Inositol 1,4,5-trisphosphate receptors (IP<sub>3</sub>Rs) are widely expressed intracellular Ca<sup>2+</sup> channels that evoke large local increases in cytosolic Ca<sup>2+</sup> concentration. By depleting the ER of Ca<sup>2+</sup>, IP<sub>3</sub>Rs also activate store-operated Ca<sup>2+</sup> entry (SOCE). Immobile IP<sub>3</sub>Rs close to the plasma membrane (PM) are the only IP<sub>3</sub>Rs that respond to physiological stimuli. The association of these ‘licensed’ IP<sub>3</sub>Rs with the ER-PM junctions where STIM interacts with Orai PM Ca<sup>2+</sup> channels may define the autonomous functional unit for SOCE. Ca<sup>2+</sup> entering cells through SOCE can be delivered directly to specific effectors, or it may reach them only after the Ca<sup>2+</sup> has been sequestered by the ER and then released through IP<sub>3</sub>Rs. This ‘tunnelling’ of Ca<sup>2+</sup> through the ER to IP<sub>3</sub>Rs selectively delivers Ca<sup>2+</sup> to different effectors.

### Highlights

- Structural studies are revealing how IP<sub>3</sub> and Ca<sup>2+</sup> together cause the IP<sub>3</sub>R to open
- Clusters of immobile IP<sub>3</sub>Rs adjacent to the plasma membrane are licensed to respond
- SOCE signals directly to effectors and through IP<sub>3</sub>Rs, after Ca<sup>2+</sup> tunnelling via ER
- Licensed IP<sub>3</sub>Rs may contribute to both activation of SOCE and Ca<sup>2+</sup> tunnelling

## Introduction

Inositol 1,4,5-trisphosphate receptors (IP<sub>3</sub>Rs) are widely expressed intracellular Ca<sup>2+</sup> channels through which IP<sub>3</sub> evokes Ca<sup>2+</sup> release from the endoplasmic reticulum (ER) [1]. All IP<sub>3</sub>Rs are large tetrameric channels that open only when they bind both IP<sub>3</sub> and Ca<sup>2+</sup> [2]. This dual regulation allows IP<sub>3</sub>Rs to propagate Ca<sup>2+</sup> signals regeneratively, with IP<sub>3</sub> and the spatial distribution of IP<sub>3</sub>Rs setting the gain on the Ca<sup>2+</sup>-induced Ca<sup>2+</sup> release (CICR) mechanism (**Figure 1a,b**). The rapid flux of Ca<sup>2+</sup> through IP<sub>3</sub>Rs generates signals on both sides of the ER membrane. On the cytosolic side, large local increases in Ca<sup>2+</sup> concentration around active IP<sub>3</sub>Rs can both propagate regeneratively between IP<sub>3</sub>Rs to give global Ca<sup>2+</sup> signals and fuel Ca<sup>2+</sup> uptake by closely apposed organelles, like mitochondria [3] or lysosomes [4]. IP<sub>3</sub>-evoked Ca<sup>2+</sup> release thereby regulates Ca<sup>2+</sup>-sensitive proteins in both the cytosol and organelles. The decrease in ER luminal Ca<sup>2+</sup> concentration activates STIM1, which then accumulates at ER-plasma membrane (PM) junctions, where its interaction with Orai channels stimulates store-operated Ca<sup>2+</sup> entry (SOCE) [5]. Ca<sup>2+</sup> provided by SOCE can regulate local effectors or, after sequestration by the ER, it can be ‘tunnelled’ to deliver Ca<sup>2+</sup> through IP<sub>3</sub>Rs to different targets [6]. Here, we review recent progress towards understanding how IP<sub>3</sub> and Ca<sup>2+</sup> regulate IP<sub>3</sub>Rs, the assembly of IP<sub>3</sub>Rs into spatially organized signalling units, and the implications of this organization for SOCE.

