ABSTRACT:

Background: Attention deficit hyperactivity disorder (ADHD) is the most frequent behavioral disorder of childhood and is characterized by hyperactivity, attention problems and impulsivity. Pharmacological and behavioral therapies have been shown to be effective. In addition, the role of dietary compounds in the etiology and possibly the treatment of ADHD has attracted increasing attention. For example, the lack of dietary essential fatty acids has been suggested to be associated with symptoms of ADHD in humans.

Objective: To investigate the effects of omega-3 polyunsaturated fatty acids (n-3 PUFAs) on locomotor activity in the spontaneously hypertensive rat (SHR) which has been proposed as an animal model of ADHD.

Methods: Two groups of randomly assigned spontaneously hypertensive rats were fed with either n-3 PUFA-deficient or n-3 PUFA-enriched food (based on AIN93G) for six weeks and this was continued during the phase of behavioral testing. Locomotor activity was subsequently assessed using an open field test.

Results: The results showed a marked difference in locomotor activity between the two groups of SHRs. In comparison with rats fed with n-3 deficient food, the animals on an n-3 enriched diet showed a statistically significant decrease in motor activity as assessed by the distance traveled.

Conclusions: The present study demonstrates a marked reduction in locomotor activity following an n-3 PUFA-enriched diet in SHRs, i.e. the dietary enrichment with n-3 PUFAs reduced the motor activity in an established animal model of ADHD. Dietary n-3 PUFAs may therefore play a role in the pathophysiology of ADHD.

Key words: omega-3 polyunsaturated fatty acids, attention deficit hyperactivity disorder, ADHD, animal model, spontaneously hypertensive rat, SHR, motor activity

BACKGROUND:

Attention deficit hyperactivity disorder (ADHD) is the most frequent behavioral disorder of childhood. The characteristic features of children and adolescents with ADHD are excessive motor activity, inattention and impulsiveness [1-4]. ADHD affects approximately 3-5 % of children and adolescents worldwide, with a higher prevalence in boys [5-7]. Genetic, neurobiological, social and environmental factors have been discussed in regard to the etiology of ADHD [5, 8, 9].

Nutrition is thought to play an important role in the behavior and cognitive functioning of children and dietary factors in the etiology of ADHD have been discussed [10, 11]. For example, it has been suggested that suboptimal omega-3 polyunsaturated fatty acid (n-3 PUFA) levels may contribute to ADHD symptoms. The rise in consumption of processed foods and vegetable oils has markedly increased the intake of omega-6 (n-6) PUFAs in Western diets, while the consumption of n-3 PUFAs in fish, nuts and seeds has declined. The ratio of n-3 : n-6 PUFAs has consequently decreased from about 1 in traditional diets to approximately 1:15 [12]. Some studies have reported that children with ADHD have reduced levels of blood n-3 PUFAs compared to matched healthy control subjects [13, 14]

INTRODUCTION:

Spontaneously hypertensive rats (SHRs) were developed by inbreeding rats of the Wistar-Kyoto (WKY) strain. The SHR is one of the best studied animal models of ADHD. In comparison to WKY rats, SHRs show several behavioral alterations characteristic of ADHD, including hyperactivity, impulsivity, poor sustained attention and an impaired ability to withhold responses [15-19]. In the present study, we have investigated the effects of an n-3 PUFA-enriched diet versus an n-3 PUFA-deficient diet on locomotor behavior in SHRs using an open-field paradigm.

ANIMALS AND METHODS:

Animals. In the present study, 20 7-week-old male SHRs were used (Charles River, Sulzbach, Germany). The rats were housed in groups of five animals per cage and kept on a 12:12 h light-dark cycle (room temperature 22 °C, humidity 50 %). They were given free access to water and the experimental diet, except for the behavioral testing period. At the beginning of the behavioral experiments water was provided ad libitum but food was restricted in order to prepare the animals for the experiments and to increase their motivation.

The rats were randomly assigned to two groups, i.e. group 1 (n-3 PUFA-enriched, n=10) received a diet enriched in n-3 PUFAs (Ssniff, Soest, Germany; based on AIN93G, for details see Table 1), while group 2 (n-3 PUFA-deficient, n=10) was fed with a diet deficient in n-3 PUFAs (see Table 1). The experimental diets were provided for six weeks and during the subsequent phase of behavioral testing.

Apparatus: The rats' locomotor activity was measured in an open field. The open field used consisted of a rectangular arena (size: 82.5 x 82.5 cm with walls 40 cm high), made of dark gray synthetic material. The locomotor activity was recorded by a fixed digital video system. This data was digitized and analyzed using the video tracking system ETHOVISION 3.0 (Noldus, Wageningen, The Netherlands). The distance traveled in the open field over 15 minutes was recorded.

