason is that most words appear almost only in written form and that direct instruction seems to play a limited role. Therefore, we would learn the meaning of words mainly from raw texts, by mentally constructing their meaning through repeated exposure to appropriate contexts.

Relying on direct co-occurrence

One way to mimic this powerful mechanism would be to rely on direct co-occurrences within a given context unit. A usual unit is the paragraph which is both computationally easy to identify and of reasonable size. We would say that:

R1: words are similar if they occur in the same paragraphs.

Therefore, we would count the number of occurrences of each word in each paragraph. Suppose we use a 5,000-paragraph corpus. Each word would be represented by 5,000 values, that is by a 5,000 dimension vector. For instance:

avalanche: (0,1,0,0,0,0,1,0,2,0,0,0,0,0,0,1,1,0,1,0,1,0,0,0,0,0,0…)
snow: (0,2,0,0,0,0,0,0,1,1,0,0,0,0,0,0,0,2,1,1,0,1,0,0,0,0,0,0…)

This means that the word avalanche appears once in the 2nd paragraph, once in 7th, twice in the 9th, etc. One could see that, given the previous rule, both words are quite similar: they co-occur quite often. A simple cosine between the two vectors can measure the degree of similarity. However, this rule does not work well (Perfetti, 1998; Landauer, 2002): two words should be considered similar even if they do not co-occur. French & Labiouse (2002) think that this rule might still work for synonyms because writers tend not to repeat words, but use synonyms instead. However, defining semantic similarity only from direct co-occurrence is probably a serious restriction.

Relying on higher-order co-occurrence

Therefore, another rule would be:

R1: words are similar if they occur in similar paragraphs.*

This is a much better rule. Consider the following two paragraphs:

Bicycling is a very pleasant sport. It helps keeping a good health.

For your fitness, you can practice bike. It is very nice and good to your body.

Bicycling and *bike* appear in similar paragraphs. If this is repeated over a large corpus, it would be reasonable to consider them similar, even if they never co-occur within the same paragraph. Now we need to define paragraph similarity. We could say that two paragraphs would be similar if they share words, but that would be restrictive: as illustrated in the previous example, two paragraphs should be considered similar although they do not have words in common (functional words are usually not taken into account). Therefore, the rule is:

R2: paragraphs are similar if they contain similar words.

Rules 1* and 2 constitute a circularity, but this can be solved by a specific mathematical procedure called singular value decomposition, which is applied to the occurrence matrix. This is exactly what LSA does. To state it in other words, LSA is not only based on direct co-occurrence, but rather on higher-order co-occurrence. Kontostahis & Pottenger (2002) have shown that these higher-order co-occurrences do appear in large corpora.

LSA consists in reducing the huge dimensionality of direct word co-occurrences to its best N dimensions. All words are then represented as N-dimensional vectors. Empirical tests have shown that performance is maximal for N around 300 for the whole general English language (Landauer et al., 1998; Bellegarda, 2000) but this value can be smaller for specific domains (Dumais, 2003). We will not describe the mathematical procedure which is presented in details elsewhere (Deerwester, 1990; Landauer et al., 1998). The fact that word meanings are represented as vectors leads to two consequences. First, it is straight-forward to compute the semantic similarity between words, which is usually the cosine between the corresponding vectors, although others similarity measures can be used. Examples of semantic similarities between words from a 12.6 million word corpus are (Landauer, 2002):

cosine(doctor, physician) = .61
cosine(red, orange) = .64

Second, sentences or texts can be assigned a vector, by a simple weighted linear combination of their word vectors. This is a powerful feature of a semantic representation to be able to go easily from words to texts. An example of semantic similarity between sentences is:

cosine(the cat was lost in the forest, my little feline disappeared in the trees) = .66

Modeling children's semantic memory

Semantic space

As we mentioned before, our goal was to rely on LSA to define a reasonable approximation of children's semantic memory. This is a necessary step for simulating a variety of children cognitive processes.

LSA itself obviously cannot form such a model: it needs to be applied to a corpus. We gathered French texts that approximately correspond to what a child is exposed to:

stories and tales for children (~1,6 million words), children's productions (~800,000 words), reading textbooks (~400,000 words) and children's encyclopedia (~400,000 words). This corpus is composed of 57,878 paragraphs for a total of 3.2 million word occurrences. All punctuation signs were ruled out, capital letters were transformed to lower cases, dashes were ruled out except when forming a composed word (like *tire-bouchon*). This corpus was analyzed by means of LSA and the occurrence matrix reduced to 400 dimensions, which appears to be an optimal value as we will see later. The resulting semantic space contains 40,588 different words. This step took 15 minutes on a 2.4 Ghz computer with 2 Gb RAM.

Tests

In order to test whether this semantic space can be an acceptable approximation of the semantic memory of children, we tested three features: its *extent*, its *organization* and its *use*. For each one, we relied on a specific task and compared the data from the simulation of the task to data obtained from children on the exact same task.

The *extent* feature has to do with the size of lexical knowledge. Does our semantic space *knows* the kind of words that a child knows? We used a vocabulary task for that: given a word, the goal is to find the correct definition from four of them. By comparing the model data with children's data at various ages, our goal is to approximately identify the kind of children we are mimicking.

The *organization* feature concerns the way words are associated to others in memory. Do we correctly mimic the semantic neighborhood of words? The task we used for testing that feature is an association task :given a word, the goal is to provide the most associated one. We will compare children's association norms to association measures in the semantic space.

The *use* feature has to do with the way semantic memory is used. Is our semantic space adequate enough so that it can account for a process that uses it? We used a recall task for studying the text comprehension process which obviously largely relies on semantic representations.

These three experiments cover different tasks and different grain sizes of language entities, from words to texts: the first one consists of word comparisons, the second one compares a word and a sentence and the third one compares texts. We expect a good match between human data and model data. In addition, we hypothesize that results will be higher with our children corpus than with adult corpora.

Experiment 1

The first experiment, which aims at validating the model, involves a vocabulary task. The design of the material as well as the experiments with children were realized by Denhière et al. (in preparation). Material consists of 120 questions, each one composed of a word and four definitions: the correct one, a close definition, a far definition and an unrelated definition. For instance, given the word *nourriture* (*food*), translations of the four definitions are:

- *what is used to feed the body (correct);*
- *what can be eaten (close)*;
- *matter which is being spoiled (far)*;
- *letter exchange (unrelated).*

Participants were asked to select what they thought was the correct definition. This task was performed by four groups of children: 2nd grade, 3rd grade, 4th grade and 5th grade. These data were compared with the cosines between the given word and each of the four definitions. For instance, the four cosines on the previous examples were: .38 (correct), .24 (close), .16 (far) and .04 (unrelated). 116 questions were used because the semantic space did not contain four rare words.

The first measure we used was the percentage of correct answers. Figure 1 displays the results. The percentage of correct answers is .53 for the model, which is exactly the same value as the 2nd grade children. Except for unrelated answers, the model data globally follow the same pattern as the children's data.

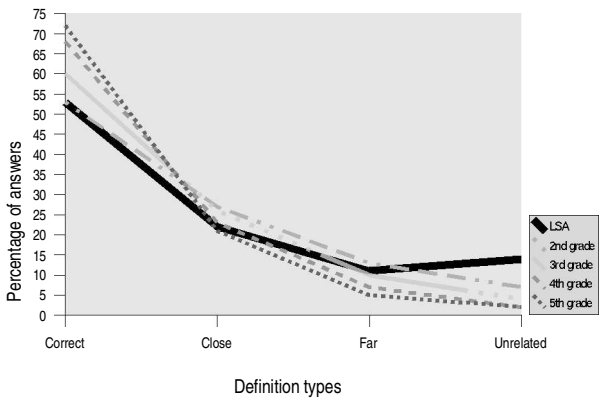

Figure 1: Percentage of answers for different types of definitions

In order to compare our semantic spaces with adult semantic spaces, we defined a measure which integrates the four values. We used a d measure, which is a normalized difference between the cosines for correct and close definitions together and the cosines for far and unrelated definitions together. The higher this measure, the better the result. Given a word W, four definitions (correct, close, far and unrelated) and a global standard deviation S, the formula is the following:

$$d = \frac{\frac{\cos(W, correct) + \cos(W, close)}{2} - \frac{\cos(W, far) + \cos(W, unrelated)}{2}}{S}$$

We also compared these results with several adult corpora, in order to test whether our semantic space was specific to children. We used five corpora: a literature corpus, composed of novels from the XIXth and XXth centuries and four corpora from the French daily newspaper *Le Monde*, of the years 1993, 1995, 1997 and 1999. Table 1 shows the results.

Table 1: Comparison between children's semantic space and adult semantic spaces

Semantic space	Size (in million words)	Percentage of correct answers	***d***
Children	3.2	.53	.69
Literature	14.1	.38	.52
Le Monde 1993	19.3	.44	.23
Le Monde 1995	20.6	.37	.21
Le Monde 1997	24.7	.40	.28
Le Monde 1999	24.2	.34	.25

In accordance with the previous experiment, the children's semantic space has the better results, although its size is much smaller. Student tests have shown that the children semantic space is significantly different from others ($p < .05$) except for the percentage of correct answers when compared to the *Le Monde* 1993 corpus ($p < .1$).

Experiment 2

This second experiment is based on verbal association norms published by de La Haye (2003). Two-hundred inducing words (144 nouns, 28 verbs and 28 adjectives) were proposed to 9 to 11-year-old children. For each word, participants had to provide the first word that came to their mind. This resulted in a list of words, ranked by frequency. For instance, given the word *cartable* (*satchel*), results are the following for 9-year-old children:

- école (*school*): 51%
- sac (*bag*): 12%
- affaires (*stuff*): 6%
...
- classe (*class*): 1%
- sacoche (*satchel*): 1%
- vieux (*old*): 1%

This means that 51% of the children answered the word *école* (*school*) when given the word *cartable* (*satchel*). The two words are therefore strongly associated for 9-year-old children. These association values were compared with the LSA cosine between word vectors: we selected the three best-ranked words as well as the three worst-ranked (like in the previous example). We then measured the cosines between the inducing word and the best ranked, the 2nd best-ranked, the 3rd best ranked, and the mean cosine between the inducing word and the three worst-ranked. Results are presented in Table 2.

Table 2: Mean cosine between inducing word and various associated words for 9-years-old children

Words	Mean cosine with inducing word
Best-ranked words	.26
2nd best-ranked words	.23
3rd best ranked-words	.19
3 worst-ranked words	.11

Student tests show that all differences are significant ($p < .03$). This means that our semantic space is not only able to distinguish between the strong and weak associates, but can also discriminate the first-ranked from the second-ranked and the latter from the third-ranked.

Measure of correlation with human data is also significant ($r(1184 =.39,\ p<.001$). Actually, two factors might have lowered this result. First, although we tried to mimic what a child has been exposed to, we could not control all word frequencies within the corpus. Therefore, some words might have occurred with a low frequency in the corpus, leading to an inaccurate semantic representation. When the previous comparison was performed on the 20% most frequent words, the correlation was much higher ($r(234 =.57$, $p<.001$).

The second factor is the participant agreement: when most children provide the same answer to an inducing word, there is a high agreement, which means that both words are very strongly associated. However, there are cases when there is almost no agreement: for instance the three first answers to the word *bruit* (*noise*) are *crier* (*to shout*) (9%), *entendre* (*to hear*) (7%) and *silence* (*silence*) (6%). It is not surprising that the model corresponds better to the children data in case of a high agreement, since this denotes a strong association that should be reflected in the corpus. In order to select answers whose agreement was higher, we measured their entropy. The formula is the following:

$$entropy(item) = \sum_{answer} freq(answer).\log(\frac{1}{freq(answer)})$$

A low entropy corresponds to a high agreement and vice versa. When we selected the 20% items with the lowest entropy, the correlation also raises ($r(234)=.48$, $p<.001$).

All these results show that the association degree between words defined by the cosine measure within the semantic space seems to correspond quite well to children's judgement of association.

We also compared these results with the previous adult semantic spaces. Results are presented in Table 3.

Table 3: Correlations between participant child data and different kinds of semantic spaces

Semantic space	Size (in million words)	Correlation with child data
Children	3.2	.39
Literature	14.1	.34
Le Monde 1993	19.3	.31
Le Monde 1995	20.6	.26
Le Monde 1997	24.7	.26
Le Monde 1999	24.2	.24

In spite of much larger sizes, all adult semantic spaces correlate worse than the children's semantic space with the data of the participants in the study. Statistical tests show that all differences between the child model and the other semantic spaces are significant ($p<.03$).

Experiment 3

The third experiment is based on recall or summary tasks. Children were asked to read a text and write out as much as they could recall, immediately after reading or after a fixed

delay. We used 7 texts. We tested the ability of the semantic representations to estimate the amount of knowledge recalled. This amount is classically estimated by means of a propositional analysis: first, the text as well as the participant production are coded as propositions. Then, the number of text propositions that occur in the production is calculated. This measure is a good estimate of the knowledge recalled. Using our semantic memory model, this is accounted for by the cosine between the vector representing the text and the vector representing the participant production.

Table 4 displays all correlations between these two measures. They range from .45 to .92, which means that the LSA cosine applied to our children's semantic space is a good estimate of the knowledge recalled.

Table 4: Correlations between LSA cosines and number of propositions recalled for different texts.

Story	Task	Number of participants	Correlations
Poule	Immediate recall	52	.45
Dragon	Delayed recall	44	.55
Dragon	Summary	56	.71
Araignée	Immediate recall	41	.65
Clown	Immediate recall	56	.67
Clown	Summary	24	.92
Ourson	Immediate recall	44	.62
Taureau	Delayed recall	23	.69
Géant	Summary	105	.58

In an experiment with adults, Foltz et al. (1996) have shown that LSA measures can be used to predict comprehension. Besides validating our model of semantic memory, this experiment shows that an appropriate semantic space can be used to assess text comprehension in a much faster way than propositional analysis, which is a very tedious task.

Conclusion

A model of the development of children's semantic memory

Our model is not only a computational model of children's semantic memory, but of its *development*. Other computational models of human memory have been developed but some of them are based on inputs that do not correspond to what humans are exposed to. They are good models of the memory itself, but not of the way it is mentally constructed. In order to be cognitively plausible, models of the construction of semantic memory need to be approximately based on the kind of input to humans.

LSA is such model. Its performance is similar to those of human people. It needs an input of a few million words, which is comparable to what humans are exposed to (Landauer & Dumais, 1997). On the contrary, PMI-IR (Turney, 2001) is a good model of semantic similarities, even better than LSA in modeling human judgement of synonymy, but it is based on an input of thousands of millions of words, since it relies on all the texts published on the web. This is of course cognitively unplausible. HAL (Burgess, 1998) is another model of human memory. It is quite similar to LSA except that it does not rely on a dimension reduction step. It is currently based on a corpus of 300 million words, which is closer to the human inputs than PMI-IR, although this could be considered quite overestimated.

Further investigations

Our semantic space provides a means for researchers studying children's cognitive processes to design and simulate computational models on top of these basic representations. In particular, computational models of text comprehension could be tested using the basic semantic similarities that the space provides. It would also be possible to investigate the development of semantic memory by looking at the evolution of various semantic similarities according to the size of the corpus in detail. In particular, Landauer & Dumais (1997) claim that we learn the meaning of a word through the exposition to texts that do not contain it. Our semantic space gives the opportunity to test this assertion by checking the kind of paragraphs that cause an increase of similarity through incremental exposure to the corpus.

Improvements

Our semantic space could be improved in many ways. Its composition (50% stories, 25% production, 12.5% reading textbooks, 12.5% encyclopedia) is very rough and work has to be done to better know the amount and nature of texts that children are exposed to. Several studies led us to think that lemmatization could significantly improve the results, especially for the French language that has so many forms for some verbs. We did perform the previous experiments on a lemmatized version of the corpus (using the Brill tagger on the French files developed by ATILF, and the Flemm lemmatizer written by Fiametta Namer). Results were worse than with the non-lemmatized version. In order to know more about this surprising result, we distinguished between verbs and nouns. We found that the overall decrease is mainly due to a decrease for the nouns. One reason could be that the singular and plural forms of a noun are not arguments of the same predicates. For instance, the word *vague* (*wave*) is generally used in its plural form in the context of the *sea*, but more frequently in the singular form in its metaphorical meaning (*a wave of success*). Therefore, if both forms are grouped into the same one, this affects the co-occurrence relations and modifies the semantic representations.

Another way of improvement would have to deal with syntax. LSA does not take any syntactic information into account: all paragraphs are just bags of words. A slight improvement would consist in considering a more precise unit of context than a whole paragraph. A sliding context window (like in the HAL model for instance) would take into account the local context of each word. This might improve the semantic representations, while being cognitively more plausible. We are working in that direction.

For the moment, our model is an estimation. We cannot precisely identify to which age it corresponds. Our goal is to stratify it so that we would have a model for each age. Developmental models would then be able to be simulated.

Acknowledgements

This work was done while the second author was in sabbatical at the university of Aix-Marseille. We would like to thank D. Chesnet, E. Lambert and M.-A. Schelstraete, for providing us with parts of the corpus, F. de la Haye for the association data as well as M. Bourguet and H. Thomas for the design of the vocabulary test. We also thank P. Dessus and E. de Vries for their comments on a previous version.

Learning relations between concepts: classification and conceptual combination

Department of Computer Science, University College Dublin,
Belfield, Dublin 4, Ireland.

Abstract

People interpret noun-noun compounds like "wind power" by inferring a relational link between the compound's two constituent concepts. Various studies have examined how people select the best relation for a compound from a set of candidate relations. However, few studies have investigated how people learn such relations in the first place. This paper describes an experiment examining how people learn which relations are possible between concepts. Participants in this experiment learned artificial, laboratory controlled relations between pairs of items and then judged how likely those relations were for new pairs of items. The results showed that people's judgement of relation likelihood was reliably influenced by the presence of facilitating features for relations and by the diagnosticity of features for relations. A simple exemplar-based model of classification, using both diagnostic and facilitating features, was applied to people's judgements of relation likelihood. This model accurately predicted people's judgements of relation likelihood in the experiment, using no free parameters to fit the data.

Introduction

When, in everyday discourse, people encounter noun-noun compounds such as "mountain stream" or "lake boat", they interpret those compounds by inferring a relation that can be used to combine the two constituent concepts (inferring that a "mountain stream" is a stream that flows down a mountain, that a "lake boat" is a boat that sails on a lake). In theoretical accounts of conceptual combination, this process involves selecting the best relation for a compound from a set of candidate relations. Some theories give a standard set of candidate relations to be used in all compounds (Gagné & Shoben, 1997), while others derive candidate relations from the internal structure of the concepts being combined (Costello & Keane, 2000; Wisniewski, 1997). Many studies have investigated how people select the best relation for a given compound (e.g. Costello & Keane, 2001, Wisniewski, 1996). However, there have been very few studies investigating how people learn and form these relations in the first place. In this paper we aim to fill this gap.

The paper describes an experiment investigating how people learn relations between two sets of novel concepts. In the experiment we designed four different relations that could hold between artificial, laboratory-generated 'beetle' and 'plant' concepts. Participants learned these relations from sets of examples, with each example showing one sort of relation holding between one type of plant and one type of beetle. After learning, participants were shown new pairs of plants and beetles, and asked to say which of the four learned relations could hold between those two items.

This experiment was designed to examine two different possible factors in people's learning of relations between concepts: the presence of *diagnostic* features for those relations, and the presence of *facilitating* features. By diagnostic features for a relation we mean features of a constituent concept that are strongly associated with a particular relation. Diagnostic features are most familiar in the case of single concepts: for example "has four legs" and "is made of wood" are diagnostic features for the single concept *chair*: most things that are chairs have those features, and most things that are not chairs do not. Similarly, the feature "has a flat surface raised off the ground" might be diagnostic for the relation *is-sat-on-by*: most instances of the *is-sat-on-by* relation have that feature; most instances of other relations do not. In the experiment we asked whether people would use the diagnostic features for relations when selecting likely relations for beetle-plant pairs.

By facilitating features we mean the features of a pair of concepts that are necessary for a given relation to be possible, and without which that relation cannot hold. For example, while the compound "steel chair" can easily be interpreted using the *made-of* relation, the compound "kitchen chair" cannot possibly be interpreted as "a chair made of kitchens" simply because kitchens are not a type of substance. Being a substance is a necessary facilitating feature for an item to take part in the *made-of* relation. Again, in the experiment we asked how people would use such facilitating features when selecting likely relations for beetle-plant pairs.

This paper is organised as follows. In the next section we discuss the representation of relations in terms of sets of examples, as used in our experiment. We then describe the experiment in detail. To foreshadow the results, we found that both diagnostic and facilitating features had a reliable influence on people's selection of likely relations for pairs of items. We then describe how an exemplar-based model of concept conjunction (Costello, 2000, 2001) can be applied to the results of this experiment, giving a close fit to people's judgements of relation likelihood. Finally, we conclude by discussing the implications of our findings for theories of conceptual combination.

Learning Relations from Exemplars

Our primary assumption is that the relations selected during conceptual combination are essentially categories, just as the concepts that they link are essentially categories. We use an exemplar representation to describe these relational categories. Exemplar theories of classification, which propose that a category is represented as the set of remembered instances of that category and that new items are classified on the basis of their similarity to those instances (e.g. Medin & Schaffer, 1978; Nosofsky, 1984), have successfully accounted for a number of patterns seen in people's learning of single categories. We extend the exemplar approach to allow both relations and the concepts that they link to be represented by sets of instances.

In a category representing a single concept, each exemplar consists simply of a single set of features. For a category representing a relation, however, each exemplar consists of two sets of features: the features of the two single-category exemplars that are being linked by that relation. For example, suppose we have two categories *A* and *B* consisting of the set of exemplars $\{a_1, a_2, a_3, a_4, a_5, a_6\}$ and $\{b_1, b_2, b_3, b_4, b_5\}$ respectively. Each category represents a single concept, and each exemplar contains features describing one example of that concept. We can compute the membership of a given item in category *A*, for example, by comparing that item to the set of stored exemplars of category *A*. Then a relation *R* linking the concepts *A* and *B* might be represented as the set of exemplars of that relation, for example $\{(a_1, b_1), (a_1, b_2), (a_3, b_3), (a_4, b_4), (a_4, b_5)\}$. Regarding *R* as a category, we can compute the membership of any pair of items (x, y) in the relation *R* by comparing that pair to the set of exemplars of that relation. If more than one relation is defined, we can compute membership in each of the relations and make assertions about which relation the given pair of items is most likely to belong to.

This representation of relations in terms of a collection of pairs of category exemplars is motivated by how mathematical relations are defined in set theory. In set theory, binary relations are defined as sets of ordered pairs. To take a well-known example, the "is equal to" relation is a set denoted by =, and is defined on the integers to be the set {…, (-1, -1), (0, 0), (1, 1), (2, 2), …}. Thus the "is equal to" relation holds between two integers *x* and *y* if and only if the ordered pair (x, y) is a member of the set denoted =. We extend this set-theoretic idea of relations and propose that a relation between two concepts can be represented as a set of relation exemplars, where each of these relation exemplars is an ordered pair of category exemplars. Membership of a pair of items in a relational category is then computed by comparing that pair of items to the stored exemplars of that relational category, as is precisely the case for exemplar models of simple categories.

This approach assumes that when people are selecting the correct relation for a pair of items they may be performing a classification task in which they compare that pair of items to various sets of relation exemplars. What factors would we expect people to be influenced by in such a classification task? First, we would expect people pay attention to the features in items that are diagnostic for particular relations (that is, features that are present in most of the items that take part in the relation, and absent in most items that do not take part in the relation). If a particular feature is diagnostic for a relation, people should use that feature to identify new items likely to take part in that relation. Such a result would be consistent with other results in the classification literature, which reveal that people are attentive to diagnostic features when making determinations of category membership.

Second, we would expect people to pay attention to whether or not a given item has the facilitating features required for a given relation (as in our "kitchen chair" example). If a particular feature is present in every item that takes part in a certain relation, then we can assume that that feature may be necessary for that relation to take place: the feature may facilitate that relation. When confronted with a new pair of items which do not possess that facilitating feature, we would expect people not to select that relation for that pair of items. Note that a facilitating feature for a given relation may also be a diagnostic feature for that relation (if it occurs in every item that takes part in that relation *and* in no items that do not take part in that relation). However, a facilitating feature for a relation may also be non-diagnostic for that relation (if the feature occurs in every item that takes part in that relation, but also occurs in many items that do not take part in that relation). Next we describe an experiment examining the influence that facilitating and diagnostic features have on people's selection of relations for pairs of items.

A Categorisation Experiment

This experiment aims to test three hypotheses: that people can learn relations from sets of examples of those relations; that diagnostic features are important in people's selection of relations for pairs of items; and that facilitating features are also important in relation selection. The design of the experiment is essentially the same as other experiments in the category learning literature: a preliminary training phase where participants are exposed to exemplars of different artificial, laboratory controlled categories is followed by a test phase where participants are presented with new items and are asked to make judgements of category membership. The categories in this experiment are four different relations that can hold between pairs of objects. Each of the training items consists of two objects linked by one of these relations. The test items also consist of two objects; however these objects are not linked by any relation, and participants are asked to judge the likelihood of different relations holding between these items.

To examine the role of facilitating features in relation selection, the training items were designed so that two of the learned relations had facilitating features: we called these two relations the facilitated relations. Every time one of these relations occurred in the set of training items, a particular beetle or plant feature (the facilitating feature) was also present in that item. The other two relations did not have facilitating features: we called these two relations the independent relations. Similarly, the training items were designed so that some beetle and plant features were particularly diagnostic for some relations, and some features were not. In the training items, the diagnostic features for a particular relation occurred most frequently in beetle or plants taking part in that relation, and occurred rarely in other relations. The pairs of objects used in the test phase of the experiment consisted of various combinations of facilitating and diagnostic features for different relations. By examining participants' choice of relations to link the objects in these test items, we can then assess the influence of facilitating and diagnostic features in relation selection.

Method

Participants. 16 postgraduate students or recent college graduates volunteered to take part in the experiment. All were native speakers of English.

Materials. The materials for the training phase consisted of 18 visual stimuli on an A5-sized card depicting a cartoon

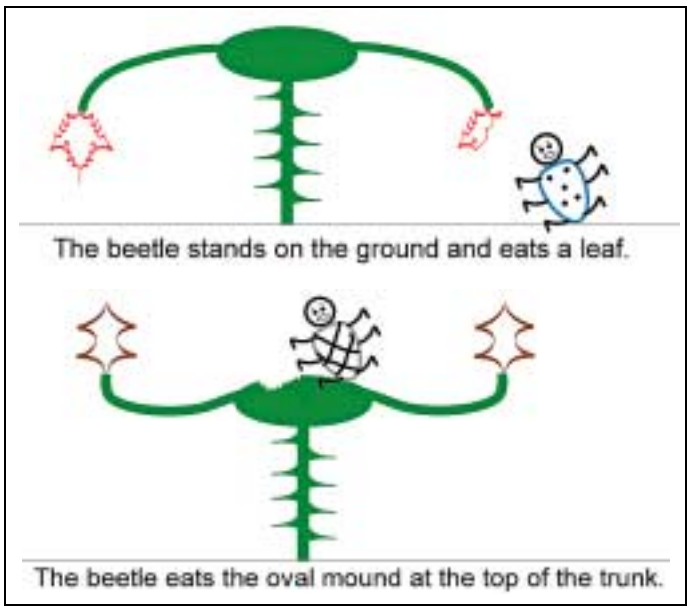

Figure 1: Two training phase stimuli.

beetle eating a plant. The beetles varied on three quaternary-valued feature dimensions: color of the shell, pattern on the shell, and facial expression. The plants varied on four feature dimensions: color of the leaves (quaternary-valued), shape of the leaves (quaternary-valued), droop of the branches (binary-valued), and whether there were buds or thorns on the trunk (binary-valued). There were four possible ways in which a beetle could eat a plant, corresponding to the four relational categories: the beetle could land on a leaf of a plant and eat the leaf (an independent relation), the beetle could eat from the top of the trunk of the plant (an independent relation), the beetle could eat from the trunk of the plant if there were buds rather than thorns on the trunk (a facilitated relation), or the beetle could stand on the ground and eat the leaf of a plant that had drooping branches (a facilitated relation). Underneath each picture was a sentence describing the eating behaviour that was talking place. Examples of the training phase's stimuli are presented in Figure 1.

These 18 items described a category structure for four relations, each relation being one of the different ways in which a beetle could eat a plant. The distribution of beetle and plant features was controlled so that some features would be facilitating for relations and so that some features would be diagnostic for relations. The distribution of beetle and plant features across the four different relation categories is shown in abstract form in Table 1. The numerical values in columns B1, B2 and B3 represent the different possible features that beetles could have; the values in columns P1, P2, P3, and P4 similarly represent the different possible features of plants. Each row in this table represents a different particular exemplar of one of the four relations R1, R2, R3 and R4.

In this experiment, we were interested in the influence which the distribution of features across items would have on people's selection of relations between items. We were not concerned with any effect which the physical properties of stimuli (e.g. the salience of different colours, the distinctiveness of different shapes) would have on people's

Table 1: The abstract relational category structures used in the training phase.

Item	Relation	Insect Features			Plant Features			
		B1	B2	B3	P1	P2	P3	P4
1	R1	1	1	1	1	1	1	2
2	R1	4	1	1	1	1	1	1
3	R1	2	2	2	4	1	1	2
4	R1	3	4	2	1	4	2	1
5	R1	3	3	3	1	1	1	1
6	R2	1	1	2	3	2	1	2
7	R2	2	2	2	3	2	1	1
8	R2	2	3	4	1	1	1	1
9	R2	3	4	3	2	3	2	2
10	R3	1	4	1	4	2	2	1
11	R3	1	1	4	2	2	2	1
12	R3	2	2	2	2	3	2	2
13	R3	3	2	4	2	3	2	1
14	R3	2	2	3	3	2	2	1
15	R4	1	3	1	4	3	2	2
16	R4	2	3	3	2	2	1	2
17	R4	3	2	3	3	3	1	2
18	R4	3	3	3	3	3	1	2

relation selection. Thus, while each participant's set of training items had the abstract structure shown in Table 1, each participant saw a unique set of physical stimuli. The abstract-to-physical mappings for the category dimensions and values for the two independent relations and for the two facilitated relations were balanced across participants. This was done so that the physical dimensions, values and relations would not be confounded with their abstract counterparts.

Facilitating and Diagnostic Features. The four relations in Table 1 were designed so that two relations had facilitating features (R3 and R4) and two did not (R1 and R2), and two relations had highly diagnostic features (R1 and R3) and two had less diagnostic features (R2 and R4). Relations R1 and R2 were the independent relations, while relations R3 and R4 were the facilitated ones. P3 is the facilitating dimension for relation R3: every exemplar of R3 involves an item with a value of 2 on dimension P3. Similarly P4 is the facilitating dimension for relation R4: every exemplar of R4 involves an item with a value of 2 on dimension P4. (In the experimental materials, the facilitating features were instantiated in a causally meaningful way. For example, the physical relation "the beetle stands on the ground and eats the leaf" had the facilitating feature "drooping branches on the plant").

Of the two independent relations, R1 has highly diagnostic features while R2 has less diagnostic features. Relation R1 has two highly diagnostic features: a 1 on P1 and a 1 on P2. Relation R2, however, has no particularly diagnostic features. (R2 is therefore a very vague category, not well distinguished by either diagnosticity or facilitating features). Of the two facilitated relations, R3 has highly diagnostic features while R4 has less diagnostic features. For relation R3, a 2 on

dimension P3 is a highly diagnostic feature for that relation, occurring five out of five times in examples of that relation and only three times outside it. (Note that this feature, a 2 on P3, is also the facilitating feature for relation R3). Relation R4, however, has no such highly diagnostic feature, although a 3 on B2 and a 3 on B3 are both moderately diagnostic for that relation. (R4's facilitating feature is not very diagnostic, occurring four times within the category and five times outside it.)

The materials for the test phase consisted of more visual stimuli depicting beetles and plants; however in these pictures the beetles and plants were shown separately, without any eating or any other interaction taking place. Underneath each test picture was the question "How likely are the different types of eating behavior?", followed by the four relation description sentences, each of which was accompanied by a 7-point scale ranging from -3 (labelled "not at all likely") to +3 ("extremely likely"). The order in which the four scales were presented was balanced across participants.

The test phase consisted of 29 beetle-plant pairs. Of these, nine pairs were selected from the 18 beetle-plant pairs that had been presented in the training phase, but now without the eating behaviour shown. These nine previously-seen pairs were used to assess how accurately participants learned the training items they had studied. The remaining 20 test items (beetle-plant pairs) had not been seen previously by participants. For these items the properties of interest are whether or not the facilitating feature of relation R3 or of relation R4 is present, and whether or not the item had features diagnostic for particular relations.

Procedure. The experiment consisted of two sections: a training phase where participants studied the training items (pairs of beetles and plants taking part in particular relations), and a test phase where they had to rate the likelihood of the different possible relations for a sequence of beetle-plant pairs. Participants were asked to pretend to be biologists interested in learning about imaginary plants and beetles and the relationship between them. The seven dimensions on which the beetles and plants could vary were explicitly pointed out to participants. It was pointed out to participants that they might find it useful to try to learn about the eating behaviour by looking for relationships between features and types of eating, or by learning the features of individual examples and remembering the type of eating occurring with them. Participants spent about five minutes reading the instructions, during which time the experimenter answered any questions they had. After reading the instructions participants were presented with the 18 training items at a large desk area. Participants were given 12 to 15 minutes to study the training items.

After the training phase, the 18 training items were removed and participants were given the 29 test items. Participants were first shown the nine test items corresponding to items they had studied in the first part of the experiment. Participants were told to mark an integer value on each of the four scales describing how likely they felt the four possible types of eating behaviour were. Following these nine items 20 new test items were presented to the participants. The order in which the items were presented was randomized for each participant, and participants were allowed to rate the items at their own pace.

Results

Participants' learning of the training items. For these nine items there was a "correct" relation (each item was a member of one category during the learning phase) and three "incorrect" relations (corresponding to the other three categories). The responses for each relation and each experimental item were classified as either positive (> 0) or non-positive (≤ 0), depending on how the participant responded on each scale. On average, participants gave a positive rating to correct relations 71% of the time and a positive rating to incorrect relations 33% of the time. Two participants gave a positive score to only four correct relations; these two participants were excluded from the analysis. The remaining 14 participants gave a positive rating to correct relations 75% of the time and a positive rating to incorrect relations only 25% of the time. These results indicate that participants learned to distinguish between the categories in the training phase.

Participants' sensitivity to facilitating features. One-tailed binomial tests with $\alpha = 0.05$ were used to identify whether the presence or absence of the facilitating features for a relation had an effect on how participants responded when grading the likelihood of that relation. The proportion of positive responses for each of the four relations was the statistic of interest.

First we considered the items in which the facilitating features for a given relation were absent. Of the 29 test items, 16 were items for which the facilitating feature for relation R3 was absent and 16 were items for which the facilitating feature for relation R4 was absent. For relation R3, the binomial test was significant for 13 of the 14 participants; in other words, 13 of the 14 participants were significantly more likely to produce a non-positive rather than a positive response to relation R3 when the facilitating feature for relation R3 was absent. (Indeed, 10 participants *never* produced a positive response). For relation R4, 10 of the 14 participants were significantly more likely to produce a non-positive rather than a positive response. (Here, five participants never produced a positive response).

A similar analysis was performed looking at the items where the facilitating feature was present. Of the 29 test items, 13 were items for which the facilitating feature for relation R3 was present and 13 were items for which the facilitating feature for relation R4 was present. For relation R3, 8 of the 14 participants were significantly more likely to produce a positive rather than a non-positive response. For relation R4, 7 of the 14 participants were significantly more likely to produce a positive rather than a non-positive response. These results are sensible considering that in many cases participants will rate a relation as having low likelihood for a given item, even when that relation's facilitating feature is present in the item: the facilitating feature doesn't mean that the relation must be selected for this item, only that it is a possibility. The difference in these results between items that had and items that had not the facilitating feature for a relation indicate that participants were highly sensitive to the presence and absence of those features.

Participants' sensitivity to diagnostic features. The diagnosticity of a feature for a category is a measure of how

good that feature is at identifying membership of that category. If a feature appears in many items in a category and few items outside a category then that feature will have high diagnosticity. More formally, we can define the diagnosticity of a feature *f* for a category *C* to be

$$D(f,C)=\frac{|C\cap E_f|}{|C\cup E_f|} \qquad \text{(Eq. 1)}$$

where E_f denotes the set of exemplars that have feature *f*. Using this formula we calculated the average diagnosticity of the features of each of the 29 test items for each of the four relational categories and compared this to the observed data. For two of the four relations, the amount of diagnosticity for items had a high correlation with the observed membership ratings for the items (for R1, $r = 0.83$, $p < 0.01$, *%var* = 69%; for R4, $r = 0.81$, $p < 0.01$, *%var* = 65%). For the other two relations, the correlation was less strong though still significant (for R2, $r = 0.66$, $p < 0.01$, *%var* = 43%; for R3, $r = 0.70$, $p < 0.01$, *%var* = 49%). These results indicate that participants were sensitive to diagnostic features when making their category judgements.

Diagnostic and facilitating features. Relations R1 and R2 were the independent relations: membership in these relations did not depend on facilitating features. Diagnosticity was very important for identifying members of R1 but was not very important for identifying members of R2. We would therefore expect the correlation of diagnosticity to the observed memberships to be higher for relation R1 than relation R2; this is the case in the above analysis of the effect of diagnostic features.

Relations R3 and R4 were the facilitated relations: membership in these relations depended on both diagnostic features and facilitating features. R3 was designed to have highly diagnostic features, while R4 was designed to have less diagnostic features. The diagnosticity analysis above, however, shows that the correlation of the observed memberships with diagnosticity was lower for R3 than for R4. The divergence between diagnosticity and membership ratings for these relations suggests an interaction between diagnosticity and facilitating features.

As a way of examining this interaction we looked at the total number of positive and non-positive responses across all participants for relations R3 and R4; they are presented in Table 2. For cases where the facilitating feature is present, there are less positive responses for R4 than for R3 and more non-positive responses for R4 than R3. Conversely, for cases where the facilitating feature is absent, there are less positive responses for R3 than for R4 and more non-positive responses for R3 than R4. These data suggest that participants are more sensitive to the presence or absence of the facilitating feature for R3 than they are for R4. This is consistent with the fact that the facilitating feature for R3 is more diagnostic for R3 than the facilitating feature for R4 is diagnostic for R4. In other words, people seem to be using both the facilitating nature and the diagnosticity of features together in deciding relation likelihood for these relations. In the next section we investigate this interaction between diagnosticity and facilitating features in more detail by applying a model of classification to our data.

Table 2: Total number of positive and non-positive responses across all participants

	Facilitating Feature Present		Facilitating Feature Absent	
	Positive	Non-positive	Positive	Non-positive
R3	130	52	14	210
R4	123	59	30	194

Modelling Relation Selection

We are interested in how people used facilitating and diagnostic features when making judgements of relation likelihood in our experiment. As we have seen, our results indicate an interaction between diagnosticity and facilitating features. We are also interested in whether or not our view of relations in terms of exemplar-represented categories can successfully account for the results of the above experiment. To explore these issues, we examined whether an exemplar model of categorization could be used to model participants' responses of how likely each relation is for each item in the experiment. We used as our starting point Costello's (2000, 2001) Diagnostic Evidence Model (DEM) which uses diagnostic features to model classification in concept combination. This model calculates an evidence score for an item *x* in a category *C* using the diagnosticity of each feature of the item for that category according to the formula

$$E(x,C)=1-\prod_{f\in F_x}\left(1-D(f,C)\right) \qquad \text{(Eq. 2)}$$

where F_x is the set of features of *x* and $D(f, C)$ is computed as in Equation 1. (Equation 2 essentially sees category membership as a disjunction of the feature diagnosticities and is not dissimilar to simply averaging the diagnosticities as we did in the previous section). As a preliminary step we applied this model to the experimental data without using any information about facilitating features: the model is only sensitive to features' diagnosticity. In this form the model still produces a reasonable fit to the data (for R1, $r = 0.88$, $p < 0.01$, *%var* = 78%; for R2, $r = 0.63$, $p < 0.01$, *%var* = 40%; for R3, $r = 0.73$, $p < 0.01$, *%var* = 53%; for R4, $r = 0.72$, $p < 0.01$, *%var* = 52%), with no free parameters.

The model in this form uses diagnostic information alone. However, the results of our experiment indicate that people make use of both diagnosticity and facilitating features in determining the relations. One possible account of how people use both these types of information is that people are applying diagnosticity information after they have been constrained by the presence or absence of the facilitating features. Perhaps people check if an item has the necessary facilitating features for a particular relation and then, if it does, use the diagnostic evidence of the features. In modifying the model we therefore assume that participants' do not use known exemplars which depict a relation that is impossible for the test item at hand: facilitating features restrict the universe of discourse so that membership of an item in a relational category is a calculation across the subset of the learned exemplars that belong to relational categories that are possible for the current item. Our formula for

diagnosticity then becomes

$$D(f,x,C) = \frac{\left|C \cap E_f \cap R_x\right|}{\left|\left(C \cup E_f\right) \cap R_x\right|} \qquad \text{(Eq. 3)}$$

where R_x is the set of known exemplars that belong to relations that are not impossible given the features of *x*. This modified model gives a much closer fit to the observed relation selection ratings (for R1, $r = 0.89$, $p < 0.01$, *%var* = 79%; for R2, $r = 0.78$, $p < 0.01$, *%var* = 61%; for R3, $r = 0.98$, $p < 0.01$, *%var* = 0.96; for R4, $r = 0.96$, $p < 0.01$, *%var* = 0.92), again with no free parameters. Clearly, both information about the diagnosticity of features and information about the presence or absence of facilitating features are required to accurately model the experimental data.

Though this modified DEM model may not be the best way of modelling the data, it does suggest that using information about both the facilitating features and diagnosticity of features of an item are important in selecting relations. The fact that an exemplar model of classification can predict how people rate the likelihood of different relations linking pairs of items is also evidence in support of the hypothesis that relations can be represented as categories. This suggests that relation selection can be thought of as a kind of classification task.

Conclusions and Discussion

Our study yields three findings. First, people can learn which relations are possible between concepts from sets of examples of those relations. Second, people pay attention to facilitating features for those relations and use those features when judging relation likelihood for new examples. Third, people also pay attention to, and use, diagnostic features for those relations. Such findings are consistent with our hypothesis that relations can be represented with an exemplar category structure, and that the selection of a relation between two constituents can be seen as a categorisation task. These findings have implications for current theories of how relational links are used in conceptual combination. In particular, these findings may be problematic for Gagné & Shoben's (1997) CARIN model, which proposes that in conceptual combination people select the correct relational link between two concepts from a fixed set of 16 relational links called *thematic relations*. First, the thematic relations used in the CARIN model have no internal structure: there is no way, in that model, in which facilitating or diagnostic features could be associated with those relations (for example, the MADE-OF relation in the CARIN model how has no way of requiring that a concept taking part in it is type of substance). Furthermore, the four different relations we used in our experiment do not occur in the CARIN model's fixed set of thematic relations: it would be hard for that model to explain how people used these relations in our experiment.

Our findings are consistent with other theories of conceptual combination (e.g. Costello and Keane, 2000; Murphy, 1988; Wisniewski, 1997) which do allow internal conceptual structure to influence relation selection. These theories use some variation of the idea that a concept representation can contain 'slots' such as MADE-OF or LOCATED and that conceptual combination involves one concept filling a slot in another concept (so that "kitchen chair", for example, would involve the "kitchen" concept filling the LOCATED slot in "chair"). The exemplar-based model of relation selection described in this paper provides an alternative to this slot-based representation of relations, showing that relations can be represented as sets of paired-item exemplars, rather than as slots in concepts. This exemplar-based model has the advantage of giving a simple account of how people learn which facilitating and diagnostic properties are associated with each relation.

As for future work: in our experiment, participants learned relational categories only, and did not learn conceptual categories (they did not learn different categories of beetle or plant, for example). A possible extension of this work would be to have participants learn, from sets of exemplars, both conceptual categories and the relational categories that link them. This experiment could reveal more both about how relations are learned and used, and about how exemplar-level and conceptual-level information interact in conceptual combination.

Abstract

Simple decision heuristics that process cues in a particular order and stop considering cues as soon as a decision can be made have been shown to be both accurate and quick. But one criticism of heuristics such as Take The Best is that these owe much of their simplicity and success to the not inconsiderable computations necessary for setting up the cue search order before the heuristic can be used. The criticism, though, can be countered in two ways: First, there are typically many cue orders possible that will achieve good performance in a given problem domain. And second, as we will show here, there are simple learning rules that can quickly converge on one of these useful cue orders through exposure to just a small number of decisions. We conclude by arguing for the need to take into account the computation necessary for not only the application but also the setup of a heuristic when talking about its simplicity.

