ABSTRACT

- A. -

As a precursor to the ESR and relaxation studies, measurements of the dielectric conscants and loss for pure single crystals of calcium tungstate have been made at 1 MHz and room temperature giving values of $\varepsilon_A^* = 11.3 \pm 0.4$, $\varepsilon_C^* = 9.1 \pm 0.4$ a company and a company of the comp
The company of the c -3 Our measurements were extended to frequencies up to 80 MHz and to samples doped with neodymium and gadolinium.

A detailed investigation has been made of the splitting of the ESR transitions in low concentration $\text{Gd}^{3+}/\text{CaWO}_A$, reported first By Buckley in 1973; this has led to the proposition of different Gd environments in both of which Gd substitutes for and oxygen vacancy model giving α risk giving different to Gd environments in both of which α substitute s for α respectively. The simulations is for α

Spin-lattice relaxation measurements for Gd^{3+} /CaWO_A were carried out at 37.5 GHz and in the temperature range from 4.2 K to 30 K. The relaxation in the 'direct' region agrees with carrie d out at 37.5 GHz and i n the temperature range from 4.2 K preliminary measurements reported by Thorp et al, 1974, i.e. to 30 K. The relaxation n in the relaxation $\mathcal{L}^{\mathcal{L}}$ is the 'direct ' region agrees with $\mathcal{L}^{\mathcal{L}}$ p and p all p all p all p all p all p all p . Those is also taken by \mathcal{L} The second term of the change from direction of \mathbf{A} . $\begin{bmatrix} a & b \\ 1 & a \end{bmatrix}$ and $\begin{bmatrix} a & b \\ c & d \end{bmatrix}$ and $\begin{bmatrix} a & b \\ c & d \end{bmatrix}$ follows behaviour in the intensity competature range is explained by the assumption of crystal imperfections. Measurements of spin-lattice relaxation were also made for $Fe^{3+}/$ MgO in the same temperature range; here a $T^{-4.6}$ variation was found in the Raman region and the transition temperature

 $\mathcal{F}_{\mathcal{F}}$, the same temperature range; here a T $\mathcal{F}_{\mathcal{F}}$ is not a T $\mathcal{F}_{\mathcal{F}}$ and $\mathcal{F}_{\mathcal{F}}$

was found in the Raman region and the transition and the transition \mathcal{C}

between the direct and Raman processes was about 20 K. The data provided another example of an S-state ion behaving in the manner predicted by the present theories of relaxation.

In the last chapter an account is given of the combined use of ESR and TEM (Transmission Electron Microscopy) techniques, in an investigation of the role of impurities (mainly iron) in the growth of cavities in neutron-irradiated magnesium oxide crystals .

ACKNOWLEDGEMENTS

I wish to express my thanks to many people to whom I owe a debt of gratitude. Special mention must be made of the following :

The University of Alexandria, Egypt, for the award of a research scholarship to study for the degree of Ph.D. in the United Kingdom.

My supervisor, Dr. J. S. Thorp, for his unfailing guidance, suggestions and helpful discussions.

Professor D. A. Wright for the use of the research facilities in the Department, and to the technical staff, headed by Mr. Frank Spence, for their assistance. In particular I would like to thank Mr. Ron Waite, Mr. Colin Savage and Mr. Trevor Harcourt for their help.

Dr. G. Brown and Dr. G. J. Russell for their fruitful collaboration and helpful discussions.

My colleagues in the Department, especially Mr. William Hutton and Miss Linda Grange for their useful discussions and co-operation.

Mrs. J. Henderson for typing this thesis and Mrs. E. Johnston for the tracing of the drawings.

E.A.E. Ammaz

CHAPTER

- 1 -

INTRODUCTION

1.1 The aim of the work

Paramagnetic resonance measurements for gadolinium trivalent ions (Gd^{3+}) in single crystals of calcium tungstate (CaWO_4) were reported first by Hempstead and Bowers, 1959 (1). These authors stated some principal advantages for using CaWO_{Λ} as a host lattice. These were mainly that the paramagnetic ion in a CaWO_{$_A$} lattice substitutes for a calcium ion leading to an identified single spectrum; its small linewidth, since the width contribution from the nuclear magnetic moments of the neighbouring ions is practically negligible, and the suitability of the material because of its hardness and stability. They concluded that Gd^+ makes a potentially useful material for three-level masers. Previously, Scovil, Feher and Seidel, 1957 (2) showed that gadolinium ethyl sulphate operates as a solid state maser and the ion G^{3+} seems suitable since its eight energy levels give the choice of several modes of maser operation.

Calcium tungstate assumed technological importance in the 1960's with the discovery that single crystals could be grown doped with neodymium (Nd^{3+}) in concentrations suitable for laser action, Johnson et al, 1962 (3). More recently there have been interests in scheelite structure tungstates and molybdates for acousto-optic device structur e tungstates and molybdates fo r acousto-optic device

These applications of scheelite structure crystals have stimulated studies of crystal growth, doping, defects, thermal and optical vibrational properties, elastic properties (Farley, 1973 (4)) and electron spin resonance measurements (Buckley, 1973 (5)). Investigation

of the ESR linewidths for $\text{Nd}^{3+}/\text{CaWO}_4$ at 35 GHz and 4.2 K was undertaken by G Brown et al, 1974 (6), both experimentally and theoretically for a range of neodymium concentrations. They concluded that the homogeneous broadening was found to be due almost exclusively to the Nd-Nd dipolar interaction indicating that the Nd^{3+} ions replace the calcium ions substitutionally in the CaWO, host lattice. A similar study for $Gd^{3+}/CaWO^A$ was reported by J S Thorp et al, 1974 (7) and their results could be regarded as additional evidence for the validity of the Gd-Gd dipolar interaction in determining the angular variation of the linewidths. This, also, implied that the Gd^{3+} ions enter the host lattice of $CaWO_A$ substitutionally at the calcium sites.

Furthermore, a study on $\text{Gd}^{3+}/\text{CaWO}_{4}$ was initiated by Thorp, $\frac{1}{\sqrt{2}}$ was interested by Thorp, a study on God $\frac{1}{\sqrt{2}}$ tion behaviour of this material at 37.5 GHz. They indicated that, over the temperature range from 1.5 to 8 K, the recovery was dominated by the direct process.

The main aim of our present studies is to investigate some problems encountered in the preceding studies on pure and gadoliniumdoped calcium tungstate. These remaining problems, regarding CaWO_A doped calcium tungstate. These remaining problems, regarding CaWO^

1. The previous published data about the dielectric constants of pure CaWO₄, by Komandin et al, 1960 (9) and Brower and Fang, 1969 (10), revealed an apparent discrepancy in the results. So we found it appropriate to make new measurements, provided in Chapter 2 , as a contribution to solving this problem. Moreover, we extended these dielectric measurements to samples of CaWO_{$_A$} single crystals doped with gadolinium and neodymium for which, to our knowledge, no previous

- 2 -

data were published. Although measurements of dielectric constants are not of a direct concern in the ESR and relaxation studies, knowledge of the dielectric behaviour of these materials is needed for the matching conditions for the ESR spectrometers.

2. The splitting of the gadolinium transitions observed in the studies of $\text{Gd}^{3+}/\text{CaWO}_{4}$ reported by H P Buckley, 1973 (5) was a rather interesting phenomenon. In Chapter 3 , we are going to investigate the cause and nature of this splitting. We suggest that this may be due to ordered oxygen vacancies in the calcium tungstate lattice.

3. The study of the spin-lattice relaxation behaviour of Gd^{3T}/CaWO_A with temperature reported by Thorp, Buckley and Brown, 1974 (8) revealed that the relaxation displayed a direct process in as far as E K. Subsequently, our aim was to extend the range of temperature and to investigate the spin-lattice relaxation at high temperatures. This is discussed in Chapter 4.

As regards magnesium oxide (MgO), the interest in its study began initially with some industrial problems. Magnesium $oxide$, because of its insulating properties, is used very often as an insulator in heating elements. It has been found that at rather high temperatures (\sim 800°C) the insulating behaviour of the MgO collapses and, consequently, the material conducts leading to the failure of the heating element. It has been suggested that the diffusion of impurities from the sheath of the element, mainly iron, into the magnesium oxide could be a possible explanation for the occurrence of such breakdown; nonetheless, this argument has not been proved yet and is still under study in this Department. Besides the current measurements of electrical conductivity and dielectric

the current measurements of electrical l conductivity α and dielectrical linear dielectrica l conductivity α

- 3 -

losses in pure and doped magnesium oxide, ESR studies on iron doped magnesium oxide were carried out in this group (Vasquez, 1975 (11) and Thorp et al, 1976 (12)).

Moreover, we were able to extend our. studies on magnesium oxide to a rather different field of interest. That is, the study of the damage caused by neutron-irradiated MgO samples and the consequent nucleation and growth of cavities when annealing these samples in an ambient of argon. The role of iron impurities in MgO is investigated in our studies. Thus, our aim in studying magnesium oxide is presented in the following.

1. With the forementioned interests in studying MgO in this Department, we found it appropriate to extend our knowledge about Fe³⁺/MaO by studying its relaxation behaviour at 37.5 GHz. This was intended as another example of an S-state ion in a cubic lattice to be compared with Gd^{3+} in the scheelite structure (tetragonal system) which is presented in Chapters 3 and 4. This study of the irondoped magnesium oxide crystals is dealt with in Chapter 5.

doped magnesium oxide crystal s i s deal t wit h i n Chapter 5.

2. The knowledge acquired from the ESR studies of iron-doped magnesium oxide was helpful in the interpretation of the ESR spectra of the annealed neutron-irradiated MgO crystals. This was achieved by collaboration with G J Russell (13) who provided the samples and made transmission electron microscope (TEM) studies on them. Transmission electron microscopy on its own was inadequate to identify impurities so the need for the ESR study as a complementary technique was necessary. ESR and TEM studies on the cavity growth in neutron irradiated magnesium oxide are presented in Chapter 6.

- 4 -

1.2 Paramagnetic relaxation

Spin-lattice relaxation is, in fact, one way of achieving thermal equilibrium for the spin system with the surrounding lattice. It is interesting to note that the phrase 'spin-lattice relaxation' is sometimes used even in other situations, such as noncrystalline or even liquid paramagnetic materials, where the term 'lattice' is not entirely appropriate and the relaxation process is rather different. In order to describe the mechanism whereby a spin system achieves thermal equilibrium within itself and with its surroundings three processes must be considered. These are spin-spin relaxation, cross relaxation and spin-lattice relaxation. The spin-spin relaxation is the process by means of which the spin system achieves thermal equilibrium within itself, cross relaxation is the attainment of equilibrium between spins of different species, while spin-lattice relaxation describes the way in which the spin system transfers energy to the lattice .

The first calculation of the spin-spin relaxation time T^2 was performed by Waller, 1932 (14) considering a simple $S = \frac{1}{2}$ system in low magnetic field. For pure paramagnetic salts with typical interatomic spacings of a few angstroms, $T_2 \simeq 10^{-9}$ sec, and even in magnetically dilute systems, T₂ is very short in comparison with the spinlattice relaxation time T_1 . An important conclusion is that since T^2 does not involve the lattice energy, it is essentially temperature The does not involve the lattice the lattice energy, i the lattice energy, i the lattice energy, i the lattice

In studying the case of $S > \frac{1}{2}$ or systems containing more than one type of spin centre, cross relaxation must be considered. This was discussed by Bloembergen et al, 1959 (15) and further by Grant, 1964 (16). When the levels of a single multi-level spin system are

-5.

FIG. 1-1 Diagramatic representation of cross relaxation between levels lb> and $|c\rangle$.

similar, but not identical (as depicted in Figure 1.1 where the levels $|b \rangle$ and $|c \rangle$ are close in energy and separated from level |a >) the difference in frequencies $(\nu \quad - \nu \quad)$ is very much less than $v_{\rm ab}$ or $v_{\rm ac}$. The spin energy may then be transferred by the transition of one, or more, excited ions (in level $|c \rangle$) to their ground state (level $|a \rangle$) with the simultaneous transition of a nonexcited ion (level $|$ a>) to an excited state (level $|$ b>); this conserves the Zeeman energy, the small unbalance of energy being taken up by the dipolar or internal energy of the spin system.

Other energy-level situations are considered by Bloembergen et al, wherein pairs of levels occurred with similar but not identical separations as illustrated in Figure 1.2. Cross relaxation can also be effective even when the levels $|$ b > and $|$ c > are quite widely separated (Figure 1.2b). It was mentioned by Standley and Vaughan, 1969 (17) that Figure 1.2a is appropriate to Ni^{2+} in an axial crystal field and a moderate magnetic field and Figure 1.2b is an example of the cr^{3+} ion in an axial field. In general, cross relaxation can occur within the spin system Λ and B with a finite transition probability with $(m + n)$ spins taking part, when m spins of type A flip up say while n spins of type B flip down so that

$$
m (h v_{ab}) = n (h v_{ac}) \qquad (1.1)
$$

The probability of this process occurring is very likely to be small unless m and n are integers close to unity. This process has become known as 'harmonic cross-relaxation'. Measurements of crossrelaxation times T_{12} (Pershan, 1960 (18), Mims and McGee, 1960 (19)), and harmonic cross-relaxation (Kopvillem, 1961 (20)) are in fairly

fli p up say while n spins of type B flight so that the type B flight so that the type B flight so that the type B

- 6 -

(a)

(b)

FIG. 1-2 Another energy-level system wherein cross relaxation is probable to occur. highly

good agreement with the theories of Bloembergen and Grant. In the context of our studies it is concluded that the minima observed in the angular plot of the spin-lattice relaxation times of Fe³⁺/MqO are probably due to such effects of cross-relaxation as mentioned **a re probably due to such effect s of cross-relaxatio n as mentioned**

1.3 The measurement of relaxation time

Several authors have described the methods which have been widely used for the determination of spin-lattice relaxation. These methods could be classified as :-

- **(a) Resonant methods**
	- **1. CW saturation (Eschefelder and Weidner, 1953 (21))**
	- 2. DC magnetization (Feng and Eloembergen, 1963 (22))
	- **3. Pulse saturdation (Davis, Strandberg and Kyhl, 1958 (23))**
	- 4. Inversion recovery (Castle, Chester and Wagner, 1960 (24))
	- **5. Pulse response (Brown and Thorp, 1967 (25))**
	- **6.** AC saturation (Herve and Pescia, 1960 (26))
	- 7. Ultrasonic method (Dobrov and Browne, 1963 (27))
- **(b) Non-resonant methods**
	- **1.. Absorption methods**
	- **2. Dispersion measurements**
	- **3.** Measurements at liquid helium temperature.

