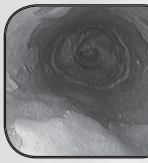
General Introduction

Chapter 1



Adenocarcinomas of the gastro-esophageal junction

Introduction & Outline of the thesis

Partly adapted from book 'Oncologie', Chapter 16: 275-280, Bohn Stafleu van Loghum 2005

Hugo W Tilanus
Linetta B Koppert
Toni Lerut

Epidemiology

Esophageal adenocarcinoma is a highly aggressive disease from which more than 80% of patients die within 5 years after diagnosis. Worldwide almost 400,000 new patients are diagnosed annually. Herewith esophageal cancer ranks eighth on the list of most common cancers, and sixth on the list of cancer mortality causes [1]. More than 90% of esophageal cancers are either squamous cell carcinomas or adenocarcinomas [2]. Esophageal cancer incidence has been rapidly increasing in Western Europe and the USA [3-5]. This could be mainly ascribed to an increase in the rate of esophageal adenocarcinoma, which by now equals or even exceeds the rate of esophageal squamous cell carcinomas. Esophageal cancer incidence in the Netherlands is 10.2/100,000 for men and 3.2/100,000 for women with around 900 newly diagnosed patients annually [6]. Adenocarcinomas of the gastric cardia and of the esophagus, commonly located in the distal esophagus, have several similarities. They show a parallel increase in incidence. Moreover, they show similarities in epidemiological and histomorphological features as well as in patterns of comorbidity [7-9]. This thesis mainly deals with molecular biological aspects of adenocarcinomas of the distal esophagus and its precursor lesion, Barrett's esophagus, but also includes work on adenocarcinomas of the gastric cardia. Adenocarcinomas from the distal third of the esophagus plus adenocarcinomas of the gastric cardia are in this thesis altogether mentioned by the description "gastro-esophageal junction (GEJ) adenocarcinomas".

Etiology

Alcohol and/or tobacco use may confer risk for GEJ adenocarcinomas whereas they are established risk factors for esophageal squamous cell carcinomas [10-14].

Gastro Esophageal Reflux Disease (GERD) is described to be the most important etiologic factor since it can lead to the formation of Barrett's esophagus [15,16]. This precursor lesion forms the main established risk indicator for the development of carcinoma [7,15,17]. Barrett's esophagus is characterized by columnar metaplasia with intestinal differentiation that has replaced the normally present stratified squamous epithelium in the lower third of the esophagus (also see 'Pathology'). Patients with Barrett's esophagus have a 30-125 times increased risk for developing esophageal adenocarcinoma, however only about 0.2-2% of patients with Barrett's esophagus will eventually get a carcinoma [18]. The true prevalence of Barrett's esophagus in The Netherlands is difficult to establish since most patients do not undergo upper endoscopy. Weekly retrosternal pain however is present in around 10% of adults. When upper endoscopy is performed in these patients, around 12.5% of these have Barrett's esophagus. Estimated prevalence in The Netherlands is therefore around 100,000 patients.

Drugs that relax the lower esophageal sfincter and increase reflux, such as anticholinergic agents, aminophyllines and beta-blockers may contribute to the development of esophageal adenocarcinoma [19,20].

It has been postulated that Helicobacter Pylori infection (in particular strains that are positive for the CagA protein) may reduce the risk of GERD and therefore may provide protection against the development of adenocarcinoma [21-24].
By increasing intraabdominal pressure and gastroesophageal reflux, obesitas may contribute to development of esophageal adenocarcinoma, however contradictory results are provided on this subject in the literature [19,25].
Familial cases of esophageal adenocarcinoma are rare and Barrett's esophagus and esophageal adenocarcinoma have no known genetic cause to date.

Clinical manifestations & Diagnosis

Dysphagia, retrosternal pain, odynophagia (pain on swallowing food and liquids), retrosternal pain, pain during food passage, weight loss and anaemia are the symptoms that lead patients with GEJ adenocarcinoma to seek medical attention. Physical examination is usually unremarkable. Lymphadenopathy, particularly in the left supraclavicular fossa (Virchow's node), hepatomegaly and pleural effusion are indicators of metastatic disease.
Physicians should consider testing high risk patients with GERD to rule out malignancy. Upper endoscopy is performed to obtain tissue samples of suspect areas of mucosa, aiming at early detection of high grade dysplasia and early adenocarcinoma (Figure 1.1). The histological identification of dysplasia in tissue biopsies is the best marker for cancer risk and is of major importance in determining the intensity of both surveillance and treatment [26]. Patients with Barrett's esophagus are usually subjected to intensive endoscopic surveillance with biopsy sampling to identify those with neoplastic progression. The surveillance program followed at the Erasmus MC is according the guidelines from the American College of Gastroenterology and the International Society for Diseases of the Esophagus. In patients with Barrett's esophagus without dysplasia, surveillance every 2 year is considered adequate. In patients with low grade dysplasia, yearly endoscopy is advised. If high grade dysplasia is found, the diagnosis should be confirmed by an experienced pathologist. If the diagnosis high grade dysplasia is confirmed, there is no agreement on the most appropriate management of these patients. Esophagectomy is recommended to eliminate the risk of cancer or to detect and treat an unsuspected cancer at an early stage. Concerns with this approach include the potential risks of surgery, especially in older patients, and the highly variable natural history of high grade dysplasia.

Pathology

Most esophageal adenocarcinomas appear to arise from dysplastic Barrett's esophagus. Norman Ruppert Barrett (1903-1979) was born in Adelaide, Australia, and devoted his carreer to thoracic surgery. He pulished in 1950 in the British Journal of Surgery on "Chronic peptic ulcer of the oesophagus and 'oesophagitis' " supporting the view of previous observers that the affected segment was actually the gastric cardia displaced by a congenitally short esophagus.

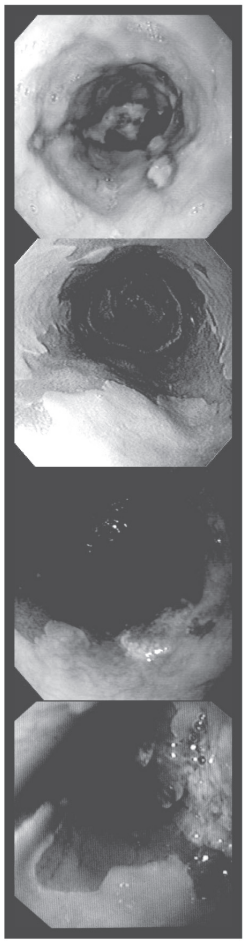


Figure 1.1 Endoscopy images. *Also see color figures page 291.*

How this concept evolved to its current understanding and Barrett's own conversion to the notion of esophageal mucosal metaplasia is told by Spechler and Goyal in Gastroenterology in 1996 [27].

Barrett's esophagus is characterized by columnar metaplasia with intestinal differentiation, as identified by Goblet cells, that has replaced the normally present stratified squamous epithelium in the lower third of the esophagus. Progression is considered to follow the 'metaplasia-low grade dysplasia-high grade dysplasia-carcinoma sequence', characterized by accumulation of cell cycle abnormalities, genetic abnormalities and aneuploidy (Figure 1.2) [28-30].

Most esophageal adenocarcinomas are located in the lower third part of the esophagus which starts at the level of the trachea bifurcation and extends to the gastro-esophageal junction ('the distal esophagus'). The gastro-esophageal junction is characterized by the Z-line, which forms the transition zone from squamous cell epithelium to cylindrical epithelium of the stomach. Carcinomas located at the gastro-esophageal junction are classified as gastric carcinomas according to the Union Internationale Contre Cancer (UICC)-TNM. With regard to epidemiology as well as histomorphology these tumors show similarities with distal esophageal adenocarcinomas [8]. Moreover the therapeutic approach is identical. In the studies described in this thesis a carcinoma was considered to arise from the distal esophagus when premalignant Barrett's mucosa was present and/or the epicenter of the mass was located in the tubular esophagus extending from the tracheal bifurcation to the gastro-esophageal junction including the intra-abdominal esophagus, according to the TNM classification (International Classification of Diseases for Oncology C15.5). The tumor was considered to be cardiac when the epicenter was immediately below the gastro-esophageal junction, extending approximately 2 cm downwards. The tumor was classified as a junction carcinoma if the epicenter was just at the GEJ, without predominance for distal esophagus or gastric cardia and if no Barrett's mucosa was present (Figure 1.3). Tumors arising from the fundus or corpus of the stomach and infiltrating the gastric cardia or distal esophagus were classified as gastric carcinomas.

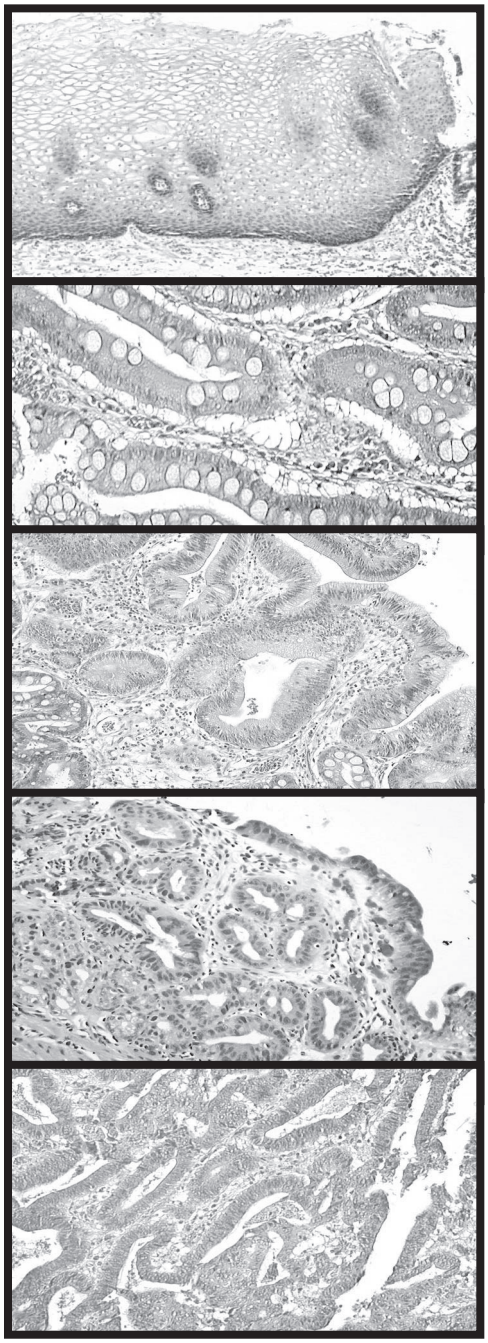

Figure 1.2 Histology of 'metaplasia-low grade dysplasia-high grade dysplasia-carcinoma sequence'. *Also see color figures page 291.*

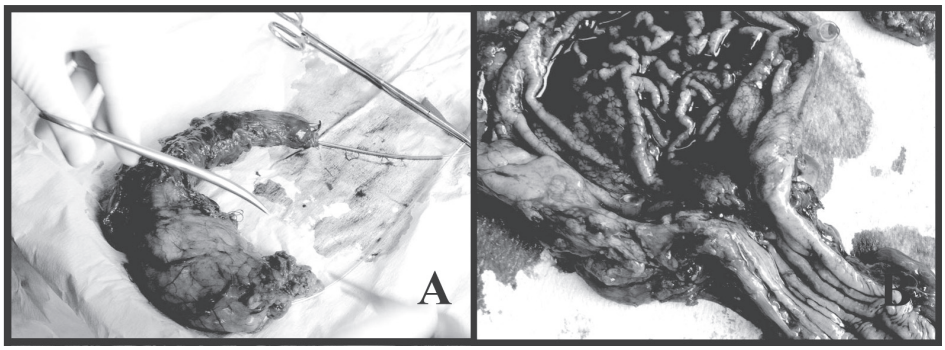

Figure 1.3 Resection specimen with GEJ adenocarcinoma. *Also see color figures page 291.*

Staging

After diagnosing esophageal carcinoma, patients' fitness for surgery needs to be established. Only in patients fit enough to undergo surgery, tumor staging is performed. Up to 50% of patients with esophageal cancer present with inoperable disease as a result of severe comorbidity or due to locally advanced or metastatic disease.