One-Reason Decision Making and Ordered Search

In the book *Simple heuristics that make us smart*, Gigerenzer and colleagues (1999) propose several decision making heuristics for predicting which of two objects or options, described by multiple binary cues, scores higher on some quantitative criterion. These heuristics have in common that information search is stopped once one cue is found that discriminates between the alternatives and thus allows an informed decision. No integration of information is involved, leading these heuristics to be termed "one-reason" decision mechanisms. These heuristics differ only in the search rule that determines the order in which information is searched. But where do these search orders come from?

"Take the Best" (TTB; Gigerenzer & Goldstein, 1996, 1999) is the heuristic that has received most attention to date, both theoretically and empirically. TTB consists of three building blocks:

1. Search rule: Search through cues in the order of their validity. Validity is the proportion of correct decisions made by a cue out of all the times that cue discriminates between pairs of options.

2. Stopping rule: Stop search as soon as one cue is found that discriminates between the two options.

3. Decision rule: Select the option to which the discriminating cue points, that is, the option that has the cue value associated with higher criterion values.

The performance of TTB has been tested on several real-world data sets, ranging from professors' salaries to fish fertility (Czerlinski, Gigerenzer & Goldstein, 1999). Cross-validation comparisons have been made against other more complex strategies, such as multiple linear regression, by training on half of the items in each data set to get estimates of the relevant parameters (e.g., cue order based on validities for TTB, beta-weights for multiple linear regression) and testing on the other half of the data. Despite only using on average a third of the information employed by multiple linear regression, TTB outperformed regression in accuracy when generalizing to the test set (71% vs. 68%).

The even simpler heuristic Minimalist was tested in the same way. It is another one-reason decision making heuristic that differs from TTB only in its search rule. Minimalist searches through cues randomly, and thus requires even less knowledge and precomputation than TTB – all it needs to know are the directions in which the cues point. Again it was surprising that this heuristic performed reasonably close to multiple regression (65%). But the fact that Minimalist lagged behind TTB by a noticeable margin of 6 percentage points indicates that part of the secret of TTB's success lies in its ordered search.

In this paper, we explore how such useful cue orders can be constructed in the first place, by testing a variety of simple order-learning rules in simulation. We find that simple mechanisms at the learning stage can enable simple mechanisms at the decision stage, such as one-reason decision heuristics, to perform well.

Experimental Evidence for Ordered Search

From an adaptive point of view, the combination of simplicity and accuracy makes one-reason decision making with ordered search, as in TTB, a plausible candidate for human decision processes. Consequently, TTB has been subjected to several empirical tests. Because TTB explicitly specifies information search as one aspect of decision making, it must be tested in situations in which cue information is not laid out all at once, but has to be searched for one cue at a time, either in the external environment or in memory (Gigerenzer & Todd, 1999).

In situations where information must be searched for sequentially in the external environment, particularly when there are direct search costs for accessing each successive cue, considerable use of TTB has been demonstrated (Bröder, 2000, experiments 3 & 4; Bröder, 2003). This also holds for indirect costs, such as from time pressure (Rieskamp & Hoffrage, 1999), as well as for internal search in memory (Bröder & Schiffer, 2003). The particular search order used has not always been tested separately, but when such an analysis at the level of building blocks has been done, search by cue validity order has received support (Newell & Shanks, 2003; Newell, Weston & Shanks, 2003).

However, none of these experiments tested search rules other than validity ordering. One other very important dimension on which cues can be ordered is discrimination rate, which refers to the proportion of all possible decision pairs in which a cue has different values for (i.e., discriminates between) the two alternatives[1]. A closer look into the experimental designs of the studies cited above reveals that they all used systematically constructed environments in which discrimination rates of the cues were held constant. Now, when the discrimination rates of cues are all the same, there are not many orders besides validity that make sense. To put it differently, identical discrimination rates make several alternative ordering criteria that combine discrimination rate and validity (e.g., Martignon & Hoffrage, 2002) all lead to the same (validity) order. Examples for such criteria are *success*, which is the proportion of correct discriminations that a cue makes plus the proportion of correct decisions expected from guessing in the non-discriminating trials (success = $v \cdot d + 0.5 \cdot (1-d)$, where v = validity and d = discrimination rate of the cue), and *usefulness,* the portion of correct decisions not including guessing (usefulness = $v \cdot d$).

Because these criteria collapse to a single order (validity) in the reported experiments, nothing can be said about how validity and discrimination rate may interact to determine the search orders that participants apply. It remains unclear what information participants would base their decisions on when both validity and discrimination rate vary. There are hints that when information is costly, making it sensible to consider both how often a cue will enable a decision (i.e., its discrimination rate) and the validity of those decisions, other criteria such as success that combine the two measures show a better fit to empirical data (e.g., Newell, Rakow, Weston & Shanks, in press; Läge, Hausmann, Christen & Daub, submitted). But these studies, too, remain silent about how these criteria, or an order based on these criteria, could possibly be derived by participants.

In sum, despite accumulating evidence for the use of one-reason decision making heuristics, the basic processes that underlie people's search through information when employing such heuristics remain a mystery. While some clues can be had by considering the size of the overlap or correlations between the search orders people use and various standard search orders (as reported by Newell et al., in press, and Läge et al., submitted), they do not come close to telling us how cue orders could possibly be learned.

Search Order Construction – the Hard Way

But how can the search order of TTB be constructed? Although TTB is a very simple heuristic to apply, the set-up of its search rule requires knowledge of the ecological validities of cues. This knowledge is probably not usually available in an explicit precomputed form in the environment, and so must be computed from stored or ongoing experience. Gigerenzer at al. (1999) have been relatively silent about the process by which people might derive validities and other search orders, a shortfall several peers have commented on (e.g., Lipshitz, 2000; Wallin & Gärdenfors, 2000). The criticism that TTB owes much of its strength to rather comprehensive computations necessary for deriving the search order cannot easily be dismissed. Juslin and Persson (2002) pay special attention to the question of how simple and informationally frugal TTB actually is, debating how to take into account the computation of cue validities for deriving the search order. They differentiate two main possibilities on the basis of when cue validities are computed: precomputation during experience, and calculation from memory when needed.

When potential decision criteria are already known at the time objects are encountered in the environment, then relevant validities can be continuously computed and updated with each new object seen. But if it is difficult to predict what decision tasks may arise in the future, this pre-computation of cue validities runs into problems. In that case, at the time of object exposure, all attributes should be treated the same, because any one could later be either a criterion or a cue depending on the decision being made. To use the well-known domain of German cities (Gigerenzer & Goldstein, 1996, 1999), the task that one encounters need not be the usual prediction of city populations based on cues such as train connections, but could just as well be which of two cities has an intercity train line based on cues that include city population. To keep track of all possible validities indicating how accurately one attribute can decide about another, the number of precomputed validities would have to be $C^2 - C$, with C denoting to the number of attributes available. In the German cities example, there are 10 attributes (9 cues plus the criterion population size), thus 90 validities would have to be pre-computed. This number rises rapidly with increasing number of attributes. Even ignoring computational complexity, this precomputation approach is not frugal in terms of information storage.

As a second possibility, Juslin and Persson (2002) consider storing all objects (exemplars) encountered along with their attribute values and postponing computation of validities to the point in time when an actual judgment is required. This, however, makes TTB considerably less frugal during its application. The number of pieces of information that would have to be accessed at the time of judgment is the number of attributes times the number of stored objects; in our city example, it is 10 times the number of known objects. With regard to computing validities for each of the $N \cdot (N-1)/2$ possible pairs that can be formed between the N known objects, each of the C cues has to be

[1] Other dimensions for ordering are possible, such as the temporal order of previous cue use, but we will not consider them here.

checked to see if it discriminated, and did so correctly. Thus the number of checks to be performed before a decision can be made is C·N·(N-1)/2, which grows with the square of the number of objects.

Although Juslin and Persson assume worst case scenarios in terms of computational complexity for the sake of their argument, they raise an important point, showing that one of the fundamental questions within the framework of the ABC research group (Gigerenzer et al., 1999) remains open: How can search orders be derived in relatively simple ways?

Many Roads Lead (Close) to Rome

From what we have said so far, the situation does not look too good for validity either in terms of empirical evidence or psychological feasibility. But what would be the consequence in terms of loss in accuracy if we drop the assumption that cue search follows the validity order? Simulation results can provide an answer. First of all, validity is usually not the best cue ordering that can be achieved. For the German city data set, Martignon and Hoffrage (2002) computed the performance of all possible orderings, assuming one-reason stopping and decision building blocks. The number of possible orders was 362,880 (9! orders of 9 cues). The mean accuracy of the resulting distribution corresponded to the performance expected from Minimalist, 70%, which was considerable above the worst ordering at 62%. Ordering cues by validity led to an accuracy of 74.2%, while the optimal ordering yielded 75.8% accuracy. More than half of all possible cue orders do better than the random order used by Minimalist, and 6,532 (1.8%) do better than the validity order. We can therefore conclude that many good orders exist. But how can one of these many reasonably good cue orders be constructed in a psychologically plausible way?

Search Order Construction – the Simple Way

A variety of simple approaches to deriving and continuously updating search orders can be proposed. Indeed, computer scientists have explored a number of self-organizing sequential search heuristics for the purpose of speeding retrieval of items from a sequential list when the relative importance of the items is not known a priori (Rivest, 1976; Bentley & McGeoch, 1985). The mechanisms they have focused on use transposition of nearby items and counting of instances of retrieval. Our problem of cue ordering is slightly different from that of the standard sequential list ordering, because cues can fail in ways that retrieved items cannot: a cue may not discriminate (necessitating the search for another cue before a decision can be made), or it may lead to a wrong decision. Still, the mechanisms of transposition and counting will be central to the heuristics we propose.

We focus on search order construction processes that are psychologically plausible by being frugal both in terms of information storage and in terms of computation. The decision situation we explore is different from the one assumed by Juslin and Persson (2002) who strongly differentiate between learning of (or about) objects and making decisions. Instead of assuming this unnecessary separation, we will explore a learning-while-doing situation. Certainly there are many occasions akin to Juslin and Persson's situation where individuals have to make decisions based on knowledge they have learned about objects encountered previously and in a different task context. But perhaps more common are tasks that have to be done repeatedly with feedback being obtained after each trial about the adequacy of one's decision. For instance, we can observe on multiple occasions which of two supermarket checkout lines, the one we have chosen or (more likely) another one, is faster, and associate this outcome with cues including the lines' lengths and the ages of their respective cashiers. In such situations, one can learn about the differential usefulness of cues for solving the task via the feedback received over time. It is this case – decisions made repeatedly with the same cues and criterion and the opportunity to learn from outcome feedback – which we will now look at more closely.

We consider several explicitly defined cue order learning rules that are designed to deal with probabilistic inference tasks. In particular, the task we use is forced choice paired comparison, in which a decision maker has to infer which of two objects, each described by a set of binary cues, is "bigger" on a criterion – the task for which TTB was formulated. Thus, in contrast to Juslin and Persson (2002), we assume individuals encounter decision situations instead of objects. After an inference has been made, feedback is given about whether a decision was right or wrong. Therefore, the learning algorithm has information about which cues were looked up, whether a cue discriminated, and whether a discriminating cue led to the right or wrong decision. There are different possibilities for taking these pieces of information into account. For example, correct decisions could be counted up for each cue (essentially keeping tallies). Or the information could be used to compute cue validities and discrimination rates based on the cases in which the cue has actually been looked up so far. These tallies, validity estimates, etc., would then be used for creating and adjusting the current cue order.

The rules we propose differ in the pieces of information they use and how they use them. We classify the learning rules based on their memory requirement – high versus low – and their computational requirements (see Table 1). The computational requirements include whether the entire set of cues is completely reordered after each decision or only adjusted locally via swapping of neighboring cue positions, and whether reordering is done on the basis of measures involving division, such as validity, or simple tallying.

The *validity rule* is the most demanding of the rules we consider in terms of both memory requirements and computational complexity. It keeps a count of all discriminations made by a cue so far (in all the times that the cue was looked up) and a separate count of all the correct discriminations. Therefore, memory load is comparatively high. The validity of each cue is determined by dividing its current correct discrimination count by its

Table 1: Learning rules classified according to memory and computational requirements

High memory load, complete reordering	High memory load, local reordering	Low memory load, local reordering
Validity: reorders cues based on their current validity Tally: reorders cues by number of correct minus incorrect decisions made so far	Tally swap: moves cue up (down) one position if it has made a correct (incorrect) decision if its tally of correct minus incorrect decisions is ≥ (≤) that of next higher (lower) cue	Simple swap: moves cue up one position if it has made a correct decision, and down if it has made an incorrect decision
Variants: - *reorder based on tally of discriminations so far* - *reorder based on tally of correct decisions only*	*Variants:* - *only upward swapping after correct decisions* - *tally of correct decisions only*	*Variants:* - *moving cues more than one position* - *only upward swapping after correct decisions*

total discrimination count. Based on these values computed after each decision, the rule reorders the whole set of cues from highest to lowest validity.

The *tally rule* only keeps one count per cue, storing the number of correct decisions made by that cue so far minus the number of incorrect decisions. So if a cue discriminates correctly on a given trial, one point is added to its tally. If it leads to an incorrect decision, one point is subtracted from its tally. The tally rule is less demanding both in terms of memory and computation: Only one count is kept, and no division is required.

While the validity and tally rules rely on a counting mechanism, the *simple swap rule* uses the principle of transposition (cf. Bentley & McGeoch, 1985). This rule has no memory of cue performance other than an ordered list of all cues, and just moves a cue up one position in this list whenever it leads to a correct decision, and down if it leads to an incorrect decision. In other words, a correctly deciding cue swaps positions with its nearest neighbor upwards in the cue order, and an incorrectly deciding cue swaps positions with its nearest neighbor downwards.

The *tally swap rule* is a hybrid of the simple swap rule and the tally rule. It keeps a tally of correct minus incorrect discriminations per cue so far (so memory load is high) but only locally swaps cues: When a cue makes a correct decision and its tally is greater than or equal to that of its upward neighbor, the two cues swap positions. When a cue makes an incorrect decision and its tally is smaller than or equal to that of its downward neighbor, the two cues also swap positions.

As indicated in table 1, many variants of these basic types of learning rules are possible. Here we will focus on these four rules spanning the space of possibilities, and look at how they perform in simulations. Elsewhere we consider evidence for their use in experimental decision settings, and use these simulation results to assess human performance.

Simulation Study of Simple Ordering Rules

To test the performance of these order learning rules, we use the German cities data set (Gigerenzer & Goldstein, 1996), consisting of the 83 highest-population German cities described on 9 cues. The question we want to address is, what would happen if a decision-maker does not search for cues in validity order from the beginning, but instead must construct a search order using feedback received about each decision made? We assume that cue directions are known. Furthermore, instead of allowing the decision maker to look up information about all 9 cues in each pair comparison, we assume that TTB's stopping and decision rule are used on all decisions. We do this because it is more natural to assume that learning happens in the ongoing context of decision making, which does not necessarily involve exhaustive information search. This runs counter the approach taken by Juslin and Persson (2002) who in their worst case scenarios assume exhaustive information search for validity computations. In our approach, only the limited information gathered until the first discriminating cue is found can be taken into account.

We simulated 10,000 learning trials for each rule, starting from random initial cue orders. Each trial consisted of 100 decisions between randomly selected decision pairs. Below we report average values across the 10,000 trials.

Results

We start by considering the cumulative accuracies (i.e., online or amortized performance – Bentley & McGeoch, 1985) of the rules, defined as the total percentage of correct decisions made so far at any point in the learning process. (The contrasting measure of offline accuracy – how well the current learned cue order would do if it were applied to the entire test set – is a less psychologically useful indication of a real decision maker's performance using some rule.) The mean cumulative accuracies of the different search order learning rules when used with one-reason decision making are shown in Figure 1. Cumulative accuracies soon rise above that of the Minimalist heuristic (proportion correct = 0.70) which looks up cues in random order and thus serves as a lower benchmark. However, at least throughout the first 100 decisions, cumulative accuracies stay well below the (offline) accuracy that would be achieved by using TTB for

all decisions (proportion correct = 0.74), looking up cues in the true order of their ecological validities.

The four learning rules all perform on a surprisingly similar level, with less than one percentage point difference in favor of the most demanding rule (i.e., validity) compared to the least (i.e., simple swap; mean proportion correct in 100 decisions: validity learning rule: 0.719; tally: 0.716; tally swap: 0.715; simple swap: 0.711). Importantly, though, the more demanding learning rules outperform Minimalist earlier. Whereas the tally swap and simple swap rule lead to accuracies that are significantly higher than Minimalist only after 48 and 61 decisions, respectively, the validity learning rule does significantly better already after 37 decisions, and the tally rule after 35 decisions ($z = 1.65$, $p = 0.05$).

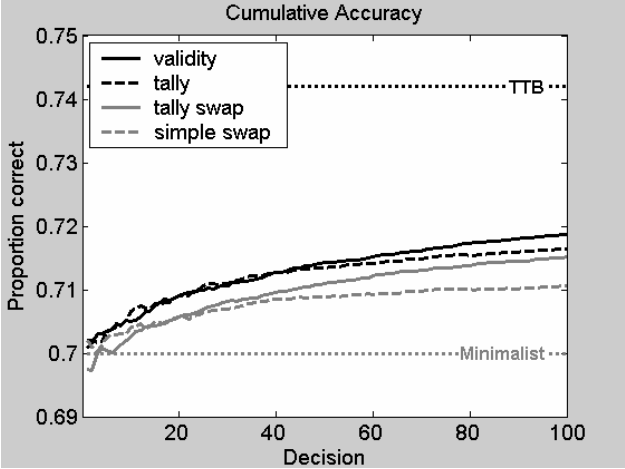

Figure 1: Mean cumulative accuracy of order learning rules

These four learning rules are, however, all more *frugal* than TTB, and even more frugal than Minimalist. On average, they look up fewer cues before reaching a decision (see Figure 2). Again, there is little difference between the rules (mean number of cues looked up in 100 decisions: validity learning rule: 3.17; tally: 3.07; tally swap: 3.13; simple swap: 3.18). The validity learning rule and the tally rule lead to cue orders that are significantly more frugal than Minimalist very early (after 16 and 14 decisions, respectively), whereas the two swapping rules take longer: The tally swap rule takes 27 decisions, and the simple swap rule 32 decisions.

Consistent with this finding, all of the learning rules lead to cue orders that show positive correlations with the discrimination rate cue order (reaching the following values after 100 decisions: validity learning rule: $r = 0.18$; tally: $r = 0.29$; tally swap: $r = 0.24$; simple swap: $r = 0.18$). This means that cues that often lead to discriminations are more likely to end up in the first positions of the order. In contrast, the cue orders resulting from all learning rules but the validity learning rule do not correlate with the validity cue order, and even the correlations of the cue orders resulting from the validity learning rule after 100 decisions only reach an average $r = 0.12$.

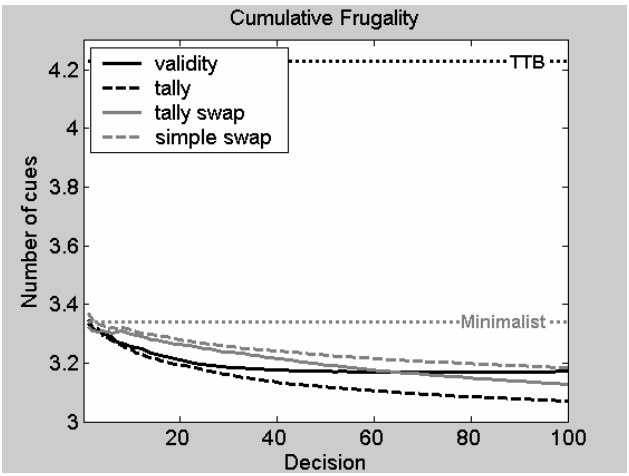

Figure 2: Mean cumulative frugality of order learning rules

But why would the discrimination rates of cues exert more of a pull on cue order than validity, even when the validity learning rule is applied? Part of the explanation comes from the fact that in the city data set we used for the simulations, validity and discrimination rate of cues are negatively correlated. Having a low discrimination rate means that a cue has little chance to be used and hence to demonstrate its high validity. Whatever learning rule is used, if such a cue is displaced downward to the lower end of the order by other cues, it may never be able to escape to the higher ranks where it belongs. The problem is that when a decision pair is finally encountered for which that cue would lead to a correct decision, it is unlikely to be checked because other, more discriminating although less valid, cues are looked up before and already bring about a decision. Thus, because one-reason decision making is intertwined with the learning mechanism and so influences which cues can be learned about, what mainly makes a cue come early in the order is producing a high *number* of correct decisions and not so much a high *ratio* of correct discriminations to total discriminations regardless of base rates.

In sum, all of the learning rules lead to accuracies between that of the heuristics TTB and Minimalist, but some rules reach orders that are better than Minimalist sooner. The rules are highly frugal, with a (slight) tendency to change the order in the direction of discrimination rate.

Discussion

The simpler cue order learning rules we have proposed do not fall far behind a validity learning rule in accuracy. This holds even for the simplest rule, which only requires memory of the last cue order used and moves a cue one position up in that order if it made a correct decision, and down if it made an incorrect decision. All of the rules considered here make one-reason decision heuristics perform above the level of Minimalist in the long run.

On the other hand, the four rules, even the validity learning rule, stay below TTB's accuracy across a relatively high number of decisions. But often it is necessary to make good decisions without much experience. Therefore, learning rules should be preferred that quickly lead to orders

with good performance. Both the validity and tally learning rules quickly beat Minimalist. At the same time, the tally rule leads to considerably more frugal cue orders.

Remember that the tally rule assumes full memory of all correct minus incorrect decisions made by a cue so far. But this does not make the rule implausible. There is considerable evidence that people are actually very good at remembering the frequencies of events. Hasher and Zacks (1984) conclude from a wide range of studies that frequencies are encoded in an automatic way, implying that people are sensitive to this information without intention or special effort. Estes (1976) pointed out the role frequencies play in decision making as a shortcut for probabilities. Further, the tally rule is comparatively simple, not having to keep track of base rates or perform divisions as does the validity rule. From the other side, the simple swap rule may not be much simpler, because storing a cue order may be about as demanding as storing a set of tallies. We therefore conclude that the tally rule should not be discounted on grounds of implausibility without further empirical evidence. Of course, a necessary next step (currently underway) will be to test how well these and other rules predict people's information search when they have to make cue-based inferences without knowing validities.

Our goal in this paper was to argue for the necessity of taking into account the set-up costs of a heuristic in addition to its application costs when considering the mechanism's overall simplicity. As we have seen from the example of the validity search order of TTB, what is easy to apply may not necessarily be so easy to set up. But simple rules can also be at work in the construction of a heuristic's building blocks. We have proposed such rules for the construction of one building block, the search order. We have seen that these simple learning rules enable a one-reason decision heuristic to perform only slightly worse than if it had full knowledge of cue validities from the very beginning. Giving up the assumption of full a priori knowledge for the slight decrease in accuracy seems like a reasonable bargain: Through the addition of learning rules, one-reason decision heuristics might lose some of their appeal to decision theorists who were surprised by the performance of such simple mechanisms compared to more complex algorithms, but they gain psychological plausibility and thus become more attractive as explanations for human decision behavior.

Abstract

Despite the current belief that much common sense reasoning is nonmonotonic in nature, research indicates that only a limited percentage of people are good at nonmonotonic reasoning. Good nonmonotonic reasoners recognize the logical strengths and weaknesses of some arguments. In the present study, we focus on differences in the probabilistic interpretation of the modifiers *typically* and *usually* and on the resulting differences in the strengths and weaknesses of arguments. We show that these implicit probabilistic strengths influence the reasoning process of good nonmonotonic reasoners.

Introduction

Most AI logicians and logic programmers, as well as philosophical logicians, ground their interest in nonmonotonic reasoning on the observation that common sense reasoning is largely nonmonotonic in nature. Ginsberg (1994, p.2), for example, states that: "*... flexibility is intimately connected with the defeasible nature of commonsense inference ... we are all capable of drawing conclusions, acting on them, and then retracting them if necessary in the face of new evidence. If our computer programs are to act intelligently, they will need to be similarly flexible*".

Pelletier and Elio (1997) argue that researchers like Ginsberg are right in grounding their research on human reasoning, but they also argue that AI researchers should bear the consequences of it.

As a first consequence, Pelletier and Elio (1997) argue for a more systematic study of human inferences. They plead against the use of the intuitions of a small group of AI researchers to decide on the acceptable answers to some 'benchmark' problems (e.g. Lifschitz, 1988). Within the AI community, at least some researchers are also supportive of this point of view (e.g. Schurz, 2001; Benferhat, Bonnefon, & Da Silva Neves, 2002).

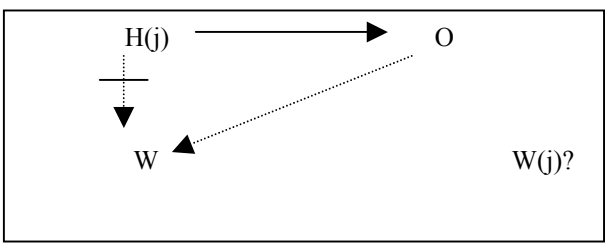
The second consequence of grounding default reasoning research on human common sense reasoning is more severe. Contrary to deductive reasoning, where classical logic is considered to be the norm, there is no standard norm for default reasoning. Since the long-term goal of most AI researchers is to simulate human reasoning, and since we do not have an objective theory of what rational default reasoning is, Pelletier and Elio (1997) argue that a psychologistic view of default reasoning should be adopted. Thus, the data that any default system should cover should be determined by the practices of ordinary people.

We agree with the importance of investigating human reasoning by controlled experimental research to gain more insight into the process of human reasoning. However, we also argue that it is important for AI not to develop a formal nonmonotonic logic or automated reasoning system on the basis of flawed reasoning.

Ford and Billington (2000) took the need for AI researchers to study human reasoning seriously and systematically investigated human nonmonotonic reasoning with abstract material. This way, participants could not rely on background knowledge, as they can do in daily life.

To clarify the discussion, we present an example of one problem, with a well-known Tweety-bird like structure:

Hittas are usually not waffs.	Penguins do not fly
All of the hittas are oxers.	All penguins are birds
Oxers are usually waffs.	Birds fly
Jukk is a hitta.	Tweety is a Penguin
Is Jukk a waff?	Does Tweety fly?



Ford and Billington (2000) summed up their main finding by presenting five negative (N) and three positive (P) factors

that influenced people's reasoning about nonmonotonic problems:
(N1) Most participants were not willing to draw a tentative conclusion when faced with conflict and with non-strict rules. (N2) Some participants weighed up the perceived number of relevant positive and negative paths, though the perceived paths were not paths. (N3) Some participants considered path length regardless of the ordering of rule types. Most participants preferred the shorter path to the longer path. (N4) Some participants gave weight to the presence of the universal quantifier, even when this was inappropriate. (N5) Some participants interpreted 'usually not' as evidence that 'some are' and thus gave preference to a positive conclusion. (See Hewson & Vogel, 1994, and Vogel & Tonhauser, 1996, for more evidence that many people have difficulty with nonmonotonic reasoning problems).
Besides these negative factors, Ford and Billington (2000) also extracted some positive factors from their experiment. (P1) Some participants recognized the relevance of the fact that if *all of the Xs are Ys* there might be *Ys that are not Xs*. (P2) Some participants recognized the relevance of the fact that if *all of the Ys are Zs* then *any Xs that are Ys are also Zs*. (P3) Some participants recognized that given a sentence *Xs are usually Ys* there are potentially many Ys that are not Xs.
People who recognize these positive points are able to see differences in the logical strength of arguments. Consider the following:

X → Y ⇢ Z (a)
(all of the Xs are Ys, Ys are usually Zs)

X ⇢ Y → Z (b)
(Xs are usually Ys, all of the Ys are Zs)

X ⇢ Y ⇢ Z (c)
(Xs are usually Ys, Ys are usually Zs)

An appreciation of P2 allows people to recognize the strength of (b): for (b), it must be the case that Xs are usually Zs because the Xs that are Ys must also be Zs. In contrast, an appreciation of P1 and P3 allows people to see the weakness of (a) and (c), respectively: for (a) and (c), it might be that none of the Xs are Zs because it could be that the Ys that are not Xs are not Zs.
Ford (2004, In Press) argues that people who see the differences in the logical strength of arguments are more likely to give logically justifiable answers on nonmonotonic reasoning problems, since they rely on logically valid principles to form their answers. For example, with problems such as (1), they answer 'unlikely' more frequently and more strongly than people who do not see differences in the logical strength of arguments. They give this answer because of their recognition of the weakness of (a).
Note that these reasoners are not relying on a notion of 'specificity', where information stemming from a subclass overrides information from a superclass; Ford and Billington's (2000) subjects did not articulate this notion of specificity as it is used in AI and the three P factors they identified make no mention of such specificity. The subjects instead rely on the logical strength of conflicting paths in an argument.
In this manuscript, we investigate further the nature of the logical strengths and weaknesses that reasoners who appreciate P2 and P3 use. We will argue for differences in the probabilistic interpretation of the modifiers *usually* and *typically* and consequent differences in the logical strengths and weaknesses of arguments. Given the results of Ford (2004, In Press), we would thus expect variations in conclusions given by reasoners who appreciate P2 and P3, with these reasoners giving more weight to the stronger side of an argument.
In a pilot experiment, we will extend a former study in which it was shown that researchers should be careful how to phrase their 'default relations' (Dieussaert, 2003). Researchers do not seem to make a distinction between sentences such as 'birds fly', 'birds normally fly', 'birds usually fly', 'birds typically fly' and so on. However, Dieussaert showed that the interpretation of these sentences, and the inferences yielded from them, differ greatly.
For the present study, we focus on the difference between *usually* and *typically*. We confirm the finding that *typically* is interpreted as indicating more instantiations of a type than *usually*. This implies that 'birds typically fly' represents a stronger relation than 'birds usually fly' since more instances of 'bird' are supposed to fly in the former case.
In a second experiment, we use this finding to show how the strengths and weaknesses of arguments can influence nonmonotonic reasoning. Reasoners who are shown to appreciate P2 and P3 are given problems with relations phrased with *typically* and *usually*. The data show clearly that the strength of arguments influences the nonmonotonic reasoning process for these subjects.

Pilot Experiment

In an earlier experiment (Dieussaert, 2003), the influence of phrasing on the interpretation of default sentences was shown. In a within subjects design, participants estimated the positive outcome of a sequence such as 'Hilo are typically waff. Jukk is a hilo. Is Jukk a waff?' significantly higher than for sequences like 'Brant are usually glent. Kerdo is a brant. Is Kerdo a glent?'
To obtain confirmatory evidence, we extended the earlier experiment.

Method

Participants

Ninety-nine first year students in Psychology at the University of Leuven, who had not taken a logic course, participated as a partial fulfillment of a course requirement.

Design
The design was completely within subjects. The dependent variable was the percentage entered per item.

Material and Procedure
Each participant received a booklet with written instructions and 18 items in randomized order. Each participant solved 18 problems: 9 positive items and 9 negative items. They solved this paper-and-pencil task individually and in a self-paced manner.
Here, we focus only on the difference between *typically* and *usually*, since these terms form the core of the main experiment.
The relevant material was:

- Nagdals are usually pirasos.
- Hittas are typically waffs
- Nilo are usually not riza
- Koki are typically not liri

The instructions for the positive items were as follows:
On each of the following pages a sentence will be presented. We ask you to mark how you interpret the underlined word within this sentence. To clarify the task, we give you an example.
The sentence: JY members are *normally* singers.
The question: Does the word '*normally*' mean that:
Mark one or more answers:
0 A certain percentage of JY members have features that characterise singers. If so, given the sentence, what would you assume would be the approximate % (0-100) of JY members that have features that characterize singers. .....% [further referred to as: **Feature**]
0 A certain percentage of time JY members are singers. If so, given the sentence, what would you assume would be the approximate % (0-100) of time JY members are singers. .....% [further referred to as: **Time**]
0 A certain percentage of JY members are singers. If so, given the sentence, what would you assume would be the approximate % (0-100) of JY members that are singers. .....% [further referred to as: **Number**]
For the negative items, the task were rephrased in a negative form e.g.: ...% (0-100) of JY members that are <u>not</u> singers.

Results

Table 1: Mean percentages given for Feature, Time, and Number (see Material).[a]

Problem	Feature	Time	Number	Mean
Typically	*91.8*	65.0	92.3	91.8
	(N=85)	(N=01)	(N=24)	[SD=11.7]
Usually	77.9	74.3	*79.6*	78.4
	(N=31)	(N=17)	*(N=70)*	[SD=12.5]
Typically not	*87.5*	88.3	89.1	87.3
	(N=73)	(N=04)	(N=36)	[SD=17.9]
Usually not	77.2	76.8	*76.4*	77.4
	(N=27)	(N=38)	*(N=52)*	[SD=14.3]

[a]The number of responses (N) do not add up to 99 because participants were allowed to mark 1-3 answers. Some participants marked only the answers and did not enter a percentage.

Overall percentages entered for *typically* are higher than percentages entered for *usually* (91.8 vs. 78.4; t (92) =7.82, $p < .00001$). Percentages entered for *typically not* are higher than percentages entered for *usually not* (87.3 vs. 77.4; t (46) =4.8, $p < .00001$).
If we take into account only the single choices of participants (and remove items for which more than one answer was marked): Feature is the preferred category for *typically*, while Number is the preferred category for *usually*. A Sign test shows a higher number of Feature choices for *typically* (73) than for *usually* (17; Sign test, non-ties = 63, $Z = 6.3$, $p < .00001$). The same pattern is found for *typically not* (59) versus *usually not* (15; Sign test, non-ties = 70, $Z = 8.3$, $p < .00001$). A Sign test shows a higher number of Number choices for *usually* (55) than for *typically* (13; Sign test, non-ties = 56, $Z = 5.5$, $p < .00001$). A similar pattern is found for *usually not* (39) versus *typically not* (23; Sign test, non-ties = 33, $Z = 2.4$, $p < .00005$).

Discussion
This experiment confirms the results of Dieussaert (2003): *typically* and *usually* are interpreted somewhat differently. Most importantly for our purposes, having *typically* in a sentence is associated with higher percentages than having *usually*, with the former term thus being considered stronger.

Main Experiment
The pilot experiment provides confirmatory evidence for the stronger relation between two propositions A and B when they are connected in a default sentence with *typically* than with *usually*.
Having established this firmly, we can now investigate how the strength of this relation influences the nonmonotonic reasoning process. In this experiment, reasoners who appreciate Ford and Billington's (2000) P2 and P3 are tested.

Method

Participants
Twenty-seven first year students in Psychology from the University of Leuven, who had not taken a logic course, participated as a partial fulfillment of a course requirement.

Design
The design was completely within subjects. The dependent variable was the score on a seven-point scale.

Material and Procedure
Each participant first received two critical questions (Ford, 2004) to see if they recognized Ford and Billington's (2000) P2 and P3.
They were told that there were no time limits. The questions were:

1) Given the following two statements:
Mary's friends are usually Ann's friends.
All of Ann's friends are Sue's friends.
Could it be the case that none of Mary's friends are Sue's friends? (Yes/No)

Given the following two statements:
Jim's friends are usually Tom's friends.
Tom's friends are usually Fred's friends.
Could it be the case that none of Jim's friends are Fred's friends? (Yes/No)

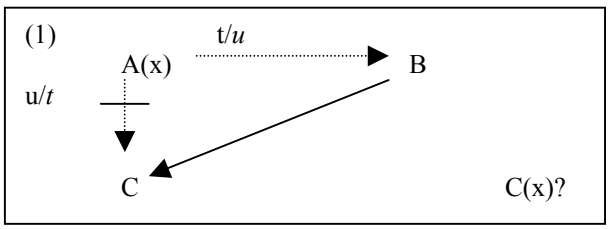
The first question contains the strong argument, with P2 relevant:
X ⋯⋯▶ Y ——▶ Z
while the second question contains the weak argument, with P3 relevant:
X ⋯⋯▶ Y ⋯⋯▶ Z

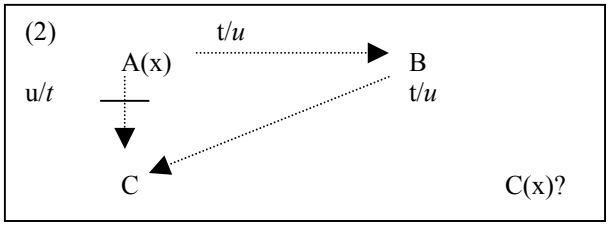
Only participants who answered the critical questions correctly (No on the first, Yes on the second) proceeded to the second part of the experiment, leaving 11 subjects.
These participants received a booklet with written instructions and 18 problems (1 per page). Each participant gave their answer to each problem verbally and then indicated a likelihood estimation on a seven point scale.

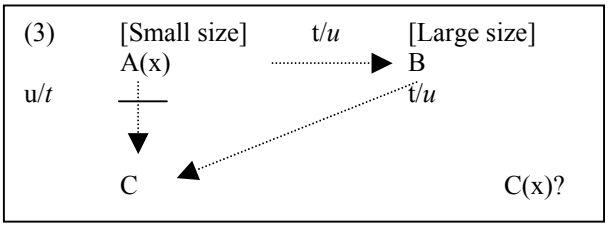
On a scale of 1 to 7, estimate the likelihood of Z(x).

extremely unlikely						extremely likely
1	2	3	4	5	6	7

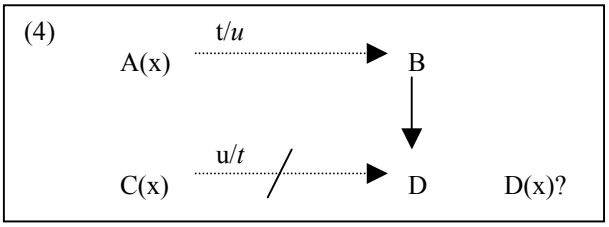
Problems in which the modifier *typically* (t) was used for the positive arguments and in which the modifier *usually* (u) was used for the negative arguments will be referred to as TU problems. Problems in which the modifier *usually* (u) was used for the positive arguments and in which the modifier *typically* (t) was used for the negative arguments will be referred to as UT problems.
Six differently structured problems can be distinguished. Participants received two examples of each of two versions of the following 3-argument structures, thus making 12 problems:

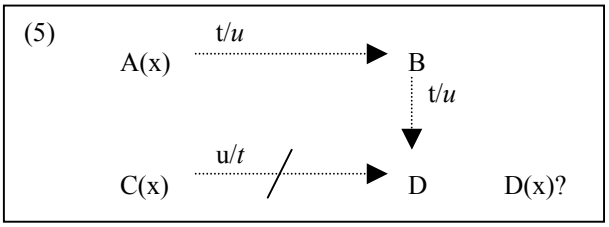


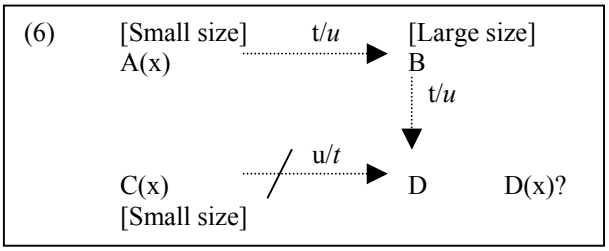




Participants also received one example of each of the two versions of the following 4-argument structures, making a further 6 problems:







It should perhaps be noted here that of the six structures studied here, the notion of specificity, if it were used, could only be applied to Problems 2 and 3, where information from a subclass (A) conflicts with information from its superclass (B). The good reasoners we are using, however, would be expected to use P2 and P3 to compare the strength of the conflicting arguments in all the problems.
Problems usually requiring 'Can't tell'
Problem 1 represents a strong positive versus a strong negative argument. The expected response when the modifier phrase is the same for both sides of the argument is thus around 4, meaning 'can't tell'. However, an additional manipulation was added.

In 1a, the positive non-strict relation was phrased with *typically* (t; As are typically Bs), while the negative non-strict relation was phrased with *usually* (u; As are usually not Cs). For problem 1b, the phrasing was vice versa (*usually* for the positive relation and *typically* for the negative one).
Problem 4 represents a similar problem to (1), but with four propositions involved. The expected response here is also 4, meaning 'can't tell', when the modifiers are the same, but again TU and UT versions were given.
Given that *typically* is stronger than *usually*, the TU versions would be expected to result in a higher rating (more positive) than the UT versions.

Problems usually indicating 'unlikely'
Problem 2 represents a weak positive versus a strong negative argument. The expected response when the modifier phrase is the same for both sides of the argument is thus lower than 4, meaning 'unlikely'. However, the phrasing manipulation could be expected to have an additional influence on the final rating.
Problem 5 is similar to Problem 2, with a weak positive versus a strong negative argument, and with the phrasing manipulation expected to influence the final rating.
Problems 3 and 6 differ from 2 and 5, respectively, in that information is given on the relative subset/superset sizes to which the respective items belong: a small subset for A and a large one for B. It seems (Ford, In Press) that relative size information can sometimes help good reasoners in their reasoning.
For problems 2, 3, 5 and 6, the ratings for the TU versions would be expected to move higher, becoming more positive than would otherwise be expected. With the UT versions, the ratings would be expected to move lower, becoming even less positive than would otherwise be expected.

Results

Table 2: The mean likelihood ratings as a function of modifiers used in the positive and negative arguments. Standard deviations are given in square brackets.

(N = 11)		Problem	TU	UT
3-arg		(1)	4.3 [1.2]	3.7 [0.8]
	w/o relative size	(2)	3.9 [1.1]	2.7 [0.8]
	with relative size	(3)	4.2 [1.1]	2.5 [0.9]
4-arg		(4)	5.0 [1.7]	3.4 [1.2]
	w/o relative size	(5)	4.2 [1.7]	2.5 [0.8]
	with relative size	(6)	4.2 [1.3]	3.4 [1.4]

3-argument problems.
The mean likelihood rating was higher for TU problems than for UT problems (4.1 vs. 3.0; $F(1,10) = 17.5$, $MSE = 1.2$, $p < .005$). Planned comparisons showed that TU ratings are higher than UT ratings for Problem 1 (4.3 vs. 3.7; $F(1,10) = 7.7$, $MSE = .2$, $p < .05$), for Problem 2 (3.9 vs. 2.7; $F(1,10) = 10.1$, $MSE = .7$, $p < .01$), and for Problem 3 (4.2 vs. 2.5; $F(1,10) = 14.4$, $MSE = 1.1$, $p < .005$).
No difference between the problems was observed ($p = .08$). However, an interaction between problem and modifier was observed ($F(2,20) = 4.4$, $MSE = .4$, $p < .05$). A planned comparison shows only a significant difference for UT between Problem 1 and 2 (3.7 vs. 2.7; $F(1,10) = 6.9$, $MSE = .8$, $p < .05$) and between Problem 1 and 3 (3.7 vs. 2.5; $F(1,10) = 31.0$, $MSE = .3$, $p < .0005$). This difference is due to the particularly low ratings of UT Problem 2 and 3.
Notice, too, that relative size information did not influence the ratings.

4-argument problems.
A similar pattern is found for 4-argument problems. The mean likelihood rating was higher for TU problems than for UT problems (4.5 vs. 3.1; $F(1,10) = 7.0$, $MSE = 4.5$, $p < .05$). Planned comparisons showed that TU ratings are higher than UT ratings for Problem 4 (5.0 vs. 3.4; $F(1,10) = 5.2$, $MSE = 2.8$, $p < .05$), for Problem 5 (4.2 vs. 2.5; $F(1,10) = 6.8$, $MSE = 2.4$, $p < .05$), but not for Problem 6 (4.2 vs. 3.4; $p = .2$).
No difference between the problems was observed ($p = 0.5$). No interaction between problem and modifier was observed.

Discussion

This study was set up to gain more insight into the role that modifiers of non-strict relations play in the nonmonotonic reasoning process. Generally, researchers do not pay much attention to the specific wording of default expressions. We showed in a pilot experiment that this neglect is undeserved: default expressions vary in interpretation. However, only if this interpretation also affects the nonmonotonic reasoning process does the topic become particularly noteworthy for AI researchers and philosophical logicians doing research on nonmonotonic reasoning.
In the main experiment we showed that the use of different modifiers in non-strict relations does indeed lead to a variation in nonmonotonic reasoning, more precisely in likelihood ratings on nonmonotonic reasoning problems. We presented reasoners who appreciate P2 and P3, with problems of two kinds: problems with structures where we would normally expect them to give a 'can't tell' answer and problems where we normally expect them to give an 'unlikely' answer. So, if participants bore only the structure of the problem in mind, we would expect a 'can't tell' answer for Problems 1 and 4, and an 'unlikely' answer for Problem 2-3 and 5-6, despite the modifier manipulation. However, if the reasoning process was influenced by the modifier used, we would see a shift in answers, depending on the specific modifier used to express the positive and negative non-strict relations.
The data show clearly that reasoners who appreciate P2 and P3 are influenced by the modifier used. Ratings on TU problems differ significantly from ratings on UT problems. With the 'can't tell' Problem 1, we observed ratings staying close to the 'can't tell' rating, although a positive shift was noted for TU problems, while a slightly negative shift was noted for UT problems, resulting in an overall difference.

With the 'can't tell' Problem 4, the pattern was more extremely pronounced, with a large positive shift for TU problems and a large negative shift for UT problems.

