Abstract: The aspergilli comprise a diverse group of filamentous fungi spanning over 200 million years of evolution. Here we report the genome sequence of the model organism *Aspergillus nidulans*, and a comparative study with *Aspergillus fumigatus*, a serious human pathogen, and *Aspergillus oryzae*, used in the production of sake, miso, and soy sauce. Our analysis of genome structure provided a quantitative evaluation of forces driving long-term eukaryotic genome evolution. It also led to an experimentally validated model of mating-type locus evolution, suggesting the potential for sexual reproduction in *A. fumigatus* and *A. oryzae*. Our analysis of sequence conservation revealed over 5,000 non-coding regions actively conserved across all three species. Within these regions, we identified potential functional elements including a previously uncharacterized TPP riboswitch and motifs suggesting regulation in filamentous fungi by Puf family genes. We further obtained comparative and experimental evidence indicating widespread translational regulation by upstream open reading frames. These results enhance our understanding of these widely studied fungi as well as provide new insight into eukaryotic genome evolution and gene regulation.

The aspergilli are a ubiquitous group of filamentous fungi spanning over 200 million years of evolution. Among the over 185 aspergilli are several that have an impact on human health and society, including 20 human pathogens as well as beneficial species used to produce foodstuffs and industrial enzymes.[1] Within this genus, *A. nidulans* has a central role as a model organism. In contrast to most aspergilli, *A. nidulans* possesses a well-characterized sexual cycle and thus a well-developed genetics system. Half a century of *A. nidulans* research has advanced the study of eukaryotic cellular physiology, contributing to our understanding of metabolic regulation, development, cell cycle control, chromatin structure, cytoskeletal function, DNA repair, pH control, morphogenesis, mitochondrial DNA structure and human genetic diseases.

We present here the genome sequence for *A. nidulans*, and a comparative genomics study with two related aspergilli: *A. fumigatus*[2] and *A. oryzae*.[3] *A. fumigatus* is a life-threatening human pathogen, and *A. oryzae* is used in the production of sake, miso, and soy sauce. *A. oryzae* and *A. fumigatus* lack known sexual cycles, and their study relies on *A. nidulans* as a genetic model. Our analysis of these organisms focused on the genomic bases of their differing physiologies, while investigating their common eukaryotic biology. Our results yield new insights into eukaryotic genome evolution, the evolution of mating-type loci, the potential for sexual reproduction in the two asexual species, and the role of conserved sequence elements in gene regulation.

Genome assembly and annotation

The genome sequence of *A. nidulans* was assembled from deep whole-genome shotgun (WGS) coverage obtained by paired-end sequencing from a variety of clone types (see Methods). An average of 13× sequence coverage was generated including ×3 coverage produced and provided by Monsanto. The Arachne package (http://0-www.broad.mit.edu/wga/) was used to assemble the sequence, and the resulting assembly consists of 248 sequence contigs with an N50 length of 282 kilobases (kb) (that is, 50% of all bases are contained in contigs of at least 282 kb). Contigs were assembled into 89 scaffolds with a total length of 30.06 megabases (Mb) (including gaps between contigs) and an N50 length of 2.44 Mb. A total of 28.5 Mb (95%) of the assembly was anchored to the *A. nidulans* genetic map[4, 5] through meiotically mapped markers with sequence and markers located by haploidization or hybridization to electrophoretically separated chromosomes (see Supplementary Information). By comparison with previously published pulse-field gel electrophoresis data, we estimate that the assembly comprises 96.3% of the complete genome. The assembly was annotated using the Calhoun system, as described in the Methods and Supplementary Information.

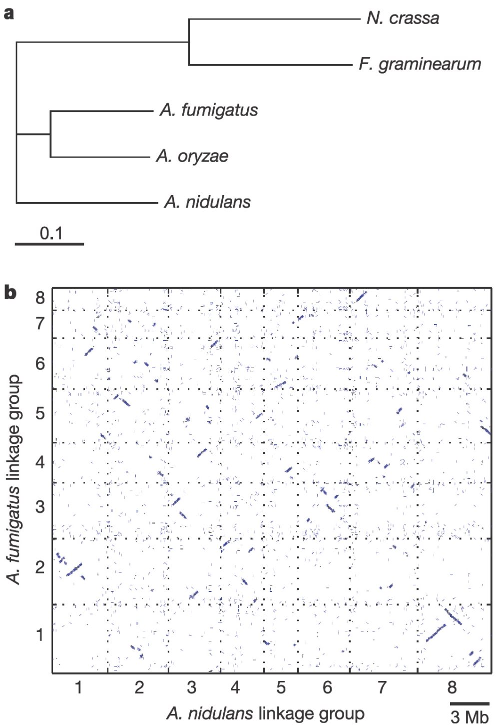

Figure 1. Phylogenetic tree and representative dot plot. **(a)** Phylogenetic tree showing the relationship between three *Aspergillus* species compared using *N. crassa* and *F. graminearum* as an outgroup. Branch lengths correspond to substitutions per site calculated using a maximum likelihood approach. An identical topology was predicted using *C. immitis* as an outgroup. **(b)** Dot plot of *A. nidulans* (horizontal) and *A. fumigatus* (vertical) genomes. Axes represent the concatenation of all chromosomes for the corresponding genome. Gridlines indicate the boundaries between chromosomes and axis labels indicate chromosome number. Elements in the dot plot represent protein homology translated to genomic coordinates.

Phylogenetic relationship

Previous work based on large subunit rDNA data has led to a widely accepted phylogeny of the aspergilli in which *A. nidulans* and *A. oryzae* are more related to one another than *A. fumigatus*.[6] However, single gene phylogenies can contradict organismal phylogenies.[7] In principle, whole-genome data provide greater resolving power by allowing trees to be constructed based on concatenated sets of genes.[7] Using this approach to study the relationship of the three aspergilli, we find support for an alternative phylogeny.[8] (Figure 1a)

We established this relationship using a set of 3,034 predicted orthologues across the three aspergilli, *Neurospora crassa* and *Fusarium graminearum*. We constructed trees for 75 randomly selected sets of 20 concatenated genes,[7] using the *N. crassa* and *F. graminearum* genes to root the trees (see Methods). All 75 cases produced the phylogeny shown in Figure 1a in which *A. fumigatus* and *A. oryzae* are sister taxa and *A. nidulans* branches earlier. This phylogeny is further supported by 86% of trees built for each of the 3,034 orthologues individually. Consistent with this phylogeny, *A. fumigatus* has over twice as many genes with top Blast hits to *A. oryzae* than to *A. nidulans*, and *A. oryzae* has almost twice as many genes closer to *A. fumigatus* than *A. nidulans*. *A. nidulans* has roughly a similar number of top hits to *A. fumigatus* and *A. oryzae*. To confirm further the rooting of the tree, we repeated the analysis using predicted gene fragments (see Methods) from the genome sequence of *Coccidioides immitis* as an outgroup (which is closer to the aspergilli than *N. crassa* and *F. graminearum*). Ninety-four per cent (34 out of 36) of 50-gene phylogenies with *C. immitis* as the outgroup support the relationship of Figure 1a, as do 60.8% (93 out of 153) of single gene phylogenies (only 21% support the rDNA phylogeny).

Overall genome and proteome comparison

Although in the same genus, the three aspergilli differ considerably in their genome sequences. Predicted orthologues shared by all three species (three-way orthologues) display an average of only 68% amino acid identity. *A. fumigatus* and *A. oryzae* share 70% identity, and each has 66–67% identity with *A. nidulans*. This protein identity is comparable to that between mammals and fish,[9] which diverged ~450 million years ago. The three species also differ considerably in genome size (Table 1). The largest, *A. oryzae* (36 Mb), is 31% bigger than the smallest, *A. fumigatus* (28 Mb), and 24% bigger than *A. nidulans* (30 Mb). This difference seems to be due to an acquisition of sequence in *A. oryzae*[3] rather than loss in both *A. nidulans* and *A. fumigatus*. Finally, the genomes show extensive structural reorganization (Figure 1b).

Conserved synteny and genome evolution

These three aspergilli provide an opportunity to study eukaryotic genome evolution over a divergence approaching the limit of conserved long-range synteny. To characterize pairwise conserved synteny, we used an algorithm based on hierarchical clustering that delineates regions of conserved synteny while also retaining information about internal micro-rearrangements (see Methods). Using this method, the majority (77–79%) of each genome assembly could be mapped to conserved syntenic blocks with at least one other genome (Table 2). Figure 2 shows a projection of the homologous blocks onto the chromosomes of *A. nidulans* and, contrasted with Figure 1b, illustrates the considerable extent of conserved synteny despite extensive rearrangement.

The results of this analysis reveal two notable trends. First, large regions lacking detectable long-range synteny are readily apparent. As has been observed for mammals, nematodes and yeasts,[10] repeats and subtelomeric sequences are associated with these heavily rearranged regions. This may have specific implications for fungi, as subtelomeric regions in the aspergilli are enriched for secondary metabolite genes thought to have a role in

Table 1. Comparison of genome characteristics

Genome characteristic	*A. nidulans*	*A. fumigatus*	*A. oryzae*
General			
Assembly size (bp)	30,068,514	27,980,910	37,047,050
G+C (%)	50	49	48
Protein coding genes	9,541	9,926	14,063
Protein coding genes >100 amino acids	9,396	9,009	12,074
Predicted protein coding sequences >100 amino acids			
Coding (%)	50	49	45
Gene density (1 gene every *n* bp)	3,151	2,938	2,613
Median gene length (mean)	1,547 (1,868)	1,389 (1,644)	1,152 (1,414)
Average number of exons per gene	3.6	2.8	2.9

niche adaptation and virulence. The rapid rearrangement of subtelomeric regions may facilitate the species-specific evolution of these genes (Supplementary Information).

The second notable trend is the distribution of lengths of unbroken regions between micro-rearrangements within pairwise syntenic blocks. The random breakage model of genome evolution predicts that such lengths should be exponentially distributed. Although the mean breakpoint lengths differ, in all three pairwise comparisons the distribution of lengths shows close agreement with the model prediction (Supplementary Information). It thus seems that syntenic blocks, comprising the majority of the *Aspergillus* chromosomes, are evolving in a manner consistent with random breakage.

For each pairwise comparison, the third *Aspergillus* genome allows the determination of rearrangements specific to each branch of the unrooted tree (see Methods). The results of this analysis provide a quantitative estimate of the different rearrangements contributing to long-term eukaryotic genome evolution (Figure 3).

Structural evolution not correlated with molecular evolution

In vertebrates, nematodes and arthropods, it has been reported that the rates of structural evolution and nucleotide evolution are correlated.[11, 12, 13] However, our analysis of the *Aspergillus* genomes suggests that this expected correlation does not always hold for eukaryotes.

The data in Figure 3 reveal a considerably higher overall rate of genome reorganization in the lineage of *A. oryzae* compared to *A. fumigatus*. Nearly all categories of disruption are at least twofold greater in *A. oryzae* relative to *A. fumigatus*. For example, *A. oryzae* displays a more than twofold greater rate of insertion than *A. fumigatus*. This is consistent with the larger genome size of *A. oryzae*.[3] Surprisingly, our analysis also indicates that chromosomal breaks are more common in *A. oryzae* than *A. fumigatus*. Although apparent intrachromosomal rearrangements could arise from successive inversion events, this cannot explain interchromosomal rearrangements. These interchromosomal breaks are also not the result of assembly error, as confirmed by optical mapping[3] and polymerase chain reaction (PCR) validation of eight predicted interchromosomal breaks.

In contrast, several measures indicate that the rates of amino acid evolution in predicted orthologues are similar between these two species. An examination of predicted three-way orthologues shows that the distribution of amino acid identity is roughly similar for both *A. oryzae* and *A. fumigatus* compared to *A. nidulans*, as are non-synonymous divergences (Supplementary Information). In addition, branch lengths predicted from phylogenetic trees (see above) indicate a comparable rate of substitution for both *A. oryzae* and *A. fumigatus*. Taken together, these data lead to the conclusion that structural and molecular evolution in the aspergilli is not correlated. A similar conclusion has been reached in the analysis of two microsporidian genomes, although in this case gene evolution seems to be accelerated relative to genome rearrangement.[14] Thus, large-scale and small-scale evolutionary processes in eukaryotes can operate at different relative rates in a species-specific manner.