## Towards a structural understanding of IP<sub>3</sub>R activation

Progress towards understanding how IP<sub>3</sub> and Ca<sup>2+</sup> control opening of the Ca<sup>2+</sup>-permeable pore of the IP<sub>3</sub>R has come from structural analyses of cytosolic fragments of the IP<sub>3</sub>R [7-10,11], cryo-EM structures of complete IP<sub>3</sub>R1 [12] and IP<sub>3</sub>R3 [13], and from similar analyses of the closely related family of intracellular Ca<sup>2+</sup> channels, ryanodine receptors [14-19]. IP<sub>3</sub>R activation begins when IP<sub>3</sub> partially closes the clam-like IP<sub>3</sub>-binding core (IBC) [7,10,13] on each of the four subunits of an IP<sub>3</sub>R [20] and it culminates with hydrophobic residues near the cytosolic end of the pore, and some 7 nm from the IBC, re-orienting to open a path through which hydrated Ca<sup>2+</sup> ions can pass. It is not yet clear how conformational changes pass from IBC to pore, but they must traverse a nexus immediately above the ER membrane, where the underside of the huge cytosolic region extends into a leaflet that interdigitates with another leaflet at the end of the pore-lining helix (**Figure 1c,d**) [11]. Residues provided by different parts of this structure together form a Ca<sup>2+</sup>-binding site [13,18]. This architecture suggests an activation scheme wherein IP<sub>3</sub> binding may be communicated from the IBC to the nexus to stabilize a Ca<sup>2+</sup>-binding site. Binding of Ca<sup>2+</sup> to

this site, part of which is formed by the C-terminal extension of the pore-lining helix, might then cause dilation of the pore to create a path for  $\text{Ca}^{2+}$  to move rapidly from the ER lumen to the cytosol [21]. However, the function of this  $\text{Ca}^{2+}$ -binding site is unproven, and an additional  $\text{Ca}^{2+}$ -binding site, which also straddles different domains, was recently identified in the IP<sub>3</sub>R cap [13"] (**Figure 1d**).

Structural analyses also shed light on another key feature of IP<sub>3</sub>Rs, namely their ability to conduct large  $\text{Ca}^{2+}$  fluxes. The narrow selectivity filter at the luminal end of the pore is shorter and wider than in related channels, and sufficient to allow passage of hydrated  $\text{Ca}^{2+}$  ions [12",16]. The cation-selectivity of the pore is provided by abundant acidic residues at its luminal and cytosolic vestibules. These features allow  $\text{Ca}^{2+}$  to move quickly through the pore ( $\sim 5 \times 10^5 \text{ Ca}^{2+}/\text{s}$  *in situ*) [22] and, because the weak cation-selectivity of the pore allows  $\text{K}^+$  to move as counterions [23], without the charge accumulation that would otherwise terminate  $\text{Ca}^{2+}$  release. These features allow IP<sub>3</sub>Rs to rapidly generate large, local cytosolic  $\text{Ca}^{2+}$  signals.

### **$\text{Ca}^{2+}$ puffs – licensed to respond**

Pioneering work from Ian Parker's lab, using confocal [24], total internal reflection fluorescence microscopy (TIRFM) [25], and most recently lattice light-sheet microscopy [26] revealed a hierarchy of  $\text{Ca}^{2+}$  release events as the IP<sub>3</sub> concentration increases (**Figure 1b**). The smallest events, probably reflecting the opening of single IP<sub>3</sub>Rs, are ' $\text{Ca}^{2+}$  blips' that typically last only a few milliseconds. Greater stimulus intensities evoke larger and more long-lasting ( $\sim 100 \text{ ms}$ ) ' $\text{Ca}^{2+}$  puffs'. These report the nearly simultaneous opening of a few clustered IP<sub>3</sub>Rs, as  $\text{Ca}^{2+}$  released by one IP<sub>3</sub>R rapidly recruits the activity of its IP<sub>3</sub>-bound neighbours. Similar  $\text{Ca}^{2+}$  puffs are observed in cells expressing each of the three IP<sub>3</sub>R subtypes, suggesting they are a conserved feature of IP<sub>3</sub>-evoked  $\text{Ca}^{2+}$  signalling [27]. As stimulus intensities increase further,  $\text{Ca}^{2+}$  diffusing between puffs ignites a regenerative wave that invades the entire cell. These waves become more frequent with increasing stimulus intensity. An important point is that the nature of the  $\text{Ca}^{2+}$  signal, local or global, and so the  $\text{Ca}^{2+}$  sensors recruited, changes with stimulus intensity.