The TU versions of problems 2-3 and 5-6 are lifted up to a 'can't tell' level, while UT versions receive an 'unlikely' rating. While adding relative size information has been shown to sometimes help good nonmonotonic reasoners (Ford, In Press), it did not affect the reasoning process in our experiment, possibly because these subjects did not need this help.

It is clear that although the matching TU and UT versions of problems have the same structure, they are not considered as being equivalent. The modifier *typically* or *typically not* makes a non-strict relation stronger compared with its counterpart *usually* or *usually not.*

It is clear that people who show an appreciation of P2 and P3 and who solve nonmonotonic problems by comparing the logical strength of conflicting arguments, rather than by using a notion of specificity, also use the strength of modifiers to guide their reasoning. Just as it is rational to take the logical strength of conflicting arguments into account, rather than using a notion of specificity, so too it is rational to take into account modifier strength in conflicting arguments.

Conclusion

Ford (2004, In Press) has shown that good reasoners use the logical strength of different sides of an argument to guide their reasoning. The present study adds credence to this effect of weighing up the strengths of the different sides of an argument. The study shows that different modifiers can differentially weaken or strengthen an argument and that they thereby influence reasoning.

The Role of Explanation Coherence of Two Premises on Property Induction

Kyung Soo Do (ksdo@skku.edu)
Ju Hwa Park (jhpark@skku.edu)
Department of Psychology, Sungkyunkwan University

Abstract

Three experiments on property induction were conducted to explore whether an incoherent premise discounted the believability of the conclusion when there were two premises. In all three experiments, a single premise increased or decreased the likelihood of the conclusion depending on the nature of explanatory coherence of a premise and a conclusion. However, when there were two premises, one that shared the reason with the conclusion (coherent premise), and one that does not (incoherent premise), the believability of the conclusion was affected differently in three experiments. When two premises and the conclusion were presented simultaneously in Experiment 1, the believability of the conclusion was increased. That is, an incoherent premise did not seem to affect the believability of the conclusion as much as the coherent premise. The incoherent premise seemed to decrease the believability of the conclusion a little bit when the two premises and the conclusion were presented sequentially so that each premise was not ignored in Experiment 2. The incoherent premise decreased the believability of the conclusion below the baseline condition in Experiment 3, where participants were asked to write down reasons for each premise being true. Results of three experiments suggested that only the confirming evidences were processed under natural conditions. A few possible theoretical implications were considered.

Introduction

When someone asks a question whether a target object has a certain property (target property), such as "Does an ostrich lay eggs?", and you do not know the answer, you might induce the answer by checking whether some object (source object), usually objects that are similar to the target object, has the target property. In the ostrich example, you would answer "yes" if you think ostriches are similar to geese and know that geese lay eggs. As this example shows, what conclusion you make depends on what objects are used as source objects.

What object is an effective source object in property induction depends on a number of factors: The nature of the target property, the level of knowledge of the person, and the cultural background of the person, to name a few. People used different source objects depending on their knowledge and occupation (Proffitt, Coley, & Medin, 2000). Also there seems to be a culture difference in property induction (Choi, Nisbett, & Smith, 1997). Even though the level of knowledge and the cultural background of the person affect the property induction, the effect of the nature of the target property on property induction has been the focus of most research. More specifically, what objects are effective as source objects in inducing two types of properties, and how the information of the source objects are used for property induction have been more widely investigated.

There are two types of target properties, blank properties and nonblank properties, and the effectiveness of source objects seems to differ between the two types. The effectiveness of a source object seems to depend on the similarity between the target object and the source object for blank properties for which we do not have any other information to rely on (e.g., 'have BCC in blood') (Osherson, Smith, Wilkie, Lopez, & Shafir, 1990; Rips, 1975; Sloman, 1993). However, the similarity between the target object and the source object does not seem to work for nonblank properties for which we have other information to infer about the target object having the target property (e.g., 'can cut the wire') (Smith, Shafir, & Osherson, 1993). As the relationship between objects and the target property are diverse (Murphy & Medin, 1985), there are many ways of inducing nonblank properties: People seem to use other relevant information, such as body size or strength, in inducing nonblank properties (Smith *et al*., 1993). People rated the believability of the conclusion differently when the target property is about shape from when the target property is about behavior (Heit & Rubinstein, 1994).

One way of inducing nonblank properties is comparing the reason for the target object having the target property with the reason for the source object having the target property. Sloman (1994, 1997) proposed that the explanation coherence between the premise and the conclusion affect the plausibility of the conclusion. If the target object and the source object share the same explanation, informing the participants that the source object has the target property increases the believability of the conclusion that the target object has the target property. For instance, computer programmers and secretaries have bad backs because they sit all day long. Therefore, informing the participants that "Computer programmers have bad backs" would make the conclusion "Secretaries have bad backs" more plausible than when the participants are not informed about the computer programmers having bad backs. However, if the target object and the source object do not share the same reason, informing the participants that the source object has the target property decreases the believability of the conclusion that the target object has the target property. In the bad back example, for instance, furniture movers had bad backs because they lift heavy things. Therefore, informing that "Furniture movers had bad backs" would make the conclusion "Secretaries

have bad backs" less plausible. That is, premises that have different explanations seem to discount the plausibility of the conclusion. Sloman called this the explanation discounting principle.

As has been described, the explanation discounting principle explains empirical results quite well when there is just one piece of relevant information. However, it is not specific about how it works when there are multiple pieces of relevant information, especially when there is conflicting information. There can be a few modified versions of the explanation discounting principle. The most extreme form of the explanation discounting principle would assume that the participants use all the information in inducing properties in equal degree (equivalence hypothesis, but hereafter I use equivalence hypothesis and the explanation discounting principle interchangeably). However, the equivalence hypothesis needs to be tested, because when there is more than one piece of relevant information, people do not use all the information they have. People are known to be cognitive misers (Nisbett & Ross, 1980). They seem to use information that confirms their predictions or hypotheses, but ignore information that disconfirms. They produced cases that confirmed their hypotheses (Wason, 1960) or they were more willing to search information that confirms than information that is likely to disconfirm (Shaklee & Fischhoff, 1982). Therefore if the confirmation strategy is the default way of using information, then it is quite likely that the explanation discounting principle may not apply when there is more than one piece of relevant information.

In this paper, we intend to explore whether the explanation discounting principle works when there are two premises in property induction tasks. There are two kinds of premises: "Same" premises, in which the source object has the target property for the same reason as the target object, and "Different" premises, in which the source object has the target property for reasons different from that of the target. In three experiments, we are mainly interested in the believability of the conclusion of the mixed conditions where one Same premise and one Different premise are presented. If the implicit equivalence hypothesis of the explanation discounting principle was correct, the conclusion in the mixed conditions should be rated not higher than that of the baseline condition, where the conclusion is presented without any premises. On the other hand, if the confirmation strategy is the default mode of using multiple pieces of information in property induction, the conclusion in the mixed conditions should be rated not lower than that of the baseline condition.

The premises and the conclusion were presented simultaneously in Experiment 1 to explore whether the explanation discounting principle applies when there are two premises. Experiment 1 is regarded as a natural condition because we did not try any manipulation to make the premises being processed. Experiments 2 and 3 were intended to find the boundary condition where the explanation discounting principle applies. Each premise and the conclusion were presented successively in Experiment 2 to make each premise salient and not be ignored. In Experiment 3, participants were asked to write down the reason why the object has the target property for each premise.

Experiment 1

There were two goals for Experiment 1. First, we wanted to replicate Sloman's (1994, 1997) finding that one Same premise increased the plausibility of the conclusion, and one Different premise decreased the plausibility of the conclusion. Second, we wanted to compare the explanation discounting principle against the confirmation strategy by presenting two premises, one Same premise and one Different premise.

Method

Design There were five experimental conditions in Experiment 1. In two single-premise conditions, one premise was presented on top of the conclusion. There was a horizontal line between premises and the conclusion. In the Same condition, one Same premise was presented, and in the Different condition, one Different premise was presented. Two premises were presented with the conclusion in the remaining three two-premises conditions: In the S+S condition, two Same premises were presented on top of the conclusion. In the S+D condition, the Same premise was presented on the top line and the Different premise was presented on the next line. In the D+S condition, the Different premise was presented on the top line and the Same premise was presented on the next line. Each participant was randomly assigned to one of the five experimental conditions. Therefore, the premise condition was a between subjects variable.

Participants Ninety-five Sungkyunkwan University students who attended an "Introduction to Psychology" course participated as a requirement for the course. Nineteen participants were randomly assigned to each experimental condition. None of them had participated in property induction experiments prior to the current experiment.

Material Twelve properties were used in the experiment as the target property. The target properties and the corresponding occupations were selected based on the results of an item selection experiment. In the item selection experiment, two hundred Sungkyunkwan University students were asked to write down at least two occupations that have the target property and the reasons they have the target properties over 24 properties. The 24 properties were selected from 32 items used in Sloman (1994, 1997) and judged appropriate in Korea. Of the 24, 12 properties were selected as experimental material. All premises and conclusions took the form of an occupation or class of people having the target property, such as "Veterans have problems getting jobs."

Procedure There were three stages in the experiment. At Stage 1, participants were presented only the conclusion of

twelve induction problems, and were asked to rate the probability of each conclusion. Each conclusion was presented on a computer monitor screen one at a time. The presentation order of the twelve conclusions was randomized within a subject. The rating at Stage 1 was used as a baseline rating of the participant. After they finished baseline estimation, they did an intervening task for more than five minutes (Stage 2). The intervening task was not related with property induction, or any of the properties or the occupations used in the experiment. After the participants completed the intervening task, they were presented twelve experimental property induction problems and asked to rate the probability of each conclusion considering the premises. After they finished rating twelve induction problems, they were given the induction problems and their ratings for each problem and were asked to type in the reason for their response. The presentation order of the twelve induction problems was randomized within a subject. Presentation of the items and recording of responses in Stages 1 and 3 were manipulated by a program written in Visual Basic 6.0. Pentium-class PCs and computer monitors were used in Stages 1 and 3.

Results and discussion

Rating Average ratings of the baseline (Stage 1) and the experiment phase (Stage 3) for each premise condition are presented in Fig. 1. As the difference between the rating in the baseline phase and that of the experiment phase was the main interest, ratings in the baseline phase and that of the experiment phase were regarded as a within-subjects variable, and one factor within-subjects ANOVA was conducted for each premise condition**.**

In single-premise conditions, presenting a Same premise increased the rating in the Same condition, $F(1, 18) = 4.87$, $p < .05$, $MSE = 92.96$, and presenting a Different premise decreased the rating in the Different condition, $F(1, 18) = 51.93$, $p < .001$, $MSE = 21.92$. Results in the single-premise conditions replicated Sloman's (1994) results and corroborated the explanation discounting principle.

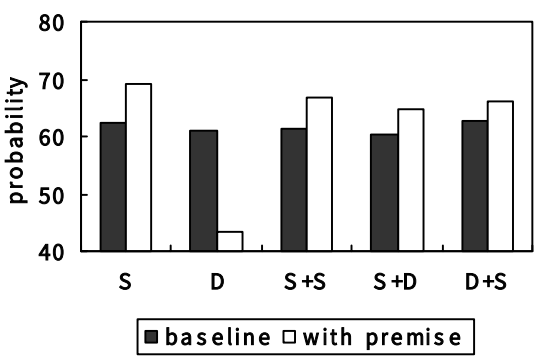

Figure 1. Average ratings of the conclusion: Experiment 1. (S: Same; D: Different)

However, the explanation discounting principle did not seem to apply in the two-premises conditions. Presenting two premises increased the rating of the conclusion in the S+S condition, $F(1, 18) = 21.92$, $p < .001$, $MSE = 13.25$, and in the S+D condition, $F(1, 18) = 11.09$, $p < .001$, $MSE = 17.54$, and did not affect the rating of the conclusion in the D+S condition, $F(1, 18) = 2.14$, ns. According to the explanation discounting principle, the conclusion in the S+D and D+S conditions, in which there was a premise that has the target property for reasons different from that of the target object, was expected to yield ratings at least not higher than that of the baseline phase. However, even in the D+S condition, where the difference from the baseline is smaller than the S+D condition, the average rating for the experiment phase was a little larger than that of the baseline, though not statistically significant. Thus, the results in S+S, S+D, D+S conditions seemed to fair better with the confirmation strategy. That is, participants might have processed only the information that can confirm or strengthen the plausibility of the conclusion when there are two pieces of conflicting information. The possibility of adopting the confirmation strategy got further support from participants' subjective reasons for their responses.

Subjective report The reasons participants wrote down for their conclusions in the experiment were classified into 11 possible categories in the single-premise condition and 20 possible categories in the two-premises conditions.

In the single-premise conditions, participants seemed to use the information in the premise. More specifically, in the Same condition, about 65% of the reasons matched that of the experimenter. In the Different condition, about 35% reported that the reasons for the premise and the conclusion did not agree. In general, results in the single-premise conditions suggested the explanation discounting principle seemed to apply when there is just one piece of relevant information.

However, participants seemed to mainly use confirming information and ignore disconfirming information when there were two premises. More specifically, in the S+S condition, 58% of the responses mentioned the premises and the conclusion had the same reason. In the S+D and D+S conditions, 29% of the responses mentioned only the Same premise, and 21% mentioned reasons they spontaneously made to make both the premise and the conclusion shared the same reason. In other words, in about half of the responses, participants searched for reasons that are the same as the conclusion. Of the remaining 50%, 22% of the response mentioned only the conclusion. As a whole, participants' subjective reports in two-premises conditions strongly suggested that they adopted the confirmation strategy.

Experiment 2

The results of Experiment 1 strongly suggested that participants processed only a part of the information given to them. That is, they seemed to use information that gave

support for the conclusion, and ignore information that was incoherent with the conclusion. Experiments 2 and 3 were intended to test this possibility of non-use of disconfirming information by making premises salient so that disconfirming information was not to be ignored. In Experiment 2, premises were made salient by presenting the premise(s) and the conclusion one after the other.

Method

Participants Ninety-five Sungkyunkwan University students participated in Experiment 2. They were recruited in the same way as that of Experiment 1. Nineteen participants were randomly assigned to one of the five premise conditions.

Material The materials of Experiment 2 were identical to that of Experiment 1.

Procedures The procedures of Experiment 2 were identical to that of Experiment 1, except for the following changes in the temporal order of presenting premises and conclusion at Stage 3. At Stage 3 of Experiment 2, the premise on the top line of the screen appeared and remained visible until participants made responses indicating their rating of the conclusion. The second premise, if there was one, appeared on the screen 3 seconds after the start of the first premise and remained visible until participants made responses. Finally, the conclusion appeared on the screen 3 seconds after the onset of the last premise, and remained visible until the response. The sequential presentation of the premises and the conclusion was intended to make sure that the premises not be ignored.

Results and Discussion

Rating Average ratings of the baseline and the experiment phase for each premise condition are presented in Fig. 2. In single-premise conditions, presenting a Same premise increased the rating in the Same condition, $F(1, 18) = 6.00$, $p < .001$, $MSE = 21.92$, and presenting a Different premise decreased the rating in the Different condition, $F(1, 18) = 16.29$, $p < .001$, $MSE = 133.96$.

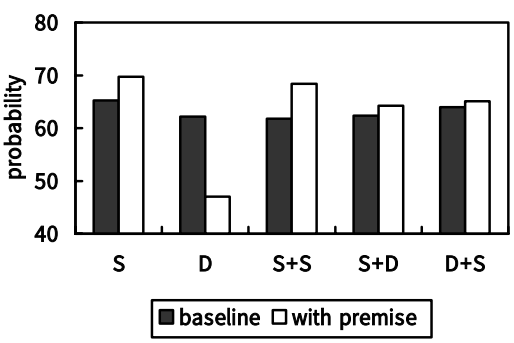

Figure 2. Average ratings of the conclusion: Experiment 2. (S: Same; D: Different)

Presenting two premises increased the rating of the conclusion in the S+S condition $F(1, 18) = 14.15$, $p < .001$, $MSE = 29.26$, but did not affect the rating of the conclusion in the S+D condition, $F(1, 18) = 1.50$, ns, and in the D+S condition, $F(1, 18) = .79$, ns. Different from Experiment 1, the ratings of the two mixed conditions, the S+D and the D+S conditions, were not different from that of a baseline, which suggested that making premises not ignored by presenting one after the other makes all the information attended and as a consequence can exert both facilitating and discounting effect on property induction, even though the discounting effect seems not as strong as the facilitating effect.

Subjective report As in Experiment 1, participants seemed to use the information in the premise in the single-premise conditions. More specifically, in the Same condition, about 73% of the reasons matched that of the experimenter. In the Different condition, about 44% reported that the reasons for the premise and the conclusion did not agree.

The pattern of responses in the two-premises conditions of Experiment 2 was similar to that of Experiment 1. 52% of the responses mentioned that the premises and the conclusion had the same reason in the S+S condition. In the S+D and D+S conditions, 28% of the responses mentioned only the Same premise, and 22% mentioned reasons they spontaneously made to make both the premise and the conclusion share the same reason. Furthermore, 26% of the responses mentioned only the conclusion.

In general, results of Experiment 2 were quite similar to that of Experiment 1, but sequentially presenting premises did at least partially succeed to make information that disconfirms the conclusion affect the believability of the conclusion.

Experiment 3

Presenting the premises and the conclusion successively changed the pattern of results a little in Experiment 2. In Experiment 3, the disconfirming premise was forced to be processed by asking participants to write down reasons why each premise could be true.

Method

Participants Ninety-five Sungkyunkwan University students participated in Experiment 3. They were recruited in the same way as that of Experiment 1. Nineteen participants were randomly assigned to one of the five premise conditions**.**

Material The materials of Experiment 3 were identical to that of Experiment 1.

Procedures The procedures of Experiment 3 were identical to that of Experiment 1, except for the following three changes. First, in Experiment 3, participants were tested in groups. Nineteen participants in each premise condition were seated in a large class room. They were seated in a way such that there was at least one seat unoccupied in all directions. Second, participants were given a small booklet. Third, participants were asked to write down the reasons for the premises being true and the believability rating of the conclusion. Separate booklets were given at each stage, so that participants could not look at their baseline ratings when they did induction problems. In the booklet for Stage 3, the conclusion was printed in a page following the page where premises and their responses for the premises were written, so that participants could not read their reasons for the premises**.**

Results and Discussion

Rating Average ratings of the baseline and the experiment phase for each premise condition are presented in Fig. 3. In single-premise conditions, presenting a Same premise increased the rating in the Same condition, $F(1, 18) = 8.03$, $p < .05$, $MSE = 61.53$, and presenting a Different premise decreased the rating in the Different condition, $F(1, 18) = 38.02$, $p < .001$, $MSE = 78.76$.

Presenting two premises increased the rating of the conclusion in the S+S condition $F(1, 18) = 9.55$, $p < .01$, $MSE = 74.76$, but decreased the rating of the conclusion in the S+D condition, $F(1, 18) = 8.70$, $p < .01$, $MSE = 38.00$, and D+S condition, $F(1, 18) = 9.71$, $p < .01$, $MSE = 65.67$.

In general, making premises salient by writing down reasons why they can be true did not affect the effects of confirming information, probably because the confirming information had already exerted its influence due to the confirmation strategy people spontaneously use in most situations. However, presenting a disconfirming premise decreased the rating of the conclusion in Experiment 3 in a much larger degree, and succeeded to give very strong support for the explanation discounting principle when there were two conflicting premises.

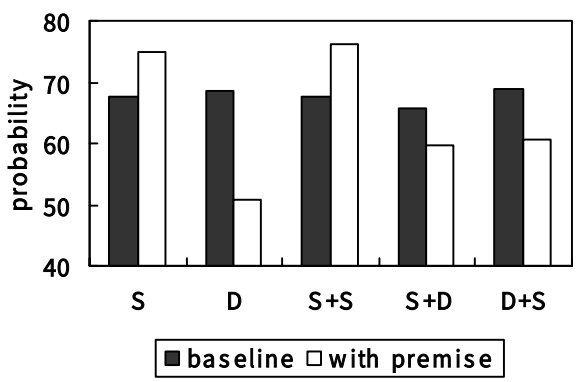

Figure 3. Average ratings of the conclusion: Experiment 3. (S: Same; D: Different)

As a whole, the results of the three experiments seemed to suggest that the explanation discounting principle seemed to work only when the disconfirming information became salient by either being presented one by one or by forcing respondents to think about the reasons.

General Discussion

Three experiments were conducted to explore whether the explanation discounting principle works when there are two conflicting premises. The results of the three experiments can be summarized as follows: (1) Both the confirmation strategy and the explanation discounting principle seemed to work when there was just one premise. In three experiments, it has been consistently observed that the Same premise increased the rating of the conclusion, supporting the confirmation strategy, and that the Different premise decreased the rating of the conclusion, supporting the explanation discounting principle. Results of the single-premise conditions suggested that people seemed to search for relevant information and use it when they had just one piece of relevant information. (2) However, only the Same premise(s) seemed to affect the plausibility of the conclusion when there were two premises under natural conditions. Ratings in the two mixed conditions were higher than or equal to the baseline in Experiment 1, but got equal or lower than the baseline when the premises were forced to be processed in Experiments 2 & 3. Our interpretation that only the confirming information seemed to influence the judgments and decisions is in good agreement with the information processing strategies generally accepted in cognitive psychology, such as Johnson-Laird & Byrne (1991) and Nisbett & Ross (1980).

However, the explanation discounting principle can explain the results of the three experiments if the implicit assumption that all information is processed in the same degree was modified. First, as I mentioned in the Introduction, the explanation discounting principle did not make any explicit assumption concerning the fate of conflicting information. Therefore, our interpretation of the discounting principle might be an unfair test of the discounting principle. Second, the relevance of the confirming premise and the disconfirming premise might be different. For instance, if we adopt the coherence of Thagard (1992), confirming premises share more attributes with the conclusion than the disconfirming premises. More specifically, the confirming premise shares the reason and the consequences of the reason with the conclusion (e.g., in the bad back example, both programmers and secretaries share two attributes, sit all day long and have bad backs), whereas the disconfirming premise shares only the consequences (e.g., furniture movers and secretaries have one attributes in common, they have bad backs). Therefore, the explanation discounting principle can explain the results of current experiments if their relevance were used as

relative weights of each premise. However, the explanation discounting principle still has problems explaining why making premises salient decreased the believability of the conclusion below the baseline in Experiment 3.

One aspect that has to be solved in the preceding argument is who, what, or when determines the processing order of the information. That is, deciding whether certain information is confirming or disconfirming to the conclusion can be solved only after we figure out the conclusion in the property induction tasks. Therefore the order of processing information might be different from the order the information is given. If this is the case, then there have to be multiple stages of processing. For instance, a primitive assessment of the relevance/confirmation of premises to the conclusion precedes the detailed processing of the relevant or confirming information.

A Fundamental Limitation of Symbol-Argument-Argument Notation As a Model of Human Relational Representations

Abstract

Human mental representations are both structure-sensitive (i.e., symbolic) and semantically rich. Connectionist models have well-known limitations in capturing the structure-sensitivity of mental representations, while traditional symbolic models based on varieties of symbol-argument-argument notation (SAA) have difficulty capturing their semantic richness. We argue that this limitation of SAA is fundamental and cannot be alleviated in the notational format of SAA itself. Finally, we review an approach to human mental representation that captures both its structure-sensitivity and semantic richness.

Relational reasoning—reasoning constrained by the relational roles that objects play, rather than just the features of the objects themselves—is ubiquitous in human mental life, and includes analogical inference, schema induction, and the application of explicit rules (Gentner, 1983; Holyoak & Thagard, 1995). In order to support human-like relational thinking, a representational system must meet two general requirements (Hummel & Holyoak, 1997): First, it must represent relations independently of their fillers and simultaneously specify how fillers are bound to relational roles (i.e., it must be a *symbol system*; Newell, 1990). Second, it must explicitly specify the semantic content of relational roles and their fillers. In this paper, we consider in detail the implications of the latter requirement, with an emphasis on symbol-argument-argument notation (SAA), which includes propositional notation, high-rank tensors, and many varieties of labeled graphs.

Properties of Relational Representations

Human Relational Representations are Symbolic

Symbolic representations have the property that symbols are invariant with their role in an expression[1], and the meaning of the expression as a whole is a function of both the symbols and their arrangement (i.e., role-filler bindings). For example, the expressions *chase* (Pat, Don) and *chase* (Don, Pat) mean different things, but Pat, Don, and *chase* mean the same things in both expressions. Formal symbol systems have this property by assumption: It is given in the definition of the system that symbols retain their meanings across different expressions, and that the meaning of an expression is a function of both its constituent symbols and their arrangement. Physical symbol systems (Newell, 1990)—such as digital computers and human brains—cannot simply "assume" these properties, but instead must actively work to ensure that both are satisfied. The claim that human mental representations are symbolic in this sense is controversial (e.g., Elman et al., 1996), however, relational generalization has proved unattainable for non-symbolic models of cognition, and there is reason to believe it is fundamentally unattainable for such models (see Doumas & Hummel, in press; Halford, Wilson, & Phillips, 1998; Hummel & Holyoak, 2003a; Marcus, 1998).

Human Relational Representations Specify the Semantic Content of Objects and Relational Roles

A second important property of human relational representations is that they explicitly specify the semantic content of objects and relational roles (e.g., the *lover* and *beloved* roles of *love* (x, y) or the *killer* and *killed* roles of *murder* (x, y)): We know what it means to be a lover or a killer, and that knowledge is part of our representation of the relation itself (as opposed to being specified in a lookup table, a set of inference rules, or some other external structure). As a result, it is easy to appreciate that the patient (i.e., *killed*) role of *murder* (x, y) is like the patient role of *manslaughter* (x, y), even though the agent roles differ (i.e., the act is intentional in the former case but not the latter); and the agent (i.e., *killer*) role of *murder* (x, y) is similar to the agent role of *attempted-murder* (x, y), even though the patient roles differ.

More evidence that we represent the semantics of relational roles explicitly is that we can easily solve mappings that violate the "n-ary" restriction (Hummel & Holyoak, 1997). That is, we can map n-place predicates onto m-place predicates where $n \neq m$. For instance, given statements such as *taller-than* (Abe, Bill), *tall* (Chad) and *short* (Dave), it is easy to map Abe to Chad and Bill to

[1] This is not to say that symbols may not have shades of meaning that vary from one context to another. For example, the symbol "*loves*" suggests different relations in *loves* (Mary, John) vs. *loves* (Mary, Chocolate). However, as noted by Hummel and Holyoak (2003a), this kind of contextual shading must be a function of the system's knowledge, rather than an inevitable consequence of the way in which it binds relational roles to their fillers.

Dave. Given *shorter-than* (Eric, Fred), it is also easy to map Eric to Bill (and Dave) and Fred to Abe (and Chad). These mappings are based on the semantics of the individual relational roles rather than the formal syntax of propositional notation, or, say, the fact that *taller-than* and *shorter-than* are logical opposites: *love* (*x*, *y*) is in some sense the opposite of *hate* (*x*, *y*), but in contrast to *taller-than* and *shorter-than* (in which the first role of one relation maps to the second role of the other) the first role of *love* (*x*, *y*) more naturally maps to the first role of *hate* (*x*, *y*). In short, the similarity and/or mappings of various relational roles are idiosyncratic, based on the semantic content of the individual roles in question. The semantics of relational roles matter, and are an explicit part of the mental representation of relations.

The semantic properties of relational roles are also evidenced in numerous other ways in human cognition, including memory retrieval (e.g., Gentner, Ratterman & Forbus, 1993; Ross, 1989), and analogical mapping and inference (Bassok, Wu & Olseth, 1995; Kubose, Holyoak & Hummel, 2002; Krawczyk, Holyoak & Hummel, in press; Ross, 1987). Indeed, the meanings of relational roles influence relational thinking even when they are irrelevant or misleading (e.g., Bassok et al., 1995; Ross, 1989), suggesting that access to and use of role-based semantic information is quite automatic. This information appears to be an integral part of the mental representation of relations. Given its centrality in human cognition, an important criterion for a general account of human mental representation is that it must represent relations in a way that captures the semantics of their roles.

SAA Accounts of Relational Representations

Numerous models of human cognition account for the symbolic nature of relational representations by postulating representations based on varieties of symbol-argument-argument notation (SAA). These include propositional notation, varieties of labeled graphs, and high-rank tensor products (e.g., Anderson & Lebiere, 1998; Eliasmith & Thagard, 2001; Falkenhainer, Forbus, & Gentner, 1989; Forbus, Gentner, & Law, 1995; Halford et al., 1998; Holyoak & Thagard, 1989; Keane, Ledgeway, & Duff, 1994; Ramscar & Yartlett, 2003; Salvucci & Anderson, 2001). In SAA notation relations and their fillers are represented as independent symbolic units, which are bound together to form larger relational structures. For example, in propositional notation the statement "John loves Mary" is represented by binding the symbol for the predicate *love* to a list of its arguments, here John and Mary, forming the proposition *love* (John, Mary). By virtue of their positions in the list of arguments, John is taken to be the filler of the first role of the *loves* relation (i.e., the *lover*), and Mary is the filler of the second role (i.e., the *beloved*). Labeled graphs use location in the graph to indicate relational bindings in much the same way: Relations are represented independently of their arguments (fillers), and relation-filler bindings are represented in terms of the fillers' locations in the graph. As such, SAA is meaningfully symbolic in the sense described above.

Because SAA systems are meaningfully symbolic they naturally support operations that require relational representations, such as structure mapping (a.k.a., analogical mapping; see e.g., Falkenhainer et al., 1989; Forbus et al., 1995) and matching symbolic rules (see Anderson & Lebiere, 1998). This is no small accomplishment. Numerous representational schemes, including traditional distributed connectionist representations (e.g., Elman, et al., 1996) and the kinds of representations formed by latent semantic analysis (e.g., Landauer & Dumais, 1997) have not succeeded in modeling relational perception or cognition, and, as noted above, there are compelling reasons to believe they are fundamentally ill-suited for doing so.

The successes of SAA notation as a model of human mental representation are thus decidedly non-trivial. At the same time, however, SAA notation has greater difficulty capturing the semantic content of human mental representations. Indeed, this limitation was a central part of the criticisms leveled against symbolic modeling by the connectionists in the mid-1980s (e.g., Rumelhart, McClelland, & the PDP Research Group, 1986; for a more recent treatment, see Hummel & Holyoak, 1997). One of the strengths of distributed connectionist representations is their natural ability to capture the semantic content of the objects they represent. By contrast, propositional notation and labeled graphs have difficulty making this semantic content explicit. As a result, symbolic models based on SAA notation often resort to a patchwork of external fixes such as look-up tables, inference rules and arbitrary, hand-coded similarity matrices (e.g., Salvucci & Anderson, 2001; high-rank tensors, e.g., Halford et al., 1998, are a notable exception, but see Doumas & Hummel, in press, and Holyoak and Hummel, 2000, for detailed treatments of the limitations of this approach).

Importantly, these fixes are external to the relational representations themselves: They are not instantiated in the notation of the representations that encode relations, but rather only at the level of the system that *processes* these representations. This separation is fine for accounts of cognition at Marr's (1982) level of computational theory, but for accounts at the level of representation and algorithm such fixes entail specifying multiple sets of representations (at minimum one for the notational system capturing the relations and a second for the system that captures the relations between different relations and/or semantics of those relations), and an interface for moving between them.

Moreover, relations in SAA are represented as indivisible wholes, leaving the roles implicit as semantically empty place-holders or arcs in a graph. For example, the *love* (*x*, *y*) relation is represented by a single symbol (in propositional notation), a single vector (in high-rank tensor products), or a single node (in a labeled graph)[2], and its roles, *lover* (*x*) and

[2] Not all models that employ labeled-graphs are based on SAA (e.g., Larkey & Love, 2003), although most are.

beloved (*y*), are not represented explicitly at all. As such, even if a relational symbol (as a whole) is assumed to have semantic content, SAA notation itself does not specify how this content is differentially applicable to its arguments. It is this limitation that gives rise to the *n*-ary restriction: Even if the symbol *taller-than* is assumed to have meaning, the expression *taller-than* (*x*, *y*) does not explicitly specify how the role filled by *x* is semantically similar to *tall* (*z*), so it provides no basis for mapping *taller-than* (*x*, *y*) onto *tall* (*z*).

Recall the semantic relations between the roles of *murder* (*x*, *y*), *manslaughter* (*x*, *y*), and *attempted-murder* (*x*, *y*). SAA notation can, at best, treat the entire relations as simply "similar" or "different". High-rank tensor systems, for instance, represent entire relations (but not their roles) as vectors, and compute the similarities between relations based on the similarities of their vectors. Models using propositional notation and labeled graphs can "recast" predicates into more abstract forms (e.g., coding both *murder* (*x*, *y*) and *manslaughter* (*x*, *y*) as *commit-violence-against* (*x*, *y*)). Neither of these approaches expresses the similarity relations between the individual roles of relations, however, because they fail to make individual relational roles (and thus their semantic content) explicit. As a result, they do not make clear how the roles of *manslaughter* (*x*, *y*) and *attempted-murder* (*x*, *y*) are related to the roles of *murder* (*x*, *y*), nor how they differ.

It is easy to imagine a look-up table or set of inference rules that would supply this information, but the number of rules required to specify the similarity relations between all relational roles would scale minimally with $(n^2 - n)/2$ (or $n^2 - n$ if equivalent bidirectional similarity is not assumed), where n is the number of relational roles in the system. Worse, these rules would be external to the system's SAA-based representational system, so an account of how the system operates at the level of representation and algorithm requires a description of the rule set, and an additional control structure to read the SAA and access the rules as necessary. All of this is obviated in a system that simply codes the semantic content of individual relational roles explicitly in the notation of the relational representations.

The convenience of "postulate them as you need them" inference rules makes it is tempting to assume that the lack of role-specific semantic information in SAA is merely a thorny inconvenience: Surely the problem of role-based semantics in SAA is solvable, and will be solved as soon as it becomes important enough for someone to give it attention. In the meantime, it is certainly no reason to abandon SAA as a model of mental representation, especially if the only alternatives are non-symbolic representational schemes (to anticipate, they are not).

But it turns out that the problem is more than just a thorny inconvenience. As elaborated in the next section, role-specific semantic information cannot be made internal to (i.e., explicit in) the notation of SAA. Instead, the knowledge of the semantics of individual roles can only be specified at the level of the whole system, instantiated in external routines or representational structures. As a result, systems employing SAA (i.e., traditional symbolic models) are at best incomplete as algorithmic accounts of human cognition.

Representing Relational Roles in SAA

In a symbol system, representing something explicitly means representing it as a structure (e.g., a proposition). Thus, to represent relational roles and their semantic content explicitly in SAA, it is necessary to represent them structurally (i.e., to *predicate* them). For example, to represent the *murder* (*x*, *y*) relation in terms of its *killer* (*x*) and *victim* (*y*) roles, SAA must represent *killer* (*x*) and *victim* (*y*) as propositions (or tensors, or nodes), and simultaneously represent the fact that together they compose the *murder* (*x*, *y*) relation.

A relation specifies that its arguments are engaged in certain specific functions or states. For instance, the statement *drive* (Brutus, the Honda) specifies that Brutus is playing the role of the individual driving, and that the Honda is playing the role of the thing being driven. This information is entailed by the relational statement itself. As a separate matter, the relation may also imply or suggest other relations (e.g., that Brutus knows how to drive, that the Honda is in running condition, etc.), but it directly entails only the *driver* and *driven-object* roles, and the binding of Brutus and the Honda to these roles.

A relation does more than simply imply its roles (just as the roles do more than simply imply their parent relation), it *consists of* them: Collectively, the roles, along with their linkage to one another, *are* the relation. Imagine a relation *R* (*p*, *q*), with roles $R_1(p)$ and $R_2(q)$, that implies relation *S* (*p*, *q*), with roles $S_1(p)$ and $S_2(q)$. Although *R* (*p*, *q*) entails or implies a total of four roles (i.e., those of *R* and those of *S*), only two (R_1 and R_2) compose *R* itself. Therefore, representing relational roles explicitly requires explicitly specifying which relations consist of which roles.

As summarized above, this information seems to come gratis (i.e., without computational cost) as an integral component of human relational representations. An adequate model of human relational representations should, therefore, capture this information in its relational representations, rather than relegating it to the processes that operate on these representations or to external representational systems. This distinction is subtle, but important. It is not enough that the system as a whole capture this information; instead the same representations that encode the relations should capture it. That is, the information should be captured at the level of the notation, or language, of the system rather than in an external system of inference rules, look-up tables, etc.

However, it is not possible to capture relations, their roles and the relation between them in the notation of SAA. In SAA representing a relation explicitly requires instantiating a proposition. If representing a relation implies representing its roles, and representing a relation's roles requires representing the relation between the relation and its roles, then representing any given relation implies a second

proposition representing the relation between the first relation and its roles. This second proposition contains a new relation, though, which implies roles of its own that must be related back to it in a third proposition, which also contains a new relation with roles that must be related back to it, and so on.

For example, imagine the propositions *love* (John, Mary) and *love* (Bill, Sally) and their role bindings, *lover* (John), *beloved* (Mary), *lover* (Bill) and *beloved* (Sally). The representations must specify which role bindings go together to form which relations (e.g., that *lover* (John) goes with *beloved* (Mary) – as opposed to *beloved* (Sally) or *lover* (Bill) – to form the complete relation *love* (John, Mary)). Specifying this composition relation in SAA notation requires a proposition of the form *consists-of* (*love* (John, Mary), *lover* (John), *beloved* (Mary))[3]. The predicate *consists-of*, however, is itself a relation, and so specifies a set of role bindings of its own, which must be explicitly represented and linked back to the original *consists-of* relation with a second *consists-of* relation. This second *consists-of* is also a relation and so specifies a set of role bindings of its own that must be linked back to it via a third *consists-of* relation, and so on.[4] The consequence is an infinite regress that can render the resulting representational system ill-typed (Manzano, 1996).

In other words, it is not possible to represent the relation between relational roles and complete relations explicitly in the notation of SAA. For the same reason, it is not possible to specify the semantic content of relational roles explicitly in SAA. As noted previously, this information can be specified in a complete *system* based on SAA (after all, many such systems are Turing complete), but it is not possible to capture this information in the SAA notation itself. Instead, the knowledge is necessarily contained in the processes that operate on the SAA representations, or in external representational systems that must be interfaced with the SAA notation. This property renders SAA notation fundamentally inadequate as a model of human mental representations. It does not imply that representing the semantic content of relational roles explicitly is impossible in an SAA based system; it simply indicates that such systems cannot capture this content in the same way that people seem to—i.e., as an integral part of the relational representation itself.

It is important to emphasize that the problem of infinite regress is by no means an argument against the general utility of SAA. On the contrary, propositional notation, for example, is an extremely useful tool for the purpose for which it was created, namely theorem proving. For this purpose, semantic emptiness is a virtue. It just happens that the design requirements for a representational system for theorem proving differ markedly from the design requirements for a representational system for supporting perception and cognition in living, behaving systems: While the former requires pristine semantic emptiness, the latter must deal with the semantically-rich, sometimes ugly realities of the world as it is. Given this, it is not surprising that a representational system designed for theorem proving should prove inadequate as a model of human mental representation.

Possible Objections and Responses

We are arguing that SAA is ill-suited for modeling human mental representations, including relational representations, for which it appears at first to be ideally suited. Proponents of traditional symbolic models of cognition are likely to object strenuously to our arguments. We shall try to anticipate some of these objections and respond to them.

One potential objection is that the infinite regress is irrelevant because it is a trivial matter to simply terminate the regress at any arbitrary point and declare it done. The problem with this objection is that the system does not finish the process it began. Once the progress halts, the relation between roles and relations remains unspecified.

Another potential objection is that although role-specific information cannot be specified in the SAA notation itself, it might be adequate to have the information specified at the level of the system as a whole. The problem with this objection is that it is an appeal to the status quo: Using lookup tables, etc., is precisely what current SAA-based models are forced to do. As we have argued, the data on the role of semantics in human cognition suggest that this approach is not adequate. Among other problems, it is too deliberate: The data on the role of semantics in memory retrieval, analogical mapping, etc., suggest that people use role-based semantic information automatically and without computational cost. Specifying information at multiple levels of representations and postulating routines for moving between the two is computationally costly. Although it is impossible, given the current state of our knowledge, to rule such an account out definitively, it certainly seems more plausible to assume that role-based information is simply a part of relational representations than to assume that the mind is equipped with a complex system of look-up tables. Indeed, the use of lookup tables is perhaps even more awkward than it appears at first blush. Without an explicit representation of role-specific semantics in its representations, an SAA system must use an external meta-system to interpret its SAA representations, decide when the look-up table (another representational system external to SAA) should be accessed, retrieve the relevant role information, translate that information into SAA, and insert it into the original SAA format. Importantly, the external control structure could not, itself, utilize SAA: if it

[3] Naming the relation that specifies the relation of a relation to its roles *consists-of* is, of course, completely arbitrary.

[4] One might argue that this problem could be solved by using binary rather than unary representations of roles. For example, representing *lover* (John) as *lover* (John, *loves* (John, Mary)), thus representing the role, its filler, and the relation to which it belongs. The problem with this approach is that it simply transfers the same problem to a new representation. In SAA binary predicates dictate relations. As a result, the system would still have to specify the roles of this binary predicate and how they relate back to it.

did, then it too would require an external meta-system to keep it's own relation and role information straight. This solution is thus both inelegant and impractical, and in the limit results in a regress, not of nested "consists-of" relations, but of external control structures.

A third objection to our argument concerns the *n*-ary restriction. This problem might be solved simply by postulating that all *n*-place predicates (where *n* is free to vary) be replaced by *m*-place predicates (where *m* is a constant, say, 3). For example, *tall* (*x*) would be recast as *tall* (*x*, -, -), and *taller-than* (*x*, *y*) as *taller-than* (*x*, *y*, -), where "-" denotes a permanently empty "dummy" slot. In this way, *tall* (*x*, -, -) could be mapped to *taller-than* (*x*, *y*, -) by virtue of their both taking three "arguments". One problem with this proposal is that it assumes some procedure for deciding how to recast the predicates. For example, should *short* (*y*) be recast as *shorter-than* (*y*, -, -) (the intuitive recasting) or as *taller-than* (-, *y,* -)? Note that this question must be answered *prior* to discovering the very mapping(s) the recasting is supposed to permit. A second problem with this proposal is that it still leaves the problem of mapping non-identical predicates: How should the system map the arguments of *taller-than* (*x*, *y*, -) to those of *shorter-than* (*x*, *y*, -) without knowing what the roles of each relation "mean"?

Semantically Rich Representations of Relational Roles

We have argued that SAA is at best incomplete as a model of human mental representation. However, this limitation does not by any means imply that we must abandon symbolic accounts of mental representation. Rather, what is needed is a representational system that makes relational roles, their semantics, their bindings to their fillers and their composition into complete relations all explicit. This approach is commonly known as *role-filler binding* (e.g., Halford, et al. 1998).

In a role-filler binding system roles are represented explicitly and bound to their fillers. Relations are composed of linked role-filler bindings. One example is the representational system employed by Hummel and Holyoak's (1997, 2003a) LISA model. LISA uses a hierarchy of distributed and localist codes to represent relational structures. At the bottom, "semantic" units represent objects and roles in a distributed fashion (e.g., for the relation *love* (John, Mary) "John" might be represented as *human*, *adult*, *male*, etc., and Mary by *human*, *adult*, *female*, etc.; similarly, the *lover* and *beloved* roles of the *love* relation would be represented by units capturing their semantic content). At the next level, these distributed representations are connected to localist units representing individual objects and relational roles. Above the object and role units, localist role-binding units (SPs) link object and role units into specific role-filler bindings. At the top of the hierarchy, localist P units link SPs into entire propositions.

In this representation, the long-term binding of roles to their fillers is captured by the conjunctive SP units, thus violating the role-filler independence required for symbolic representation. However, when a proposition becomes active, its role-filler bindings are also represented dynamically by synchrony of firing: SP units in the same proposition fire out of synchrony with one another, causing object and predicate units, along with their corresponding semantics, to fire in synchrony with each other if they are bound together, and out of synchrony with other bound roles and objects. On the semantic units, the result is a collection of mutually desynchronized patterns of activation, one for each role-filler binding. Thus, when a proposition is active, role-filler independence is maintained on its object, predicate and semantic units, with the role-filler bindings carried by the synchrony relations among these units.

This is only one way to represent relational knowledge in a role-filler binding scheme (see also Halford et al, 1998, Smolensky, 1990). As demonstrated by Hummel, Holyoak and their colleagues (see Hummel & Holyoak, 2003b for a review), however, it is a very useful one. LISA has been shown to simulate aspects of memory retrieval, analogical mapping, analogical inference, schema induction, and the relations between them. It also provides a natural account of the capacity limits of human working memory, the effects of brain damage and normal aging on reasoning, the relation between effortless ("reflexive") and more effortful ("reflective") reasoning, and aspects of the perceptual-cognitive interface. It inherits these abilities from its ability to capture both the relational structure and the semantic richness of human mental representations.