Procedure: Rats were tested once daily for six consecutive days. Each rat was individually placed in the center of the open field and allowed to explore freely for 15 minutes. Prior to each trial all open-field surfaces were cleaned with 70 % alcohol in order to remove odors and/or residues of rats tested previously. The rats were tested each day in random order. The animals' body weight was measured daily in order to ensure normal weight gain and to prevent a weight loss of more than 10 %. At the time of behavioral testing, there were no significant differences in body weight between the two experimental groups.

Statistics: The statistical analysis of differences between the two groups (n-3 PUFA-enriched and n-3 PUFA-deficient) was performed with Mann-Whitney U-test using the Statistical Package for Social Sciences 17.0 (SPSS) for Windows. An alpha level of .05 was applied.

Ethics: This study was performed in accordance with national laws (German Law on Protection of Animals) and European laws, and the principles of laboratory animal care (NIH publication No. 86-23, revised 1985).

RESULTS:

The locomotor activity on six consecutive days (i.e. the distance travelled within 15 minutes) of SHR following consumption of n-3 deficient or n-3 enriched diet for six weeks (plus six days of testing) is given in Table 2. The distance travelled of the n-3 deficient SHR group was significantly increased on days 2, 4, 5, 6 and over the total of 6 days when compared to the animals fed with the n-3 enriched diet.

Table 2. Distance travelled in the open field of the n-3 PUFA-deficient and n-3 PUFA-enriched SHR groups (means \pm standard errors)

	n-3 PUFA-deficient	n-3 PUFA-enriched	p-value	z-value

DISCUSSION:

Long-chain PUFAs are essential for the central nervous system, e.g. the most predominant n-3 PUFA in the brain, docosahexaenoic acid (DHA) [20, 21], increases cellular membrane flexibility and is involved in the regulation of neurotransmission, myelination, and other cellular activities. An impoverished n-3 PUFA diet in rodents over several generations has been shown to result in a 50 to 80 % deficit in brain DHA phospholipids and in cognitive deficits including the performance in spatial learning and other learning tasks [22-24].

Dietary factors including the dietary lack of n-3 PUFAs have been discussed in regard to dyfunctions found in ADHD [for review of animal research see 25]. Several clinical trials with mixed results have been conducted to investigate whether some behavioral or cognitive symptoms of children with ADHD can be improved by long-chain PUFA supplementation [26]. Locomotor hyperactivity is the most easily discerned symptom of ADHD. The present study investigated the effects of a diet rich or impoverished in n-3 PUFAs on locomotor activity in rats using an open-field paradigm. We have used SHRs which have been proposed as an animal model of ADHD [e.g. 19].

The present results showed a marked difference in locomotor activity between the two groups of SHRs. In comparison with rats fed with n-3 PUFA-deficient food, the animals on an n-3 PUFA-enriched diet showed a statistically significant decrease in motor activity as assessed by the distance traveled in the open field.

Previous studies investigating the role of dietary PUFAs on locomotion in rodents reported inconsistent findings. A study in mice investigating the effects of a diet deficient in α -linolenic acid followed or not by supplementation with phospholipids rich in n-3 PUFAs found no significant effect between diet groups on open-field motor activity [27]. A fish oil enriched diet was reported to reduce ambulatory activity in Wistar rats [28]. In SHRs, dams were given n-3 PUFA-enriched feed during pregnancy and their offspring continued on this diet [29]. This study showed an n-3 PUFA-induced reduction in spontaneous locomotion.

Given the hypothesis that SHR is a valid animal model of ADHD symptoms including hyperactivity [for critical review see 30], one could conclude from our data that the diet enriched with n-3 PUFAs reduced the rats' hyperactivity. However, the present results were obtained by comparison with animals fed with n-3 PUFA-deficient food. Further studies are therefore needed in order to establish if the (hyper) activity of SHRs can also be ameliorated when the animals are fed with a balanced diet. In addition, it remains of interest whether other ADHD core symptoms such as inattention or impulsivity are affected by dietary n-3 PUFAs.

CONCLUSIONS:

The present study demonstrated a marked reduction in locomotor activity following an n-3 PUFA-enriched diet in SHRs, i.e. the dietary enrichment with n-3 PUFAs reduced the activity in an established animal model of ADHD when compared with an n-3 PUFA-deficient diet. Dietary n-3 PUFAs appear to affect locomotor activity in rats and may play a role in the pathophysiology of ADHD.
