Cu₂O photocatalyst

Heterojunction

ABSTRACT

Simultaneous photocatalytic reduction of water to H₂ and CO₂ to CO was observed over Cu₂O photocatalyst under both full arc and visible light irradiation (>420 nm). It was found that the photocatalytic reduction preference shifts from H₂ (water splitting) to CO (CO₂ reduction) by controlling the exposed facets of Cu₂O. More interestingly, the low index facets of Cu₂O exhibit higher activity for CO₂ photoreduction than high index facets, which is different from the widely-reported in which the facets with high Miller indices would show higher photoactivity. Improved CO conversion yield could be further achieved by coupling the Cu₂O with RuO_x to form a heterojunction which slows down fast charge recombination and relatively stabilises the Cu₂O photocatalyst. The RuO_x amount was also optimised to maximise the junction's photoactivity.

1. Introduction

Our world is facing complex and intertwined issues on pollution and energy. Rapid economic growth promotes insatiable demand for energy, causing spikes in energy prices coupled with depleting natural resources. At the same time, consumption of energy, fossil fuels in particular, contributes significantly to the increase of greenhouse gases such as CO₂. Many strategies were proposed, but a viable solution requires the utilisation of a renewable energy source and low (initial and running) costs. Photochemical reduction of CO₂ to fuels or value-added chemicals using inorganic semiconductor is an attractive solution for both rising demand for clean energy and the need for greenhouse gas reduction.

Cu₂O is a cheap, relatively abundant and intrinsically *p*-type semiconductor with a low bandgap of about 2–2.2 eV [12,13]. In theory, the narrow bandgap and appropriate positioning of the conduction and valence bands make Cu₂O an ideal photocatalyst for water splitting and CO₂ reduction.

It is acknowledged that Cu₂O has photo-stability issue that remains a challenge [11,16]. Several correlation studies between photocatalytic reduction activity (of water to H₂) on various Cu₂O exposed facets have been reported previously [22,23], indicating that unconventional Cu₂O shapes consisting mostly of high-index facets display significantly higher activities than conventional ones (cubes, etc.) with mainly low-index facets. We very recently found that Cu₂O is an appropriate candidate photocatalyst for CO₂ photoreduction driven by visible light [4]. It is very interesting to observe the influence of Cu₂O facets on CO₂ photoreduction and the correlation between different Cu₂O shapes and product selectivity between water and CO₂ photoreduction. In this paper, the morphology/exposed Cu₂O facets were tuned and the photocatalytic reactions were investigated in an aqueous suspensions system. Tuneable product selectivity was observed and discussed. Finally, heterojunction of RuO_x/Cu₂O was optimised to improve Cu₂O photoactivity.

2. Experimental

Two types of Cu_2O powders used in this study, cuboid and octahedral-shaped, were prepared using solvothermal method. Typical synthesis of cuboid-shaped Cu_2O involves the dissolution of $\text{Cu}(\text{NO}_3)_2 \cdot 2.5\text{H}_2\text{O}$ in a PTFE lined hydrothermal reactors containing ethanol-water mixture (64:36 volume ratio), and formic acid (1.3 M). Octahedral-shaped Cu_2O was synthesised by adding 0.65 M of NH_4OH . Deep red/purple precipitates obtained after 2 h reaction at 145°C were washed repeatedly (5–6 times) with copious amount of water (50 ml) and dried in a convection oven (70°C) overnight. Different Cu_2O - RuO_x junctions were prepared by impregnation method using appropriate $\text{RuCl}_3 \cdot x\text{H}_2\text{O}$ concentration in water followed by heat treatment then washed for a final time and let to dry at 70°C before finally heated at 200°C for 3 h.