There are, however, some puzzling features of these elementary  $\text{Ca}^{2+}$  release events. First, most IP<sub>3</sub>Rs appear to be mobile yet  $\text{Ca}^{2+}$  puffs repeatedly initiate at fixed sites [28,29, see discussion in 30"]. What is so special about the few IP<sub>3</sub>Rs that repeatedly respond? Second,

since all four IP<sub>3</sub>-binding sites of an IP<sub>3</sub>R must be occupied for the channel to open [20], how do enough IP<sub>3</sub>Rs within a small cluster become fully occupied and capable of generating a Ca<sup>2+</sup> puff [31]? How is IP<sub>3</sub> binding distributed across IP<sub>3</sub>Rs and what are the functional consequences? Third, numerous studies suggest regulated assembly of IP<sub>3</sub>Rs into clusters [32 and references therein], but others suggest that the clusters from which Ca<sup>2+</sup> puffs initiate are pre-assembled [33]. Does regulated clustering of IP<sub>3</sub>Rs contribute to IP<sub>3</sub>-evoked Ca<sup>2+</sup> signals?

Whether activated by endogenous signalling pathways, where IP<sub>3</sub> might be selectively delivered to IP<sub>3</sub>Rs [34], or by photolysis of caged-IP<sub>3</sub>, where IP<sub>3</sub> is uniformly delivered to the cytosol, Ca<sup>2+</sup> puffs initiate at the same fixed sites [28,29]. In each case, the sites are all close to the PM [26,30]. By tagging native IP<sub>3</sub>R with EGFP, it was possible to observe the geography of IP<sub>3</sub>Rs as they evoke Ca<sup>2+</sup> signals (**Figure 1d**) [30]. Most IP<sub>3</sub>Rs are assembled into rather loose clusters (each typically including ~8 IP<sub>3</sub>Rs), wherein some IP<sub>3</sub>Rs are several 100 nm apart. These clusters are distributed throughout the cell and most are mobile. However, the only IP<sub>3</sub>R clusters that initiate Ca<sup>2+</sup> puffs are those that are parked near the PM, adjacent to the ER-PM junctions where SOCE occurs. These IP<sub>3</sub>Rs, a small fraction of the several thousand expressed in a cell, are ‘licensed’ to respond to IP<sub>3</sub>. Neither the licensing factor nor the scaffold that holds IP<sub>3</sub>Rs within their loose clusters has been identified. We speculate, based on patch-clamp analyses suggesting that IP<sub>3</sub> promotes local clustering of IP<sub>3</sub>Rs [32], that IP<sub>3</sub> may cause the loose confederations of IP<sub>3</sub>Rs to huddle more closely and so increase the opportunity for CICR between them. A similar clustering of IP<sub>3</sub>Rs has been proposed to underlie the increased sensitivity of IP<sub>3</sub>Rs to IP<sub>3</sub> as oocytes mature in preparation for fertilization [35].

It is not clear whether licensing of IP<sub>3</sub>Rs increases their affinity for IP<sub>3</sub> and so diverts IP<sub>3</sub> binding to a subset of IP<sub>3</sub>Rs, or whether licensing acts downstream of IP<sub>3</sub> binding. The latter would entail that to achieve complete occupancy of at least a few of the IP<sub>3</sub>Rs within a licensed cluster, most IP<sub>3</sub>Rs in the cell would have some of their subunits bound to IP<sub>3</sub>. We might then ask whether partial occupancy of an IP<sub>3</sub>R has functional consequences, possibly driving local clustering, for example [31,32]. Furthermore, since the intracellular concentration of IP<sub>3</sub>Rs (~7200 IP<sub>3</sub>Rs/cell, ~100 nM of IP<sub>3</sub>-binding sites) is similar to their affinity for IP<sub>3</sub> (K<sub>D</sub> = 119 nM under physiological conditions [36]), IP<sub>3</sub>Rs may provide appreciable buffering and thereby slow IP<sub>3</sub> diffusion [31]. That appears to be the case; indeed the intracellular buffering of IP<sub>3</sub> may be greater than can be explained by IP<sub>3</sub>Rs alone [37].