Sex and the evolution of the mating-type loci

Unlike *A. nidulans*, which has a known sexual cycle, *A. fumigatus* and *A. oryzae* are only known to reproduce through asexual mitotic spores. We sought insight into the evolution of this apparent difference by comparing the three genomes. Our results, in conjunction with an accompanying paper and another study,[2, 15] suggest that both *A. fumigatus* and *A. oryzae* may be capable of sexual reproduction.

Sexual reproduction in ascomycete filamentous fungi is governed, in part, by two different mating-type genes that establish sexual compatibility: one gene encodes a protein with a high mobility group (HMG) domain, whereas the other encodes a protein with an alpha box domain. We refer to these genes here as the HMG and alpha mating-type genes, and to their chromosomal locations as MAT loci. Homothallic fungi typically possess both mating-type genes and are self-fertile. Heterothallic fungi possess only one mating-type gene and require a partner with a different mating-type gene. In heterothallics, the two mating-type genes typically occupy the same chromosomal location in different haploid genomes but lack sequence similarity, and are thus termed idiomorphs rather than alleles.[16]

A. nidulans is known to be homothallic, and both HMG and alpha mating-type genes have been identified.[17, 18] Our analysis confirmed that the HMG and alpha loci are unlinked, which is unusual although not unprecedented in homothallic fungi.[19] We identified a single HMG mating-type gene in *A. fumigatus*, as previously reported,[20] and a single alpha mating-type gene in *A. oryzae*.

A comparison of all four MAT loci revealed extensive conserved synteny (Figure 4a). The *A. oryzae* alpha locus and the *A.*

Table 2. Characteristics of pairwise conserved synteny

Reference	Coverage (Mb) (percentage of reference)*				Maximum/mean block length (kb)‡		
	A. nidulans	*A. fumigatus*	*A. oryzae*	Either †	*A. nidulans*	*A. fumigatus*	*A. oryzae*
A. nidulans	–	20.5 (68)	20.4 (68)	21.6 (72)	–	175	114
A. fumigatus	20.4 (73)	–	20.7 (74)	21.5 (77)	2,429	–	168
A. oryzae	23.3 (63)	24.3 (66)	–	25.4 (69)	943	1,159	–

* Coverage of reference organism assembly by pairwise conserved syntenic blocks (>10 kb in length) to each target genome.

† Coverage of reference organism assembly by pairwise conserved syntenic blocks (>10 kb in length) in either other genome.

‡ Upper right half shows mean blocks sizes and lower left half shows maximum sizes across all blocks using either organism as reference.

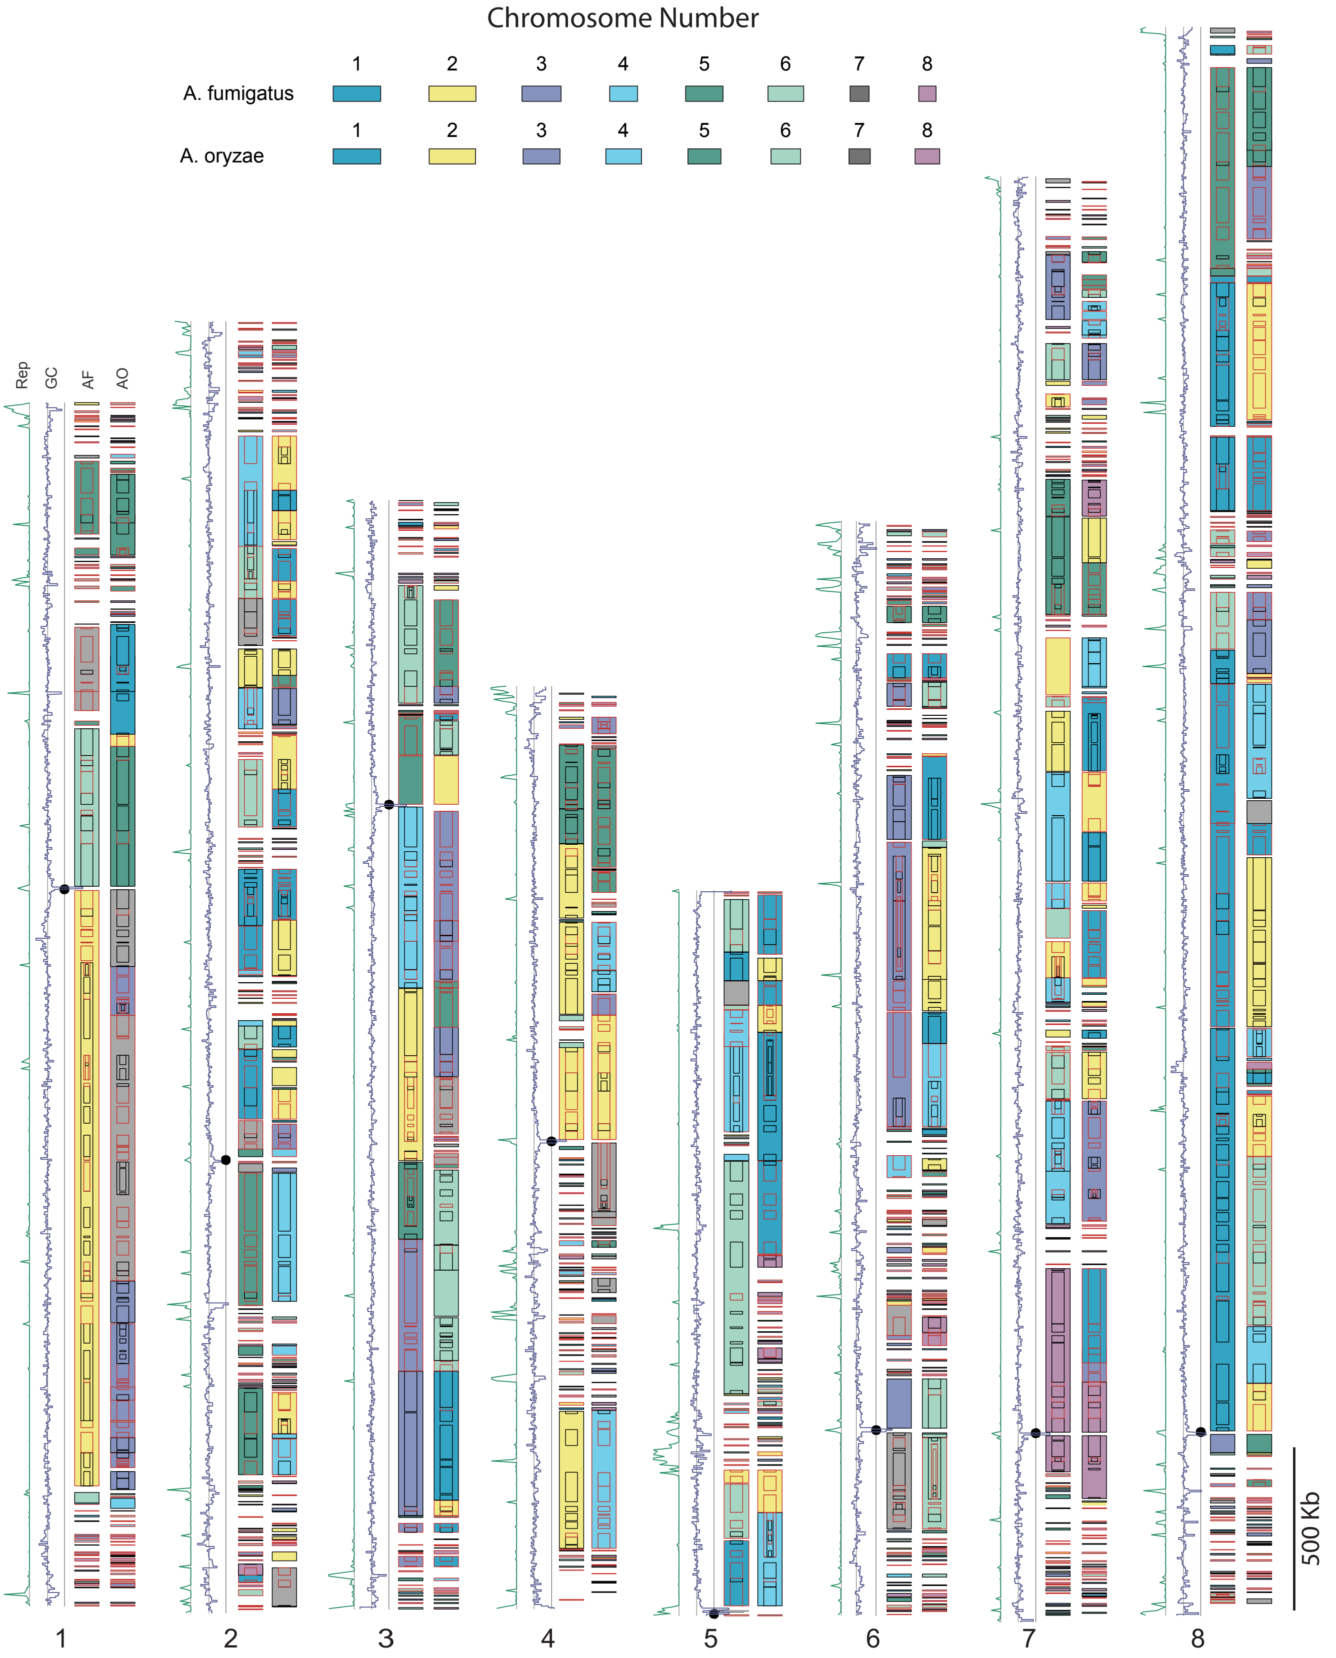

Figure 2. *Aspergillus* comparative map. Conserved synteny between *A. nidulans* and *A. oryzae* and *A. fumigatus*. Syntenic regions are represented by two vertical columns of colored blocks. The left and right columns represent syntenic blocks to *A. fumigatus* and *A. oryzae*, respectively, colored by chromosome as indicated by the key. Nested blocks show synteny at finer resolutions. Blocks outlined in black are in opposite orientations in *A. nidulans* relative to those in red. Red blocks in black blocks (and vice versa) represent inversions. The green and purple lines display repeat density (Rep) and G + C content (G + C) in *A. nidulans*, both in 5-kb windows with increasing values to the left. Black circles represent centromeres.

fumigatus HMG locus display conserved synteny over 1.7 Mb on either side of the mating-type genes. Within this region of conserved synteny, the two mating-type genes occupy nearly identical positions, although offset with different orientations. Furthermore, one flank of both the *A. fumigatus* and *A. oryzae* loci is syntenic with 409 kb of the *A. nidulans* HMG locus downstream region, whereas the other flank is syntenic with 34 kb of the *A. nidulans* alpha locus downstream region (Figure 4a). The four loci also show conservation of a number of genes associated with MAT loci in other species including *N. crassa* or one of nine yeast species previously analyzed.[21]

Extending the analysis to 215 genes implicated in the fungal mating process, pheromone response, meiosis and fruiting body development revealed that every gene (except for the mating-type genes) that can be identified in *A. nidulans* is also present in both *A. fumigatus* and *A. oryzae* (Supplementary Information), including several genes for which the only known function is related to sexual reproduction.

Although sexual reproduction may have been lost very recently in both *A. fumigatus* and *A. oryzae*, providing one explanation for the residual presence of mating process genes, these data suggested the possibility that both *A. fumigatus* and *A. oryzae* may be capable of sexual reproduction. Moreover, the pattern of synteny among the four MAT loci leads to an evolutionary scenario for this hypothesis, as shown in Figure 4b. According to this model, it is predicted that *A. oryzae* and *A. fumigatus* isolates exist with the opposite mating-type genes to those present in the strains that were sequenced. In addition, these opposite mating-type genes should be present at the identical locus, consistent with a heterothallic idiomorphic configuration.

As reported in detail in another study,[15] these predictions have been experimentally verified. Using a PCR-based multiplex mating-type assay, isolates of both mating types of *A. fumigatus* and *A. oryzae* were identified. For both species, the opposite MAT locus from the complete genome was sequenced and demonstrated to have the idiomorphic organization predicted. Within the idiomorphic region the opposite mating-type genes appear to be offset with respect to one another, as predicted by our model. In addition, the *A. fumigatus* alpha MAT locus was found to contain a 360-base pair (bp) fragment of an HMG gene[15] neighboring the idiomorphic region, suggesting that the transition from homothallism to heterothallism in the *A. oryzae* and *A. fumigatus* ancestor occurred by gene loss (Figure 4b).