The experimental results of the latter methods have been summarized **and discussed by Gorter, 1947 (28) and Cooke, 1950 (29) . The concentrate d magnetic salt s usuall y employed i n the non-resonant experiments do not conform at al l to the models used i n the theoretica l approaches** **to spin-lattic e relaxation , nor are the parameters determined generall y directl y comparable with those found by the resonance techniques (17).**

In our measurements we adopted the pulse saturation method both for being a widely accepted technique for measuring spin-lattice **relaxatio n times and als o fo r the sake of comparison with previous** results (8) that were already made with this technique.

i.3.1 The pulse saturation method

This technique has been used many times, principally by **Davis, Strandberg and Kyhl, 1958 (23), Bowers and Mims, 1959 (30),** Pace, Sampson and Thorp, 1960 (31). Recently it was used by **H** P Buckley, 1973 (5) for preliminary studies of T_1 for $Gd^{3+}/CawO_A$. The method employs two klystrons; one for monitoring the resonance (low power klystron) and the other for providing a saturating pulse (high power klystron) at the same frequency. The saturating pulse equalizes the populations of the two spin levels being investigated and hence absorption of power from the monitor klystron siezes to **accur.** After the end of the pulse the populations of the levels begin to revert to their thermal equilibrium values, and as this **begin to the intereasing amount of power is absorbed from the monitor** klystron. The receiver picks up this increasing absorption signal and it is recorded as a function of time on a cathode-ray oscilloscope. By definition, the spin levels revert to their undisturbed state in \mathbf{a} an exponential manner, the time constant of which is the spin lattice relaxation time T_1 , and it is this exponential which is recorded on the display. Figure 1.3 shows a block diagram of the circuitry of the Q-band spectrometer used for these measurements with the

of the Q-band spectrometer used fo r these measurements with the

- 8 -

10 c 5

facilities required for the pulse saturation method. This has become the standard technique for measuring relaxation times; it is theo**reticall y possibl e fo r thi s method to resolve any number of relaxa** tion times which may be present. This is demonstrated in our measure-ments of T_1 for Fe^{3+}/MgO where two components in the recovery traces **were observed (Chapter 5).**

- 9 -

1*o***3.2 Relaxation rat e equations**

When a spin makes a relaxation transition in one direction or the other, it simultaneously exchanges a quantum of energy with **the lattic e thermal vibration s and, hence, i t i s termed 'spin-lattic e relaxation ¹ . A treatment to derive the relaxatio n rat e equations** was reported by Siegman, 1964 (32) which led to the form

$$
\Delta n(t) = \Delta N + (\Delta n_0 - \Delta N) e^{-(\omega_{12} + \omega_{21})t}
$$
 (1.2)

This says that if the population difference Δn is initially somehow **perturbed away from the thermal-equilibrium value AN, then the relaxatio n process wil l ac t to return the system to thermal equilib** rium with a relaxation time constant which can be written as $T_i = (\omega_{12} + \omega_{21})$; the spin-lattice relaxation time. (It is some**times als o termed the longitudina l relaxatio n time T) . The terms** and ω_{21} are the upward and downward relaxation transiti probabilities per spin per unit time, respectively. In the case **which usuall y applie s a t microwave frequencies, the condition**

$$
(E_2 - E_1) / kT \ll 1
$$
 (1.3)

is obeyed, where $(E^{\text{}}_2 - E^{\text{}}_1)$ is the energy difference between levels **2** and **1**, then the approximation $\omega_{12} = \omega_{21}$ may be made in which case

$$
T_1 = 1/2\omega_{12} \tag{1.4}
$$

This was evaluated for a two-level spin system. Generally, in the case of a multilevel spin system containing p levels, relaxation. **wil l be a complex process involving al l the levels , and the general th rat e equation for the i leve l wil l be**

$$
\frac{d n_i}{dt} = \sum_{\substack{j=1 \ j \neq i}}^p (\omega_{ji} n_j - \omega_{ij} n_i)
$$
 (1.5)

where n_i is the spin population of the ith level, and the transition **probabilitie s between any two level s wil l be i n the Boltzmann rati o** of the populations of those two levels

$$
\omega_{ij}/\omega_{ji} = \exp\left[(E_j - E_i)/kT \right]
$$
 (1.6)

The relaxation behaviour of the system will be controlled by $(p - 1)$ $relaxation times T₁$ ^(ij), where

$$
T_1^{(ij)} = (\omega_{ij} + \omega_{ji})^{-1}
$$
 (1.7)

Using this relation, the rate equation for the ith level can be writte n i n the form

$$
\frac{d n_i}{dt} = -\sum_{j=1}^{p} \frac{\Delta n_{ij} - \left[(n_i + n_j) / (N_i + N_j) \right] \Delta N_{ij}}{2 T_1^{ij}} + W_{ij} \Delta n_{ij}
$$
 (1.8)
 $j \neq i$

where N_i , n_i are the thermal-equilibrium population and the instantaneous population of level i also,

$$
\begin{array}{rcl}\n\Delta n_{i,j} &=& n_i - n_j \\
\Delta N_{i,j} &=& N_i - N_j\n\end{array}\n\qquad \text{(1.9)}
$$

The solution of equation (1.8) for the time varying population of level i will be the sum of exponential terms of the form

$$
n_{i} (t) = n_{i0} + \sum_{j=1}^{p} C_{i j} \exp - (t/T_{1}^{i j})
$$
 (1.10)

which must be evaluated numerically. In experiments, the relaxation behaviou r of a particula r leve l wil l frequentl y be dominated by one of th e I'^^^'s , havin g a larg e amplitud e constan t ^c ^ j ^f anc ^ thi s wil ^l be the time constant of the observed relaxation recovery, although more than one exponential may be observed.

1.4 Experimenta l Technique s

Pegarding the ESR measurements we have used a conventional **Q-band spectromete r wit h a low power refle x klystro n working ove r a** frequency range 33.0 - 37.75 GHz, with facilities for broad-line **ESR displa y and puls e saturatio n relaxatio n time measurements. The experimenta l arrangement of th e spectromete r i s shown i n bloc k diagram form i n Figur e 1.3. Thi s spectromete r was running previousl y** with a superhet detection system, e.g. as reported by Kirkby, 1967 (33). Buckley in 1973 (5) found that, without using the superhet detection s ystem, the phase-sensitive detector was sufficient to produce **relativel y nois e fre e signals . I n our presen t work we ar e adopting Buckley' s techniqu e sinc e i t has prove d it s reliability . We ar e not going t o discus s the functio n o f th e spectromete r i n detai l sinc e a** thorough study of spectroscopic techniques at millimetric wavelengths had been reported by G Brown, 1967 (34) in this group.

However, there is a specific feature for our Q-band spectro**meter tha t makes i t slightl y differen t from other conventional ones.** This is that we are not using a proper cavity to contain the paramagnetic sample. Instead, we have short-circuited the waveguide by a brass plunger which was fitted inside the end of the waveguide where the outside d.c. magnetic field could be applied to the sample. **The only disadvantage i n vsing thi s technique i s the reduction of the Q-factor of the system\ which was estimated by Kirkby (using a technique described by Montgomery, 1948 (35)) as an unloaded value of around 400.** On the other hand, the absence of a cavity made it **easie r for the settin g of the two klystron s used during measurements of spin-lattic e relaxatio n time. Besides, we were able to use simpler cryogenic facilitie s than would have been possibl e with a large r cavit y i n the restricte d pole-piece gap.**

The low power signal source was an E.M.I. reflex klystron type R9546, mounted in an oil-bath for good frequency stability. **Measurement of frequency was made by means of a combined transmission**absorption wavemeter, which was also used in relaxation measurements for bringing the high power klystron frequency into coincidence with the signal klystron. The high power saturating pulses were obtained **from an Elliot t water-cooled klystron , type 4TFK4 working around** 37.5 GHz and fed into the system by means of a manual switch. The **bridge element was a magic tee by which the microwave power entering** from arm 1 was split equally between the sample arm 3 and the matching **arm 4 tha t composed of an E.H. tuner and a matched load. The two** reflected waves were detected in arm 2 with a crystal detector. In the off-resonance condition the E.H. tuner was adjusted until the **reflected power at the crystal detector was zero. This meant that** the reflected power from the sample was balanced out by the reflected

- 12 -

power from the adjustable E.H. tuner arm. Then, the bridge was taken **slightl y of f balanc e i n amplitud e onl y i n orde r to observe pur e absorptio n signal . When resonance occurre d an off-balanc e signa ^l was detected . Detectio n and displa y o f th e absorptio n spectrum was carried out in several ways depending on the type of measurements t o be made. Fo r vide o displa y the signa l was fe d through a d.c. amplifie r t o an oscilloscope , usin g a larg e amplitud e 5C Hz modulation o f th e magnetic fiel d t o sweep completel y through each line . Thi s** 50 Hz modulation was achieved by placing an auxiliary modulation coil **designe d t o be a push fi t int o the magnet bore and it s magnetic fiel d bein g coaxia l wit h tha t o f the magnet. I n the cas e o f displayin g relaxatio n recover y traces , th e 50 His modulation was switche d off . I n** plotting derivatives of the absorption spectrum a higher sensitivity was found necessary and for this purpose a modulation of high frequency and small amplitude was used, together with phase-sensitive detection. **The system was then connected t o a pen-recorder , th e x-axi s of which was driven from the slow sweep of the magnetic field. The high frequenc y modulation was achieve d by usin g an oscillato r a t 160 kHz and coil s attache d t o the plunge r which terminate d th e waveguide such that the samples were nearly concentric with the coils. The magnetic** fields necessary for ESR at Q-band were found to be of the order of 1.5 tesla, with a homogeneity of better than 1 part in 10⁵ over a **1.5 tesla , wit h a homogeneity of bette r tha n 1 par t i n 10 ove r a** volume of 1 cm³. The calibration of the field was carried out using a combined proton-lithium magnetometer. The magnet used with this spectrometer was a Newport type D electromagnet provided with a $current$ stabilizing unit and a slow sweep unit. Cryogenic facilities **were used to enable measurements at liquid helium, liquid nitrogen** $temperatures and temperatures inter-between.$

- 13 -

1.4.1 Measurement of spin-lattice relaxation time T_1

Applying the pulse saturation method (Davis et al, 1958 (23)) we were able to measure the spin-lattice relaxation times for both $\texttt{Gd}^{3+}/\texttt{CaWO}$ (Chapter 4) and $\texttt{Fe}^{3+}/\texttt{MgO}$ (Chapter 5). With this technique **the behaviour qf the spin system was observed following the removal of a saturation pulse of the high power klystron (20 W); changes were monitored by observing the absorption of power from the low** power klystron (20 mW). As the spins relaxed after the pulse, and the population difference was restored towards thermal equilibrium, **the recovery trace s could be represented by the variatio n i n spi n** populations with time which obeyed either equation (1.2) or equation **(1.10), depending upon whether we are observing** *ona* **or more relaxatio n constants.**

Experimentally, the samples were oriented and the frequencies of the high power and monitor klystron s were brought int o coincidence using the transmission-absorption wavemeter. The spectrometer was then adjusted for balance and the magnetic field was set at the centre **of the absorption transition . Next,.saturation pulses with time** duration of 30 m sec and rate of repetition within 1-10 cycle/sec were **applied to the sample. The pulse trai n displayed on the oscilloscop e was of constant height, except for a slight 50 Hz ripple which was** due to the A.C. heaters. This was greatly improved by using a **separate D.C. supply for the klystron heaters. The relaxation to equilibrium, as monitored by the low power source, was displayed on** the C,R.O., using the d.c. amplifier. We used a Polaroid camera to **record the recovery curves photographically, using a slow pulse repetitio n rate . A typica l photograph i s shown i n Figure 1.4. The** relaxation times were derived from the photographs by replotting the ordinates (which are proportional to $\Delta n(t)$) in semilogarithmic form,

- 14 -

FIG. 1-4 Typical behaviour for relaxation of a simple spin system. **agains t time on a linea r scale . Thi s produced a singl e straigh t lin ^e 3+ ⁱ n the cas e of Gd /CaWO^ (Chapter 4, Figur e 4.4) and more than one** slope in the case of $Fe^{3+}/$ MgO (Chapter 5, Figure 5.1). CHAPTER 2

THE DIELECTRIC CONSTANT'S OF CaW04, Nd/CaW04 and Gd/CaW0⁴

2.1 Introductio ⁿ

Although two measurements of the dielectric constants of pure **calciu m tungstat e have been reporte ^d (1,2) , the value s quoted show a considerabl e divergence . I n the earlie r paper (1) , Komandin e t al , who** u an immersion method, stated that the dielectric constant was $\epsilon' = 21.4$ at 25[°]C and 1.72 MHz for solid material, apparently in powder form. Calcium tungstate, however, crystallizes in the scheelite structure; **it** belongs to the tetragonal system having $a = b = 5.243$ \overline{X} and $c = 11.376$ \overline{X} **(3); more detail s o f th e structur e ar e give n i n th e nsx t chapter , sectio ⁿ 3.1 . Consequently , two components ar e necessar y t o describ e the dielectric tensor.** In the later paper, Brower and Fang (2) gave results **f o r measurements on oriente d pure singl e crysta l slices . They found** that the dielectric constant was anisotropic, that the dielectric con**stan s paralle l t o th e a-axi s and c—axi s were 11.7 and 9.5 , respectively , ^a ^t 24.5°C, and tha t thes e value s were th e same fo r frequencie s o f 1.59 KHz and 1 MHz. The measurements reporte d her e were made primaril y t o clarif ^y t h e situatio n i n pur e calciu m tungstat e and als o t o obtai n dat a on some neodymium- and gadolinium-doped calciu m tungstat e singl e crystal s i n orde r to assis t optimizatio n of th e matching condition s durin g electro ⁿ spi n resonanc e and relaxatio n studie s i n them; t o our knowledge no previou ^s** $measurable on doped calcium tungstate have been published.$

2 . 2 Experimenta l

The single crystals used, (obtained from I.R.D. Co. Ltd., **Newcastle) , were grown by th e Czochralsk i method (4). I n the pure and** **gadolinium-doped crystals , charge compensation was achieve d by vacanc y incorporation , and i n the neodymium-doped crystal s by sodium eddition .** The single crystal boules, whose dimensions were typically 5 cm long and **1.5 cm diameter , were firs t oriente d by Lane back-reflectio n X-ray methods which gave orientation accuracies of** $\pm 15'$ **of arc. Specimens of known orientatio n were then prepare d by making appropriat e slice s wit h a diamond wheel cuttin g machine and precisio n polishin g thei r face s wit h diamond** paste to a 0.25 μ m finish. The larger faces of the specimens were limited by the boule dimensions to about 1 cm x 1 cm in area and were cut in the plane of either the a- or c-axis (see Figure 2.1). The specimen **thickness , usuall y 0.3 mm, represente d the minimum which coul d readil y be achieve d withou t fracturin g th e slic e durin g fabrication . Circula r gol d electrode s were deposite d by evaporatio n on th e large r polishe d face s t o ensur e good electrica l contac t over a define d are a between th e crysta l and th e electrode s o f th e dielectri c testin g jig .**

The measurements were made i n ai r a t room temperatur e ove r the frequenc y range 1 t o 40 MHz usin g a standar d Q~meter (Marconi TF 1245) and the oscillator (Marconi TF 1246). Measurements were then extended to **80 MHz usin g an oscillato r (Marconi TF 1247) whose operatin g range extended** from 20 to 300 MHz. The dielectric testing jig (Marconi TJ 155C/1) was **modifie d to allo w the use o f 10 o r 6 mm diamete r circula r ji g electrode s a s specimen dimensions were limite d by the siz e of th e singl e crystal s available . I n thi s technique , measurements were made firstl y wit h the specimen mounted i n th e ji g and secondly , a t the same ji g electrod e** s pacing, without the specimen. The difference in capacity enabled the **real** part of the dielectric constant, ε ', to be derived; in a similar **manner the difference in Q-value with and without the specimen allowed t h e dielectri c loss , ta n 6 , t o be evaluated .**

- 17 -

FIG. 2**-1 General form of specimens and dielectric testing jig.**

2.3 Derivatio n o f e ¹ and tan 6

When using the Q-meter with or without the specimen we actually observ e th e resonanc e condition ,

$$
\omega = \sqrt{\frac{1}{LC}} \tag{2.1}
$$

where ω is the operating frequency, L and C are the total inductance and **total capacitance of the circuit, respectively.** So, maintaining ω and L **constan t whethec th e sample i s i n or ou t of the testin g jig , we can equate** C in both cases to a value which we will denote as C_{η} . The total cap**acitance** C_{T} is the sum of the air gap capacitance C_{O} when the sample is out, with the spacing of the jig electrodes exactly as the thickness of the **sample, th e Q-meter capacitanc e i n thi s case , , th e holde r capacitanc e** C_H , the leass capacitance C_L and the internal capacitance of the equip**ment C^. Thus a t resonance , withou t th e sample,**

$$
C_{\text{T}} = C_{1} + C_{0} + C_{\text{H}} + C_{\text{L}} + C_{\text{i}} \qquad (2.2)
$$

I n the cas e when th e sample i s i n the testin g jiy , we refe r t o the.sample capacitance by C_y. Thus, at resonance with the sample in,

$$
C_T = C_2 + C_X + C_H + C_L + C_i
$$
 (2.3)

From (2.1) , (2.2) and (2.3) we find that

A

$$
c_1 - c_2 = c_x - c_0 \qquad (2.4)
$$

Neglecting the edge effects, it can be shown that the capacitance C_v **of A a paralle l plat e capacito r wit h a relativ e permittivit y (dielectri c constant) E " i s expresse d as**

- 18 -

$$
C_X = \epsilon C_0
$$

\n
$$
C_0 = \epsilon_0 \frac{A}{d}
$$
 (2.5)

where A i s the area of the electrodes i n square metres, d the thickness of the sample in metres and ϵ is called the permittivity of free space having a value of 8.854 pF m^{-1} ; this yields the value of the capac**itanc e i n pico Farad.**

Therefore, from (2.4) and (2.5) we get

 $\mathbf{c}_{\mathbf{1}}$

$$
C_1 - C_2 = \epsilon C_0 - C_0
$$

= $C_0 (\epsilon - 1)$
or

$$
\epsilon = \frac{C_1 - C_2}{C_0} + 1
$$
 (2.6)

Also, the numerical value of the loss , tan 6 , can be evaluated from the expression (5)

$$
\tan \delta = \frac{Q_1 - Q_2}{Q_1 - Q_2} \cdot \frac{C_1}{C_1 - C_2} \tag{2.7}
$$

in which C_1 and C_2 are the capacitances indicated by the Q-meter at resonance with the specimen out of and in the testing jig, respectively, and Ω_1 and Ω_2 are the corresponding Q-values.