Conclusion

Few would claim that people literally think in the predicate calculus. However, many researchers have argued that SAA-based representations serve *at least* as a plausible shorthand for human mental representations. We have argued that SAA notation is *at most* a shorthand for human relational representations—a shorthand that must necessarily leave the messy business of the semantics of relational roles to fundamentally external representations and processes. Inasmuch as the semantics of roles are an important internal component of human mental representation, as we, and others, have argued they are, this fact leaves an important facet of human mental representation necessarily beyond the reach of SAA-based models. The solution to this problem is not to abandon symbolic representations altogether, as proposed by some, but rather to replace SAA with a role-filler binding approach to the representation of relational knowledge in models of cognition. Doing so provides a natural basis for capturing both the symbolic structure of human mental representations and their semantic richness.

Structure Mapping and the Predication of Novel Higher-Order Relations

Leonidas A. A. Doumas (adoumas@psych.ucla.edu)

Abstract

Relations play a central role in human perception and cognition, but little is known about how relational concepts are acquired and predicated. For example, how do we come to understand that physical force is a higher-order multiplicative relation between mass and acceleration? We report an experiment demonstrating that structure mapping (a.k.a., analogical mapping) plays a key role in the predication of novel higher-order relations. This finding suggests that structure mapping—i.e., the appreciation of analogies—may play a pivotal role in the acquisition and predication of novel relational concepts.

Relational Reasoning

The processing of relations plays a central role in human perception and thought. It permits us to perceive and understand the spatial relations among an object's parts (Hummel, 2000; Hummel & Biederman, 1992; Hummel & Stankewicz, 1996), comprehend arrangements of objects in scenes (see Green & Hummel, 2004, for a review), and comprehend abstract analogies between otherwise very different situations or systems of knowledge (e.g., between the structure of the solar system and the structure of the atom; Gentner, 1983; Gick & Holyoak, 1980, 1983; Holyoak & Thagard, 1995). The power of relational thinking resides in its ability to generate inferences and generalizations that are constrained by the *roles* that elements play, rather than strictly the properties of the elements themselves: The sun is similar to the nucleus of an atom, not because of its literal features, but because of their shared relations to planets and electrons, respectively.

Experience can cause profound changes in the way we process relations. The difference between an expert chess player and a novice, for example, lies in the ability to quickly perceive and reason about the meaningful relations among the pieces on the board (and relations among those relations). Relational learning is central to both the most abstract and uniquely human cognitive abilities (including mathematical and scientific reasoning), and the most "everyday" reasoning using analogies, schemas and rules (Gentner, 1983; Holland, et al., 1986; Hummel & Holyoak, 1997, 2003).

In order to reason explicitly about a relation it is necessary to *predicate* that relation, that is, to represent it as an explicit predicate that takes arguments. Consider an example. In a match-to-sample task, an animal is shown a sample stimulus (e.g., a red square), and two alternatives, one that matches the sample (another red square) and one that does not (e.g., a green square). The animal's task is to indicate which alternative matches the sample. Many animals, including honeybees (Giurfa et al., 2001), can learn to perform this task with simple stimuli such as colors and shapes (see Holyoak & Thagard, 1995, Thompson & Oden, 2000). The computational requirements for performing this task include the ability to explicitly represent values of the relevant feature dimension (e.g., "red" for the dimension "color"), and the ability to remember the value of that dimension in the sample for the purposes of choosing the correct alternative. Despite initial appearances, the task does *not* require the animal to explicitly appreciate that the correct choice item is in any way the "same" as the sample. For example, if color is the relevant dimension, then after the presentation of a red sample, the animal need only maintain a representation of "red" until the choice items appear. The animal need never reflect explicitly on the fact that the sample and the correct choice are the same color (Thompson & Oden, 2000).

However, the task can be generalized to require an explicit appreciation of "sameness." Consider a *relational* match-to-sample task, in which the sample depicts two triangles, alternative A depicts of circle and a diamond, and alternative B depicts two squares. Choosing B as the correct match to the sample requires the reasoner to represent B and the sample in terms of their shared relation (i.e., *same-shape* (x, y)). College students find this comparison trivial, yet only humans and symbol-trained chimpanzees are known to be able to perform this task reliably (Thompson & Oden, 2000). (Fagot, Wasserman & Young, 2001, claim to show relational matching to sample in the baboon, *Papio papio*. However, their data—in particular, the baboons' failure to learn the task when the sample and choice options each contained only two objects—are more consistent with the baboons' responding to stimulus entropy as a holistic perceptual feature, akin to color, rather than *same* as an explicit relation; Hummel & Holyoak, 2003.)

The assumption that people represent the relation *same-shape* in the same way for the squares as for the triangles provides an intuitive account of our ability to perform the relational match to sample, but it begs the question of *why* we see the relation "same shape" in the squares, whereas most other animals only see squares. What are the mental operations that allow us to discover and predicate *same-shape* as an explicit relation that retains its properties over

the sameness of squares to squares and the sameness of triangles to triangles?

The question of how we discover and predicate new relations is central to cognitive science because the kinds of problems a person (or cognitive model) can solve, and the characteristics of its solutions, depend critically on the relations the person (or model) does and does not represent explicitly. Models of human perception and cognition that represent relations explicitly (i.e., as predicates that take arguments) can solve problems far beyond the scope of models that do not represent relations explicitly (e.g., traditional connectionist models, which represent all concepts as simple lists of features; for reviews see Doumas & Hummel, in press; Hummel & Holyoak, 1997, 2003; Marcus, 1998). But to date, all the models that do represent relations are simply given, by the modeler, a vocabulary of relational concepts with which to reason (examples include ACT-R [Anderson & Lebiere, 1998], LISA [Hummel & Holyoak, 1997, 2003], SME [Falhenhainer, Forbus & Gentner, 1989] and, SOAR [Rosenbloom, Newell, & Laird, 1991], among many others). The question of where these concepts come from, and the related question of how we know which relations to predicate in which contexts, is rarely if ever addressed, and the answer to this question is far from well understood. Understanding how the mind comes to represent relations as explicit predicates would contribute substantially to our understanding of the origins of human perception and thinking, and to the development of symbolic thought (Smith, 1989).

Relational Predication

The question of relational predication subsumes at least two related questions: First, how do we recognize and predicate familiar relations for use in novel situations? It is one thing to understand abstract relational notions such as *same-as*, *threatens* or *covaries-with*; it is another to recognize that a relation applies in a given situation and to explicitly predicate it in the service of understanding that situation. Second, how do we discover new relations? For example, what happens in the mind of a child between the time when she does not understand the relation *same-shape* (x, y), and the time when she does? Inasmuch as new relations are learned as combinations of familiar relations, or as familiar relations applied to novel dimensions, the question of relational discovery is clearly related to the question of predication: Especially for adults, discovering new relations may often be a process of discovering which familiar relations apply in a novel situation, and discovering how they are linked together by higher-order relations. Consider, for example, the physics student who is first learning to reason about force as a relation between mass, a basic property of an object, and acceleration, itself a relation between velocity and time. It is this version of the relation discovery question—how do we discover novel higher-order relations among familiar relations—that is the focus of the present paper.

Our ability to appreciate that the relation between the squares in the relational match to sample task is the same as the relation between the triangles—and to choose a pair of squares over a circle and a diamond as the correct match to a pair of triangles on the basis of that relation—illustrates that relations are *invariant* with their arguments (Hummel & Holyoak, 2003): *same-shape* (x, y) is the same relation, regardless of the particular shapes that happen to be bound to x and y at the time. It is precisely this invariance that allows us to appreciate what *same-shape* (triangle1, triangle2) has in common with *same-shape* (square1, square2). As a result of this invariance, *same-shape* ranges over *all possible* shapes, so it is not learnable in terms of the perceptual features of any particular pair of shapes (see Kellman, Burke, & Hummel, 1999). The ability to perform tasks based on such relations—and to discover and predicate them—is therefore fundamentally beyond the reach of any learning algorithm based strictly on the statistical regularities among the elements of the stimuli in its training set—i.e., the vast majority of all theories of learning (see Hummel & Holyoak, 2003).

The problem of relational learning and predication is further complicated by the sheer number of potentially relevant relations present in any given situation. The number of first-order relations among n items increases minimally with $(n^2 - n)/2$ (and this assuming that all relations are commutative, which is not the case for most relations). Worse yet, the number of higher-order relations over these first-order relations is literally unbounded. Any task (e.g., category learning, problem solving, etc.) that calls for the discovery of new higher-order relations is therefore functionally impossible without additional constraints on the selection of which relations to predicate.

Given this, how do people discover and predicate new relations? An important theme that has emerged in the literature on relational reasoning is that *structure mapping* (a.k.a. *analogical mapping)*—the process of finding relational correspondences between the elements of two systems—plays a central role in all forms of relational reasoning (see Hofstadter, 2001; Holyoak & Thagard, 1995). A primary hypothesis motivating the present research is that structure mapping may also play a central role in discovery and predication of new relations. The reason is that structure mapping is driven more by the relational roles that objects play than by the features of the objects themselves. By revealing relational similarities between otherwise different-seeming systems, structure-mapping may bootstrap the discovery of any higher-order relations the two systems have in common. Consistent with this hypothesis, several previous studies have demonstrated that structure mapping bootstraps the induction of abstract relational schemas (e.g., Gick & Holyoak, 1983; Ratterman & Gentner, 1998; Sandhofer & Smith, 2001; Yamauchi & Markman, 2000), and that comparison helps people appreciate what lower-order relations might be relevant to a specific task (Gentner & Namy, 1999; Namy & Gentner, 2002; Yamauchi & Markman, 1998).

The current experiment was designed to investigate whether analogical mapping may also help people to discover the higher-order relations that analogous systems have in common—that is, whether analogical mapping may bootstrap the discovery of novel higher-order relations. If it does, then analogical mapping may not only be a process that depends on the relations we can predicate, but may also be a process that aids us in the predication of new relations.

Experiment

The experiment used a category-learning paradigm to measure relational predication. Categories were defined by an unfamiliar higher-order relation between the elements of exemplars. Each exemplar consisted of drawings of three simple "cells" inside a circular frame (see Figure 1). Within an exemplar, the cells varied in their location in the frame, their shape, the thickness of their membrane, the roundness of their nucleus, and the number of organelles. Categories were defined by a higher-order relation between the cells' membrane thickness and the roundness of their nuclei: In Category A, the thicker a cell's membrane, the rounder its nucleus; in Category B, the thicker the membrane the more elliptical its nucleus. The cells' locations in the frame, shape, and number of organelles varied randomly and were uncorrelated with category membership.

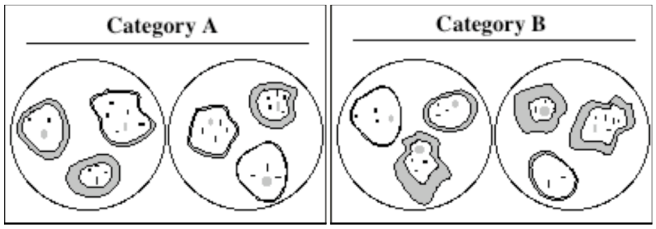

Figure 1. Two stimuli from Category A and two from Category B.

The exemplars were designed to make category learning impossible without discovering the higher-order relation between relative membrane thickness and nucleus roundness. Absolute thickness and roundness were non-predictive of category membership because the thinnest membrane (or least round nucleus) in one exemplar of a category was potentially the thickest (or roundest) in another exemplar of the same category. For the same reason, conjunctions of specific roundnesses and thicknesses were also non-predictive. Every exemplar, regardless of category, had three cells, one of which had a thickest membrane and another of which had a thinnest (with the third in between), so the categories were not learnable in terms of relative (or absolute) membrane thickness. Likewise, every exemplar, regardless of category, had one cell with a more round nucleus than the others and one with a more elliptical nucleus (with the third in between). In other words, the categories were not definable, or learnable, in terms of any basic features or even first-order relations.

For this reason the category structure is unlearnable by any model that codes exemplars in terms of their features (e.g., location, color, width, orientation, etc.) or conjunctions of their features, but cannot explicitly represent relations among those features and relations among relations. Such models constitute the vast majority of mathematical and computational models of category learning (e.g., Krushke, 1992, 2001; Nosofski, 1988; Nosofski & Palmeri 1998), including all connectionist models (see Doumas & Hummel, in press; Hummel & Holyoak, 2003; Marcus, 1998).

By contrast, the categories are learnable in the space of *conjunctions* of *relative* membrane thickness and *relative* nucleus roundness—that is, in terms of a higher-order relation between the first-order relations of relative thickness and relative roundness (which is simply a restatement of the category-defining higher-order relation).

Two groups of subjects were trained to categorize exemplars into the two categories. One group (the *Map* group) performed a mapping task halfway through the category-learning task; the other group (the *No Map* group) did not. Subjects in the No Map condition simply studied a pair of exemplars from the same category (either A or B, counterbalanced); subjects in the Map condition viewed a pair of exemplars from the same category and were asked to indicate which cell in one exemplar corresponded to which in the other and why.

Our predictions were as follows: (1) To the extent that the category-relevant higher-order relation between cells' relative membrane thickness and relative nucleus roundness is unfamiliar to our subjects, categorization performance on the pre-mapping trials ought to be near chance. (2) To the extent that mapping helps subjects to predicate this relation, post-mapping categorization performance of subjects who map correctly in the Map condition should jump abruptly to ceiling (as a result of predicating the category-defining relation), but performance in the No Map condition, and the performance of those who map incorrectly in the Map condition, should remain near chance.

Methods

Participants: 20 UCLA undergraduates participated for course credit.

Materials: Each exemplar consisted of three drawings of simple cells in a circular frame. The cells differed in their shapes, location, membrane thickness, nucleus roundness, and number of organelles (see Figure 1).

Seven membrane thicknesses and seven nucleus roundnesses were used to construct the stimuli, making it possible for the thickest membrane (or roundest nucleus) in one exemplar of a category to be the thinnest (or most elliptical) in another exemplar of the same category, thus making it impossible for subjects to categorize correctly based on absolute thickness or roundness (i.e., it is necessary to respond on the basis of *relative* thickness and roundness between cells in an exemplar).

The locations, shapes, and number of organelles of the cells in an exemplar varied randomly, subject to the constraint that no cells ever overlapped in the frame. Each cell was one of 6 different shapes and contained between 1 and 6 organelles.

We created exemplars used in the pre-mapping, post-mapping, and mapping phase of the experiment (described more fully below) withholding membrane thicknesses 3 and 7 (the thickest), and nucleus roundnesses 1 (least round) and 5 for construction of transfer exemplars. The exemplars used in the transfer phase were created under the constraints described above, with the additional constraints that at least one novel thicknesses and one novel roundness appeared in each exemplar, and each novel thickness and roundness appear in at least three of the six transfer exemplars (see below). The withheld thicknesses and roundnesses consisted of values both within the bounds of the values seen by subjects during the training and test phases of the experiment and values outside those bounds. Thus, transfer trials required subjects to both interpolate and extrapolate learning to new values.

The exemplars used during the mapping phase consisted of two exemplars from the same category placed side by side.

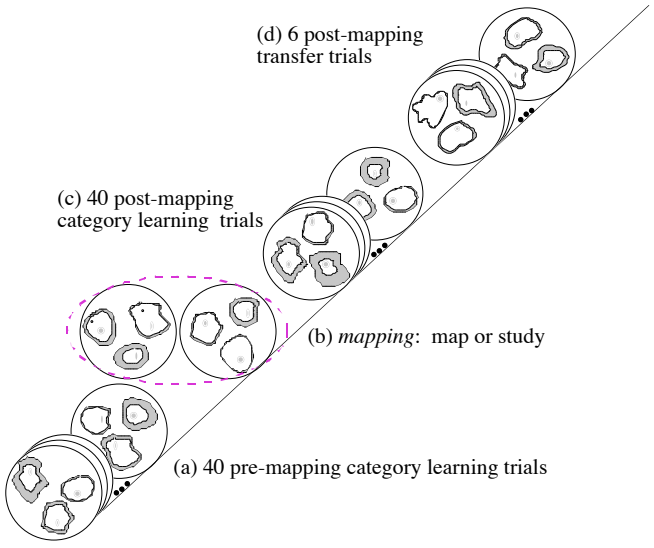

Figure 2. Structure of the experimental procedure. (a) Training phase, 40 trials; (b) mapping phase; (c) test phase, 40 trials; (d) transfer phase, 6 trials.

Procedure: Ten subjects were randomly assigned to each experimental condition. All stimuli were presented on a computer screen. All subjects received 40 pre-mapping training exemplars (20 A's and 20 B's) in a random order (Figure 2a). Their task was to indicate (with a key press) whether each exemplar belonged to Category A or B. Each response was followed by accuracy feedback. Following the initial training phase, subjects were presented with one of the two mapping sets (either two As or two Bs; Figure 2b). Subjects were informed that both exemplars belonged to the same category but they were not told which category they belonged to. Subjects in the No Map condition were instructed to study the mapping set for one minute. Subjects in the Map condition were asked to indicate which cell in the exemplar on the left corresponded to each cell in the exemplar on the right, and to state the reason or reasons for each correspondence. Conditions and mapping sets were fully counter-balanced. All subjects then received 40 post-mapping training trials (20 A's and 20 B's) in a random order (Figure 2c). Responses were followed by accuracy feedback as before. In the final transfer stage of the experiment subjects were presented with the six transfer exemplars (3 A's and 3 B's) in random order and their task was to categorize each (Figure 2d). They received no accuracy feedback during this part of the experiment.

Scoring: All participants were scored for number of correct responses in the pre- and post-mapping trials (maximum 40 correct for each) and the transfer trials (maximum 6 correct). We also recorded the mappings made by participants in the Map condition. At the end of the experiment all subjects were also asked to state the rule(s) they had used to categorize the exemplars.

Results

The results of the experiment were exactly as predicted. An independent-samples t-test showed no main effects for mapping, $t(18) = 1.13$, $p > .25$, on the pre-mapping training trials (mean-proportion-correct$_{MAP}$ = .52, mean-propotion-correct$_{NO\text{-}MAP}$ = .47), which is expected, as the groups received exactly the same treatment prior to mapping. Performance in neither group differed significantly from chance (50% correct).

A second independent-samples t-test was run for performance on the post-mapping trials (Figure 3a). Post-mapping, categorization performance in the Map condition was significantly more accurate (mean-proportion-correct$_{MAP}$ = .77) than in No Map (mean-propotion-correct$_{NO\text{-}MAP}$ = .48), $t(18) = 3.84$, $p < .01$. Accuracy in the No Map group did not differ from chance.

A similar pattern of results obtained on the transfer trials (Figure 3b). Subjects in the map condition performed significantly more accurately (mean-proportion-correct$_{MAP}$ = .83) than those in the no map condition (mean-propotion-correct$_{NO\text{-}MAP}$ = .42), $t(18) = 4.16$, $p < .01$. Performance of the No Map group on the transfer trials did not differ from chance.

The participants' reports of their mappings and rule use also revealed interesting patterns. First, none of the 10 subjects in the No Map group, and 7 of the 10 subjects in the Map group correctly stated the rule defining category membership at the end of the experiment. Second, there was a perfect 1:1 correspondence between subjects who correctly mapped the cells during the mapping phase and those who correctly stated the rule: All and only those subjects who identified the correct mappings were able to

state the category-defining rule at the end of the experiment. All other subjects either missed the relevant dimensions completely or mapped based on absolute membrane width and absolute nucleus roundness, which, as stated previously, were not sufficient for correct categorization.

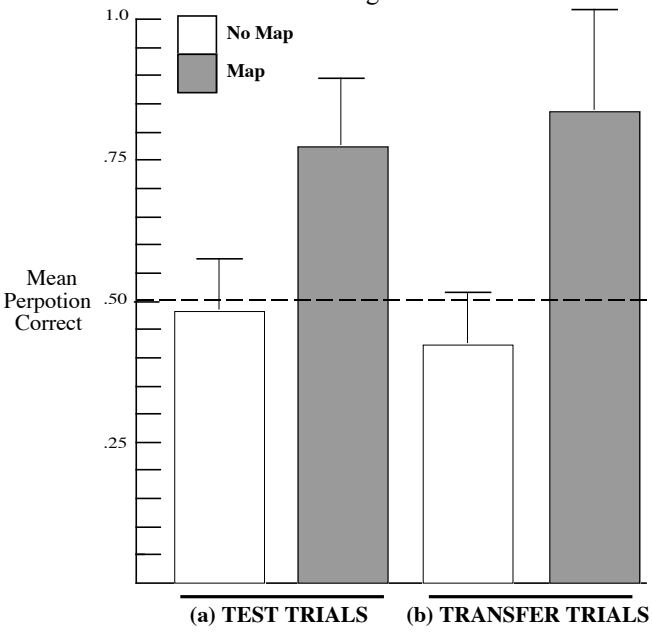

Figure 3. (a) Mean number of correct responses on post-mapping trials as a function of condition. (b) Mean number of correct responses on transfer trials as a function of condition. The dashed line indicates chance.

Discussion

Relations play a central role in human perception and thinking, yet little is known about how relational concepts are acquired and predicated. The problem of relational predication is especially difficult because it is underconstrained. We hypothesized that structure mapping might aid in the discovery and predication of novel higher-order relations.

The results of a category learning experiment support this hypothesis. Subjects who mapped exemplars from the same category onto one another were much better able to learn the novel, category-defining higher-order relation than subjects who did not map. Indeed, performance of the latter group never got above chance.

Additionally, subjects who mapped were able to both interpolate and extrapolate learning to new exemplars with novel stimulus values (i.e., novel membrane thicknesses and nucleus roundnesses) and to verbally state the relational rule that defined category membership. Subjects who did not map were unable to either transfer to new stimuli or to state the category-defining rule. These findings suggest that mapping aids in the predication of novel relations, and that the resulting relations are explicit, in the sense of being available to bind to novel inputs (recall the transfer trials; also, see Hummel & Holyoak, 1997, 2003).

More broadly, the findings reported here suggest that the same cognitive mechanisms that underlie our ability to make analogies—namely, those underlying structure mapping—may also underlie our ability to discover and predicate new relational concepts. If this suggestion is correct, then the evolution of the capacity for generalized structure mapping may well be the "great leap forward" (Newell, 1990) that ultimately gave rise to our capacity for generalized symbolic thought.

Abstract

Two experiments tracked the emergence of lexical competition effects for newly learnt spoken words (e.g., "cathedruke"). Experiment 1 compared form-only learning with learning in semantically rich sentence contexts. In both cases, although immediate explicit recognition of the novel words was good, lexical competition effects (e.g., "cathedruke-cathedral") emerged only after a delay of at least 24 hours. Experiment 2 evaluated the timecourse of learning in more detail and used embedding (rather than cohort) new competitors (e.g., "shadowks"). Again results showed no evidence of lexicalization immediately after exposure, but clear lexical competition effects after 24 hours. Furthermore, recognition and free recall improved over time. These results are interpreted in terms of a consolidation process that integrates words into the mental lexicon over a relatively protracted period of time.

1. Introduction

Our knowledge about what information is relevant for language acquisition has increased greatly in the last decade. Factors such as statistical properties of the input (Saffran, Aslin, & Newport, 1996) and current lexical knowledge (Dahan & Brent, 1999) have been shown to influence lexical development. However, less is known about exactly how new vocabulary items are integrated into one's mental lexicon, a process called "lexicalization". The main reason for this state of affairs is that studies on word acquisition have typically used only direct measures of learning, such as the performance in familiarity judgment or recollection tasks. Yet, such measures only tell us about the strength of the traces left by exposure, not whether a new lexical entry *per se* has been created.

A critical methodology for addressing the lexicalization issue looks at whether newly learnt words influence how the learner recognizes preexisting words. For models of spoken word recognition, a key feature of a lexical entry is its ability to be evoked when compatible with the input, and to compete with similar-sounding entities for identification (e.g., McClelland & Elman, 1986). Therefore, a strong test of whether a speech sequence has been lexicalized is whether it engages in lexical competition, and thereby affects the activity within the mental lexicon.

In a recent study (Gaskell & Dumay, 2003), we began to explore how and when newly learnt spoken words become involved in the lexical competition process, or in our terms, produce a "lexical footprint". Adults were familiarized with made-up words that overlapped strongly with existing words (such as "cathedruke" for "cathedral"), through repeated presentation in a phoneme-monitoring task. In one experiment, good explicit knowledge of the novel words was obtained after only one training session (i.e., 12 presentations of each item), whereas the inhibitory influence of these new competitors on the identification of existing words in a lexical decision task (LD) required three (successive) days of exposure to emerge.

In another experiment, we disentangled the roles of time and level of exposure in the lexicalization process, using a single training session at a high exposure rate (i.e., 36 presentations). We also swapped LD with a more implicit test of lexical activity, the pause detection task. Here, participants made speeded decisions as to whether a short silence was present towards the offset of the existing words (e.g., "cathedr_al"). As Mattys and Clark (2002) showed, pause detection latencies are positively correlated with the amount of lexical activity elicited by the portion of speech preceding the pause. They hypothesized that the activation of lexical candidates involves the use of processing resources that would otherwise be allocated to pause detection. Our experiment showed good explicit recognition of the novel items right after exposure. In contrast, an increase in lexical activity as indexed by longer pause detection latencies when a new competitor had been learnt was not immediately observed, but had emerged when re-tested a week later.

So, in contrast to phonological storage, lexicalization is apparently not instantaneous and in fact may require a substantial amount of time, possibly to allow the consolidation of episodic traces (cf. O'Reilly & Norman, 2002). Nonetheless, on the basis of the above findings, it is not possible to tell how long it takes after a sufficient level of exposure has been reached for a newly learnt word to be lexically operational.

Furthermore, in Gaskell and Dumay (2003) participants had to learn only the sound-form of the novel words in quite an artificial situation, i.e., phoneme monitoring. Therefore, whether these data give us a good picture of what happens in more normal circumstances when semantic and thematic information are usually available must be addressed. In particular, the delay observed in the emergence of lexical

footprint could well result from the relatively impoverished conditions in which the novel words were acquired. Word learning, as measured by recognition and recall, is often improved when a meaning is available to attach to the novel phonological form (e.g., Rueckl & Olds, 1993; Whittlesea & Cantwell, 1987). On these grounds, linking the form of the novel words to some semantic representations during encoding may give rise to a faster lexicalization and, potentially, to a "deeper" lexical footprint.

Finally, so far the onset-matched competitors that have been used to test for the emergence of lexical competition were cohort competitors, i.e., novel and existing items that mismatch towards their offset. Therefore, we do not know whether these effects can be extended to a more general view of lexical competition encompassing all words that overlap to any degree (cf. McQueen, Norris, & Cutler, 1994). The following experiments address these issues.

2. Experiment 1

Experiment 1 examined whether providing some semantic information along with the form of the novel words during exposure would result in a deeper lexical footprint and/or the faster emergence of this effect. On two successive days of learning, novel words (e.g., "cathedruke" for "cathedral") were heard 12 times either in isolation, as carriers in a phoneme monitoring task, or in a sentential context during a semantic verification task. Here, they were associated with the name of a conceptual category (e.g., "vegetable"). The effect of exposure to these new cohort competitors on identification of the base words was evaluated immediately, 24 hours later (before the second exposure) and after a week, using a LD task. In addition, whether the novel words learnt under semantic exposure had acquired a meaning was tested in two ways. First, during the LD task, we also presented each novel word followed directly by their category name, and measured the extent to which the former could speed up responses to the latter (cf. Dagenbach, Horst, & Carr, 1990). Second, we looked at how much the novel words would elicit production of a word related to the meaning of the category name in a free association task.

2.1. Method

2.1.1. Participants. Thirty native British English speakers with no known auditory or language impairment were tested. They were students at the University of York (UK) or lived in the surrounding area, and were all paid for their participation.

2.1.2. Materials and Design. The key materials contained 12 bisyllabic and 24 trisyllabic item triplets (based on Gaskell & Dumay, 2003, Experiment 2). Each triplet included a base word, such as "cathedral", and two nonwords, such as "cathedruke" and "cathedruce". The nonwords diverged from the base word at the final vowel and from each other at the final consonant or consonant cluster. One nonword (e.g., "cathedruke") was presented as novel word, whereas the other one was used as alternative choice in a recognition test. Base words were monomorphemic nouns that ranged in frequency between 2 and 19 occurrences per million and had their uniqueness point (UP) located at or before the final vowel. Hence, if exposure led to lexicalization of the novel word, the latter was expected to become the main competitor of the base word, shifting its UP towards its offset.

For the semantic exposure phase, each novel word was assigned a meaning, based on a conceptual category unrelated the base word (cf. Battig & Montague, 1969). For example, "cathedruke" was associated with "vegetable". Two sentences in which each novel word appeared were then constructed. One explicitly conveyed information about the category membership of the novel word, such as "*A cathedruke is a variety of vegetable*"; the other provided a more general semantic context, such as "*The cook served the boiled cathedruke with a steak and baked potatoes*".

The test items were divided into three groups, as were the participants. During exposure, a given group of participants heard 12 novel words in a phoneme monitoring task and 12 others in a semantic verification task, the items being assigned to a different exposure condition (phonological, semantic or unexposed) across the three alternative versions of the experiment. Participants were presented with all base words during the LD lexicalization test. Thus, for any participant, new competitors were potentially acquired for 2/3 of the existing words, and overall each item was equally represented at the three levels of the factor "exposure".

Base words, novel words, alternative nonwords, category names and sentences were produced in a soundproof booth by a male native speaker of British English, recorded onto CD, and stored as separate files using CoolEdit.

2.1.3. Procedure. On day 1, participants were exposed to the novel words through the phoneme monitoring and semantic verification tasks, with task order counterbalanced across participants. Next, they were tested for lexicalization effects in a LD task, followed by a two-alternative forced choice (2-AFC) recognition test which assessed explicit knowledge of the novel words, and, finally, a free association task. On day 2, participants performed the LD task, the 2-AFC recognition test and the free association task before a second exposure phase took place. On day 8, the procedure was the same as on day 2 except that there was no further exposure.

The phoneme monitoring component of the *exposure phase* involved 12 novel words and consisted of 12 blocks in which each novel word occurred once. A target phoneme was specified for each block, and in all 6 phonemes were used (/n/, /d/, /t/, /s/, /p/ and /m/). Participants had to make speeded decisions as to whether the target was present or absent in the word, by pressing one of two buttons. The semantic verification component used 12 other novel words, each presented 6 times by way of their "category membership" sentence, and 6 times by way of their "semantic context" sentence. On each trial of a given block, participants had to make a yes/no judgment about the

meaning of the novel word. In all 6 questions were used, asking whether the novel word referred to something that was (1) man-made, (2) alive, (3) edible, (4) audible, (5) touchable, or (6) liked by the participant.

The *lexicalization test* required making timed LD to all the base words, the novel words and their associated category names intermixed with a large set of fillers (i.e., 64 words, 102 nonwords). The order of stimulus presentation was the same for each participant but varied every day. It was pseudorandomized such that each base word (e.g., "cathedral") occurred at least 20 trials before its related novel word (e.g., "cathedruke"), which was then immediately followed by the associated category name (e.g., "vegetable"). The proportion of semantically related pairs, i.e., a novel word followed by its category name, was 4.4%. Participants were instructed to press "yes" only to the existing real words, and had 3 s. from stimulus onset to respond. The inter-trial interval was 1 s. The LD latencies to the base words allowed us to estimate the amount of lexical competition induced by prior exposure to the novel words during the training phase. The LD latencies to the category names allowed an estimate of the extent to which these words were semantically associated with the immediately preceding novel word (which could act as a prime).

In the *2-AFC recognition test*, novel words and alternative nonwords were presented in pairs (e.g., "cathedruke-cathedruce"), and participants had to press a button to indicate the item they had to learn. The acoustic exemplar of the newly learnt words was the one presented at exposure.

Finally, in the *free association task*, only the novel words presented during the semantic exposure phase were played. After each item, participants had to write down the first word that came to mind. This gave us a second measure of how strongly the novel word was linked to the category name or its meaning.

2.2. Results and Discussion

Table 1. Top: Correct response rate in 2-AFC recognition. Bottom: Response probability in the free association task.

	Day		
	1	2	8
2-AFC recognition			
Phonological exposure	93.6	91.9	97.5
Semantic exposure	86.4	91.7	95.8

Performance in the *2-AFC recognition test* was good, with a rate of correct responses of at least 90% on each session (see Table 1). Analyses of variance (ANOVAs) showed an effect of day ($F1(2,58) = 14.7$, $p < .01$; $F2(2,66) = 12.9$, $p < .01$), an effect of exposure, though marginally significant by participant ($F1(1,29) = 3.9$, $p < .06$; $F2(1,33) = 6.6$, $p < .05$), and a day x exposure interaction ($F1(2,58) = 5.1$, $p < .01$; $F2(2,66) = 5.6$, $p < .01$). As planned comparisons revealed, the performance was better on day 8 than on days 1 and 2 ($ps < .01$), which did not differ from each other. More interestingly, only on day 1 was the performance better for phonological than semantic exposure ($ps < .01$).

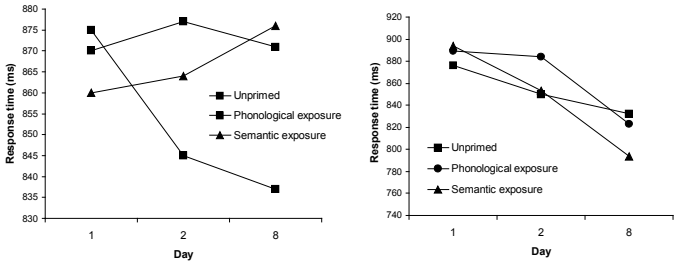

Figure 1. (Exp. 1) Left: Mean lexical decision latency to the base word. Right: Mean lexical decision latency to the category name.

In the *LD lexicalization test* (see Figure 1), latencies to the base words revealed an interaction between day and exposure ($F1(4,108) = 2.6$, $p < .05$; $F2(4,132) = 3.0$, $p < .05$). Here, the important thing was to assess the occurrence of reliable priming effects. Planned comparisons examined the difference between the unprimed condition and both the phonological and semantic conditions. No sign of delayed recognition caused by competition with the novel words was found right after exposure. However, 24 hours later, a clear inhibitory effect had emerged for the novel words trained phonologically ($F1(1,28) = 5.0$, $p < .05$; $F2(1,33) = 7.9$, $p < .01$), but still no significant effect was found in the semantic encoding condition. Finally, on day 8, both phonologically and semantically trained novel words induced inhibition of the base word recognition ($F1(1,28) = 4.1$, $p = .052$; $F2(1,33) = 9.3$, $p < .01$; $F1(1,28) = 6.8$, $p < .05$; $F2(1,33) = 7.4$, $p < .05$). Analyses of errors (2.8%) revealed no significant effect or interaction.

LD latencies to the *category names* also showed an interaction between day and exposure to the preceding novel word (i.e., untrained, phonologically trained vs. semantically trained), although marginally significant by participant ($F1(4,108) = 2.1$, $p = .081$; $F2(4,132) = 3.7$, $p < .01$). Planned comparisons revealed no effect of exposure on day 1. On day 2, an inhibitory effect was found unexpectedly for the phonological condition ($F1(1,28) = 4.3$, $p < .05$; $F2(1,33) = 8.3$, $p < .01$), whereas there no effect for the semantic condition. On day 8, the inhibitory effect in the phonological condition had disappeared, and a facilitatory effect only significant by item had emerged for the semantically trained novel words ($F1(1,28) = 2.3$, $p < .15$; $F2(1,33) = 6.8$, $p < .05$). Analyses of errors (2.2%) revealed no significant effect or interaction.

Responses in the *free association task* were classified using the taxonomy presented in Table 1. Base words and words related to the meaning of the novel words represented the majority of the responses (overall 76%). More interestingly, response probability showed an interaction

between day and response type ($F1(8,232) = 5.3$, $p < .01$; $F2(8,264) = 14.7$, $p < .01$). From day 1 to day 2, the probability of producing the base word increased with no parallel reduction in that of producing the meaning of the novel word. By contrast, from day 2 to day 8, there was an increase in the probability of producing the meaning of the novel word, clearly to the detriment of the probability of producing the base word.

Taken together, these results suggest that exposure to a novel word in a meaningful semantic context does not result in faster or deeper lexicalization compared to simple exposure to its phonological form. On day 2, only the competitors learnt on the basis of just their sound-form were able to delay recognition of the existing words, and on day 8, the two conditions of exposure did not differ in terms their lexical footprint effects. Interestingly, the emergence of competition effects on day 8 for the novel words learnt through semantic exposure coincided with a significant change in the ability of these words to prime their related category name, both in the semantically primed LD and in the free association task.

3. Experiment 2

The finding of a lexical footprint effect in the form-only condition after only 24 hours and 12 exposures in Experiment 1 stands in contrast with the late emergence of this effect after three days of exposure under similar conditions in Gaskell and Dumay's (2003) Experiment 2. This new result suggests that lexicalization may take place during the first 24 hours following exposure. To gain further evidence that this really is the case, the present experiment examined more closely the timecourse of lexicalization for phonologically trained novel words using another paradigm than LD as lexicalization test: pause detection. Contrary to LD, this paradigm provides a measure of lexical activity without requiring participants to make any judgment about the lexical properties of the input. Examination of the lexical footprint effect induced by a single massed exposure phase was performed at three time points: immediately after exposure, 24 hours later and a week later. To test whether the lexical footprint would generalize to the level of competition for segmentation, embedding rather than cohort competitors (e.g., "shadowks") were used.

3.1. Method

3.1.1. Participants. Thirty-two native British English speakers with no known auditory or language impairment were tested. They were all students at the University of York (UK), and none had taken part in Experiment 1. They received course credits or were paid for their participation.

3.1.2. Materials and Design. The key materials consisted of 72 bisyllabic item triplets. Each included a base word ending in an unreduced vowel, such as "shadow", and two nonwords such as "shadowks" and "shadowkt", derived from the base word by adding a consonant cluster and which differed from each other in one of the final consonants. As in Experiment 1, one nonword (e.g., "shadowks") was presented as novel word, whereas the other one was used as alternative choice in a recognition test.

Base words were stress-initial morphologically simple nouns that ranged in frequency between 0 and 403 occurrences per million and had their UP located before or at the final vowel. Here, in contrast to Experiment 1 which used cohort competitors, the novel word, if lexicalized, would be the only longer (embedding) competitor of the base word. To have a better chance to index lexicalization of this longer word, base words were therefore not presented in isolation during the pause detection paradigm but in longer carriers, such as "shadowk" or "shadow_k", derived from the new competitor itself (e.g., "shadowks").

In addition, 12 other novel words along with their alternative nonwords were devised, such as "trogist" and "trogisk". They were used as fillers to increase the amount of materials to be learnt, and potentially enhance the sensitivity of the 2-AFC recognition test.

All speech materials were produced by the same speaker and acquired using the same procedure as for Experiment 1.

The test items were divided into four groups, as were the participants. In the lexicalization test (i.e., pause detection) half of the carriers contained a short silence (e.g., "shadow_k"), whereas the other half did not, and within each of these groups, half of the items had potentially a longer competitor as a result of exposure, and the other did not. Four versions of the experiment allowed each item to be equally represented in the four (exposure x pause occurrence) subcells of the design.

3.1.3. Procedure. On day 1 participants were exposed to the novel words through a phoneme monitoring task. Then, the immediate effect of exposure on lexical activity was assessed using the pause detection paradigm. Finally, explicit knowledge of the novel words was examined in a free recall task and a 2-AFC recognition test. The effect of exposure on lexical activity and explicit knowledge of the novel words were re-tested on two subsequent occasions: 24 hours after exposure, and one week later. On each occasion, the pause detection task was administered first, followed by the free recall task and the 2-AFC recognition test.

The *exposure phase* was similar to the phoneme monitoring component of Experiment 1. Here, the 36 test novel words and the 12 lexically unrelated fillers were involved. Each of them was presented 36 times over 12 blocks of trials. The 6 target phonemes were /n/, /d/, /k/, /l/, /t/ and /s/.

The *lexicalization test* used the pause detection task. On each trial, participants had to decide by pressing one of two buttons whether a short silence (of 200 ms) was present in any location within a bisyllabic spoken item. On the pause-present trials, base word carriers had the silence inserted just before the final consonant (e.g., "shadow_k"). Fillers were 144 bisyllabic words ending in a consonant or consonant cluster, half of which contained a pause. The pause was inserted just before or after the first or second vowel.

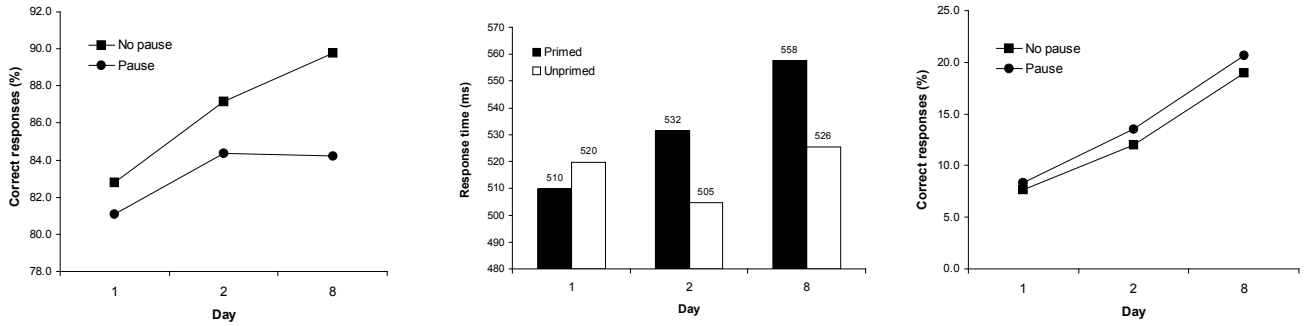

Figure 2. (Exp. 2) Left: Correct response rates in 2-AFC recognition. Middle: Mean pause detection latency (across pause-present and pause absent trials) as a function of day and exposure. Right: Correct response rates in free recall.

In the *free recall task*, participants had 3 min. to recall orally as many novel words as they could from the exposure phase. Finally, the *2-AFC recognition test*, similar to that of Experiment 1, involved all the 48 novel words presented during exposure, along with their choice (e.g., "shadowks-shadowkt").

3.2. Results and Discussion

Performance in the *2-AFC recognition test* was good, with a rate of correct responses of at least 80% on each session (see Figure 2). ANOVAs taking into account day and whether the item had been disrupted by a pause during the lexicalization test revealed that the main effects were significant (day: $F1(2,56) = 6.1$, $p < .01$; $F2(2,136) = 6.2$, $p < .01$; pause: $F1(1,28) = 6.9$, $p < .05$; $F2(1,68) = 7.9$, $p < .01$), but did not interact with one another (*Fs* close to 1). As planned comparisons showed, performance increased from day 1 to day 2 (*p*s < .05), but not from day 2 to day 8.

In the (pause detection) *lexicalization test*, latencies revealed a clear-cut interaction between day and exposure ($F1(2,56) = 6.4$, $p < .01$; $F2(2,114) = 6.9$, $p < .01$). On day 1, the immediate effect of exposure to a novel competitor was to speed-up the pause detection performance, although this effect was only marginally significant by participant ($F1(1,28) = 4.0$, $p < .06$; $F2(1,57) = 1.9$, $p < .2$). In contrast, 24 hours after exposure as well as one week later, the performance on the carriers for which a longer competitor had been learnt was clearly inhibited ($F1(1,28) = 5.7$, $p < .05$; $F2(1,57) = 7.0$, $p = .01$; $F1(1,28) = 9.0$, $p < .01$; $F2(1,57) = 14.0$, $p < .01$). There was no effect of exposure or interaction involving exposure and day on errors (7.4%).

In the *free recall task*, an ANOVA with day and presence or absence of a pause during the lexicalization test only revealed a significant effect of day ($F1(2,56) = 27.8$, $p < .01$; $F2(2,136) = 64.5$, $p < .01$), with better performance on day 2 than on day 1 ($F1(1,28) = 18.7$, $p < .01$; $F2(1,68) = 21.7$, $p < .01$), and better performance on day 8 than on day 2 ($F1(1,28) = 21.3$, $p < .01$; $F2(1,68) = 51.1$, $p < .01$).

On the basis of these results, it thus seems that following a sufficient amount of exposure, lexicalization of the novel word occurs within the next 24 hours, but not immediately. Whereas, on day 1, pause detection was facilitated by prior exposure to a new longer competitor of the base word, on day 2 (as on day 8), there was clear evidence that the new competitor was now contributing to lexical activity. Interestingly, the performance in direct recognition and free recall gradually increased over time.

4. General Discussion

The two experiments reported above allow us to make substantial progress in understanding the full range of factors involved in lexicalization of novel words. Gaskell and Dumay (2003) showed that when words are learned on the basis of only their phonological form, there is a delay associated with their engagement in lexical competition. Experiment 1 looked at whether this delay was eliminated when a richer linguistic context was available during learning. We found no evidence of any earlier or deeper lexicalization using a richer learning environment; if anything, the meaning and sentential context available at encoding led to an increased delay in lexicalization. This result suggests that exposure to a phonological form is both necessary and sufficient for normal engagement in lexical competition, supporting models of language acquisition that have a similar focus on phonological form (e.g., Saffran, Aslin, & Newport, 1996).

