**Abstract**

**Objectives:** The aim of this study was to develop a statistical model based on patient parameters in order to predict the length of stay (LOS) on the Intensive Care Unit (ICU) following cardiac surgery in a single centre.

**Design:** Data was collected from patients admitted to the ICU following cardiac surgery over a 10-year period (2006-2016). Both the additive and logistic EuroSCORE were calculated and logistic regression analysis was carried out to formulate a model relating the predicted LOS to the EuroSCORE. This model was used to stratify patients into short stay (less than 48 hours) or long stay (more than 48 hours).

**Setting:** Intensive care unit (ICU) at Papworth Hospital, Cambridgeshire

**Participants:** 18,377 consecutive patients who had been in ICU following cardiac surgery (coronary graft bypass surgery, valve surgery or a combination of both)

**Interventions:** This was an observational study

**Measurements and main results:** We have shown that both the additive and logistic EuroSCORE can be used to stratify cardiac surgical patients in various predicted length of stay in ICU. Further adjustments can be made to increase the number of patients correctly identified as either short stay or long stay. Comparison of the model predictions to the data demonstrated a high overall accuracy of 79.77% and ROC curve analysis showed the AUC to be 0.7296.

**Conclusions:** This analysis of an extensive data set shows that patient LOS in ICU after cardiac surgery in a single centre can be predicted accurately using the simple cardiac operative risk scoring tool EuroSCORE. Using such predictions has the potential to improve ICU resource management.

**Keywords:** cardiac surgery, EuroSCORE, intensive care unit, length of stay

## Introduction

1  
2 Bed availability in intensive care units (ICUs) is a critical factor in determining patient flow  
3  
4 in hospitals providing cardiac surgery. An accurate tool to predict patient length of stay (LOS)  
5  
6 would facilitate efficient patient scheduling and maximise available capacity. Patients  
7  
8 requiring a prolonged stay make up a significant proportion of total patient days on the ICU  
9  
10 (1) and there is a much greater financial cost for their care in addition to the high-cost cardiac  
11  
12 surgery. (2)  
13  
14

15  
16 A variety of approaches have been used in order to predict LOS on the ICU for patients. (3-6)  
17  
18 Scoring tools that provide an indication of the severity and type of illness, such as APACHE  
19  
20 (Acute Physiology and Chronic Health Evaluation) have been used. (7-9) These predictions  
21  
22 are not always accurate for individual patients, (5) are based on physiological factors obtained  
23  
24 at the point of admission to ICU and often require the use of complex statistics or modelling.  
25  
26  
27 (10)  
28  
29

30  
31 We sought to develop a simple model that would allow straightforward pre-operative  
32  
33 stratification of patients according to a predicted ICU LOS. We took the view that such a  
34  
35 model should be based on variables routinely available to the clinical team before the  
36  
37 operation, such as the ones used to calculate the EuroSCORE, a tool for calculating cardiac  
38  
39 operative risk. (11,12)  
40  
41

## Methods

### *Patient population and data collection.*

It is a tertiary centre accepting referrals from the whole country, and operates within the English national Health Service.

The study was conducted in accordance with our local review board and the need for informed consent was waived as no identifiable data were used.

### ***Patient management***

All patients underwent cardiac surgery at a single institution with a standard, but not rigid, perioperative protocol. All patients were admitted postoperatively in a level 3 unit (ICU) and progressed rapidly to level 1. The unit is led by consultant intensivists and all patients are reviewed at least once a day by a multidisciplinary team that decides if they are fit for discharge to the ward.

### ***Data***

In addition to age and length of stay on the unit, the following parameters were extracted: gender, serum creatinine, left ventricular ejection fraction, systolic pulmonary pressure, the presence of extracardiac arteriopathy, pulmonary disease, neurological dysfunction, previous cardiac surgery, recent myocardial infarct, active endocarditis, unstable angina or critical perioperative state, and the type of surgery (emergency operation, ventricular septal rupture, thoracic aortic surgery, other than isolated coronary surgery).