In the present experiments, however, the specimens were, for convenience, cut in the form of squares and so some crystal protruded beyond the circular jig electrodes. Consequently, a correction for edge effects was necessary. Various formulae have been given previously (6), and following similar methods, equation (2.6) can be modified to

$$
\varepsilon' = \frac{c_1 - c_2}{c_0 + c_e} + 1 \tag{2.8}
$$

where $C_{\rm e}$ is the edge correction for the capacitance given by

$$
C_{e} = \frac{1.113D}{3\pi} \left[\ln \frac{8\pi D}{d} - 3 \right]
$$
 (2.9)

for the experimental conditions used in which, for any electrode diameter D employed, the thickness of each evaporated gold electrode was very small compared with d, the specimen thickness. These equations were used in deriving the numerical data presented; it was found that the correction term amounted to about 8%. The edge effect correction for tan 6 was negligible .

2.4 Results

The dielectric constant data obtained at 1 MHz are summarized in Table 2.1 in which the values given under 'present week' represent averages for several measurements on each individual specimen. For the pure material at 1 MHz we find that parallel to the a-axis, $\varepsilon^1_n = 11.3 \pm 0.4$ and that parallel to the c-axis, ϵ^1 = 9.1 ± 0.4. In the doped crystals, the values of ε_A^1 and ε_C^1 at 1 MHz were the same within experimental error, as those for pure calcium tungstate.

The variation of the dielectric constants at frequencies above **1** MHz is shown in Figure 2.2. A very slight increase in both ϵ_1^1 and ϵ_0^1 a c was observed above about 20 MHz to 40 MHz, but the anisotropy of the dielectric constant, as measured by the ratio $\varepsilon_A^{\dagger}/\varepsilon_C^{\dagger}$ remained unaltered. a c calcium tungstate crystals and the neodymium- or gadolinium-doped specimens.

In contrast to the anisotropy of the dielectric constant, the losses measured parallel to the a- and c-axes were the same. With both neodymium- and qadolinium-doped crystals, similar increases in loss at the higher frequencies were observed (Figures 2.3 and 2.4) . The measurements on the doped crystals also showed that, above about 20 MHz, the dielectric loss was larger the higher the dopant concentration. With heodymium doping the effect was quite marked; the true neodymium concentrations in these specimens were determined by optical spectrographic analysis (The Chemical Inspectorate) and, as Figure 2.3 shows, the loss at 40 MHz increased from 4.5 x 10^{-3} to 7.2 x 10^{-3} as the concentration rose from 0.05% Nd to 0.1% Nd. In the gadolinium-doped specimens, the effect was not so marked, probably because the true gadolinium concentrations were all very low, \sim 50 p.p.u., and the differences between the specimens were not so pronounced. (The analyses were made by emission spectro-chemistry by the Analytical Services Laboratory, Imperial College). It was also found, as with the pure material, that in all the doped specimens examined, the dielectric loss parallel to the a-axis was the same as that measured parallel to the c-axis.

Measurements of the dielectric loss, tan δ , were extended to 80 MHz for the neodymium-doped samples with concentrations of 0.05% and 0.1% Nd, Figure 2.5. The increase of tan δ with frequency continued 0.16 Nd, Figure 2.5 . The increase of tan 6 with frequency continued of tan 6 with

showing tha t tan <5 a t 80 MHz had increased about fiv e times tha t a t 40 MHz.

2.5 Discussion

Considering first the pure calcium tungstate single crystals, the measured values of ε_n^* and ε_n^* at 1 MHz (11.3 ± 0.4 and 9.1 ± 0.4 \mathbf{r} and \mathbf{r} and \mathbf{r} respectively)agree very closely with those given by Brower and Fang both as regards the numerical values and in that $\epsilon_2^+ > \epsilon_1^+$. The measurements

a c

- 21 -

 $FIG. 2.5$ Variation of dielectric loss, $\tan \delta$, with frequency for Nd/CaWO4.

reported here were made on vacancy compensated crystals, whereas those of Brower and Fang were made on sodium compensated crystals, so it appears that the dielectric constants are not very sensitive to differences in growth methods. The present work shows further that there is little increase in either ε_n^* or ε_n^* over the frequency range 1 to 40 MHz.

With regard to the dielectric constants of the doped single crystals, the results showed that doping with neodymium or gadolinium did not produce a measureable change in either ϵ_1^{\prime} or ϵ_i^{\prime} ; this conclusion was not unexpected as both the neodymium and gadolinium concentrations was not uncerpected as both the neutration $\mathcal{L}_\mathcal{A}$ as both the neutrations of $\mathcal{L}_\mathcal{A}$ (7) and by Thorp et al, 1974 (8), had previously confirmed that the rare

The dielectric loss data, on the other hand, established that The dielectric contribution of loss data, on the other hand, established that the other hand, established that tha ⁱ n the neodymium calcium tungstate, the high frequency values of tan 6 were concentration dependent. This effect may be associated with Debye were concentration dependent. This effect the associated with the associated with D relaxatio n of the neodyrnium ion , although thi s has not yet been proved. $\mathcal{L}_{\mathcal{L}}$ is a more sensitive in sensitive energy measurement in sensitive energy $\mathcal{L}_{\mathcal{L}}$ small composition changes than the dielectric constant measurement; this might be useful in an analytical context where the application of conventional methods, particularly for gadolinium, is difficult.

CHAPTER 3

SITE OCCUPATION BY GADOLINIUM IN CALCIUM TUNGSTATE

3.1 The Crystal Structure

Calcium tungstate, 'scheelite', crystallizes in the tetragonal system (1) and has a space group c_{4h}^6 (I 4 ₁/a) with four molecules to the unit cell (2). The lattice parameters are $a = b = 5.243$ β and $c = 11.376$ Å. Figure 3.1 shows the unit cell with the oxygen atoms $c \in \{1,376\}$ and unit the unit t cell with the unit t cell with the oxygen atoms the oxygen atoms $\{1,476\}$ that cleavage and slip occur parallel to these layers in $CaWO_{\lambda}$. Each calcium atom is surrounded by eight oxygen atoms at an average distance calcium atom i s surrounded by eight oxygen atom is surrounded by eight oxygen at an average distance α of 2.46 **8** In the shape of a distorted cube. The four calcium sites are equivalent in pairs, one pair being derived from the other by body are equivalent in pairs , one pairs ϕ centering about a calcium site as reflected in the (001) plane. This is shown in the projection of the eight oxygen atoms on the (001) plane through the calcium atom for the two sites, Figure 3.2. The tungsten $\frac{1}{\pi}$ surrounded by four oxygen atoms in the same $\frac{1}{4}$ group as nearly -regular tetrahedra l (4 μ) with h bonding distance 1.784 A. The site estimate μ a. The site estimate μ of both the Ca and W atoms in CaWO₄ is S₄. The distorted cube of oxygen
atoms surrounding the Ca²⁺ site is twisted at an angle of about 9[°] ± 2[°] atoms surrounding the Ca $^+$ sit e i s twisted a t angle of about 9 \pm 3 $^+$ s twisted a t angle of about 9 $^+$ from the unit cell a-axes in the (001) plane. These surrounding oxygens from the unit t cell a-axes i n the (001 \pm 001 \pm 001 2+ the direction of which was first determined by Hempstead and Bowers (2) and was confirmed recently by Buckley (5) . This property was used to identify the sense of the + z axis in Gd/CaWO_A crystals for alignment in ultrasonic experiments made by Farley (6).

3.2 Crystal Growth

Single crystal boules of $CaWO^{\dagger}$ doped with Gd were grown by the Czochralski technique (7) by I.R.D. Ltd., Newcastle upon Tyne, with the c-direction along the growth axis. It had been reported by Nassau and Broyer (8) that the melting point was about 1600°C and this temperature was used for growth. Gadolinium was added in the form of the oxide Gd_oO₂ to the powdered calcium tungstate. In pulling from th melt, trivalent rare earths can be incorporated without the presence of a univalent ion by vacancy compensation. As a rare earth ion, gadolinium substitutes at the calcium sites (8) giving rise to one calcium vacancy for each pair of gadolinium ions to maintain local charge neutrality. Alternatively N_a^+ or Y^3 might have been used for charge compensation, as well as other monovalent and trivalent ions; these two icns are especially convenient since they are not paramagnetic, the very close to the right size $\binom{2+}{2}$ radius is 0.99 $\frac{2}{3}$ M₂ is 0.94 $\frac{2}{3}$ radius is 0.99 A, Na is 0.94 A are very close to the right to the righ $^{3+}$ is 0.92 $^{\circ}$), an the specimens used here were vacancy compensated. The nominal doping levels used were 0.005, 0.01 and 0.05 atomic per cent, although independent analysis (by the Analytical Services Laboratory, Imperial College) showed that the actual levels were all less than about 100 p.p.m. This concentration level is well below that at which substitution at W sites has been reported by Kedzie and Kestigian (9). The very compact nature of the structure of \texttt{CaWO}_A makes the interstitial sites very unlikely. Thus, in the material examined the strongest probability is that the gadolinium would have entered the lattice substitutionally at calcium sites.

3.3 The Energy Levels of G a^{3+} in CaWO_A

substitutional. The calcium sites \mathcal{S} at calcium sites . The calcium sites \mathcal{S}

The trivalent gadolinium ion has seven unpaired electrons in

the 4f unfilled shell which make it half-filled and give rise to a $7,8,$ ground state (4f) $S_{7/2}$. In a host lattice the gadolinium ions will be subjected to a crystal field whose symmetry and order of magnitude be subjected to a crystal d whose symmetry and order or feature discussed by Bleaney and Stevens (10). However, the ESK of the initial splittings of Gd ³⁺ ions in crystals of the scheelite series were reported by Vinokurov et al (11). They gave crystal field series were reported by \mathbb{R}^d . splitting constants $\frac{b^{\circ}}{2}$ for Gd/CaWO $\frac{1}{4}$ at 77 K and 290 K as 916.7 x 10 $^{-4}$ cm $^{-1}$ -4 -1 and 892.4 x 10 cm respectively. This is in exact agreement with the value of b_2^0 at 77 K given by Hempstead and Bowers. It was also shown that all the b_n^0 values decrease on passing from CaWO₄ to BaMoO_{Λ} in the scheelite series. This is because of the regular increase in the unit cell constants (a and c) with increase in the ionic radius of the corresponding cation. Consequently, the Gd-O distance in GdO_g complex will increase in an unchanged local field symmetry which leads to a fall in the strength of the electric field and thus amounts to a decrease in the b_n^0 constants (11,12).

and thus amounts t o a decrease i n the b° constants (11,12). $\ddot{}$ ion to exhibit splitting of the energy levels, it is necessary to go to a high order perturbation of the crystal field applied to direct spin-orbit interactions. But, Abragam and Pryce in 1951 (14) concluded that these splittings were in fact too big to be explained by the above process. They suggested instead that they are due to a spinspin interaction which also couples orbits with spins, since it depends on position variables. Their idea was that in the crystal field, even though the ion is in an S-state, there will be some

field,.even the ion is in an experimental behavior in an S-state, the ion is in an S-state, there will be some

- 25 -

distortion of the orbits. This is supposing that instead of the charge cloud being a perfect sphere it is slightly ellipsoidal. Then the dipole-dipole energy of the spins varies with their orientation with respect to the axes of the ellipsoid, and thus the eigenvalues depend on the spin orientation. They were able to put forward convincing arguments that this is indeed the correct mechanism. So, in the tetragonal field of calcium tungstate the $J = 7/2$ state splits into four Kramers' doublets and paramagnetic resonance then occurs between the Zeeman levels of these four doublets. The energy level diagram for Gd^{3+} in calcium tungstate at Q-band was drawn by Buckley (5) using straight line extrapolation from that predicted by Harvey and Kiefte in 1971 (15) at X-band frequencies. A convincing fit in Buckley's ESR results and several others, especially those of Dernov-Pegarev et al (16) for Gd/CaMoO_,, was attained. The ESR spectrum of only seven lines for $M = 1$ transitions, which was observed by Thorp et al (1974) in their study of dipolar broadening mechanism in Gd^{3+} /CaWO $\,$, gives a further evidence for Gd $^{3+}$ substitution at Ca $^{2+}$ sites in a tetragonal symmetry (17).

3.4 The Spin-Hamiltonian

A spin Hamiltonian containing relatively few terms will give a complete description of the experimental data when given the right size of the coefficients of these terms together with the directions of the appropriate axes relative to the crystal axes where anisotropy is present. The most general form of the spin Hamiltonian contains terms representing the Zeeman interaction of the magnetic electrons with an external field, level splittings due to indirect effects of the crystal field; usually referred to as 'fine structure', hyperfine

- 26 -

structure due to the presence of nuclear magnetic dipoles, quadrupole moments in the central ion or in the ligand ions, and the Zeeman interaction of the nuclear moments with the external field. In general, the spin Hamiltonian can be represented by

$$
H = g \beta H . S + D \left[S_Z^2 - S (S + 1) \right] + E (S_X^2 - S_Y^2) . \qquad (3.1)
$$

The first term gives the interaction with the applied magnetic field and the other two terms arise from crystal field effects. Further terms must be added if the ion possesses a resultant nuclear magnetic moment.

Knowing the structure of CaWO_A crystal and the symmetries of the CaO_g, Hempstead (2), Vinokurov (11) and Kurkin (12) published the spin Hamiltonian for $Gd/CaWO^A$ as

$$
H = g_{\text{II}} \beta H_{\text{Z}} S_{\text{Z}} + g_{\text{I}} \beta (H_{\text{X}} S_{\text{X}} + H_{\text{Y}} S_{\text{Y}}) + \frac{1}{3} b_{\text{2}}^{\text{O}} 0_{\text{Z}}^{\text{O}}
$$

+ $\frac{1}{60} (b_{\text{4}}^{\text{O}} 0_{\text{4}}^{\text{O}} + b_{\text{4}}^{\text{4}} 0_{\text{4}}^{\text{4}}) + \frac{1}{1260} (b_{\text{6}}^{\text{O}} 0_{\text{6}}^{\text{O}} + b_{\text{6}}^{\text{4}} 0_{\text{6}}^{\text{4}}).$ (3.2)

where z is in the c-axis of the crystal and $S = 7/2$. To simplify this expression the constants were re-written as

$$
b_2^{\circ} / B_2^{\circ} = 3
$$

$$
b_4^{\circ} / B_4^{\circ} = b_4^4 / B_4^4 = b_6^4 / B_6^4 = 60
$$

$$
b_6^{\circ} / B_6^{\circ} = 1260
$$
 (3.

and then, the spin Hamiltonian reduced to

 27

$$
H = g_{\mu} \beta H_{Z} S_{Z} + g_{\perp} \beta (H_{X} S_{X} + H_{Y} S_{Y})
$$

$$
+ B_2^O O_2^O + B_4^O O_4^O + B_4^4 O_4^4 + B_6^O O_6^O + B_6^4 O_6^4 \qquad (3.4)
$$

where each 0_{n}^{m} is an operator function having the same transformation properties as the corresponding spherical harmonic Y^{In}_{n} , and the coefficients B_n^m are parameters to be determined by the experiment. The parameters g_n , g_n , b_2^0 , b_4^0 , b_4^4 , b_6^0 , and b_6^4 can effectively be determined from the measurements of the gadolinium transitions with the magnetic field H parallel to the c-axis of the crystal (i.e. $\theta = 0^{\circ}$ and with H perpendicular to the c-axis (i.e. $\theta = 90^{\circ}$). It is noticed that for Gd^{3+} , as well as for Mn^{2+} (2) the arrangement of 2+ $\frac{1}{\sqrt{2}}$ the dopant ion , (or the dopant ion , $\frac{1}{\sqrt{2}}$ surrounding the Cassive surrounding ion , (or the Cassive surrounding ion , $\frac{1}{\sqrt{2}}$ surrounding ion , (or the Cassive surrounding ion , $\frac{1}{\sqrt{2}}$ sur gives b_4^4 = 10 b_4^6 which differs from that of a cubic environment where normally $b_4^4 = 5 b_4^0$. This conclusion is in agreement with Wyckoff's discussion of the crystal structure referred to in