Endoscopic ultrasonography (EUS) identifies preoperative depth of tumor growth (T stadium) and involvement of lymph nodes (N stadium). Reliability of EUS in predicting T and N stadium is 84% and 77% respectively [31]. Computer tomography scanning (CT, Figure 1.4) of thorax and abdomen as well as cervical ultrasonography are used to discover possible distant metastases (M stadium). Metastases comprise most often celiac lymph nodes, supraclavicular lymph nodes and liver metastases. Cytological confirmation of distant metastases can be obtained by percutaneous biopsies [32].

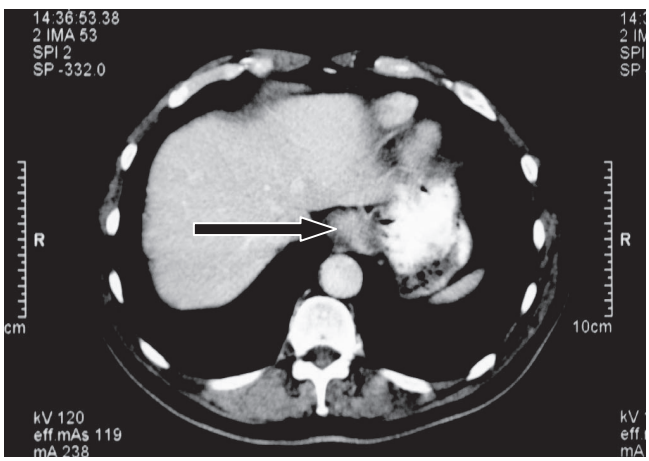

Figure 1.4 CT scan with GEJ adenocarcinoma (arrow)

AJCC-TNM (T-stage in Figure **1.5)**

Stage 0 (pTisN0M0) tumor restricted to mucosa (pTis/carcinoma in situ/high grade dysplasia) ; no regional lymph nodes (No); no distant metastasis (M0).

Stage I (pT1N0M0): tumor infiltrating in lamina propria or in submucosa (pT1); no regional lymph nodes (N0); no distant metastasis (M0).

Stage IIA (pT2-T3N0M0): tumor restricted to muscularis propria (pT2) or adventitia (pT3); no regional lymph node metastasis (N0); no distant metastasis (M0).

Stage IIB (pT1-T2N1M0): tumor restricted to mucosa or submucosa (pT1) or tumor infiltrating muscularis propria (pT2); regional lymph node metastasis (N1); no distant metastasis (M0).

Stage III (pT3N1M0 or pT4NxM0): tumor restricted to adventitia (pT3) with regional lymph node metastasis (N1); or tumor invading neighbouring structures (pT4) with or without regional lymph node metastasis (Nx); no distant metastasis (M0).

Stage IV Any T, Any N, distant metastasis M1a (i.e. metastasis in celiac lymph nodes in case of distal esophageal carcinomas) or M1b (other distant metastasis).

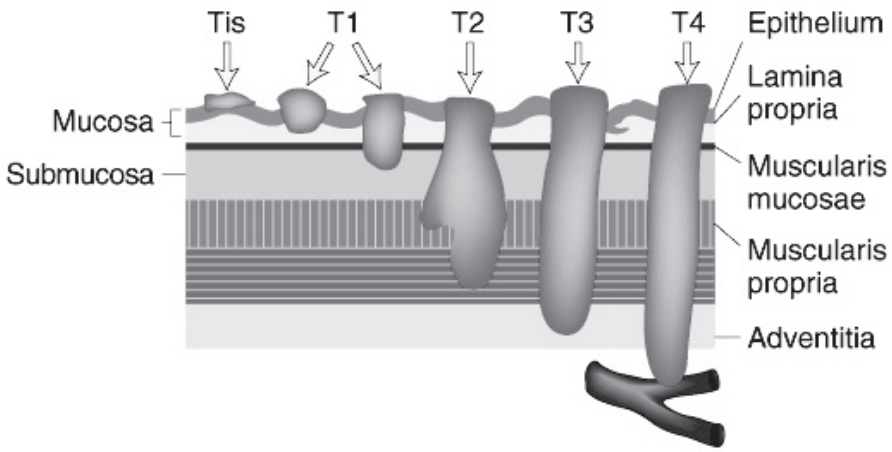

Figure 1.5 TNM classification (T-stage). *Also see color figures page 291.*

Treatment & prognosis

Surgical resection is the only curative treatment for GEJ adenocarcinoma. Survival rates mostly depend on pathological stage and are still poor despite recent achievements in surgical, anaesthesiologic and postoperative care [33]. Surgical resection is currently the preferred treatment for fit patients with tumors that are considered resectable and without distant metastases at preoperative workup (T1-3 N0-1 M0). Tumor depth restricted to the mucosa (Tis) is associated with a mean 5-year survival of 88%, whereas tumor restricted to adventitia (T3) is associated with a mean 5-year survival of 10-20% only. Tumor ingrowth in neighbouring structures (T4) and the presence of distant metastases are considered contra-indications for

surgical resection. Recent advances in non-surgical palliative procedures, such as esophageal stenting and brachytherapy have been proven safe alternatives to secure passage of food and provide a comparable quality of life [34-36].

Surgical treatment for esophageal cancer is still associated with a significant risk of mortality and a high incidence of postoperative morbidity. In the 1980s, esophagectomy was the procedure with the highest mortality risk (29%) in general surgery at that time [37]. Nowadays, the average reported mortality varies from 4% in specialized centres to more than 10% in low volume hospitals [38,39].

Esophagectomy with removal of esophagus and gastric cardia including primary tumor as well as neighboring regional lymph nodes is performed with or without opening the thorax (transthoracic and transhiatal approach respectively). Extensive surgical resection is difficult due to proximity of trachea, main bronchi, pericardia, aorta and diaphragm. Moreover tumor spread to lymph nodes occurs rather early in tumorigenesis due to the presence of a submucosal lymph plexus [40]. Extended lymph node dissection can be obtained by opening abdomen and thorax (and neck) in order to obtain long term survival. On the other hand, performing a less extensive, transhiatal, resection can decrease postoperative morbidity as well as mortality. In the literature a survival advantage has been described for distal esophageal adenocarcinoma patients when a thoracotomy with extensive lymph node dissection was performed as compared to patients that underwent regional lymph node dissection only by means of a transhiatal approach [41,42]. In our clinic, a transhiatal approach is first choice for resection of GEJ adenocarcinomas since 1989 (Figure 1.6). A 'blunt dissection' of the esophagus under direct vision through the widened hiatus of the diaphragm is performed with en-bloc dissection of tumor and adjacent lymph nodes. A gastric tube is constructed to form the new esophagus. Esophago-gastrostomy is performed in the neck.

In general, microscopically irradical resections are performed in approximately 30% of patients [41,43,44]. Several regimens of neoadjuvant therapy have been investigated in order to achieve tumor shrinkage in order to increase resectability rate and improve survival. Several randomised studies and reviews show that a possible benefit, if any, of neoadjuvant chemotherapy is small and it is uncertain whether such a potential survival benefit outweighs the morbidity caused by such a treatment [43-51]. Several studies show that preoperative radiotherapy in combination with chemotherapy is recommended compared to surgery alone. Preoperative chemoradiotherapy might improve local control and therefore improve the prognosis of esophageal carcinomas. Currently, a randomized phase III trial is being conducted in The Netherlands.

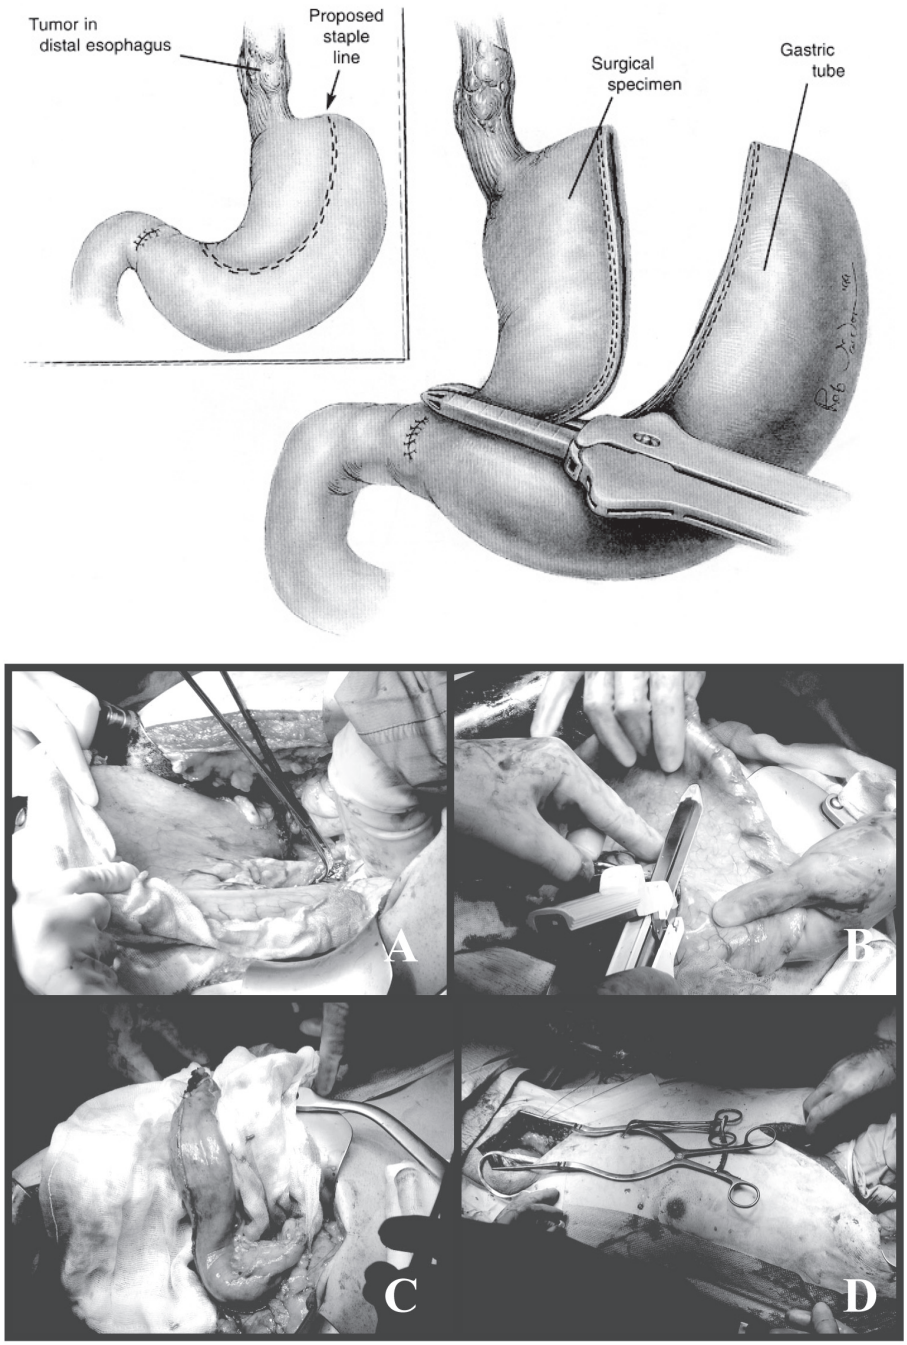

Figure 1.6 Schematic overview of surgical resection of GEJ adenocarcinoma. Photographs below the scheme show upper abdominal incision (A.), and creation of the gastric tube (A. B. C.) to restore continuation of the gastrointestinal tract after transhiatal en-bloc removal of esophagus and gastric cardia including tumor and adjacent lymph nodes (D.). Esophagogastrostomy will be performed in the neck (smaller incision left side of picture D.). *Also see color figures page 291.*