### ***Statistical methods***

All data analysis was performed using the statistical software package R. (13) The logistic model was fitted by the glm() function, a standard operation in R. The primary objective of this model was to predict the LOS in ICU of individual patients. The data was classified into two distinct sets based on LOS, with short stay arbitrarily defined as less than 48 hours and long stay more than 48 hours. The EuroSCORE, a cardiac mortality risk scoring tool was used as the basis of the logistic regression model. (11) Initial analysis was carried out with the

1 EuroSCORE (additive), which gives an integer score for each patient between 0 and 24. The  
2 EuroSCORE (logistic) was also used, which gives a probability of early mortality following  
3 cardiac surgery, expressed as a percentage. The logistic EuroSCORE provides a more  
4 accurate estimate of mortality in higher risk patients than the additive EuroSCORE and hence  
5 both scoring systems were analysed to compare the overall accuracy. (11)  
6  
7  
8  
9

10  
11 Fitting the logistic regression model to the data yielded estimates for the parameters used,  
12 along with the standard errors and  $p$ -values, indicating which were statistically significant.  
13  
14 Using these parameter estimates, predicted outcomes were generated and a contingency table  
15 of observed and predicted outcomes was produced. This was then analysed to determine the  
16 true and false positive rates for the model and the overall accuracy.  
17  
18  
19  
20  
21  
22

23 Testing the model accuracy in this way has the potential to overestimate accuracy since the  
24 data the model is being compared against is the same data used to generate the model. In  
25 order to overcome this issue  $k$ -fold cross-validation was used.(14) This method divides the  
26 data into  $k$  groups (in this case 10) and assesses the model accuracy on each of the groups. An  
27 average is then taken as the mean test accuracy. This value was not found to show a  
28 statistically significant difference from the initial accuracy result, validating this method of  
29 analysis.

## 40 **Results**

41 A summary of patient characteristics is shown in table 1. The maximum LOS on the ICU was  
42 123 days, with a mean stay of 2.4 days and a median of 1.0 days. Of the patients admitted to  
43 the unit, 13,637 were admitted as an elective case, 3,822 were urgent and 918 were  
44 emergency admissions.

Initially, the LOS data was plotted in relation to the additive EuroSCORE to evaluate its distribution and other characteristics. There was a wide range of LOS with varying EuroSCORE, with no clear initial structure. To elucidate an underlying distribution, the data was separated into three categories of length of stay: short (less than 48 hours), intermediate (48 to 120 hours) and prolonged (over 120 hours). A cutoff of 48 hours for short stay patients was used as this is a commonly used value in previous LOS prediction models. (15,16) The distribution of data when separated into these categories showed a clear difference in the short stay category, but a large degree of overlap in the intermediate and prolonged stay categories (Figure 1a). Box-plots revealed similar medians and overlapping interquartile ranges for the intermediate and prolonged stay categories (Figure 1b). Due to this degree of overlap, further analysis was carried out with data separated into just two categories: short stay (less than 48 hours) and long stay (over 48 hours), which demonstrated a clear difference between categories (Figure 1c) and is confirmed by the box-plot analysis which shows only slightly overlapping distributions (Figure 1d). The above analysis, carried out with the additive EuroSCORE, was repeated with the logistic EuroSCORE and revealed a similar pattern of distribution.

In order to develop a predictive scoring tool based on the EuroSCORE, a logistic regression model was used to model the probability of a patient requiring a long stay conditional on the associated EuroSCORE (additive).

$$P(\text{stay} = \text{long} \mid \text{EuroSCORE} = X) = \frac{e^{\beta_0 + \beta_1 X}}{1 + e^{\beta_0 + \beta_1 X}}$$

Fitting this model to the patient data yielded the following parameter estimates:  $\beta_0 = -0.0323 \pm 0.0475$  and  $\beta_1 = 0.2666 \pm 0.0060$ . To use the logistic regression model to predict patient length of stay a classifier,  $\eta$  was chosen with  $0 < \eta < 1$ , so that a patient is predicted to have a long stay if

$$P(\text{stay} = \text{long} \mid \text{EuroSCORE} = X) \geq \eta$$

1 for the EuroSCORE value  $X$  calculated for that patient. Initially  $\eta$  was chosen to be 0.5,  
2 however, the importance of this choice and implications on the predictive accuracy of the  
3 model is discussed later. As an example, with a EuroSCORE value of 15, the conditional  
4 probability of a long stay is calculated to be 0.724. Assuming that  $\eta = 0.5$ , then any patients  
5 with a EuroSCORE of 15 would be assigned to the predicted long stay category. Repeating  
6 this calculation with the EuroSCORE values from the patient data set and comparing the  
7 predicted LOS category with the actual outcome is shown in table 2. **Formulating a model**  
8 **which assigns patients to one of two predicted categories enables the stratification of patients**  
9 **into either a short stay or long stay pathway, with the aim of optimising patient flow.**