Although the model of Figure 4b predicts a homothallic ancestor for all three species, it is possible that heterothallism was ancestral and a transition to homothallism occurred in the *A. nidulans* lineage. This would be consistent with data from *Cochliobolus* species for which heterothallism appears to be ancestral, and conversions to homothallism have been described.[19] However, two factors conflict with this scenario for the aspergilli. First, the offset positions of the mating-type genes within the idiomorphic regions of the *A. fumigatus* and *A. oryzae* MAT loci, and the apparent fragment of the HMG gene neighboring the *A. fumigatus* alpha locus, are consistent with gene loss from a homothallic ancestor. Second, heterothallism in the aspergilli is rare.[22, 23] Only three heterothallic aspergilli have been previously characterized, of which one, *A. heterothallicus*, groups in phylogenies with known homothallic species, suggesting a conversion to heterothallism in this case as well.[22] Mitotic, homothallic and heterothallic species are observed intermixed in several fungal lineages, leading to debates about the fungal ancestral state.[19, 24, 25, 26] Taken together, our results provide evidence that conversion from homothallism to heterothallism is possible, and suggest that the predominance of a particular sexual strategy may vary within different clades.

Although the finding of MAT genes in supposedly asexual fungi has been previously reported[15, 27, 28, 29, 30, 31, 32] and genes related to sexual reproduction have been found in the "asexual" yeast *Candida albicans*, this report is the first comprehensive survey of sexual reproduction genes in two different filamentous fungi thought to be asexual. In addition, our results provide an experimentally supported evolutionary model associating large-scale synteny and genome rearrangement with a specific and significant difference in biology between these aspergilli. These results for *A. fumigatus* and *A. oryzae* have important and specific potential implications for health and industry. The lack of a sexual cycle in *A. fumigatus* and *A. oryzae* has precluded classical genetic analysis, impeding efforts to study these organisms and necessitating the use of the relatively distant *A. nidulans* as a genetic model. The possibility for mating—still speculative at this stage—raises the medically and industrially important potential for developing genetic tools for these fungi.

Conserved non-coding sequences

Detecting and characterizing conservation of sequences outside of protein coding regions is a promising method for identifying potential functional elements. Regulation in yeast has been extensively studied; however, in the aspergilli few transcription factor binding sites have been experimentally verified. Comparing the three aspergilli provides an opportunity to identify the most constrained functional elements.

To do so we aligned three-way orthologous genes including 1 kb of sequence upstream and downstream using Mlagan.[33] Strict filters were then applied to delineate unambiguous orthologous intergenic regions (see Methods). Given the divergence of the aspergilli, it is expected that intergenic regions would not show significant conservation, and frequently this was found to be the case. However, in many instances, blocks of nearly perfect

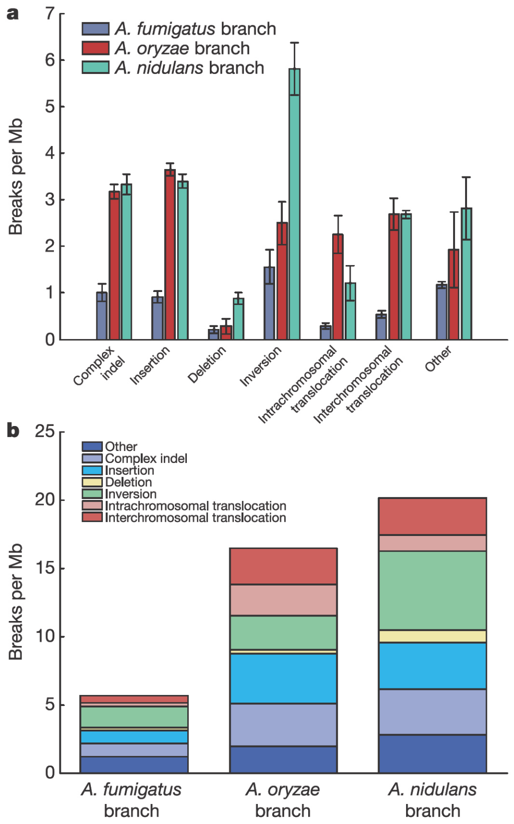

Figure 3: Rates of branch-specific rearrangements. **(a)** The rates of different breaks broken down by break type for each branch. Bars represent minimum and maximum values obtained using either of the two non-target genomes as reference (see Methods). **(b)** A stacked plot of the same data showing the relative contribution of break types within each branch for all three branches. See text and Methods for more details.

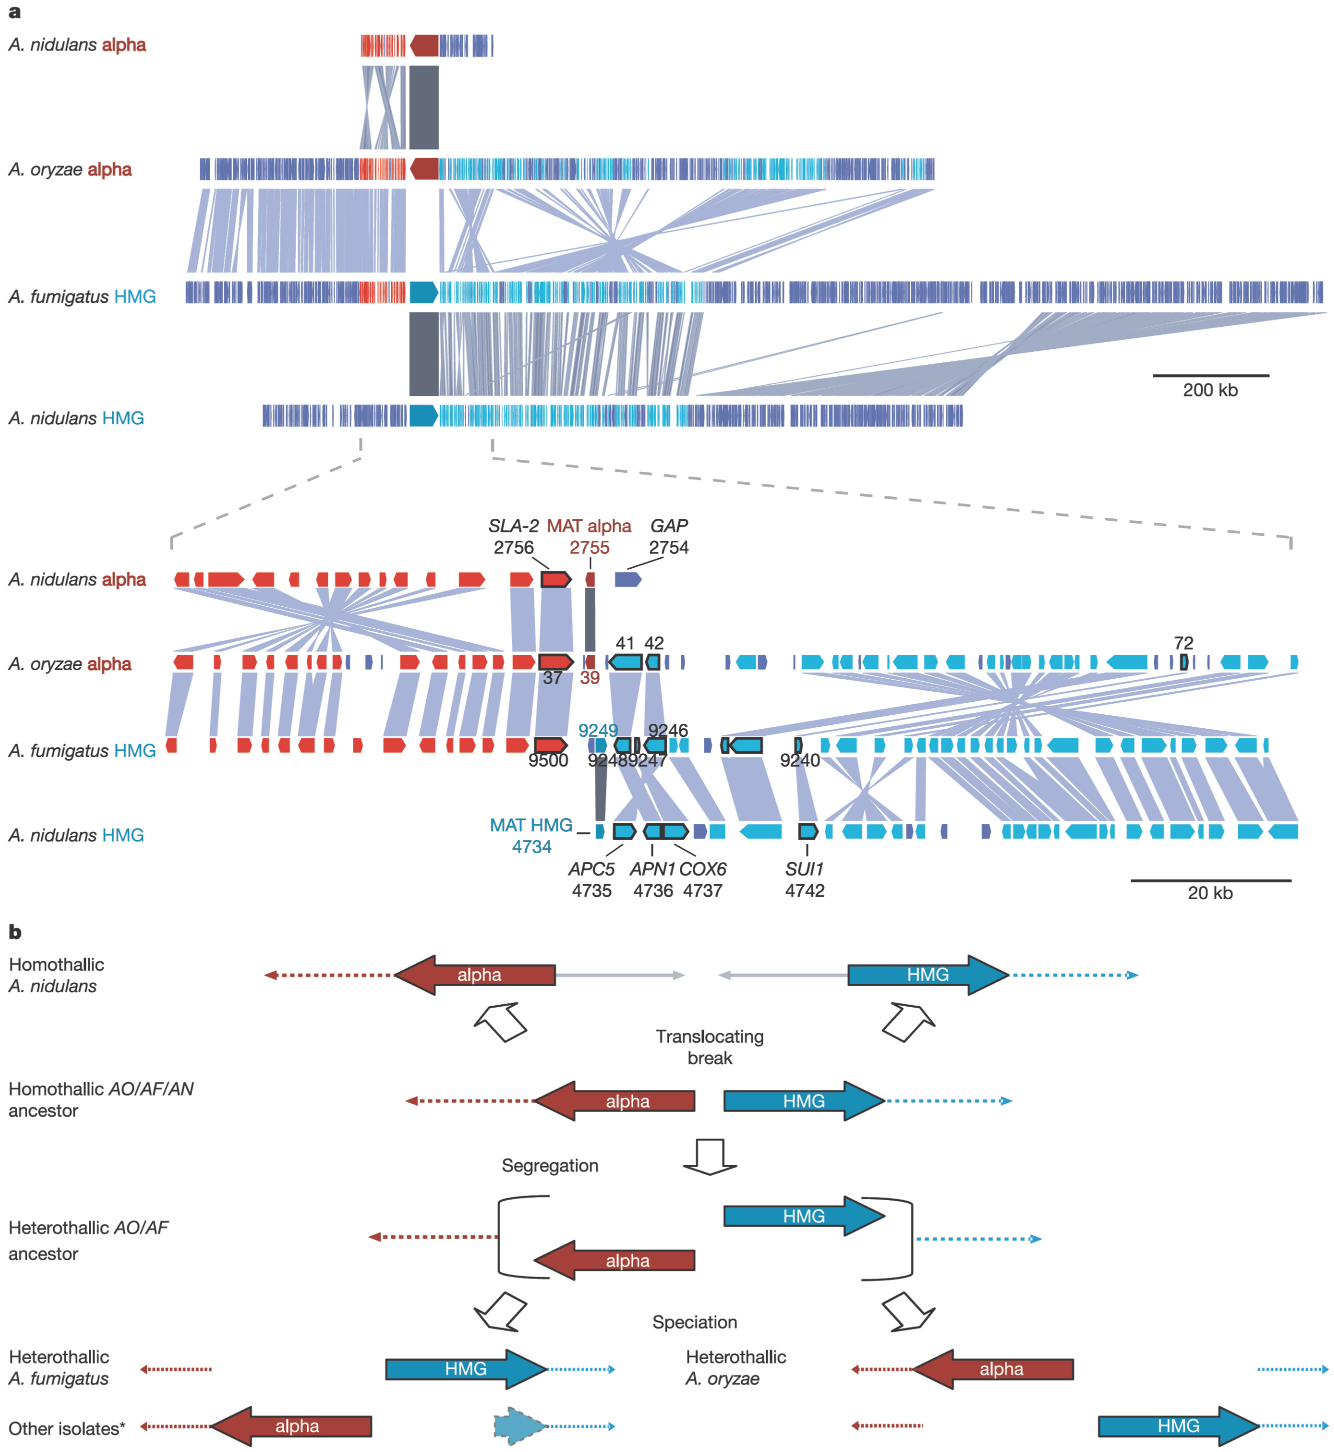

Figure 4. Comparison and evolutionary model of *Aspergillus* MAT loci. (**a**) Conserved synteny between loci. Grey lines indicate predicted orthologues. Red genes indicate orthologues from the left flank (as drawn) of the *A. nidulans* alpha locus with the left flanks of the *A. fumigatus* and *A. oryzae* loci. Cyan genes indicate orthologues with the right flank of the *A. nidulans* HMG locus. The bottom panel shows the region near mating-type genes. Genes labeled and outlined in black are associated with MAT loci in other fungi. Only partial accession numbers (suffixes) are shown in the figure. For full accession numbers, the numbers shown in the panel should replace the asterisks in the following examples: *A. nidulans* (AN****.1); *A. fumigatus* (59.m0****); *A. oryzae* (AO0703270000**). (**b**) Model of structural evolution of the MAT loci. Braces represent multiple haplotypes at the same genomic locus. The experimental identification of other isolates (indicated by an asterisk) was reported in another study[15]. The light blue arrow indicates a 360-bp HMG gene fragment. *AF*, *A. fumigatus*; *AN*, *A. nidulans*; *AO*, *A. oryzae*.

three-way conservation are observed. An example for one intergenic region is shown in Figure 5a.

To assess which regions were conserved owing to purifying selection rather than neutral mutation or chance, we developed models for alignments of neutral and random sequence. Unlike mammals, where ancient conserved repeats provide a natural model for neutral evolution, few such repeats exist in the aspergilli (see below). Instead, we synthesized alignments of neutral sequence by concatenating randomly selected aligned columns of fourfold degenerate sites. We also controlled for chance alignment introduced by potential aligner bias by aligning randomly selected intergenic regions. Using a simple conservation scoring function we calculated maximal scoring subsequences and compared results between orthologous regions and the control models (Figure 5b). A noteworthy aspect of the data in Figure 5b is the similarity between the neutral and random models. According to our models, neutral sequence is effectively saturated for mutation, confirmed by an independent analysis of synonymous sites in protein coding sequences.