AIMS AND OUTLINE OF THIS THESIS

Aims

Esophageal adenocarcinoma is a highly aggressive disease from which more than 80% of patients die within 5 years after diagnosis. Patients with Barrett's esophagus have a 30 to 125 times higher risk of developing esophageal adenocarcinoma as compared to the general population. Presently, histological detection of dysplasia is the best available marker for cancer risk. Intensive endoscopic surveillance, including tissue biopsies, is aiming at early detection of high grade dysplasia and early adenocarcinoma. Patients with high grade dysplasia or early adenocarcinoma have a survival rate of 80% after surgery, which stress the importance of early detection. To date it is not possible to predict which patients with Barrett's esophagus will progress to invasive carcinoma. Stratification of Barrett's esophagus patients that are at risk of esophageal adenocarcinoma and those not at risk, is therefore urgently needed. This would allow more aggressive or preventative treatment of the people at risk, but also release the vast majority of people who are not at risk from unnecessary endoscopic surveillance.
The genetic alterations underlying esophageal carcinogenesis remain poorly understood. Knowledge of molecular biology could be of additional value to the histological diagnosis of dysplasia in predicting neoplastic progression. The aim of this thesis was, first, to better understand the molecular mechanisms in GEJ adenocarcinomas and its neoplastic progression and, second, to identify genetic markers that, in the end, might distinguish Barrett's epithelia that will progress to esophageal adenocarcinoma from Barrett's epithelia that will not progress to malignancy. Genetic alterations in Barrett's esophagus and GEJ adenocarcinoma were correlated to clinicopathological characteristics and patient survival. Moreover, aspects on epidemiology and treatment were investigated.

Outline

Chapter 2 provides a review of the literature on the molecular biology of esophageal adenocarcinoma. In general, genetic instability forms the hallmark of cancer development resulting in the activation of proto-oncogenes and inactivation of tumor suppressor genes. In this thesis, mutation analyses (Single Stranded Conformation Polymorphism (SSCP) studies) and Loss of Heterozygosity (LOH) studies aiming to identify alterations in (candidate) proto-oncogenes and tumor suppressor genes formed the main approach to study genetic alterations in GEJ adenocarcinomas. A schematic overview of the LOH analysis is provided in Figure 1.7.
Part II concerns molecular biological studies within GEJ adenocarcinomas. The contribution of the Wnt signaling pathway, an oncogenic pathway with great importance in colorectal carcinomas amongst others, was studied in **Chapter 3.** This chapter presents immunohistochemical data on diverse components of the Wnt signaling pathway in GEJ adenocarcinomas. Expression data were correlated to clinicopathological characteristics. In **Chapter 4** mutation and LOH analysis of the AXIN1 locus was performed in primary GEJ adenocarcinomas and in

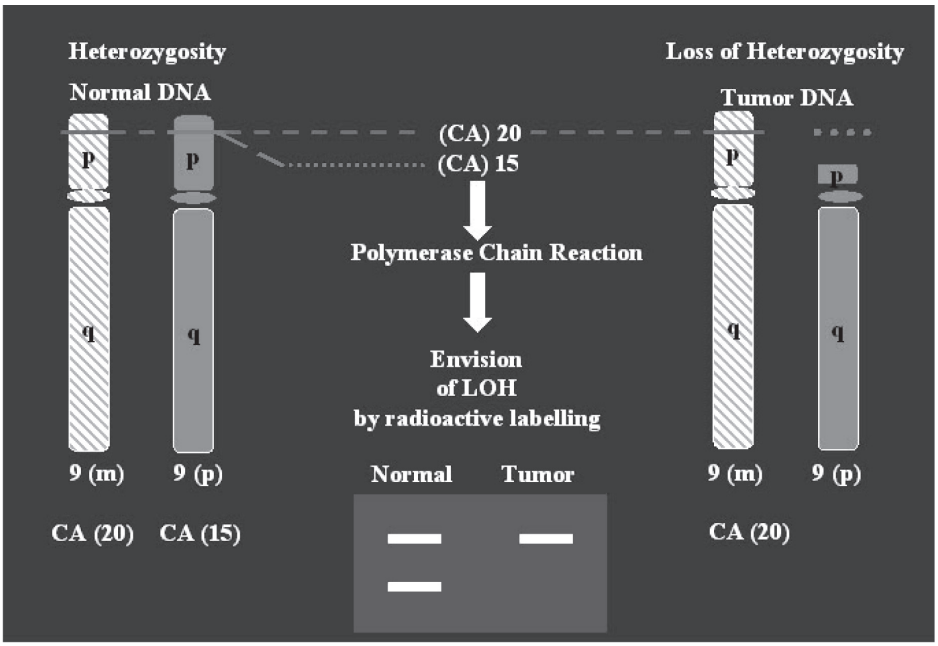

Figure 1.7 Schematic overview of Loss of Heterozygosity (LOH) analysis. Amplified fragments of maternal and paternal DNA of chromosome 9 are compared between normal and tumor DNA of a patient. Length of CA repeats within the fragments differs in the normal DNA, i.e. there is heterozygosity (maternal contains 20 CA repeats and paternal contains 15 CA repeats). In patients tumor DNA part of the short arm of paternal chromosome 9, containing the 15 CA repeat, is lost and therefore the heterozygosity is lost. This is visualized on a gel after radioactive labeling. Only the maternal 20 CA repeat is visualized in the tumor as compared to the normal DNA in which both fragments are shown and therefore this tumor shows LOH. Within LOH analysis, a separation of fragments takes place through difference in length, whereas Single Strand Conformation Polymorphism (SSCP) analysis separates fragments by a different conformation between normal and mutated DNA. *Also see color figures page 291.*

GEJ adenocarcinoma cell lines aiming to find an explanation for Wnt pathway activation in GEJ adenocarcinomas.

Chapter 5 describes the identification of an overlapping region of LOH at the long arm of chromosome 14, possibly harboring a GEJ adenocarcinoma suppressor gene. The 7.1 mega base pairs minimal deletion was located at 14q31.1-32.11 and identified using primary GEJ adenocarcinomas, GEJ adenocarcinoma xenografts as well as GEJ adenocarcinoma cell lines. In **Chapter 6** an immunohistochemical study of neuroendocrine cells in GEJ adenocarcinoma and adjacent Barrett's esophagus is described using chromogranin A antibody. Expression was correlated to TNM stage, tumor differentiation grade and survival.

Part III of the thesis focuses on epidemiological aspects of GEJ adenocarcinomas. Comorbidity patterns in esophageal adenocarcinomas were compared with patterns in cardia adenocarcinomas, esophageal squamous cell carcinomas and subcardia gastric carcinomas to gain more insight in variation of risk factor profiles in **Chapter 7**. Moreover, comorbidity patterns in these tumor types were, retrospectively, correlated to clinicopathological characteristics,

treatment choice (either curative or palliative) and survival in **Chapter 8**. This was done in order to determine a possible role for comorbidity in prognosis and treatment choice.

Part IV deals with aspects of surgery. Surgical resection of cancers of the esophagus and GEJ is associated with substantial morbidity and mortality. Local endoscopic techniques to detect and to treat high grade dysplasia and early carcinoma have become more and more available in recent years. A retrospective study described in **Chapter 9** evaluated the outcome of transhiatal esophagectomy in 120 patients with early adenocarcinoma of the esophagus or gastro-esophageal junction. The question was addressed whether surgical resection is necessary in patients with early malignancies or whether local endoscopic techniques might be suffcient. In order to precisely classify this series of early cancers, the mucosa and submucosa were subdivided into six successive layers. Additionally the depth of tumor infiltration was correlated to lymphatic dissemination and recurrence free period. **Chapter 10** describes the development and validation of a simple risk score combining clinical characteristics along with hospital volume to predict surgical mortality after esophagectomy which may be useful for risk adjustment in quality of care assessment.

Part V of this thesis aims to identify patients at high risk for developing GEJ adenocarcinoma. Patients with Barrett's esophagus receive endoscopic surveillance to detect dysplasia and to diagnose carcinoma at an early and possibly treatable stage. The identification of genes that confer susceptibility for adenocarcinoma formation in Barrett's esophagus would imply improved manageability of Barrett's patients. The CHEK2 gene, located on human chromosome 22q12, encodes a cell cycle checkpoint kinase that is implicated in DNA damage responses. CHEK2*1100delC is a truncating germline variant that abrogates kinase activity and confers low-penetrance susceptibility to breast cancer. As CHEK2 and p53, having an important role in the development of esophageal adenocarcinoma, are participants of the same biological pathway, we aimed to establish whether CHEK2*1100delC confers susceptibility to esophageal cancer in **Chapter 11**.
In recent literature, single nucleotide polymorphisms, defined as germline variant sequences of DNA in the population that are non-pathogenic, have been described to confer susceptibility to development of various cancers. **Chapter 12** describes the investigation of a possible prognostic role of different genetic polymorphisms in a large cohort of GEJ adenocarcinoma patients as compared to healthy persons. Moreover the distribution of polymorphism genotypes was investigated in a large cohort of esophageal squamous cell carcinoma patients.
Finally in **Chapter 13**, it was aimed to identify molecular markers that predict progression to malignancy in Barrett's patients. First, the question was addressed whether GEJ adenocarcinomas are monoclonal or polyclonal proliferations. To this end, multiple biopsies per carcinoma were selected from GEJ adenocarcinoma resection specimens. These were investigated for loss of heterozygosity (LOH) of chromosomal loci 17p (p53), 9p (p16), 5q (APC, MCC), 13q

(Rb) and 18q (DCC, DPC4/SMAD4), for p53 mutations (exon 5 to 8) and for mutations in the homopolymeric C-stretch (D310) within the mitochondrial DNA (mtDNA) displacement loop. Second, the usefulness of these aberrations as molecular progression markers was studied in the 'metaplasia-low grade dysplasia-high grade dysplasia-carcinoma sequence' in Barrett's esophagus adjacent to GEJ adenocarcinoma.

