Gamma-ray bursts (GRBs) are the most powerful explosions in the universe and probe physics under extreme conditions. GRBs divide into two classes, of short and long duration¹, thought to originate from different types of progenitor systems^{2,3}. The physics of their γ -ray emission is still poorly known, over 40 years after their discovery, but may be probed by their highest-energy photons. Here we report the first detection of high-energy emission from a short GRB with measured redshift, GRB 090510, using the Fermi Gamma-ray Space Telescope. We detect for the first time a GRB prompt spectrum with a significant deviation from the Band function. This can be interpreted as two distinct spectral components, which challenge the prevailing γ -ray emission mechanism: synchrotron – synchrotron self-Compton⁴. The detection of a 31 GeV photon during the first second sets the highest lower limit on a GRB outflow Lorentz factor, of >1200 , suggesting that the outflows powering short GRBs are at least as highly relativistic as those powering long GRBs. Even more importantly, this photon sets limits on a possible linear energy dependence of the propagation speed of photons (Lorentz-invariance violation) requiring for the first time a quantum-gravity mass scale significantly above the Planck mass.

On May 10th, 2009, $T_0 = 00:22:59.97$ UT, the Gamma-ray Burst Monitor (GBM)⁵ and the Large Area Telescope (LAT)⁶ on-board Fermi triggered on the very bright short GRB 090510, which was also detected and located with multiple satellites (Swift⁷, Konus-Wind⁸, Agile⁹, Suzaku¹⁰ and INTEGRAL-ACS). Ground-based optical spectroscopy data, taken 3.5 days later¹¹, exhibited prominent emission lines at a common redshift of $z = 0.903 \pm 0.003$, corresponding to a luminosity distance of $d_L = 1.8 \times 10^{28}$ cm (for a standard cosmology, $[\Omega_\Lambda, \Omega_M, h] = [0.73, 0.27, 0.71]$). The host galaxy of GRB090510 was identified as a late-type elliptical or early-type spiral star-forming galaxy, in contrast to the dwarf irregular, star-forming galaxies that have been observed to harbor long-duration GRBs^{12,13}, but consistent with the diverse types of hosts identified with short GRBs^{14,15}.

The GBM light curve (Fig. 1b,c; 8 keV – 40 MeV) consists of 7 main pulses. The main LAT emission above 100 MeV starts at $T_0 + 0.65$ s and lasts ~ 200 s; a single 31 GeV photon – the highest-energy photon detected from any GRB, coincides with the last GBM pulse at $T_0 + 0.829$ s (Fig. 1-b,c,f; see Supplementary Information 1). Using the combined high-energy resolution Time-Tagged Events from the three brightest GBM detectors we estimate the T_{90} (T_{50}) duration of the event – the time within which 90% (50%) of the 50–300 keV event counts are collected – to be 2.1 s (0.2 s), placing GRB090510 within the short GRB range (see also Supplementary Information 2-A). We estimate the photon-energy associated delays (spectral-lags) of the emission, using two independent methods (described in Supplementary Information 2-B). We find no lags below 1 MeV (in agreement with the thus far known short GRB lags in that energy range), and above 30 MeV; however, we find that the bulk of the photons above 30 MeV arrive 258 ± 34 ms later than those below 1 MeV.

We performed combined GBM+LAT spectral-fits from $T_0 - 0.1$ s to $T_0 + 2.0$ s (Table 1; see Supplementary Information 3). The *time-integrated* spectrum from $T_0+0.5$ s to $T_0+1.0$ s is best fit by two spectral components: a Band function (two power-laws smoothly joined near the peak photon-energy, E_{peak}) and a power-law. The addition of the latter component with a photon-index of -1.62 ± 0.03 significantly improves the fit ($>5 \sigma$) compared to a single Band function and fits the data up to the highest-energy (31 GeV) photon (see Fig. 2a). We obtain $E_{\text{peak}} = 3.9 \pm 0.3$ MeV - the highest Band function E_{peak} ever measured in a GRB time-integrated spectrum. *Time-resolved* spectroscopy (Fig. 2c) from $T_0 + 0.5$ s to $T_0 + 0.8$ s, indicates that the GRB spectrum evolves from soft to hard (see also Table 1). The two spectral components (Band and power-law) show significant temporal correlation (while they are both detected; see supplementary information 3-A-3), suggesting that they originate from the same physical region (the 200 s extended LAT emission is not reported in this paper).