Experiment 1 also examined another hallmark of lexical processing: semantic/associative priming. The results suggest that this aspect of lexicalization emerges hand-in-hand with engagement in lexical competition. As for the lexical footprint in the semantic condition, a significant priming effect was observed on day 8, but not at the two preceding test points. We should be careful in interpreting this effect, since the associate of the novel item was repeatedly presented during the exposure session. It is possible that this exposure induced a repetition priming effect instead of, or in addition to, the associative facilitation caused by the pairing of novel items and their associates in LD (e.g., "cathedruke-vegetable). Yet, this account would predict that priming should be just as apparent on days 1 and 2 (cf. Tenpenny, 1995), whereas no such effects were found. Thus, the data do seem to be best

explained in terms of the emergence of a lexical link between the novel items and their associated superordinates. This link appears to rely on the establishment of a lexical entry capable of engaging in competition rather than simply a phonological trace.

Experiment 2 widened the domain of reference for our lexical footprint test. Previously we had employed standard "cohort" competitors, in which the novel and existing items mismatch towards the end of the word. In Experiment 2 the novel items had no segmental mismatch with the existing items, but instead they were embedding competitors (e.g., "shadowks"). This experiment marks the beginning of an extension of our research to lexical competition at the level of lexical segmentation. These items appeared to behave in a very similar way to standard cohort competitors, strengthening the general conceptualization of lexical competition as involving lexical items with any degree of overlap (cf. McQueen et al., 1994).

Experiment 2 had the further advantage of involving a larger set of stimuli with more sensitive measures of explicit recall and recognition performance. The explicit measures demonstrate that even in the absence of further exposure to the novel sequences, recall and recognition performance improves. One potential explanation of this finding is that the processes that operate to engage the novel representations in lexical competition also refine or focus the phonological representations. This interpretation has some support from developmental studies suggesting that well-established lexical representations are more clearly specified in terms of phonological form than newly learnt ones (Stager & Werker, 1997; Swingley & Aslin, 2000).

Perhaps the most conspicuous finding relates to the timecourse of lexicalization. In the phonological condition of Experiment 1, and more crucially in Experiment 2, we found a clear profile of lexical competition effects across the three testing occasions. Immediately after learning, there was no evidence that lexicalization had emerged, as defined by engagement in lexical competition. However, without further exposure, this lexical competition effect was observed 24 hours later, and was essentially unchanged by day 8. We can therefore narrow down the critical time period for emergence of lexical competition to somewhere between 1 and 24 hours after exposure. This suggests that under normal circumstances, lexicalization will not be hurried. This profile of learning fits in with the idea that engagement in lexical competition requires the new information to be interleaved with existing representation as is the case for distributed connectionist networks (O'Reilly & Norman, 2002). Our current research effort is focused on whether lexicalization is reliant on the kind of memory consolidation thought to occur during sleep (Walker, in press).

Acknowledgments

This research was supported by a grant from the UK Medical Research Council (G0000071) to Gareth Gaskell, and Experiment 1 was part of Xiaojia Feng's MSc. thesis. We thank Graham Hitch for valuable comments and discussions.

Abstract

We compare our model of unsupervised learning of linguistic structures, ADIOS [1, 2, 3], to some recent work in computational linguistics and in grammar theory. Our approach resembles the Construction Grammar in its general philosophy (e.g., in its reliance on structural generalizations rather than on syntax projected by the lexicon, as in the current generative theories), and the Tree Adjoining Grammar in its computational characteristics (e.g., in its apparent affinity with Mildly Context Sensitive Languages). The representations learned by our algorithm are truly emergent from the (unannotated) corpus data, whereas those found in published works on cognitive and construction grammars and on TAGs are hand-tailored. Thus, our results complement and extend both the computational and the more linguistically oriented research into language acquisition. We conclude by suggesting how empirical and formal study of language can be best integrated.

The empirical problem of language acquisition

The acquisition of language by children — a largely unsupervised, amazingly fast and almost invariably successful learning stint — has long been the envy of natural language engineers [4, 5, 6] and a daunting enigma for cognitive scientists [7, 8]. Computational models of language acquisition or "grammar induction" are usually divided into two categories, depending on whether they subscribe to the classical generative theory of syntax, or invoke "general-purpose" statistical learning mechanisms. We believe that polarization between classical and statistical approaches to syntax hampers the integration of the stronger aspects of each method into a common powerful framework. On the one hand, the statistical approach is geared to take advantage of the considerable progress made to date in the areas of distributed representation, probabilistic learning, and "connectionist" modeling, yet generic connectionist architectures are ill-suited to the abstraction and processing of symbolic information. On the other hand, classical rule-based systems excel in just those tasks, yet are brittle and difficult to train.

We are developing an approach to the acquisition of distributional information from raw input (e.g., transcribed speech corpora) that also supports the distillation of structural regularities comparable to those captured by Context Sensitive Grammars out of the accrued statistical knowledge. In thinking about such regularities, we adopt Langacker's notion of grammar as "simply an inventory of linguistic units" ([9], p.63). To detect potentially useful units, we identify and process partially redundant sentences that share the same word sequences. We note that the detection of paradigmatic variation within a slot in a set of otherwise identical aligned sequences (syntagms) is the basis for the classical distributional theory of language [10], as well as for some modern works [11]. Likewise, the *pattern* — the syntagm and the *equivalence class* of complementary-distribution symbols that may appear in its open slot — is the main representational building block of our system, ADIOS (for Automatic DIstillation Of Structure).

Our goal in the present paper is to help bridge statistical and formal approaches to language [12] by placing our work on the unsupervised learning of structure in the context of current research in grammar acquisition in computational linguistics, and at the same time to link it to certain formal theories of grammar. Consequently, the following sections outline the main computational principles behind the ADIOS model, and compare these to select approaches from computational and formal linguistics. The algorithmic details of our approach and accounts of its learning from CHILDES corpora and performance in various tests appear elsewhere [1, 2, 3]. In this paper, we chose to exert a tight control over the target language by using a context-free grammar (Figure 1) to generate the learning and testing corpora.

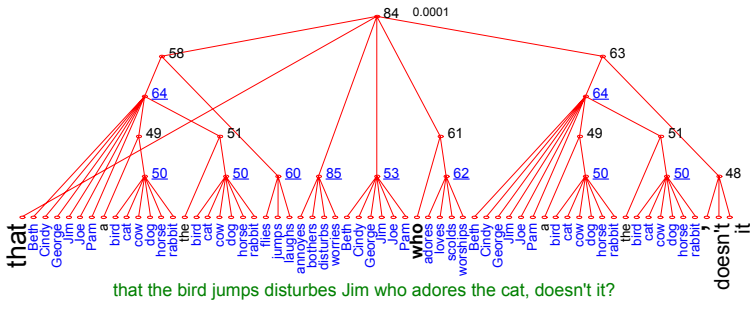
Figure 1: the context free grammar used to generate the corpora for the acquisition tests described here.

The principles behind the ADIOS algorithm

The representational power of ADIOS and its capacity for unsupervised learning rest on three principles: (1) probabilistic inference of pattern significance, (2) context-sensitive generalization, and (3) recursive construction of complex patterns. Each of these is described briefly below.

Probabilistic inference of pattern significance. ADIOS represents a corpus of sentences as an initially highly redundant directed graph, in which the vertices are the lexicon entries and the paths correspond, prior to running the algorithm, to corpus sentences. The graph can be informally visualized as a tangle of strands that are partially segregated into *bundles*.



P84 → "that" P58 P63
E63 → E64 P48
E64 → "Beth" | "Cindy" | "George" | "Jim" | "Joe" | "Pam" | P49 | P51
P48 → "," "doesn't" "it"
P51 → "the" E50
P49 → "a" E50
E50 → "bird" | "cat" | "cow" | "dog" | "horse" | "rabbit"
P61 → "who" E62
E62 → "adores" | "loves" | "scolds" | "worships"
E53 → "Beth" | "Cindy" | "George" | "Jim" | "Joe" | "Pam"
E85 → "annoyes" | "bothers" | "disturbes" | "worries"
P58 → E60 E64
E60 → "flies" | "jumps" | "laughs"

Figure 2: *Left:* a pattern (presented in a tree form), capturing a long range dependency (equivalence class labels are underscored). This and other examples here were distilled from a 400-sentence corpus generated by the grammar of Figure 1. *Right:* the same pattern recast as a set of rewriting rules that can be seen as a Context Free Grammar fragment.

Each of these consists of some strands clumped together; a bundle is formed when two or more strands join together and run in parallel, and is dissolved when more strands leave the bundle than stay in. In a given corpus, there will be many bundles, with each strand (sentence) possibly participating in several. Our algorithm, described in detail elsewhere [3],[1] identifies significant bundles iteratively, using a context-sensitive probabilistic criterion defined in terms of local flow quantities in the graph. The outcome is a set of patterns, each of which is an abstraction of a bundle of sentences that are identical up to variation in one place, where one of several symbols (the members of the equivalence class associated with the pattern) may appear (Figure 2). This representation balances high compression (small size of the pattern lexicon) against good generalization (the ability to generate new grammatical sentences from the acquired patterns).

Context sensitivity of patterns. Because an equivalence class is only defined in the context specified by its parent pattern, the generalization afforded by a set of patterns is inherently safer than in approaches that posit globally valid categories ("parts of speech") and rules ("grammar"). The reliance of ADIOS on many context-sensitive patterns rather than on traditional rules can be compared to the Construction Grammar idea (discussed later), and is in line with Langacker's conception of grammar as a collection of "patterns of all intermediate degrees of generality" ([9], p.46).

Hierarchical structure of patterns. The ADIOS graph is rewired every time a new pattern is detected, so that a bundle of strings subsumed by it is represented by a single new edge. Following the rewiring, which is context-specific, potentially far-apart symbols that used to straddle the newly abstracted pattern become close neighbors. Patterns thus become hierarchically structured in that their elements may be either terminals (i.e., fully specified strings) or other patterns. The ability of new patterns and equivalence classes to incorporate those added previously leads to the emergence of recursively structured units that support generalization (by opening paths that do not exist in the original corpus). Moreover, patterns may refer to themselves, which opens the door for true recursion (Figure 3, right; automatic detection of recursion is not currently implemented).

Two experiments in grammar induction

The results outlined next focus on the power of the ADIOS algorithm, which we assessed by examining the (so-called "weak") generativity of the representations it learns.

Experiment 1. In the first of the two studies described here, we trained ADIOS on 400 sentences produced by the context free grammar shown in Figure 1. We then compared a corpus C_{target} of $3,607,240$ sentences generated by this CFG (with up to three levels of recursion) with a corpus $C_{learned}$ of $1,916,061$ sentences generated by the patterns that had been learned by ADIOS from the 400-sentence training set. In both cases the sentences were generated randomly in batches of size $1.5{\cdot}10^7$ and merged until convergence, defined as 95% overlap between new and existing data. With these data, we obtained precision of 97%, with a recall value of 53% (as customary in computational linguistics, we define recall as the proportion of C_{target} sentences appearing in $C_{learned}$, and precision as the proportion of $C_{learned}$ appearing in C_{target}). In this demonstration, no attempt was made to optimize the two parameters that control pattern acquisition.

Experiment 2. The second experiment involved two ADIOS instances: a teacher and a student. In each of the four runs, the teacher was pre-loaded with a ready-made context free grammar (using the straightforward translation of CFG rules into patterns), then used to generate a series of training corpora with up to 6400 sentences, each with up to seven levels of recursion. After training in each run i ($i = [1 \ldots 4]$), a student-generated test corpus $C^{(i)}_{learned}$ of size 10000 was used in conjunction with a test corpus $C^{(i)}_{target}$ of the same size produced by the teacher, to calculate precision and recall. This was done by running the teacher as a parser on $C^{(i)}_{learned}$ and the student – as a parser on $C^{(i)}_{target}$. The results, plotted in Figure 4, indicate a substantial capacity for unsupervised induction of context-free grammars even from very small corpora.

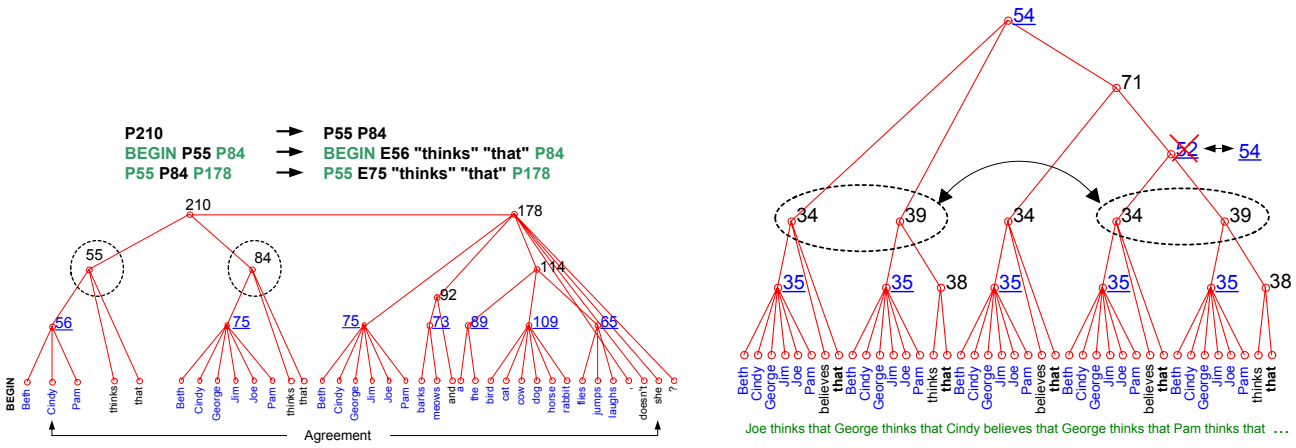

Figure 3: *Left:* because ADIOS does not rewire all the occurrences of a specific pattern, but only those that share the same context, its power is comparable to that of Context Sensitive Grammars. In this example, equivalence class #75 is not extended to subsume the subject position, because that position appears in a different context (e.g., immediately to the right of the symbol BEGIN). Thus, long-range agreement is enforced and over-generalization prevented. The context-sensitive "rules" corresponding to pattern #210 appear above it. *Right:* the ADIOS pattern representation facilitates the detection of recursive structure, exemplified here by the correspondence between equivalence classes #52 and #54.

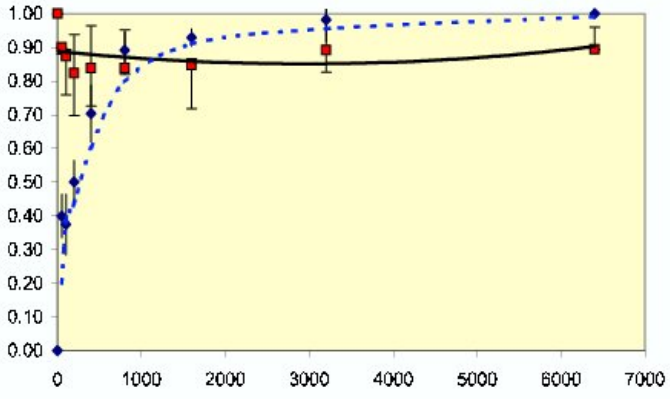

Figure 4: the results of Experiment 2; precision (squares) and recall (diamonds), plotted vs. the size of the training corpus; the error bars are std. dev. computed over four separate training/testing runs. Note that even the largest training corpus size, 6400 sentences, is a tiny proportion of the approximately $1.6 \cdot 10^8$ sentences that can be generated by the target grammar under the chosen depth constraint (7).

Related computational and linguistic formalisms and psycholinguistic findings

Unlike ADIOS, very few existing algorithms for unsupervised language acquisition use raw, unannotated corpus data (as opposed, say, to sentences converted into sequences of POS tags). The only work described in a recent review [6] as completely unsupervised — the GraSp model [13] — does attempt to induce syntax from raw transcribed speech, yet it is not completely data-driven in that it makes a prior commitment to a particular theory of syntax (Categorial Grammar, complete with a pre-specified set of allowed categories). Because of the unique nature of our chosen challenge — finding structure in language rather than imposing it — the following brief survey of grammar induction focuses on contrasts and comparisons to approaches that generally stop short of attempting to do what our algorithm does. We distinguish below between approaches that are motivated by computational considerations (Local Grammar and Variable Order Markov models, and Tree Adjoining Grammar), and those whose main motivation is linguistic and cognitive psychological (Cognitive and Construction grammars).

Local Grammar and Markov models. In capturing the regularities inherent in multiple criss-crossing paths through a corpus, ADIOS superficially resembles finite-state Local Grammars [14] and Variable Order Markov (VOM) models [15] that aim to produce a minimum-entropy finite-state encoding of a corpus. There are, however, crucial differences, as explained below. Our pattern significance criteria [3] involve conditional probabilities of the form $P(e_n|e_1, e_2, e_3, \ldots, e_{n-1})$, which does bring to mind an n'th-order Markov chain, with the (variable) n corresponding roughly to the length of the sentences we deal with. The VOM approach starts out by postulating a maximum-n VOM structure, which is then fitted to the data. The maximum VOM order n, which effectively determines the size of the window under consideration, is in practice much smaller than in our approach, because of computational complexity limitations of the VOM algorithms. The final parameters of the VOM are set by a maximum likelihood condition, fitting the model to the training data. The ADIOS philosophy differs from the VOM approach in several key respects. *First*, rather than fitting a model to the data, we use the data to construct a (recursively structured) graph. Thus, our algorithm naturally addresses the inference of the graph's structure, a task

that is more difficult than the estimation of parameters for a given configuration. *Second*, because ADIOS works from the bottom up in a data-driven fashion, it is not hindered by complexity issues, and can be used on huge graphs, with very large windows sizes. *Third*, ADIOS transcends the idea of VOM structure, in the following sense. Consider a set of patterns of the form $b_1[c_1]b_2[c_2]b_3$, etc. The equivalence classes $[\cdot]$ may include vertices of the graph (both words and word patterns turned into nodes), wild cards (i.e., any node), as well as ambivalent cards (any node or no node). This means that the terminal-level length of the string represented by a pattern does not have to be of a fixed length. This goes conceptually beyond the variable order Markov structure: $b_2[c_2]b_3$ do not have to appear in a Markov chain of a finite order $||b_2|| + ||c_2|| + ||b_3||$ because the size of $[c_2]$ is ill-defined, as explained above. *Fourth*, as we showed earlier (Figure 3), ADIOS incorporates both context-sensitive substitution and recursion.

Tree Adjoining Grammar. The proper place in the Chomsky hierarchy for the class of strings accepted by our model is between Context Free and Context Sensitive Languages. The pattern-based representations employed by ADIOS have counterparts for each of the two composition operations, substitution and adjoining, that characterize a Tree Adjoining Grammar, or TAG, developed by Joshi and others [16]. Specifically, both substitution and adjoining are subsumed in the relationships that hold among ADIOS patterns, such as the membership of one pattern in another. Consider a pattern $\mathcal{P}_i$ and its equivalence class $\mathcal{E}(\mathcal{P}_i)$; any other pattern $\mathcal{P}_j \in \mathcal{E}(\mathcal{P}_i)$ can be seen as substitutable in $\mathcal{P}_i$. Likewise, if $\mathcal{P}_j \in \mathcal{E}(\mathcal{P}_i)$, $\mathcal{P}_k \in \mathcal{E}(\mathcal{P}_i)$ and $\mathcal{P}_k \in \mathcal{E}(\mathcal{P}_j)$, then the pattern $\mathcal{P}_j$ can be seen as adjoinable to $\mathcal{P}_i$. Because of this correspondence between the TAG operations and the ADIOS patterns, we believe that the latter represent regularities that are best described by Mildly Context-Sensitive Language formalism [16]. Importantly, because the ADIOS patterns are learned from data, they already incorporate the constraints on substitution and adjoining that in the original TAG framework must be specified manually.

Psychological and linguistic evidence for pattern-based representations. Recent advances in understanding the psychological role of representations based on what we call patterns, or *constructions* [17], focus on the use of statistical cues such as conditional probabilities in pattern learning [18, 19], and on the importance of exemplars and constructions in children's language acquisition [20]. Converging evidence for the centrality of pattern-like structures is provided by corpus-based studies of the prevalence of "prefabricated" sequences of words [21], and of the entrenchment of such sequences in the lexicon [22]. Similar ideas concerning the ubiquity in syntax of structural peculiarities hitherto marginalized as "exceptions" are now being voiced by linguists [23, 24].

Cognitive Grammar; Construction Grammar. The main methodological tenets of ADIOS — populating the lexicon with "units" of varying complexity and degree of entrenchment, and using cognition-general mechanisms for learning and representation — fit the spirit of the foundations of Cognitive Grammar [9]. At the same time, whereas the cognitive grammarians typically face the chore of hand-crafting structures that would reflect the logic of language as they perceive it, ADIOS discovers the primitives of grammar empirically and autonomously. The same is true also for the comparison between ADIOS and the various Construction Grammars [17, 24], which are all hand-crafted. A construction grammar consists of elements that differ in their complexity and in the degree to which they are specified: an idiom such as "big deal" is a fully specified, immutable construction, whereas the expression "the X, the Y" – as in "the more, the better" [25] – is a partially specified template. The patterns learned by ADIOS likewise vary along the dimensions of complexity and specificity (e.g., not every pattern has an equivalence class).[2]

Related computational work on grammar induction

In natural language processing, a distinction is usually made between unsupervised learning methods that attempt to find good structural primitives and those that merely seek good parameter settings for predefined primitives. ADIOS, which clearly belongs to the first category, is also capable of learning from raw data, whereas most other systems start with corpora annotated by part of speech tags [26], or even rely on treebanks, or collections of hand-parsed sentences [4]. Of the many such methods, we can mention here only a few.

Global grammar optimization using tagged data. Stolcke and Omohundro (1994) learn structure (the topology of a Hidden Markov Model, or the productions of a Stochastic Context Free Grammar), by iteratively maximizing the probability of the current approximation to the target grammar, given the data. In contrast to this approach, which is global in that all the data contribute to the figure of merit at each iteration, ADIOS is local in the sense that its inferences only apply to the current bundle candidate. Another important difference is that instead of general-scope rules stated in terms of parts of speech, we seek context-specific patterns. Perhaps because of its globality and unrestricted-scope rules, Stolcke and Omohundro's method has "difficulties with large-scale natural language applications" [27]. Similar conclusions are reached by Clark, who observes that POS tags are not enough to learn syntax from ("a lot of syntax depends on the idiosyncratic properties of particular words." [5], p.36). His algorithm attempts to learn a phrase-structure grammar from tagged text, by starting with local distributional cues, then filtering spurious non-terminals using a mutual information criterion. In the final stage, his algorithm clusters the results to achieve a minimum description length (MDL) representation, by starting with maximum likelihood grammar, then greedily selecting the candidate for abstraction that would maximally reduce the description length. In its greedy approach to optimization (but not in its local search for good patterns or its ability to deal with untagged data), our approach resembles Clark's.

[2] Similarly to constructions, the ADIOS patterns carry semantic, and not just syntactic, information — an important issue that is outside the scope of the present paper.

Probabilistic treebank-based learning. Bod, whose algorithm learns by gathering information about corpus probabilities of potentially complex trees, observes that "[...] the knowledge of a speaker-hearer cannot be understood as a grammar, but as a statistical ensemble of language experiences that changes slightly every time a new utterance is perceived or produced. The regularities we observe in language may be viewed as emergent phenomena, but they cannot be summarized into a consistent non-redundant system that unequivocally defines the structures of new utterances." [4], p.145. This memory- or analogy-based language model, which is not a typical example of unsupervised learning, is mentioned here mainly because of the parallels between its data representation, Stochastic Tree-Substitution Grammar, and some of the formalisms discussed earlier.

Split and merge pattern learning. The unsupervised structure learning algorithm developed by Wolff between 1970 and 1985 stands out in that it does not need the corpus to be tagged. An excellent survey of his own and earlier attempts at unsupervised learning of language, and of much relevant behavioral data, can be found in [28]. His representations consist of SYN (syntagmatic), PAR (paradigmatic) and M (terminal) elements. Although our patterns and equivalence classes can be seen as analogous to the first two of these, Wolff's learning criterion is much simpler than that of ADIOS: in each iteration, the most frequent pair of contiguous SYN elements are joined together.[3] His system, however, had a unique provision for countering the usual propensity of unsupervised algorithms for overgeneralization: PAR elements that did not admit free substitution among all their members in some context were rebuilt in a context-specific manner. Unfortunately, Wolff's system has not been tested on unconstrained natural language.

Summary, prospects and challenges

The ADIOS approach to the representation of linguistic knowledge resembles the Construction Grammar in its general philosophy (e.g., in its reliance on structural generalizations rather than on syntax projected by the lexicon), and the Tree Adjoining Grammar in its computational capacity (e.g., in its apparent ability to accept Mildly Context Sensitive Languages). The representations learned by the ADIOS algorithm are truly emergent from the (unannotated) corpus data, whereas those found in published works on cognitive and construction grammars and on TAGs are hand-tailored. Thus, our results complement and extend both the computational and the more linguistically oriented research into cognitive/construction grammar.

To further the cause of an integrated understanding of language, a crucial challenge must be met: a viable approach to the evaluation of performance of an unsupervised language learner must be developed, allowing testing both (1) neutral with respect to the linguistic dogma, and (2) cognizant of the plethora of phenomena documented by linguists over the course of the past half century (see, e.g., Figure 5).

[3] An even simpler criterion, that of mere repetition, is employed by the related approach of [29], resulting in a rule set that appears to grow linearly with the size of the corpus, rather than reaching an asymptote as in our case.

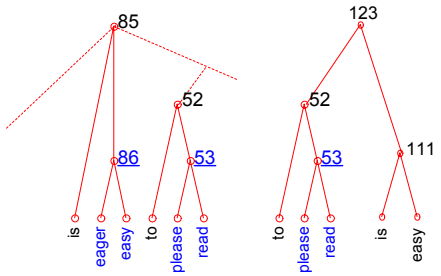

Figure 5: As a token of our intention to account, eventually, for the entire spectrum of English syntax-related phenomena described in the textbooks — agreement, anaphora, auxiliaries, *wh*-questions, passive, control, etc. [30] — we illustrate here the manner in which ADIOS treats tough movement (another phenomenon, long-range agreement, was discussed in Figure 2). When trained on sentences exemplifying "tough movement", ADIOS forms patterns that represent the correct phrases (... is easy to read, is easy to please, is eager to read, is eager to please, to read is easy and to please is easy), but does not over-generalize to the incorrect ones (*to read is eager or *to please is eager).

Unsupervised grammar induction algorithms that work from raw data are in principle difficult to test, because any "gold standard" to which the acquired representation can be compared (such as the Penn Treebank [31]) invariably reflects its designers' preconceptions about language, which may not be valid, and which usually are controversial among linguists themselves [32]. Moreover a child "...must generalize from the sample to the language without overgeneralizing into the area of utterances which are not in the language. *What makes the problem tricky is that both kinds of generalization, by definition, have zero frequency in the child's experience.*" ([28], p.183, italics in the original). Instead of shifting the onus of explanation for this "miracle" onto some unspecified evolutionary processes (which is what the innate grammar hypothesis amounts to), we suggest that a system such as ADIOS should be tested by monitoring its acceptance of massive amounts of human-generated data, and at the same time by getting human subjects to evaluate sentences generated by the system (note that this makes psycholinguistics a crucial component in the entire undertaking).

A purely empirical approach to the evaluation problem would, however, waste the many valuable insights into the regularities of language accrued by the linguists over decades. Although some empiricists would consider this a fair price for quarantining what they perceive as a runaway theory that got out of touch with psychological and computational reality, we believe that searching for a middle way is a better idea, and that the middle way can be found, if the linguists can be persuaded to try and present their main findings in a theory-neutral manner. From recent reviews of syntax that do attempt to reach out to non-linguists (e.g., [33]), it appears that the core issues on which every designer of a language acquisition system should be focusing are dependencies (such as co-reference) and constraints (such as islands), especially as seen in a typological (cross-linguistic) perspective [24].

Fast and Frugal Reasoning Enhances a Solver for Hard Problems

Abstract

This paper describes how a program that learns to solve hard problems has been enhanced with fast and frugal, recognition-based reasoning methods. The program uses these methods to help manage its own heuristics for solving constraint satisfaction problems. The result is a constraint solver that reasons quickly, much the way people appear to induce reasonable decisions in real-world situations. Empirical evidence on a variety of problems indicates that fast and frugal reasoning can accelerate the solution of very difficult problems, often without introducing additional error.

The thesis of this work is that the same *fast and frugal* reasoning which people use to formulate decisions in real-world situations (Gigerenzer, Todd, & The ABC Research Group, 1999) can accelerate autonomous decision makers without endangering their reliability. We investigate this premise with a program that learns how to combine heuristics to solve constraint satisfaction problems (*CSPs*). The principal result reported here is that, on difficult CSPs, when recognition alone is not sufficient, fast and frugal, recognition-based reasoning enhances the solver. This is particularly noteworthy because the program first learns how to apply its CSP heuristics within its problem environment, and then hones its performance using fast and frugal reasoning. We believe this to be the first exploration of fast and frugal reasoning on a large body of challenging problems whose difficulty can be explicitly characterized and whose solution can be incisively assessed.

Many large-scale, real-world problems in areas such as design and configuration, planning and scheduling, and diagnosis and testing are readily understood, represented, and solved as CSPs. CSP solution is, in general, not known to be solvable by algorithms of any but exponential complexity. Thus the effectiveness of fast and frugal reasoning on these problems is counterintuitive.

Fast and frugal reasoning assumes pre-acquired, accurate, problem-area knowledge (Gigerenzer, Todd, & The ABC Research Group, 1999). In real-world decisions, fast and frugal reasoning adaptively exploits the environment's structure. A program provided with heuristics must learn their accuracy before turning to fast and frugal decision making. The first sections of this paper provide background information on fast and frugal reasoning, and on CSP. Subsequent sections describe how we addressed these ideas in a program that learns, describe the experimental design, discuss the results, and sketch future work.

Background

As often happens in interdisciplinary work, terminology overlaps here, but meaning does not. Thus we alert the reader to the fact that, although "domain" means "problem area" in some fields, it has a different connotation (described below) in constraint solving, for which we reserve it. Similarly, fast and frugal researchers generally refer to their general problem-solving methods (e.g., Minimalist, Take the Last, Take the Best) as heuristics, but so too do CSP researchers, and again we take the CSP definition. As a result, we describe fast and frugal methods as "strategies that consult heuristics" rather than "heuristics that consult cues." Finally, the notion of recognition, which underlies the fast and frugal strategies, is itself a heuristic, albeit a more general one, defined below.

Fast and frugal reasoning

Under limited time, there exists a trade-off between decision making speed and correctness. When pressed for time, people may limit their search for information to guide them in the decision process with *non-compensatory* strategies, strategies that use a single heuristic to prefer a single option (Gigerenzer & Goldstein, 1996). People appear to work from an *adaptive toolbox*, a collection of cognitive mechanisms for inference in specific problem areas (Gigerenzer, Todd, & The ABC Research Group, 1999). This adaptive toolbox includes low-order perceptual and memory processes, including fast and frugal strategies that may be combined to account for higher-level mental processes. Such a model of cognitive heuristics is *ecologically rational*, grounded in environment-specific structure and characteristics (Goldstein & Gigerenzer, 2002; Gigerenzer & Selten, 2001; Gigerenzer, Todd, & The ABC Research Group, 1999).

In *one-reason* decision making, a set of heuristics is consulted one at a time, until some heuristic is able to *discriminate*, that is, able to select a single option. *Recognition* is the *foundation heuristic* for fast and frugal reasoning: it favors recognized options over unrecognized ones. Recognition discriminates if and only if exactly one option is recognized (Gigerenzer & Goldstein, 1996). In that case, it is sufficient for one-reason decision making, and no further computation is required.

When recognition alone does not discriminate, each strategy considered here may be thought of as a meta-heuristic that speeds the selection of the next heuristic. All three strategies initially try recognition on all the available options. If more than one option is recognized, other heuristics are consulted, one at a time, on a randomly-

selected pair of recognized options, until some heuristic does discriminate. The preferred option is then selected. The way these "other" heuristics are chosen defines the decision-making strategy. The following are drawn from Gigerenzer, Todd and the ABC Research Group (1999):

- *Minimalist*: Select a heuristic at random, until one discriminates among the options and a decision is made.
- *Take the Last*: Use the last heuristic, the one that discriminated the last time a decision was made, when recognition did not. This captures the human tendency to re-use the most recent successful strategy.
- *Take the Best*: Use the heuristic known to work best in a specific environment. The insightfulness of a heuristic on a set of problems is called its *ecological validity*.

Constraint satisfaction problems (CSPs)

CSPs are a good vehicle with which to explore fast and frugal reasoning. They arise in classes whose difficulty has a mathematical characterization, and many examples can be readily generated within each class. Furthermore, well-established criteria exist with which to gauge the performance of a program that solves them.

A CSP consists of a set of variables, each associated with a *domain* of possible values for assignment, and a set of *constraints* that specify which combinations of values are allowed. To represent a real-world problem as a CSP, one casts the entities involved as variables, and expresses the relationships required among these variables as constraints. A simple example appears in Figure 1. Real-world CSPs, however, involve many more variables, substantial domains, and a broad variety of interacting, more sophisticated restrictions as constraints. A solution for a CSP is one value for each variable such that all constraints are satisfied. Every CSP has an underlying *constraint graph* that represents each variable by a vertex. An edge in the graph represents a constraint between the corresponding variables, and is labeled by their permissible pairs of values. The *degree* of a variable is the number of edges to it in the graph. (For simplicity we restrict discussion here to binary CSPs.)

How hard a CSP is to solve is determined by how difficult it is to find values that satisfy all its constraints at once. A *class* of CSPs groups together problems with four parameters thought to estimate their difficulty. A CSP class may be described by <*n*,*k*,*d*,*t*>, where *n* is its number

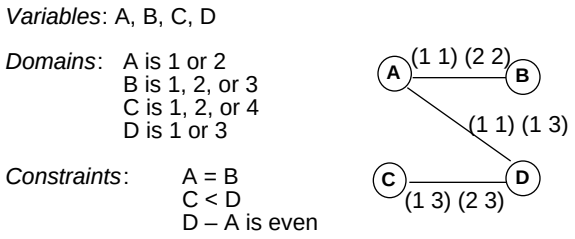

Figure 1: A simple constraint satisfaction problem and its underlying constraint graph. Edges in the graph are labeled with acceptable value pairs, computed from the domains and the constraints.

of variables and *k* its maximum domain size. The *density d* is the fraction of possible edges in the underlying constraint graph. The *tightness t* is the percentage of possible value pairs the constraints exclude. Thus in <30,8,.26,.66> every problem has 20 variables, each with domain size at most 8, and 30^8 possible value assignments. In a given class, every CSP has the same values for *n, k, d,* and *t,* and the same minimal number of decisions for solution.

To solve a CSP, one can repeatedly select a variable and assigns it a value consistent with its constraints. For example, Figure 2 represents a possible search for a solution to the problem in Figure 1. Reading from top to bottom and from left to right, each circle (*node*) represents a decision. There, Variable A was selected first, and assigned the value 2, then D was selected, and both its values (1 and 3) were tried without success. Therefore, search backed up, the value 2 was withdrawn (*retracted*) from A, and the value 1 was assigned to A instead.

The black nodes in Figure 2 represent the correct decisions, and the solid path on the right represents the solution. When a value assignment is inconsistent with the constraints, it is retracted and another assignment is tried. In Figure 2, white nodes are errors, assignments that cause subsequent decisions (the gray nodes) to be retracted, so that an error can be corrected. For example, the assignment D = 1 is *inconsistent* because it leaves no values for C. When that happens, values are retracted until all current assignments are once again consistent, and new values tried. Finding a single solution to a solvable problem this way requires at least *n* assignments.

Although CSP solution is NP-hard, some problem classes surrender readily to heuristics. For a solvable CSP, the order in which one selects variables (*variable ordering,* e.g., A, D, C, B in Figure 2) can speed solution, as can the order in which one assigns a value to a just-selected variable (*value ordering,* e.g., 2, 1 for A in Figure 2). There are dozens of variable-ordering and value-ordering heuristics in the CSP literature, but their interactions are ill-understood. The best approximation for CSP problem difficulty is currently *kappa*, which is defined as a function of *n, k, d,* and *t* (Gent, MacIntyre, Prosser, & Walsh, 1996). Nonetheless, two problems from the same class may still require different amounts of effort to solve.

During search, a CSP solver can apply a variety of inference and retraction methods. When a *partial solution* (a set of values assigned to a proper subset of the variables) is incompatible with the constraints, all the nodes that include it (e.g., gray in Figure 2) may be eliminated. An *inference* method can propagate the implications of a newly-assigned value on to the remainder of the as-yet-unassigned variables. Different amounts of inference are possible, and there are tradeoffs between inference effort and search savings. A specific inference method (the central one is arc consistency) can be carried out to varying degrees (Sabin & Freuder, 1994) and with different algorithms (Bessière & Régin, 2001). A *retraction* method re-

sponds to an inconsistent partial solution (a subtree of discarded nodes rooted at an error node in Figure 2). The standard retraction method is *chronological backtracking*, withdrawal of the most recent assignment(s).

ACE

ACE (the Adaptive Constraint Engine) is an autonomous system that learns to solve classes of CSPs (Epstein, Freuder, Wallace, Morozov, & Samuels, 2002). ACE is based on *FORR* (FOr the Right Reasons), a cognitively-oriented architecture for learning and problem solving that supports the development of expertise (Epstein, 1994). Here, "cognitively-oriented" means that FORR's reasoning structure emulates approaches readily observable in human problem solving, highly-effective approaches not always found in traditional AI artifacts (Biswas, Goldman, Fisher, Bhuva, & Glewwe, 1995; Crowley & Siegler, 1993; Klein & Calderwood, 1991; Kojima & Yoshikawa, 1998; Novick & Coté, 1992; Schraagen, 1993). FORR is based on the premise that decisions are composed from more and less trustworthy rationales. One constructs a FORR-based program by specifying heuristics that underlie decision making in a particular problem area.

ACE is an ambitious program – armed with many heuristics, it can tackle difficult problems. The version we used here begins with 40 CSP heuristics which are initially classified into a hierarchy of three *tiers* by the user. ACE moves through those tiers to make a decision. The heuristics in tiers 1 and 2 are consulted sequentially; the heuristics in tier 3 are consulted (effectively) in parallel.

Tier 1 consists of *perfect* (i.e., error-free) heuristics consulted sequentially. If any heuristic supports an action, that action is executed without reference to any subsequent heuristics. Consulting perfect heuristics first ensures that obvious correct decisions (e.g., a checkmate at chess) will be reached without devoting resources to other, less reliable heuristics. A perfect heuristic that opposes an action (e.g., "don't move into checkmate") removes that action from consideration by all subsequent heuristics, thereby preventing obvious errors. Thus placing perfect heuristics in tier 1 permits easy problems to be solved easily, a feature all too rare in complex systems. (The second tier is not applicable to the work reported here; the interested reader is referred to (Epstein, 1998)).

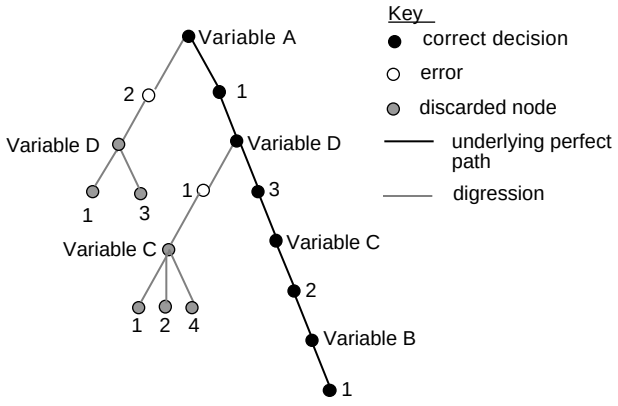

Figure 2: A search tree for solution to the simple CSP in Figure 1, depicted here as alternating variable selections and value selections. When a value selection violates some constraint, that decision is retracted, and search backtracks. New values are assigned until all variables have a value consistent with the constraints.

Tier-3 heuristics are the ordinary ones; they produce single-action *comments* that are not guaranteed to be correct. All but two of the ACE heuristics in this version lie in tier 3. Because they are fallible, their comments are combined to select the next action in a process called *voting*. Each heuristic may vote on different actions with different strengths, or it may remain silent. ACE's tier 3 heuristics were, for the most part, drawn from the CSP expert community. In every case, however, the dual of a popular heuristic was also implemented. For example, the CSP literature suggests that the next variable to have a value assigned to it should have a minimum *dynamic domain size* (set of values that would still be consistent with existing variable assignments). ACE therefore has a heuristic that comments in favor of such variables, but it also has its dual, a heuristic to maximize the dynamic domain size of a variable.

One-Reason Decision Making in ACE

ACE learns to solve CSPs efficiently by winnowing through its heuristics and balancing them appropriately. Laden with CSP knowledge, ACE's decisions are carefully reasoned but time-consuming. Fast and frugal, one-reason decision making seemed a reasonable enhancement, but its adaptation for ACE required careful thought about recognition, ecological rationality, ecological validity, and preference functions.

Recognition in ACE

Recognition is familiarity with something previously experienced. Recall that, during CSP solution, there are only two kinds of experience: variable selection and value selection. Therefore, we define recognition to be the identification of a current option as one previously selected during search *in the current problem*. Note that recognition for ACE is a selection heuristic rather than a trigger for situation assessment and re-evaluation, because mere recognition of a single option is sufficient for decision making without any consideration of the similarities of the different search states (situations) in which it previously occurred. For example, in Figure 2 assigning 1 to Variable D after Variable A is set to 1, eventually proves to be an error, since all possible assignments to Variable C are then incompatible with the constraints. In response to the detected error, the gray nodes corresponding to the selection of Variable C and the values tried for it are retracted. The decisions made in this subtree, *excluding* the error node, will be recognized during subsequent search. Effectively, later in search, a decision point that includes

options previously found attractive will find them attractive again.

A counterargument to the role of recognition in human reasoning is that recognition is often associated with other cues to obtain a given judgment, and is thus *compensatory* (Oppenheimer, 2003). When an object is recognized, other information about that object is also recalled at the moment of recognition. If this "extra" information is relevant to the judgment being made, it will be taken into account while making the decision. The relevant information may support or oppose the judgment about the recognized object. Although the additional information may be contradictory, for our purposes, the influence it has on recognition is considered as a whole. Recognition may have an attached positive or negative correlation with respect to the judgment being made.

For ACE, recognition always has a positive correlation, because it treats a previous decision as one it wants to make again. The idea here is that, if no further knowledge about ACE's tier 3 heuristics has been acquired during search on the current problem, and consulting these same heuristics previously led to making certain decisions, they should remain valid, if the option is still available. (Consistency checking may have eliminated it.) By "recognizing" such previously-computed but subsequently-retracted decisions, ACE can avoid reconsulting all its heuristics on the same (or most of the same) options. For example, in Figure 2, ACE initially assigned 2 to A and then chose Variable D. Later, when 2 is retracted and 1 assigned to A, the next variable must be selected. At that point D is recognized and so need not be recomputed. Note too that recognition can lead ACE to repeat an error. It tries 1 before 3 for D on both sides of the search tree in Figure 2.

Ecological rationality and ecological validity

ACE must have acquired problem-class-specific knowledge before it attempts speed-up through one-reason decision making. Tier-3 heuristics are ACE's version of the adaptive toolbox, its knowledge about how CSP works. ACE's heuristics, however, are not all of equal significance or reliability in a particular problem class. Therefore, ACE learns weights to combine them.

DWL (Digression-based Weight Learning) learns problem-class-specific weights for tier-3 heuristics (Epstein et al., 2002). It is specifically designed to minimize errors during solution (and therefore minimize the number of nodes in the tree of Figure 2). After ACE solves a problem, DWL examines the solution trace, and adjusts the weight of each heuristic according to whether or not it supported the correct decisions. All heuristics start with the same weight. DWL provides the ecological validity for the heuristics in a given problem class.

DWL also employs non-voting, baseline heuristics that discriminate with randomly-generated strength on randomly-chosen options. DWL uses them to gauge ACE's own heuristics, so that ACE learns to value only those heuristics that make comments more valuable than random ones. These baseline heuristics provide ACE's ecological rationality.

From preference to binary decisions

The one-reason decision-making model assumes binary heuristics, ones that vote either in favor of or against an option. Recall that, if recognition does not discriminate, the model considers other heuristics on randomly-selected pairs of options, until some heuristic discriminates. Recognition is a binary heuristic, and we translate it as such for ACE: a decision was either previously made or not. A tier-3 heuristic, however, expresses its preference for, or opposition to, an option in a comment whose *strength* lies between 0 and 10. To adapt ACE for one-reason decision making, the option with the higher strength is deemed the positive one. If a heuristic comments on both options with the same strength, or it does not comment at all, the heuristic does not discriminate, and another heuristic is consulted, depending upon the particular strategy in use.

Experimental Design

The ACE project maintains a large library of problem classes, each with many examples. In each experiment here, ACE learned by attempting to solve at most 600 problems (the *learning phase*) and then was tested on 200 different problems from the same class, with learning turned off (the *testing phase*). This learn-and-then-test approach was repeated 10 times, each time with different learning problems but the same testing problems. Fast and frugal reasoning was applied only in the testing phase.