The studies described in this thesis are summarized in **Part VI**, **Chapter 14**. The Epilogue, **Chapter 15**, contains a general discussion. Moreover clinical applications as well as potential directions for future studies are addressed.

ABSTRACT

Barrett's esophagus is an acquired metaplastic change that occurs in the distal esophagus secondary to chronic gastroesophageal reflux. This premalignant condition forms the most important risk factor for developing esophageal adenocarcinoma, which is an extremely aggressive tumor with a 5-year survival rate of less than 25%. Carcinomas that arise in the setting of Barrett's esophagus are thought to develop as part of the metaplasia-dysplasia-carcinoma sequence. We aimed to review the current knowledge on the genomic alterations involved in the development of Barrett's esophagus and its progression to dysplasia and/or cancer. Several changes in gene structure, gene expression and protein structure are associated with the progression of Barrett's esophagus to adenocarcinoma. Accumulation of these changes seems to be essential, rather than the exact sequence of these changes. Multiple molecular pathways are involved and interact with each other. Alterations in tumor suppressor genes, amongst which p53 and p16, are early events in the metaplasia-dysplasia-adenocarcinoma sequence, followed by loss of cell cycle checkpoints. Ongoing genomic instability leads to cumulative genetic errors and thereby the generation of multiple clones of transformed cells. Within the multistep process of esophageal adenocarcinogenesis, to date no single molecular marker came forward able to predict who will and who will not develop cancer in the setting of Barrett's esophagus. Instead, panels of markers need to be developed in the future allowing to indicate disease progression. Identification of crucial molecular pathways involved in esophageal adenocarcinogenesis would ultimately improve therapy and facilitate development of new treatment strategies.

INTRODUCTION

Cancer of the esophagus represents the 9th leading cancer in the world and is associated with a five-year survival rate under 25%. Understanding of the molecular biology is a prerequisite to predict prognosis and to tailor treatment. The development of esophageal cancer is a multistep phenomenon involving genetic events that result in key abnormalities of cell cycle regulation, growth factor activity and intercellular adhesion mechanisms [1]. This review focusses on esophageal adenocarcinoma, which is associated with an increasing incidence in the Western world as compared to squamous cell carcinomas.

It is now generally accepted that esophageal adenocarcinomas develop from a premalignant lesion of the esophagus, referred to as Barrett's esophagus. Barrett's esophagus is an acquired condition in which the normal squamous cell epithelium of the esophagus is replaced by metaplastic columnar epithelium due to chronic gastroesophageal reflux disease. Barrett's esophagus is associated with a predisposition to adenocarcinoma of the distal esophagus or the gastric cardia, i.e. an about 30-125 fold higher risk compared to the general population, with an estimated incidence of 1 in 180 patient-years [2-5]. Although high grade dysplasia of Barrett's esophagus is generally considered a precursor to invasive carcinoma, the endoscopic as well as histopathologic recognition of this lesion can be rather difficult. Problems concern amongst others, sampling errors, intra- and interobserver variation in diagnosis and grading of dysplasia, differentiation of high grade dysplasia and cancer, indetermination for dysplasia due to reactive or regenerative changes. Efforts are required to better understand the pathophysiology of Barrett's esophagus and its progression to cancer. Molecular genetic analysis and development of novel biomarkers might help to identify those patients at increased risk for malignant transformation. Biopsy samples of Barrett's esophagus that histologically appear as low risk for neoplastic progression might in fact harbor genetic alterations that are indicative for a high risk profile. Molecular genetic knowledge might ultimately lead to more adequate cancer prevention and therapeutic interventions. In recent years a considerable amount of data has been accumulated regarding the molecular biological characterization of esophageal adenocarcinoma.

Genetic alterations in human cancers

Cancer is a disease of the genome with accumulation of sequence alterations (mutations) in premalignant tissue, leading to evolution of cell clones with increasing genomic instability and finally to cells with invasive and metastatic capabilities [6]. Most mutations found in human malignancy are somatic and found only in the patient's tumor tissue. It is generally accepted that some of these alterations are causally involved in the transition of a normal cell into a tumor cell [7]. Additionally, epigenetic alterations like methylation of DNA sequences resulting in gene silencing can play a role in the cellular transformation, which is a multistep process of genetic and epigenetic alterations [8]. These alterations render the cell independent

of regulated proliferative and cell death pathways and deliver the cells with proliferative, invasive and metastasizing capacities. Evidence has been presented that at least 5 to 10 specific genetic alterations are necessary to generate the malignant phenotype and most tumors are characterized by genomic instability facilitating the accumulation of mutations [9]. As a consequence, a malignant tumor is generated composed of cells with an increased proliferative activity, a prolonged lifespan and with metastasizing capacity. The genomic instability occurs in two different forms: one characterized by chromosomal instability (aneuploidy) and the other characterized by microsatellite instability [10]. The targets of the genomic instability, at the nucleotide or at the chromosomal level, comprise 4 classes of genes:

1. Proto-oncogenes. These are regulatory genes found in normal cells that perform a regulated role in activation of cell proliferation or inhibition of apoptosis (regulated cell death). Upon activation (through point mutation, gene amplification, chromosomal translocation, insertion etcetera) these dominant genes turn into oncogenes with continuous stimulation of cell proliferation or continuous inhibition of apoptosis.
2. Tumor suppressor genes. Tumor suppressor genes are recessive genes, with in normal cells a role in inhibition of cell proliferation or stimulation of apoptosis. Both gene copies need to be inactivated for their tumor suppressive effect to be lost which can be caused by both genetic and epigenetic phenomena: mutation, deletion of (part of) the gene and epigenetic silencing through promoter methylation.
3. Mismatch repair genes. These genes are in normal cells involved in repair of DNA sequence mistakes occurring primarily during DNA replication. Inactivation of both copies of these recessive genes results in defective DNA repair and as a consequence in a genome wide accumulation of mutations, also in proto-oncogenes and tumor suppressor genes. Because tandem repeat DNA sequences (microsatellites) are especially vulnerable for DNA replication mistakes, microsatellite instability is a hallmark of a defect in DNA repair [11]. The genes PMS1, PMS2, MLH1, MSH2, MSH6 and the recently discovered MBD4 (MED1) are all associated with microsatellite instability [12,13].
4. Mitotic checkpoint genes. These genes are involved in control mechanisms ensuring the proper separation of chromosomes during cell division. When the mitotic checkpoint is defective, improper allocation of the chromosomes to the daughter cells takes place during mitosis. This results in chromosomal instability and an abnormal number of chromosomes per cell (aneuploidy) [14]. To date nine human genes with a role in mitotic checkpoint control have been discovered[14]. Inactivation of mitotic checkpoint genes results in chromosomal instability and an abnormal chromosome number (aneuploidy) [14]. Mutation analysis of the human mitotic checkpoint genes in aneuploid cancers revealed only few alterations and probably genes yet to be discovered are responsible for most of the checkpoint defects found in aneuploid cancers.

The activation of proto-oncogenes and inactivation of tumor suppressor genes as the result of genetic instability form the key genetic foci contributing to tumor development. To date there are no proto-oncogenes nor tumor suppressor genes that are activated or inactivated in all cancers. Even comparable cancers from the same organ and cell type never share alterations in the same genes completely. However, comparable tumors might probably have alterations in the same molecular pathways but with different components affected [15].
To date, evidence is accumulating that cancer cells originate from transformation of tissue stem cells. These transformed tissue stem cells are thought to function as cancer stem cells that maintain the generation of neoplastic clones in a tumor. The existence of cancer stem cells is established in leukemia more than a decade ago, and recently in breast and brain tumors [16-18]. In all these tumors it is thought that the cancer is a reflection of the corresponding normal tissue stem cells. However, Houghton et al. recently proposed a new concept in gastric carcinogenesis, i.e. that bone marrow-derived cells might represent a potential source of epithelial cancers [19]. Working with mice infected by a Helicobacter strain, they found that these bone marrow-derived cells were able to home, repopulate the chronically inflamed gastric mucosa and contribute over time to metaplasia, dysplasia and cancer [19,20]. This results supports the idea that chronic inflammation fosters cancer development. Even more remarkable, the results of Houghton et al. provide evidence that epithelial cancers can originate from bone marrow derived stem cells. A similar phenomenon could perhaps occur in different types of inflammation-linked cancers as well. To date there are no literature data on esophageal adenocarcinogenesis concerning involvement of bone marrow-derived stem cells. The value of these new findings and concepts in carcinogenesis awaits future experimental confirmation.

This review aims to summarize current knowledge on genomic aberrations in esophageal adenocarcinomas as from recent years. Described genomic abberations are categorized as follows: Proto-oncogenes, Tumor suppressor genes, Mismatch repair genes (microsatellite instability), Mitotic checkpoint genes (DNA content and chromosomal abnormalities), Cell proliferation and Apoptosis, Genes involved in controlling the cell cycle, and Cell-cell adhesion genes. For comprehensive overviews published before, the authors refer to reviews by Jenkins et al. and Wijnhoven et al. [21,22].

PROTO-ONCOGENES

Proto-oncogenes are cellular genes, which can be converted into oncogenes by activating mutations. These mutations are somatic events.

Growth factors and their receptors EGF, TGF-α and EGFR

The Epidermal Growth Factor (EGF) has a stimulatory effect on epithelial cell proliferation in the gastrointestinal tract. EGF and Transforming Growth Factor-α (TGF-α) belong to the family of growth factors that binds to the epidermal growth factor receptor (EGFR or c-erbB1). EGFR directed therapies are already available for treatment of human tumors with epithelial origin. EGFR is located at chromosome 7p12-13, a frequently amplified region in esophageal adenocarcinomas which has been correlated with the occurrence of lymph node metastasis [23,24]. EGFR overexpression correlated with decreased postoperative survival of patients with locally advanced esophageal adenocarcinoma treated with preoperative chemoradiotherapy [25]. EGFR directed therapies such as the EGFR kinase inhibitor Gefitinib (Iressa) are already available for treatment of human tumors with epithelial origin with clinical responses in EFGR mutated non-small cell lung cancers [26-28]. Barber et al. recently published about mutations in colorectal carcinomas [29].