Powder XRD was performed using Panalytical X'Pert powder diffraction system fitted with X'cellerator scanning linear detector in 0.0167° steps, at 10 s acquisition time per step. The incident X-ray is nickel filtered Cu radiation ($\text{CuK}_{\alpha 1}$: 1.540596 \AA , $\text{CuK}_{\alpha 2}$: 1.544493 \AA , $\text{CuK}_{\alpha 1}/\text{CuK}_{\alpha 2}$ ratio ca. 65/35). Particle morphology was observed using JEOL-7400 high resolution field emission electron microscope operated at 3 kV accelerating voltage and 10 mA current 0° stage tilt on gold coated powders. TEM measurements were conducted using JEOL-2000-EX-MKII transmission electron microscope (200 kV). Ten points adsorption-desorption tests on the powder samples were performed on Micromeritics® TriStar 3000 with N_2 carrier gas to get an estimate of their surface area using BET calculation method.

CO_2 reduction reaction was carried out in photocatalyst suspension system using septa-sealed glass chambers fit with flat borosilicate top window ($>90\%$ transmittance for $\lambda \geq 350 \text{ nm}$). Prior to measurements, Cu_2O powders and glass chamber were treated at 200°C for 3 h in a convection oven and under 300 W Xe lamp light source for ca. 1 h to remove traces of organic contaminants. A typical photocatalytic

experiment is conducted using 0.5 g of photocatalyst in 3 ml of CO_2 saturated deionised H_2O (Elga Centra). Excess (0.7 M) sodium sulphite was added in each run as hole scavenger while deionised H_2O was being purged with CO_2 , to achieve close to neutral condition ($\text{pH} \approx 7.6$) before introducing the Cu_2O photocatalyst. 150 W Xe lamp (Newport) was used as a light source. Various long pass filters (Comar Instruments) were applied to evaluate the visible light activity. The reaction products were monitored by periodical sampling of the gas phase from the glass chambers using a gas tight syringe to a gas chromatograph (Varian GC-450) fit with thermal conductivity detector (TCD) connected to molecular sieve column to detect H_2 , CO_2 , O_2 and N_2 and flame ionization detector (FID) connected to CP-SIL 5CB (Varian) capillary column to detect hydrocarbons. Argon was used as the GC carrier gas. A methaniser was installed to enable the FID to detect CO and CO_2 with $1000\times$ higher sensitivity.

3. Results and discussions

Representative XRD data of both Cu_2O powders morphologies are shown in Fig. 1. While all peaks can be matched with the standard Cu_2O reference [7], octahedral- Cu_2O (Fig. 1a) displayed much sharper and more intense peaks compared to the cuboid- Cu_2O (Fig. 1b), suggesting much larger crystallite size. It was also noticed that the intensity ratio between the (111) and (002) reflexions for octahedral- Cu_2O was much higher at 3.3 vs. 2.9 for cuboid- Cu_2O . This indicates a pronounced {111} preferred orientation on octahedral- Cu_2O which are not seen on cuboid- Cu_2O .

Fig. 2 shows the different morphologies of as-grown Cu_2O . In line with the findings from XRD, it was observed that the octahedral- Cu_2O particles were larger than the cuboid- Cu_2O (Fig. 2a), in excess of $10 \mu\text{m}$ (Fig. 2c). Each octahedral displays eight uniform faces, which can be assigned to the Cu_2O {111} plane according to the preferred orientation found in the XRD

Fig. 1 – Representative XRD data of (a) octahedral- Cu_2O and (b) cuboid- Cu_2O aggregates. All peaks can be matched with standard Cu_2O reference.

Fig. 2 – Different morphologies of as-grown Cu_2O particles or particle aggregates: (a) FESEM and (b) TEM micrographs of cuboid- Cu_2O aggregate, showing exposed $\{100\}$ facets with irregular edges and corners. (c) Octahedral-shaped Cu_2O particles with exposed $\{111\}$ on its eight octahedral faces. (d) FESEM and (e) TEM micrographs of $\text{RuO}_x/\text{Cu}_2\text{O}$ heterojunction (f) Electron diffraction data of cuboid- Cu_2O TEM micrograph shown in b.

data. Cuboid- Cu_2O on the other hand, tends to form spherical aggregates of approx. 2 μm diameters (Fig. 2a). The BET surface area of the samples was measured, it is ca. 0.12 $\text{m}^2 \text{g}^{-1}$ for octahedral Cu_2O and 0.55 $\text{m}^2 \text{g}^{-1}$ for cuboid- Cu_2O .