This has important implications because, with IP<sub>3</sub> diffusing some 30-times slower than expected, its range of action is reduced. Hence, IP<sub>3</sub>, like Ca<sup>2+</sup> [38], probably functions as a local intracellular messenger [37\*].

### **IP<sub>3</sub>Rs and SOCE: short-cuts and tunnels**

Activation of SOCE requires substantial loss of Ca<sup>2+</sup> from the ER [39-41]. Yet the ER forms a lumenally continuous network [42,43], and during Ca<sup>2+</sup> signalling it must support other Ca<sup>2+</sup>-requiring activities, including protein folding [44]. Furthermore, the ER-PM junctions where SOCE occurs, perhaps 400 junctions in a HeLa cell [5\*], are just 10-20 nm wide and involve no more than a few percent of the PM area [5\*,45]. How, then, do physiological stimuli both activate SOCE without compromising ER functions and deliver Ca<sup>2+</sup> signals beyond ER-PM junctions? In most analyses, SOCE is activated by using thapsigargin to inhibit the sarcoplasmic/endoplasmic reticulum Ca<sup>2+</sup>-ATPases (SERCA) responsible for ER Ca<sup>2+</sup> uptake. However, under physiological conditions, IP<sub>3</sub>Rs mediate the loss of ER Ca<sup>2+</sup> that triggers SOCE, and SERCA remain active throughout. Both features are important.

Licensed IP<sub>3</sub>Rs are immobilized alongside the ER-PM junctions where SOCE occurs [30\*\*]. These IP<sub>3</sub>Rs, with their large Ca<sup>2+</sup> conductances [22], may provide a transient ‘short-circuit’ for Ca<sup>2+</sup> that briefly drains the ER within the ER-PM junction, thereby causing the large drop in ER Ca<sup>2+</sup> concentration needed to activate SOCE (**Figure 2a**). The active IP<sub>3</sub>Rs will also drain Ca<sup>2+</sup> from the more central ER, but that Ca<sup>2+</sup> pool is much larger and, with Ca<sup>2+</sup> diffusing rapidly within the ER lumen [46], its luminal Ca<sup>2+</sup> concentration will be minimally affected. These ideas lead to the proposal that each ER-PM junction forms an autonomous SOCE unit, regulated by its associated licensed IP<sub>3</sub>Rs. We envisage this scheme operating during the low stimulus intensities that evoke Ca<sup>2+</sup> oscillations, which are sustained by SOCE but with no discernible decrease in the overall ER Ca<sup>2+</sup> concentration [39]. The model would allow IP<sub>3</sub>Rs to stimulate SOCE without trespassing into other ER functions. It also entails only local movements of STIM after store depletion, which might allow local activation of SOCE to be very rapid.

Several effectors, including activation of the transcription factor NFAT by calcineurin [47] and some adenylyl cyclases [48] are directly regulated by Ca<sup>2+</sup> signals evoked by SOCE, but for others the route from SOCE to effector is through the ER [6\*\*,39,49-51\*, reviewed in 52]. Here, Ca<sup>2+</sup> entering the cell through SOCE is sequestered by the ER and then released back to