The progressively harder spectral behavior in GRB 090510 may be key to understanding particle acceleration and radiation in short GRBs. If the low-energy (10 keV – 10 MeV) spectral component is synchrotron radiation from non-thermal electrons, the high-energy (>10 MeV) power-law component may be synchrotron self-Compton^{16,17}. However, the ~ 0.1 – 0.2 s observed delayed onset of the LAT high-energy photons is not expected in the simplest leptonic models unless magnetic fields, electron energy distribution or outflow Lorentz factors change rapidly during the GRB. A hadronic γ -ray emission component could arise from ultra-relativistic protons and ions, either through photo-meson¹⁸ or synchrotron¹⁹ processes. In the latter case, short GRBs would have to accelerate protons and ions to ultra-high energies, making short GRBs a possible source of ultra-high-energy cosmic rays, along with long GRBs and active

galactic nuclei. This requires, however, a much larger total energy than that observed in γ -rays, thus straining the GRB energy-budget. The similarity in the high-energy emission of short and long GRBs, including delayed onset and temporally extended \sim GeV radiation²⁰, suggests similarities in the underlying radiation physics of these two classes of GRBs, despite the currently prevailing paradigm that short GRBs originate from the coalescence of two neutron-stars or a neutron-star and a black-hole², whereas the long GRBs progenitors are very massive, rapidly rotating stars³.

The distance of GRB 090510 is at the high-end of the redshift range for short GRBs and implies a very energetic event²¹. The total (0.5–1.0 s) energy fluence measured in the 10 keV – 30 GeV band is $(5.02 \pm 0.26) \times 10^{-5}$ ergs/cm², implying a total apparent isotropic energy release of $\approx (1.08 \pm 0.06) \times 10^{53}$ erg. The high-energy spectral component accounts for \sim 37% of the total fluence. The fluence could be higher if the emission extends to higher energies. However, the attenuation of the highest-energy photons by the extragalactic background light has a negligible ($\leq 1\%$) effect on the fluence in the observed energy-range (see Supplementary Information 4).

The spectra at the time intervals 0.6 s – 0.8 s and 0.8 s – 0.9 s include a 3.4 GeV and a 31 GeV photon, respectively. Such high-energy photons may pair-produce ($\gamma\gamma \rightarrow e^+e^-$) with radiation within the emitting region. To avoid such intrinsic attenuation, the emitting region must move toward the observer ultra-relativistically^{22,23}. Thus for the 3.4 GeV and 31 GeV photons to pass through the lower-energy radiation within the source without pair-producing, the implied lower limits on the region bulk Lorentz factors, Γ_{\min} , are 950 ± 40 and 1220 ± 60 , respectively (see Supplementary Information 5 for details). The Γ_{\min} values we obtain for GRB090510 are the highest for any GRB²⁰,

and by far the highest for a short GRB²¹. This suggests that the outflows powering short GRBs are at least as highly relativistic as those powering long GRBs.

Finally, the detection of multi-GeV photons < 1 s from the onset of GRB 090510, and its known distance, allow us to tightly constrain Lorentz Invariance Violation (LIV). Some quantum-gravity theories²⁴ predict LIV, where the photon-propagation speed v_{ph} depends on its energy E_{ph} and is expected to significantly differ from the (low-energy) speed of light, $c \equiv v_{\text{ph}}(E_{\text{ph}} \rightarrow 0)$ only near the Planck scale ($E_{\text{ph}} \sim M_{\text{Planck}}c^2 \approx 1.22 \times 10^{19}$ GeV)²⁴. For $E_{\text{ph}} \ll M_{\text{Planck}}c^2$ the leading LIV term is expected to be $|v_{\text{ph}}/c - 1| \sim (E_{\text{ph}}/M_{\text{QG},n}c^2)^n$ where $n = 1$ or 2 is usually assumed. For linear LIV ($n = 1$), this induces a difference $\Delta t = (\Delta E/M_{\text{QG},1}c^2)D/c$ in the arrival time of photons emitted simultaneously at a distance D from us, and differing by $\Delta E = E_{\text{high}} - E_{\text{low}}$ (at cosmological distances this simple expression is somewhat modified; see Supplementary Information 6-A). Because of their short duration and cosmological distances GRBs are well-suited for constraining LIV^{24,25,20}.