It was also observed using TEM that the individual cuboid-shaped Cu_2O particles were defined as 50–100 nm particles with round edges and corners (Fig. 2b). Electron diffraction data (Fig. 2e) suggested that the six exposed faces of cuboid- Cu_2O could be assigned to the Cu_2O $\{002\}$ plane, judged by the unusually bright $\{002\}$ diffraction spot and much weaker $\{111\}$ diffraction at the same time.

UV–Vis absorption spectra of both Cu_2O morphologies are shown in Fig. 3. While both Cu_2O morphology show similar band edge around 660 nm, although the cuboid- Cu_2O spectra were slightly blue-shifted, probably because of its smaller crystallite size. The estimated bandgaps of cuboid and octahedral- Cu_2O are approx. 1.87 and 1.83 eV respectively.

Despite having over four times lower surface area, octahedral- Cu_2O ($\{111\}$ terminated) produces much more H_2 with

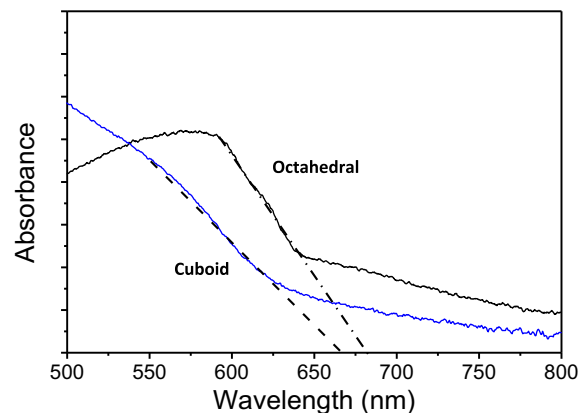

Fig. 3 – UV–Vis spectra of Cu_2O with various morphologies.

trace amounts of CO (Fig. 4a and b), indicating the surface area is not the dominating factor in the studies. Cuboid-Cu₂O aggregates ({100} terminated) on the other hand display a peculiar preference towards CO₂ reduction to CO in expense of reduced H₂ production. As the same photocatalytic reaction conditions were applied on both Cu₂O shapes, the photoreduction selectivity shift from H₂ to CO can only be attributed to the exposed Cu₂O facets taking into account the similar UV–Vis absorption of the two samples.

It has been shown previously that catalytic activity can be altered with varying catalyst shape and sizes [9]. The key argument is that the different catalyst shapes dictate the fraction of atom located on the edges, corners, or high-index facets [22]. These locations possess much greater density of unsaturated (slightly under-coordinated) steps, and imperfections like ledges, kinks compared to low indexed planes, which can serve as active sites for breaking chemical bonds [10,17,19]. In some other oxides like ZnO, higher catalytic activity could also rise from the different polarity of the exposed facets [20,21].

Reports on the use of Cu₂O for photocatalytic water splitting have always been based on tetrapod-shaped Cu₂O, which consists of mainly {111} exposed facets [5,6]. From the different photoreduction products observed in this study, it is