TGF-α binds to EGFR and stimulates cell division. Amplification of the TGF-α gene at chromosome 2p13 has been found in the progression of esophageal adenocarcinoma [30]. TGF-α protein expression was significantly associated with tumor progression and lymph node metastasis [31]. In Barrett's tissue, TGF-α has been found to activate Vascular Endothelial Growth Factor (VEGF) which plays a role in the vascularization of adenocarcinomas [32]. Expression of VEGF was indeed increased in Barrett's adenocarcinomas [33].

c-erbB2

The c-erbB2 proto-oncogene (HER2/neu) is localized at chromosome 17q21 and shares significant homology with EGFR. As a result of its potential role in the selection of therapy, HER2/neu has reached a near-standard-of-practice status in breast cancer. The humanized monoclonal antibody Trastuzumab (Herceptin, Hoffmann-La Roche, Grenzach-Wyhlen, Germany) that inhibits the proliferation of c-erbB2 overexpressing tumor cells has become available commercially for the treatment of patients with breast cancer. C-erbB2 protein overexpression and/or amplification of the c-erbB2 gene occurred in approximately 10-70% of esophageal adenocarcinomas [30,34-41]. Overexpression of c-erbB2 was not demonstrated in metaplastic or low grade dysplastic Barrett's epithelium suggesting that it is a late event in the dysplasia-carcinoma sequence [35,42]. Walch et al. showed that both c-erbB2 and Growth Factor Receptor-bound protein 7 (GRB7) alterations displayed concomitant elevated expression levels and increased copy numbers in high grade dysplasia and carcinoma [42]. C-erbB2 overexpression in adenocarcinomas correlated significantly with tumor invasion, lymph node involvement, distant metastasis and status of residual tumor after resection [38,39]. Furthermore, c-erbB2 amplification correlated with shortened patient survival and independently predicted poor outcome in patients with Barrett related adenocarcinoma [43]. We found c-erbB2 amplification to be present in 5 out of 13 esophageal adenocarcinoma cell lines and in 18 out of 49 primary esophageal or gastric cardia adenocarcinomas (Dinjens et al., Van Dekken et al., unpublished results).

FGF

The Fibroblast Growth Factors (FGFs) form an important proangiogenic factor with the capability to regulate growth and differentiation of various cell types. The expression of acidic and basic FGF (aFGF, bFGF) has also been studied in esophageal adenocarcinoma and Barrett's metaplasia. bFGF expression levels were significantly increased in Barrett's adenocarcinomas and dysplastic tissues as compared to normal esophageal mucosa and metaplasia [33].

TGF-β

Transforming Growth Factor (TGF-β), a potent mediator of cell growth, plays various roles in the process of malignant progression. TGF-β is a potent inhibitor of cell proliferation, an inducer of differentiation in epithelial cells of the intestine in vitro, and a suppressor of genomic instability [44]. Cancer cells can become resistant to TGF-β cell growth inhibition. TGF-β induces diverse cellular changes trough heteromeric complexes of TGF-β receptor type I and II such that the loss of either receptor dramatically alters the cellular response [45]. Loss of TGF-β receptor type II expression appeared to be associated with Barrett's esophagus and esophageal adenocarcinomas [46,47]. Pathways of TGF-β signaling involve SMAD proteins, of which the SMAD2 and SMAD4 protein were originally isolated as the MADR2 and DPC4 tumor suppressor gene respectively, both located at chromosome 18q, a locus which frequently shows loss in esophageal adenocarcinomas. Mutational inactivation of TGF-β signaling pathways was investigated by Tanaka et al. and was found to be rare [48]. The Runt domain transcription factor 3 (RUNX 3) tumor suppressor gene was shown to inhibit cell proliferation and induce apoptosis by reinstating TGF-β responsiveness in an esophageal adenocarcinoma cell line [49].

Ras-family

Activation of the Ras oncogene is commonly found in gastrointestinal tract cancers. The 3 Ras isoforms comprise H-Ras, K-Ras and N-Ras and are essential components in normal cell division and differentiation. Reports at point mutations in K-Ras in Barrett's esophagus and in esophageal adenocarcinomas showed them to be rare [50-52]. Another report described K-Ras mutations in 0% of Barrett's metaplasias, 0% of low grade dysplasias, 30% of high grade dysplasias and 40% of adenocarcinomas [53]. Activation of the Ras proto-oncogenes seems to be of little importance in Barrett's adenocarcinomas.

c-myc

The c-myc gene forms a transcription factor with a role in regulation of proliferation-associated genes crucial for cell cycle control. C-myc is located on chromosome 8q24 and activation may contribute to tumor progression by preventing cells from entering the G0-resting phase. Amplification was reported in none of metaplasias and low grade dysplasias, but in 25% of high grade dysplasias and 44% of adenocarcinomas [54]. Studies suggested that c-myc is the target gene of the chromosome 8q high level amplifications found in esophageal adeno-

carcinomas [55-58] (Figure 2.1). Tselepis et al. showed upregulation of c-myc protein in 50% of metaplasias and 90% of adenocarcinomas with a role for bile acids in an acid environment as potent inducers of this oncogene in vitro [59].

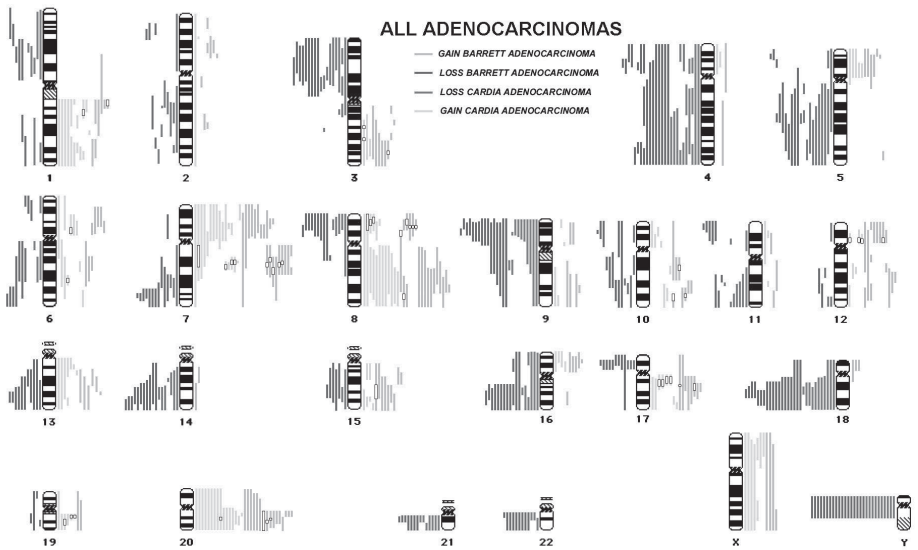

Figure 2.1 Combined CGH data from Van Dekken et al. (20 gastric cardia adenocarcinomas) and from Riegman et al. (30 Barrett adenocarcinomas) [167,171]. Boxes indicate regions of high-level amplification. *Also see color figures page 291.*

src

The cellular oncogene c-src and its viral homologue v-src are cellular oncogenes, which encode a nonreceptor tyrosine kinase involved in a number of signal transduction pathways. Src may deregulate cell-adhesion by anchorage-dependent growth control, thereby maintaining cells in the proliferative state [60]. Increased src activity was found in Barrett's epithelium with a 6 fold increase in esophageal adenocarcinomas [61]. Moreover, Jankowski et al. found that 20% of a series of esophageal adenocarcinomas and Barrett's esophagus expressed src [62].

Prostaglandins

The rate-limiting step in the synthesis of prostaglandins is the conversion of arachidonic acid to prostaglandin. The enzyme that controls this crucial step is cyclooxygenase (COX), of which there are 2 isoforms, COX-1 and COX-2. COX-1 expression is predominantly constitutive whereas COX-2 expression is inducible by mediators of inflammation. The mechanisms by which COX-2 is thought to be involved in carcinogenesis include resisting apoptosis, increasing cell proliferation, stimulating angiogenesis and modulating the invasive properties of cancer cells [63]. COX-2 was shown to be functionally active in Barrett's esophagus since treat-

ment with COX-2 inhibitors hindered proliferation of Barrett cells in culture as well as adenocarcinoma cells [64,65]. Proliferation was restored by prostaglandin treatment [64]. Enhanced COX-2 expression was detected in high amount in metaplasia (75-91%), low grade (83%) and high grade dysplasia (100%) and adenocarcinoma (97-100%) [66,67]. Elevated COX-2 protein expression was significantly associated with reduced survival after esophagectomy for adenocarcinoma [68]. Moreover, COX-2 inhibition with the selective inhibitor rofecoxib showed a reduction of COX-2 expression, prostaglandin release and cell proliferation in Barrett's patients, thereby forming a promising chemoprevention agent against dysplasia and carcinoma [69]. Results of clinical studies to investigate the effect of COX-2 inhibitors as a novel treatment modality for patients with Barrett's esophagus and adenocarcinoma have to be awaited. Since complex interactions seemed to exist between COX-2 and autocrine production of gastrin on Barrett's adenocarcinogenesis, this needs to be considered when evaluating chemopreventive strategies in Barrett's adenocarcinoma [70].

BRAF

The Ras oncogene transmits extracellular growth signals trough the MAP kinase pathway, resulting in the activation of RAF kinase. The 3 isoforms of RAF comprise ARAF, BRAF and CRAF. Activating BRAF mutations were discovered in a variety of malignancies [71]. BRAF mutations are generally nonoverlapping with K-Ras, suggesting that only one mutational event in the pathway, comprising RAS, MAP kinase and BRAF, may be needed for tumorigenesis [72-74]. Sommerer et al. detected activating BRAF mutations in 0% of low grade dysplasias, in 4% of high grade dysplasias and in 11% of adenocarcinomas [75]. Interestingly, K-Ras mutations were detected in 11% and 21% of high grade dysplasias and adenocarcinomas respectively, all lesions with K-Ras mutations having an intact BRAF gene [75]. The inhibition of the RAS-MAP-RAF kinase pathway might be a new diagnostic or even therapeutic strategy in Barrett's adenocarcinogenesis [76].

PIK3CA

Systematic cancer genome analysis has recently led to the discovery of somatic mutations in the PIK3CA gene, a member of the phosphatidylinositol 3-kinases (PI3Ks) [76]. PIK3CA is a lipid kinase located at chromosome 3q26 that regulates signaling pathways important in cell proliferation, adhesion, cell survival and motility. Somatic PIK3CA mutations were detected in colon cancers, brain cancers, gastric, breast and lung cancers [77]. Mutant PIK3CA is likely to function as an oncogene and therefore may prove useful for diagnostic and therapeutic purposes [77]. No data exist on PIK3CA gene mutation analysis in esophageal adenocarcinomas, although amplification of PIK3CA was detected in 5.7% of 87 Barrett's adenocarcinomas [78]. Interestingly PIK3CA amplification showed significant correlations with low tumor stage, absence of nodal involvement, small tumor size and lower T-status [78].

HNF3α

The Hepatocyte Nuclear Factor 3α (HNF3α) gene is located at 14q13 and forms a member of the forkhead gene family. HNF3α is involved in liver differentiation and regeneration, amongst others. Amplification of chromosome 14q13 with overexpression of the HNF3α in esophageal adenocarcinomas suggested a potential oncogenic role for this gene [79].

TUMOR SUPPRESSOR GENES

In tumor suppressor genes both gene copies need to be inactivated for the tumor suppressive effect to be lost. One allele of these genes is frequently inactivated by Loss of Heterozygosity (LOH). The remaining copy is often inactivated by mutation or promotor methylation. To define chromosomal regions of deletion LOH-analysis is used, also referred to as Microsatellite Allelotyping or Allelic Imbalance analysis. Using the Comparative Genomic Hybridization (CGH) technique, genome wide detection of amplifications and losses can be performed. Frequent loss of one allele involving a chromosomal arm or locus suggests the presence, at or near that locus, of a tumor suppressor gene. Several groups have evaluated chromosomal regions for LOH in Barrett's metaplasia, dysplasia and adenocarcinomas of the gastro-esophageal junction (Table 2.1B). Most common areas of chromosomal loss with their target genes will be discussed.