Comparing results between real and control alignments, we selected a minimum score of 22 for regions unlikely ($P < 0.015$) to be conserved by neutral evolution or chance. We denote a subsequence scoring above this threshold as a high-scoring conserved sequence (HCS). On the basis of this analysis, we predict 5,801 HCSs corresponding to ~2% of alignable orthologous intergenic regions.

Prediction of functional motifs

We expect HCSs to be enriched for functional elements. The challenge is to discover these functional elements and make testable predictions about their biological functions. In preliminary analyses, several conserved regions could be identified as known functional elements. For example, we observed conservation delimiting a known 3′ untranslated region (UTR) element of the *A. nidulans areA* gene that regulates messenger RNA stability in response to cellular nitrogen levels.[34] We also identified three TPP binding riboswitches, one of which has not been described in *Aspergillus* (Supplementary Information).

To enrich computationally HCSs for sequences corresponding to functional elements, and to derive clues about their biological functions, we modified the approach used by Reference 35 (see Methods). Briefly, we identified common subsequences (or ‘patterns’) that appeared in at least four HCSs across all three *Aspergillus* genomes. These patterns were searched in three-way conserved orthologues to identify genes in which the subsequence occurred in the 500-bp upstream or downstream regions (a “co-occurrence”). A number of conservation criteria were then applied (see Methods). We identified a total of 69 conserved patterns (“conpats”), occurring in at least four HCSs, that showed enrichment for co-occurrences and exhibited a bias for occurring 500 bp upstream or downstream of genes.

The results of this analysis for the 35 most common patterns are shown in Figure 6 (all 69 patterns available in Supplementary Information). These include motifs that match known or predicted *Aspergillus* or other fungal functional sequences. For example, CPCA/GCN4, the master regulator of the cross pathway control system in fungi, is known to bind to the palindromic site TGASTCA.[36] In yeast, microarray studies have identified 539 genes probably regulated by GCN4 that show a preference for amino acid biosynthetic genes and several ribosomal proteins and translation factors.[37] One of the patterns identified by our analysis (ID 2483) matched the CPCA binding site, co-occurred preferentially upstream of genes, and was enriched in genes associated with amino acid transport and metabolism (COG category E), and translation, ribosomal structure and biogenesis (category J). Furthermore, the 19 genes with co-occurrences of this pattern include 7 (37%) predicted orthologues to the 539 known yeast regulated

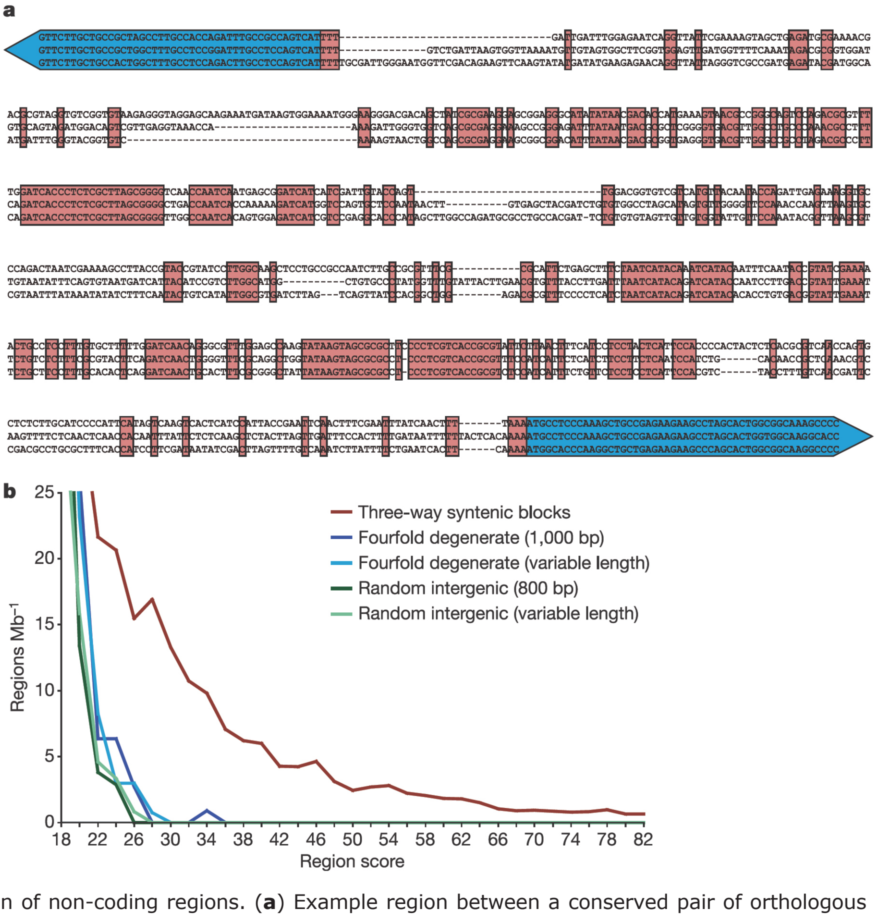

Figure 5. Active conservation of non-coding regions. (**a**) Example region between a conserved pair of orthologous histone H2A and H2B genes (left and right blue arrows). The three lines from top to bottom correspond to the sequences of *A. nidulans*, *A. fumigatus* and *A. oryzae* aligned using Mlagan. Letters on the red background indicate 100% conserved bases. (**b**) Conservation scores of maximal subsequences for observed intergenic alignments (red), and models of neutral and random sequence alignment (both fixed and variable length).

genes, representing a sixfold enrichment (*P*-value $< 1 \times 10^{-5}$). This includes two known *A. nidulans* CPCA regulated genes (*trpB*[38] and *hisHF*[39]). This pattern probably corresponds to the known *Aspergillus* CPCA binding site.

A second pattern shows strong correspondence with the binding site for Puf family genes.[40] Puf proteins regulate mRNA translation and mRNA decay through interactions with 3′ UTR sequences. In *Saccharomyces cerevisiae*, which has five Puf genes, Puf3p has been shown to bind specifically mRNAs encoding mitochondrial proteins[40] and requires a 3′ UTR motif with consensus UGUANAUA.[40] Four different patterns identified by our analysis (ID 1710, 2077, 1144 and 2378; see the full table in Supplementary Information) match or include the Puf binding motif and display a strong downstream bias. Three also show enrichment for predicted orthologues in *S. cerevisiae* that localize to mitochondria. Taking all four patterns together, we find a 6.8-fold enrichment ($P < 4.3 \times 10^{-11}$) for genes with orthologues to yeast mitochondrial genes. In addition, we find a threefold enrichment ($P < 0.0003$) for genes with yeast orthologues predicted to be bound by Puf genes in a genome-wide affinity tag analysis.[40] Although a functional role for the Puf family has not been experimentally demonstrated in *Aspergillus*, all three genomes possess five loci with 5–8 Puf domains, as predicted by HMMER and PFAM (including one with a predicted RNA binding domain, as with Puf1p and Puf2p in yeast). Together these data suggest that, as in yeast, Puf genes may bind to and regulate mitochondrial mRNAs in the aspergilli.

Only a small number of transcription factor binding sites and control elements are known for filamentous fungi in general, including *Aspergillus*. These predicted patterns are thus promising targets for future experimental validation.

Regulatory upstream open reading frames

A significant proportion (32%) of HCSs are conservatively predicted to lie within transcribed but untranslated regions of genes (UTRs), consistent with the known role of UTRs in regulating gene expression, particularly mRNA translation (for example, Puf binding domains). One important class of translational control elements is short upstream open reading frames (uORFs) in 5′ UTRs,[41] which can regulate the expression of downstream protein-coding genes in several ways. First, they can modulate the efficiency of ribosome re-initiation at downstream start codons in

Figure 6. Selected conserved patterns. Column one shows the conpat unique ID. Column two shows the sequence logo representation of conpat weight matrix. Column three shows fungal binding factors with sequence similarity to the conpat. Columns four and five show the number of genes with a co-occurrence of conpat upstream and downstream. Column six shows the preference for co-occurring preferentially 5′ or 3′ of the gene. Column seven shows the fraction of co-occurrences overlapping three-way conserved regions. Column eight shows the preference for co-occurring on a particular strand relative to the gene. Column nine shows COG categories showing significant enrichment (the number of genes with co-occurring conpats in the category is indicated in parentheses). Enrichment results for yeast orthologue cellular location are available in the Supplementary Information. * $P < 1 \times 10^{-3}$; ** $P < 1 \times 10^{-4}$; *** $P < 1 \times 10^{-5}$. bHLH, basic helix-loop-helix.

a manner dependent on cellular state. Second, uORFs can produce *cis*-acting peptides that stall ribosomes. Finally, the presence of uORFs can affect mRNA stability. Functional uORFs can be as short as three amino acids and occur at varying distances and multiplicity upstream of the protein-coding gene, occasionally overlapping the downstream start codon. Functional uORFs have been reported in a range of species including plants, animals and fungi.[41] In *Aspergillus*, a small number of genes with validated uORFs have been reported (Supplementary Information). To determine the full extent with which they may regulate gene expression, we analyzed the three *Aspergillus* genomes for uORFs.

We identified UTR sequences using expressed sequence tag (EST) alignments for *A. nidulans* genes, and examined them for open reading frames (see Methods). Of 1,606 genes with identified UTRs, 21% (358) have upstream ORFs. A similar proportion was found (18% or 82 out of 463) when we restricted our analysis to three-way orthologues for which the start codons align exactly within multiple alignments, suggesting that these uORFs are not due to misannotation. A corresponding analysis of genes with ESTs in the *N. crassa*, *F. graminearum* and *Magnaporthe grisea* genomes found uORFs associated with 22%, 10% and 16% of genes, respectively. We further extended the analysis in *A. nidulans* using a conservative estimate of 5′ UTR length (see Methods), and identified an additional 958 genes with potential uORFs of which 165 genes have three-way orthologues. In total, 1,316 genes in *A. nidulans* are predicted to possess uORFs.

Not all identified uORFs have a detectable impact on gene expression.[41] To enrich the set of predicted uORFs for those likely to be functional, we looked for those conserved in all three aspergilli. On the basis of a strict criterion requiring alignment of the uORF start and stop codons, we find 38 conserved uORFs (13% of 331 genes with uORFs and predicted orthologues) (Supplementary Information). Of these corresponding *Aspergillus* genes, 14 have predicted uORFs upstream of orthologues in *N. crassa*, *F. graminearum* or *M. grisea*. Additionally, three also have predicted orthologues in *S. cerevisiae* with uORFs conserved across four related yeast species.

These 38 conserved uORFs represent strong candidates for experimental investigation. As a preliminary validation, we tested two novel conserved uORFs for their ability to modulate protein synthesis *in vitro* (Figure 7). Briefly, oligonucleotides containing each uORF were fused to a luciferase reporter gene, and controls were constructed with disabled uORF and/or reporter gene start codons. Differential expression in a cell-free translation system between intact and control constructs measures the impact of the uORF on translation. This system can detect small (twofold) changes in translation, and can discriminate uORFs that do not reduce translation *in vivo* from those that do (see Methods). As can be seen in Figure 7, both uORFs tested display a 5–10-fold repressive effect on the translation of the downstream reporter gene.

These results provide the first genome-wide list of predicted conserved uORFs for any organism, and suggest that uORFs could have a substantial role in regulating gene expression in *Aspergillus*. Previous reports estimate that 2–4% of genes in *S. cerevisiae* contain uORFs,[42] whereas a review of sequences in UTRdb predicted that 5–10% of eukaryotic UTRs contain ORFs.[43] Our results predict that in filamentous fungi the proportion may be twice as high.