the cytosol through IP<sub>3</sub>Rs that may be remote from ER-PM junctions where SOCE occurs [52]. This ‘tunnelling’ of Ca<sup>2+</sup> from SOCE through the ER is reminiscent of the original ‘capacitative’ model for SOCE [53]. Patrick Hogan has estimated that the handful of active Orai channels within each maximally activated ER-PM junction collectively deliver ~30,000 Ca<sup>2+</sup>/s [5<sup>\*</sup>], most of which will rapidly diffuse out of the junction. By contrast a single IP<sub>3</sub>R in a replete ER can deliver 500,000 Ca<sup>2+</sup>/s to the cytosol, while SERCA working at its maximal capacity can remove fewer than 40 Ca<sup>2+</sup>/s [5<sup>\*</sup>,54]. Hence, unless SERCA are very concentrated within ER-PM junctions and adequately provisioned with ATP therein, they are unlikely to have much impact on Ca<sup>2+</sup> concentrations within an active junction, but SERCA can deliver Ca<sup>2+</sup> to the ER lumen and so sustain Ca<sup>2+</sup> tunnelling [6<sup>\*\*</sup>,51<sup>\*</sup>,55,56]. Recent studies suggest three different categories of effectors for which SOCE can be important (**Figure 2b**). Effectors in the first category, typified by calcineurin [47], are closely associated with the SOCE apparatus and directly regulated by Ca<sup>2+</sup> signals in the ER-PM junction. The second category, typified by Ca<sup>2+</sup>-activated K<sup>+</sup> and Cl<sup>-</sup> channels in the PM, is regulated by SOCE, but only after the Ca<sup>2+</sup> has been sequestered by the ER and then released through nearby IP<sub>3</sub>Rs [6<sup>\*\*</sup>,51<sup>\*</sup>]. These may be the licensed IP<sub>3</sub>Rs that sit alongside the SOCE machinery (**Figure 2a,b**). The third category, which includes the mitochondrial uptake system (MCU) in HeLa cells [51<sup>\*</sup>], is activated by IP<sub>3</sub>-evoked Ca<sup>2+</sup> release from replete ER, but not during SOCE and Ca<sup>2+</sup> tunnelling. These effectors are probably coupled to IP<sub>3</sub>Rs deeper within the cell. These IP<sub>3</sub>Rs are deprived of Ca<sup>2+</sup> when licensed IP<sub>3</sub>Rs respond and divert Ca<sup>2+</sup> sequestered from the ER-PM junctions back to the cytosol before it can fill the deeper ER [51<sup>\*</sup>].

### **Concluding remarks**

Remarkable progress has brought us close to understanding the structural basis of IP<sub>3</sub>R activation and of the interactions between STIM and Orai that mediate SOCE [57]. Licensed IP<sub>3</sub>Rs adjacent to the ER-PM junctions where SOCE occurs may contribute to both local activation of SOCE and allow delivery of Ca<sup>2+</sup> tunnelled through the ER to specific intracellular effectors.

••The first structure of a complete  $\text{IP}_3\text{R}$  derived from single-particle analysis of cryo-EM images with sufficient resolution to cast light on structural determinants of  $\text{IP}_3\text{R}$  behaviour. The structure, from purified cerebellar  $\text{IP}_3\text{R}$  in a closed state, shows the pore occluded at its

cytosolic end by hydrophobic residues that must move when the pore opens. The four IP<sub>3</sub>-binding cores (IBC) sit at the top of a large mushroom-like structure, with the stalk formed by the transmembrane (TM) helices that enclose the pore. About 7 nm separates the IBC from the residues that occlude the closed channel. The only contact between the large cytosolic region and pore domain occurs at a small platform immediately above the ER membrane, where structures from the C-terminal end of the cytosolic region and the cytosolic end of the pore-lining TM form an interleaved assembly that may also provide a Ca<sup>2+</sup>-binding site.

- Gene-editing to attach EGFP to native IP<sub>3</sub>R allowed the subcellular distribution of IP<sub>3</sub>Rs to be determined at the same time as the Ca<sup>2+</sup> signals they evoke. The results demonstrate that IP<sub>3</sub>Rs are assembled into loose clusters (typically 8 IP<sub>3</sub>Rs) that are distributed throughout the cell. Most of these IP<sub>3</sub>Rs are mobile, but only immobile clusters tethered close to the PM are 'licensed' to respond to IP<sub>3</sub>. The licensed IP<sub>3</sub>R clusters are parked adjacent to the ER-PM junctions within which STIM activates Orai, suggesting a close link between their activity and regulation of SOCE.