Chromosome 3p: FHIT, VHL and PPARγ

Fragile sites are genomic regions that predispose for structural chromosome aberrations such as translocations or deletions. The Fragile Histidine Triad (FHIT) gene is localized on chromosome 3p14 and spans the common fragile site FRA3B. Even though its role in carcinogenesis is still unclear, this gene is frequently inactivated by carcinogen-induced intragenic deletions in many types of cancers. Rare silent point mutations were found in esophageal adenocarcinomas [80]. A relationship between genomic deletions and the presence of abnormal FHIT transcripts (observed in 86% of Barrett's esophagus and 93% of associated carcinomas) was found by Micheal et al. [81]. Esophageal adenocarcinoma cell line experiments provided evidence for selection of loss of a functional FHIT gene by translocation events at the fragile site harboring FHIT [82]. Abnormal FHIT transcript were observed in 44% of 18 esophageal adenocarcinomas, genomic deletions were found in 44% also with overlap of both types of alterations in only 2 out of 18 patients [83]. Since genomic deletions were observed in 80% of squamous cell carcinomas of the esophagus, the authors propose the FHIT gene to be a common target for carcinogens such as smoking and alcohol, known risk factors for the development of particularly esophageal squamous cell cancer [83]. Array-based CGH showed DNA sequence copy number loss of FHIT in 28% of 18 Barrett's carcinoma samples as part of approximately 50 genes identified [84]. However, aberrant FHIT transcripts were also detected in normal, non-cancerous tissues of the gastrointestinal tract, questioning the role of FHIT as

a tumor suppressor [85]. Its apparent involvement might simply reflect its location within an unstable region of the genome.

Frequent loss is described at chromosome 3p25-26 encompassing two candidate tumor suppressor genes: the Von Hippel-Lindau (VHL) gene and the peroxisome proliferator activated receptor-gamma (PPARγ) gene. Both genes are mutated in VHL disease and colon carcinomas, respectively [86,87]. LOH analysis revealed 3p25-26 loss in 67% of 36 distal esophageal and gastric cardia carcinomas whereas no mutations were detected [88]. A high percentage of LOH at the 3p VHL locus was also shown by Dolan et al., Sanz-Ortega et al. and Raja et al. suggesting that other candidate tumor suppressor genes located at 3p might be involved in esophageal adenocarcinogenesis [89-91]. Moreover, LOH at the VHL gene locus (and also at the APC, p16, DCC and MSH3 mismatch repair gene locus) could be detected in histologically normal tissue and in adjacent adenocarcinoma, being potential markers of early neoplastic progression [92].

Chromosome 5q: MCC and APC

The Mutated in Colorectal Cancer (MCC) tumor suppressor gene is closely linked to the Adenomatosis Polyposis Coli (APC) tumor suppressor gene at chromosome 5q21. Bektas et al. performed LOH analysis in 36 patients with Barrett's metaplasia and/or low grade dysplasia and/or high grade dysplasia and adenocarcinoma [93]. MCC allelic loss percentages were 6%, 0%, 0% and 25% respectively [93]. So far, no reports have been published on MCC mutation analysis in esophageal adenocarcinomas. Also in colorectal and gastric cancers, with high MCC LOH, mutation of the retained MCC allele is uncommon, suggesting that MCC does not function as a tumor suppressor gene in gastrointestinal malignancies.

Performing LOH analysis we observed APC allelic loss in 16% of Barrett's metaplasias, 23% of low grade dysplasias, 48% of high grade dysplasias and 50% of adenocarcinomas (Chapter 13). Analogous to Zhuang et al. patterns of allelic loss of the APC gene in premalignant tissue and in carcinomas were identical in all stages of neoplastic progression, suggesting the emergence of a clonal population of cells [94]. A very low rate of APC mutations was described in esophageal cancers [95-97]. Another putative tumor suppressor gene might therefore be the target of the frequent LOH on 5q and deletion of the APC locus may just be the result of large deletions on 5q and may therefore not be important in esophageal carcinogenesis [96]. On the other hand, an alternative mechanism could be responsible for inactivation of the APC gene. In gastric cancer, methylation of the promotor region of the APC gene was strongly associated with silencing of its expression [98]. Kawakami et al. observed hypermethylation of the promotor region of the APC gene in 92% of 52 Barrett's adenocarcinomas and in 40% of 43 patients with Barrett's metaplasia [99]. Interestingly, hypermethylated APC DNA was observed in the plasma in part of the patients and high levels significantly correlated with reduced patient survival [99]. Monoallelic APC promotor methylation was found to be frequently altered in histologically normal-appearing gastric mucosa from patients with gastric or esophageal adenocarcinoma [100].

Chromosome 9p: p16

Inactivation of the p16 tumor suppressor gene (also MTS1 or CDKN2A gene) at 9p21 is one of the most common genetic abnormalities in human cancers. P16 encodes a cell cycle regulatory protein that inhibits cyclin-dependent kinases 4 and 6, preventing the phosphorylation of the Rb protein and the release of a transcription factor. This blocks cell cycle progression in the G1-S phase. P16 becomes inactivated by a two-hit mechanism that can involve 9p21 LOH, mutation, homozygous deletion or CpG island methylation (i.e. an epigenetic event). In esophageal adenocarcinomas frequent allelic loss at 9p21 has been described [89-91,95,101-105]. Point mutations in exons 1 and 2 of the p16 gene were found to be rare in esophageal adenocarcinomas (ca. 5%) in contrast to squamous cell carcinomas [80,106-108]. Barrett et al. reported a higher prevalence (23%) of p16 gene mutations in adenocarcinomas with LOH of 9p21 [109]. However, in this study only aneuploid cell populations were investigated, which might not be representative for esophageal carcinomas in general and thus might explain the higher prevalence of p16 gene mutations. Gonzalez et al. reported homozygous deletions of the p16 gene in 3 of 12 (25%) esophageal adenocarcinomas [95]. P16 promoter methylation (with or without p16 LOH) is a common mechanism of p16 inactivation during neoplastic progression in Barrett's esophagus, and is already present in non-dysplastic premalignant Barrett's epithelium [110-114]. Wong et al. stated that p16 lesions are the earliest known somatic genetic/epigenetic abnormalities in Barrett's esophagus occurring in more than 85% of cases at all histological grades of dysplasia [112]. Cells with p16 aberrations, either hemizygous or nullizygous clones, undergo clonal expansion to involve large regions of the esophagus, creating a field in which other premalignant lesions can arise that can result in the formation of esophageal adenocarcinoma [112]. P16 inactivation may therefore be a useful biomarker to stratify patients' risk of progression of Barrett's metaplasia to esophageal cancer [115,116]. Suspiro et al. reported 9p LOH in 35% of 18 Barrett's metaplasia patients without dysplasia or cancer (as well as 39% 17p LOH) regarding 9p and 17p LOH as useful markers for risk stratification within endoscopic surveillance programs [117]. Other tumor suppressor genes on 9p being p15 and $p14^{ARF}$ were rarely altered in esophageal adenocarcinomas [106,109,114].

Chromosome 13q: retinoblastoma

The Retinoblastoma (Rb) gene encodes a cell cycle-associated protein important in regulating the G1-S checkpoint of the cell cycle. Functional alterations play a key role in carcinogenesis and cell proliferation. Rb allelic loss was found in none of the Barrett's metaplasias, 7% of the low grade dysplasias, 8.3% of the high grade dysplasias and 18.5% of the carcinomas by Sarbia et al [118]. There are no reports on mutation analysis of the Rb gene in esophageal adenocarcinomas.

Chromosome 17p: p53

Loss or mutation of tumor suppressor gene p53 is probably the most common single genetic change in cancer. This reflects the central importance of p53, which has several functions in the cell. One is as a transcription factor. Tetramers of p53 bind DNA and can activate transcription of reporter genes situated downstream of a p53 binding site. However, p53 is believed to have a much broader role in the cell, which has been summarized as 'the guardian of the genome'. Normal cells with damaged DNA arrest at the G1-S cell cycle checkpoint until damage is repaired, cells that lack p53 or have a mutant form do not arrest and replication of damaged DNA presumably leads to random genetic changes, some of which are oncogenic, similar to cells with a defective mismatch repair system. In addition, cells that lack p53 or contain mutant p53 escape apoptosis. Molecular techniques can detect p53 gene alterations, such as single strand conformation polymorphism (SSCP) analysis, sequencing and LOH analysis. The prolonged half-life of the mutant p53 protein and the concomitant increased cellular p53 concentration makes visualization by immunohistochemistry possible. Deletion of one allele of p53 in combination with a functionally inactivating mutation of the other p53 allele is among the most common combinations of genetic alterations documented in human cancer. P53 was the first such gene to be investigated in esophageal adenocarcinomas [119-121]. P53 LOH and mutations seem to be relatively early events in neoplastic progression in Barrett's esophagus because it develops in diploid cells before aneuploidy and other LOH events involving 5p, 13p and 18q [105,115,122,123]. LOH of the p53 locus has been found in 75-80% of esophageal adenocarcinomas as well as in 79% of high grade dysplasias, 42% of low grade dysplasias and 14% of Barrett's metaplasias [102,124,125]. P53 mutations were found in 29-66% of Barrett's metaplasias/low grade dysplasias and in 40-88% of high grade dysplasias/adenocarcinomas [126-130]. In contrast, nuclear p53 protein overexpression was found often in absence of p53 mutations, therefore immunohistochemistry seems to be a poor indicator of p53 gene mutations and probably an alternative mechanism is responsible for p53 protein expression [126-131].

17p LOH analysis performed on endoscopic biopsies identified patients with Barrett's esophagus at risk of neoplastic progression within surveillance programs, therefore it could supplement histology in determining the frequency of endoscopy during surveillance [117,132]. Moreover, since p53 mutations could be detected before development of high grade dysplasia or adenocarcinoma in Barrett's esophagus patients in surveillance programs, it may also be useful in stratifying the risk for development of adenocarcinoma within Barrett's esophagus [133]. Reid et al. found patients with p53 LOH in the flow cytometric-purified biopsy samples to be at increased risk for progression to adenocarcinoma, high grade dysplasia, increased 4N and aneuploidy [134]. LOH at 17p13 (but also LOH at 3p21, 5q21 and 9p21) might have a role as potential biomarker for high chance of developing adenocarcinoma in patients with Barrett's esophagus [90]. Several groups have investigated clinical significance of p53 mutations. Patients

with p53 mutations and/or p53 protein overexpression in the tumor after surgical resection had significant reduced 5-year survival relative to patients with wild-type p53 [135-137].
In conclusion, there is overwhelming evidence that p53 gene alterations are early and frequent events in esophageal adenocarcinomas and that this gene is associated with malignant transformation of Barrett's esophagus. Moreover, p53 alterations could be of value in the prevention as well as planning of treatment strategies in future studies.