Aspergillus physiology

Peroxisomes are organelles containing enzymes for the breakdown of fatty acids (β-oxidation), removal of hydrogen peroxide and synthesis of cholesterol and bile acids. Peroxisomes have critical roles in fungi where they are involved in growth, secondary metabolism and pathogenesis. In mammals, defects can lead to developmental and neurological disorders. Proteins are targeted to the peroxisome either by a carboxy-terminal tripeptide sequence or an amino-terminal nine-amino-acid sequence. Using these signals we predicted peroxisomal proteins in *Aspergillus* (Supplementary Information). Our analysis reveals peroxisomes in *Aspergillus* to be more similar to mammals than yeasts in two respects. First, our data suggest that the aspergilli, like mammalian cells, perform β-oxidation in both peroxisomes and mitochondria and possess two sets of genes for all β-oxidation enzymes targeted to both the mitochondria and the peroxisome, as supported by recent experimental results.[44] In contrast, *S. cerevisiae* metabolizes fatty acids fully to acetyl-CoA only in peroxisomes.[45] Second, *Aspergillus* peroxisomes are more similar to those of mammals than those of yeasts in that they possess putative peroxisomal acyl-CoA dehydrogenases. In addition, all three aspergilli appear to encode both mitochondrial and peroxisome forms of an ATP-dependent protease of the LON (La domain) family associated with peroxisomes in mammals.[46] *S. cerevisiae* has a single copy of this protease (*Pim1*/*Lon1*) targeted to mitochondria.[47]

One of the hallmarks of the filamentous fungi is their ability to undergo polarized hyphal growth. This requires positional cues that mark polarized growth sites, locally activating Rho-related GTPase signaling modules that promote cytoskeletal reorganization.[48] The three aspergilli possess the expected genes involved in signaling and cytoskeletal organization for polarized growth, but there is a marked lack of known positional markers (such as the yeast bud site markers Bud3p, Bud8p and Bud9p; see Supplementary Information). Proteins implicated in the transport or modification of bud markers, including Axl1p, Rax1p, and Bud7p, were predicted, however. This suggests that filamentous fungi mark polarized growth sites with positional cues, but that the markers themselves may consist of novel cell wall proteins.

Most of the interspersed repeats in all three genome sequences correspond to relics of transposable elements (see Supplementary Information). Surprisingly, only 1.3% of the largest genome

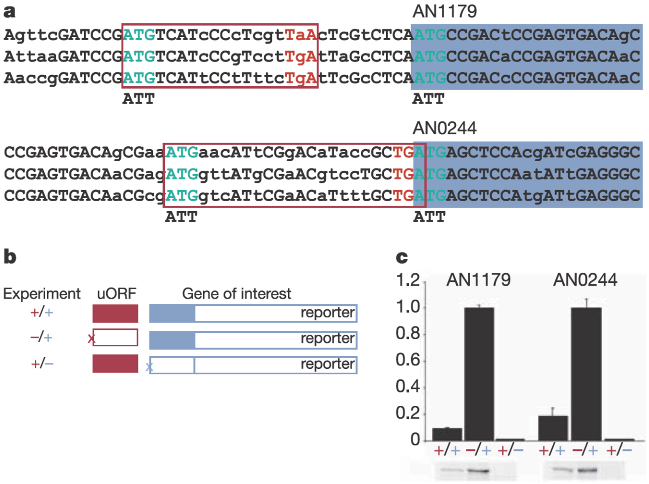

Figure 7. Prediction and validation of conserved uORFs. Conserved uORFs show a 5–10 times repressive effect on reporter gene translation. (**a**) Alignments of two tested uORFs. uORFs are shown in purple boxes, and protein-coding genes in a blue background. Conserved bases are in upper case and start/stop codons are highlighted. (**b**) Experimental design. The *A. nidulans* sequence from 26 nucleotides upstream of each uORF to four codons in the protein-coding gene was fused with a firefly luciferase gene. Controls were generated with start codons for both the uORF and the luciferase gene (+/+), the luciferase gene only (-/+), and the uORF only (+/-). Starts were deleted by alteration to ATT. mRNA from each construct was used to program a cell-free translation system. **c**, Results of translation assays. The luciferase activity of all constructs (normalized to the -/+ construct) is shown on the *y* axis. Error bars show the average of the absolute deviation from the mean. The autoradiogram shows ^{35}S-Met-labeled firefly luciferase obtained by *in vitro* translation of the same mRNAs.

assembly of *A. oryzae* consists of transposable elements, compared to 3% of *A. nidulans* and *A. fumigatus*. All three genomes contain essentially all major classes of eukaryotic transposable elements, although the overall variety is relatively low. A number of unusual features were also observed in *Aspergillus* transposable elements (Supplementary Information). Copy numbers per family range from 1 to ~100; there are also many fragments and "footprints" (evidence of recombinational excision). In addition, some members of all transposable element families longer than ~400 nucleotides are characterized by numerous C to T transitions. In *A. nidulans* and *A. fumigatus*, these predominantly affect cytosines in CpG and CpA doublets (no preference is apparent in *A. oryzae*). Moreover, repeat density is correlated with A + T richness in all three species (Figure 2). The predominance of transition mutations is consistent with the operation of RIP (repeat-induced point mutation),[49] and all three aspergilli have a single predicted homologue (called DmtA) to the DNA methyltransferase *rid* that is essential for RIP in *N. crassa*.[49] Apart from the putative *rid* homologue, no additional DNA methyltransferase genes were identified, consistent with failures to demonstrate methylation in these fungi. Although RIP has not been demonstrated in any *Aspergillus* species, if active it may be more similar to the mild form in *M. grisea*,[49] as many transposable elements in these species are mutation-free.

Conclusion and perspective

The *A. nidulans* genome sequence and our comparative analysis with the genome sequences of *A. fumigatus* and *A. oryzae* have shed new light on the physiology of these fungi, as well as insight into aspects of genome evolution and gene regulation likely to be common to all eukaryotes. These results represent the initial step in realizing the full potential of these genomes. As a result of the genome analysis, efforts are underway to cross different isolates of *A. fumigatus* and *A. oryzae*. The identified conserved sequences also represent a rich set of targets for further experimental investigation. These efforts and ongoing sequencing projects for additional aspergilli promise to change fundamentally our understanding of this important group of medically, industrially and scientifically relevant fungi.

Methods

Complete details of the methods used are available in the Supplementary Information section.

A. nidulans sequencing, assembly and analysis

The *A. nidulans* genome strain FGSC A4 was sequenced by the WGS method to a depth of 10 ×. An additional 3 × sequence coverage was provided by Monsanto (http://www.monsanto.com/). All sequence was assembled using Arachne. The *A. nidulans* genome was annotated as described in Supplementary Information. *A. fumigatus* and *A. oryzae* were assembled and annotated as described separately.[2, 3]

Phylogenetic analysis

A total of 3,034 predicted orthologues among *A. nidulans*, *A. oryzae*, *A. fumigatus*, *N. crassa* and *F. graminearum* were aligned at the protein level, back translated to DNA codons, and large gaps (> 9 bp) were removed. Random sets of 20 DNA alignments were concatenated and passed to Phylip to generate 100 bootstrap replicates and a consensus maximum parsimony tree. Maximum likelihood trees were calculated on each replicate and a consensus tree was produced. Repeating with 1,000 bootstrap samples led to essentially identical results. For rooting with *C. immitis*, *C. immitis* orthologous CDS regions based on TBlastN were retrieved, translated and aligned at the protein level with the aligned portions of the *Aspergillus* genes. Maximum parsimony trees were then generated and filtered for those with 100% bootstrap values at all nodes. The *C. immitis* sequence is available at http://www.broad.mit.edu/annotation/genome/coccidioides_immitis/MultiHome.html

Hierarchical synteny mapping and branch-specific rearrangements

Protein homology anchors were detected using BlastP and filtered to retain only hits scoring >80% of the score of the best hit to each query protein. Contiguous sets of homologous proteins with conserved order and orientation were grouped into clusters. Pairs of clusters were then merged into successively larger clusters by tolerating successively larger breaks between clusters. Branch-specific breaks were determined by identifying regions without breaks between a reference species and query species, and then identifying breaks in that region between the reference and the third (target) species. Such breaks were considered specific to the third species. Breaks were classified according to the pattern of apparent rearrangement.

Identification of non-coding conserved sequences

Genomic sequence for predicted three-way orthologues, including 1 kb upstream and downstream, were multiply aligned using Mlagan.[33] An additive scoring function was used to identify maximal scoring subsequences. A cutoff of 22 was used to define HCSs unlikely to occur by chance ($P < 0.015$) according to models of neutral sequence and random sequence alignment. To model alignments of neutrally evolving sequence, aligned columns of fourfold degenerate sites were selected randomly and concatenated. To model alignments of random sequence, randomly selected intergenic regions from each genome were aligned. Fixed and variable length alignments were generated for both models. For each model, 1,000 simulated alignments were generated and maximal scoring subsequences were identified. The number of subsequences for each score was normalized by the number of aligned nucleotides. These rates were used to determine the score cutoff above.

Prediction of functional motifs

Each HCS was represented as a position-specific probability matrix (PSPM) derived from the three-way alignment. Each PSPM was compared to each other PSPM and matching PSPMs were clustered. Local multiple alignments for each cluster were generated and the resulting multiple alignments and corresponding weight matrices were termed conpats. For each conpat, we used the corresponding weight matrix with MAST to identify instances where the conpat co-occurred upstream or downstream of orthologous genes in all three of the aspergilli. A series of conservation tests was then applied to the set of predicted co-occurrences for each conpat as described in Supplementary Information.

Prediction and validation of upstream open reading frames

Genome sequences for three-way orthologues, including 1,000 bp upstream and downstream, were multiply aligned using Mlagan. For 25% of *A. nidulans* genes 5′ UTR sequences were predicted from EST alignments. On the basis of the length distribution of these EST-predicted UTRs, we used 60 bp upstream of predicted AUG codons as a conservative estimate of 5′ UTRs for genes lacking ESTs. When no ESTs were available, UTRs for orthologues where considered when all three annotated start codons aligned within 40 bp. We identified uORFs ≥ 12 bp, with a maximum 1-bp overlap with the protein-coding gene's ATG. Conserved uORFs were identified as those for which the start and stop codons were exactly aligned within the multiple alignments. To experimentally validate uORFs, synthetic oligonucleotides containing each uORF, 26 nucleotides upstream of the uORF, the region between the uORF and the protein coding AUG, and the first four codons of the protein coding gene were fused in frame with a firefly luciferase gene. Three different control constructs were also generated. Capped and polyadenylated synthetic mRNA were prepared from each construct and equal amounts were used to program cell-free extracts from *N. crassa*. Differential translation between the intact construct and the controls was measured using a luciferase activity assay as well as through the production of ^{35}S-Met-labeled firefly luciferase obtained by *in vitro* translation of the same mRNAs.

The *A. nidulans* genome sequence is available at http://www.broad.mit.edu/annotation/genome/aspergillus_nidulans/MultiHome.html and has been deposited at DDBJ/EMBL/GenBank under the project accession AACD00000000.

Acknowledgments

The authors would like to thank M. Zody, X. Xie, M. Kellis, M. Kamal, J. Taylor, G. Turgeon, and E. Lander for numerous helpful conversations, comments and critical readings of the paper. We also thank all members of the sequencing platform at the Broad Institute. We thank R. Dean for providing the BAC library used in sequencing. We especially thank M. Brudno for his help in using Mlagan to align the three genomes, and R. Morris for his many contributions to the *A. nidulans* sequencing project and subsequent analyses. This work was supported in part by grants from the NIH, as well as the NIH Research Supplement for Underrepresented Minorities, the DFG, the CMPB, and the BBSRC.

Author Contributions

B.W.B. developed and led the *A. nidulans* sequencing project. J.B. performed the assembly of *A. nidulans*. C.C. and J.E.G. analyzed the phylogenic relationship of the three organisms. J.E.G. performed the analysis of conserved synteny and genome evolution. R.F., B.M., and P.D. performed the comparative analysis of sexual reproduction genes. J.E.G., M.P., P.D., and B.M. analyzed the mating-type loci. S.E.C. and J.E.G. analyzed conserved non-coding sequences and computationally analyzed uORFs. S. Batzoglou and S.-I.L. assisted with the use of Mlagan. M.B., C.C.S., and M.S.S. performed the experimental uORF validation. M.C., M.H., G.H.B., O.D., and C.D. analyzed transcription, known transcription factors, and binding sites. A.P. and S.G.J. predicted non-coding RNAs using PFAM and RFAM. J.C., V.K., J.J., S.P., and J.E.G. analyzed repeat sequences and RIP. M. Farman analyzed telomeres and subtelomeric gene content. M.H. analyzed the *Aspergillus* peroxisomes. S.H. and M. Momany analyzed hyphal growth and RhoGTPases. J.R.W. and W.C.N. provided the sequence and annotation for *A. fumigatus*. T.T., T.K., K.A., and M. Machida provided the sequence and annotation for *A. oryzae*. D.W.D. co-ordinated interactions between the different sequencing centers and scientific communities. J.E.G. and S.A.O. coordinated the comparative analyses. J.E.G. wrote and edited the paper, and produced the figures.