- By photoreleasing a metabolically stable analogue of IP<sub>3</sub> focally or across the entire cell, the authors use the latency before the first Ca<sup>2+</sup> puff to report intracellular diffusion of IP<sub>3</sub>. These measurements, alongside diffusion models, indicate that IP<sub>3</sub> diffuses some thirty-times more slowly than hitherto supposed. While binding of IP<sub>3</sub> to IP<sub>3</sub>Rs contributes to the hindered diffusion, IP<sub>3</sub>Rs alone seem not to provide sufficient buffering to account for the massive reduction in diffusion. The data provide compelling evidence that IP<sub>3</sub>, like Ca<sup>2+</sup>, is a local messenger.

## Figure 1

Regulation of IP<sub>3</sub>Rs by IP<sub>3</sub> and Ca<sup>2+</sup>. **(a)** IP<sub>3</sub> is produced when G-protein coupled receptors (GPCRs) or receptor tyrosine kinases (RTK) stimulate phospholipase C (PLC). IP<sub>3</sub> binding to IP<sub>3</sub>Rs in the ER unmasks a Ca<sup>2+</sup>-binding site, and when Ca<sup>2+</sup> binds to it the channel can open. Ca<sup>2+</sup> signals can then propagate regeneratively by Ca<sup>2+</sup>-induced Ca<sup>2+</sup> release (CICR). **(b)** As the IP<sub>3</sub> concentration increases, it evokes a hierarchy of Ca<sup>2+</sup> release events. **(c)** The IP<sub>3</sub>R is a large tetrameric mushroom-like structure [12<sup>\*\*</sup>]. IP<sub>3</sub> binding near the cap of the mushroom causes the clam-like IBC to close and initiate conformation changes. These propagate to the pore-lining helices to cause the gate, formed by hydrophobic residues near the cytosolic surface of the ER membrane, to open. A nexus of entwined structures from the pore and cytosolic domains allow communication between them, and may provide a critical Ca<sup>2+</sup>-binding site [13<sup>\*\*</sup>,18<sup>\*\*</sup>]. A second Ca<sup>2+</sup>-binding site is formed at the interface of two of the cytosolic domains [13<sup>\*\*</sup>]. **(d)** Within the ER (red), most IP<sub>3</sub>Rs (green) assemble into small clusters of loosely associated IP<sub>3</sub>Rs [30].

## Figure 2

Licensed IP<sub>3</sub>Rs and SOCE. **(a)** IP<sub>3</sub>Rs licensed to respond to IP<sub>3</sub> are anchored alongside the ER-PM junctions where SOCE occurs. Activation of a licensed IP<sub>3</sub>R cluster may ‘short-circuit’ the ER by transiently providing a large-conductance Ca<sup>2+</sup> leak. The leak drains Ca<sup>2+</sup> from the small ER region within the ER-PM junction, causing its luminal Ca<sup>2+</sup> concentration to fall, providing an effective signal for activation of SOCE (right panel). Draining Ca<sup>2+</sup> from the more extensive ER on the other side of the leak will minimally affect its luminal Ca<sup>2+</sup> concentration. We suggest that the fundamental functional unit for SOCE is the ER-PM junction with its associated licensed IP<sub>3</sub>Rs. **(b)** Ca<sup>2+</sup> entering cells through SOCE can directly regulate effectors (1, eg, calcineurin) within ER-PM junctions. SERCA allows sequestration by the ER of some incoming Ca<sup>2+</sup>, which may then be tunnelled through the ER lumen (red arrows) to licensed IP<sub>3</sub>Rs close to the PM, from which it is released and regulates distinct effectors (2, eg, Ca<sup>2+</sup>-activated K<sup>+</sup> channels). We suggest that the short-circuit provided by licensed IP<sub>3</sub>Rs diverts Ca<sup>2+</sup> to the cytosol before it can reach ER deeper within the cell. The IP<sub>3</sub>Rs within this ER direct Ca<sup>2+</sup> to different effectors only when the ER is replete with Ca<sup>2+</sup> (3, eg, mitochondria in HeLa cells).