3.5 Experimental observations of ESR spectra of gadolinium in calcium tungstate

When discussing the crystal structure of CaWO, in Section 3.1, it was shown that all four possible positions of the a^{2+} in the unit i t was shown that the transformation s of the unit that the unit the unit the unit the unit the unit the unit
The unit the unit th cel l possess a local later a local later a local later and are magnetically of 5 α equivalent. This leads t o the same single spectrum fo r each paramagnetic ion introduced into the host lattice. The ESR spectrum of 8 Gd $_{7/\gamma}$ in CaWO $_{4}$ single crystals was reported by Hempstead and Bowers (2) as consisting of seven widely spaced strong lines due to $\Delta M = \pm 1$ and a number of weaker transitions corresponding to $\Delta M = \pm 2$, (such

and transition s corresponding to $\mathcal{L}_\mathcal{A}$, $\mathcal{L}_\mathcal{A}$,

transitions are to be expected as b° **is so large as to be comparable** w ith g β H). They also observed that other weak lines flanked the strong ones which represent the hfs due to the odd Gd isotopes $(Gd^{155}$ 14.7% **ones which represen t th e hf s due t o th e odd Gd isotope s (Gd 14.7% ' aach hfs component has only about 5% of the intensity of the main line.** Here, we will regard the $\Delta M = \pm 1$ transitions due to the even isotopes As "clean" lines. A clean line is defined as one characteristic of $text{tetragonal symmetry, appearing as a symmetrical, well-balanced signal}$ **on a derivative output.** Such a spectrum is obtained with the 0.005% Gd sample, and one of the transitions, observed with the magnetic field H parallel to the crystallographic a-axis in the (001) plane (i.e. **with** $0 = 90^{\circ}$ and $\phi = 0^{\circ}$, is reproduced in Figure 3.3. The line is "clean" and the transition remains single at room temperature, 77 K and 4.2 K. This form of lineshape is also observed for all the Gd **transitions** over a wide range of angles ϕ except near $\phi = 55^\circ$. Near this angle some distortion in line shape is observed. This distortion **becomes more pronounced as we lower the temperature of the sample where** the distortion seems to be "splitting" in each transition. These **effects are illustrated by the spectra shown in Figures 3.4, 3.5 and 3.6.** The splitting effect was first observed in the first quadrant **3.6 1.6 h** ϕ **plane with** $0 \leq \phi \leq 90^\circ$, and $+z$ axis is upwards per-**(i.e . i n the <}> -plane wit h 0 < <|> < .90 , and + z axi s i s upwards per** to the other quadrants and it was found that the splittings are very **pendicula r to the plan e of observation) j measurements were extended** much more pronounced in the first and third quadrants than in the second and fourth. With the higher concentration sample (0.05% Gd) **much more pronounced i n the firs t and thir d quadrant s than i n th e** the splitting was observed over a much wider range of angles ϕ , as **second and fourth . With th e highe r concentratio n sample (0.05% Gd)** was reported by Buckley (5). This is shown in Figure 3.7.

t h e splittin g was observe d ove r a much wider range o f angle s \$, as

was reporte d by Buckle y (5) . Thi s i s shown i n Figur e 3.7 .

X-irradiated glycylglycine, reported by Randolph (18)

3.6 Comparison with the previous ESR data

The aim of this chapter, as was mentioned earlier in Chapte ^r 1, i s £0 investigat e the cause and natur e of th e splittin ^g in the Gd main transitions observed by Buckley (5) and confirmed by **o ur results . Tha t i s one of th e reason s why we used the same samples of referenc e (5) i n our studies . I t i s interestin g to show tha t the** shapes of the derivatives presented here as Figures $4 - 7$ are due to **genuine effects and they are not, for example, due to lack in balancing t h e spectrometer . Thi s coul d be shown by comparison wit h Figur e 3.0 which shows the derivative of the ESR curve of about** 10^{18} **resonant** centres produced by C⁶⁰ gamma irradiation of glycylglycine reported by Randolph in 1960 (18). However, it could not be a matter of unbalance in the signal for Figure 3.3 shows that a quite good balance **unbalance i n th e signa l fo r Figur e 3.3 shows tha t a quit e good balanc e coul d be attaine d i n any case . Severa l worker s have studie d the ESR** find the following features in their investigations as described in **fin d the followin g feature s i n thei r investigation s as describe d i n**

3..6.1 'Anomalous' transition s of trivalen t rar e eart h icn s i n scheelite s

By 'anomalous' transitions we mean any transition other than **the normal electronic transitions for which** $\Delta M = \pm 1$ **in the ESR spectra o f rar e eart h ion s i n scheelite s havin g an undistorte d tetragona l** s ymmetry. Four kinds of anomalies could be established from the **previou s publishe d work.**

(a) Transition s due t o the variou s compensation mechanisms fo r the exces s charge , which arise s from doping the hos t scheelite s wit h trivalent rare earth ions, to achieve charge neutrality. The published

- 30 -

ESR data indicated the presence of centres of lower symmetry in addition **3+ ^t o tetragona l centres . Thre e nontetragona l centre s i n the E r doped** samples and two such centres in the Tb³⁺ doped crystals were reported by Abdulsabirov et al in 1972 (19). These authors concluded that all the published information on the nontetragonal Ce³⁺ by Mims-Gillen (20), **b b** $^{3+}$ by Garrett-Merritt (22), (21), and **Volterra-Bronstein-Rockni** (21), Nd² by Garrett-Merritt (22), (21), and **Volterra-Bronstein-Rockn ⁱ (21), Nd ³ ⁺ by Garrett-Merrit ^t (22),(21) , and** \mathbf{Yb} by Ranon-Volterra (23) and their data on the nontetragonal Tb is centres in CaWO_{$_A$} can all be interpreted on the assumption that the com**pensating defects are located in one of three positions denoted by I, I I , II I i n th e crystal , Figur ^e 3.9 . The 'strongest ' nor.t^tragona l centre ^s** $\frac{+}{2}$ **+** $\frac{1}{2}$ $\frac{1}{2}$ $\frac{1}{2}$ $\frac{2+}{2}$ are formed when a compensating defect, an Na fion or a Ca vacancy for **crystal s grown wit h and withou t sodium compensation respectivel y i s** located at the Ca^{2+} site nearest to the trivalent ion (position I in Figure 3.9). We also notice that these additional nontetragonal centres have different parameters and g-values, in other words, they would appear in the ESR spectra at different field positions from those of the normal i **tetragonal transitions.**

(b) As Kedzie and Kestigian reported (9), substitution would occur at **(b) As Kedzi e and Kestigia n reporte ^d (9), substitutio n would occu r a t W^^H site s a s wel l a s Ca^ ⁺ site s wit h and withou t adding Na ⁺ ion s fo r charge compensation. A spectrum of fiv e main line s (plu s smalle r line ^s due t o hyperfin e structure) was observe d fo r Nd /CaWO^ crystals . The centra l lin e of the fiv e transition s was th e most intens e and was attri** buted to Nd³⁺ in the Ca site, while the four remaining lines were thought **butted** to Nd³⁺ ions in a W site. Although Garrett and Merritt (22) and Ranon and Volterra (23) found that the chemical evidence argues strongly for the substitution of Nd^{3+} in Ca sites, we still regard substitution of rare earth ions in W sites as a source for anomalous tran s **itions.** In fact, substitution in W sites, whenever it occurs, will give

sitions . . I n fact , substitutio n i n W sites , whenever i t occurs , wil l giv ^e

t

(c) A thir d kin d of transitio n coul d be observe d a s weaker transition ^s corresponding to $\Delta M = \pm 2$ **(known as forbidden transitions). These lines** are to be expected whenever b_2^O is so large as to be comparable with **as reported by Hempstead and Bowers in 1960 for Gd** $^{3+}$ **in CaWO** $_{\textbf{4}}$ **crystals (2). (d) Hyperfin e transitions , due t o the odd isotopes , i f present , havin g a ne t nuclea r spi n I , giv e a hf s of low intensit y compared t o th e main transitions . Examples of thes e effect s coul d be demonstrated by the** $spectra$ of $Gd^{3+}/CawO^{(2)}$ (2), $Nd^{3+}/CawO^{(2)}$ (9,22) and $Yb^{3+}/CawO^{(2)}$ (23).

From the above classification we see that none of the four mentioned **causes** can be the reason for the splitting reported here in our results; **Sectio ⁿ 3.5 . This , therefore , must be classifie d a s a separat e kin d of anomaly. The onl y previou s work i n which a fairl y clos e similarit y of behaviou r existe d was -thac o f Forreste r and Hempstead (24) who observe ^d** $unresolved doublets$ in the ESR spectra of $\text{TD}^{3+}/\text{CaWO}$ single crystals, and suggested that this might be due to non-equivalence of the Ca²⁺ sites. Their observations, as far as splitting is concerned, are as follows. As they increased the angle θ between the applied magnetic field and the **c-axis of the crystal the lines were broadened. At K band (23 GHz) and a** temperature of 4.2 K, the linewidth increased from 1.4 gauss when $\theta = 0^\circ$, **to** about 15 gauss when $\theta = 60^\circ$. The line shape was distorted as θ was further increased, the peaks became somewhat flattened and at angles **greater** than about 70[°] the lines became partially resolved into doublets. The highest field transition was better resolved than the lowest field **line.** And, finally, they interpreted this behaviour as indicating **that the two types of Ca site are not completely equivalent.**

tha t th e two type s of Ca sit e ar e not completel y equivalent .

3.7 Interpretatio n of presen t result s

We attempted to resolve our derivative curves into separate **absorptio n peaks i n orde r t o ge t more informatio n about the 'extr a com-' ponent'.** This was done by integrating $\int y \, dx$, where y is the ordinate of the derivative curve and dx is a small, arbitrary, increment of mag**neti c field . The result s depicte d i n Figure s 3.10 and 3.11 show the calculate d absorptio n curve s fo r th e derivative s i n Figure s 3. 6 and 3.5 , respectively . I t i s unfortunat e tha t we couJd not ge t significan t informatio n about the separatio n of th e absorptio n peaks or . thei r inten** sities for they are, in most cases, unresolved. However, from our experimental data we have two important features which might serve as clues **t o a correc t interpretation .**

li) **The occurrenc e o f splittin g a t specifi c angle s i n the <j>-pla.ne; thi s should draw the attentio n t o th e uni t cel l structur e t o inspec t th e crysta l a t thes e angles .**

(ii) The relativ e increas e i n th e signa l of th e 'extr a component' compared with the main transition as we reduce the temperature from 290 K **t o 4.2 K, which indicate s tha t the dependence on temperature fo r th e two** components is not exactly similar.

Thus, t o solv e thi s problem two possibilitie s arise: -

(a) We sugges t tha t some of the Gd^⁺ ion s may have slightl y defecte d sites which would not disturb the crystal field symmetry radically in \cdot **thei r vicinity , bu t cause th e transition s t o shif t slightl y on the fiel d axis.** If we examine the unit cell of CaWO_{Λ} we see in the (001) plane; **((j> plane) , Figur ^e 3.12^a s reporte d by Farley , Saunders and Chung (25), that the nearest neighbours to a Ca site at an angle** ϕ **about 50[°] are**

- 33 -

FIG. 3-10 ESR absorption curve calculated **from the derivative shape in Fig. 3-6**

- **O Oxygen sites**
- **® Tungsten sites**

® Calcium site

FIG. 3-12 Projection onto the (001) plane of the scheelite structure unit cell. The conventional +Z axis emerges from the plane of paper, S is the angle between the crystal axis and the magnetic axis **oxygen ions.** Knowing that the oxygen ions provide the framework of the **crysta l fiel d symmetry a t th e Ca sit e we shoul d expec t some change i n crysta l fiel d due t o oxygen vacancies . I n effect , we propose an ordered ' oxygen vacancy model.** By this model we can also understand the behaviour **^o f the "extr a component" wit h temperature. As we reduce th e temperature t h e possibilit y fo r thes e oxygen vacancie s t o settl e i n an ordere d form** increases and this leads to a corresponding increase in the signal from the Gd³⁺ ions in defected sites. This may explain the relative increase in the signal of the "extra component" as the temperature decreases.

(b) Another possibility lies in the interpretation of Forrester and **Hempstead (24) of their results on Tb³⁺ in CaWO_{** $_A$ **}, which is mentioned above in Section 3.6.1. Consequently, we may conclude that the distortion of '** the Gd³⁺ in CaWO_A which we are reporting is probably an indication that t he two types of Ca sites are not completely equivalent.

In fact, we favour very much the first suggestion which needs still more experimental work to test its validity. The second probability, **however, could be excluded because it is a very well established fact that t h e fou r possibl e position s of Ca site s i n th e uni t cel l of CaWO^ when substitute d by paramagneti c ions , lea d t o identica l paramagneti c resonance ^a s was firs t indicate d by Hempstead and Bowers (2) and confirmed by al l othe r workers i n thei r studie s on scheelites .**

3.7.1 Heat-treatment s of Gd/CaWO^ samples i n oxygen ambient

and their interpretation

t h e two type s of Ca site s ar e not completel y equivalent .

We found it necessary to heat treat our samples in oxygen atmosphere in order to establish the ordered-oxygen vacancy model. Our aim was **^t o see whether i t i s possibl e t o fil l the proposed vacancie s wit h oxygen**

- 34 -

from outside the crystal, in which case we would expect the observed **distortio n t o vanish , o r a t leas t t o reduce . The furnac e use d i n thes e** heat treatments was built by W. Hutton and could reach a maximum tem**perature of about 1200°C.** The 0.005% Gd sample was put to this test, firstly for 1 hour at 1000[°]C, secondly for 40 hours at 1000[°]C, and thirdly for 40 hours at 1200°C. The results of these heat treatment experiments **were as follows . Afte r th e firs t experiment ther e was no change i n the** ESR behaviour of the sample. The change came after the second experiment **and distortion of the line shape was observed at all angles** ϕ **, (it was o** No furthor **originall y limite d t o angle s <j> nea r 55) . No furthe r change was observe d afte r th e thir d hea t treatmen t o f th e sample.**

Our interpretation of these results is that the extended heat treatments at 1000^oC and 1200^oC failed to reduce the number of oxygen **vacancies, and that the consequence was simply a more random distribution** of these vacancies. This manifested itself in the persistent appearance **of splitting, but now at all field orientations. It was decided not to** i attempt higher heat treatment temperatures, because of the possible changes in the single crystal structure which could have attended such treatments, **as reported by Nassau and Broyer (8).**

a s reported, by Nassau and Broye r (8) . fact, supported by some other experimental observations. The relevant f **evidence comes from measurements of spin-lattice relaxation time of the** s ame samples under investigation, and is summarised as follows.

same samples under investigation , and i s summarised a s follows . reported by Thorp, Buckley and Brown (26) showed the dependence of T. on temperature over the range from 1.5 K to 8 K for the 0.01% Gd sample **at** $\phi = 10^{\circ}$. This was illustrated by two lines of slopes 1.0, 0.9

- 35 -

indicativ e of direc t proces s o f relaxatio n i n thi s region . These two lines were attributed to the two components of Gd transition which was s plit and their separation was about 2 mT at that angle.