ACE's performance here is evaluated by three standard CSP criteria: average number of nodes in the decision tree (e.g. Figure 2), average number of mistakes during solution (number of retractions), and average computation time (in seconds). Any differences identified in the following discussion are statistically significant at the .95 level. Learning was terminated early if the heuristics' weights *stabilized* (did not vary in their standard deviation by more than 0.1 over the most recent 20 problems) before 600 problems. ACE used chronological backtracking for retraction and MAC3 (Mackworth, 1977) for consistency checking. What we varied in our experiments was the problem class, and which non-compensatory search strategy was used in the testing phase.

Results

We tested ACE alone, and then with each of the fast and frugal strategies on each of three problem classes. The results appear in Table 1. The first class of problems was <30, 8, .26, .66>, an extremely difficult set of randomly-generated CSPs. (The state of the CSP art does not yet support labeling them "the most difficult" for their size, but these are certainly "exceptionally difficult.") On this class, each of the three non-compensatory strategies, combined with recognition significantly improved overall execution time. Speed-up came with a price, however. Although ACE solved every problem, it made more (albeit relatively trivial) errors, and explored more nodes during search. The most reasoned and ecologically ra-

Table 1: Performance of ACE alone and with the recognition heuristic guided by three different non-compensatory, one-reason decision making strategies, on two classes of CSPs: < 30, 8, .26, .66> and < 30, 8, .12, .5>. Time (in seconds), errors and nodes are per problem. Figures in bold represent a statistically significant improvement over ACE without recognition.

Class	Criterion	ACE		Minimalist		Take the Last		Take the Best	
30-8-.26-.66	Overall time	3.10	(3.04)	**2.72**	(2.57)	**2.85**	(2.73)	**2.37**	(2.19)
	Tier 3 time	1.41	(1.51)	**0.70**	(0.62)	**0.75**	(0.68)	**0.61**	(0.68)
	Errors	105.11	(107.64)	119.12	(134.69)	116.97	(129.27)	113.77	(127.33)
	Nodes	165.11	(107.64)	179.12	(134.69)	176.97	(129.27)	173.77	(127.33)
30-8-.12-.5	Overall time	0.76	(0.57)	**0.71**	(0.49)	**0.71**	(0.42)	**0.66**	(0.44)
	Tier 3 time	0.44	(0.38)	**0.37**	(0.31)	**0.37**	(0.28)	**0.36**	(0.34)
	Errors	13.80	(15.52)	13.38	(15.26)	14.12	(16.17)	12.97	(14.36)
	Nodes	73.80	(15.52)	73.38	(15.26)	74.12	(16.17)	72.97	(14.36)

tional strategy (Take the Best) outperformed the other two.

The next class of problems on which we tested this approach was <30, 8, .12, .5>, a somewhat easier set. Here again, all three strategies achieved significant speedup, this time without increasing the number of errors or the size of the search tree. Finally, we tested our approach on a relatively easy class, <30, 8, .1, .5> (results not shown) where no changes could be detected.

Discussion

ACE is *complete*, that is, as constructed it is guaranteed to solve any solvable CSP — eventually. Expertise, however, requires that one solves problems efficiently. (All solutions to a CSP are defined to be equally good. When CSP researchers talk about *optimal* search, they refer one that does the least work, as measured by propagation.) Although extensive computation can minimize, or even eliminate, incorrect value selection, such computation may simply not be worth the time. Indeed, a solver that makes many inexpensive mistakes may actually arrive at a solution more quickly, despite a somewhat larger search tree. In this sense, ACE is a satisficer — it makes "good enough" decisions (Simon, 1981). Even when fast and frugal reasoning introduces additional error, the program solves problems faster. Both satisficing and our implementation of recognition, it should be noted, are tolerable only on problems where errors are relatively harmless.

The results of these experiments indicate that enhancing an intelligent and ecologically rational system with fast and frugal reasoning can save computation time, but is not guaranteed to do so. Because recognition, as we have implemented it, is a consequence of previous errors on the current problem, performance on these three problem classes requires individual explanations. On the relatively easy problems of <30, 8, .1, .5>, fast and frugal reasoning does not improve performance because there are not enough retractions during search to support subsequent recognition.

Fast and frugal reasoning that is also ecologically rational (i.e., Take the Best) provided more speed-up here than the other strategies. Recognition serves as a filter for the best of the options; it recycles earlier reasoning inherently. Nonetheless, ACE still needs to select from among the recognized options the one which is likely to be the most productive, and Take the Best is one way to do that.

On the problems of medium difficulty of <30, 8, .12, .5>, fast and frugal reasoning achieves speedup because it avoids some repeated computation. It also does so without significantly introducing more error, because recognition forces persistence by attempting to restrict ACE to previously-chosen options. Even if these "recycled decisions" are wrong, there are simply not enough wrong ones to introduce many new retractions.

On the very difficult problems of <30, 8, .26, .66>, Take the Best introduces significantly less error and does less work than the other fast and frugal strategies do. The additional errors on these problems suggest that accurate decision making here is more subtle and complex than a single heuristic can support, and certainly more than recognition alone can handle. Even without fast and frugal methods, ACE makes more mistakes solving these problems, simply because the problems are harder, Therefore there are more errors that may be recycled by recognition, as well as simply more recognized options to choose from. Take the Best introduces significantly fewer errors because it uses ecological rationality to avoid recycling some of them. Here again the speedup is achieved through the tradeoff between inexpensive errors and savings in computation time.

ACE's version of recognition is not the situation-based recognition described in (Klein & Calderwood, 1991). In that work, particular features of a situation bring to mind possible solution approaches, approaches that may require adaptation for the current situation. There, recognition may be paraphrased as "I was once in a similar situation where this sequence of decisions worked well, so I will see if I can adapt it to work again here, testing it first in simulation." ACE's recognition, in contrast, may be paraphrased as "I have seen that option before, considered it carefully (perhaps with different alternatives and in a somewhat different context at the time), and have decided to prefer it once again, without considering any potential consequences." ACE's recognition applies only to a single decision, not to a sequence; it does not permit adapta-

tion; it makes no situation assessment; and it relates to previous experience in the same problem.

To make use of fast and frugal reasoning, as we have implemented it, a system needs to have a body of heuristics with which to make decisions and, if it is to take the best, it needs a metric on those heuristics. Furthermore, since recognition, as we have interpreted it, requires decisions that are made under some erroneous circumstances and then withdrawn (gray nodes in Figure 2), the system must not have perfected decision making, or there will be no prior, within-problem decisions to recycle. Thus, fast and frugal reasoning can improve mediocre or even fairly reputable performance, but cannot improve flawless performance, for without errors there can be no recognition.

Future Work and Conclusion

Previously-made decisions are here recycled through the recognition heuristic. Whether or not ACE would have remade those decisions, and in the same sequence, without recognition remains to be determined. Future work will examine ACE's decisions at the same level but in different branches of the search tree, with and without fast and frugal reasoning.

Although we did not use it in these experiments, ACE can partition its tier-3 heuristics into any number of subclasses. We intend to compare ACE's performance with different numbers of tier-3 subclasses to ACE's performance with Take the Best, which can be thought of as a "one heuristic to a subclass" partition.

Fast and frugal reasoning has been shown here to have a significant impact on an already competent CSP solver. The premise that attractive options remain attractive as problem solving progresses enables at least this program to solve problems better. Furthermore, the problems we have used here are sufficiently general to suggest that our results have a potentially broad impact. We are optimistic that, in problem areas that tolerate errors, fast and frugal reasoning, as implemented here, can make an important contribution to problem solving.

Abstract

Vergence eye-movements occur not only in real environments, but also in virtual 3D environments. Autostereograms can cover large visual angles without requiring vergence beyond natural parameters and are thus well-suited for the investigation of vergence movements in virtual 3D images. We developed an anaglyph-based 3D calibration procedure and used a *parametrized self-organizing map* (PSOM) to approximate the 3D gaze point from a subject's binocular eye-movement data. Besides analyzing the general pattern of vergence eye-movements in autostereogram images, the present study examined the influence of image granularity on these movements. Unlike previous research on random-dot stereograms, we found substantially overshooting convergence eye-movements, especially for medium granularities. Moreover, divergence movements were completed more quickly for coarse than for fine granularities. Results are discussed in the context of granularity effects on autostereogram perception and the dissociation between convergence and divergence eye-movements.

Vergence Eye-Movements in Autostereograms

In everyday life, we employ vergence eye-movements to successively fixate objects at different distances. It is interesting to note that these movements are also produced in virtual 3D environments. Some work has been done on the analysis of vergence movements occurring while viewing *Random-Dot Stereograms* (*RDS*). For *RDS* two slightly different images for the left and the right eye seen through a special device, a so-called stereoscope, lead to the perception of 3D information. Mowforth, Mayhew and Frisby (1981) found that *RDS* are perceptually filtered by spatial frequencies. Low frequencies enable the 3D perception of *RDS* with larger disparities and lead to faster vergence movements than do high frequencies. Furthermore, vergence velocities were found to be faster for convergent than for divergent eye movements.

In another study, Rashbass and Westheimer (1961) found reaction times of about 160 ms for both convergent and divergent eye movements in response to suddenly introduced target vergence changes. The authors reported start velocity varying with stimulus amplitude, and vergence reaching asymptotically its final level after approximately 800 msec without any overshoots or a prolonged period of oscillations. They also found turnabouts in the response before the target vergence change reaches zero, showing the anticipatory behavior of the eye-vergence system.

For our experiment, however, instead of *RDS* we used *Single Image Random Dot Stereograms (SIRDS)*, also called *autostereograms*. The difference between *RDS* and *SIRDS* is that in *SIRDS* the two slightly different images of the *RDS* are combined into a single image. No stereoscope is necessary to perceive the 3D information in a *SIRDS*. To achieve the 3D perception of a *SIRDS*, observers have to combine the information of the two images for the left and the right eye to one depth perception by focusing a point before (*cross-eyed method*) or behind (*wide-eyed method*) the image plane, whereby our preliminary studies (Essig, 1998) demonstrated that the later method leads to a more stable perception of the depth information and was therefore used for the reported experiments. Once the observers perceive the 3D scene, they may move their gaze to any position in the image without losing the 3D impression. Most important in the present context, *SIRDS* can cover large visual angles without requiring vergence beyond natural parameters, which makes them appropriate stimuli for studying vergence movements in virtual 3D images.

In our natural environment, and when looking at *RDS*, we move our eyes inward (*convergence*) to inspect near objects and outward (*divergence*) to inspect distant objects. An obvious question is: Do these vergence movements also occur during the observation of autostereogram images? Belopolskii and Logvinenko (1994) found that vergence movements are not *necessary* to get the 3D perception of an autostereogram. However, in recent experiments (Essig, 1998) we found that in fact vergence eye-movements are executed during the examination of autostereogram images. These results encouraged us to conduct further experiments investigating stereogram parameters that are likely to influence vergence movements.

A distinguishing feature of autostereogram images is their grain size (granularity). Figure 1 shows examples for autostereogram images with small (upper panel) and big grain sizes (lower panel). The reported experiment used autostereogram images with different grain sizes to systematically investigate the influence of this parameter on the vergence movements. According to Mowforth et al. (1981), overshoots and oscillations should be more likely for autostereogram images with coarser granularities, i.e. lower spatial frequencies, which, however, is in-

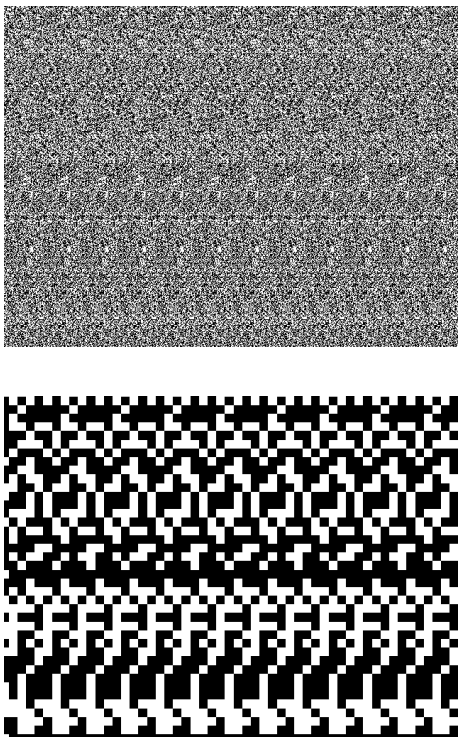

Figure 1: Autostereogram images with granularities 1 (upper panel) and 12 (lower panel).

consistent with the findings of Rashbass and Westheimer (1961). For a clarifying analysis of this issue, we measured vergence eye-movements with a modern binocular eye tracker with a sampling rate of 250 Hertz. For increased precision of vergence and 3D gaze-position measurement, we developed and applied a novel neural-net based calibration interface, which is described in the following section.

A Neural Approach to 3D Gaze-Point Calculation

During the examination of autostereograms shown on the computer screen, the intersection of the viewing axes is in general in front of or behind the screen plane, depending on the 3D gaze position. As a consequence, the correct coordinates for the actual gaze position are different from the screen coordinates which the eye tracker provides, because the system uses a 2D calibration to calculate the relation between the pupil positions and the gaze point on the screen. We tackled this problem by developing a 3D calibration that precedes the experiment and uses a *parametrized self-organizing map* (PSOM) to approximate the 3D gaze point from a subject's binocular eye-movement data.

Since the experimental conditions change from subject to subject (e.g. subjects have physical differences, their gaze characteristics are individually different, and the eye-tracker setup varies across sessions), it is clearly advantageous to use a method which is able to "learn" these individual parameters. Additionally, we have to take into consideration that the mapping from pupil to screen coordinates is non-linear. Hence neural nets are suitable for the solution of these problems, because they are able to "learn" nonlinear functions. Kohonen (1990) developed the so-called *self-organizing maps* (SOMs), which could learn the correct mapping from the pupil to the screen coordinates. However, SOMs have two disadvantages: They supply only the position of the most stimulated neuron in a "neuron lattice" instead of a continuous output, and they usually require thousands of training examples. Therefore, we use a variant of SOMs, namely a so-called *parametrized self-organizing map* (PSOM) (Ritter, 1993). This variant does not have the disadvantages mentioned above, because it provides the demanded continuous output and gets only some selected input/output pairs as parameters, i.e. the coordinates of the calibration points and the related positions of the pupils measured by the eye tracker.

A 2D version of the PSOM was already used in (Pomplun, Velichkovsky & Ritter, 1994), reducing the average calibration error to about 30% of its previous value. In opposition, our "new" PSOM does not only enhance the accuracy of measurement, it also approximates the subject's 3D gaze position from the two 2D coordinates of the eye tracker system.

A PSOM can be considered as a recursive neural net that realizes a distinct, mostly multi-dimensional projection **f**. The input data of this projection consist of the "correct" coordinates of 27 calibration points $k \in \mathbf{A}$ (standardized in the interval from 0 to 2 by the PSOM), where $\mathbf{A} = \{k_{xyz} | k_{xyz} = x\hat{e_x} + y\hat{e_y} + z\hat{e_z}; x, y, z = 0...2\}$

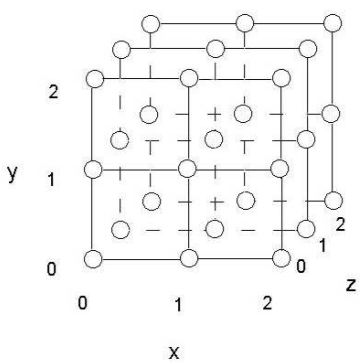

Figure 2: The calibration points in the virtual 3 x 3 x 3 cuboid. For the PSOM the coordinates are standardized in such a way that they only have the values 0, 1, and 2.

(see Figure 2) arranged in a 3 x 3 x 3 grid and presented to the subjects during the calibration procedure. In order to create a virtual 3D perception, the calibration grid was presented as an anaglyph image, viewed through red-green glasses. The calibration points were drawn on the planes of a cuboid, where the planes before and behind the screen plane formed its surfaces. This made it perceptually easier for the subjects to locate the stimuli on one of the three planes of the cuboid. For each of these

27 calibration markers, we have the associated gaze coordinates measured by the eye tracker and the x-divergence between the gaze positions of the left and right eye on the screen calculated from this data. Thus, the reference vector is $w_k = (x_{plk}, y_{plk}, x_{prk}, y_{prk}, x_{dk}) \in \boldsymbol{R}^5$. x_{plk} is the x-coordinate for the left eye, and y_{plk} the corresponding y-coordinate for the left eye belonging to the vector w_k. For the right eye the corresponding values are x_{prk} and y_{prk}. The fifth element of w_k results from $x_{dk} := x_{prk} - x_{plk}$.

We introduce the divergence (x_{dk}) as the fifth dimension of w_k because the z-coordinate of the 3D gaze-position mainly depends on this divergence. Since the differences in the divergence are smaller than those in the x- and y-directions, the divergence has to be weighted by a specific factor. This method leads to a faster termination of the PSOM-calculations. Hence, every fixation point $k \in \mathbf{A}$ is associated with a corresponding reference vector $w_k \in \boldsymbol{R}^5$. With the reference vectors w_k we could already construct a SOM which could enable the projection from the 2D coordinates of the system to the "correct" 3D coordinates. This SOM would only enable a crude approximation to the real 3D coordinates, because it could only choose one of the calibration points as a possible output. In the present context, however, we are looking for a projection which can interpolate between the vectors w_k. This projection can be done by a PSOM.

The desired interpolation function $\mathbf{f}$(s) can be constructed from the superposition of a suitable number of simpler basis functions H(.,.) as follows:

$$\mathbf{f}(s) = \sum_{k \in A} H(s,k) w_k \tag{1}$$

The values of the basis functions are within the interval [0,1] depending on different values s, so that the coordinates of a calibration point, which is close to the desired gaze position, is weighted strongly (near 1) and points which are far away are weighted weakly (near 0). The basis functions $H : \boldsymbol{R}^3 \times A \rightarrow \boldsymbol{R}$ have to comply with the requirement

$$H(s,k) = \delta_{s,k} \qquad \forall \;\; s,k \in A \tag{2}$$

where δ represents the Kronecker symbol. It is defined as: $\delta_{ij} = \begin{cases} 1 & : \quad i = j \\ 0 & : \quad i \neq j \end{cases} \quad \forall \;\; i,j = 0,1,2$
(in this special case). This ensures that

$$\mathbf{f}(s) = w_s \qquad \forall \;\; s \in A$$

Thus, it is guaranteed that the interpolation function passes through the given points. But how can we choose suitable functions H that obey equation (2), that are smooth and simple to handle?

One convenient solution is to make a product ansatz and to derive the suitable function by combining three 1D functions (one in each case for every coordinate direction x, y, and z). The new 1D functions must then have the property $H^{(1)} : \boldsymbol{R} \times \{0,1,2\} \rightarrow \boldsymbol{R}$:

$$H^{(1)}(q,n) = \delta_{q,n} \quad \forall \;\; q \in \boldsymbol{R}, n \in \{0,1,2\} \tag{3}$$

Because n has only three possible values (0, 1, and 2), it is sufficient to choose an account of three basis functions $\boldsymbol{R} \rightarrow \boldsymbol{R}$. For this purpose, polynomials of second degree are especially suitable, because they have no redundant degrees of freedom.

Now we have built a function which projects 3D coordinates onto 2D gaze-positions for both eyes. Our final aim is to find a function which does just the opposite though, namely to approximate the 3D gaze-position of the subject from the system's 2D measurements. Therefore, we have to calculate the inverse function $\mathbf{f}^{-1}$ of $\mathbf{f}$. The non-linearity of $\mathbf{f}$ forces us to use a numerical procedure. Thus we have to create an error function $E(s)$, which is defined as:

$$E(s) = \frac{1}{2}(\mathbf{f}(s) - \mathbf{f}_{et})^2 \tag{4}$$

i.e. the deviation of the pupil coordinates provided by the eye tracker ($\mathbf{f_{et}}$) from the eye tracker data calculated by the PSOM $\mathbf{f}(\mathbf{s})$ for the actually assigned two screen points.

If this difference exceeds a specified threshold, the coordinates of these points are modified in an iterative gradient-descent procedure until the results of Equation (1) closely approximate the actual eye tracker data provided by the system:

$$s(t+1) = s(t) - \epsilon \cdot \frac{\delta E(s)}{\delta s} \quad , \text{with } \; \epsilon > 0 \tag{5}$$

This means that the iteration process stops if $E(s(t))$ falls below the threshold, which we should adapt to the screen resolution. In this way, an exact 3D gaze position of the subject during the examination of a 3D stimulus is assigned to the 2D eye tracker data for the left and right eye.

We conducted an experiment in which the accuracy of the PSOM gaze-point calculation is compared to one provided by a geometrical solution. Subjects had to visually track a dot that appeared at positions of a 4 x 4 x 4 grid in 3D space in a random sequence. In the geometrical method the equations for the right and left visual axes are calculated on the basis of both the measured gaze-positions on the screen and the subjects' (assumed) constant head position. The gaze point is determined as the point where the visual axes are closest to one another. It results as the center of the shortest straight link between the visual axes.

The results show that the neural net calculates gaze positions from the eye tracker data which are nearly 46% closer to the actual gaze positions than those of the geometrical solution. The average total error for all subjects, separated for the individual coordinates, is shown in Table 1 (the values for the geometrical method and the neural net show the average total error and the standard error).

It is obvious that the z-error is always higher than the $x-$ and $y-$errors, because the z-coordinate is much more sensitive to small changes in the binocular gaze position than the $x-$ and $y-$coordinates. We also found that the measurement errors decrease from the back to the front

Table 1: Average total error for individual coordinates.

	both methods	**geometrical method**	**neural net**
coordinate	average total error	average total error	average total error
x	$0.97cm$	$1.41cm \pm 0.04cm$	$0.52cm \pm 0.05cm$
y	$1.03cm$	$1.24cm \pm 0.05cm$	$0.82cm \pm 0.05cm$
z	$4.16cm$	$5.79cm \pm 0.36cm$	$2.53cm \pm 0.11cm$

plane. The neural net compensates the errors in the back plane better than the geometrical method, because small changes in the gaze position at the back plane lead to severe inaccuracies. Obviously, the precision of our novel method of 3D gaze-position measurement provided an appropriate basis for the autostereogram study.

The Autostereogram Experiment

Method

Subjects. Eight paid subjects (1 female, 7 male), all of them were students at the University of Bielefeld, participated in this experiment. They had normal or corrected-to-normal visual acuity and were experienced in viewing autostereogram images.

Stimuli. The stimuli in this experiment were autostereogram images whose depth impression arose from two horizontally divided half planes, which were recognized at different virtual distances. The autostereogram images used in the experiment varied in their granularities. Using the autostereogram generation program *rdsgen V1.2b* by Frederic N. Feucht[1], we produced different autostereogram images in which one dot of the autostereogram image corresponded to one, two, four, eight, or twelve screen pixels in height and width. The subjects always got the spatial perception that the lower plane was nearer than the upper one. The depth difference between the two planes corresponded to a vergence angle difference of 0.859^o.

By using *rdsgen* we created two autostereogram images for each of the granularities 1, 2, 4, 8, and 12[2]. These 10 autostereogram images were presented to the subjects in a random order on a 20-inch screen and a spatial resolution of 640x480 pixels. The images consisted of black and blue (luminance: 24 cd/m^2) points, where one pixel corresponded to 4.17 min arc. The distance from the subject to the screen was 50 cm.

[1] http://www.bcc.cc.nc.us/graphics/g2c.html.

[2] We first changed the distance between the repeating patterns of the autostereogram image and magnified it with the corresponding "enlargement factor" (grain size) to keep the distance between the repeating patterns (and therefore the depth impression) constant.

Apparatus. We used an SMI EyeLink eye tracker for the experiments. This system employs a headset with two cameras to enable binocular eye-movement recording. Further features of the EyeLink system are a high sampling rate of 250 Hz and an average on-screen gaze position error between 0.5^o and 1.0^o.

Procedure. Prior to the experiment, subjects were presented with autostereogram images without using the eye tracker. This way the subjects could practice the perception of the depth information. A lamp fixed behind the subjects to create reflections on the screen helped the subjects to fixate a virtual point behind the screen plane, facilitating the 3D perception of the autostereogram image. When the subject got the 3D impression, the light from behind was switched off.

At the beginning of every trial the light was switched on as soon as the autostereogram image appeared on the screen. When the subject got the 3D impression of the image, the experimenter switched off the light and started the eye-movement recording. It was the subjects' task to change their view from the front plane to the back plane and vice versa (every few seconds). Between these eye movements subjects kept their view on one plane for a while before changing their view to the other one. The vergence movements were recorded over a duration of 1 minute per image. If subjects "lost" the 3D impression during the recording interval, they had to press the right mouse button, recover the 3D impression, and press the left button to continue recording. Ten autostereogram images were shown to the subject in a random order so that every granularity appeared twice.

Data Analysis. In general, the vergence angle α is used to make statements about a subject's vergence. The bigger the vergence angle is, the stronger the eyes converge, i.e. the nearer the (virtual) surface fixated by the subject. The time course of vergence movements was the most important data to be analyzed in this experiment, especially during the period right before and after subjects changed their gaze point from one plane to another. We distinguished between eye movements from the near to the far plane and vice versa. For the evaluation process we summarized the data of all subjects and calculated the arithmetic mean and the standard error of the vergence angle as a function of time relative to gaze transitions between the two depth planes.

There were two criteria for the presence of a gaze transition between planes: First, there had to be a change in the measured y-value that indicated a crossing of the horizontal boundary. Second, any such change from plane A to plane B had to be preceded by a contiguous sequence of 50 measured gaze positions (200 msec) on plane A, and succeeded by a contiguous sequence of 250 gaze positions (1000 ms) on plane B. To account for a small fraction of measurement errors, we allowed a maximum of 4 violations of these conditions among the 300 measurements. After detecting a plane transition, the time course of vergence from 200 ms before to 1000 ms after the transition was calculated.

Results and Discussion

Our first observation was that subjects had problems to achieve a stable 3D perception of autostereogram images with large grain size (granularities 8 and 12). Once achieved, it was difficult for them to maintain the stable depth impression when changing their gaze point from one plane to the other. Subjects classified the autostereogram images with the granularities 2 and 4 as most pleasant to view. Figure 3 shows the temporal progress of the convergence and divergence movements during the examination of autostereogram images across granularities. The vergence angles are standardized, i.e. 0 corresponds to the back and 1 to the front plane. In the figures the value 0 on the time axis signals the time of plane transition. Each panel shows the vergence data from 200 ms before to 1 s after an eye movement between the two planes. Figure 3 also illustrates that, for all granularities, the convergence movements are obviously faster than the divergence movements. This is in line with the observations in Mowforth, Mayhew and Frisby (1981). The final values are reached after a period of about 800 ms, as stated in Rashbass and Westheimer (1961). As can clearly be seen, both convergence and divergence movements already start before the onset of an eye movement between planes, suggesting that the imagination of the target distance is already sufficient for the execution of vergence eye-movements (proximal vergence). Similar results were already obtained by Yarbus (1967).

The high overshoot of the convergence movements (Figure 3, upper panel) for the granularities 2 and 4 is very obvious. Both show an overshoot of 1.8 and approach the end value at nearly 900 ms. The similarity between those vergence movements is in line with the subjects reporting that it is easier to get and stabilize the 3D illusion of these two types of autostereogram images. One reason could be that the perception of the depth planes is particularly stable for these granularities. Subjects can perceive the near plane very well, even if they fixate a point on the back plane. As a consequence, the visual system might perform a particularly fast, overshooting vergence movement towards an angle that would project the pattern of the near plane to corresponding points on the retina. This mechanism allows us a fast focussing of near or approaching objects, which is an important capability to react in dangerous situations.

The vergence movements during the observation of the autostereogram image with granularity 1 are similar to those for granularities 2 and 4. It is obvious, though, that the overshoot of the convergence movements for granularity 1 is smaller (1.5) than for granularities 2 and 4 (granularity 1 seems too fine for a stable extrafoveal perception). Also the approaching to the end value is shorter (nearly 750 ms instead of approx. 900 ms). These results further support the finding that vergence movements can clearly be driven by relatively high spatial frequencies (fine granularities), as stated in Mowforth, Mayhew and Frisby (1981).

The data for the coarse granularities 8 and 12 are clearly different from those for 1, 2, and 4. Hence it

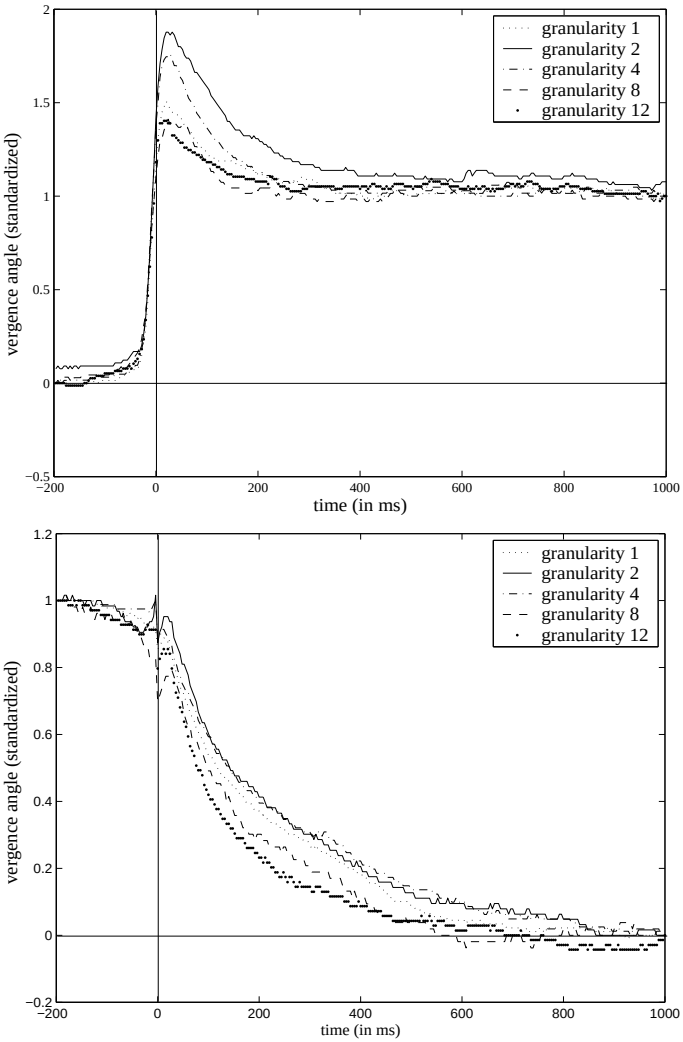

Figure 3: Convergence (upper panel) and divergence movements (lower panel) occurring during the examination of autostereogram images with different granularities.

is much more difficult for the subjects to perceive both planes simultaneously in those autostereogram images, which is consistent with the subjects' impressions. An important point is that the overshoot of the convergence movements is substantially weaker (1.4) than for those occurring in the images with finer granularities. The standard error for the convergence as well as for the divergence movement is high. This can be interpreted as indicating an instable perception of the depth planes. Furthermore, the progress of the divergence movements is faster and finishes sooner than 600 ms after the gaze shift.

The finding of overshoots for convergence movements is inconsistent with the results obtained by Rashbass and Westheimer (1961). It is possible that either the apparatus used in their study did not allow the detection of these overshoots, or that vergence eye-movements in *RDS* – in contrast to those in *SIRDS* – do not show

overshoots. Rashbass and Westheimer describe the vergence system as a damped system, because it does not show any oscillations. In the present study, however, we found overshoots, but no following undershoots or any kind of oscillations. It seems therefore correct to speak of a damped system but with a strong tendency towards overshoots for convergence movements in *SIRDS*.

With regard to divergence movements (Figure 3, lower panel), we found faster approximation of the target angle for the autostereogram images with coarser granularities than for those with finer granularities. This is just the opposite of the results we got for the convergence movements. A possible explanation is a fundamental difference in nature between convergence and divergence movements, as can be seen from Figure 3. Convergence movements are fast and impulse-like, whereas divergence movements are slower and smoother. From an evolutionary standpoint, since distant or vanishing objects are less dangerous, there is no need for fast divergence eye-movement mechanisms. Instead, this divergence resembles more a relaxation process. And this relaxation might be facilitated by easily losing the perception of the near plane. In other words, for the finer granularities 1, 2, and 4, the continuous stable perception of the front plane might impede the subjects' effort to focus attention – and consequently vergence – on the far plane.

All in all, some findings for the *RDS* were confirmed in our experiments with *SIRDS*, in particular that convergence is faster than divergence, that the vergence mechanism can clearly be driven by relatively high spatial frequencies, and that vergence response occurs even before the disparity reaches zero. Inconsistent with previous studies, however, our experiment demonstrates substantial differences in vergence movements between *SIRDS* and previously investigated *RDS*, especially with regard to the overshoot for convergence movements. This difference, however, might have been caused by the possibly low resolution of the apparatus used in the *RDS* study (Rashbass & Westheimer, 1961).

Furthermore, our experiments show a clear influence of granularity on vergence movements. The pattern of influence seems to be more complex than described in Mowforth, Mayhew and Frisby (1981), because, according to our results, lower frequencies (coarser granularities) do not always lead to faster vergence movements. One reason might be the more difficult simultaneous perception of different depth planes in the stimuli of very low frequencies. At any rate, these complex granularity effects on vergence eye-movements in autostereogram images indicate that there may be rather non-intuitive factors that can have a significant impact on the coordination of both eyes. Future research will have to address further issues, such as the timing of coordinated binocular saccades and its dependence on various pattern features. This is a research area that so far has been explored very little, and the rather recent possibility of fast and accurate binocular eye tracking, combined with appropriate techniques for 3D gaze measurement like the approach presented here, will greatly contribute to its advancement.

Abstract

To study the development of graphical conventions we had members of a simulated community play a series of graphical interaction games with partners drawn from the same pool (Experiment 1). Once the community was established, a conventional graphical referring scheme emerged that facilitated high levels of semantic coordination, with reduced communicative effort. Next, a forced choice reaction time study (Experiment 2) demonstrated that the graphical conventions developed in the simulated community offer distinct processing advantages when compared with those developed by isolated pairs (i.e. participants who always interact with the same partner). This is interpreted as evidence that the graphical conventions that evolve within a closed community constitute higher order cognitions, the whole being greater than the sum of its parts.

Background

Vygotsky (1981) claims that higher order cognition is a product of social interaction, that novel structures emerge as a consequence of interpersonal, as opposed to intrapersonal, communication. Hutchins (1995) shares this view, arguing that higher order cognition is a cultural product, a consequence of interaction (human-environment and human-human) that is distributed across time and space. According to Hutchins, higher order cognitions emerge from "an adaptive process that accumulates partial solutions to frequently encountered problems" (p.354). Lewis (1969, 1975) defines conventions in a related way, as arising from situations where a community faces the recurrent problem of coordination.

If we agree that conventions are cultural products, should we accept that they represent higher order cognitions? Using Chinese characters as an example (Figure 1), we argue that conventions are culturally evolved higher order cognitions.

Over several thousand years the original Chinese character that represents mountain (left) has evolved into its current, less complex, form (right). We argue that this change is not arbitrary; it is a result of global coordination that took place over time and space, culminating in a refined, conventional form that promotes rapid communication with reduced effort. This is an example of an evolutionary process where the whole is greater than the sum of its parts.

Figure 1. The changing form of the Chinese character that represents mountain (Vacarri & Vacarri, 1961; cited in Arbib, in press)

Having partners collaborate on a graphical referential communication task, Fay, Garrod, Lee and Oberlander (2003) studied the influence of interaction upon representational form. The task requires pairs of participants to graphically communicate a series of recurring concepts. Figure 2 illustrates the changing representation of the concept 'Clint Eastwood' over 6 games, where partners' drawing and identifying roles alternated from game to game.

What is initially a designed, iconic representation of Clint Eastwood, develops, through a process of adaptation and entrainment, into a simplified, symbolic form (an arrow pointing East). Although there are obvious similarities between this process and the evolution of Chinese characters, the derived representation of Clint Eastwood does not constitute a convention in Lewis' terms. According to Lewis, a convention must be common knowledge within the

wider community. At best, Figure 2 illustrates the development of a 'local' convention.

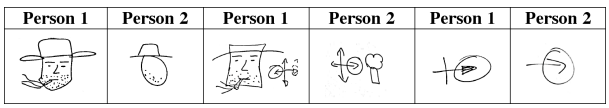

Figure 2. Partners' changing representation of the concept 'Clint Eastwood' over 6 games

Garrod & Doherty (1994) distinguish this 'local' process from the 'global' coordination process that produces conventions. To study the development of linguistic conventions, Garrod et. al. had members of a simulated community play a series of computerized maze games with partners drawn from the same pool. After several games, community members demonstrated higher maze description scheme convergence and more closely coordinated linguistic entrainment when compared with interacting pairs, or participants drawn from a non-community (i.e. interacting partners not drawn from the same pool).

This effect was interpreted as indicating the establishment of the community, and the development of a robust referring convention. Garrod et. al. argue that referring conventions emerge on account of a global coordination constraint based upon two factors; pressure to converge upon the most popular description scheme with each new partner, and the consequent polarization of this scheme throughout the community. This is contrasted with the local coordination process evident among pair and non-community members, a process based upon the less stable heuristics of salience (pressure to choose the most salient description scheme) and precedence (pressure to choose the previously used scheme).

In much the same way that Garrod et. al. studied the development of linguistic conventions, we investigate the development of graphical conventions (Experiment 1). Furthermore, we demonstrate that these cultural products represent higher order cognitions (Experiment 2).

Experiment 1

Experiment 1 investigates the development of graphical conventions within a simulated community of drawers.

Task and Procedure

Fay et. al.'s (2003) graphical referential communication task was employed. This task requires pairs of participants to communicate a series of concepts using only graphical means. Like the game 'Pictionary', participants are not allowed to speak or use text in their drawings. Concepts are drawn from a list of 16 items that are known to both partners. The list was designed to contain a set of graphically confusable concepts (theatre, art gallery, museum, parliament, Robert De Niro, Arnold Schwarzenegger, Clint Eastwood, drama, soap opera, cartoon, television, computer monitor, microwave, loud, homesick, poverty).

Participants played six consecutive games, using the same item set, with their partner. On each game the director, or drawer, depicted the first 12 items from an ordered list (12 items plus 4 distracters) such that their partner, the matcher, could identify each drawing from their unordered list. Item order was randomized on each game. Partners' roles, as drawer or matcher, alternated from game to game, although participants were permitted to draw in either role. Drawing took place on a standard whiteboard. The completed drawings were recorded on digital camera for later analysis.

Subjects

The community was composed of 8 undergraduate students who were paid to participate in the study.

Community Design

A simulated community was created through a series of one-to-one interactions among partners drawn from the same pool. Over 7 rounds, each participant interacted with the other members of the community. As discussed, participants completed a series of 6 consecutive graphical interaction games with each partner. The structure of the community is illustrated in Figure 3.

It was so designed that community could first establish itself at Round 4. This was the earliest point the community could converge upon a conventional graphical description scheme. For example, if person 1 influences person 2 (Round 1), person 2 influences person 3 (Round 2), and person 3 influences person 8 (Round 3), person 1 and 8 will share some interactive history upon meeting in Round 4. Thus, Rounds 1-3 represent pre convergence games, whereas Rounds 4-7 represent post convergence games.

ROUND	PAIR	PAIR	PAIR	PAIR
1	1&2	3&4	5&6	7&8
2	1&4	3&2	5&8	7&6
3	1&6	3&8	5&2	7&4
4	1&8	3&6	5&4	7&2
5	1&3	2&4	5&7	6&8
6	1&5	2&6	3&7	4&8
7	1&7	2&8	3&5	4&6

Figure 3. Structure of the simulated community

Three independent measures were employed to determine the establishment of a conventional graphical referring scheme: identification accuracy (i.e. participants' ability to more successfully identify conventional graphical representations), graphical complexity (i.e. the reduced effort required to negotiate

the meaning of conventional graphical representations) and graphical convergence (i.e. the greater uniformity of a conventional graphical description scheme).

Results

Identification Accuracy. Figure 4 details the identification rate (proportion of items correctly identified by matchers) of pre convergence (Rounds 1-3) and post convergence representations (Rounds 4-7) over the six games played by each pair. In pre convergence rounds there is a steady improvement in identification accuracy from games 1 to 3. After this identification rates reach ceiling level. In contrast, post convergence identification rates begin from, and are maintained at, ceiling level across games. Analysis of Variance (ANOVA) confirms these observations.

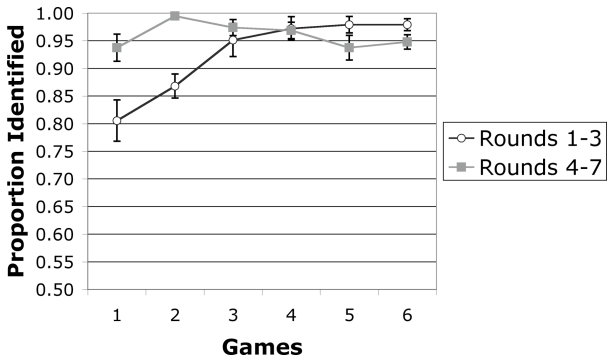

Figure 4. Mean proportion of items correctly identified by matchers in games 1 to 6 during Rounds 1-3 (pre convergence) and 4-7 (post convergence)

Proportion scores were entered into a 2 x 6 ANOVA. Analyses were conducted by subject (F_1) and by item (F_2). By subject tests used a mixed design, treating Game (1 to 6) as a within subject factor and Round (1-3 and 4-7) as between. Item tests used a within subject design. A main effect of Game $F_1(5, 130) = 6.78$, $F_2(5, 55) = 4.51$, and Round $F_1(1, 26) = 8.69$, $F_2(1, 11) = 5.97$, $p<.05$, was qualified by their interaction $F_1(5, 130) = 7.14$, $F_2(5, 55) = 6.68$ (for all results reported $p<.01$ unless otherwise stated). Tests of simple effects corroborate the observations made above; identification accuracy improves in the pre convergence rounds (1-3), $F_1(5, 130) = 11.07$, $F_2(5, 55) = 8.17$, but not in the later post convergence rounds (4-7) where identification rate is maintained at ceiling from game 1 onwards, $Fs<1.48$.

The consistently high identification rate in Rounds 4 to 7 indicates the establishment of the community and the emergence of a robust referring scheme.

Graphical Refinement. Through interaction partners minimize their collaborative effort, stripping away unnecessary graphical information, leaving only the salient properties of the image (Fay et. al., 2003). As a result, what is initially an iconic representation becomes increasingly symbolic (see Figure 2). Comparable graphical refinement was evident in the community members' drawings.

Drawing complexity was measured using the Perimetric Complexity formula developed by Pelli, Burns, Farrell and Moore (accepted with minor revisions) to measure the visual complexity of letters, Complexity = Perimeter^2/Ink. This measure compares favorably with human judgments of drawing complexity (Fay et. al., 2003).

Figure 5 illustrates the mean complexity of drawings made in games 1 to 6 during Rounds 1-3 and 4-7. Mean complexity scores were calculated after the removal of scores 2.5 standard deviations (SD) from the condition mean. Extreme values were replaced with values corresponding to the mean plus or minus 2.5 SDs. Such cases accounted for 2.4% of the data.

In both the pre and post convergence rounds (Rounds 1-3 and 4-7 respectively) the complexity of community members' drawings is reduced across games. However, this effect is more marked in the early, pre convergence rounds. This observation is corroborated by ANOVA.

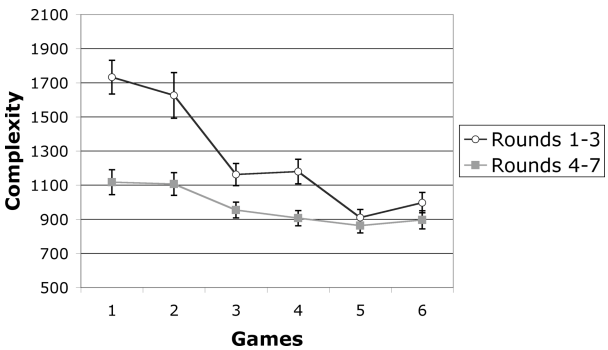

Figure 5. Mean Complexity (Perimeter^2/Ink) of pre and post convergence drawings (Rounds 1-3 and 4-7 respectively) in games 1 to 6

As before, complexity scores were entered into a 2 x 6 ANOVA. This returned a main effect of Game $F_1(5, 130) = 58.57$, $F_2(5, 55) = 34.48$, and Round $F_1(1, 26) = 13.01$, $F_2(1, 11) = 39.11$, that was qualified by their interaction $F_1(5, 130) = 15.35$, $F_2(5, 55) = 12.43$. Tests of simple effects show that graphical complexity is reduced across games in both the pre convergence rounds $F_1(5, 130) = 58.33$, $F_2(5, 55) = 39.34$, and post convergence rounds $F_1(5, 130) = 8.48$, $F_2(5, 55) = 4.24$, (Rounds 1-3 and 4-7 respectively). Between condition differences in drawing complexity in games 1 to 4, $ps<.05$, and the comparable complexity of drawings at games 5 and 6, $Fs<1.07$, explain the interaction.