When allowing for LIV-induced time-delays, the measured arrival time, t_{h} , of the high-energy photons might not directly reflect their emission time, t_{em} (i.e. their arrival time if $v_{\text{ph}} = c$). Therefore, we make reasonably conservative assumptions on t_{em} , based on the observed lower-energy emission (for which LIV-induced time-delays are relatively negligible). To constrain a positive time-delay ($v_{\text{ph}} < c$ implying $t_{\text{h}} > t_{\text{em}}$) we assume that $t_{\text{em}} > t_{\text{start}}$, where t_{start} (see Fig. 1) corresponds to the onsets of the various lower-energy emission episodes at different photon-energies (see Supplementary Information 6 for discussion). This implies $\Delta t < t_{\text{h}} - t_{\text{start}}$ and thus sets a lower-limit on M_{QG} . For linear LIV ($n = 1$), the tightest limit can be placed by the photon with the highest $E_{\text{high}}/\Delta t$,

which in GRB 090510, is the 31 GeV photon. We conservatively use the 1- σ lower-limits on the GRB redshift ($z = 0.900$) and photon energy (28.0 GeV; Table 2). Table 2 shows the resulting lower-limits on $M_{\text{QG},1}$ for the different assumed values of t_{start} for a positive time delay (see limits (a)–(d)), as well as time-delays of either sign, including negative ones ($v_{\text{ph}} > c$ implying $t_{\text{h}} < t_{\text{em}}$; limits (e)–(g)); these limits are all above M_{Planck} .

Our new limit, $M_{\text{QG},1}/M_{\text{Planck}} \geq \text{several}$ (see Table 2), is much stronger than the previous best limit of this kind ($M_{\text{QG},1}/M_{\text{Planck}} \geq 0.1$ from GRB080916C²⁰) and fundamentally more meaningful. Since, in most quantum gravity scenarios, $M_{\text{QG},n} \ll M_{\text{Planck}}$, even our most conservative limit (Table 2; (a)) greatly reduces the parameter space for $n=1$ models^{26,27}. Our intermediate limits (Table 2; (b)–(d)), and even more so, our least conservative limit (Table 2; (e): $M_{\text{QG},1}/M_{\text{Planck}} > 102$), based on associating the 31 GeV photon with the contemporaneous low-energy spike, makes such theories highly implausible (models with $n > 1$ are not significantly constrained by our results). Thus, we do not expect to see any evidence for other predictions of such $n = 1$ models, such as a reduction in the absorption of ≥ 10 TeV γ -rays by $\gamma\gamma \rightarrow e^+e^-$ interactions with extragalactic infrared photons²⁸ due to an increase in the required threshold energy, that would make the universe more transparent to γ -rays than expected^{29,30}.

Acknowledgements The Fermi LAT Collaboration acknowledges support from a number of agencies and institutes for both development and the operation of the LAT as well as scientific data analysis. These include NASA and DOE in the United States, CEA/Irfu and IN2P3/CNRS in France, ASI and INFN in Italy, MEXT, KEK, and JAXA in Japan, and the K. A. Wallenberg Foundation, the Swedish Research Council and the National Space Board in Sweden. Additional support from INAF in Italy for science analysis during the operations phase is also gratefully acknowledged. J.G. gratefully acknowledges a Royal Society Wolfson Research Merit Award. The Fermi GBM Collaboration acknowledges the support of NASA in the United States and DRL in Germany. We are grateful to John Ellis for helpful comments.

All authors contributed extensively to the work presented in this paper.