(ii) Our investigation of T_1 in the temperature range 4.2 K to 30 K for Gd³⁺/CaWO_A reported in Chapter 4 leads to a r^{-3} Raman-type of relaxa**f** tion. This suggests the existence of a substantial number of defects k which may lead to defected Gd sites, although the exact nature of these **defect s i s not ye t full y resolved .**

CHAPTER 4

SPIN-LATTICE RELAXATION IN GADOLINIUM-DOPED CALCIUM TUNGSTATE

4.1 ,Theorie s of spin-lattic e relaxatio n

Befor e th e discover y of magnetic resonanc e (by E. Zavoisk y i n 1944) , Waller in 1932 (1), by measuring susceptibility at low frequency, suggested that the spin and orbital angular momenta of a paramagnetic ion were com**pletel y decoupled, and tha t th e spi n was influence d by th e lattic e vibra tion s (phonons) onl y by thei r modulation o f the dipola r coupling . Tha t ⁱ s to say , the loca l magnetic field , Which exist s a t one io n because of t h e magnetic dipol e on a neighbourin g ion , fluctuate s due t o fluctuation s o f the distanc e between th e two ion s under -the actio n of th e lattic e vibra tions . The resultin g relaxatio n time was too long to explai n the experi mental results of the Leiden group;** Gorter 1936 (2), or the more recent **ESR studies . However, Waller' s postulate s were th e firs t advances i n thi s field- , he distinguishe d spin-spi n from spin-lattic e relaxation , recognize d the principa l type s o f transition , processe s concerned i n th e latte r (now known as direc t and Raman processes) and se t up th e quantum mechanica l framework fo r the calculatio n of thei r probabilities .**

Kronig (3) and Van Vleck (4,5) independently suggested that there **ⁱ s no direc t interactio n between th e phonon vibration s of a crysta l lattic ^e** and the paramagnetic energy levels of an atomic spin in the lattice. Their **mechanism i s tha t when th e lattic e vibrate s th e orbita l motion undergoes periodi c changes due t o vibration s i n th e crystallin e electri c fields .** These changes react on the spins through the spin-orbit interaction, and **thereb y alte r thei r orientatio n i n the externa l magnetic field . The spi n level s ar e thus, indirectl y connected t o th e lattic e vibrations , and quant a o f energy can be exchanged between th e two. The agreement wit h th e experi** n mental data then in existence, (Gorter and his co-workers), was disappointing,

- 37 -

especiall y i n tha t the observe d dependence on the temperatur e and on the strength of the applied magnetic field was not as predicted. Also, accordin g t o Kroni g and Van Vleck , th e spin-lattic e relaxatio n time of a $\frac{1}{2}$ **spin** should be independent of the spin-density, since the process involves **only the individual spin and the surrounding lattice, and not any other** \cdot **spin s which may be present . Consequently , i t i s conclude d tha t th e Kronig - Van Vleck theory seems to be valid only at very low spin concentrations,** much smaller than those generally used in practical maser crystals, Paxman (6) and Zverev (7).

According to the detailed theory worked out by Kronig and Van Vleck **ther e shoul d be two contribution s t o th e relaxatio n rate . The first , i s from a"direc t process " i n which the spi n relaxe s i n eithe r direction , by emittin g or absorbin g a singl e phonon a t th e spi n transitio n frequency .** The second contribution is from an "indirect" or "Raman" process in which **a** much higher frequency lattice-phonon is scattered by a spin and, thus, changing its frequency be enough to absorb the relaxation energy from the \mathbf{f} **spin.** The direct process should predominate at liquid helium temperatures, and somewhere above these temperatures the Raman mechanism should become **significant . One o f the aims o f thi s chapte r i s to investigat e thes e** $\mathsf{features}\ \text{in}\ \mathsf{Gd}^{3+}/\mathsf{CaWO}_{\mathsf{A}}$.

Another important theory involving two-phonon process was suggested by Orbach (8) and verified experimentally by Finn, Orbach and **Wolf i n 1961 (9) and by Manenkov and Prokhorov i n 1962 (10) . The theoretica l treatmen t i s appropriat e t o rar e eart h ion s and lead s t o prediction s which agree both wit h th e experimentall y observe d temperature dependence and wit h th e magnitude of the relaxatio n time. The dominant relaxatio ⁿ proces s i s one i n which a phonon of hig h energy (> > kT) i s absorbed by**

t h e spi n system resultin g i n a transitio n from one of the ground stat ^e

4

- 38 -

doublet levels to the nearest excited level. Then, in a separate step, anothe r hig h energy phonon i s emitte d and a transitio n i s effecte d t o the other level of the ground state doublet. The net result of this "twoste p direc t process " i s th e relaxatio n of the ground stat e double t level ^s which bring s th e spi n system towards therma l equilibrium . Some reason s f o r th e succes s i n the applicatio n o f Crbach' s theor y to th e rare-eart h ions are given by Huang (11); the situation is unlike that applicable **t o ion s of the iro n group where the Kronig-V.^n Vlec k treatmen t i s much** m **h** n **d d e n n e earths ,** the spin-orbit coupling is in general **stron g compared wit h crysta l fiel d effects , ah effec t which i s due t o t h e "screening " of the paramagneti c electron s i n th e embedded 4 f unfille ^d shell.** Thus the states of an ion are primarily of the type $J = L + S$, and, therefore, contain non-zero components of orbital angular momentum. **Through th e orbita l angula r momentum direc t interactio n between th e** magnetic states and the lattice vibrations is possible by means of orbit**lattic e interactions . The magnetic** *spin* **i s thu s relativel y strongl y coupled** to the lattice. For this reason spin-lattice relaxation times are generally very short $(T_1 \sim 10^{-12}$ sec at normal temperatures) and low t emperatures $(\sim 20 K)$ are often necessary to eliminate spin-lattice $relaxation$ **broadening** of paramagnetic resonance absorptions.

relaxatio n broadening o f paramagneti c resonanc e absorptions . 3 , Eu , Fe and Mn **The S-stat e ion s such a s Gd , Eu " , F e and Mn must be excepte d from th e foregoin g discussio n sinc e thei r almost tota l lac k of orbita ^l momentum ensure s tha t they ar e littl e affecte d by crysta l fields . The** $spin$ -degenerate ground state of the free ion becomes in the crystal a **group of closely spaced levels whose splitting rarely exceeds 1 cm⁻¹** and the levels immediately higher, whose energies are likely to be greater **4** -1 **by a t leas t 10 cm , ar e derive d from state s differen t i n orbita l and**

- 39 -

 s pin degeneracy. In crystals, owing to the combined effects of the **crysta l field , spin-orbi t and spin-spi n coupling s withi n th e ion , the lowes t spi n multiple t i s admixed wit h highe r state s havin g orbita l momentum** and different spin multiplicity, and thus becomes sensitive **t o lattic e strain . The resultin g relaxatio n has been considere d by Blume and Orbach i n 1962 (12,13) and Leushi n i n 1963 (14) . The relaxation , instea d o f bein g entirel y withi n the lowes t Kramer's doublet , as might have been th e cas e i f th e splittin g were greater , ⁱ s now dominated by transition s between doublets . A comprehensive surve y of the theorie s of spin-lattic e relaxatio n i s now availabl e ⁱ n some text s by Abragam and Bleaney , 1970 (15) , Poole and Farach , 1971 (16) , and Standle y and Vaughan, 1969 (17) .**

On applyin g thes e theorie s t o th e availabl e experimenta l dat a they gave, i n most cases , beside s the qualitativ e fitting , a reasonabl e quantitativ e explanatio n of th e way i n which th e spin-lattic e relaxa tio n time varies , particularl y wit h temperature . A brie f revie w o f t h e relaxatio n processe s and thei r variatio n wit h temperature i s give n below.

4.2 Relaxatio n processe s and thei r temperatur e dependence

As is mentioned in Section 4.1, two relaxation processes were **postulate d by Kroni g and Van Vleck . These processe s were distinguishe d earlier , i n 1932, by Walle r and became known a s direc t and Raman processes .**

4.2.1 The direct (or one phonon) process

^I t i s th e absorption , or emission , of a phonon o f th e same energy "h["] as the splitting energy " δ _{ab}" between two states

- 40 -

 $|a>$ and $|b>$ required for a resonance transition in the spin system and resulting in an upwards or downwards transition in that system. **Thi s i s illustrate d diagramaticall y i n Figur e 4.1a. Calculatio n of t h e transitio n probabilit y fo r thi s proces s fo r a Kramer's double t (one i n which the two spi n state s ar e time conjugate s of eac h othe r** and have half integral quantum numbers) leads to the dependence of

T, on temperature and applied magnetic field as

$$
T_1 = a H^{-4} T^{-1}
$$
 (4.1)

$$
T_1 = a^{\prime} H^{-2} T^{-1}
$$
 (4.2)

¹ (4.2)

$$
 (4.3)

where v i s th e velocit y of sound i n the crystal .

The energy distribution of phonons according to a Debye spectrum at any particular lattice temperature could be illustrated as in Figure **4.2. Only thes e phonons, which have energie s equa l t o th e transitio n energy** between the two relaxing levels, in other words, those which **a r e on "speakin g terms" wit h th e spins , can tak e par t i n th e direc t proces s o f relaxation . Thi s i s onl y an extremel y smal l fractio n o f** the total number of phonons and it can be shown that the direct **proces s wil l predominate onl y a t lower temperature s (liqui d heliu m temperatures) .**

 $\mathcal{E}^{\text{R}}_{\text{max}}$

FIG.4-2 The energy distribution of phonons according to a Debye spectrum where $f(X) =$ X 3 /(e ^x -1) - and X="hw/kT.

4.2.2 The two-phonon, Raman proces s

Thi s process , involvin g two hig h frequenc y phonons, i s simila r ^t o tha t introduce d by Walle r but , here , th e interactio n mechanism i s explaine d by the ligan d fiel d theor y rathe r than by the magnetic spin-spi n interaction . I n thi s proces s the magnetic io n makes a transition from state $|b\rangle$ **to state** $|a\rangle$ **, or vice versa, accompanied** by the virtual absorption of a phonon of angular frequency ω_1 and the emission of a phonon of frequency ω_2 . The energy difference $\int h\omega_1$ - $\int h\omega_2$ is absorbed, or emitted, by the spin system effecting a **transitio n as illustrate d i n Figur e 4..lb. I n th e Raman proces s any two phonons can participat e provide d tha t thei r frequenc y differenc e** is equal to the resonance frequency of the spin system. So, the much m ore abundant phonons near the peak of the energy distribution of the **phonon spectrum, Figure 4.2, are also available. The calculated** dependences for T_1 due to this process are, for the Kramers ions,

$$
T_1 = b T^{-9} + b_1 H^{-2} T^{-7}
$$
 (4.4)

where b and b₁ are constants. The dependence on $H^{-2}T^{-7}$ is only **where an** are the constances, as discussed by Orbach, 1961 \cdot **(18).** For non-Kramers ions the dependence is

$$
T_1 = b^{\dagger} T^{-7} \tag{4.5}
$$

where b" i s a constant .

4.2.3 Resonant two-phonon relaxatio n or Orbach proces s

As is mentioned earlier, this two phonon resonance process was suggested by Orbach in 1961 and first verified by Finn et al in **1961.** Suppose that the magnetic ion has a set of energy levels such **a s tha t shown i n Figur e 4.1c, where ther e ar e two low lyin g state s | a > , |** b > (such as a Kramer's doublet), and an excited state $|c|$ > whose energy separation $\Delta_{\mathcal{L}}$ is less than the maximum phonon energy, or

$$
\Delta_{\rm c} \leqslant \hbox{for } \omega_{\rm p} \tag{4.6}
$$

where ω_n is the phonon frequency.

In the Raman process there were no phonons of energy $\Delta_{\mathbf{A}}$, so that transi- \sim **tibn s involvin g a virtua l leve l c had to be imagined. I t is , here , possible for an ion in , say, state** $|b\rangle$ **to absorb a phonon of the** appropriate frequency by a direct process, and be excited to the state **| c > . Then, a second phonon i s emitte d by a spontaneous or induce d emission from that state** $|c \rangle$ **to fall down to state** $|a \rangle$ **. This gives an indirect transfer of ions from state** $|b \rangle$ **to** $|a \rangle$ **, and in so doing. relaxation** occurs between state $|b \rangle$ and $|a \rangle$; this may be faster than the direct transfer between them because of the much higher density of phonons **of energy** $\Delta_{\mathcal{L}}$ in the phonon spectrum. Orbach deduced a relaxation rate **which i n genera l practic e becomes ,**

$$
T_1 = C \exp \left(\Delta \right) / kT
$$
 (4.7)

independent o f an applie d magnetic fiel d excep t i n so fa r a s thi s may filte r th e valu e A . Thi s relatio n hold s fo r both non-Kramers and Kramers c ions provided that we consider a similar treatment for the excited states **a s fo r the Kramers doublet s i n th e Raman analysis .**

4.2.4 Multipl e ground stat e proces s

Orbach and Blume (12,13) considered the case where a multilevel Kramers state is lowest in energy. This is illustrated in Figure 4.1d,

- 43 -

where the states $|c \rangle$ and $|d \rangle$ have virtually the same energy as the states $|a \rangle$ and $|b \rangle$. Therefore, Δ is very small and, consequently, taking this into account in the derivation of the Raman process, as discussed by Abragam and Bleaney (15), another type of relaxation dominates with a **temperature dependence as ,**

$$
T_1 = C^1 T^{-5} \t\t(4.8)
$$

where C i s constant .

Walker in 1968 (19) has described a mechanism that also gives a \textbf{T}^{-5} **dependence with T₁, for non-Kramers doublets, than can operate between** states of a multiplet which are not time-conjugates. Recently, an **sccount of the various processes of electron spin relaxation was given** by Gill, 1975 (20) concerning the establishment of thermal equilibrium in dielectric crystals containing paramagnetic ions of the transition **i n dielectri c crystal s containin g paramagneti c ion s of the transitio n**

4.2.5 Modification s due t o lattic e imperfection s

The theorie s mentioned above al l dea l wit h paramagneti c ion s i n crystallographicall y perfec t diamagneti c lattice . The assumption of a perfec t lattic e i s unlikel y t o be tru e fo r a doped singl e crysta l because the paramagneti c ions , substitutin g a t lattic e points , usuall y diffe r i n both mass and ne t electri c charge from th e ion s the y replace . They will , therefore , constitut e defec t site s tha t cause distortio n o f t h e symmetry of th e surroundin g ligan d ion s and als o modificatio n of the lattice waves. Moreover, any material grown at high temperature (for our Gd/CaWO the growth temperature is about 1600°C, using a Czochralski **method), wil l contai n a hig h number of crystallographi c imperfection s**

due t o the thermal stresse s involve d i n the growth process . Also , defect s o f othe r type s can pla y an importan t role , fo r instance , microfractur e resulting when the crystal is cooled to the temperature of liquid helium.

As i s established , spin-lattic e interactio n depends upon the exten t t o which th e distance s between a paramagneti c centr e and the surroundin g atoms change under th e influenc e of lattic e vibrations . The disturbanc e of th e crysta l fiel d a t th e paramagneti c io n due t o the alteratio n of th e normal position s of the ligand s wil l have the effec t of introducing terms proportional to the lattice strain at the ligand ion into the expressions of the lattice potential.

An additional effect of lattice defects such as interstitial **ion s and substitutiona l ions , which ar e of differen t mass from those they replace , i s modificatio n o f th e assumed Debye spectrum of phonon modes. Thi s involve s th e introductio n of extr a phonon modes, tha t may eithe r be localize d a t th e defec t sit e o r propagated through the lattice ,** and also scattering of normal phonon modes at the defect site. The **scatterin g of thes e waves on crysta l defects , though producin g smal l changes i n oscillatio n amplitudes , can however, lea d to relativ e displace ments of adjacen t atoms much bigge r tha n th e displacement s produced by** Debye waves, as discussed by Kochelaev in 1960 (21). He considers that **f o r two-phonon processe s th e influenc e of defect s can be unimportan t and that the greatest effect occurs in the direct process. He also derives** an expression for the transition probability, taking as an example the. ion Cr³⁺ in octahedral environment; his analysis shows that it is independent of magnetic field and inversely proportional to the distance between the paramagnetic ion and the defect site. This means that the **relaxation time depends upon the concentration of the paramagnetic ions**

relaxatio n time depends upon the concentratio n of th e paramagneti c ion s

- 48 -

The samples used in this work are described earlier in Section 3.2. We were careful to use the same samples as those of Thorp et al (27) for the sake of comparison with their results and to explore the relaxation behaviour over an extended temperature range. The pulsesaturation method used in the previous work was again adopted. To allow measurement of spin-lattice relaxation times to be made over a wide temperature range above 4.2 K, the waveguide housing the specimen was surrounded by an araldite block (type AT1), as suggested by W. Hutton, Figure 4.3. The specific heat of this araldite was given by Parkinson and Quarrington (28), and due to its high thermal capacity at low temperatures it seemed to be a suitable material. The araldite, which was originally in a powdered form, was melted at \sim 120 $^{\sf O}$ C and cured at $\,$. \sim 140°C overnight. Then it was machined to fit the waveguide and another piece of araldite was prepared as a plunger; this had a piece of brass attached to its end for short-circuiting the waveguide where the sample was located. With this arrangement the warming-up time was sufficiently slow to permit measurements at intermediate temperatures between 4.2 K and 30 K to be made without any additional temperature stabilization equipment; Copper-copper/constantan thermocouples were used for the temperature measurements.