Supplementary Information — Contents

Contents listings are actively linked to the first page of the supplementary sections.

§S0. Detailed Methods

***A. nidulans* Sequencing and Assembly.** The *A. nidulans* genome strain FGSC A4 was sequenced by the whole-genome shotgun method. A total of 10x coverage was produced at the Broad Institute from Plasmid (4kb and 10kb inserts), Fosmids (40kb inserts), and BACs (110kb inserts) (http://www.broad.mit.edu/annotation/fungi/aspergillus/background.html). The BAC library for strain FGSC A4 was provided by Ralph Dean at North Carolina State University and is available at Clemson University Genomics Institute (https://www.genome.clemson.edu/orders/). All inserts were sequenced from both ends to generate paired-reads. An additional 3x sequence coverage was provided by Monsanto (http://www.monsanto.com/). All sequence was assembled using Arachne[1]. The assembly was anchored to a genetic map based on 260 markers (201 with unambiguous sequences in Genbank). Six discrepancies in the genome assembly were detected by comparison with the genetic map and corrected (see http://www.broad.mit.edu/annotation/fungi/aspergillus/markers.html for more details). *A. fumigatus* and *A. oryzae* genomes were assembled as described in separate reports[2,3].

***A. nidulans* Annotation and Analysis.** The *A. nidulans* genome was annotated using the Calhoun annotation system. The genome sequence was searched against the public protein databases using BLASTX with threshold $E \leq 1e\text{-}5$. Genes were predicted using a combination of FGENESH, FGENESH+, and GENEWISE. Predicted genes were validated against ESTs aligned to the genome using Blat[4]. All predicted proteins were searched against the PFAM set of hidden Markov models[5] using the HMMER program and the public protein databases using BLASTP. Transfer RNAs were identified using the tRNAScan-SE program[6]. Repeat sequences were detected by searching the genome sequence against itself using CrossMatch, filtering for alignments longer than 200bp in length, and clustering pairs based on region overlap. Repeats were characterized using RepeatMasker (http://ftp.genome.washington.edu/RM/RepeatMasker.html) and RepBase[7] followed by manual inspection. The *A. fumigatus* and *A. oryzae* genomes were annotated as described in separated reports[2,3].

Phylogenetic Analysis. A total of 3034 orthologs among *A. nidulans, A. oryzae, A. fumigatus, N. crassa,* and *F. graminearum* were predicted using the COG definition[8] using BlastP ($e<10^{-5}$ and alignment length at least 60% of both genes) and aligned at the protein level using ClustalW[9]. Alignments were then back translated to DNA codons and large gaps (>9b) were removed. Random sets of 20 DNA alignments were concatenated and passed to Phylip to generate 100 bootstrap replicates of alignments using seqboot and a consensus maximum parsimony tree using protpars and consense. Maximum likelihood trees were calculated on each replicate and a consensus tree produced. Repeating the analysis with 1000 bootstrap samples led to essentially identical results. For rooting with *C. immitis*, orthologs from each Aspergillus species were compared to the *C. immitis* genome sequence with TBlastN (e<1e-10). Results were filtered such that: (1) only genes in the Aspergilli that hit to a single locus in *C. immitis* were considered, (2) the best HSP for each gene must not contain a stop codon in *C. immitis* not aligned with a gap position, and (3) all three Aspergillus orthologs must hit the same locus in *C. immitis*. Regions of the *C. immitis* genome corresponding to the intersection of the Aspergillus hits were retrieved, translated, and aligned at the protein level with the aligned portions of the Aspergillus genes. Alignment regions with large gaps (>9bp) were removed. Maximum parsimony trees were then generated using the protpars program of Phylip and trees filtered for those with 100% bootstrap values at all nodes. Raw data are available in Supplementary Material. The C. immitis genome sequence is available at http://www.broad.mit.edu/annotation/fungi/coccidioides_immitis/.

Hierarchical Synteny Mapping. Protein homology anchors were detected using BlastP (e<1e-5 and length >60% of longest protein) and then filtering to retain only those hits scoring >80% of the score of the best hit to each query protein. The clustering algorithm was initiated by finding contiguous sets of homologous proteins with conserved order and orientation and grouping each into a cluster. Then during each iteration of the algorithm, pairs of clusters were merged into successively larger clusters by tolerating successively larger breaks between clusters. The distance between cluster X and Y was the Euclidean distance between the two nearest points of the rectangle bounding the clusters in a dot plot if (1) the cluster X is orientated toward cluster Y and (2) both are on the same supercontig. Otherwise the distance was infinite. After merging two clusters, the slope of the resulting merged cluster was determined as the slope of a line through the merged clusters. During each merge, the characteristics of the break (microrearrangement) between the merged clusters were tracked. The algorithm was terminated when no clusters within 100Kb of one another were available to be merged.

Branch-Specific Rearrangements. Branch-specific breaks were determined by identifying regions without breaks between a reference species, R, and query species, Q, and then identifying breaks in that region between R and a target species, T. Such breaks are considered specific to T. For example, if region 1-10Kb in *A. nidulans* (R) is conserved without microrearrangements when compared to *A. fumigatus* (Q), but the same region shows an inversion when compared to *A. oryzae* (T), this inversion would be considered an *A. oryzae*-specific rearrangement. For a given R, Q, and T, only pairwise blocks longer than 20kb, breaks between R and T larger than 10 kb on either genome, and breaks between R and Q larger than 5kb on either genome were considered. Also, breaks between R and T within 5 kb of contig ends were not considered. Breaks in T that are wholly contained within an inversion between R and Q were considered T specific breaks. The number of breaks specific to T was converted to a rate by dividing by the total number of nucleotides in R used in the analysis. For each target genome, two different R versus Q comparisons were possible. The error bars in **Error! Reference source not found.**A correspond to the minimum and maximum values for the two comparisons. Breaks were characterized as follows:

- Insertion – at least 10Kb is present in T that does not map to R,Q
- Deletion – at least 10Kb is present in R,Q but does not map to T
- Complex Indel – a combination of Insertion and Deletion
- Inversion – a block of at least 10kb is inverted in T relative to R,Q
- Intrachromosomal Translocation – a break between two syntenic blocks between R,T that are adjacent in R and where the blocks between R,T are on the same chromosome.
- Interchromosomal Translocation – a break between two syntenic blocks between R,T that are adjacent in R and where the blocks between R,T are on different chromosome.

Identification of Non-coding Conserved Sequences. Pairwise orthologs were identified as best bidirectional hits (BBHs) within all-vs-all comparison of two genome protein sets using Blastp (e<1e-5) and requiring > 60% coverage of each gene. Threeway orthologs were identified as sets of three genes from each genome in which each gene is a BBH of each of the other two genes. A total of 4936 threeway orthologs were thus predicted.

Genomic sequence for threeway orthologs including 1kb upstream and downstream were multiply aligned using the Mlagan program[10] with the phylogenetic tree (AN, (AF, AO)). Within the multiple alignments, unambiguous non-coding regions were defined as regions not annotated as a coding sequence in any of the three genomes. Duplicate regions in alignments of neighboring genes were removed. An additive scoring function (match=3, mismatch=-2, and gap=-20) was used with a linear time algorithm[11] to identify maximal scoring subsequences. A score cutoff of 22 was used to define High-scoring Conserved Sequences (HCSs) unlikely to occur by chance ($p<0.015$) according to models of neutral sequence and random sequence alignment as described next.

Models of Neutral and Random Alignments. To model alignments of neutrally evolving sequence, ortholog protein sequences were aligned using ClustalW and subsequently back-translated to DNA codons. Aligned columns of 4-fold degenerate sites from these alignments were placed into a pool, and columns from this pool were then selected randomly with replacement and concatenated to generate synthetic aligned sequences. Both 1000bp fixed length synthetic alignments were generated as well as variable length alignments drawn from a normal distribution approximating observed intergenic lengths in *A. nidulans* ($\mu=1110$, $\sigma=140$). To model alignments of random sequence, randomly selected intergenic regions were aligned from unrelated loci from each of the three genomes. Both fixed length alignments (800bp clipped from selected intergenic regions) and variable length alignments (full length of each intergenic region aligned) were generated.

A total of 1000 simulated alignments from both the fixed and variable length neutral and random models were generated. For each set of alignments from each model, maximal scoring subsequences were identified as described above. The number of subsequences for each score was normalized by the number of aligned nucleotides in the set of the alignments to produce a spatial rate of the number of subsequences of score X per Mb. These distributions were used to determine a threshold for identifying HCSs as described in the text.

Prediction of Functional Motifs. Each HCS was represented as a position specific probability matrix (PSPM) derived from the threeway alignment. The probability assigned to each base at each position of the matrix was (Cn+B/4)/(N+B) where Cn is the number of occurrences of the letter at that position, N is the number of sequences, and B is the total number of pseudocounts added at each position (0.001). Pseudocounts adjust for the small number of observed sequences by preventing entries of zero in the PSPM as required for log-odds scoring[12]. Each PSPM was then compared to each other PSPM to find the best scoring pairwise local alignment. Local alignments were scored by summing a log-odds function, F, across each aligned column where F=log2(q/p) and q=dot-product of the columns from the two PSPMs and p=0.25. A minimum length of 8bp and score of 12 was required for local alignments. PSPMs were then clustered according to an iterative greedy clustering algorithm. Specifically, at each iteration if PSPMs X and Y share a local alignment and are part of cluster C, and PSPMs X and Z share a local alignment, and if the local alignments overlap on X within 3bp at each boundary, Z would be added to cluster C. The region of X and Z covered by the corresponding local alignment was then masked, and the algorithm re-iterated. Given clusters of PSPMs, local multiple alignments for each cluster were generated from the genomic sequences corresponding to each PSPM. Specifically, the sequences from all three species corresponding to each PSPM, as well as 6bp of padding on each side, were aligned using the program MEME[13] (with the “oops” model). The resulting multiple alignments and corresponding weight matrices were termed CONserved PATterns (conpats). Raw conpats from MEME were trimmed to require 2 consecutive bases with information content exceeding 0.75 bits/position at each end. Additionally, low quality patterns (MEME expect >1e-5 or conpats with <1.2 bits/base information content) were removed.

For each conpat, we used the corresponding weight matrix with the MAST[14] program to identify instances where the conpat co-occurred upstream or co-occurred downstream of orthologous genes in each of the three Aspergillus species. Matches on either strand were permitted. To associate matches with upstream/downstream regions, we identified a unique non-coding “upstream-half region” and “downstream-half region” for each ortholog triplet: for orthologs with no neighboring gene within 1000bp, 500bp of aligned sequence upstream/downstream was used; for orthologs with a neighboring gene, the unambiguous intergenic region was split in half. The MAST expect threshold was determined in order to generate <1 false positive co-occurrence in the 4936 orthologous genes, based on a null model assuming randomly occurring motifs will occur independently in each of 3 orthologous regions according to background base frequency. A series of conservation tests were then applied to the set of predicted co-occurrences for each conpat:

- ◊ *Co-occurrence enrichment*: used to identify conpats that co-occur more often than random patterns of the same length and degeneracy. For each conpat, we generated 1000 different patterns by randomly assigning the weights at each position of the conpat to letters (A,C,G,T). Co-occurrences of randomized patterns were then identified as described above. The co-occurrence p-value was defined based on the number of random patterns with co-occurrence counts at least as great as the actual conpat. Conpats with p-values <0.01 were considered enriched by this test.

- ◊ *Upstream/Downstream Bias*: used to identify conpats with a preference for co-occurring in upstream or downstream regions. We assigned p-values based on binomial distribution with Prob(upstream co-occurrence)=p=0.56 (calculated from upstream/downstream distribution of all HCSs). Conpats with p-values <0.01 were considered biased by this test.