1 Evaluation of this table gives the accuracy of the model to be 79.77% with a true positive rate  
2 of 0.1946 and a false positive rate of 0.0262 for the identification of long stay patients. This  
3 analysis suggests that whilst the overall accuracy of the model is good, it is particularly  
4 effective at identifying short stay patients, but less reliable for long stay patients. This simple  
5 analysis using the EuroSCORE as a single predictive variable allows a cut-off value to be set,  
6 above which a patient is classified as long stay. Plotting the EuroSCORE (additive) against  
7 the threshold probability, shows that for a classifier value of  $\eta = 0.5$ , the classification  
8 threshold value is 11.35 (Figure 2a), i.e. any patients with a EuroSCORE above this value will  
9 be predicted to be long stay. Plotting this value on the EuroSCORE distribution curves  
10 discussed earlier illustrates that whilst the model has a good specificity for the identification  
11 of long stay patients, there are still a significant number of patients in this category that are  
12 incorrectly assigned (Figure 2b).

13 To assess the effect that the classifier threshold value of  $\eta$  has on the true and false positivity  
14 rate, a receiver operating characteristic (ROC) curve was plotted. For an ideal predictive  
15 model with a true positive rate of 100% and a false positive rate of 0%, the ROC curve would  
16 have an area under the curve (AUC) of 1. Conversely, a random selector which arbitrarily  
17 assigns a patient to either the short or long stay category would have an AUC of 0.5, with the  
18 true positive rate varying linearly with the choice of  $\eta$ . Figure 3 shows that for the logistic  
19 regression model used herein, the AUC is 0.7267 and the black dot indicates the true and false  
20 positive rates for the chosen classifier value of  $\eta = 0.5$ . The curve clearly demonstrates the  
21 impact that the choice of classifier value has on the rates of true and false positives and the  
22 implicit trade-off between the two.

23 To explore this further, additional analysis was carried out with different values of  $\eta$ . As  
24 would be expected, decreasing  $\eta$  allows correct identification of more long stay patients, i.e.  
25 the true positive rate increased. However, there is also a corresponding increase in the number  
26 of short stay patients incorrectly predicted to be long stay, i.e. the false positive rate also  
27 increases. Table 3 shows a summary of statistical measures for different  $\eta$  values, which

demonstrates that the increase in true positive rate with decreasing  $\eta$  comes at the expense of a decrease in overall accuracy. For the purpose of resource management, it may be preferable to accept a decrease in accuracy in order to correctly identify more long stay patients. Failure to identify a significant proportion of long stay patients could result in an unexpected demand for bed space, nursing requirements and higher unanticipated costs.

1 The detailed analysis described above was repeated with the EuroSCORE (logistic) data  
2 which yielded similar results. Evaluation of the resulting contingency table gave an overall  
3 accuracy of 79.73%, almost identical to that of the EuroSCORE (additive) of 79.77%. The  
4 false positive rate was 0.0278, true positive rate 0.1982 and cut-off value 26.09% with a  
5 classifier value of  $\eta = 0.5$ . ROC curve analysis showed the AUC to be 0.7296.  
6  
7

8 Since analysis using the EuroSCORE (additive) and EuroSCORE (logistic) yielded extremely  
9 similar results, further investigation was carried out to determine whether the model accuracy  
10 could be improved. Both forms of the EuroSCORE are calculated from a weighted model  
11 based on 18 underlying parameters measured peri-operatively. The logistic regression model  
12 was adapted to treat each parameter as an individual variable with different weightings using  
13 the following conditional probability  
14  
15  
16  
17  
18  
19  
20  
21  
22  
23  
24

$$25 \quad P(\text{stay} = \text{long} \mid X_1, X_2, \dots, X_{18}) = \frac{e^{\beta_0 + \beta_1 X_1 + \dots + \beta_{18} X_{18}}}{26 \quad 1 + e^{\beta_0 + \beta_1 X_1 + \dots + \beta_{18} X_{18}}}$$