The amplifier system used to detect the recovery to thermal equilibrium had a dead $-$ time of 10 µsec; this dead time determined the upper temperature limit for measurements since it was found that T_1 decreased to the same order as the dead-time at about 30 K. An estimate of the total error in measurements of T^1 was between 10 and 15%, the main error resulting from misbalance of the bridge, Mason (29).

- 49 -

At tem**perature s below ?_bout** 8 **K th e variatio n follows , t o withi n experimenta l error, a T₁** α **T⁻¹ law. In this temperature range the magnitudes of T₁ a r e found t o be** 5.8 **mse c a t** 4.2 **K and** 2.8 **mse c a t** 8 **K, which ar e i n** close agreement with the previous measurements. The transition temperature between the two relaxation regimes is shown to be at nearly 8 K, and above this temperature the spin-lattice relaxation time varies as $T_1 \alpha T^{-3}$, giving a value of $T_1 = 1.6$ m sec at 10 K and falling only **a s T j a T , givin g a valu e of T^ =** 1.6 **mse c a t** 10 **K and fallin g onl y**

The corresponding temperature variation for the nominally higher gadolinium concentration sample, i.e. 0.05 at.% Gd, is depicted

highe r gadoliniu m concentratio n sample, i.e . 0.05 **at. % Gd, i s depicte d**

FIG. 4.7 Angular variation of T_1 in the ϕ - plane for **G d ³ yCaWO ^A (0 005%) , temperature 4-2K , frequency 37-5 GHz.**

in Figure 4.6. A very similar behaviour was obtained as with the first $sample_t$ with two distinct variations with temperature. The exponents of T, in the lower region of temperature are (-1) , indicative of a direct process, and (-3.6) indicative of a Raman-type relaxation in the higher temperature region. These values are in agreement with those obtained from Figure 4.5. The actual magnitudes of $T^{}_{1}$ at corresponding temperatures, e.g. 5.8 m sec for the 0.005 at.% Gd sample and 5.6 m sec for the 0.05 at.% Gd at 4.2 K suggests that at these gadolinium levels T_1 is not strongly dependent on concentration.

4.3.2 T_1 - angular dependence measurements

Investigation of the angular variation of T_1 was carried out for the sample 0.005 at.% Gd. Measurements were made in the ϕ -plane at 4.2 K and the results are shown in Figure 4.7. It is found that T^1 is anisotropic in the plane of measurements. In the first quadrant; (0 < ϕ < 90[°]), there is a fairly broad but distinct minimum between $\phi = 45^{\circ}$ and $\phi = 65^{\circ}$. It is shown that T_1 varies from a maximum of 11.6 m sec at $\phi = 25^\circ$ to a minimum of 4.1 m sec at $\phi = 55^\circ$; at this angle T_1 is reduced by a factor of about three. Rotation of the crystal through 180[°] in order to examine the range 180[°] < ϕ < 270[°]; in the third quadrant, revealed a similar variation of T_i with a minimum near ϕ = 235[°] and a maximum at ϕ = 205[°].

4.4 Discussion

4.4.1 The temperature dependence of T^1

From the theories of relaxation mentioned in Section 4.1, we may formulate a general equation that gives the dependence of spin-lattice

- 51 -

relaxation time on temperature as

$$
T_1^{-1} = RT^m + BT^1 + C \exp(-\Delta_c/kT)
$$
 (4.15).

where A, B and C are constants. In the first term, in the absence of a bottleneck or cross-relaxation effects, $m = 1$ indicating the occurrence of a direct process. In the second term; corresponding to the Raman process, $n = 7$ for a non-Kramers ion or $n = 9$ for a Kramers ion. The last term represents the Orbach mechanism, where $A_{\rm c}$ is the energy **splitting of the excited state above the ground level. Usually equation** (4.15) **i s applicable only to salt s where the paramagnetic ion concentratio n i s low so tha t the experimental conditions approximate to the** assumptions of a single ion theory where any co-operative mechanisms **such as cross-relaxatio n or exchange interaction s between cluster s of ions are not involved. As we are dealing with an S-state ion we may ex**pect that the Orbach-Blume mechanism will be effective, giving rise 5 **to a dominating T term i n equation** (4.15) **instead of the normal Raman** There is, in fact, experimental evidence for the \overline{T}^5 Raman process. behaviour in several S-state ions. For example, Bierig et al (30) found this kind of temperature dependence for Gd³⁺/CaF₂, Chao-Yuan **found the set of temperature dependence for** $2+\sqrt{2}$ **,** $2+\sqrt{2}$ **,** $2+\sqrt{2}$ Huang (11) also observed it in Eu $^{\circ}$ /CaF₂, Mn $^{\circ}$ /BaF₂ and Mn $^{\circ}$ /S

3 that the Orbach process is absent. It is known that the Orbach process is only important if the splitting $\Delta_{\mathcal{L}}$ is less than the Debye energy $k\theta_{\text{n}}$, which is that of the highest energy phonon in the lattice phonon **k 0 ^Q , which i s tha t of the highest energy phonon i n the lattic e phonon spectrum, i.e . i f**

$$
\Delta_{\rm C} \leq k \theta_{\rm D} \tag{4.16}
$$

 \mathbb{R}^n \mathbb{R}^n

where θ_{n} is the Debye temperature. For the gadolinium-doped crystals

- 52 -

used we may (in the absence of a direct determination), reasonably take 6_n as the value for pure CaWO_{$_A$} since the gadolinium concentration is low. Farley (32), using ultrasonic techniques for elastic constant determina**tions, reported that** $\theta_n = 155$ **K for pure CaWO,. From spectroscopic data** the value of Δ is about 30000 cm $\overline{}$, Dieke (33), and so k θ is much less than $\Delta_{\mathbf{C}^{\mathbf{i}}}$ (k = 0.695 cm Δ K Δ). We thus conclude that the Orbach process is not a possible mechanism. Moreover, if defect centres are present in the crystals the effective Debye temperature may be less than θ_{n} for **a perfec t lattice j hence the conclusion that the Orbach process i s not possible remains valid for imperfect crystals. Reference back to the general equation** (4.15), **suggests therefore that for Gd^ ''/CaWO a varia tio n of the form**

$$
T_1^{-1} = AT^m + BT^m \tag{4.17}
$$

may apply with m = 1, **and n =** 5. **The absence of the Orbach term i ^s confirmed by the experimental data because when plotting log T₁⁻¹ versus** T^{-1} we do not get a straight line as should be expected if the recovery **followed an Orbach mechanism, Figures** 4.8 **and** 4.9. **A simila r treatment was followed by Scott and Jeffrie ^s** (34) **. This absence of an Orbach type contribution was als o found i n the result s obtained with the doped** fluorides quoted above.

Our results, however, show that although there is a good fit to a $T^{-1.0}$ variation at low temperatures, the variation above about 8 K is much less rapid that r^{-5} . To obtain a formula that fits the experimental results we followed an analysis similar to that used by Scott and **Jeffries.** Starting with equation (4.17) we can obtain the values of m **and n from the log-log plot s i n Figures** 4.5 **and** 4.6. **Knowing them, we**

of 0 005 % Gd

FIG.4-11 *1]]* **T" ^m versus T ⁿ ~ m for sample (0 05 % Gd)**

then plot T_i ⁻¹ T ^{-m} versus T ^{n-m} as in Figures 4.10 and 4.11. These give **straigh t line s whose slope s and intercept s determin e th e constant s A** and B. Thus, the experimental data may be fitted by the expressions

$$
T_1^{-1} = 35 T + 0.5 T^3 \tag{4.18}
$$

f o r the 0.005 **at. % Gd crystal , and**

whic h reduce s t o

$$
T_1^{-1} = 35 T + 0.1 T^{3.6}
$$
 (4.19)

for the 0.05 at.⁸ crystal so that, on the average, one can take the variation as nearly r^3 in the Raman-type region. Inspection of these **equations shows that the contributions of the direct and Raman-type** processes become equal at about 9 K, above which temperature the Ramankind process is dominant as shown in Tables 4.1 and 4.2.

We may evaluate T_{c} , the temperature at which the direct and Raman processes are comparable, using Klemens' procedure, equation (4.10), **Raman processe s ar e comparable, usin g Klemens' procedure , equatio n** (4.10),

$$
T_c \simeq \frac{1}{2} \theta_D^{\frac{2}{3}}
$$
 (4.20)

for the constants A and B may be comparable in magnitude and $(E/k)^{\frac{1}{3}}$ is about unity in the microwave band we used. Next, we should take into **accoun t th e change i n th e Debye temperature arisin g from th e differenc e** in masses of the dopant ion, Gd³⁺, and the ion it substitutes, Ca²⁺. **Mason and Thorp** (35) **i n thei r studie s o f the influenc e of th e crystallin ^e** imperfections on spin-lattice relaxation in ruby, adopted the relation

$$
\theta_{i} = m^{-\frac{1}{2}} \theta_{D} \tag{4.21}
$$

to correlate between the Debye temperature for a defected crystal (θ, θ)

- 54 -

Table 4.1: Evaluation of the fitting equation,

 T^{2} = 35 T + 0.5 T³ for temperatures from 2 **K up t o** 30 **K.**

Table 4.2: Evaluation of the fitting equation ,

 T_1^{-1} = 35 $T^{1.008}$ + 0.1 $T^{3.6}$

for temperatures from 2 K to 30 K.

and that of a perfect crystal (θ_n) , where m is the mass ratio of the dopant ion to that which it replaces. Knowing that $\theta_{\text{D}} = 155$ K and the **atomic weights of Gd and Ca are 157.25 and 40.08 respectively , we find** that $\theta_i = 78$ K. Substituting this value, θ_i instead of θ_n in equation **(4.20)** we get $T_c \approx 9$ K which is almost the same as the values given **from the experimental data (Figures 4.5 and 4.6) and those given from** fitting expressions (Table 4.1 and 4.2).

The explanation of the observed r^3 variation appears to lie in the presence of defects in the crystals. As is mentioned in Section 4.2.5, a T^{-3} variation with T_1 in the Raman region was predicted by Castle et al (23) and fitted the observed behaviour of irradiation **Castl e e t a l (23) and fitte d the observed behaviour of irradiatio n**

Also, a study of the temperature dependence of the relaxation times for ruby single crystals from 1.5 K to 120 K reported by Mason and Thorp (35) has shown that the chromium ions occupy two types of sites within the lattice, one perfect and the other distorted. Although these workers were studying different crystals with a different dopant their suggestion of the type of defect present in the ruby crystals is of in Section 3.7. It seems likely that this sort of defect is a possible **i n Section 3.7. I t seems likel y tha t thi s sor t of defect i s a possibl e** i readed for confirmation.

In order to present some figures for defect densities in $\text{Gal}^{3+}/\text{CaWO}_{4}$ we notice that with the entry of Gal^{3+} ion into a Ca^{2+} site the formation of one calcium vacancy for every two Gd^{o+} ions occurs, which amounts to a calcium vacancy density of about 10^{18} cm^{-3} . Besides, concentrations of calcium and oxygen vacancies are also formed as Schottky

- 55 -

defects even in pure CaWO_A in air at the melting point. These are $\frac{1}{2}$ $\frac{1}{2}$ **and subscript s indicat e the crysta l lattic e site , Nassau (36) . For** CaWO_A, calculations of Schottky defects give the same order of magni**tude mentioned above for calcium vacancy density, and hence for oxygen vacancy density. Furthermore, etching studies , Farle y (32) , showed** that the dislocation density in calcium tungstate single crystals, grown by the same Czochralski technique as that used here, was about 10^5 cm^{-3} . We also notice that the temperature required for growth of calcium tungstate is about 1600[°]C_j that is considerably higher than that required for the fluorides in which (although data was not specifically given in the references quoted) a much lower dislocation density might be expected. Consequently there are substantial grounds for attributing the r^3 variation to defects although their exact nature is not yet fully resolved.

tio n to defects although thei r exact nature i s not yet full y resolved.

4.4.2 The angular variation of T₁

No theoretical treatment is attempted for the observed anisotopy of $T^{}_{1}$ in the ϕ -plane. However, an interesting comparison of results **comes from previous ultrasonic studies on CaWO_A single crystals made recentl y by Farley , Saunders and Chung i n 1975 (37) . These authors investigate d the elasti c properties of scheelit e structur e molybdates** and tungstates and found that in the ϕ -plane of calcium tungstate the **Young's modulus was anisotropic . Two features were noted, a maximum at** $\phi = 68.8^{\circ}$ and a minimum at $\phi = 23.6$, and these were identified with the "axes of acoustic symmetry" which correspond to extrema in the ultrasound velocities and are the acoustic pure mode directions for which the **acousti c energy flu x directio n i s collinea r with the propagation vector.**

- 56 -

FIG. 4.12 T₁ - Angular variation in the φ - plane for Gd/CaWO₄ **(0 005%) , temperature 4-2K, frequency 37-5 GHz , compared with ultrasonic measurements of Youngs modulus in the same plane (dotted curve).**

The positions of extrema in our T_1 variation show a remarkable coinci**dence with the "acoustic axes of symmetry" of the crystal . The ultra** sonic and relaxation data are compared in Figure 4.12. They show a **close fit between the direction of the minimum of** $T^{}_{1}$ **and the accustic Y-axis, and also of the maximum of** $T^{}_{1}$ **with the acoustic k-axis. The rati o of Young's modulus along the** *y* **and k axes was given as 2.1 at 295 K,** compared with the ratio of about 2.1 at 4.2 K for the spin-lattice relaxa**tio n rate s i n these directions . I t appears that the maximum relaxatio ⁿ** rate (i.e. minimum T₁) occurs when the ultrasound velocity is greatest and vice versa. The acoustic axes have 4/mmm symmetry in calcium tungstate and this accounts, on the same basis, for the maximum and minimum values **of T₁** found between $\phi = 180^\circ$ and $\phi = 270^\circ$.

- 57 -

CHAPTER 5

SPIN-LATTICE RELAXATION OF Fe³⁺ IN IRON DOPED MAGNESIUM OXIDE **SPIN-LATTICE RELAXATION OF Fe IN IRON DOPED MAGNESIUM OXIDE**

The main interest in studying the spin-lattice relaxation of Fe^{3+} **ⁱ n magnesium oxide singl e crystal s i s that i t provides another example of an S-state ion i n a wel l known lattic e structure . Although iro n doped magnesium oxide has received a great deal of attentio n from previous workers, most of their ESR studies were at X-band frequencies (** \sim **9 GHz).** The ESR spectrum of Fe³⁺/MgO at magnetic fields of 13.5 KG (i.e. Q-band frequencies) was reported by Cheng and Kemp in 1971 (1). They used a f method combining magnetic-circular-dichroism (MCD) and electron spin **resonance (ESR) for studying the spin-lattice relaxation mechanism. No** T_1 values were published in their work. Spin-lattice measurements, however, received less attention and almost nothing was published at higher freugnecies. Hence, our measurements of T₁ at Q-band (37.5 GHz) are thought to contribut something to this field.

