61

62

63 **Abstract**

64 *Purpose:* To assess sampling bias in national viral suppression (VS) estimates derived from the Medical  
65 Monitoring Project (MMP) resulting from use of an abbreviated (four-month) annual sampling period. We aimed  
66 to improve VS estimates using cohort data from the North American AIDS Cohort Collaboration on Research and  
67 Design (NA-ACCORD) and a novel cohort-adjustment method.

68 *Methods:* Using full calendar years of NA-ACCORD data, we assessed timing of HIV care attendance (inside  
69 versus exclusively outside MMP's four-month sampling period), VS status at last test (<200 vs. ≥200 copies/mL),  
70 and associated demographics. These external estimates were used to standardize MMP to NA-ACCORD data  
71 with multivariable regression models of care attendance and VS, yielding adjusted 2009–2013 VS estimates with  
72 95% confidence intervals (CI).

73 *Results:* Weighted percentages of VS among persons in HIV care were 67% in 2009 and 77% in 2013. These  
74 estimates are slightly lower than previously published MMP estimates (72% and 80% in 2009 and 2013,  
75 respectively). The number of persons receiving HIV care was previously underestimated by 20%, because  
76 patients receiving care exclusively outside the MMP sampling period did not contribute toward the weighted  
77 population estimate.

78 *Conclusions:* Careful examination of national surveillance estimates using data triangulation and novel  
79 methodologies can improve the robustness of VS estimates.

80 *Keywords:* HIV viral suppression, HIV clinical care, surveillance, indirect standardization

81

82

83

## 84 **Introduction**

85 Sustained viral suppression (VS), which can be achieved through consistent use of antiretroviral therapy (ART),  
86 greatly improves health <sup>1</sup> and life expectancy <sup>2</sup> for persons living with HIV, while effectively eliminating HIV  
87 transmission risk <sup>3,4</sup>. Monitoring population-level VS is important for demonstrating progress toward reaching  
88 national goals of improving the health of persons living with HIV and reducing new infections <sup>5</sup>. The Centers for  
89 Disease Control and Prevention (CDC) has used two sources of surveillance data to measure VS. The Medical  
90 Monitoring Project (MMP) is a surveillance system that provides data to estimate VS among persons in HIV care,  
91 and the National HIV Surveillance System (NHSS) provides data to measure VS among persons with diagnosed  
92 HIV in a subset of jurisdictions.

93 MMP collects behavioral and clinical data from annual, cross-sectional samples of persons living with diagnosed  
94 HIV using interviews and medical record abstraction <sup>6</sup>. During 2009–2015, MMP described U.S. adults in HIV  
95 clinical care by sampling U.S. jurisdictions and territories, followed by HIV clinical care facilities within those  
96 jurisdictions, then persons seeking care within those facilities during January – April of a given year. The January  
97 – April sampling period was used to expedite data collection for annual estimates, and at the time of MMP's  
98 inception, this sampling period captured 88% of adults in clinical care <sup>7</sup>. This coverage estimate has not been  
99 reassessed.

100 Surveillance estimates should be periodically revisited in light of temporal changes and methodological  
101 advances. One important temporal change over MMP's lifespan is that the recommended number of clinical  
102 visits to monitor virologic response for persons on ART has decreased over time <sup>8</sup>. As a result, persons engaged  
103 in HIV clinical care during a given year may be less likely to seek care during the four-month sampling period,  
104 and thus less likely to be sampled for MMP. The result of this sampling bias would be an underestimated  
105 weighted population size of persons receiving HIV clinical care and possibly biased estimates of the number and  
106 percentage of persons in HIV care with VS.

107 We previously published findings from MMP indicating VS among persons in HIV clinical care increased from  
108 72% to 80% during 2009–2013 <sup>9</sup>. A recent assessment of potential sampling bias in MMP indicates these  
109 estimates should be revisited <sup>10</sup>. Using 2012 data from a single clinical cohort, the HIV Outpatient Study (HOPS),  
110 in combination with a novel methodology to adjust for possible sampling bias, we demonstrated that MMP may  
111 have undercounted persons in HIV clinical care and that VS prevalence may have been differential among  
112 sampled versus un-sampled persons. Here, we assess the potential effect of sampling bias on MMP-derived VS  
113 estimates during 2009–2013 using data from a large, geographically diverse group of clinical cohorts from the  
114 North American AIDS Cohort Collaboration on Research and Design (NA-ACCORD).

## 115 **Material and methods**

116 NA-ACCORD is the largest multisite collaboration of clinical and interval cohorts in the United States and Canada,  
117 representing over 20 cohorts and 200 clinical care sites. Cohorts contribute data using standardized methods for  
118 patients  $\geq 18$  years including demographics, ART prescription, laboratory test results, and dates of primary HIV  
119 clinical visits. Participants are consented locally and all study activities have been approved by the local  
120 institutional review boards for each site and for Johns Hopkins University School of Medicine <sup>11</sup>.

