## 6 What is microplastic?

7 Unless you've been out of contact with global media for a while, you will have heard of microplastic.

8 Microplastic is a word coined to describe the vast tide of microscopic plastic debris that is now found  
9 throughout the worlds' oceans. Where ever we look, from beaches and coastlines, to subtropical  
10 oceanic gyres, polar ice caps and even the deepest parts of the ocean, we find microplastic.

11 Microplastic (<1mm in size and with no lower size limit) is formed by the fragmentation of larger  
12 plastic items, ropes and synthetic fabrics through the mechanical action of wind and waves or sunlight-  
13 induced photo oxidation. It is also made up of items manufactured to be small, such as the microbeads  
14 added to cosmetics and shower gels as exfoliators to make skin feel soft and which then wash down  
15 the drain into the wastewater system, or the tiny particles generated by 3D printers or used in paints  
16 and coatings which reach the oceans through a similar route.

17 Plastics are synthetic polymers, which make up around 25% of the output of the global chemical  
18 industry, with around 4000 different formulations in current manufacture, worth billions to the global  
19 economy. Plastics are wonderful materials; lightweight and durable, cheap to manufacture and non-  
20 toxic. They can be made into endless colours, shapes and materials (Figure 1) depending on the  
21 addition of dyes, plasticisers, hardeners, softeners, UV screens and antimicrobial agents, allowing us  
22 to manufacture many of the constituents of daily modern life that we take for granted: plastic bags

23 and bottles, packaging materials, computer screens, plant pots, construction materials, clothes,  
24 medical disposables and even medicines themselves.

25 Hence the term 'microplastic' refers to a complex mixture of shapes and sizes, fragments, fibres and  
26 particles made from a multitude of polymer types and chemical additives. Unsurprisingly, it is our  
27 favourite plastics in terms of global tonnage that also form the major constituent of marine debris.  
28 Polymers that are less dense than seawater, like polyethylene and polypropylene are more likely to  
29 float on the ocean surface, whilst polymers with a greater density such as polyvinylchloride and  
30 polystyrene settle in the water column or accumulate on the ocean floor.

31

### 32 **How much is too much?**

33 Think of a number, any number, multiply it by a million and you are probably not even close to the  
34 amount of plastic currently in the oceans. Globally, we produce around 300 million tonnes of plastic,  
35 of which around 50% is intended for single use before being discarded. Conservative estimates suggest  
36 that there are over 5 trillion individual pieces of plastic floating on the oceans' surface, that's a million  
37 pieces for each human being living on the planet! These eye watering numbers don't include the tiny  
38 fragments at the nanoscale that form as microplastic breaks down to form nanoplastic, since we're  
39 not yet able to measure this size range in the environment. If a gazillion was an actual number, it might  
40 come close to describing this immensity and it has been suggested that there is now enough plastic to  
41 form a permanent and distinct layer in the fossil record. Interestingly, fibres outnumber fragments  
42 and beads, at the sea surface, in sediments and in the bodies of marine animals. Black and blue fibres  
43 are more common than any other colour.

44

### 45 **What harm does it do?**

46 Just because microplastic is in the oceans, doesn't mean that it is doing any harm. Plastic is safe, right?  
47 The problem is that microplastic has accumulated in immense quantities in locations and in a form  
48 that was never envisaged when it was manufactured, and so most of the tests that have been  
49 performed to guarantee its safety in consumer items are inappropriate for determining its risk to  
50 marine life.

51

## 52 **Size matters**

53 Microplastic raises concern because its small size overlaps with the preferred prey items of many  
54 marine animals, including indiscriminating filter, suspension and detritus feeders near the base of the  
55 food web, allowing them to be ingested along with, or instead of, normal food. Field studies have  
56 revealed microplastic in the guts or tissues of hundreds of marine species, including planktonic species  
57 from surface waters such as copepods and larval fish, and in bivalves, crustaceans, and worms from  
58 the ocean floor. Microplastic is also found in the guts of larger animals such as sea turtles and in the  
59 scat of seals and other marine mammals. Whether they got there through direct ingestion or through  
60 consumption of contaminated prey is not yet known, but transfer of microplastic from prey to  
61 predator has been demonstrated in laboratory studies.

62

## 63 **It's all about the surface**

64 As things become smaller, so their relative surface area increases, providing a larger area for  
65 interaction with the outside environment. The hydrophobic nature of plastic attracts other  
66 substances, including organic and plant matter, bacteria, chemical contaminants and metals which  
67 absorb onto the surface. Following ingestion, these substances can potentially transfer to the tissues  
68 of animals. The jury is out over the relative contribution that microplastic makes to the transfer of  
69 contaminants to marine species compared to direct transfer across the skin or ingestion of

70 contaminated food, since many hazardous persistent organic pollutants, such as organochlorine  
71 pesticides or polyaromatic hydrocarbons, are also prevalent in seawater. An intriguing possibility is  
72 that microplastic is selective in what else it binds, preferentially accumulating certain chemicals or  
73 substances deliberately secreted or exuded by marine life, including signalling molecules, pheromones  
74 and predator prey infochemicals. When combined with the buoyancy and persistence of microplastic  
75 and its tendency to be moved long distances across the ocean surface through the action of wind,  
76 currents and tides, the resulting widespread distribution of these selected substances could alter  
77 ecological processes in many ways.

78

### 79 **An emerging paradigm**

80 If levels of microplastic contamination are sufficiently high, chronic exposure studies in the laboratory  
81 suggest a consistent pattern of adverse effects. Ingesting microplastic leads to altered feeding  
82 behaviours, leaving animals with lower lipid stores which then reduces growth and reproductive  
83 output. Carry-over effects in the next generation include reductions in offspring quality and growth  
84 rates. Other reported adverse effects relate to the uptake of particles across the gut and across cell  
85 membranes, triggering apoptosis and the upregulation of stress and damage repair pathways. Far  
86 fewer studies have been able to extrapolate from these findings to higher levels of biological  
87 organisation, and none to date have been able to identify populations in the wild which have been  
88 adversely affected. In part this is due to the technical challenges of identifying microplastic-  
89 contaminated animals *in situ*. It is also challenging to link cause and effect against the backdrop of  
90 degraded marine habitats and multiple anthropogenic stressors to which many populations and  
91 communities are subjected.

92

### 93 **What would it take to do it differently?**

94 Microplastic is on the face of it an easy problem to solve. It is a problem entirely generated by our  
95 own behaviour. We could simply stop throwing plastic into the oceans. Achieving this aim is less  
96 straightforward. Complex problems relating to patterns of consumer use, societal behaviour and  
97 waste disposal infrastructure across developed and developing nations remain a barrier to  
98 international agreements. The technological achievements that brought us plastic in the first place  
99 could offer us the solution. Biodegradable biopolymers, which degrade completely to non-toxic  
100 monomers, changing fashions in reusable containers and consumer preference for more thrifty use  
101 and sustainable packaging can all make a difference. Societal pressure is potentially the most  
102 compelling of these. By improving ocean literacy, ie teaching people more about how the oceans  
103 function and the human behaviours that threaten them, we might stand more chance of achieving the  
104 UN Sustainable Development Goal of conserving the oceans for future generations.