5.1 Crysta l structure , doping and charge compensation

The magnesium oxide structur e i s that of the well-known sodium chloride ; of the type MX, where M denotes the metal ion or atom and X an electronegative element, e.g. oxygen in the oxides, or fluorine or **chlorin e i n the halides , etc . The lattic e i s face-centred cubic of** space group o_h^5 as indicated by Cornwell (2), (the point group o_h and the assignment of superscript by Schonflies is rather arbitrary). Each m agnesium atom has a coordination number of six, the neighbours being at the vertices of a regular octahedron. In this octahedral co-ordination **^a t the vertice s of a regular octahedron. In thi s octahedral co-ordination** and 0 **0.65 Å and 1.40 Å respectively.** Wyckoff (4) gave the lattice parameter

0.65 ? and 1.40 A respectively . Wyckoff (4) gave the lattic e parameter

as $a = 4.2112 \, \text{Å}$. By doping the single crystals of MgO with iron, the latter is expected to go into the lattice by substitution at the magnesium sites; the predominant valency state is Fe^{3+} as concluded by Thorp, Vasquez, Adcock and Hutton (5) in their recent work on FSR linewidths of Fe³⁺ in MgO, whose optical measurements also revealed features \mathbf{r} is a second feature optical \mathbf{r} is a second feature \mathbf{r} is a second feature optical features \mathbf{r} is a second f Further support is given by the comparison of the ionic radii of Fe^{3+} **which at 0.64 Å (3) is almost the same as the corresponding** M_S^{2+} **ion.** The extra positive charge on the Fe³⁺ ion however requires that there should be some mechanism for charge compensation in the crystal. Actually, three processes for achieving charge neutrality could be effective as discussed by Wertz and Auzins (6). First, compensation might occur with an extra electron on an oxygen ion, O⁻³. However, this was dismissed as representing a very unstable configuration. This leaves us with two reasonable possibilities outside the oxygen octahedron. One is replace**reasonable possibility** $\frac{2^+}{10}$ **s** $\frac{1}{100}$ **b** $\frac{1}{100}$ $\frac{1}{100}$ $\frac{1}{100}$ $\frac{1}{100}$ $\frac{1}{100}$ $\frac{1}{100}$ $\frac{1}{100}$ **2+ +1 ment of a Mg ion by a unipositiv e ion such as the L i ion, which v/as postulated by Prener (7) . From the ioni c radi i point of view, thi s should f i t readil y i n the crysta l (with Na⁺ * les s likely) , while any other unipositiv e ion i s probably too large to fi t without undue distortion .** The alternative is to have Mg²⁺ vacancies distributed at random throughout the crystal. The possibility of interstitial o^{-1} ions was rejected, since there is hardly room in the lattice to accommodate them.

5.2 Experimental results and discussion

The single crystals of iron-doped magnesium oxide upon which measurements were made were obtained from W & C Spicer Ltd. (Cheltenham), having been grown by electrofusion using pure powdered ferric oxide and pure

since there i s hardly room i n the lattic e to accommodate them.

- 59 -

powdered magnesia as the startin g materials . Since there was no deliberat e doping of a univalent element to maintain charge neutralit ^y one may invoke the vacancy compensation mechanism. The iron concentration s i n the samples used i n thi s work were 140, 310 and 710 p.p.m.; these had been determined by optical spectrographic analysis (Johnson-Matthey Ltd.) to an accuracy of about 2%. Neither optical examination nor x-ray back reflection photographs, used to orient the samples, **revealed any evidence of macroscopic cracking, flaws, strai n or mosaic** formation. This led us to assume that the samples were of good crystal**lin e quality .**

The pulse saturation technique, as mentioned before, was used for the spin-lattice relaxation measurements at 37.5 GHz. Measurements were **carried** out for the central $\frac{1}{2} \leftrightarrow -\frac{1}{2}$ transition at 4.2 K, except when **otherwise mentioned elsewhere.**

5.2.1 Observation of two decay rates

The crystals were oriented so that the magnetic field H was along **the <100> direction . I n most of the semi-logarithmic plot s produced from the photographs of the exponential decay curves, the existence of two relaxatio n rate s could be observed as i n Figure 5.1. The longer relaxa tion time was taken as the spin-lattice relaxation time** T^1 **, whilst the shorter relaxatio n time could be attribute d to some contribution from** the energy levels of the system in a cross-relaxation mechanism, as **discussed by Manenkov and Prokhorov (8) . Previous experimental result ^s on Fe^+/MgO a t 10 GHz by Castl e and Feldman gave two values for the exponents in the rate equation and were published by Shiren (9). In a preceding publication , Shiren (10) reported measurements of spin-phonon** interactions for iron group ions Cr^{3+} , Mn^{2+} , Fe^{3+} , Fe^{2+} and Ni^{2+} in MgO,

- 60 -

Table 5.1: Observations of more than one decay constant i n the relaxatio n of 3+ Fe /MgO at 4.2 \'.

utilizin g microwave ultrasoni c spin resonance techniques. Using hi s measured spin-phonon coupling constants, Shiren (9) calculated the **relaxatio n times from the theories as proposed by Van Vleck (11) and** modified by Mattuck and Strandberg (12). Our results are given in Table 5.1 in which they are compared with Shiren's computed values and **the measurements of Castl e and Feldjnan of T^ for Fe"^⁺ /MgO. Thi s table** shows the presence of more than one component in the relaxation decay **of Fe^⁺ /MgO, i n both the experimental and predicted data, although direc ^t** comparison of the results is not convenient at this stage because of the **differenc e i n the operating frequencies. Shiren's computations were based on deriving the rate equations, as already given by Andrew and** Tunstall (13), for the different energy levels available in the system. For ions with $S = \frac{5}{2}$ and the $\Delta m = 1$ transitions there are, in general, **three relaxatio n rate s i n the return to equilibrium from saturatio n or** inversion. Experimentally, the relaxation behaviour of a particular level will frequently be dominated by one of the relaxation rates if it has a large amplitude constant. In our measurements we have taken the final part of the recovery curve, which gives the longest component, to derive the spin-lattice relaxation time T^{\prime} .

3+ 5.2.2 Temperature dependence of T^ for Fe /MgO

Measurements of spin-lattice relaxation time T₁ were made in the temperature range from 4.2 K to 27 K for the Fe³⁺/MgO sample of 310 p.p.m. Fe doping. The magnetic field was directed along the <100> direction of the crystal and we monitored the relaxation of the $\frac{1}{2} \leftrightarrow -\frac{1}{2}$ transition. The araldite block was again used, as mentioned in the preceding chapter, **Section 4.3, as a means of letting the system warm up slowly enough for** monitoring the change of spin-lattice relaxation time with temperature.

- 61 -

The variation of T₁ in the range of temperatures studied, is depicted in **Figure 5.2. This shows two regimes of dependence on temperature T₁** as T^{-1} at lower temperatures and $T^{-4.6}$ above about 20 K. The values of **T**₁ were derived from the photographs of the exponential decay traces at the corresponding temperature by choosing the longest relaxation time as the spin-lattice relaxation time at that temperature. The observed dependence of T₁ on temperature agrees with the theoretical predictions demonstrating a T^{-1} behaviour as a direct process at low temperatures $d \cdot \mathbf{b} = \mathbf{b} \cdot \mathbf{b}$ $\frac{3+1}{2}$ and $\frac{3+1}{2}$ and $\frac{1}{2}$ and $\frac{5}{2}$ usuistion of $\frac{1}{2}$ with tomorphus in **S-state ion, Fe** should obey a T \blacksquare variation of T \blacksquare with temperature in \blacksquare the Raman region as discussed in Section 4.2.4. Knowledge of the transi**tion temperature** $T^{}_{\alpha}$ **, at which the Raman process begins to dominate over '** the direct process, can provide information about the Debye temperature of the crystal. This was attempted by carrying out a similar treatment **as previously made for Gd^/CaWO^ i n Section 4.4.1. The only difference,** here is that we start with a known value for T_c to derive the Debye tem**perature** $\theta_{\bf n}$ **, whereas in the previous treatment we have done the reverse.** Quoting equation (4.20) in Section $4A.1$, this gives the relation of T , and θ , as

$$
T_C \simeq \frac{1}{2} \theta_i^{2/3}
$$

From Figure 5.2, $T_C = 20 K$, hence

 θ_i = 253 K.

l

Also, as we are dealing with Fe^H ions which substitut e for Mg ions i n the MgO single crystal we may use the relation

$$
\theta_{\mathbf{i}} = m^{-1/2} \theta_{\mathbf{D}}
$$

where m is the ratio of the atomic masses of iron to magnesium ions.

- 62 -

Therefore ,

$$
\theta_{\mathbf{i}} = \left(\frac{55.847}{24.305}\right)^{-\frac{1}{2}} \theta_{\mathbf{D}}
$$

or ,

0 ^D = 383 K .

For comparison, we find from the physical tables (14) that the Debye **temperature for MgO has been given as 946 K. This was reported by** Barron et al, 1959 (15), when studying the heat capacity of crystalline **magnesium oxide. I t was found that thei r published value was the Debye temperature at 0 K (** θ_0 **) and from their plotting of** θ_n **versus temperature** in the range 20 < T < 300 K we found that θ_{p} at 77 K is nearly 750 K. This shows that our estimated θ is far below that published by Barron **e t al . Reasons fo r the discrepancy i n the result s may be (a) the difference s i n the experimental techniques, (b) the preparation of tiie samples examined.** This latter condition may include the particle size of MgO, the surface roughness and other possible factors such as con**tamination of the surfaces by adsorbed gases.**

This value of T_n is in exact agreement with that reported by Pace, Sampson and Thorp, 1961 (16) in their studies on synthetic sapphire **(Fe^/Al^O) at 34.6 GHz. Using a pulse saturatio n method, they found** that the main features of the variation of the relaxation times show a T^{-1} dependence on temperature up to 10 K and a transition to a region of T^{-5} occurs at about 20 K.

Kask et al, 1963 (17) studied the paramagnetic relaxation of the Fe^{3+} ion in corundum (Al_2O_3) in the 3-cm range by utilizing the pulse saturation method. The temperature dependence of T₁ was determined in the interval $2 - 80$ K. It was shown that T_1 varies approximately as

 T^{-1} in the region from 2 to 5 K. In the interval 5 - 15 K, T_1 varied anomalously slowly and in the 20 - 80 K range T_1 varied as T^{-6} .

5.2.3 Concentration dependence of T_1

Measurements of T₁ for the Fe^{3+} /MgO samples available gave the values presented in Table 5.2. Again, we emphasize that the spin-lattice relaxation time T₁ was chosen as the longer time in the semi-logarithmic plots of the recovery traces photographs. These were taken at 4.2 K with the magnetic field **H** along the <100> direction.

It has long been observed that at sufficiently low temperatures and sufficiently high concentrations of paramagnetic impurities the transfer of energy from a spin system to the lattice may be dominated by concentration-dependent relaxation processes. One explanation was suggested by Van Vleck, 1960 (18), i.e. that the spins in the crystal cross relax to some paramagnetic sites which relax rapidly to the lattice. The rapidly **relaxin g site s may, for example, consis t of spins of a paramagnetic species** having exceedingly short spin-lattice relaxation times, spins located in **distorte d crysta l fields , or exchange-coupled cluster s of two or more** ions which relax rapidly to the lattice as a result of phonon modulation **of** the exchange coupling. In studying the spin-lattice relaxation of cr^{3+} **ions i n ruby crystals , Standley and Vaughan, 1965 (19) suggested that the observed concentration-dependence i s possibl y due to impurity ions that constitute the fast relaxing centres. Solomon in 1966 (20) studied the** concentration-dependence of spin-lattice relaxation times for Mn²⁺ and **concentration-dependence of spin-lattic e relaxatio n times for Mn and** He found that T_1 is roughly proportional to the inverse of concentration. Similarly, we apply this law to our results and it gives the values presented in the last column in Table 5.2. The agreement between the

presented i n the las t column i n Table 5.2. The agreement between the

Table 5.2: Concentration dependence of T₁

experimental and predicted values of $T₁$ is good and it is tempting to conclude that for Fe³⁺/MgO the spin-lattice relaxation time obeys $_{\rm (concentration)}$ ⁻¹ law.

5.2.4 The angular variation of T_1

The variation of relaxation time T_1 with crystal orientation **1** f o r th e \mathcal{L} is the result of respectively. investigated. Three samples of iron concentrations 140, 310, 710 p.p.m. were examined a t liqui d heliu m temperatur e **(4.2** K) . The spin-lattic ^e relaxation times were measured in the angular range from $\theta = 0^\circ$ to θ = 90°, where θ is the angle between the magnetic field **E** and the <100> direction of the crystal. The angular dependence behaviour of these three samples is depicted in Figure 5.3. The sample of 310 p.p.m. Fe showed two apparent minima at angles θ of about 30[°] and 75[°], having values of T₁ as 0.44 m sec and 0.49 m sec, respectively. This behaviour was not evident for the other two samples; 140 p.p.m. Fe and 710 p.p.m. Fe. However, we noticed that the 310 p.p.m. Fe sample did not show 'extra' lines in the ESR spectrum as did the 140 and 710 p.p.m. Fe \cdot samples, which might indicate that they are not exactly similar and differences in behaviour might arise. The decrease in T_1 values at certain angles could be explained by the cross-relaxation between two, or more, transitions. It is interesting to know that, from Thorp et al's (5) the straight straight straight $3+$ \cdot **3+** the $-\frac{3}{2} \leftrightarrow -\frac{1}{2}$ and $\frac{1}{2} \leftrightarrow \frac{3}{2}$ transitions are expected to overlap with the main transition $(\frac{1}{2} \leftrightarrow -\frac{1}{2})$.

Donoho, 1964 (21) worked out the theoretical investigation which predicted the form of the angular dependence for Cr^{3+} in ruby. No such theoretical treatment was attempted for Fe^{3+} /MgO. But, in general,

 $N_{\rm eff}$ theoretica l treatmen t was attempted for $\sigma_{\rm eff}$, in general , in general , in general , in general ,

4.2K and 37.5 GHz

we may conclude that the angular dependence of the relaxation time is a consequence of the variation in admixture between states as the angle θ changes; this is in agreement with Standley and Vaughan (19).

5.2.5 Frequency dependence of T_1

Since the measurements of T_1 reported here were made at one frequency of 37.5 GHz, they provide by themselves no information on the frequency dependence of the relaxation time. However, Shiren (10) has reported computed values of T_1 at 10 GHz, also, in the same publication, Castle and Feldman have published measured values for T_1 at 10 GHz. On reviewing the laws of dependence of T_1 on frequency f , two particular cases arise, as discussed by Thorp, Sturgess and Brown, 1972 (22), viz. (a) the behaviour of the ion represented by an isolated Kramers doublet showing a T₁ α f⁻⁴ dependence, and (b) the non-Kramers ion which gives a $\texttt{T}^{-}_{\texttt{1}}$ $\texttt{\alpha}$ \texttt{f}^{-2} dependence. Applying these two laws to our results we find a f dependence. Applying thes e two law s t outros e two law s t output s we find α For comparison of tha t th e a f law i s bette r obeyed , Tabl e **5.3.** Fo r compariso n o f results we refer to Davis and Wayner, 1964 (23) who showed that potassium $\text{colsalticyanide containing }\text{Fe}^{3+}\text{ obeyed equation T, }\text{ = a H }^{-4}\text{ T}^1\text{ very closely, }$ displaying a T₁ α H $^{-4}$ dependence (or T₁ α (frequency) $^{-4}$) for the direct process at helium temperatures from 4 GHz to 12 GHz. This, in fact, agrees with the predictions of Van Vleck, 1940 (11) for the spin-lattice relaxation time dependence on magnetic field at low temperatures in the direct region of relaxation, for an isolated Kramers doublet. Van Vleck concluded that regarding the dependence on field strength his calculations also apply to Fe^{3+} (in iron alum) as well as Cr^{3+} (in chrome alum).

5.3 **Conclusion**

The observation of two decay rates in the recovery curves may

- 66 -

Table 5.3: Application of f^{-2} and f^{-4} laws of

dependence of T_1 on frequency.

indicate that there is a contribution from the other energy levels of the Fe^{3+} system. However, this could not be due to a fast relaxing centre, as in the case of exchange interaction, because the two measured 3+ rate s are comparable in magnitude. We may conclude that re- fens in MgC crystals behave as expected from the theory for an S-state ion regarding the T₁-temperature dependence, since it has shown an approximate r^{-5} dependence. With the iron concentrations available we have seen that T_i varies approximately as the inverse of the concentration; a behaviour which was reported previously for several materials. The angular variation of T_1 revealed some features of cross-relaxation of certain transitions with the main transition under experiment. This manifested itself in the decrease of T_1 at specific angles. Finally, comparison of our measurements of T_1 at 37.5 CHz with published results compariso n o f ou r measurements o f T^ a t 37.5 GHz wit h publishe d result ^s a t 10 GHz reveale d tha t tha t tha t the dependence of $\mathbf{1}$ T_1^{\dagger} α (frequency) $^{-4}$ behaviour which is expected for Kramers' ions according to the present theories.

CHAPTER **6**

- 68 -

CAVITY GROWTH IN NEUTRON IRRADIATED MAGNESIUM OXIDE.

With the knowledge acquired about the ESR behaviour of $Fe³⁺$ in MgO single crystals we were able to contribute to the study of cavity growth in neutron irradiated magnesium oxide. This was achieved by the investigation of the ESR spectra after annealing the samples in the temperature range from 1475 to 1775[°]C and a subsequent study followed (in collaboration with G J Russell) using transmission electron microscopy (TEM). Since we will be dealing with a rather new topic, we think it may be reasonable to begin with some introduction to the nucleation and growth of cavities.