- ◊ *Functional Category Enrichment*: used to identify conpats that were enriched in co-occurrences neighboring genes of particular COG categories. COG categories were assigned using the NCBI COG database followed by manual inspection. For each conpat and each category C, we calculated the enrichment p-value according to a hypergeometric distribution and corrected for multiple testing using the Bonferroni correction (multiplying by the number of categories associated with the particular conpat). If a conpat exhibits upstream/downstream preference, only the corresponding upstream/downstream co-occurrences were used for category enrichment testing. Categories with corrected p-values<0.01 were considered enriched.

- ◊ *Cellular Location Enrichment*: used to identify conpats that are enriched in co-occurrences associated with genes whose predicted yeast BBHs have a particular cellular localization. Cellular localization for S. cerevisiae genes from http://yeastgfp.ucsf.edu/[15]. Categories "ambiguous" and "punctuate" were not considered. The enrichment p-value was calculated using a hypergeometric distribution with Bonferroni corrections in the same manner as with the functional category enrichment test.

Conpats with similar weight matrices (CompareACE[16] score>0.85 and manual inspection) and identical statistical signatures were collapsed. A total of 69 conserved patterns ("conpats") that occurred in at least 4 HCSs, showed enrichment in co-occurrences, and a bias for occurring upstream or downstream of genes were identified and considered in this analysis. The full set of conpats are provided in Supplementary Material.

Prediction of Upstream Open Reading Frames. Genome sequences for the set of 4936 ortholog triplets, including 1000bp upstream and downstream, were multiply aligned using Mlagan. For 25% of *A. nidulans* genes with overlapping EST alignments, the entire length of the EST alignment upstream of the predicted AUG was taken as the 5' UTR. Using the length distribution of these EST-predicted UTRs, we found that 60% of all predicted 5' UTR first exons were longer than 60bp. Thus for genes lacking EST alignments, we used 60bp upstream of predicted AUGs as a conservative estimate of 5' UTRs. To correct for annotation ambiguities when no ESTs were available, UTRs for orthologs where considered when all three annotated start codons aligned within 40bp. For each species, we identified all upstream open reading frames >= 12bp, with a maximum 1bp overlap with the protein-coding gene's ATG. Conserved uORFs were identified as those whose start and stop codons were aligned within the multiple species alignment, with no minimum uORF protein identity.

Experimental Validation of Upstream Open Reading Frames. The impact of predicted uORFs on downstream gene translation was assessed by adapting a protocol previously described[17-20]. Synthetic oligonucleotides were designed to obtain 5'-leader sequences containing each uORF including 26nt upstream of the uORF, the region between the uORF and the protein coding AUG, and the first four codons of the protein coding gene. Oligonucleotides were obtained from Sigma-Genosys. These leader sequences were fused in frame with a firefly luciferase gene. Three different control constructs were also generated: one eliminated the initiation codon for the uORF, one eliminated the initiation codon for the predicted gene luciferase fusion, and the third eliminated both. Thus four constructs were made for each uORF: +/+ (both uORF and downstream product AUG codons), -/+ (no uORF AUG), +/- (no downstream AUG) and -/- (neither AUG). The first two constructs evaluate uORF function; the latter two establish that reporter activity is arising from initiation at the correct downstream start codon. Capped and polyadenylated synthetic mRNA were prepared from each construct and equal amounts were used to program cell-free extracts from *N. crassa*. Each set of transcripts was produced by two independent transcription reactions and analyzed in the linear activity range using two independently prepared extracts from each organism. All reactions contained Renilla luciferase mRNA as an internal control for normalization. Differential expression of the reporter gene between the intact construct and the controls was measured using a luciferase activity assay[21] as well as through the production of ^{35}S-Met labeled firefly luciferase obtained by in vitro translation of the same mRNAs.

Only a small number of genes in Aspergillus with validated uORFs have been previously reported[22-27].

§S1 Aspergillus Phylogenetic Analysis - Raw Data

Methods

A total of 3034 orthologs between *A. nidulans, A. oryzae, A. fumigatus, N. crassa,* and *F. graminearum* were predicted using the COG definition[89] using BlastP ($e<10^{-5}$ and alignment length at least 60% of both genes) and aligned at the protein level using ClustalW[90]. Alignments were then back translated to DNA codons and large gaps (>9b) were removed. Random sets of 20 DNA alignments were concatenated and passed to Phylip to generate 100 bootstrap replicates of alignments and a consensus maximum parsimony tree. Maximum likelihood trees were calculated on each replicate and a consensus tree produced. For rooting with *C. immitis*, orthologs from each Aspergillus species were compared to the *C. immitis* genome sequence with TBlastN (e<1e-10). Results were filtered such that: (1) only genes in the Aspergilli that hit to a single locus in *C. immitis* were considered, (2) the best HSP for each gene must not contain a stop codon in *C. immitis* not aligned with a gap position, and (3) all three Aspergillus orthologs must hit the same locus in *C. immitis*. Regions of the *C. immitis* genome corresponding to the intersection of the Aspergillus hits were retrieved, translated, and aligned at the protein level with the aligned portions of the Aspergillus genes. Alignment regions with large gaps (>9bp) were removed. Maximum parsimony trees were then generated using the protpars program of Phylip and trees filtered for those with 100% bootstrap values at all nodes.

Tabs

Orthologs: Five way orthologs (*A. nidulans, A. oryzae, A. fumigatus, F. graminearum*, and *N. crassa*) used in analysis

Concatenated Genes: The random sets of concatenated genes. Each set is identified by an "ID" (i.e. concat1), and for each ID there are 20 groups of five way orthologs

Concatenated Tree Topologies: Summary of tree topologies for all concatenated gene sets

Single Gene Topologies: Summary of topologies for all single fiveway ortholog trees

§S2. Synteny Analysis

§S2.1. Hierarchical Synteny Clustering Method

Blocks of snyteny were predicted using a hierarchical clustering technique (Figure S2.1A). The algorithm is initiated by detecting clusters of sequence anchors with conserved order and orientation. These regions are then merged in to successively larger syntenic clusters by tolerating successively larger rearrangements within blocks. Specifically:

Given: two genome sequences with a set of pairwise alignments defined on a two-dimensional coordinate system formed by the concatenation of the contigs of each genome.

Step1: Calculate Exact Syntenic Clusters. Find blocks of anchors with exact conservation of order and orientation and cluster them. The orientation of each cluster is either "+" or "-" (defined as expected from the given coordinate system). Create a list, L, of these seed clusters.

Step2: Initialize the Cluster Distance Matrix. Define the bounds of a cluster as its endpoints on each axis of the coordinate system (this defines a box). Define the asymmetric distance between cluster X and cluster Y as the cartesian distance between the two nearest points on the bounds if (a) these clusters are on the same supercontig, (b) the distance is less than a scale factor D, and (c) *only if cluster X is oriented toward cluster Y* (see Figure S2.1). Otherwise the distance is infinity. Calculate the complete distance matrix, d_{ij}, between all pairs of clusters (in practice only one half of the matrix is required).

Step3: Merge Nearest Cluster. Find the minimum entry in the distance matrix and merge the two corresponding clusters into a new cluster. Create pointers in the new cluster to the merged clusters. Remove the merged clusters from L, and add the new cluster.

Step4: Calculate Merged Cluster Orientation. The orientation of the new cluster is defined according to the slope of the line through the merged clusters.

Step5: Update Distance Matrix. Remove the entries in d_{ij} for the merged clusters and create an entry for the new cluster. Recalculate those entries impacted by this procedure. Increase the scale factor D and repeat steps 3-5 until D exceeds the size of the largest supercontig.

Output: When no new clusters can be merged, output L. Each cluster in L is a tree defining a hierarchical relationship between merged clusters.

An example of the algorithm applied to a 1Mb region of synteny between *A. nidulans* and *A. fumigatus* is shown in Figure S2.1B. The clustering function produces a tree-based data structure that can be manipulated by standard tree traversal algorithms. Using these structures, the number of rearrangement events (at a any given level of resolution) in pairwise comparisons can be calculated. Given multiple pairwise comparisons, branch specific rearrangements can be calculated as described in the methods.

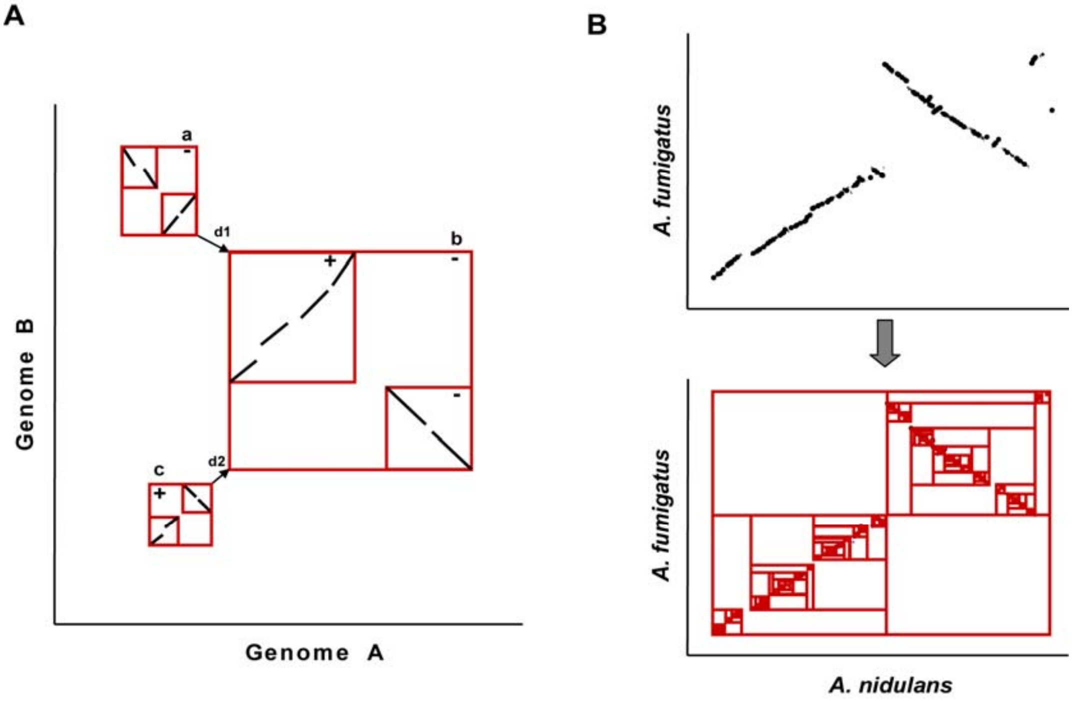

Figure S2.1. Hierarchical clustering algorithm for whole genome synteny mapping. (A) Algorithm schematic. Each cluster (boxes) is associated with an orientation ('+' or '-' symbols). An asymmetric distance is defined between all pairs of clusters. If a cluster is oriented "toward" another, the distance is defined to be the cartesian distance (e.g. d_{ab}=d1). Otherwise the distance is infinity (e.g. $d_{ba}=\infty$). The method merges the closest pair of clusters at each iteration. Information about merged clusters is maintained (boxes within boxes). See text for more details. (B) Application to 1Mb region of synteny between *A. nidulans* and *A. fumigatus*. The method identifies the large inversion, as well as rearrangements within rearrangements (boxes within boxes).

§S2.2. Syntenic breaks are associated with repeats and telomeres

As described in the main text, an examination of the pattern of pairwise syteny between the three Aspergilli reveals large regions lacking detectable long range synteny. Repeat sequences are enriched in these non-syntenic regions, with 40% of *A. nidulans* repeats sequences in breaks with both *A. fumigatus* and *A. oryzae*, compared to 27% expected ($p<1e-116$ – similar enrichments for *A. fumigatus* and *A. oryzae*). Extensive rearrangement is also observed at the ends of Aspergillus chromosomes. This association of large-scale genome rearrangement with repeats and chromosome ends has been observed for a number organisms including mammals, nematodes, and yeasts[7,9-13], and our data confirm these trends for the Aspergilli.