Table 1 | Prompt Emission Spectral Fit Parameters

T – T ₀ (s)	Model	Band				PL or Comptonized			Castor

Upper section: fits of the time-integrated spectrum of GRB090510 from T₀+0.5 s to T₀+1.0 s. The Band+PL model improves significantly (>5 σ) the fit compared to the standard Band function. The Band+Comptonized fit implies a lower-limit of 4 GeV for the energy of a possible spectral-break (softening) in the additional power-law. The various models are compared using the castor Castor statistic (C-stat), which is a likelihood method similar to χ² when there is high enough statistics. Simple comparison of the C-stat values and degrees of freedom between the various models allows us determine the best model.

Lower section: best-fit spectral-models of GBM+LAT data for each selected time-interval from T₀+0.5 s to T₀+1.0 s, corresponding to the main GBM emission episode. The spectrum during 0.6 – 0.8 s shows a clear excess relative to a single Band function at high energies, which is

best fitted with an additional power-law, indicating an additional spectral component. At 0.8 – 0.9 s, the additional component is not statistically justified anymore and both a Band function and Band+PL provide a good fit, if we fix β to its value from the previous time bin. At later times, a single Band function is marginally preferred over a Band+PL fit.

Table 2 | Limits on Lorentz Invariance Violation

#	$t_{\text{start}} - T_0$ (ms)	Limit on $ \Delta t $ (ms)	Reasoning for choice of t_{start} or limit on Δt or $ \Delta t/\Delta E $	E_i^\dagger (MeV)	Valid for s_n^*	Lower limit on $M_{\text{QG},1}/M_{\text{Planck}}$
(a)*	-30	< 859	start of any < 1 MeV emission	0.1	1	> 1.19
(b)*	530	< 299	start of main < 1 MeV emission	0.1	1	> 3.42
(c)*	648	< 181	start of main > 0.1 GeV emission	100	1	> 5.63
(d)*	730	< 99	start of > 1 GeV emission	1000	1	> 10.0
(e)*	—	< 10	association with < 1 MeV spike	0.1	± 1	> 102
(f)*	—	< 19	If 0.75 GeV ‡ γ -ray from 1 st spike	0.1	-1	> 1.33
(g) [^]	$ \Delta t/\Delta E < 30 \text{ ms/GeV}$		lag analysis of > 1 GeV spikes	—	± 1	> 1.22

Details for the derivations of these limits are given in the Supplementary Information. Limits (a) through (e) rely on the 31 GeV photon, and use the 1- σ lower limit on its energy (28.0 GeV).

The 1- σ lower limit on the redshift ($z = 0.900$) is used for all our limits.

[†]The typical energy of the low-energy photons that were used for reference.

* $s_n = 1$ and -1 stand for a positive ($v_{\text{ph}} < c$) and negative ($v_{\text{ph}} > c$) time-delay, respectively.

[‡]We conservatively used the 1- σ lower limit on this photon's energy (0.694 GeV).

*The different choices of t_{start} in limits (a)–(d) are ordered from the most conservative, (a), to the somewhat less conservative but still very reasonable, (d); for a detailed discussion see the Supplementary Information 6.

*We constrain time-delays of either sign, including negative ones ($v_{\text{ph}} > c$ implying $t_{\text{h}} < t_{\text{em}}$) using two methods; (e)–(f) by associating two high-energy photons with contemporaneous spikes in the low-energy lightcurve (see also the gray shaded regions in Fig. 1).

[^](g) by testing for an energy-dispersion in the high-energy lightcurves (that might smear the sharp observed spikes) we find an upper limit for a linear dispersion of photons above 100 MeV of $|\Delta t/\Delta E| < 30 \text{ ms/GeV}$ (at 99% confidence; see Supplementary information 2-B-2).