6.1 Introduction

The growth of cuboidal cavities is a feature of irradiation damage occurring in ionic single crystals. To nucleate these defects and to sustain their growth it is necessary to create a sufficient numbar of vacancies with a mobility high enough to allow agglomeration. For this to occur in magnesium oxide, Morgan and Bowen, 1967 (1) have shown that it is necessary to irradiate to a dose exceeding 10^{20} n v t (in this notation n is the number of neutrons per unit volume, v the velocity of neutrons and t is the time of exposure) and subsequently to anneal in argon at a temperature greater than 1500 $^{\circ}$ C for one hour. In addition to the production of vacancies, exposure to such irradiation results in the transmutation of magnesium and oxygen nuclei thereby producing mainly inert gas atoms of neon and helium, as discussed by Wilks, 1966 (2). Morgan and Bowen demonstrated that the cavities in annealed material contained these gases demonstrate d tha t these gases in anneale d materia l contained these gas

In the case of the alkali halides it has been shown that impurity atoms often play an important role in radiation damage processes. The MgO studied by Morgan and Bowen was known to contain a relatively large impurity concentration of about 500 ppm which was chiefly Fe, Al, Ca and Si. Thus it is expected that at least some of these impurities may be involved in the cavity growth process. However, to date, no evidence for the correlation between impurity content and cavity growth has been reported and the aim of this study was to investigate if any such relationship existed. Transmission electron microscopy on its own was inadequate to identify impurities so a complementary technique was necessary. Such a technique is that of electron spin resonance which is not only capable of detecting very low levels of certain impurities, but is also useful for $\dot{}$ monitoring changes in local environments. ESR has already been used extensively in the study of neutron irradiation damage in MgO and of the effect of annealing at temperatures below that necessary to nucleated cavities, as indicated by Henderson et al, 1971 (3). Thus it was intended in this work to extend the use of this technique to the study of samples containing cavities and to correlate the results with TEM of the same samples .

6.2 Experimental

The single crystals of MgO used for this study were obtained from Semi-Elements Inc., Saxonburgh, Pa. Cleaved specimens having dimensions 3 of about 10 x 4 x 0.5 mm were given a heat treatment for 18 hours at 1300 $^{\circ}$ C in an ambient of hydrogen before being irradiated to a dose of 3.66 x 10^{20} nvt in the Harwell Dido reactor. The irradiation temperature was about 150°C. Post-irradiation annealing treatments, each of one hour duration, were carried out over a range of temperatures at 50° C intervals

duration , were carrie d ou t ove r a rang e o f temperature s a t 50°C interval s

69 -

between 1475 and 1775 $^{\circ}$ C in an atmosphere of argon. The heating up and cooling periods were short compared with one hour annealing time; to achieve the latter. the samples were air-cooled.

ESR spectra in the region of magnetic field corresponding to the g-value of the free electron were obtained for each of the annealed samples. All measurements were made at Q-band (35 GHz) and liquid nitrogen temperature (77 K). The magnetic field direction was in a $\{100\}$ plane of each specimen. Calibration of this magnetic field was made using a trace of $D.P.P.H.,$ the g-value of which was taken to be $2.0037,$ supplementing the electromagnet calibration obtained employing the proton/lithium resonance technique.

After examination by ESR the samples were cleaved and the flakes · so produced were further reduced in thickness by chemical polishing using phosphoric acid at about 150^oC (see for instance Washburn et al (4)). The thinned samples were examined in a JEM 120 electron microscope by G J Russell (5) who produced a number of micrographs recorded from different areas for each annealed specimen to determine the size distribution of the cavities. The sample orientation was close to a <100> direction in all cases.

6.3 Results

6.3.1 Transmission Electron Microscopy

Examination by TEM showed that the sample annealed at 1475° C contained interstitial dislocation loops and tangles as seen in Figure 6.1. This damage is similar to that described and discussed by Groves and Kelly, 1963 (6) and by Bowen and Clarke, 1964 (7). In all the samples annealed above 1500°C cuboidal cavities as seen in Figures 6.2a and 6.2b were present. These figures, which were recorded from the sample annealed

were present . These figures , which is the sample and m these figures , which example and m the sample and an

- 70 -

at 1675 C, show that the cavities range in size from about 50 to 300 \AA and are bounded by $\{100\}$ faces. The dislocations which were still present in those samples annealed at temperatures greater than 1500 $^\mathsf{O}\mathsf{c}$ were often associated with cavities. This observation is in agreement with that of Morgan and Bowen (1) , but we would further point out that dislocations frequently appeared to be pinned by the cavities as at A in Figure $6.2a$. This pinning was such that the orientation of the dislocations close to the cavities was near to a <110> direction, as at A in Figure $6.2b$.

The histograms in Figure 6.3 show the size distribution of the cavities as a function of annealing temperature. They were derived from at least ton micrographs taken from different areas for each annealed sample. The main observation to be made from these size distributions is that the mean cavity size increases dramatically on annealing at a temperature exceeding some value between 1575 and 1625 $^{\circ}$ C. Annealing at higher temperatures than this does not appear to produce any further increase in cavity size or significant change in the size distribution.

The total cavity volume per unit crystal volume and the concentration of cavities for each annealed sample have also been estimated and are given in Table 6.1. For the purpose of these calculations a mean specimen thickness for the total area from which the size distributions were obtained was taken to be 1000 $\overline{\mathrm{R}}$, a typical sample thickness for transmission microscopy. Accepting the crudeness of this approximation, Table 6.1 shows that the large increase in cavity size which occurs at 1625° C (see Figure 6.3) is accompanied by a large increase in the ratio of the total cavity volume to crystal volume. The cavity concentration remains more or less unchanged.

6.3.2 Electron Spin Resonance

The main results of the ESR studies are illustrated by the spectra obtained from the specimens annealed at 1475° C, 1575° C and 1625° C respectively. Although detailed analyses of the particular specimens used were not available, data on other MgO crystals made by the same supplier (Semi-Elements Inc.) has been given by Martin, 1968 (8) whose results showed that the major paramagnetic impurity was iron at about 100 ωt . ppm; it is also generally accepted from analytical evidence on other MgO crystals that both manganese and chromium are often present at low trace levels.

Figure 6.4 shows the spectrum obtained with the magnetic field parallel to <100> for the specimen annealed at 1475[°]C which contained interstitial loops but no cavities, (c.f. Figure 6.1). The prominent features are (a) six lines marked A, (b) a line B having $g = 1.9785$ and (c) a line C having $g = 2.0034$. Features A and B were identified by comparison with Henderson and Wertz's data, 1968 (9) as arising from the $+\frac{1}{2} \longrightarrow -\frac{1}{2}$ transition of Mn²⁺ and from Cr³⁺ respectively. The origin of line C is in some doubt. Further measurements showed that it was isotropic, indicating that it could not be ascribed to an interstitial atom with an associated vacancy; although the g-value is reasonably close to that of the vacancy α is reasonable that the gradient $3+$ th e that the that the that of the that the that of the that the theory $\frac{1}{2}$ $\frac{1}{2}$ $\frac{1}{2}$ cransition of Fe in octahedral symmetry, this interpretation is precluded because the $\pm \frac{3}{2} \leftrightarrow \pm \frac{1}{2}$ transitions are absent; and finally the g-value does not fit with any of those of the impurities listed in the review by Henderson and Wertz. Evidence given later suggests that line C may arise from an electron trapped in a vacancy to form a centre persistent even at the annealing temperatures used.

o, I n th e spectr a obtaine d fro m specimens anneale d a t bot h **1525** C and 1575 $^{\circ}$ C, i.e. just above the temperature necessary to nucleate cavities, new features were observed. These are shown in Figure 6.5 which refers

- 72 -

to a specimen annealed at 1575[°]C. The most important change is the **occurrence of the new lines marked D and E; the g-value of 2.0031 for t h e D transition , togethe r wit h th e observed anisotrop y o f E lines , 3+ f i t wel l wit h reporte d dat a on Fe (9,10) and enabl e them t o be i**dentified as the $-\frac{1}{2} \leftrightarrow \frac{1}{2}$ and $\pm \frac{3}{2} \leftrightarrow \pm \frac{1}{2}$ transitions respectively of Fe^{3+} in octahedral symmetry, i.e. Fe³⁺ ions occupying magnesium sites. The other differences appear to be associated with localised detailed changes in the manganese environment; they include additional transitions **close to each of the six A lines and also transitions F situated midway between the A lines.** The transitions F are of low intensity and have b the same separation as the A lines.

The spectra of specimens annealed above 1575° C (e.g. Figure 6.6) differ from those just described in two major respects. In the first place there is no indication of the D and E lines corresponding to Fe³⁴ in octahedral symmetry; secondly, the additional lines in Figure 6.5 **i n octahedra l symmetry; secondly , the additiona l line s i n Figur e 6.5** $2 +$ **a** \int_{0}^{3+} lines remained approximately constant throughout all the annealing **C r** restments and consequently the byperfine components of Mn^{2} could be used as an intensity reference, c.f. (11). On this basis it appears that in Figure 6.6 the intensity of line C has increased by approximately two times, indicating that annealing at 1625[°]C produces a two-fold increase in the number of centres responsible for line C.

6-4 Discussio n

An important conclusion of Morgan and Bowen (1) from their studies **of neutro n irradiate d and anneale d MgO was tha t t o nucleat e cavitie s** it was necessary to anneal samples irradiated to a dose in excess of

10 nv t a t a temperatur e greate r than 1500 C i n an ambient o f argon. Thi s minimum critica l temperatur e was attribute d t o the activatio n energy associated with vacancy mobility. In addition, the results of t h e annealin g studie s describe d her e concernin g the nucleatio n and growth ^o f cavitie s would sugges t tha t anothe r critica l temperature fo r the growth exist s i n th e temperatur e range of 1575 t o 1625°C. While annealin g above some temperature s withi n thi s range does no t produce any significan t change ⁱ n the concentratio n o f cavities , th e rati o of tota l cavit y volume t o unit volume of crystal increases by an order of magnitude. This must similarl y be accounted fo r by the movement o f vacancie s and consequentl y Russel l e t a l (12) proposed that , followin g the nucleatio n of cavities , some mechanism exists which impedes further growth of these defects until **anothe r critica l temperatur e (fo r an hour annealin g period) i s exceeded. An indicatio n of th e natur e of thi s mechanism can be inferre d from the result s of.ou r ESR measurements a s wil l be discusse d later .**

One feature of cavities which was noted by Morgan and Bowen (1) was tha t they were ofte n locate d a t cusps i n dislocatio n lines . I n the presen t annealin g studie s we have found tha t thes e cusp s correspon d t o two sections of dislocation each pinned to a corner of a cavity and lying **clos e t o a <110> directio n i n the immediate proximit y o f the cavit y as ⁱ n Figure s 6.2a and 6.2b. The associatio n o f cavitie s wit h dislocation s ⁱ s interprete d a s follows . When an interstitia l loop, which i s stil ^l present in a sample at an annealing temperature greater than 1500°C,** m oves through the crystal it is probable that the interaction with the **cavitie s presen t wil l resul t i n partia l annihilatio n of th e loop by vacancie s from th e cavities . The movement o f th e part s o f th e loop near cavitie s wil l consequentl y be impeded. I t i s furthe r suggeste d tha t t h e observe d <110> orientatio n o f dislocation s i n th e regio n o f cavitie s**

- 74 -

is related to a favourable configuration for the above annihilation **proces s t o occur . Thi s i s attribute d t o th e fac t tha t i n the NaCl** structure (which also applies to MgO), the uninterrupted rows of anions and of cations in <110> directions make diffusion of vacancies of either type more likely in these directions than in others.

The ESR results show that the nucleation of cavities, in the samples annealed at 1525^{O} C and 1575^{O} C, is accompanied by the appearance **samples anneale d a t 1525 C and 1575 C, i s accompanied by th e appearance c** material made by the same supplier has shown that iron was present in the specimens (8). Due to the pre-irradiation heat treatment in hydrogen it is most likely that any iron present will be in the divalent state, **c.f.** (13); this view is supported by the absence of $\text{Fe}^{\frac{3}{1}}$ lines in specimens annealed at temperatures below 1500°C (Figure 5.4).

specimens anneale d a t temperature s below 1500 C (Figur e 6.4) . As th e post-irradiatio n annealin g took plac e i n an iner t atmosphere 2^+ into $\mathbf{F}e^{3\mathbf{T}}$ **t he catio n vacancie s necessar y fo r th e conversio n o f F e int o Fe on** increasing the annealing temperature from 1475[°]C to 1525[°]C must have come from within the crystal. An adequate supply of vacancies is known to be **f** produced when the vacancy clusters, which are about 7 $\frac{0}{0}$ in diameter and which are present in similarly treated specimens, suddenly collapse on **annealing at about 1500°C, Martin, 1966 (14). The disappearance of the annealin g a t about 1500°C, Martin , 1966 (14) . The disappearanc e o f the** lines at temperatures above 1625 C **F e line s a t temperature s above 1625 C coul d be explaine d eithe r by a 3+ 2+ reductio n of F e int o Fe by the outward diffusio n of catio n vacancie s** or by the trapping of vacancies near the Fe³⁺ sites, creating an Fe³⁺ **vacancy complex, as reported by Henderson et al, 1971 (15), whose ESR would probabl y fal l i n the low magnetic fiel d regio n outsid e the presen t** range of measurement. Since the subsequent growth of the cavities indicates that a large number of vacancies are retained in the crystal **t he outward diffusio n explanatio n appear s unlikel y and th e trappin g**

- 75 -

mechanism more probable .

In view of the ESR evidence we envisage the cavity nucleation and growth proceeding by two stages as follows. On annealing just above **1500°C** a critical vacancy mobility is exceeded and small cavities are **nucleate d i n the manner describe d by Morgan and Bowen (1) . Simultan eousl y ther e i s a conversio n o f iro n t o Fe i n octahedra l symmetry a t magnesium sites ; thi s conversio n use s vacancie s release d when cluster s collaps e a t about 1500°C which then form charge compensating centre s fo r the Fe³⁺ ions.** After mucleation negligible cavity growth occurs until **an** annealing temperature of 1625°C (for one hour) is reached, see Figure **6.3. Thi s behaviou r i s attribute d t o mobile vacancie s bein g trappe d** ³⁺ ³⁺ sites in preference to condensation at cavities. A calcu**lation , based on the observe d cavit y growth between th e annealin g tem**peratures of 1575^oC and 1625^oC and an iron impurity level of 100 ω t. ppm. shows that the number of vacancies required to associate with all the **shows that-th e number of vacancie s require d t o associat e wit h al l the R** account for the cavity growth. When this stage is completed, cavity **arowth can proceed. It is suggested that the presence of iron is not** expected to alter the magnitude of ultimate growth significantly. However, the extent to which growth is impeded, and hence the annealing **temperature necessary for the last growth stage, would be expected to increase with iron concentration. Further evidence which indicates that** cavity growth is incomplete when annealing at 1500°C is provided by the **measurements of Bowen (16), who recorded the density variation with** annealing temperature for similarly treated MgO. His results suggest that cavity formation is a two stage process, as our studies using **different techniques (TEM and ESR) have confirmed to be the case. In** \cdot **addition, the high precision X-ray measurements of Briggs and Bowen,**

addition , the hig h precisio n X-ray measurements of Brigg s and Bowen,

- 76 -

1968 (17) showed that complete recovery of the lattice parameter to the **unirradiated value did not occur until the annealing temperature reached about 1750°C. However, interpolatio n of thei r dat a would sugges t tha t most of the recovery had occurred at about 1650°C. So, allowing for t h e fac t tha t thei r materia l was irradiate d t o more than twic e th e dose o f tha t used i n thi s study , i t i s concluded tha t ther e i s a reasonabl e correlatio n between the minimum temperature a t which we have found i t necessar y t o annea l t o produce most of th e cavit y growth and tha t reporte d by Trigg s and Bowen t o obtai n almos t complete recover y o f th e lattic ^e** parameter. To our knowledge this influence of an impurity on the move m ent of vacancies and cavity growth has not previously been reported. **Here it appears that iron plays a significant role. It is possible that othe r impuritie s may ac t i n a simila r way, bu t thi s remains t o be established .**