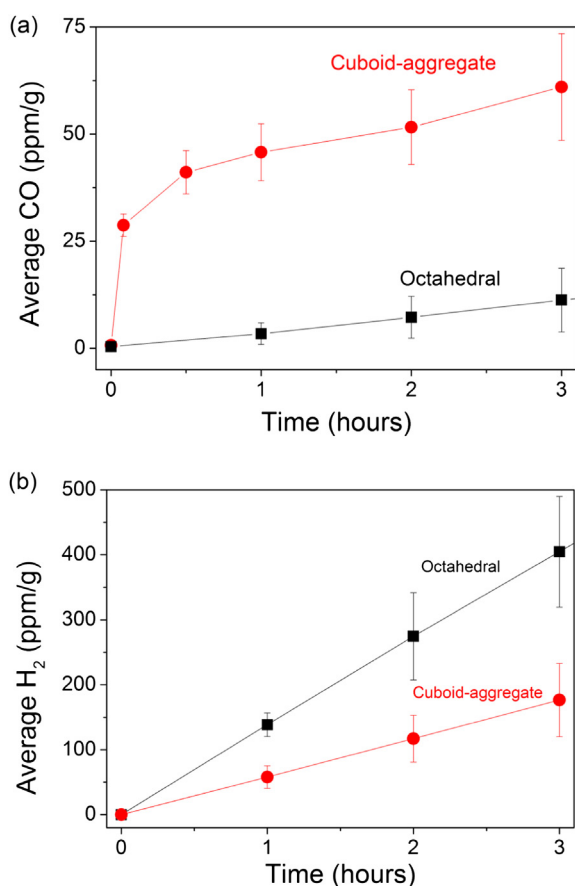

Fig. 4 – Averaged photocatalytic activity of various Cu₂O particles or aggregates (a) CO yield, (b) H₂ yield under full arc of 150 W Xe lamp. Test conditions: 0.5 g photocatalyst, 3 ml of CO₂ saturated deionised H₂O, 0.7 M Na₂SO₃ scavenger.

proposed the Cu₂O {111} facets, seen on the octahedral-Cu₂O may be the dominant surface for proton reduction. The Cu₂O {100} facets and the irregular edges observed in cuboid-Cu₂O aggregates on the other hand is likely dominant for CO₂ photoreduction sites. In other words, the low index facets exhibit higher activity for CO₂ photoreduction than high index facets, which is different from the common rules mentioned in the introduction. The possible reason for this might be due to the adsorption of CO₂ on different facets of Cu₂O. More detailed studies are underway.

It was also noticed that the gas evolution rate profile of H₂ and CO were different. H₂ evolution rates for both Cu₂O morphologies are more or less linear with time (Fig. 4b), while the CO evolution rate, especially in the spherical-shaped Cu₂O, decreases after the first hour (Fig. 4a). It is possible that this is caused by differing stability of Cu₂O {111} and {100} facets in presence of aqueous sulphate as reported previously [15]. Indeed the cuboid-Cu₂O was more severely degraded after photocatalytic reactions than octahedral shaped particles (see Supporting Information Figs. S1 and S2), implying that the {111} facets seen on octahedral-shaped Cu₂O are much more stable and indeed responsible for proton reduction reactions.

Rapid charge recombination is the key issue in photocatalytic reactions over many photocatalysts [18]. It has preliminarily been observed that a solid-state heterojunction based on CuO₂ can efficiently separate holes from electrons, observed by time resolved spectroscopy [4]. Similar phenomenon was also observed on cobalt phosphate coated Fe₂O₃ photoelectrodes [1]. RuO_x is a conductive metal oxide with large work function [2,3], which has been proven effective as oxidation catalyst for many substances including water [8,14,24]. Different loading amounts of RuO_x were therefore investigated in detail herein on cuboid-shaped Cu₂O aggregates to find out the optimum RuO_x loading. The amounts of CO evolved for the first 30 min were plot in Fig. 5a. It is apparent that the photoreduction activity of the RuO_x/cuboid-Cu₂O ({100} dominated) junction generally increases with increasing RuO_x amount up to 0.25%, due to the enhanced in-situ charge separation effect. However as shown in the SEM micrograph of 0.25 wt% RuO_x/Cu₂O sample (Fig. 2d), the Cu₂O surface is nearly fully covered by RuO_x, above the amount the light screening effect by the RuO_x particulates becomes dominant. The photoactivity decreases after this point onwards until 1.5 wt% of the RuO_x loading. Furthermore, the stability of the cuboid-Cu₂O ({100} dominated) is relatively enhanced by the surface coating of RuO_x layer (see Supporting Information Figs. S1 and S3). It is also noted that the increase of CO production occurs at the expense of H₂, the H₂ production rate decreases from ca. 50 ppm g⁻¹ h⁻¹ for bare cuboid Cu₂O to around 12 ppm g⁻¹ h⁻¹ for 0.25% RuO_x loaded cuboid Cu₂O. This is likely because the low availability of suitable H₂ evolution sites on the cuboid Cu₂O surface is further blocked by the RuO_x loading.