27 where  $X_1, X_2, \dots, X_{18}$  are the values of the 18 parameters.  
28  
29  
30

31 Fitting the patient data to the logistic regression model provided estimates for  $\beta_0, \beta_1, \dots, \beta_{18}$   
32 and the  $p$  value of each variable in the model. Out of the 18 parameters, three were found not  
33 to be statistically significant: gender, diagnosis of active endocarditis and presence of  
34 ventricular septal rupture. We hypothesise that due to the extremely small number of patients  
35 with active endocarditis or ventricular septal rupture (81 and 58 respectively), there are  
36 simply not enough data points for these variables to influence the model.  
37  
38  
39  
40  
41  
42  
43  
44  
45

46 As before, the contingency table for the model was calculated and analysed with  $\eta = 0.5$ , and  
47 revealed an overall accuracy of 80.54%. This is a modest increase compared to the initial  
48 analysis with EuroSCORE as the only variable. However, with each parameter modelled  
49 individually, the true positive rate increased to 0.2504, a 29% rise compared to the single-  
50 variable model. Additionally, the false positive rate remained extremely low at 0.0326.  
51 Repeat calculations with the three non-significant variables removed resulted in very similar  
52 results with accuracy 80.56%, true positive rate 0.2506 and false positive rate 0.0323.

1 This simple logistic regression model does not currently take into account patient deaths  
2 which has the potential to influence LOS. In this data set there were 376 deaths out of a total  
3 of 18,377 admissions (2.05%). The mean and median EuroSCORE (additive) values for these  
4 patients were both 10, with mean and median LOS of 249 and 119 hours respectively. This  
5 data demonstrates that the patients that died were more likely to have higher EuroSCORE  
6 values and require a longer LOS and including these patients in the analysis is unlikely to  
7 affect the results.

## 16 **Discussion**

17 We have used the simple cardiac risk scoring tool, EuroSCORE to predict LOS on the ICU.  
18 Statistical analysis using a logistic regression model has demonstrated no significant  
19 difference in results using either the additive or logistic EuroSCORE. Using this model, it is  
20 possible to determine a threshold EuroSCORE above which, a patient would be predicted to  
21 have a long stay in ICU. Analysis has demonstrated that altering this threshold affects the  
22 overall predictive accuracy, in addition to the positive and negative predictive values of the  
23 model, as would be expected. This illustrates the balance that must be chosen between  
24 maximising the overall accuracy of the model and correctly identifying all patients who will  
25 require a long stay.  
26

36  
37  
38  
39  
40

41 We have shown that higher overall accuracy can be achieved by analysing the variables used  
42 to calculate EuroSCORE individually. Modelling each parameter as an independent variable  
43 demonstrated that some of these parameters had no statistical influence on the accuracy of the  
44 model. In particular, gender was not found to be a statistically significant variable in terms of  
45 accurately predicting LOS. The presence of either active endocarditis or ventricular septal  
46 rupture was also found not to influence accuracy, most likely due to the small number of  
47 patients with these conditions in the data set. By removing these variables from the model and  
48 treating the other parameters as individual variables, the model accuracy was improved  
49 compared to using EuroSCORE as a single variable.  
50

63  
64  
65

1 Implementation of this model in clinical practice could influence the patient cohort selected  
2 for admission to the ICU. For example, by setting the EuroSCORE threshold to a low value, it  
3 would be possible to select patients who are highly likely to only require a short stay.  
4

5  
6 Conversely, admitting patients with a EuroSCORE above a high threshold value would  
7 increase the likelihood of this cohort requiring a long stay. This strategy faces one challenge  
8 as patients with a high EuroSCORE have a higher mortality rate, and therefore average LOS  
9 could be lower than predicted if patients do not recover.  
10  
11  
12  
13  
14  
15