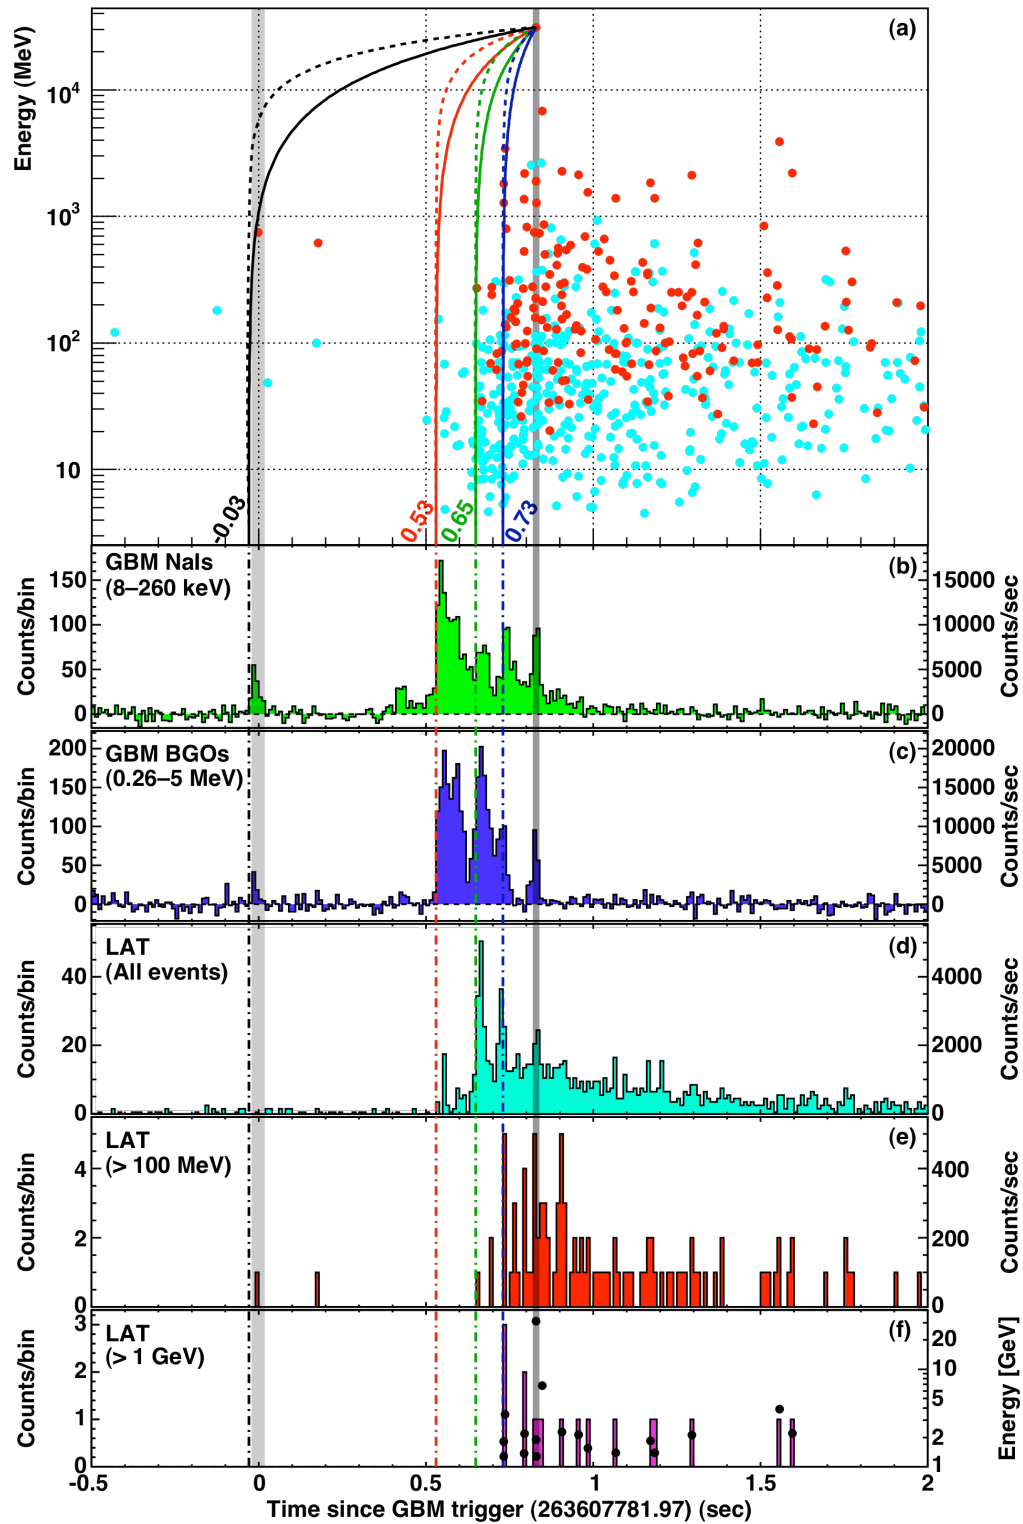

Figure 1. Panel (a): energy vs. arrival time w.r.t the GBM trigger time for the 160 LAT photons that passed the transient off-line event selection (*red*) and the

161 photons that passed the onboard γ -ray filter (*cyan*), and are consistent with the direction of GRB 090510. The *solid* and *dashed* curves are normalized to pass through the highest energy (31 GeV) photon and represent the relation between a photon's energy and arrival time for linear ($n=1$) and quadratic ($n=2$) LIV, respectively, assuming it is emitted at $t_{\text{start}} - T_0 = -30$ ms (*black*; first small GBM pulse onset), 530 ms (*red*; main $< \text{MeV}$ emission onset), 648 ms (*green*; > 100 MeV emission onset), 730 ms (*blue*; $> \text{GeV}$ emission onset). Photons emitted at t_{start} would be located along such a line due to (a positive) LIV induced time delay. **Panels (b)–(f)**: GBM and LAT lightcurves, from lowest to highest energies. Panel (f) also overlays energy vs. arrival time for each photon, with the energy scale displayed on the right side. The *dashed-dotted* vertical lines show our 4 different possible choices for t_{start} . The gray shaded regions indicate the arrival time of the 31 GeV photon ± 10 ms (*on the right*) and of a 750 MeV photon (*during the first GBM pulse*) ± 20 ms (*on the left*), which can both constrain a negative time delay. Panels (b) and (c) show background subtracted lightcurves for GBM NaI in the 8–260 keV band and a GBM BGO in the 0.260–5 MeV band, respectively. **Panels (d)–(f)** show, respectively, LAT events passing the onboard γ -ray filter, LAT transient class events with $E > 100$ MeV, and LAT transient class events with $E > 1$ GeV. In all lightcurves, the time-bin width is 10 ms. In panels (b)–(e) the per-second count rate is displayed on the right for convenience.