Chromosome 18q: SMAD4 (DPC4) and DCC

LOH analysis revealed allelic loss of 18q in 63-70% of esophageal adenocarcinomas [89,91]. Putative tumor suppressor genes in this region comprise the Deleted in Colorectal Cancer (DCC) and SMAD4 (Deleted in Pancreatic Cancer: DPC4) genes. Allelic loss of SMAD4 was described in 46% of 35 Barrett's esophagus patients with premalignant epithelium and/or adenocarcinoma [138]. Mutational analysis of SMAD4 did not reveal inactivating alterations indicating that the targeted gene remains to be identified [138].

MISCELLANEOUS TUMOR SUPPRESSOR GENES AND INACTIVATION

Chromosome 7q

Frequent LOH has been described at 7q31 in numerous malignancies. Suppressor of Tumorigenicity 7 (ST7) has been identified as a candidate tumor suppressor gene at this region. 7q LOH was detected in 32% of 25 esophageal adenocarcinomas, but no mutations were detected in this region [139]. Therefore ST7 is not the target gene at 7q in esophageal adenocarcinomas [139].

Chromosome 14q

LOH at 14q31-32.1 (harboring candidate gene Thyroid Stimulating Hormone Receptor TSHR) occurred in 46% of Barrett's adenocarcinomas and gastric cardia adenocarcinomas [57]. To date there is no clear indication as to what 14q tumor suppressor gene is the target for 14q loss.

Methylation

The bi-allelic inactivation of tumor suppressor genes cannot always exclusively be explained by genetic alterations. LOH at for example the APC locus has been detected frequently without mutations in the remaining allele in esophageal adenocarcinoma [94,105]. Therefore other non-genetic events could contribute to gene inactivation in esophagal adenocarcinoma. Hypermethylation of CpG islands in the promotor region is such a non-genetic inactivation mechanism. Methylation of p16 is described to be the predominant mechanism for p16 inactivation in esophageal adenocarcinogenesis as early as metaplasia [112-114,140,141]. Methylation of APC is described in esophageal adenocarcinoma as well as Barrett's metaplasia [99,141]. Patients

whose tumors had more than 50% of a 7 gene-profile methylated had significantly poorer survival and earlier tumor recurrence [142]. Moreover aberrant hypermethylation at many different loci within a panel of 20 genes suggested an overall deregulation of methylation control in Barrett adenocarcinogenesis [143]. Interestingly, normal and metaplastic tissues from patients with evidence of associated dysplasia or cancer had a significantly higher incidence of hypermethylation than similar tissues from patients with no further progression of metaplasia [143].

MISMATCH REPAIR GENES:

Microsatellite instability

The Mismatch Repair (MMR) system is one of the mechanisms by which rapid repair of damaged DNA can be achieved. This system primarily removes nucleotides mispaired by DNA polymerases, and insertion or deletion loops resulting from slippage during replication or recombination. MMR failure results in the accumulation of single nucleotide mutations and alterations in length of simple, repetitive microsatellite sequences throughout the genome. This is known as Microsatellite Instability (MSI). MMR deficiency has been shown to be an important defect in about 15% of sporadic and hereditary colorectal cancers, gastric, ovarian and endometrial cancers. In Hereditary Non-Polyposis Coli Colorectal Cancer (HNPCC) syndrome germline mutations in MMR genes (most frequently MLH1 and MSH2) are commonly found. Concerning colorectal cancer a panel of 5 microsatellites has been validated and is recommended to characterize cancers as 'MSI-high' (2-5 markers out of 5 markers show instability), 'MSI-low' (1 marker) or 'MSS (stable)'. Such criteria lack for other human solid tumors. Several groups published on MSI and MMR in esophageal carcinomas. These studies are summarized in Table 2.3.

Meltzer et al. suggested that the instability may develop as an early event in Barrett's associated neoplastic progression since among 25 flow cytometry sorted adenocarcinomas instability occurred in 8 (32%) [144]. Moreover in 4 of these 8 positive cases, the diploid component of the tumor showed instability [144]. Several studies have confirmed the low prevalence of MSI, between 5-10%, in esophageal adenocarcinomas [89,103,107,125,145]. Interestingly, Wu et al. found a trend towards an improved survival for esophageal adenocarcinomas demonstrating MSI, whereas others could not establish an association with survival or clinicopathologic features such as tumor grade, pathologic stage, perineural or vascular invasion, and also not with p53 alterations or mutations in the recently reported DNA repair gene MBD4 [125,146,147]. It is not yet known which mismatch repair genes are responsible for the MSI observed in Barrett's adenocarcinoma.

Table 2.3 Microsatellite Instability in GEJ adenocarcinomas, a summary of the literature

Publication	Number of markers used	Number of carcinomas investigated	Results MSI			Mismatch repair genes investigated
Meltzer et al.[144]	5	(28 Barrett's metaplasias) 36 esophageal adenocarcinomas	(2/28) 8/36	(7%) 22%	(1 or more markers) 1 or more markers	No data
Gleeson et al. [250]	139	17 esophageal adenocarcinomas	1/17 16/17	6% 94%	58/128 markers 1/128 to 10/123 markers	No data
Keller et al. [145]	8	15 Barrett's adenocarcinomas	2/15	13%	At least 1 marker	No data
Muzeau et al. [251]	39	26 Barrett's adenocarcinomas	6/26 3/26	23% 12%	1 marker 2 markers	No data
Wu et al. [125]	14	92 esophageal or GEJ adenocarcinomas (56 with Barrett)	5/92	5%	4-13 markers	No data
Kulke et al. [146]	5	80 Barrett's adenocarcinomas	13/80	16%	1-2 markers	No cases with loss of MLH1 or MSH2 staining
Wijnhoven et al. [88]	2	43 GEJ adenocarcinomas	1/43	2%	1-2 markers	No data
Evans et al. [147]	15	27 esophageal adenocarcinomas	18/27	65%	1-5 markers	4/18 with loss of MLH1 and/or MSH2 staining
Falkenback et al. [252]	7	59 Barrett's adenocarcinomas	No data			2/59 with loss of MLH1 or MSH2 staining; both MSI-high (5 loci)
		395 adenocarcinomas	73/395	18%		

MITOTIC CHECKPOINT GENES:

DNA content and chromosomal abnormalities

DNA content/aneuploidy

Due to defects in mitotic checkpoint genes cells can obtain an abnormal number of chromosomes, defined as aneuploidy [148]. To date nine human genes with a clear role in mitotic checkpoint control and prevention of aneuploidy have been discovered [14,149]. Despite the fact that 95% of esophageal adenocarcinomas is aneuploid, the gene(s) involved in aneuploidy in these tumors are still unknown. Gene expression levels of the MAD2 and BUB1 mitotic spindle checkpoint genes were assessed in 37 Barrett's patients by real time PCR, although no correlation with aneuploidy could be established [150]. The APC tumor suppressor gene plays a role in chromosome segregation by binding to the microtubules that form the spindle apparatus [15,149,151]. In Barrett's epithelium and related adenocarcinomas frequent loss of the APC gene (5q21) as well as gene inactivation by hypermethylation has been described but few gene mutations (see Tumor Suppressor Genes paragraph). Whether loss of APC function plays a role in aneuploidy observed in Barrett and carcinoma remains to be demonstrated. Aneuploidy can be detected by measuring the DNA content of individual cells. With flow cytometry normal cells have a DNA content ranging from 2N (in G1 phase of cell cycle) to 4N (in G2/M phase of cell cycle). By using flow cytometry it has been shown that the evolution from normal esophagus to premalignant Barrett's metaplasia was frequently associated with aneuploidy and increased G2/M fraction (4N) of the metaplastic cells [152-154]. It has been suggested that nuclear DNA ploidy analysis on flow cytometry might provide a more objective and reliable biomarker associated with progression from metaplasia to carcinoma than the histological diagnosis of high grade dysplasia [155,156]. Indeed, prospective studies indicate that both aneuploidy and dysplasia may be prognostic factors for malignant transformation in Barrett's epithelium [153,157,158]: 70% of the patients with aneuploidy or increased G2/tetraploid fractions in biopsy specimens obtained during initial endoscopic evaluation developed high grade dysplasia or cancer, whereas none of the patients without flow cytometric abnormalities on initial evaluation showed progression to invasive carcinoma or high-grade dysplasia [153]. A combination of histological dysplasia any grade and the measurement of DNA abnormalities might therefore help identify Barrett's esophagus patients at risk for adenocarcinoma [155,156]. Rabinovitch et al. proposed that patients with negative, indefinite or low-grade dysplasia biopsy results in a surveillance program without increased 4N or aneuploidy may have subsequent surveillance deferred for up to 5 years [159].

Specific Chromosomal abnormalities

Detection of aneuploidy is based on the nuclear DNA content. No information is obtained about detailed chromosomal abnormalities in these cells. Techniques to investigate these chromosomal abnormalities comprise karyotyping, for which cells have to be cultured, In

Situ Hybridization (ISH), by which numerical aberrations can be detected as well as amplification or loss of specific DNA loci, and LOH analysis, which investigates specific chromosomal regions for amplification or loss. The CGH technique allows genome wide screening for chromosomal imbalances.

The most consistent numerical chromosomal abnormalities found in cytogenetic studies of dysplastic Barrett's mucosa and adenocarcinoma comprised loss of the Y-chromosome, namely in 31-93% of tumors, correlating with the development of carcinoma [160-162]. Karyotyping revealed frequent structural rearrangements in esophageal adenocarcinomas in the 1p, 3q, 11p-13, and 22p regions [160,163]. Using Fluorescence In Situ Hybridization (FISH), Doak et al. showed chromosome 4 and 8 hyperploidy to represent the earliest and most common alterations identified using tissue from endoscopic cytology brushings (metaplasia 89% and 71%, low grade dysplasia 90% and 75%, high grade dysplasia 88% and 100%, carcinoma 100% and 100% respectively)[164]. CGH showed significant chromosome changes to be absent in low grade dysplastic lesions whereas a large amount of widespread instability was present in high dysplastic lesions (most often chromosome 4 amplification) and adenocarcinomas (with chromosome 8 amplified most frequently) [165]. Furthermore, trisomies for chromosomes 5 and 7 and translocations involving chromosome 3 and 6 in Barrett's esophagus were described [162]. LOH studies and CGH studies reported in the literature showed frequent chromosomal losses in the metaplasia-dysplasia-adenocarcinoma sequence concerning amongst others chromosomes 4q, 5q, 7q, 9p, 13q, 17p and 18q and revealed over representation of chromosomes 6p, 7, 8q, 11, 12q, 14 and 20q [55,57,58,84,89-91,102,104,105,109,112,125,160,161,164,166-176], with a detailed summary of part of these studies in Tables 2.1A, 2.1B (losses) and Table 2.2 (gains and high level amplifications). Figure 2.1 shows combined CGH data from Van Dekken et al. (20 gastric cardia adenocarcinomas) and from Riegman et al. (30 Barrett adenocarcinomas) [167,171]. It remains to be determined whether any of these abnormalities are predictive markers of progression to malignancy. However, loss of 7q33-q35 was found to represent a significant distinction between low grade and high grade dysplasia whereas loss of 16q21-q22 and gain of 20q11.2-q13.1 were disclosed to significantly discriminate between high grade dysplasia and adenocarcinoma [167]. Detection of DNA sequence copy number changes using array CGH revealed changes, mainly gains, of approximately 50 genes in Barrett's adenocarcinoma, providing new candidate biomarkers in esophageal adenocarcinogenesis [84].