16 Whilst predictive models of this type have good accuracy for the patient population as a  
17 whole, they are generally poorer at predicting the outcome of an individual patient. (3,7,17)  
18 As such, the primary use of these models is in the assessment of efficiency and patient flow  
19 through ICUs, and comparison between units. There is also the potential to identify  
20 institutional factors that may influence ICU stay, which would have implications for costs of  
21 care and resource use. (7,18-20) The value of this model for resource planning is to enable  
22 cohorts of patients to be chosen so that the relative proportions of likely short stay and long  
23 stay patients remains constant. In practice, this could mean ensuring that only a certain  
24 number of high EuroSCORE patients are scheduled for elective procedures within a particular  
25 time frame. (4) The optimal proportions of short and long stay patients would need to be  
26 evaluated to ensure uninterrupted flow of patients through the unit and allowing flexibility for  
27 emergency cases.

42  
43

44 The advantage of this method of predicting LOS over previous studies is multifactorial.

45 Firstly, EuroSCORE is a cardiac specific scoring tool, which is now widely used in specialist  
46 centres and therefore predictions based on this will be straightforward to calculate.  
47  
48

49 EuroSCORE also has the advantage over other scoring systems of taking into account peri-  
50 operative factors which can have a significant influence on LOS in previously well  
51 patients.(16) Our predictive model compares favourably with previous studies with an AUC  
52 equivalent to or greater than that calculated by other methods.(15, 21)  
53

57  
58  
59  
60  
61  
62  
63  
64  
65

1 Unlike, previous studies, we have not only calculated the accuracy of predictions based on the  
2 EuroSCORE but have demonstrated the flexibility of the model to enable more accurate  
3 predictions in specific circumstances. For example, our model can be varied to ensure a  
4 higher proportion of long stay patients are identified to avoid unexpectedly high bed  
5 occupancy.  
6  
7  
8  
9

10  
11 The strength of this model lies in its use in resource allocation and patient flow management.  
12 By selecting an acceptable proportion of short and long stay patients that are treated on the  
13 ICU at any particular time, the model can be used to select patients for elective surgery and to  
14 calculate the number of contingency beds required for emergency cases. This allows  
15 resources to be used as efficiently as possible **by maintaining a relatively constant bed**  
16 **occupancy**, whilst aiming to avoid bed shortages.  
17  
18  
19  
20  
21  
22  
23  
24  
25

26 **The main limitation of this study is the use of data from a single centre, and hence the results**  
27 **may not all be transferrable to all other intensive care units. However**, the large data set  
28 means that the model is likely to be valid to similar units admitting patients following cardiac  
29 surgery but this needs to be tested. Furthermore, it would be straightforward to generate  
30 parameters specific to different units if similar data sets were available.  
31  
32  
33  
34  
35  
36  
37

38 **There are clearly other variables which will influence length of stay including many operative**  
39 **factors, however, for the purposes of this study we have chosen to focus on pre-operative**  
40 **scoring systems which will be simpler to evaluate for patient flow management.**  
41  
42  
43  
44  
45

46 **Similarly, we have elected not to evaluate any temporal changes in length of stay over the**  
47 **period of data collection. This enables the use of a much larger data set on which to develop**  
48 **the model, however, integrating trends in length of stay over time would provide another area**  
49 **of interest for further research.**

65

Finally, the model could be used to select an appropriate ratio of short stay to long stay patients described above, which would be transferable to other units that may have alternative ICU LOS prediction tools.

A number of options could be explored to further improve the accuracy of the model. The more recently published EuroSCORE II system has been shown to be a better predictor for cardiac mortality than either the additive or logistic EuroSCORE due to the changes in cardiac surgical mortality over time. (22) Whilst the logistic regression model is the standard initial choice for a problem of this type, there are alternatives that may improve accuracy, but require more rigorous statistical assumptions to be made.

### **Conclusions**

Being able to predict LOS on the ICU has a number of advantages for both individual patients whose management can be planned accordingly, and for organisations, where resource utilisation can be optimised. Using a simple logistic regression model based on the cardiac operative risk scoring tool EuroSCORE, we have demonstrated that the LOS can be accurately predicted. With EuroSCORE data alone, the overall accuracy of the model is 79.77%. The model can be adapted to focus on the correct identification of long stay (or short stay) patients alone, which may be of more practical use for improved resource allocation.