Results support Garrod and Doherty's (1994) distinction between local and global coordination

processes, signaled by the emergence of a conventional graphical referring scheme during Rounds 4-7. Unlike the initial exchanges in Rounds 1-3, where partners must negotiate a common description scheme, the establishment of a conventional referring scheme from Round 4 requires considerably less local negotiation.

Graphical Convergence. Graphical convergence concerns the degree to which community members' drawings converge, or become more similar, as a consequence of their interaction. To investigate the emergence of a common referring scheme, the similarity of the first drawings of each concept produced by community members at Rounds 1, 4 and 7 (i.e. pre convergence, convergence and post convergence rounds) was compared.

Figures 6, 7 and 8 illustrate the 8 community members' changing representation of the concept 'cartoon' at Rounds 1, 4 and 7 respectively. In addition to the reduction in graphical complexity across rounds, observe the community members' convergence upon a conventional description scheme for cartoon, in this case a Mickey Mouse-like depiction, characterized two large circular ears above the head.

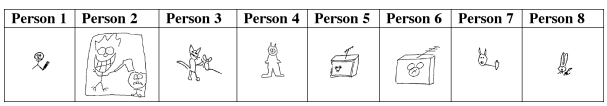

Figure 6. Community members' drawings of the concept 'cartoon' at Round 1

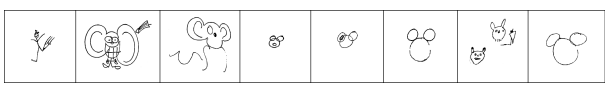

Figure 7. Community members' drawings of the concept 'cartoon' at Round 4

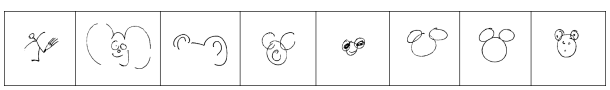

Figure 8. Community members' drawings of the concept 'cartoon' at Round 7

Graphical convergence was analyzed by having 12 subjects, who had no experience of the graphical communication task, rank sets of images in terms of similarity. Each subject individually ranked three sets of 8 images (e.g. Round 1, 4 and 7 drawings of the concept 'cartoon' produced by each of the 8 community members) in terms of similarity. This was done for each of the 12 target items drawn by community members. The set of images thought to be most similar was given a rank of 1; those deemed least similar a rank of 3. The presentation order of item type (e.g. television, cartoon etc.) and round (Rounds 1, 4 or 7) was randomized.

Graphical convergence was measured by calculating the proportion of Round 1, 4 and 7 images ranked as most similar. As can be seen from Figure 9, graphical convergence increased across Rounds. A substantially higher proportion of Round 4 images were ranked as most similar when compared with Round 1 images. In addition, more Round 7 images were ranked as most similar when compared with Round 4 images.

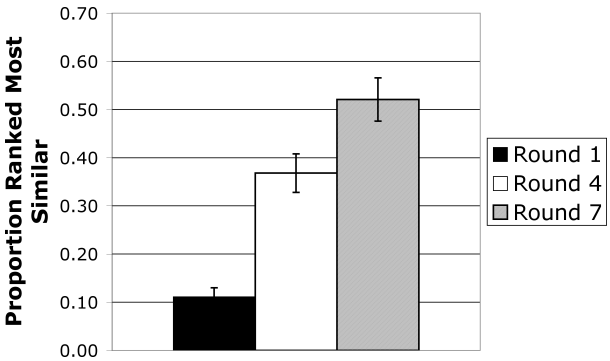

Figure 9. Mean proportion of drawings ranked most similar in Rounds 1, 4 and 7 (pre convergence, convergence and post convergence rounds respectively)

Proportion scores were entered into two repeated measures t-tests. Results were as predicted; Round 4 images were ranked as most similar more often than Round 1 images $t_1(11) = 5.82$, $t_2(11) = 2.91$, $p<.05$. This effect was less clear when Round 4 and Round 7 images were compared; by subject tests revealed a marginal effect $t_1(11) = 1.84$, $p<.10$, whereas there was no effect of round when tested by item, $p>.10$.

Consistent with the previous identification and complexity analyses, convergence tests indicate the emergence of a conventional referring scheme at Round 4. Tests show a large jump in drawing convergence from Rounds 1 to 4 and a smaller, marginally significant, increase in graphical convergence from Rounds 4 to 7. This indicates the establishment of a conventional graphical referring scheme at Round 4, and its continued development in the later rounds.

Experiment 2

Having detailed the emergence of a conventional graphical description scheme in Experiment 1, Experiment 2 demonstrates that these graphical productions constitute higher order cognitions.

Experiment 2 contrasts representations that emerge as a product of design, local coordination and global coordination processes. Pre interaction drawings (i.e. subjects' first drawing of each item) represent pure design, an intrapersonal process whereby the drawer designs a representation to meet the needs of his/her partner. This is consistent with the notion of 'audience

design' (Isaacs & Clark, 1987). Local coordination, or adaptation, is illustrated in the interacting pair's final drawing of Clint Eastwood in Figure 2. In this example partners' drawings serve their local needs. Global coordination, or evolution, is exemplified by the development of a conventional referring scheme that meets the needs of the wider community (see Figure 8).

A forced choice reaction time (RT) experiment was designed to compare the processing efficiency of graphical representations that are a product of design, local coordination and global coordination processes. If graphical conventions constitute higher order cognitions they will provide a processing advantage when compared with designed or locally developed representations.

Task and Procedure

The RT experiment required subjects to make binary judgments regarding a set of learnt images. Community (Experiment 1) and isolated pair images (from Fay et. al., 2003) were used as stimuli, presented on a computer screen using PsyScope (Cohen, MacWhinney, Flatt & Provost, 1993).

24 undergraduate students, who were unfamiliar with the graphical communication experiment, were paid to act as subjects. Prior to taking part in the RT experiment, subjects learnt the identity of 48 images (50% community generated and 50% pair generated). Each image set (community and pair) was composed of 50% pre interaction images (i.e. the first drawing of each item) and 50% post interaction images (i.e. the last drawing of each item). Pre and post interaction drawings (matched by drawer) were sampled quasi-randomly from the community and isolated pair conditions. Although pre interaction drawings were more complex than post interaction drawings, there was no difference between community and isolated pair drawings (Community, *M* pre = 1796, *M* post = 906; Pair, *M* pre = 1669, *M* post = 932). Participants were judged to have learnt the images when each drawing could be identified on three consecutive presentations of the set.

Each experimental trial consisted of the following sequence; a fixation point (a small cross presented in the middle of the screen for 25 msecs), the learnt image (50 msecs), a mask (the screen was blacked out for 25 msecs) and a forced choice (text that either matched or mismatched the presented image, e.g. a cartoon image followed by the text 'drama'). The time required to make a match/mismatch judgment, by key press, was recorded. Subjects completed 384 trials, with each drawing appearing 4 times in each condition.

Results

There was a 4.8% error rate on match/mismatch questions, suggesting that participants had adequately learnt the task materials. Mean RTs were calculated after the removal of times 2.5 SDs from the population mean. These extremes were replaced with values corresponding to the mean plus or minus 2.5 SDs. This accounted for 2.5% of the data.

Mean RTs for matching image and text judgments are shown in Figure 10. As predicted, the community generated graphical conventions (post interaction) were processed more rapidly than the designed (pre interaction) or locally developed pair representations (post interaction). The same pattern is evident in the mismatching text condition, but at a slower response rate (*M* match = 781 msecs; *M* mismatch = 884 msecs).

RTs were entered into a 2 x 2 x 2 ANOVA, treating Communication (Community or Pair), Image (Pre and Post) and Text (Match or Mismatch) as within subject factors. Analyses returned a main effect of Text $F_1(1, 23) = 43.79$, $F_2(1, 11) = 65.26$, indicating subjects' faster response times when the image and text stimuli matched. There was also a reliable interaction between Communication and Image $F_1(1, 23) = 10.08$, $F_2(1, 11) = 3.16$, $p = .10$. Tests of simple effects confirmed that community generated representations were processed more rapidly than those developed in isolated pairs $F_1(1, 23) = 5.63$, $p<.05$, $F_2(1, 11) = 6.34$, $p<.05$. Pre interaction images and post interaction pair representations were processed at a comparable rate, $Fs<1$.

The RT experiment distinguishes between representations that emerge as a product of design, local coordination and global coordination processes. The graphical conventions that evolved within the simulated community, a society composed of the pairwise interactions of its members, outperformed those produced by pairs who interacted in isolation. These graphical productions provide a clear example of higher order cognition, where the whole is greater than the sum of its parts.

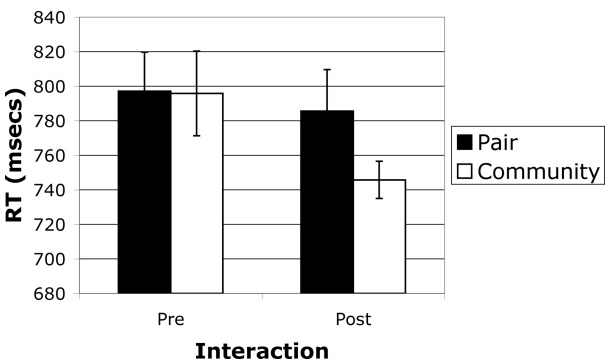

Figure 10. Mean time required to process pre and post interaction community and pair representations in the matching text condition (image and text match)

Discussion

Experiment 1 details the emergence of a conventional graphical description scheme within a simulated community of drawers. Once established, community members exhibit near perfect semantic coordination (identification accuracy) with reduced communicative effort (graphical complexity). This is a consequence of the development of a conventional graphical description scheme (convergence). Experiment 2 distinguishes between graphical productions that develop as a product of design, local coordination and global coordination. The graphical productions that evolved within the simulated community offer substantial processing advantages when compared with designed or locally developed representations. Thus, conventional graphical representations constitute higher order cognitions, the whole being greater than the sum of its parts.

However, there are two potentially confounding factors in Experiment 2. Community members played more games with more partners (42 games; 6 games with each of 7 partners) than pair members (6 games with 1 partner), exposing them to a greater variety of description schemes. Number of games played can be discounted for the simple reason that isolated pairs rapidly negotiate and maintain a locally stable description scheme (Fay et. al., 2003; Garrod & Doherty, 1994). Community members' exposure to a greater number of exemplars is likely to have a profound effect, as people are better able to learn a prototype when exposed to its variants (Posner & Keele, 1968). However, number of exemplars alone is not enough; global coordination is necessary to derive a stable underlying representation (Garrod & Doherty, 1994).

So what is 'better' about the graphical conventions developed in the simulated community? We believe there are two factors at play; iconicity and systematicity. Like the present day Chinese character for mountain (Figure 1), community representations retain a degree of iconicity, i.e. once told what a drawing represents it can be 'seen' as such. Again, like Chinese characters, community drawings exhibit a degree of systematicity that makes them easily differentiable. We believe these factors explain the RT advantage for graphical conventions found in Experiment 2. At present this is pure conjecture. Further testing is required.

As the saying goes, 'A picture is worth a thousand words'. That pictures have advantages over words is supported by research showing that meaning is extracted more quickly from pictures than from text (Smith & McGee, 1980). The current study demonstrates that some pictures do this better than others.

Abstract

This paper investigates the nature of verbal working memory (WM) in sentence comprehension and provides evidence for overlapping pools of verbal WM resources between on-line sentence comprehension and other verbally-mediated tasks. We report the results of two dual-task experiments. In Experiment 1, participants simultaneously performed a self-paced reading task and a self-paced arithmetic addition task in a 2x2 design crossing syntactic complexity (low, high) and arithmetic complexity (low, high). In addition to two main effects, the most interesting result was a significant interaction between syntactic and arithmetic complexity during the critical region of the linguistic materials: participants processed the complex/complex condition more slowly than would be expected if the two tasks relied on independent resource pools. To address a potential confound of shared attentional resources, Experiment 2 was conducted, where participants simultaneously performed a self-paced reading task and a self-paced spatial-rotation task in a similar 2x2 design crossing syntactic complexity with the complexity of the spatial task. As in Experiment 1, there were two main effects of complexity in the critical region. However, in contrast to Experiment 1, these effects were strictly additive, with no trace of interaction. The results of the two experiments therefore support a WM framework where on-line linguistic processing and on-line arithmetic processing rely on overlapping pools of verbal WM resources.

Introduction

A major question in psycholinguistic research concerns the nature of the working memory (WM) resources used in language processing. Empirical research has suggested that different pools of WM resources are used for processing visuo-spatial information and verbal information (e.g., Baddeley & Hitch, 1974; Baddeley, 1986; Vallar & Shallice, 1990; Hanley et al., 1991; Jonides et al., 1993; Shah & Miyake, 1996). Some researchers (Caplan & Waters, 1999; cf. Just & Carpenter, 1992) have hypothesized that the verbal WM pool can be further divided into two sub-pools: (1) verbal WM for natural language comprehension and production; and (2) verbal WM for non-linguistic verbally-mediated cognitive tasks. This paper attempts to empirically evaluate this hypothesis.

One way to address this question is via dual-task paradigms in which participants perform two tasks simultaneously: (1) on-line sentence processing, and (2) a non-linguistic verbally-mediated task. The underlying assumption is that we should observe a super-additive interaction when the complexity of both tasks is high only if the two tasks rely on overlapping pools of resources.

Previous dual-task experiments found either no interaction or only a suggestion of one (e.g. King & Just, 1991; Just & Carpenter, 1992; Caplan & Waters, 1999; Gordon et al., 2002). In all of the previous experiments, however, the secondary task involved storage of words or digits across the sentence-processing task. Although storage – in a very general sense of keeping track of previously encountered information – plays an important role in on-line sentence comprehension (e.g., Chomsky & Miller, 1963; Kimball, 1973; Gibson, 1991; 1998; Lewis, 1996), it may be qualitatively different from the kind of storage involved in the secondary tasks in the earlier experiments.

According to one recent resource-based theory of on-line syntactic processing, the dependency locality theory (DLT; Gibson, 1998, 2000), there are two working memory components to sentence comprehension: storage and integration. The *storage* component involves keeping track of partially processed syntactic dependencies that are still awaiting their second element in order for the sentence to be grammatical, whereas the *integration* component involves connecting a newly input word into the structure that has been built so far. Critically, the storage component of on-line sentence comprehension is unlike the storage involved in keeping track of a list of unconnected items. Consequently, it is possible that the lack of on-line interactions between syntactic complexity and memory load in earlier studies could be a result of the distinct nature of the storage processes involved. Moreover, there have been no previous attempts to explore the potential interaction between integration processes in sentence comprehension and secondary verbally-mediated tasks, which involve similar but non-linguistic on-line integration processes. In the current paper, we propose a novel paradigm to address this issue.

Experiment 1

This experiment had a dual-task design, in which participants read sentences phrase-by-phrase, and at the same time were required to perform simple additions. The on-line addition task is similar to on-line sentence comprehension in that an incoming element – a number – must be integrated into (i.e., added to) the representation constructed thus far: the working sum. Both tasks had two levels of complexity, resulting in a 2x2 design. Critically, there was no difference in linguistic complexity between the easy and hard arithmetic conditions: the complexity of the arithmetic task was manipulated in terms of the difficulty of the arithmetic operations (by making the addends larger), while keeping the linguistic form of the two conditions identical (number + number + number, etc.). Therefore, if we observe a super-additive interaction between the two tasks when the complexity of both tasks is high, then we may infer that the verbal WM resources that are involved in performing the arithmetic task overlap with those that are involved in syntactic integration processes. In contrast, if language processing relies on an independent verbal WM resource pool, there should be no such interaction.

Methods

Participants Forty participants from MIT and the surrounding community were paid for their participation. All were native speakers of English and were naive as to the purposes of the study.

Design and materials The experiment had a 2x2 design, crossing syntactic complexity (subject-extracted relative clauses (RCs), object-extracted RCs) with arithmetic complexity (simple additions (low initial addend, consequent addends between 1 and 3) vs. complex additions (higher initial addend, consequent addends between 4 and 6)).

The language materials consisted of 32 sets of sentences, having four different versions as in (1):

(1) a. *Subject-extracted, version 1*:
The janitor | who frustrated the plumber | lost the key | on the street.

b. *Subject-extracted, version 2*:
The plumber | who frustrated the janitor | lost the key | on the street.

c. *Object-extracted, version 1*:
The janitor | who the plumber frustrated | lost the key | on the street.

d. *Object-extracted, version 2*:
The plumber | who the janitor frustrated | lost the key | on the street.

As described above, there were only two levels of syntactic complexity – subject- and object-extractions – but there were four versions of each sentence in order to control for potential plausibility differences between the subject- and object-extracted versions of each sentence. As a result, no independent plausibility control is needed in this design. Each participant saw only one version of each sentence, following a Latin-Square design.

The numbers for the addition task were randomly generated online for each participant with the following constraints: (1) the value of the initial addend in the easy-math condition varied from 1 to 10, whereas the value of the initial addend in the hard-math condition varied from 11 to 20, and (2) the addends varied from 1 to 3 in the easy-math condition and from 4 to 6 in the hard-math condition.

In addition to the target sentences, 40 filler sentences with various syntactic structures other than relative clauses were included. The length and syntactic complexity of the filler sentences was similar to that of the target sentences. The stimuli were pseudo-randomized separately for each participant, with at least one filler separating the target sentences.

Procedure The task was self-paced phrase-by-phrase reading with a moving-window display (Just, Carpenter & Woolley, 1982). The experiment was run using the Linger 2.85 software by Doug Rohde. Each experimental sentence had four regions (as shown in (1a)-(1d)): (1) a noun phrase, (2) an RC (subject-/object-extracted), (3) a main verb with a direct object (an inanimate noun phrase) and (4) an adjunct prepositional phrase. The addends for the addition task were presented simultaneously with the sentence fragments, above and aligned with the second character of each fragment. The first sentence region had a number above it (e.g. "12") and all the consequent regions had a plus sign followed by a number (e.g. "+4"), as shown in Figure 1.

Time 1:	12 The janitor	--- ---------- --- -------	---- --- ---	-- --- ------.
Time 2:	+4 --- ------- who frustrated the plumber		---- --- ---	-- --- ------.
Time 3:	+5 --- -------	--- ---------- --- -------	lost the key	-- --- ------.
Time 4:	+4 --- -------	--- ---------- --- -------	---- --- ---	on the street.

Figure 1: Sample frame-by-frame presentation of an item.

Each trial began with a series of dashes marking the length and position of the words in the sentence. Participants pressed the spacebar to reveal each region of the sentence. As each new region appeared, the preceding region disappeared along with the number above it. The amount of time the participant spent reading each region and performing the accompanying arithmetic task, was recorded as the time between key-presses.

To make sure the participants performed the arithmetic task, a window appeared at the center of the screen at the end of each sentence and the participants were asked to type in the sum of their calculations. If the answer was correct, the word "CORRECT" flashed briefly on the screen, if the answer differed by up to 2 from the correct sum, the word "CLOSE" flashed briefly, and if the answer was off by more than 2, the word "INCORRECT" flashed briefly on the screen. To assure that the participants read the sentences for meaning, two true-or-false statements were presented

sequentially after the sum question, asking about the propositional content of the sentence they just read. Participants pressed one of two keys to respond "true" or "false" to the statements. After a correct answer, the word "CORRECT" flashed briefly on the screen, and after an incorrect answer, the word "INCORRECT" flashed briefly.

Participants were instructed not to concentrate on one task (reading or additions) more than the other. They were asked to read sentences silently at a natural pace and to be sure that they understood what they read. They were also told to answer the math and sentence questions as quickly and accurately as they could, and to take wrong answers as an indication to be more careful.

Before the experiment started, a short list of practice items and questions was presented in order to familiarize the participants with the task. Participants took approximately 35 minutes to complete the experiment.

Results

Arithmetic accuracy Participants answered the arithmetic sum correctly 88.7% of the time. A two-factor ANOVA crossing arithmetic complexity (easy, hard) and syntactic complexity (easy, hard) on these question-answering data revealed a main effect of arithmetic complexity ($F1(1,39)=9.45$; $MSe=0.120$; $p < .005$; $F2(1,31)=7.21$; $MSe=0.087$; $p < .02$), but no other significant effects.

Comprehension question performance There were two comprehension questions following each experimental trial. Participants answered the first question correctly 80.2% of the time, and the second question 78.1% of the time. The percentages of correct answers by condition were very similar for the two questions, so we collapsed the results in our analyses. A two-factor ANOVA crossing arithmetic complexity (easy, hard) and syntactic complexity (easy, hard) on the responses to the two comprehension questions revealed a main effect of syntactic complexity ($F1(1,39)=9.8$; $MS=0.1$; $p < .005$; $F2(1,31)=4.04$; $MS=0.074$; $p=.05$) and a main effect of arithmetic complexity in the participants analysis ($F1(1,39)=4.31$; $MS=0.047$; $p <.05$; $F2(1,31)=2.9$; $MS=0.042$; $p =.10$), but no significant interaction ($Fs < 1$).

Reaction times Because participants had to answer three questions (one math, two language) for each sentence, the odds of getting all three correct were not very high overall (55.6%). As a result, we analyzed all trials, regardless of how the comprehension questions were answered. The data patterns were very similar in analyses of smaller amounts of data, in which we analyzed (1) trials in which one or both of the language comprehension questions were answered correctly, or (2) trials in which the math question was answered correctly. To adjust for differences in word length as well as overall differences in participants' reading rates, a regression equation predicting reading times from word length was derived for each participant, using all filler and target items (Ferreira & Clifton, 1986; see Trueswell, Tanenhaus & Garnsey, 1994, for discussion). At each word position, the reaction time predicted by the participant's regression equation was subtracted from the actual measured reaction time to obtain a residual reaction time. The statistical analyses gave the same numerical patterns for analyses of raw reaction times. Reaction time data points that were less than 100 msec in the raw data (indicating erroneous key presses) or more than 2.5 standard deviations away from the mean residual RT for a position within a condition were excluded from the analysis, affecting 3.3% of the data. Figure 2 presents the mean residual RTs per region across the four conditions of the experiment.

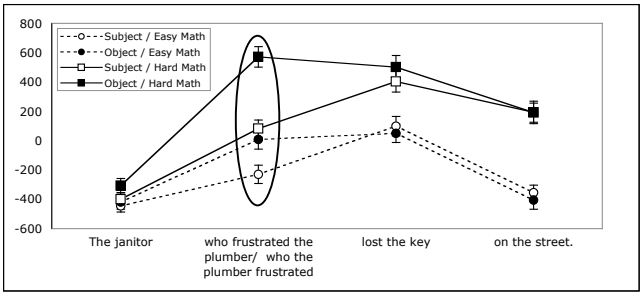

Figure 2: Reaction times per region in the four conditions of Experiment 1. The critical region is circled.

We present the analysis of the critical region (Region 2) first, followed by the analyses of the other regions. The critical region included the RC ("who frustrated the plumber" / "who the plumber frustrated"). A 2x2 ANOVA (easy-math / hard-math, subject-extracted RC / object-extracted RC) in this region revealed two significant main effects and a significant interaction. First, the hard-math conditions were read significantly slower than the easy-math conditions ($F1(1,39)=47.26$; $MSe=7641827$; $p < .001$; $F2(1,31)=42.58$; $MSe=5880083$; $p < .001$). Second, the syntactically more complex object-extracted RC conditions were read significantly slower than the subject-extracted conditions ($F1(1,39)=38.74$; $MSe=5283587$; $p < .001$; $F2(1,31)=33.4$; $MSe=4072481$; $p < .001$). Third, and most interestingly, there was a significant interaction, such that in the hard math conditions, the difference between subject- and object-extracted RCs was larger than in the easy math conditions ($F1(1,39)=4.74$; $MSe=623599$; $p < .05$; $F2(1,31)=7.15$; $MSe=526415$; $p < .02$). This interaction is predicted by the hypothesis whereby sentence processing and arithmetic processing rely on overlapping pools of resources, but not by the hypothesis that the pools of resources are independent.

In Region 1, consisting of the main clause subject (e.g., "The janitor") together with the initial addend, a 2x2 ANOVA revealed a main effect of arithmetic complexity (marginal in the items analysis), but no other significant effects. The hard-math conditions were read slower than the easy-math conditions ($F1(1,39)=5.08$; $MSe=245326$; $p < .05$; $F2(1,31)=3.62$; $MSe=149836$; $p = .067$). In Region 3, the top-level verb and its object ("lost the key"), a 2x2 ANOVA revealed a main effect of arithmetic complexity ($F1(1,39)=30.21$; $MSe=5726294$; $p < .001$; $F2(1,31)=33.32$; $MSe=3978352$; $p < .001$), but no other effects. Finally, in

Region 4, the sentence-final prepositional phrase ("on the street"), there was again an effect of arithmetic complexity ($F1(1,39)=72.58$; $MSe=13066602$; $p < .001$; $F2(1,31)= 105.06$; $MSe=10545386$; $p < .001$), but no other effects.

Discussion

The results of Experiment 1 are consistent with a WM framework where online sentence comprehension and arithmetic processing rely on overlapping resource pools. Most importantly, there was an interaction between syntactic complexity and arithmetic complexity in the critical region of the linguistic materials, where syntactic complexity was manipulated between subject-extracted RCs (low complexity) and object-extracted RCs (high complexity). There was no evidence of any interaction of this kind in any of the other three regions. Critically, linguistic complexity was not varied in the arithmetic task, so the observed interaction is not due to an overlap in the linguistic processes that are involved in the two tasks.

It should be noted, however, that there is an alternative explanation for the observed pattern of results in terms of attentional resources required for the simultaneous performance of the two tasks. In dual-task paradigms, resources are needed in order to direct attention to one task or another. It is possible that in the difficult conditions, more attention switches are required, or the switches between tasks are more costly. The observed interaction could therefore be a result of additional task-switching costs in the high syntactic complexity / high arithmetic complexity condition. Experiment 2 was designed to address this issue.

Experiment 2

This experiment used a similar dual-task paradigm as the first experiment. In contrast to Experiment 1, however, the secondary task was a spatial-rotation task matched for difficulty with the addition task used in Experiment 1. In this task, participants were instructed to visually imagine adding different-size sectors of a circle and to keep track of the angle subtended by the combined segments. The most natural way to solve this task is to mentally rotate each incoming sector until it abuts the estimated sum of the previous sectors. The on-line spatial-rotation task is similar to the addition task in that an incoming element – a sector – must be integrated into, or added to, the representation constructed thus far. Critically though, the spatial-rotation task does not rely on verbal WM resources, and should not therefore interact with the sentence-processing task if the cause for the observed interaction in Experiment 1 is an overlap in the use of verbal WM resources. However, if the attentional costs are responsible for the interaction, we should observe a similar interaction, regardless of the nature of the secondary task.

Methods

Participants Twenty-four participants from MIT and the surrounding community were paid for their participation. All were native speakers of English and were naive as to the purposes of the study. None of the participants took part in Experiment 1.

Design and materials The experiment had a 2x2 design, crossing syntactic complexity (subject-/ object-extracted RCs) with the complexity of the spatial-rotation task (simple rotations with small-angle sectors/ complex rotations with larger-angle sectors). The language materials were exactly the same as those used in Experiment 1.

The sectors for the spatial-rotation task were randomly generated online for each participant in the following way: the size of the sectors for the easy condition varied from 5 to 90 degrees, whereas the size of the sectors for the hard condition varied from 30 to 180 degrees. As a result, it was more likely in the hard condition for the sum of sectors to be more than 360 degrees, thus "wrapping around" the circle. Pilot testing of the pie task by itself suggested that the task is easier to perform with smaller sectors.

As in Experiment 1, 40 filler sentences with various syntactic structures other than relative clauses were included, and the stimuli were pseudo-randomized separately for each participant, with at least one filler separating the target sentences.

Procedure The procedure was identical to that of Experiment 1, except for substituting the spatial-rotation task for the arithmetic task. Above each sentence fragment, participants saw a small circle. They were instructed to think of it as a plate for a pie. On each "plate", there was a "pie-slice" shown in blue. The size of the "pie-slices" varied (as described in Materials and Design above), but they all started at the 12:00 position, as shown in Figure 3.

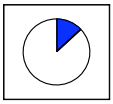

Figure 3: Sample figure of the spatial-rotation task.

Participants were instructed to visually imagine adding each new "pie-slice" to the previous one(s) by mentally "putting" them next to each other. To assure that the participants performed the task, at the end of each trial a large blank circle appeared at the center of the screen with a vertically-pointing radius. Participants were instructed to drag this radius (by using the mouse) to the end-point where all the "pie-slices" they just saw would come to when placed next to each other. If the answer was within 10 degrees of the correct answer, the words "Very Close!" flashed briefly on the screen; if the answer was within 35 degrees, the words "Pretty Good" flashed briefly; if the answer was within 90 degrees, the words "In The Ballpark" flashed briefly; finally, if the answer was not within 90 degrees, the words "Not Very Good" flashed briefly on the screen. The participants were warned that sometimes the "pie-slices", when added together, would form more than a complete pie. In such cases, they were told to assume that the slices "wrapped around" and to ignore the complete portion of the pie.

As in Experiment 1, this task was followed by two comprehension questions about the content of the sentences.

Results

Spatial-rotation task accuracy On average, participants' estimates were 30.3 degrees off of the correct answer. A two-factor ANOVA crossing spatial-rotation task complexity (easy, hard) and syntactic complexity (easy, hard) revealed a main effect of complexity of the spatial-rotation task ($F1(1,23)=18.36$; $MSe=2676$; $p < .0005$; $F2(1,31)=22.28$; $MSe=3568$; $p < .0005$), but no other significant effects. It is worth noting that this pattern of results for the spatial-rotation task accuracy is parallel to that of the results for the arithmetic task accuracy in Experiment 1.

Comprehension question performance There were two comprehension questions following each experimental trial. The percentages of correct answers by condition were very similar for the two questions, so we collapsed the results in our analyses. Across conditions, participants answered the questions correctly 83% of the time. A 2x2 ANOVA crossing spatial-rotation task complexity (easy, hard) and syntactic complexity (easy, hard) on the responses to the comprehension questions revealed no significant effects or interactions ($Fs<1$). This pattern of results differs slightly from that in Experiment 1 in that there was no effect of syntactic complexity in Experiment 2. Note, however, that overall, subjects performed better on comprehension questions in Experiment 2 (83% across conditions), compared with Experiment 1 (79% across conditions). This accuracy difference across the experiments may have resulted from greater interference of the secondary task in Experiment 1 with subjects' memory of the propositional content of the sentences, due to its verbal nature. The lack of syntactic complexity effect in Experiment 2 could then be explained by a possible ceiling effect in the comprehension performance: without a verbally interfering task, people perform well on both the subject- and object-extracted relative clause sentence types.

Reaction times As in Experiment 1, we analyzed all trials, regardless of how the comprehension questions were answered. Also, as in Experiment 1, reaction time data points that were more than 2.5 standard deviations away from the mean residual RT for a position within a condition or less than 100 msec in the raw data were excluded from the analyses, affecting 3.7% of the data. Figure 4 presents the mean reaction times per region across the four conditions in the experiment.

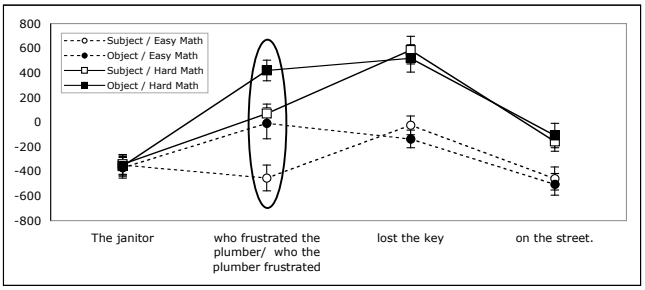

Figure 4: Reaction times per region in the four conditions of Experiment 2. The critical region is circled.

We first present the analysis of the critical region, Region 2, which included the RC ("who frustrated the plumber" / "who the plumber frustrated"). A 2x2 ANOVA conducted on this region revealed two significant main effects. First, the hard-spatial-task conditions were read significantly slower than the easy-spatial-task conditions ($F1(1,23)=22.98$; $MSe=5451605$; $p < .001$; $F2(1,31)=40.08$; $MSe=6428277$; $p < .001$). Second, the syntactically more complex object-extracted RC conditions were read significantly slower than the subject-extracted RC conditions ($F1(1,23)=15.59$; $MSe=3791349$; $p < .001$; $F2(1,31)=22.94$; $MSe=4675397$; $p < .001$). Critically, there was no trace of an interaction between syntactic complexity and the complexity of the spatial task ($Fs<1$). Moreover, the effect of syntactic complexity in the hard-spatial-task conditions was numerically *smaller* than that in the easy-spatial-task conditions. This result rules out the attentional explanation of the interaction that was observed in Experiment 1.

In Region 1, consisting of the main clause subject (e.g., "The janitor") together with the initial "pie-slice", a 2x2 ANOVA revealed no significant effects. In Region 3, the top-level verb and its object ("lost the key"), a 2x2 ANOVA revealed a main effect of spatial task complexity ($F1(1,23)=39.36$; $MSe=9601145$; $p < .001$; $F2(1,31)=62.5$; $MSe=12710598$; $p < .001$), but no other effects. Finally, in Region 4, the sentence-final prepositional phrase ("on the street"), there was again an effect of spatial task complexity ($F1(1,23)=16.1$; $MSe=2925378$; $p < .001$; $F2(1,31)=45.2$; $MSe=4061993$; $p < .001$), but no other effects.

Discussion

The attentional account of the interaction between syntactic and arithmetic complexity that was observed in Experiment 1 predicted a similar interaction between syntactic and spatial-rotation complexity in Experiment 2. No such interaction was observed. In fact, the numerical trend was in the reverse direction. The lack of such an interaction therefore argues against the attentional account of the interaction observed in Experiment 1.

In general, the lack of an interaction between the complexity of two tasks could arise for at least two different reasons: (1) independent resource pools required for each task; or (2) ceiling or floor effects on one or both of the tasks, such that resources are either abundant or insufficient. Hence, in order to argue that the results of Experiment 2 are

due to independent resource pools for the two tasks, we need to be confident that the secondary task is neither too complex nor too simple. It is unlikely that the spatial-rotation task is too simple, because we observed a highly significant complexity effect for this task. Neither is it likely that the spatial-rotation task is too complex for the following reasons. First, the performance on the spatial-rotation task was extremely good, averaging only 30.3 degrees off from the target position. Second, the range of the reaction times across conditions for the two experiments was almost identical, suggesting that the arithmetic and spatial-rotation tasks were comparable in difficulty.

Conclusions

In summary, using a dual-task paradigm, we have demonstrated an on-line interaction between syntactic complexity and arithmetic complexity in Experiment 1 suggesting that these two cognitive functions rely on overlapping pools of verbal WM resources. Furthermore, in Experiment 2, we have ruled out an attentional account of the observed interaction by showing that a spatial task, which does not rely on verbal WM resources, does not interact with on-line sentence comprehension. These results therefore support a WM framework in which sentence processing and arithmetic processing overlap in the use of verbal WM resources. The results are not consistent with the hypothesis whereby sentence processing relies on an independent pool of verbal WM resources (Caplan & Waters, 1999).

An open question that we have not yet addressed is the exact nature of the overlap in verbal working memory resources for sentence and arithmetic processing. One possibility is that both syntactic and arithmetic processes involve a subservant mechanism for integrating verbal symbolic information units. In this mechanism, the difficulty of integrating linguistic elements depends on the distance between elements to be connected. Relatedly, the difficulty of adding numbers depends on the distance between the initial addend and the resulting sum in the computation on the number line. We leave it to future work to distinguish this hypothesis from other possibilities.

Talking about space: A cross-linguistic perspective

Michele I. Feist (m-feist@ northwestern.edu)

Abstract

What do people attend to when describing the locations of objects in space? This paper describes a study of the ways in which speakers of seventeen languages describe static spatial relations, delving into the meanings of two kinds of spatial relational terms evident cross-linguistically: specific spatial terms and generalized spatial terms. The findings provide support for the importance of geometry, function, and qualitative physics to the meanings of specific spatial terms and suggest an interplay between semantic and pragmatic elements of meaning for generalized spatial terms.

Introduction

Multiple times each day, speakers make use of a relatively small set of spatial relational terms (Landau & Jackendoff, 1993) in order to localize themselves and the entities with which they interact. Use of these terms is practically automatic; from the point of view of the native speaker, they are simple, clear, and obvious. However, the difficulty that spatial terms present to second language learners belies this apparent simplicity. Furthermore, the prodigious cross-linguistic variability in spatial terms (cf, Levinson, Meira, & The Language and Cognition Group, 2003) suggests that they are anything but simple, clear, and obvious.

The variability evident in spatial language takes on many different forms. As Bowerman and her colleagues have shown, distinctions that are drawn in one language may not be drawn in another. For example, while English distinguishes between support and contact, on the one hand, and containment, on the other, this distinction does not appear in Korean spatial terms (Bowerman & Choi, 2001). Instead, Korean distinguishes between a tight fit and a loose fit between two objects, a distinction not evident in English spatial terms. Thus, in Korean, the act of putting a Lego *onto* a stack of Legos would be described by the same term as the act of putting a book *into* its sleeve: both are instances of tight fit. Further, the act of putting a Lego *onto* a stack of Legos is distinguished from the act of putting a book *onto* a desk: while the former is a tight fit relation, the latter represents loose fit.

Even closely related languages are not immune from such differences in the distinctions drawn between spatial relational terms. For example, as Bowerman has pointed out (Bowerman, 1996; Bowerman & Pederson, 1992, 1996; Gentner & Bowerman, 2000), Dutch makes a three-way distinction where English does not: between a cup *on* a table (Dutch *op*), a picture *on* a wall (Dutch *aan*), and a ring *on* a finger (Dutch *om*).

Even if two languages appear to draw the same distinction, the boundaries between the contrasting categories often differ. For example, both English and Finnish mark a distinction between a very intimate relation such as containment and a less intimate relation such as surface contact, but the set of configurations placed in each group differs dramatically between the two languages (Table 1): rather than categorizing a handle *on* a pan as an instance of the less intimate relation, along with a cup *on* a table and a picture *on* a wall (as English does), Finnish places this configuration in the more intimate category along with an apple *in* a bowl (Bowerman, 1996).

A similar example comes from a comparison of English and Berber spatial terms. Spatial relational terms in Berber fail to make a distinction between inclusion and contact with/support via an external surface of the Ground (Bowerman & Choi, 2001) akin to the English *in-on* distinction. Rather, reminiscent of the case in Finnish, the distinction is between "being loosely in contact" and "being 'incorporated' into" the Ground, with "incorporation" including both being inside and being tightly attached to an external surface or point (Bowerman & Choi, 2001).

Table 1: English and Finnish categorizations of some Figure-Ground relations (adapted from Bowerman, 1996, Figure 4).

	Apple in bowl	Handle on pan	Bandaid on leg	Ring on finger	Fly on door	Picture on wall	Cup on table
English	In	On	On	On	On	On	On
Finnish	Inessive case	Inessive case	Inessive case	Inessive case	Inessive case	Adessive case	Adessive case

Despite this variability, all humans have the same ability to perceive spatial relations. As suggested by the cross-linguistic variability, spatial relational terms encode a variety of factors of the scenes they are used to describe (Bowerman, 1996; Levinson, 1996; Sinha & Thorseng, 1995), including geometric, functional, and qualitative physical factors. Furthermore, there is evidence from studies of English spatial prepositions that the influences of the factors interact, leading to complex meanings (Feist, 2002; Feist & Gentner, 2003). What are the roles of these factors in the spatial terms of a diverse set of languages? Are there some factors that recur in spatial meaning across languages? If so, these factors could underlie our conception of space in general.

How Do Speakers of Different Languages Talk About Space?

In a wide-reaching cross-linguistic survey, Bowerman and Pederson (1992, 1996) presented a set of carefully drawn pictures to speakers of thirty-four languages. Each picture depicts a spatial relation, with the Figure colored in yellow and the Ground in black and white. Informants provided descriptions of the pictures, including the spatial relational term that would most naturally be used to describe the relation depicted.

Bowerman and Pederson examined the ways in which the languages in their survey grouped the spatial relations in their pictures, as defined by description by the same term. This led to the discovery of a "similarity gradient" (Bowerman & Choi, 2001) along which they could arrange the scenes from their study. At one end of the gradient lie configurations in which a Figure is supported from below by a Ground (e.g., a cup on a table); at the other end lie configurations in which a Figure is completely included within a Ground (e.g., a pear in an otherwise empty bowl). In between lie configurations bearing similarities to both endpoints, arranged according to whether they are more similar to support from below or to complete inclusion.

Although Bowerman and Pederson found variation in how linguistic terms grouped spatial configurations, this variation was systematic. In particular, all of the languages in their sample respected the similarity gradient that Bowerman and Pederson had identified, only describing non-adjacent configurations with the same term if all configurations that lie between them are also described by the term. In other words, the ranges of use of spatial terms were found to be continuous with respect to the similarity gradient.

I borrowed Bowerman and Pederson's pictorial elicitation technique for collecting spatial terms, asking speakers of seventeen languages to describe a single set of simple pictures taken from the larger set used by Bowerman and Pederson. This resulted in the elicitation of a narrow set of spatial relational terms across a diverse set of languages. The ranges of use of the elicited terms illuminated the importance of a few attributes of spatial scenes instantiating relations along Bowerman and Pederson's similarity gradient, providing clues to the likely organizing dimensions of spatial terminology.

Method

Informants Twenty-eight speakers of seventeen languages (representing twelve language families, with 1-4 participants per language) were recruited from around the Northwestern University/Evanston community; one additional informant was recruited from the New York area. Informants ranged in age from 18 to 69 and were all native speakers of the languages in which they participated.

Stimuli The stimulus set consisted of twenty-nine line drawings, each depicting two objects in a simple spatial relation. The relations depicted span the similarity gradient described by Bowerman and Pederson (1992, 1996; Bowerman & Choi, 2001). Following their methodology, one of the objects in each picture, the Figure, was colored yellow; and the other, the Ground, was black and white. Twenty-seven of the twenty-nine drawings were borrowed from Melissa Bowerman and Eric Pederson's Topological Picture Series (cf., Bowerman & Pederson, 1992, 1996; Gentner & Bowerman, 1996, 2000; Levinson et al., 2003); one of the remaining two, a picture of an address on an envelope, was modified from a picture in the Topological Picture Series, and the other, a picture of flowers in a vase, was borrowed from an example in Coventry (1998).

Procedure Each informant participated individually in a session lasting an average of one hour. In the first part of the session, informants were shown each picture in the set individually. They were asked to provide a description in their native language of the location of the yellow object with respect to the other object. Responses were both tape-recorded and phonetically transcribed. After all of the pictures had been described, informants provided as close to a morpheme-by-morpheme translation as could be elicited.[1] Finally, informants for languages using the same orthography as English were asked to provide a written transcription of their responses.

[1] Variation in the exactness of the morpheme-by-morpheme translations resulted from informants' inability and/or unwillingness to provide translations below the level of the word.

Picture coding In previous work, there are numerous arguments for the importance of geometry (e.g., Bennett, 1975; Feist & Gentner, 1997, 1998, 2003; Herskovits, 1986; Landau, 1996; Miller & Johnson-Laird, 1976), function (Coventry, 1998; Coventry, Carmichael, & Garrod, 1994; Feist & Gentner, 1998, 2003; Vandeloise, 1991, 1994), and qualitative physics (Bowerman & Choi, 2001; Feist & Gentner, 2003; Forbus, 1983, 1984; Talmy, 1988) to spatial relational meaning. In order to determine whether there are attributes of spatial scenes that figure in the meanings of spatial relational terms across a range of languages[2], I coded each of the pictures for whether it matched each of a small set of attributes related to geometry, function, and qualitative physics.

For geometry, I coded for *a difference in vertical position* (important to terms such as *above, below, over,* and *under* (O'Keefe, 1996)), *contact* (important to terms such as *on* (Cienki, 1989; Herskovits, 1986; Miller & Johnson-Laird, 1976)), and *inclusion* (important to terms such as *in* (Cienki, 1989; Herskovits, 1986; Miller & Johnson-Laird, 1976)), as well as for *relative size*. Although not argued for in previous work, *relative size* was coded because a larger Ground might facilitate the matching of other attribute values, such as *support* or *inclusion* of the Figure, thus influencing spatial term use.

For function, I coded for the *functional relatedness* of the Figure and the Ground – the likely interaction resulting from an object's function (cf, Coventry, 1998; Coventry et al., 1994; Vandeloise, 1991, 1994 on the importance of function in general). For example, a lamp and a table are functionally related; a cloud and a mountain are not.

For qualitative physics, I coded for *support* by the Ground (important to terms such as *on* (Bowerman & Pederson, 1992, 1996; Herskovits, 1986; Miller & Johnson-Laird, 1976)). In addition, I coded for *animacy*[3] and the ability of the Ground to constrain the location of the Figure, which both influence what predictions can reasonably be made about the qualitative physics of a scene. Specifically, if a Ground can constrain the location of a Figure, the configuration may seem less subject to outside forces and thus more likely to remain as pictured. In addition, *animacy* of the Figure and the Ground was found in past research to influence speakers' choice between English *in* and *on* (Feist & Gentner, 1998, 2003). In addition, *constraint of location* may be important to some functional relations (such as functional containment; see Coventry et al., 1994), prompting its inclusion as an independent factor.