In addition, the observed subtelomeric rearrangement may have specific implications for fungi. Growing evidence suggests that subtelomeric regions in fungi contain genes with roles in niche adaptation and virulence. It is thus noteworthy that sub-telomeric regions in both *A. nidulans* and *A. fumigatus* show enrichment for gene clusters with predicted roles in secondary metabolism. In *A. fumigatus*, 8 of 24 secondary metabolite clusters are found within 100Kb of the nearest telomere ($p<1e5$), while in *A. nidulans*, 11 different secondary metabolite gene clusters, including a penicillin and a sterigmatocystin cluster, are situated within 100 kb of the nearest telomere. Further, over 30% of predicted non ribosomal peptide synthetases and polyketide synthases genes in *A. nidulans* and *A. fumigatus* reside within just 100 kb of a telomere (a 5.5-fold enrichment). This enrichment suggests that these genes may play an important role in the ecology of these fungi. The rapid rearrangement of subtelomeric regions may facilitate the species specific evolution of these genes, and in this regard it is conspicuous that *A. nidulans* and *A. fumigatus* do not have any telomere-associated secondary metabolite gene clusters in common.

§S2.3. The Random Breakage Model of Genome Evolution

As described in the main text, it has long been proposed that genomes evolve according to random breakage model which predicts that distances between breakpoints should follow an exponential distribution of the form $f(x) = 1/L\ e^{-x/L}$, where L is the average size of all unbroken segments[14,15]. To determine whether conserved syntenic blocks in Aspergilli follow random breakage, we analyzed the distribution of lengths of unbroken regions between micro-rearrangements within pairwise syntenic blocks (see Methods). As shown in XXXXX, although the mean breakpoint length differs between the three pairwise comparisons, in all three cases the distribution of lengths shows close agreement with the model prediction. It thus appears that syntenic blocks, comprising the majority of the Aspergillus chromosomes, are evolving in a manner consistent with random breakage.

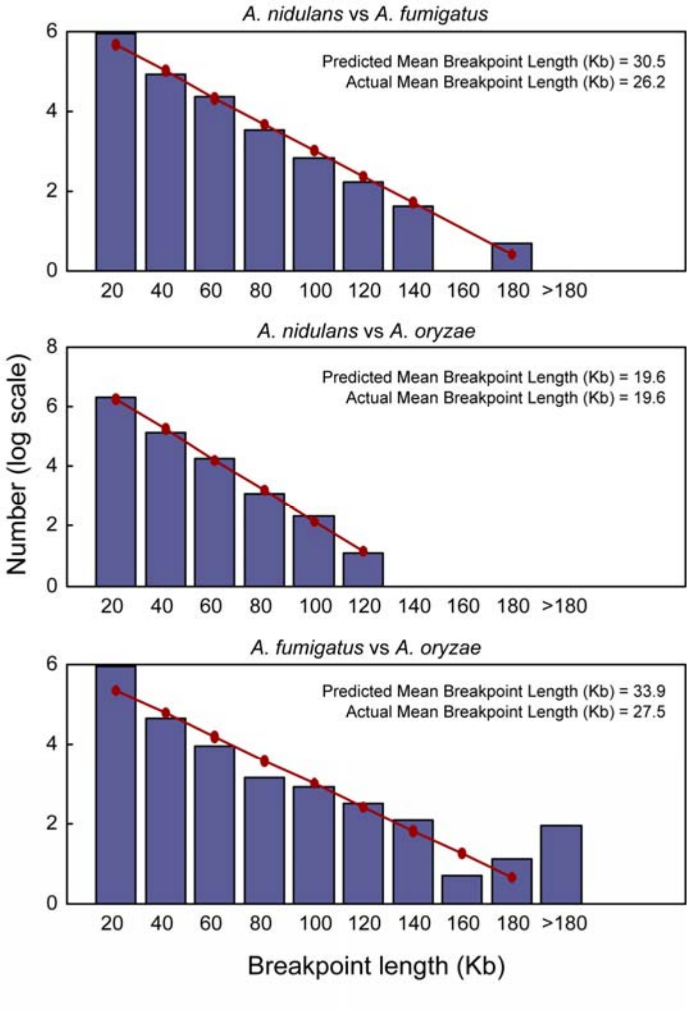

Figure S2.2 Random Distribution of Breakpoints in Conserved Syntenic Blocks. Histogram of length distributions between microrearrangement breakpoints within conserved pairwise syntenic blocks. Red line indicates fit to random breakage model which predicts an exponential distribution of breakpoint lengths of the form $f(x)=e^{-x/L}$ where L is the predicted mean breakpoint length.

§S2.4. No Deceleration of Rearrangement in A. fumigatus

The data in Figure 4 reveal a greater rate of rearrangement in *A. oryzae* relative to *A. fumigatus*. In principle, this could be due to a deceleration in breakage in *A. fumigatus*, possibly consistent with parasitic lifestyle. However, if this were the case, and the rate remained constant in *A. oryzae* and *A. nidulans*, syntenic blocks between *A. fumigatus* and *A. oryzae* would be larger than those between *A. fumigatus* and *A. nidulans*. Instead the opposite is observed Table 2. We note also that a greater rate of rearrangement is consistent with the smaller average syntenic block sizes for *A. oryzae* (Table 2).

§S2.5. Similar Rates of Protein Evolution in A. fumigatus and A. oryzae

We compared the rates of molecular evolution in *A. oryzae* and *A. fumigatus* with *A. nidulans* as an outgroup using a number of different but related methods. First, an examination of threeway orthologs revealed the distribution of amino acid identity to be nearly identical for both *A. oryzae* and *A. fumigatus*, relative to *A. nidulans*. Equivalently, a scatter plot of non-synonymous divergences of *A. fumigatus* and *A. oryzae* threeway orthologs relative to A. nidulans reveales a strong correlation between *A. fumigatus* and *A. oryzae* divergences with an overall slope of nearly 1. Finally, branch lengths predicted from both single gene and concatenated gene phylogenies indicate a comparable rate of substitution in both the *A. oryzae* and *A. fumigatus* lineages.

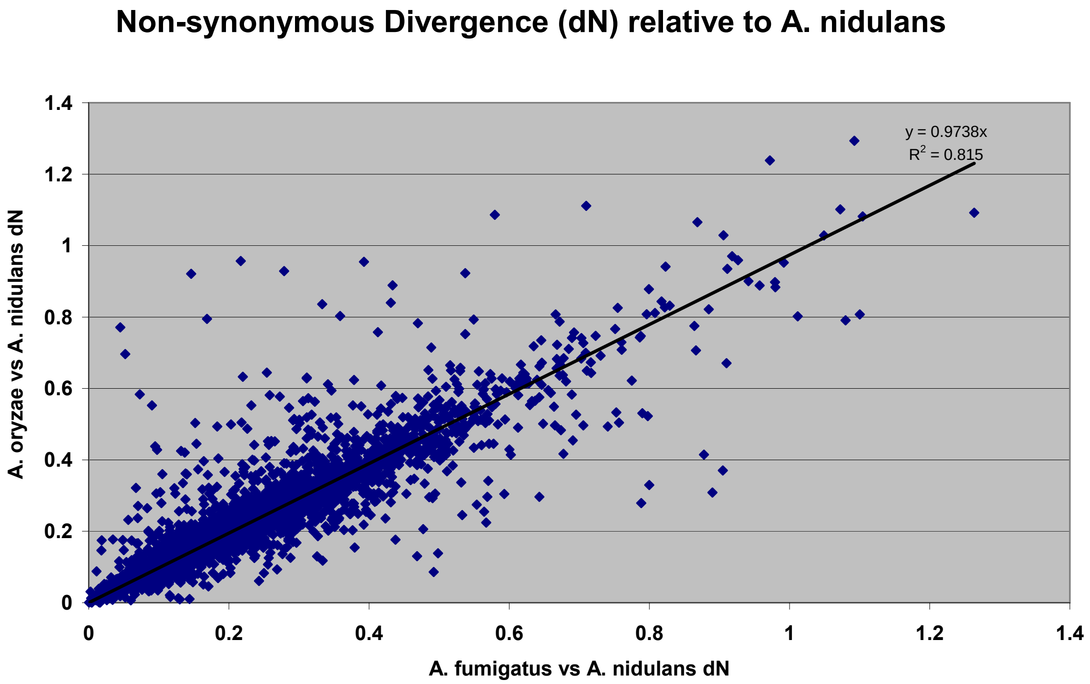

Figure S2.3. Correlation between non-synonymous divergence rates (substitutions/site) of three way orthologs in *A. fumigatus* and *A. oryzae* relative to *A. nidulans*.

§S3 Upstream open reading frames (uORFs)

Method:

To search for uORFs conserved between the three Aspergillus species, we started with the set of 4936 ortholog triplets and 1000bp upstream regions multiply aligned using MLAGAN. For the 25% of A. nidulans genes with EST alignments indicating 5’ UTRs, the entire length of the EST alignment was searched for uORFs. Otherwise the search was conservatively constrained to the upstream 60bp region, since 60% of all 5’ partial ESTs extend beyond 60bp (considering only the final UTR exon that overlaps the gene start). Additionally, to avoid annotation errors if there were no ESTs, we limited the search to those unambiguous intergenic regions upstream of the 2372 orthologs with all three annotated start codons aligned within 40bp. For each species, we identified all upstream open reading frames >= 12bp, with a maximum 1bp overlap with the protein-coding gene’s ATG. *Conserved uORFs* were

We also include here, under the "extended_data_300bp" tab, those uORFs not within 60bp or in UTRs, but within 300bp of aligned upstream sequence. These may not be within the mRNA transcript.

For each data set, we also search for uORFs in the An gene's ortholog in other fully-sequenced fungi: Neurospora crassa (Nc), Fusarium graminearum (Fg), Magnaporthe grisea (Mg), Saccharomyces cerevisiae (Sc), Saccharomyces bayanus (Sb), Saccharomyces mikatae (Sm), and Saccharomyces paradoxus (Sp). Orthologs are defined as best bidirectional hit within an all-vs-all blastp analysis (expect < 1e-5, coverage > 60% of each gene). For the filamentous fungi Nc, Fg, and Mg, we search for uORFs only within known UTRs (defined by unique EST blat alignments) or within 60bp since these genomes often have 5' UTR introns. For Sc, since introns are rare and ESTs are not available, we search within 100bp upstream of the gene start. For Sc orthologs, we also check whether a uORF co-occurs upstream of the 4 closely related yeast species (Sc,Sb,Sm,Sp) based on the 4-way

The 38 uORFs mentioned in the text that are conserved in all three Aspergilli are provided in the tab "Aspergillus

Abbreviations:

an: *Aspergillus nidulans*
af: *Aspergillus fumigatus*
ao: *Aspergillus oryzae*

Data fields: (use tab "data" below)

uORF_id: unique identifier for each uORF

ortholog_cluster_id: unique identifier for each 3-way ortholog

species: species that contains the uORF; "conserved" indicates uORF is found in all 3 species with the start and stop codons aligned

an_gene,af_gene,ao_gene: locus identifier for each of the 3-way orthologs

in_utr: 1 if the location of the uORF overlaps a 5' An UTR (as defined by an EST alignment)

an_rel_start, af_rel_start, ao_rel_start: coordinate of the uORF's ATG relative to the protein-coding gene's start codon

an_rel_stop, af_rel_stop, ao_rel_stop: coordinate of the stop codon relative to the protein-coding gene's start codon (1 indicates that the "A" of the stop codon's TGA/TAA overlaps with the gene's ATG) consensus_dna: uORF consensus DNA sequence, using the degenerate DNA code if the uORF is conserved

an_dna,af_dna,ao_dna: DNA sequence of the uORF in each species

consensus_aa: uORF amino acid sequence from An, with capital letters representing 3-way conserved amino acids (if not conserved, use the species specific amino acid sequence)

an_aa, af_aa, ao_aa : uORF amino acid sequence in each species

context_up_consensus: 10bp upstream of uORF start codon, in degenerate code if the uORF is conserved

context_down_consensus: 10bp down of uORF stop codon, in degenerate code if the uORF is conserved

within_60bp : 1 if the uORF is within 60bp of the protein-coding gene's start codon

COG category: functional category designation of the An gene

fg_uorf_utr: name of Fusarium ortholog with a uORF contained within the 5' UTR (defined by EST alignment)

mg_uorf_utr: name of Magnaporthe ortholog with a uORF contained within the 5' UTR (defined by EST alignment)

nc_uorf_utr: name of Neurospora ortholog with a uORF contained within the 5' UTR (defined by EST alignment)

sc_uorf_utr: name of S.cerevisiae ortholog with a uORF contained within the upstream 100bp

sc_cooccur_orf_100bp: name of S.cerevisiae ortholog with a uORF contained within the upstream 100bp, where uORF is also found upstream of orthologs in Sb, Sm, and Sp