121 For this analysis, we included nine United States clinical cohorts: Fenway Community Center (MA), the HIV  
122 Outpatient Study, the HIV Research Network (multi-state), Johns Hopkins HIV Clinical Cohort (MD), Retrovirus  
123 Research Center (PR), University of Alabama at Birmingham 1917 Clinical Cohort (AL), University of Washington

124 HIV Cohort (WA), Veterans Aging Cohort Study (multi-state), and Vanderbilt Comprehensive Care Clinic HIV  
125 Cohort (TN). We chose these cohorts based on the following criteria: being observational in nature, being  
126 located in the United States, and being willing to participate in this analytic activity. For each of the years 2009–  
127 2013, we considered adult patients who had  $\geq 1$  CD4 test, viral load measurement, or HIV clinical care visit during  
128 January 1 – December 31 as having received HIV care during that year, yielding approximately 30,000 patients  
129 annually. Within each year, we categorized patients as receiving care within the MMP sampling period (January  
130 1 – April 30) or exclusively outside the sampling period. We used individual data on age (categorized as 18–24,  
131 25–34, 35–44, 45–54, and 55+ years) and race/ethnicity (categorized as non-Hispanic white, non-Hispanic black,  
132 Hispanic, and other) as predictors of clinical care receipt exclusively outside the MMP sampling period. Sex at  
133 birth was not associated with care receipt exclusively outside the sampling period.

134 We applied our previously described cohort-adjustment method<sup>10</sup>, which uses principles of indirect  
135 standardization<sup>12</sup> and synthetic estimation<sup>13</sup> to adjust MMP-derived estimates of VS among persons in HIV care  
136 using 2009–2013 NA-ACCORD data. First, separately for each year of NA-ACCORD data, we fit a logistic model  
137 regressing receipt of care exclusively outside the sampling period on age group, race/ethnicity, and the  
138 interaction term age group\*race/ethnicity. This model yields estimated odds of care receipt exclusively outside  
139 the sampling period, among all persons receiving care during the year, within each age group\*race/ethnicity  
140 stratum. These odds, multiplied by the MMP-derived weighted estimate for number of persons receiving HIV  
141 medical care during the sampling period, yielded adjusted estimates for the number of persons who would not  
142 have been included in the MMP sample despite receiving care during the year.

143 Next, for each year of NA-ACCORD data, we fit a logistic model regressing VS (viral load <200 copies/mL or  
144 undetectable) at most recent test (last in calendar year) on care receipt exclusively outside the sampling period,  
145 age, race/ethnicity, and the interaction term age\*race/ethnicity. We estimated the predicted marginal  
146 prevalence ratios of VS among those receiving care exclusively outside versus inside the sampling period, within  
147 each age\*race/ethnicity stratum<sup>14</sup>. Multiplying these prevalence ratios by MMP-derived VS estimates yielded VS  
148 estimates for persons who would not have been sampled.

149 We combined these estimates with the original MMP weighted population size estimates for VS, yielding revised  
150 estimates for the total number of persons receiving care and VS, and the percent VS among persons in care.  
151 Point estimates for all outcomes and the 95% confidence intervals for the percent VS were obtained from the  
152 50<sup>th</sup> (point estimates), 2.5<sup>th</sup>, and 97.5<sup>th</sup> percentiles (confidence intervals) of Monte Carlo bootstrap simulations.  
153 Simulations were based on 100,000 runs in which we jointly sampled normal distributions with means and  
154 standard deviations, respectively, defined by the point estimates and the standard errors for all regression  
155 model parameter estimates and MMP weighted frequency estimates.

## 156 **Results**

157 The cohort-adjustment method yielded weighted population estimates of 355,156 persons VS and 526,850 in  
158 care in 2009 and 441,619 persons VS and 595,807 in care in 2013 (Table 1). Therefore, weighted percentages of  
159 VS among persons in HIV care in the United States were 67% in 2009 and 77% in 2013. The estimated number of  
160 persons in HIV care using the MMP data alone was approximately 20% lower in each year than the estimate  
161 yielded by the cohort-adjustment method and the two data sources together. Similarly, the estimated number  
162 of persons who were VS using the MMP data alone was 15–17% lower in each year than the estimate yielded by  
163 the two data sources together. This pattern held across age and race categories, although the percent

164 differences for weighted estimates of the numbers of persons in HIV care and virally suppressed were larger in  
165 each year among younger versus older age groups (Supplemental table).

166 In 2009, VS among persons in HIV care ranged from 60% among non-Hispanic blacks to 70% among  
167 Hispanic/Latinos and 75% among non-Hispanic whites (Table 2). In 2013, VS ranged from 72% among non-  
168 Hispanic blacks to 78% among Hispanic/Latinos and 84% among non-Hispanic whites. The VS percentages  
169 generally increased with increasing age group in each year. In 2009, 54% of 18-24 year olds in HIV care were VS  
170 compared to 79% of persons aged 55 years or older. In 2013, 58% of 18-24 year olds in HIV care were VS  
171 compared to 84% of persons aged 55 years or older. The largest percentage increases in VS from 2009 to 2013  
172 were observed among non-Hispanic blacks and among persons aged 25–34 years, while only modest increases  
173 were observed among the youngest and oldest age groups.