Figure 2. Panel (a): time-integrated count-spectrum from $T_0+0.5$ s to $T_0+1.0$ s.

Following a ~ 0.5 s gap after the first GBM small peak, comes the most intense part of the burst, comprising 5 pulses, lasting from $\sim T_0+0.5$ s to $\sim T_0+0.9$ s. The peak of the emission (at $T_0+0.54$ s), appears during the second pulse, which is detected up to ~ 10

MeV with significant substructure. The third pulse however, although weaker, shows up to much higher energies (~ 40 MeV) and is visible in GBM and in the LAT all-events light curve, showing a delayed onset of the high-energy emission. The overall LAT emission is visible for ~ 200 s. Front and back LAT events are analyzed as if from separate detectors; the signal is highly significant up to ~ 5 GeV. The data are adequately fit by a Band+PL spectrum as indicated by the fit-residuals. **Panel (b)**: best-fit spectral model (Band+PL) for the time-integrated (0.5 – 1.0 s) spectrum (see also text and upper part of Table 1). **Panel (c)**: spectral evolution from $T_0+0.5$ s to $T_0+1.0$ s (see also lower part of Table 1). While a single component (Band function with a very soft β) is adequate during $T_0+(0.5 - 0.6)$ s, an additional power-law component is required only at $T_0+(0.6 - 0.8)$ s. After $T_0+0.9$ s the signal in GBM is too weak and the LAT only data can be fit by a power-law. However, this power-law is inconsistent with the GBM upper-limits, requiring a spectral break between the LAT and GBM energy-range