Results

Two kinds of spatial relational terms appeared in the elicited descriptions. The first, *specific spatial terms*, occur only in limited contexts and impart relatively specific information about the location of the Figure[4]. This kind of term can be exemplified by the English prepositions *in* and *on* and by the terms in examples (1) (from Croatian) and (2) (from Swedish).

(1) Jabuka je *v* zdjeli.
apple is *in* bowl
The apple is in the bowl.

(2) Koppen står *på* bordet.
cup-definite stands *on* table-definite
The cup is on the table.

The second kind of term, *generalized spatial terms*, occur in all spatial descriptions and impart no specific information about the location of the Figure. Rather, these terms just serve to relate the Figure to the Ground. Such terms do not occur in English, but can be exemplified by terms such as Japanese *ni* (example (3)) and Indonesian *di* (example (4)), both glossed simply as LOC (locative).

(3) Kaban no naka[5] *ni* haite iru hako.
bag genitive inside *LOC* put-in is box
The box is in the bag.

(4) Cincin itu *di* jari.
ring that *LOC* finger
The ring is on the finger.

Although generalized spatial terms are often glossed as *at, in*, or *on*, such glosses are hardly appropriate characterizations of the meanings of the terms, as will become clear below. In particular, generalized spatial terms appear in environments where the glosses would be unacceptable, raising questions about whether the glosses can capture the true meaning of the generalized spatial term.

Specific spatial terms For each specific spatial term collected, I grouped together the pictures that the term had been used to describe. Then, for each group, I isolated the attributes that were common to all of the pictures in the group. Only four of the attributes coded

[2] Here I consider only those terms whose distribution suggests that they are specific spatial terms (see below).

[3] I used a fairly broad definition of animacy, namely, things that are capable of self-determination (e.g., human legs, cats) were taken as animate, while objects incapable of self-determination (e.g., jackets, doors) were not. Looking across languages, this is not the only way to look at the notion of animacy.

[4] I include here spatial nominals and locative cases along with adpositions, as both occur (in languages using them) as answers to *where*-questions, and neither is expected to display semantic patterns different from those of adpositions (Levinson et al., 2003).

[5] Specific spatial terms like the Japanese spatial nominal *naka* often appear in spatial descriptions with generalized spatial terms, as will be discussed further below.

appeared as unifying factors for the ranges of use of the terms I collected: *difference in vertical position of the Figure and the Ground, contact, support of the Figure by the Ground, and inclusion of the Figure within the Ground*. This is exemplified by the terms in Table 2[6]; each term listed is marked with a plus under those attributes that must be true of scenes described by the term and a minus under those that may not be true. Attributes with neither a plus nor a minus may, but need not, be true of scenes described by the term. For example, the Polish term *na* requires that the Figure and the Ground be in contact and that the Ground support the Figure, regardless of which, if either, is higher, and regardless of whether the Figure might be included in the Ground[7].

These four attributes highlight the importance of geometry, function, and qualitative physics (cf., Feist & Gentner, 2003). The first two, *difference in vertical position of the Figure and the Ground* and *contact*, both encode information about the geometry of the relation between the Figure and the Ground. The next attribute, *support*, encodes information about the physics of the interaction (the Ground is constraining the location of the Figure in one dimension) and about the function of the Ground. Lastly, *inclusion* provides information about geometry, function, and physics, as the typical situation when a Figure is geometrically included in a Ground is that the Ground functions as a container for the Figure and thereby constrains the location of the Figure in more than one dimension.

In addition to highlighting the importance of geometry, function, and qualitative physics across a sizable sample of languages and spatial terms, this data demonstrates that important similarities co-exist with cross-linguistic variation (cf., Bowerman & Pederson, 1992, 1996; Levinson et al., 2003; Regier, 1996).

Generalized spatial terms The criterial factor for identifying generalized spatial terms is that they occur in all spatial descriptions. These terms can either appear alone or in combination with a more specific term, as exemplified by the Indonesian examples in (5) – (7).

(5) Buku itu *di* meja.
book that *LOC* table
The book is on the table.
⇒ *di atas* may be substituted for *di*

Table 2: Example terms and the attributes characterizing them.

Example terms	Figure higher than Ground	Contact	Ground supports Figure	Inclusion
ue (Japanese)	+			
taas (Tagalog)	+			
[nad][8] (Russian)	+	-		
[upar] (Hindi)	+	-		
na (Polish)		+	+	
på (Swedish)		+	+	
sur (French)		+	+	
auf (German)		+		
an (German)		+		
u (Croatian)				+
-bVn (Hungarian)				+
iqinde (Turkish)				+

(6) Parmen itu *di* kotak.
candy that *LOC* box
The candy is in the box.
⇒ *di dalam* may be substituted for *di*

(7) Meja itu *di* *bawah* lampu.
table that *LOC* beneath lamp
The table is under the lamp.
⇒ *di* may not occur alone

As mentioned earlier, generalized spatial terms such as Indonesian *di* are often glossed as *at, in*, or *on* (e.g., Macdonald, 1976). However, examination of the range of uses evident for *di* reveals that no single English preposition can occur in the entire range. Although *di* may occur alone in situations where English uses *at, in,* or *on*, it also appears in combination with locational nouns in situations where the English glosses are unacceptable (e.g., example (7)). Thus, glosses – which are a function of both the scene and the sentence as a whole (Ameka, 1995) – fail to capture their meaning.

What then is the meaning of the generalized spatial term? To account for both classes of use, I propose one basic element of meaning appropriate to all uses (8) and two pragmatically licensed elements of meaning (9).

(8) di = location of the Figure in the region of interaction of the Ground

[6] Due to space constraints, I only present a representative subset of the terms collected.

[7] Although the norm when the Figure is included in the Ground is to use a term marking inclusion, such as Polish *w*, terms such as *na* may be used to describe configurations such as a face on a stamp, in which the Figure may be conceived of as included in the Ground.

[8] Terms from languages that do not use the English alphabet are presented as phonetic transcriptions in square brackets.

(9) (a) the Figure is in contact with the Ground.
(b) the Figure-Ground relation is canonical.

The element of meaning in (8) serves to unite the disparate range of uses of *di* without falsely implying equivalence between *di* and its English prepositional glosses. Additionally, the pragmatically licensed elements of meaning proposed in (9) make a clear prediction about when *di* felicitously appears alone and when the addition of a locational noun is preferred. The default assumption when *di* appears alone is that the elements in (9) are true, although this is not always the case (see (11) and (12)). The use of a locational noun emphasizes the specifics of the relation and highlights any deviations from this assumption.

To test this analysis, I created spatial descriptions that violate each of the proposed elements of meaning (example (10) violated (8); (11) violated (9a); and (12) violated (9b)). Each sentence involved a use of *di* without the addition of a more specific term.

(10) *Buku itu *di* meja, tapi bukan dekatnya.
Book that *LOC* table but not near-possessive
The book is on the table but not near it.

(11) Buku itu *di* meja tapi tidak menyentuh.
Book that *LOC* table but not touching
The book is on the table but it's not touching it.

(12) Buku itu *di* meja tapi menempel dengan aneh.
Book that *LOC* table but stuck manner weird
The book is on the table but it's attached in a weird manner.

Eleven speakers of Indonesian were asked to assess the acceptability of the created sentences. The different violations resulted in quite different acceptability judgments: violations of (8) were rarely accepted (9%); violations of (9), while odd, were more acceptable (55% for (9a); 73% for (9b)), $F(2,32) = 6.09$, $p < .01$. These data support the hypothesis that (8) is part of the semantics of *di*, while the elements in (9) are pragmatically licensed.

Discussion

Analysis of the terms used to describe spatial locations across seventeen languages revealed spatial terms that fall into two classes: specific spatial terms, which provide semi-precise information about the location of a Figure; and generalized spatial terms, which simply serve to locate the Figure in the region of interaction of a named Ground.

By investigating spatial semantics in many languages, we can gain insights into the range of attributes of spatial scenes to which humans attend when localizing objects. By grouping pictures described by each individual specific spatial term, it was possible to isolate those attributes of the spatial scenes described that are important to the use of each term. Across seventeen languages, four attributes recurred in the meanings of specific spatial terms: a difference in vertical position, contact, support, and inclusion. This finding corroborates recent work by Levinson and his colleagues (Levinson et al., 2003) suggesting the importance of *attachment, a difference in vertical position (both super- and subadjacency), proximity,* and *containment* to spatial meanings across languages. These attributes together highlight the importance of geometric, functional, and qualitative physical factors, all of which have been argued in previous work to be important to spatial relational meaning in a small set of languages, to the meanings of spatial relational terms more generally.

Whereas specific spatial terms have received a fair amount of attention in linguistics and cognitive science, the attention accorded generalized spatial terms has been far sparser. However, an understanding of the uses of generalized spatial terms, both with and without accompanying specific spatial terms, is integral to an understanding of the range of spatial meanings evident in human language. The analysis of Indonesian *di* presented here provides a step towards a comprehensive account. Further testing of this analysis, including a study of the applicability of sentences without specific terms as descriptions of a variety of pictures, will be necessary to solidify the conclusions reached here. In addition, in order to arrive at a descriptively adequate account of generalized spatial terms, these studies will need to be repeated for generalized spatial terms of further languages.

Although more work, including the examination of a wider range of languages, is necessary to completely understand the factors influencing how humans talk about locations in space, I have presented here two windows into spatial relational meaning. The view from these windows, illuminating both cross-linguistic variation and commonalities in specific spatial terms through one, and a coherent meaning for a previously misunderstood set of terms through the other, furthers our understanding of cross-linguistic variation and linguistic universals in the semantics of space.

Acknowledgments

Explorations of the (Meta)Representational Status of Desire in the Theory-Theory of Mind Framework

Abstract

Some researchers have proposed that what accounts for children's earlier ability to reason by means of desire compared to reasoning by means of belief is the fact that desires do not necessarily invoke the ability to metarepresent. In this paper, I argue that this is a misconception stemming from the confusion between desire ascription and simple desire states. In other words, there would be no way to entertain a thought about someone's desire without metarepresenting, in Leslie's (1991) terms. I provide some empirical evidence in the fashion of Bartsch and Wellman (1995) that also points in this direction.

The problem

Although the concept of desire is at least as important as the concept of belief for describing, explaining and predicting the behavior of different entities (Fodor, 1987; Dennett, 1978b, 1987), substantially more attention has been paid to the development of the concept of belief in Theory-Theory of Mind research (henceforth, TToM) (Wellman, Cross, & Watson, 2001; Astington, 2001). In fact, quite often, metarepresentation (defined here as the internal representation of an epistemic relation (Leslie, 1991), a "second-order" representation (Sperber, 1999)) has been somewhat fused with the child's ability to entertain/ascribe a belief that stands for a counterfactual state of affairs (Dennett, 1978a; Davies & Stone, 1995), without any reference to the explanatory power of the concept of desire or to its being an epistemic relation itself.

This incipient collapsing of metarepresentation and reasoning by false beliefs (beliefs that stand for counterfactual states of affairs) in TToM research is due, in part, to the assumption that the concept of belief, and especially that of false belief, taps the child's metarepresentational capacities; while, arguably, the concept of desire does not. This is a common assumption despite the fact that beliefs and desires share several important characteristics (such as defining opaque contexts, being intentional in the philosophical sense, being subject and object specific (Wellman & Woolley, 1990), etc. to name but a few). In the developmental literature, more often than not, desires have been understood as a special case of mental state ascription; namely, one that does not demand of the agent doing the ascription (a child in our case), that he or she be able to metarepresent.

The previous assumption appears to have been brought about by a body of evidence that suggests that the concept of desire is acquired around a year before the concept of belief (Wellman, 1991; Tan & Harris, 1991; Astington & Gopnik, 1991; Harris, 1996; Bartsch & Wellman, 1995). Thus, in order to make it fit the evidence available from research on the concept of belief, it has been claimed that at least until three or four years of age –that is, until they acquire the concept of belief– desire ascriptions are to be thought of as non-metarepresentational. The reasoning behind this claim, I presume, goes along the following lines: on the one hand, a) reasoning by means of beliefs taps an organism's (children's, for example) metarepresentational capacities; on the other hand, b) the capacity to reason by means of beliefs is acquired at age X. Thus, if (a) and (b) hold, then c) metarepresentation should be acquired at age X, and not before X. Now, *because* of this conclusion, the rest of the argument tells us that if (c) is the case, then e) reasoning by means of desires taps an organism's metarepresentational capacities if and only if f) the capacity to reason by means of beliefs is acquired at age X. However, it is not the case that (f). Therefore, the argument goes on to say, reasoning by means desire does not tap an organism's metarepresentational capacities.

However, characterizing reasoning by means of the concept of desire as non-metarepresentational simply because it is acquired before the concept of belief and the latter is, only by assumption (as we saw a couple of paragraphs above), the flagship of the child's metarepresentational capacities is, at all extents, an *ad hoc* solution. In these pages, I will take position against the conclusion of the argument that reasoning by means of desire does not tap on metarepresentational capacities. In other words, it is, I will argue, far from clear that reasoning by means of the concept of desire is non-metarepresentational in nature, even though it is acquired a year before the concept of belief.

Desires as Metarepresentational

For reasoning by means of desires to be non-metarepresentational at ages younger than four years means that a child at those ages does not represent other people (or even themselves) as representing the desired object as part of the desire relation. Thus, these children are supposed to be merely in some sort of "connection"

to the desired object. According to this view, then, when a two-year-old child says something like "Peter wants a car", he or she is not ascribing Peter (representing Peter as entertaining) a desire for a given car, but merely putting Peter in some sort of connection to either the car he wants (Wellman, 1990; Wellman & Bartsch, 1994; Bartsch & Wellman, 1995) or to a hypothetical situation in which Peter has the car (Perner, 1991). Consider the following proposition as a state of affairs in the world; that is, a proposition that holds:

Loreto wants to be in Chile. [1]

Within the general Theory of Mind (ToM) framework, there are two ways to interpret this proposition, and they have usually been confounded. In a first, trivial interpretation, Loreto is just in a state such that she wants to be in Chile. That merely means that she has tokened the proposition "I am in Chile" in her desire box (Fodor, 1975) and will take action to bring it about that she is in Chile. This interpretation is useless at the time of explaining behavior because the agent trying to explain Loreto's behavior (maybe Loreto herself) may not know that *that* is the proposition she is tokening in her desire box. The second interpretation, however, is the non-trivial interpretation that to be able to explain someone else's (even one's own) behavior in terms of desires, one must entertain a belief about the organism's desire state (Davies & Stone, 1995). To explain or predict behaviors and actions, it is not enough that we are able to be in desire states (unlike, for example, the case of Simulation-Theory of Mind, see Gordon (1995)). What is a conditio sine qua non is that we are able to entertain beliefs about an organism's desire states (Dennett, 1987; Sperber, 1999). For example, one way to explain why Loreto is buying a ticket to Chile this morning is to entertain a belief with the embedded proposition in [1] above. Thus, in order to engage in folk psychological practice (Davies & Stone, 1995), we need to entertain a thought along the following lines:

$$B_u[D(Loreto, P) \wedge \neg P] \quad [2]$$

where B_u stands for the agent's belief state at the time of ascription of the desire state, D stands for the "desire" predicate which takes two arguments, the organism to which the agent is ascribing the desire ($Loreto$, in [2]) and the organism's desired state of affairs (the variable P in [2] or "I am in Chile" or any other proposition). For this quasi-formalization of desire ascription to work, P should also be part of the belief state as a proposition that does not hold; since, for something to be a desire, it is by definition that the conditions are false. Simplifying the issue slightly, it would indeed be a contradiction to desire something that one already has.

Notice further that there is in fact no way to formalize the first (trivial) interpretation of [1] above in the TToM framework. You may be able to formalize it for logical purposes as something like $D(Loreto, P) \wedge \neg P$, but that will be of no use to someone trying to explain behavior. The proposition in [1] is independent of any folk psychological theory-theory because it is not tokened as a belief about the world in the mind of a particular agent engaging in folk psychological practice. It is just a true proposition (of the external world) at time T. Thus, part of the argument here is that if it is so difficult for us as adults to imagine a non-metarepresentational account of desire at early ages, then it might be the case that this non-metarepresentational characterization is wrong (Astington & Gopnik, 1991).

There seems to be no obvious alternative formalizing of desire ascription (not desire states) except for [2] above. Thus, even at younger ages, every time children talk about their own or other people's desires, they should be entertaining a thought along the lines of [2]. It is hard to characterize the thoughts the child is entertaining when explaining or reporting behaviors by means of desires when the latter are merely understood as "subjective connections" to objects. Suppose for the sake of argument, that children do in fact see desires as a "subjective connection" between the organism they are trying to explain the behavior of and the object that this organism desires. This could be relatively easy to see for desire ascription to organisms other than self. However, it would be hard to believe that when talking about their own desires and explaining their own behaviors by means of desires ("because I wanted to go to the park"), children think of *themselves* as just holding a subjective connection to a state of affairs that does not hold. It is in fact very hard to believe that when reasoning about their own behaviors by means of desires, children are not representing themselves as wanting something in particular; to be in the park, for example. But suppose further that they do not representing themselves as wanting something in particular. It is undeniable that the very act of communicating those desires involve a metarepresentation of both the communicator and the person the speaker is talking to. When communicating, and more so when communicating mental states, there should be mutual metarepresentation of the communicator and the addressee (Sperber, 1999).

Given the arguments above, it is hard to take desire ascriptions to either other people ("Peter wants to have a car") or to oneself ("I want to be in Chile") as non-metarepresentational (at least) in Leslie's (1991) terms. Now, assuming desire talk stands proxy for desire reasoning about the behavior of other people (see, for example, Dennett (1978a), Bretherton and Beeghly (1982), Tager-Flusberg (1993), Bartsch and Wellman (1995) and the literature spawned by these studies), then we would expect desire talk to actually tap on the child's metarepresentational capacities, albeit indirectly. One way to look at this is to follow Wellman and Bartsch (1994) and Bartsch and Wellman (1995). If we were able to tell genuine psychological references to desire apart from mere communicative uses of particular words associated to the expression of desire, then we should find difference between talk about desires and talk about other communicative uses of these words. Specifically, while genuine psychological references to desire should change

as a function of age (because they are presumably tapping on metarepresentational abilities), communicative uses should not. They should not because there is no need to be in a belief state about an epistemic state when using a mental state term for mere communicative purposes. If a child repeats an adult's utterance, for example, it may be that he or she is just repeating it for the sake of not being silent during an interaction, but without having analyzed the utterance itself. More arguably, when a child says something like "I want a cookie" while the cookie is in plain view, the child might be actually saying something like "pass me the cookie", without imputing a mental state either to self or to someone else. Instead of entertaining a thought such as $B_u[D(self, IHaveACookie) \wedge \neg IHaveACookie]$, the child is simply in a desire state, maybe, such that $D_u(self, IHaveACookie) \wedge \neg IHaveACookie$. But that does not qualify as a metarepresentational state in our terms here. The following study tests the prediction that there should be a difference between communicative uses of "want" (the desire term par excellance (Wellman & Bartsch, 1994; Bartsch & Wellman, 1995)) and its genuinely psychological uses.

Method

Data. A total of 14,896 child utterances were taken from the Wells corpus (Wells, 1981) in the CHILDES database (MacWhinney, 2000). These data come from the longitudinal observation of spontaneous speech production of 12 children (6 boys and 6 girls) whose ages ranged from 18 months at the time of the first observation to 60 months at the time of the last observation and who were acquiring English as their mother tongue. Each child was observed a total of 10 times, for about 40 minutes each, in 3-month intervals. Since the objective of Well's (1981) research was to obtain spontaneous speech samples, a timing mechanism was devised to set off a tape recorder – connected to a wireless microphone in the child's garment – at different times between 9am and 6pm, to prevent parents from planning activities, for example. Twenty-four 90-second samples were recorded in each observation. These were later transcribed into several files using normal English orthography. Table 1 in page 3 gives some general information about the samples, where $Ages(mo.)$ means ages in months, N means number of participants in each age group (all twelve participants are the same children at different ages), $\#TotUtt$ means the total number of utterances in the samples, $MLU(\overline{x})$ means the average mean length of utterance for that age group, and $MLU(SD)$ means the standard deviation of the mean for the MLU values for that group.

Procedure. The first step was to identify all and only the instances of the term "want" in all and only the target child's exchanges. Once the "want" utterances were identified and cleaned for false positives, they were coded as belonging to one of five mutually exclusive categories: genuine psychological references to desire (GPRDs), behavioral requests(BRs), direct repetitions (DRs), idiomatic expressions (IEs) and uncodable utterances (UUs). While GPRDs refer to mental states, the other three categories do not, they fulfill a mostly communicative function.

Table 1: Information on the samples.

Ages (mo.)	N	#TotUtt	MLU($\overline{x}$)	MLU(SD)
18-24	12	3483	1.480	0.252
25-28	12	1830	1.697	0.430
29-32	12	2694	2.246	0.566
33-36	12	2972	2.709	0.446
37-40	12	2041	2.981	0.390
41-44	12	1876	3.202	0.425

Genuine psychological references to desire (henceforth, GPRDs) are instances of children's unequivocally referring to themselves or other people as being in a mental state of desire. Behavioral requests, in turn, (henceforth, BRs) are 'unadorned' instances in which the child uses a desire term to fulfill an immediate goal, like receiving something that is beyond her reach but in plain view. Bartsch and Wellman (1995) take these instances to mean nothing more than "give me x". Direct repetitions (henceforth, DRs) are dialog turns in which the child merely repeats the adult (or his own) utterance. Idiomatic expressions (henceforth, IEs) are high-frequency collocation of words in the particular language. This is the case of Spanish "I don't want to" or "I want more", when they appear without an object. Uncodable utterances (henceforth, UU) are instances of the desire term "want" for which categorization was impossible, due mainly to failure in retrieving contextual information from the dialog.

To code each of them into one of the five mutually exclusive categories, child utterances containing "want" were not taken in isolation, but embedded in a window of the four previous and the four following utterances of the whole sample. However, sometimes this short context did not help defining which category the utterance belonged to. Thus, the whole transcript had to be analyzed in order to assign a category to the utterance in question. An independent rater, unaware of the hypothesis of the study rated a subset of the data (10%=60 utterances, Cohen's κ=.85). Disagreements were resolved by discussion and, in the light of the discussions, there was a second coding pass to the whole data set.

Results

There were a total of 602 "want" utterances in the analyzed corpus. 347 (57.35%) were GPRDs, 145 (23.96) were other communicative uses of "want". Of those 145 communicative uses, 37 (6.11% of total "want" utterances) were behavioral requests, 92 (15.20%) were direct repetitions and 16 (2.65%) were idiomatic expressions. Figure 1 below shows the average frequency of talk about genuine desires as a percentage of the total number of utterances for each particular child at each particular age. It is evident that the developmental picture I have obtained resembles the one in Bartsch and Wellman (1995) very closely, even the ranges of the percentages are similar (see Bartsch and Wellman (1995),

p. 73, Figure 4.2B). Talk about genuine desire seems to be present at the first age analyzed (AGE1, 18-24 months), to increase slowly by AGE2 (25-28 months of age) and then more drastically again at AGE3 (29-32 months). The frequency of genuine talk about desires seems to peak at around AGE4 (33-36 months) to drop and stabilize thereafter. In order to test for significant differences in children's talk about desires at any given age group, a repeated measures ANOVA with age as a 6-level variable was used. There was an overall significant main effect $F(5, 55)=6.72$, p<.000. Post hoc analyses using the Bonferroni criterion for significance indicated that the average frequency of GPRDs for AGE1 (M=0.51, SD=0.55) and AGE2 (M=0.96, SD=0.80) were significantly lower than frequency of talk about GPRDs at AGE4 (M=4.28, SD=2.24) and AGE6 (M=3.54, SD=2.10).

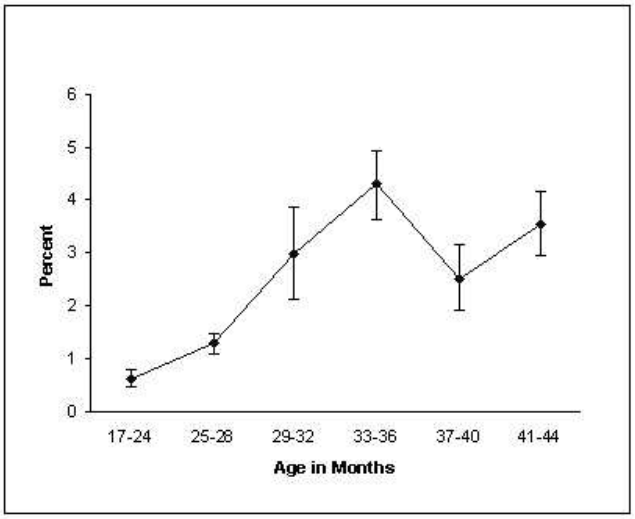

Figure 1: GPRDs by age as a percentage of the total number of utterances for that child at that age, error bars are standard errors.

Figure 2 below shows the development of children's communicative uses of "want" as a function of age. Except for direct repetitions, both idiomatic expressions and behavioral requests do not appear in the first age stage sampled (AGE1=18-24). By AGE2, all three categories of communicative uses are present, although not extremely different from the previous age. The frequency of DRs seems to grow and separate from the main trend at AGE3 and then again at AGE4, while at AGE3 both BRs and IEs are at the same level. Something indeed seems to happen at AGE4, when all three categories seem quite different in their frequencies, with DRs leading the frequency count, followed by BRs and IE in the last place. Both AGE5 and AGE5 seem to show the new convergence of these categories. It seems then that after AGE4, all three kinds of communicative uses of "want" stabilize. To test for significant effects, a repeated measures ANOVA with age as the within-subject variable was carried out for each communicative use of "want". The tests show that, taken one by one, there is no significant effects for age and each of the communicative uses of "want", $p > .05$. However, a repeated measures ANOVA with age and communicative uses as within-subjects variables yielded a significant effect for both age $F(2.96, 32.61)$[1]$=3.174$, p=.038 and communicative uses $F(2, 22)=12.708$, p<.000. No main effect was found for the interaction between age and communicative uses $F(3.36, 36.97)$[1]$=0.682$, p>.05, n.s.

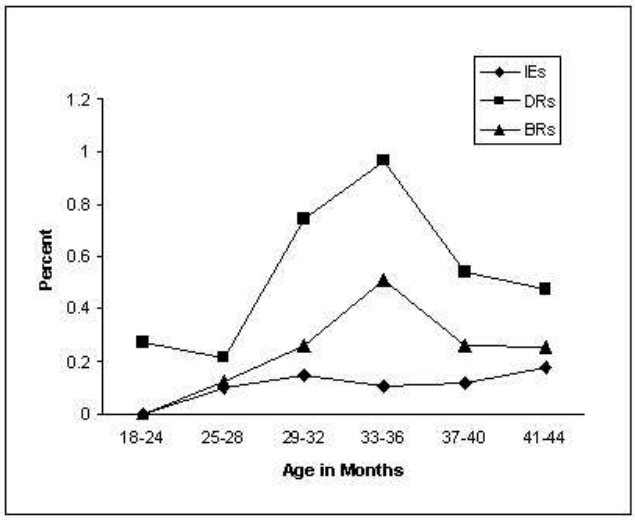

Figure 2: Communicative uses of "want" by age as a percentage of the total number of utterances for that child at that age.

Figure 3 shows quite clearly that although both GPRDs and all communicative uses start at roughly the same frequency, it is only GPRDs that increase the frequency significantly, while the other communicative uses of "want" stay roughly the same across ages. A repeated measures ANOVA with AGE as a 6-level variable (Ages 1 through 6) and communicative uses as a 4-level variable (GPRDs, BRs, IE, DRs) was used to test for differences. As expected from the previous analyses, there was an overall significant main effect of communicative uses, $F(3, 33)=59.545$, p<.000, a significant main effect for age, $F(5, 55)=7.444$, p<.000 and a significant interaction of Age and Communicative uses, $F(3, 33)=4.861$, p<.000.

Discussion

From the theoretical discussion above, we concluded that if children undergo some metarepresentational change of the concept of desire as a function of age, then while the developmental picture of GPRDs reflect this change, communicative uses of "want" should stay relatively the same across ages.

The analyses carried out yield some results that point towards this direction. Although there are differences among the communicative uses themselves (that is, there are differences between DRs and IEs, for instance, at 33 months, see Figure 2), there is no main effect for

[1] F corrected for sphericity by Greenhouse-Geisser.

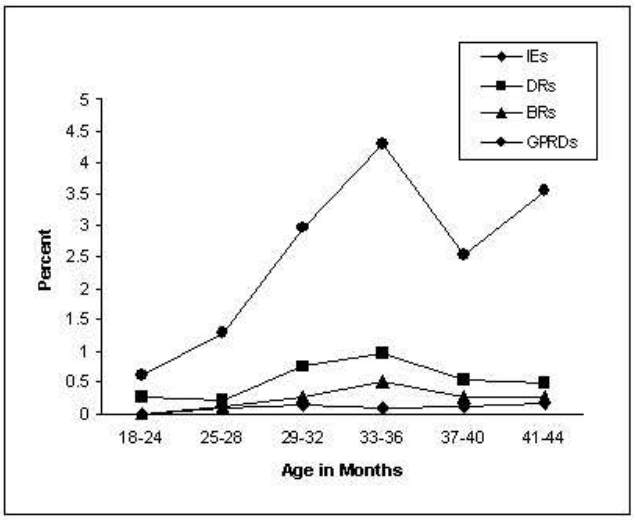

Figure 3: Communicative uses of "want" by age as a percentage of the total number of utterances for that child at that age.

age for each of these communicative uses taken in isolation. However, there is a main effect for GPRDs between the first age analyzed (18-24 months) and AGE4 (33-36 months) and AGE6 (41-44 months). This, obviously, draws a difference between the communicative uses of "want" and genuine psychological references to desire. This difference, I am inclined to say, may be related to metarepresentational issues during the acquisition of the concept of desire. If it were not about matters metarepresentational, it would be very difficult to explain why the other communicative uses (BRs, in particular), which are morphosyntactically very similar to GPRDs, do not provide a main effect for age.

This paper is not calling into question the hypothesis that belief (and particularly false belief) taps an organism's representational capacities, nor that belief is acquired at whatever age (probably, on all conservative accounts, at 4 years of age). What is being questioned here is the working assumption that if belief taps on representation and belief is acquired at 4 years of age, then metarepresentation is acquired at 4 years of age.

The argument that uses the premise above seems to be, at least, enthymematic. It could be said that reasoning by means of belief is tapping certain kinds of metarepresentational abilities, the kinds for which many computational resources have to be in place (Wimmer, Hogrefe, & Perner, 1988; Leslie, 1988; Davies & Stone, 1995). As an analogy, you can take the difference that exists between a belief attribution such as "Loreto believes there's a blue car outside school" and "Loreto believes Namic thinks there's a blue car outside school". Terminological differences aside, children seem to acquire the ability to solve problems like the latter by around 6 years of age (Perner & Wimmer, 1985), two years after they have allegedly acquired the ability to metarepresent (metarepresent by false belief, that is). However, just because of this empirical fact, one would not argue that by passing this more complicated task, the child has now acquired another ability, one different from the metarepresentational abilities acquired two years earlier. The same argument holds for desires: just because children talk and reason by means of desired a year before they do so with belief, that does not mean that a new ability has been acquired. That children are able to calculate this double-embedding of *the same belief concept* a couple of years later than 4 years of age points in the direction of problems with some of the computational mechanisms that help children deal with metarepresentation (Fodor, 1992), but not with the ability to metarepresent itself.

General conclusions and future work

The main point of this paper is that it is extremely hard to consider reasoning by means of desire (at any age stage) as a non-metarepresentational endeavor. This hypothesis has been analyzed in two ways: a) by means of a logical analysis of what is involved during desire reasoning and communication and b) by providing some preliminary empirical evidence that even talk (as a proxy for reasoning) about desire shows a clear developmental trend when compared to communicative uses of the same words used to talk about desire ("want", in this case).

If the main point of this paper is right, then the most pressing issue to deal with is the lag between the acquisition of the concept of belief and that of desire. In other words, if metarepresentation lies in the nature of both belief and desire but children have less difficulty understanding the representational nature of the latter while failing to understand the equivalent metarepresentational character of the former (Astington & Gopnik, 1991), then again it may be the case that something other than metarepresentation is at stake. Of course, much more work is needed in this area. Nonetheless, I would like to propose that the answer to this riddle lies in the computational mechanisms dealing with metarepresentation at the different stages. Not with metarepresentational abilities themselves. In other words, I would like to propose that the ability to metarepresent is acquired as soon as children start talking about and reliably communicating their own and other people's mental states, starting with desire at around the 30th month of life. This is somewhat earlier than previously thought, but it would help explain and make sense of the whole philosophical tradition of belief and desires as belonging to roughly the same theoretical arena as the rest of the propositional attitudes.

Acknowledgments

This paper was written while the author was holding a postdoctoral fellowship at the Human-Oriented Technology Laboratory at Carleton University. I would like to thank, particularly, John Logan, Andrew Brook and Gitte Lindgaard for insightful comments and support.

Abstract

False recognition of verbal information has long been established with word lists. Current research examines the phenomenon of false recognition with pictorial stimuli. Experiment 1 demonstrated that similar to word-lists, pictorially presented information elicits memory intrusions, and that rates of intrusions differ across stimuli sets. Experiment 2 investigated the effects of focusing on category-level versus item-specific information on the rates of false recognition. Results of Experiment 2 suggest that memory accuracy decreases dramatically when participants perform category-based processing compared to item-based processing. Experiment 3 confirmed that processing manipulations rather than other extraneous factors influence levels of false recognition in Experiment 2.

Introduction

People strive for accurate and reliable memories; however their memories often get distorted. Although forgetting is one of the most obvious types of memory distortions, it is not the only one. There is much research demonstrating that people often distort memories in systematic and predictable ways. For example, prior knowledge has previously been implicated in memory distortions: people often falsely recognize new information when it is consistent with their knowledge (e.g., Alba & Hasher, 1983). For instance, after reading a story describing a famous person, participants tended to falsely recognize statements that were not part of the story they had read, but were thematically related to this person (Sulin & Dooling, 1974).

Systematic memory distortions are not limited to sentence information, and are often found with word lists. These types of memory distortions were first demonstrated by Deese (1959), who presented participants with word-lists (e.g., "bed", "rest", and "awake") consisting of associates of a single non-presented word (e.g., "sleep"). When asked to recall the words from the list, participants often erroneously recalled words consistent with the overall theme of the list, which was never actually presented. Deese's fundings were followed up by Roediger and McDermott (1995), who replicated Deese's results, demonstrating that memory intrusions of non-presented words persist in recall as well as in recognition, thus giving the name of DRM (for Deese-Roediger-McDermott) to this phenomenon. However, the nature of the phenomenon is still unclear.

According to one explanation, during recognition, participants perceive both studied items, and semantically related critical lures, to be more familiar than unrelated distracters. Because familiarity strongly affects the decision criterion for accepting items as studied or "old", those items that have elevated familiarity are more likely to be accepted both correctly and erroneously. This increased familiarity may stem from a summary or "gist" representation that reflects the general meaning of the list (in addition to representing individual items in the list), with critical lures being consistent with the gist (Brainerd, Reyna, & Mojardin, 1999). Therefore, on a recognition test, item-specific representations drive hits or correct acceptance of studied items, whereas "gist" representations drive both hits and false alarms on critical lures (i.e., erroneous acceptance of items semantically related to studied items).

According to another explanation, processing of items (either at study or at test) activates a critical lure, an item strongly associated with studied items. However, during recognition participants fail to monitor the source of this activated information, and as a result of confusing internally generated and externally presented information, participants falsely recognize critical lures (Gallo & Roediger, 2002; Koutstaal & Schacter, 1997; Roediger, et al., 2001).

If participants can represent both the "gist" and individual items (Brainerd, et al., 1999), and distortions (or false alarms) are driven by the gist representations, then it should be possible to facilitate the formation of either representation by focusing participants on the overall theme or on individual items. If our contention is correct, then a manipulation focusing on a gist representation should lead to elevated memory distortions (due to an elevated level of false alarms on critical lures).

This manipulation can generate evidence capable of distinguishing between the two theoretical positions because

the source confusion explanation does not predict these effects.

Note, however that much of DRM-based research has been based on word-lists rather than pictures (see Koutstaal & Schacter, 1997; Seamon Luo, Schlegel, Greene, & Goldenberg, 2000, for notable exceptions). At the same time, pictures are well suited for this manipulation: participants could be focused on an entire category (e.g., *Cats*) or on individual items, such as a picture of a particular cat.

Another advantage of pictorially presented information is that pictures can drastically decrease the tendency to make source monitoring errors: it is highly unlikely that one would spontaneously generate a particular unique picture serving as a critical lure (see Koutstaal & Schacter, 1997, for related arguments). Therefore, persistence of memory intrusions with pictures would further suggest that these intrusions do not stem solely from source monitoring errors.

It has been previously demonstrated that pictures do generate memory intrusions (Koutstaal & Schacter, 1997; Seamon, et al., 2000). However some of these findings are based on a procedure that used large 120-study-item stimuli sets, and a 3-day delay between the study and the recognition phases. In this research, we will use the procedure that follows more closely the DRM procedure with word lists: we present participants with a reasonably small stimulus set, and impose no delays between the study and recognition phases. We have demonstrated elsewhere (Sloutsky & Fisher, in press) that false recognition of information presented pictorially can be obtained in a procedure that closely follows the original DRM task. However, these results were obtained with a single picture set, and it is unclear how well they can be generalized to a greater number of categories.

Overall, the reported research has two goals: (1) to examine whether or not pictorially-presented information can generate DRM-type phenomena and, if yes, then (2) whether false recognition in DRM stems from source-monitoring errors or from gist representation of information.

The goal of Experiment 1 was to replicate these findings using multiple categories. Experiment 2 had a more theoretically important goal: to generate evidence capable of distinguishing among the proposed theoretical accounts of the DRM-effect. Recall that finding increased memory intrusions as a result of processing manipulations would support the position that DRM-type memory intrusions stem from gist-type representations, while weakening the position that these intrusions stem from source-monitoring errors.

Experiment 1

Method

Participants Participants were introductory psychology students at a large Midwestern university (N = 103, *M* age= 19.7 years, *SD* = 1.8 years; 51 women and 52 men) who received a partial course credit for participation.

Design, Materials and Procedure Materials were 90 color photographs of animals presented against a white background. The photographs represented five different animal categories (*Cats*, *Bears*, *Squirrels*, *Fish*, and *Birds*) with 18 photographs per category.

The task consisted of a study and a recognition phase. During the study phase participants were presented with 30 pictures from three different animal categories: 10 items from the Target category, and 20 items from the two Filler categories. Participants were instructed to remember the presented pictures as accurately as possible for a f uture recognition test. During the recognition phase, which immediately followed the study phase, participants were presented with 28 pictures: 14 previously studied pictures (7 from the Target category and 7 from one of the Filler categories), and 14 new pictures (7 new pictures from the Target category, and 7 pictures from a novel category, which served as control items). Participants were asked to determine whether each picture presented during the recognition phase was "old" (i.e., exactly the same as previously seen in the study phase) or "new".

The categories that were designated to be Targets were rotated such that *Cats*, *Bears*, *Squirrels*, *Fish*, and *Birds* served as Targets in one of five between-subject conditions. All participants were tested individually, and had all instructions and stimuli presented to them on a computer screen in a self-paced manner.

Results and Discussion

Some participants did not reliably reject control items (i.e., at least 5 out of 7 correct), and their data were excluded from further analyses; 11 participants were excluded overall. The rest of the participants were very accurate in recognizing previously studied items (on average over 88% of correct recognitions across the target categories) and in rejecting items from novel categories (over 97% of correct rejections across categories).

Most importantly, participants often mistakenly recognized new items from the Target category, or critical lures. Proportions of "old" responses to previously studied items from the Target category (Hits), to new items from the Target category (False Alarms), and to novel items from a novel category (Control Items) are presented in Figure 1.

Data in the figure indicate that (a) although for all categories, the proportion of Hits was significantly higher than the proportion of False Alarms (FA), all paired-sample *t*s > 6, *p*s < .0001, some pictorially presented categories (e.g., *Bears*) elicited sizable memory intrusions (Hits = .86, FA = .54, Hits –FA = .32), and (b) proportions of memory intrusions varied across the categories, ranging from relatively high for *Bears* to almost non-existent for *Birds*. To examine the significance of differences across categories, accuracy measures (i.e., Hits – FA) were subjected to a one-way between-subjects ANOVA with Target category as a factor. The results point to significant differences in accuracy across the Target categories, F (4, 91) = 27.3, MSE = 0.04, p < .0001, with the following

pattern of accuracy *Birds* > *Fish* = *Squirrels* = *Cats* > *Bears*, post-hoc Tukey test, for all differences *p*s < .05. Therefore, major DRM phenomena that were previously found with word-lists are replicable with pictures. First, pictures generated substantial levels of memory intrusions. And second, similar to word-lists, pictures elicited different levels of memory intrusions across different target conditions: while little false recognition occurred for the Target category *Birds,* other Target categories (*Bears, Cats, Fish, and Squirrels*) elicited sizeable levels of false recognition.

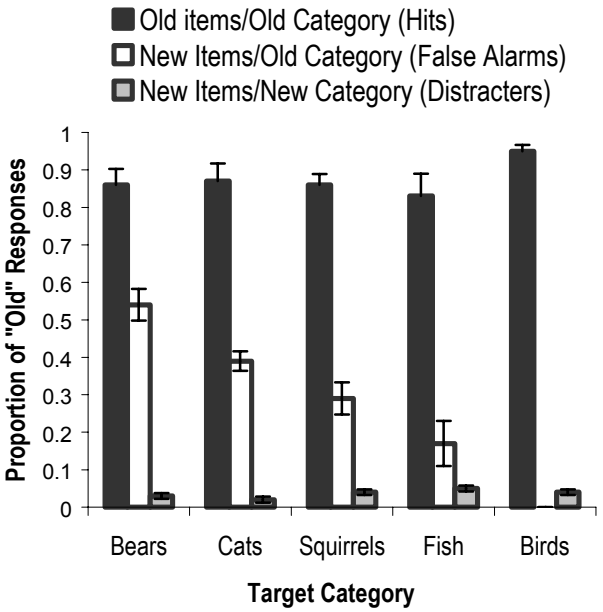

Figure 1: Mean proportions of "Old" responses across target types in the recognition memory test of Experiment 1

It could be argued, however, that Birds were an odd category that stood out in the context of mammals, which resulted in a more accurate processing of this odd category. To test this alternative, we conducted an additional experiment, using *Cats* as the Target category presented in the context of reptiles, with *Frogs* and *Alligators* used as Filler Categories. When *Cats* were an odd category, the level of false recognition of critical lures was statistically equivalent to that in Experiment 1 (42% versus 39%, respectively).

It is also possible that during the study phase, participants spontaneously labeled species of birds (but not cats, squirrels, fish, or bears), which dramatically reduced memory intrusions for the Target category *Birds*. To rule out this possibility we asked 23 undergraduates to label pictures of birds used in Experiment 1: no more than 4 out of 18 birds received unique labels, which was comparable to the labeling of cats.

Overall, these results suggest that DRM-type memory distortions are a robust phenomenon independent of the mode of presentation. More importantly, the fact that patterns of memory intrusions are similar for verbally and pictorially presented stimuli suggests that DRM-type memory intrusions do not stem solely from source monitoring errors. The goal of Experiment 2 was to examine directly whether a task that facilitates category-level processing will lead to an increase in memory intrusions compared to the baseline of Experiment 1.

Experiment 2

Method

Participants Participants were introductory psychology students at a large Midwestern university (N = 134, *M* age= 20.26 years, *SD* = 2.5 years; 64 women and 70 men) who received a partial credit for participation.

Design, Materials and Procedure Materials in Experiment 2 were identical to Experiment 1, however the study phase of the experiment was different. Participants were first presented with a picture of an animal from a Target category, and informed that the animal had "beta-cells inside its body". Participants were then presented with 30 pictures (10 from the Target category and 20 from two Filler categories), and asked to determine whether each presented animal also had beta-cells inside. Participants were provided with feedback, which indicated that only animals from the Target category had the property in question, whereas animals from the Filler categories did not. Participants were not warned about an upcoming recognition test.

Similar to Experiment 1, during the recognition phase participants were presented with 28 pictures: 14 previously studied pictures (7 from the Target category and 7 from one of the Filler categories), and 14 new pictures (7 new pictures from the Target category, and 7 pictures from a novel category). Participants were asked to determine whether each picture presented during the recognition phase was "old" (i.e., exactly the same as previously seen in the study phase) or "new".

The categories that were designated to be Targets were rotated such that *Cats*, *Bears*, *Squirrels*, *Fish,* and *Birds* served as Targets in one of five between-subject conditions. All participants were tested individually, and had all instructions and stimuli presented to them on a computer screen in a self-paced manner.

Results and Discussion