174

## 175 **Discussion**

176 Using two large, geographically diverse data sources and a novel methodology, we estimated that the  
177 percentage of persons in HIV clinical care who were VS increased from 67% in 2009 to 77% in 2013. These  
178 estimates are similar to, but lower than, previously published MMP-derived estimates, which indicated VS in this  
179 population increased from 72% (95% confidence interval [CI]: 69–74) in 2009 to 80% (95% CI: 78–83) in 2013<sup>9</sup>.  
180 Conversely, weighted population sizes presented here suggest that the *numbers* of persons in HIV care and the  
181 number VS were previously underestimated.

182 The estimated percentage of persons in HIV care who were VS was overestimated due to lower VS prevalence  
183 among persons un-sampled by MMP. NA-ACCORD cohort data indicated persons not receiving care during the  
184 sampling period had lower VS prevalence than those receiving care in the sampling period, which may be  
185 explained by a lower frequency of visits, thus a lower probability of receiving care during the sampling period  
186 and sub-optimal engagement in care. The finding likely reflects a higher likelihood of any care receipt during the  
187 four-month sampling period due to a higher overall number of care visits during a given year, which is associated  
188 with a higher probability of VS.<sup>15</sup> In other words, the more frequently a patient seeks care during the year, the  
189 more likely they are to be seen during a defined period, regardless of the period used. After making adjustments  
190 for these biases, the 2013 estimate of VS prevalence among persons in HIV care was 77.3%, which is nearly  
191 identical to the 77.2% among persons in NHSS with an indication of HIV care during 2013 (as indicated by  $\geq 1$   
192 reported CD4 or viral load test).<sup>6</sup>

193 The weighted population size for the total number of persons in HIV care in the United States was previously  
194 estimated to be 421,186 in 2009,<sup>16</sup> which is 20% lower than the 526,850 estimated using the cohort-adjustment  
195 method to account for un-sampled persons. Similarly, the weighted population size for the total number of  
196 persons in HIV care in the United States who were VS was previously estimated at 301,403 in 2009 (Medical  
197 Monitoring Project, unpublished data), which was 15% lower than the 355,156 presented here. These are  
198 substantially higher weighted population estimates for persons who are in HIV care and VS than those  
199 previously published. If used together with the number of persons living with diagnosed HIV during this period,  
200 this refinement of the weighted population estimates may also provide additional information about how many  
201 persons with diagnosed HIV were receiving care and VS at this time.<sup>17</sup>

202 In 2015, MMP expanded to represent all persons living with diagnosed HIV and now samples directly from the  
203 NHSS register of all persons with diagnosed HIV. The four-month sampling period is no longer used, and HIV care

204 and treatment outcomes are now estimated for all diagnosed persons. Despite this change, examining bias in  
205 pre-2015 estimates is important for accurate interpretation of current estimates in their historical context.  
206 Historical estimates are used routinely in transmission models and for projecting goals and feasibility of change  
207 in clinical outcomes over time. Additionally, periodic quantitative evaluation of HIV surveillance estimates in  
208 light of temporal changes in population characteristics, clinical practices, and other external factors is good  
209 scientific practice and may help to increase the perceived (and real) reliability of estimates derived from  
210 imperfect data systems with inexact methods.

211 This analysis has limitations. First, data adjustments can only be applied reliably within strata defined by at most  
212 two factors due to stratum-specific sample sizes<sup>10</sup>. We chose age group and race/ethnicity for stratification  
213 because, of the variables we could measure in both NA-ACCORD and MMP, these characteristics were most  
214 strongly associated with both care receipt exclusively outside the sampling period and VS. Notably, sex at birth  
215 was not associated with care receipt exclusively outside the sampling period. Second, we used slightly different  
216 age groups for this analysis compared to age groups used for the previously published MMP VS estimates, which  
217 limits comparability by age between previous and current estimates. However, the age groups used for the  
218 present analysis are nearly identical to those in other national HIV surveillance reports using NHSS data, so this  
219 may facilitate comparisons to, and joint use with, national case surveillance data. Last, while annual estimates of  
220 VS among persons in HIV care from the cohort-adjustment method overlap with confidence intervals for the  
221 previously published MMP estimates, statistical tests cannot be used to compare previous and current estimates  
222 because they rely on data from the same MMP participants.

223 VS among persons in HIV care is an important indicator of quality of clinical care and of the need for non-clinical  
224 care services that may help close the gap between the number of people in HIV clinical care and the number VS.  
225 These findings are an improvement upon previously published estimates<sup>9</sup> and likely bring them closer to truth.  
226 VS increased during 2009–2013, but more work is needed for further gains, particularly among racial/ethnic  
227 minority groups and young people. Careful examination of national surveillance estimates using data  
228 triangulation and novel methodologies can improve the robustness of VS estimates and help to identify groups  
229 for which focused interventions are needed for sustained health improvements and prevention of new  
230 infections.