Cu₂O is a narrow bandgap semiconductor. Its photoactivity was also investigated under visible light. The activities of bare and 0.25 wt% RuO_x/cuboid-Cu₂O were observed by filtering wavelengths below 420 nm using a long pass filter (Fig. 5b). The results clearly show that both bare Cu₂O and RuO_x/Cu₂O junction exhibit visible driven activity for CO₂

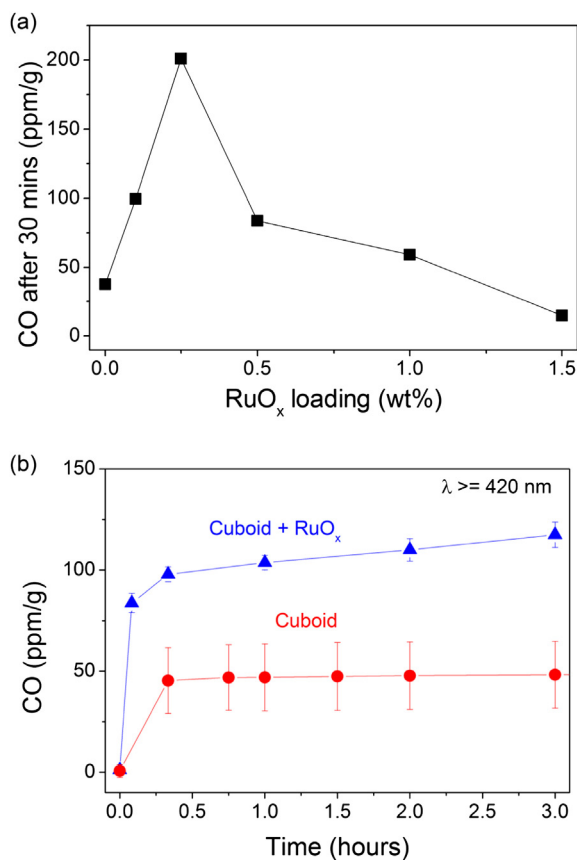

Fig. 5 – (a) The first 30 min of CO yield of cuboid-Cu₂O aggregates with different amount of RuO_x co-catalyst loading, (b) Activity of cuboid Cu₂O and the heterojunction under visible light ($\lambda \geq 420$ nm). Test conditions: 0.5 g photocatalyst, 3 ml of CO₂ saturated deionised H₂O, 0.7 M Na₂SO₃ scavenger.

photoreduction, however the RuO_x/Cu₂O is much more active than bare Cu₂O and able to sustain the CO evolution rate better after the first hour.

4. Conclusions

In summary, we highlighted that the photocatalytic reaction selectivity shifted in favour of CO₂ reduction by tuning the shape and exposed sites of Cu₂O photocatalyst. Furthermore, different from the many reports in which the facets with high Miller indices show higher photoactivity, e.g. for water splitting, low index facets of Cu₂O is beneficial for CO₂ photoreduction. It was also found that bulk Cu₂O instability is a serious issue for photocatalytic CO₂ reduction than H₂ evolution, because the {111} exposed facet that prefers H₂ evolution reaction were found to be much more stable than the {100} in aqueous solution containing sulphates. As expected RuO_x loading improves the CO evolution yield under both full arc and visible light irradiation, and the optimum loading for the cuboid-Cu₂O aggregates were found at 0.25 wt%, above which the light blocking effect from RuO_x dominates and reduce the overall photocatalytic activity.