CELL PROLIFERATION AND APOPTOSIS

In the light of molecular concepts about carcinogenesis it is important to realize that the accumulation of genetic alterations is only effective in combination with cell division. Dividing normal cell populations maintain the balance between cell proliferation and cell loss. If there

is increased proliferation, decreased apoptosis or both, uncontrolled growth occurs and this may result in tumor formation [177].

Cell proliferation

In order to assess the amount and distribution of cell proliferation in paraffin-embedded tissues monoclonal antibodies have been developed to detect cell cycle modulators. Several studies used a monoclonal Ki-67 (MIB-1) and PCNA antibody to study the proliferative properties in Barrett's esophagus and adenocarcinomas. An increased number of proliferating cells and an expansion of the proliferative compartment was demonstrated in Barrett's esophagus and adenocarcinoma [178-181]. PCNA immunostaining was mainly seen in the basal cells of the neck/foveolar epithelial compartment of the glands in Barrett's esophagus. However, in mucosa with high-grade dysplasia, the proliferative compartment extended upwards into the superficial layers of the glands [182-184]. Ki-67 staining pattern also correlated with the histologic findings in Barrett's esophagus: the number and localization of Ki-67 positive nuclei was significantly different between non, low and high grade dysplastic Barrett's and adenocarcinoma [182,185-190]. Interestingly, effective intra-esophageal acid suppression decreased cell proliferation and favored differentiation in Barrett's epithelium, but had no effect on the grade of dysplasia [191].

Apoptosis

Apoptosis, or programmed cell death, is one of the mechanisms responsible for cell loss. The net effect of cell division and apoptosis determines tissue growth. Apoptosis provides a protective mechanism by removing senescent, DNA-damaged, or diseased cells that could either interfere with normal function or lead to neoplastic proliferation. Apoptosis itself can be detected by use of immunohistochemical detection of DNA fragmentation as markers for apoptosis. An increase in apoptotic rate with increasing histologic severity in intestinal metaplasia/dysplasia and carcinoma was noted [178], whereas others found few apoptotic cells in Barrett's high-grade dysplasia and adenocarcinoma [192,193].

Fas and Fas Ligand

The Fas/APO-1 (CD95) gene encodes a transmembrane protein that is involved in apoptosis and is a member of the tumor necrosis factor receptor superfamily. Loss of its expression during carcinogenesis can result in the interruption of the apoptotic pathway. Hughes et al. found that expression of Fas on the cell surface by esophageal adenocarcinomas is reduced or absent whereas high levels of Fas mRNA were detected in these tumors [194]. Furthermore, they demonstrated in an esophageal adenocarcinoma cancer cell line that wild-type Fas protein is retained in the cytoplasm. Apparently, retention of wild-type Fas protein within the cytoplasm may represent the mechanism by which malignant cells evade Fas-mediated apoptosis [194]. Fas ligand binds to Fas, activating an apoptotic pathway. Younes et al. found that

Fas ligand was overexpressed in cases of Barrett's metaplasia with dysplasia and esophageal adenocarcinomas but that Fas was usually undetectable or expressed at low levels [195,196]. They propose that decreased Fas expression might protect Barrett's metaplasia with dysplasia and carcinoma from self-destruction while allowing them to evade immune surveillance [195,196].

Bcl-2 family (Bcl-2, Bcl-xl, Bax)

The Bcl-2 proto-oncogene at 18q21 encodes a protein that blocks apoptosis [197]. Divergent results have been published in the literature concerning Bcl-2 expression. It was found to be increased in reflux esophagitis, non dysplastic Barrett's and low grade dysplastic Barrett's epithelium, but low or virtually absent in high grade dysplasia and carcinomas [182,187,193,198-200]. Inhibition of apoptosis by overexpression of Bcl-2 protein occurs mainly early in the neoplastic progression. As malignancy appears, cells acquire other ways of avoiding apoptosis for instance by mutations in the p53 gene, since p53 dysfunction plays a major role in the progression from dysplasia to carcinoma in Barrett's esophagus and appears unrelated to Bcl-2 expression [201]. Van der Woude et al. proposed that the apoptotic balance in the transformation of metaplasia to adenocarcinoma switches from a pro- to a antiapoptotic phenotype due to increased Bcl-xl and decreased Bax expression [200]. Bcl-xl expression was shown to be elevated in the metaplasia-low grade-high grade dysplasia-adenocarcinoma sequence (27%, 60%, 71% and 59% respectively) [202]. Loss of Bcl-2 expression in Barrett's dysplasia and adenocarcinoma was associated with tumor progression as well as worse survival but not with response to neoadjuvant chemoradiation [203].

Mdm2

The p53 gene is an important tumor suppressor gene functioning both in cell cycle arrest and apoptosis. The human homologue of the murine double minute-2 gene (mdm2) at 12q15 is a known regulator of p53 activity. Its expression results in stabilization of the wild-type p53 protein and loss of its tumor suppressor function. Soslow et al. showed mdm2 to be overexpressed in esophageal adenocarcinomas [128]. Recently, a mdm2 promotor polymorphism was described that decreased p53 function in Li Fraumeni patients without a p53 mutation [204].

Survivin and other IAPs

Survivin forms an inhibitor of apoptosis protein (IAP) [205]. It is expressed in the G2/M phase of the cell cycle and its interaction with the mitotic spindle apparatus has been reported to be essential for anti-apoptotic function [205]. The expression of survivin has been shown to predict a poor prognosis in terms of survival and disease recurrence for patients with colorectal cancer, neuroblastoma and bladder cancer [206-209]. Beardsmore et al. found survivin immunostaining in 95% of esophageal carcinomas (both squamous cell and adenocarcinomas) with a strong positive correlation between levels of survivin expression and the number of proliferating cells in the malignant tissue [199]. Although a predictive role for surviving in the response

to neoadjuvant chemoradiotherapy has been suggested in the literature, Beardsmore et al. were not able to show such a correlation in esophageal cancers [199]. Expression of survivin and other IAPs (cIAP1, cIAP2, NAIP, and XIAP) was elevated in a series of esophageal squamous cell carcinomas [210].

Telomerase

The limited life span of normal somatic cells is characterized by telomere shortening. Cells that are not subject to replicative senescence such as germline cells, stem cells and cancer cells are able to maintain telomere length. Telomerase is a ribonucleoprotein enzyme complex that is capable of restoring and maintaining telomere length by providing its own RNA template for the addition of telomeric sequences to chromosome ends. Telomerase activation is associated with increased expression of the telomere reverse transcriptase catalytic subunit (hTERT). Lord et al. measured mRNA expression levels of hTERT in Barrett's metaplasia, dysplasia and adenocarcinoma and found a significant increase in upregulation in the metaplasia-dysplasia-adenocarcinoma sequence as compared to patients normal tissue [211]. Moreover, a significant difference was found in hTERT activation when normal tissues of cancer patients were compared to squamous cell epithelia of non-cancer patients[211]. Another study demonstrated that the vast majority of esophageal adenocarcinomas and high grade dysplasias contained high levels of telomerase RNA and that the greatest increase occurred during the transition from low to high grade dysplasia [212].

Because of the tight link between cell proliferation and apoptosis in tumor growth the assessment of both parameters in a neoplasm is suggested to be a sensitive marker for neoplastic progression [179].

Genes involved in controlling the cell cycle

Proliferation is crucial for tumor development. Cell cycle progression is the result of proliferation promoting factors: the Cyclin Dependent Kinases (CDKs) and the Proliferation Inhibiting components (CDK-inhibitors, CDKIs). Cyclins form a family of proteins that complex with CDKs. The CDKIs can be categorized in the Kip/Cip proteins (p21, p27, p57) and the INK4 proteins (p15, p16, p18, p19). The development of dysplasia is characterized by a disregulation of cell cycling. In Barrett's metaplasia progression of an increased fraction of S-phase and G2/M phase cells is described, suggesting that cells escape G1-G0 phase checkpoints [213]. The Rb gene (mediating cell cycle progression), p16 gene (a CDKI) and p53 gene (inhibits cell cycle when DNA is damaged) have been described in the section 'Tumor suppressor genes'.

CYCLINS

Cyclin D1 (11q13)

Disregulation of the cell cycle in the development of dysplasia is in part due to increased cyclin D1 expression and hypermethylation or mutation of p16 with mobilization of cells from G0 to G1 with subsequent accumulation in the G2 phase [1]. Amplification of the cyclin D1 gene was observed in 16-26% of the esophageal adenocarcinomas, whereas increased nuclear expression of cyclin D1 was observed in 22-64% of the esophageal adenocarcinomas [214-219]. Within a prospective cohort of Barrett's patients a statistically significantly increased risk of progression to adenocarcinoma was shown in patients with cyclin D1 positive biopsy specimens [220]. The Rb protein is phosphorylated by cyclin D1 and thereby inactivated. The inactivated Rb facilitates transition of the cell from G1 into S-phase. Another group of CDKIs is the Cip/Kip family and includes p21, p27 and p57.

Cyclin B1 (5q12)

Cyclin B1 is synthesized in the early G2-phase and is believed to be involved in the control of G2-M-phase transition by promoting chromosome condensation, destruction of the nuclear membrane and assembly of the mitotic spindle. Overexpression of cyclin B1 is a frequent and early finding in the metaplasia - dysplasia - carcinoma sequence [221].

Cyclin E (19q12)

Cyclin E is involved in the process of cell entry into the S-phase of the cell cycle. Expression of the cyclin E protein was reported in dysplastic Barrett's mucosa as well as in adenocarcinomas, and increased nuclear staining was associated with regeneration and proliferation of adjacent metaplastic epithelium of erosions or ulcerations in Barrett's esophagus [222]. Amplification of 19q12 with cyclin E as the best candidate gene was observed in 13.8% of esophageal adenocarcinomas [223].

P21$^{WAF1/CIP1}$ (6p21)

The wild type p53 tumor suppressor gene can induce the CDKI p21. Through inhibition of CDKs the G1-S phase of the cell cycle can be downregulated. P21 expression was elevated in low grade dysplasia, high grade dysplasia and in Barrett's adenocarcinoma, but not in Barrett's metaplasia [224]. Interestingly no correlation between p21 and p53 staining in esophageal adenocarcinomas was found, indicating a p53 independent mechanism for upregulation of p21 [224,225]. Elevated p21 expression was significantly associated with better prognosis [217].

P27^{Kip-1} (12p13)

P27 induces a block during G1 in the cell cycle. Loss of p27 expression is thought to be tumorigenic and may lead to tumor progression. Most Barrett related adenocarcinomas are associ-

ated with loss of p27 as well as altered cellular localization (cytoplasmic instead of nuclear) [226]. Loss of nuclear and/or cytoplasmic staining for p27 correlated with higher histological grade, depth of invasion, presence of lymph node metastasis and shorter survival [226].

Cell-cell adhesion genes

Reduced cell-cell adhesion promotes growth of epithelial cells because contact inhibition of proliferation is lost. Moreover cell adhesion molecules are involved in the process of invasion and metastasis of cancers.

E-cadherin-catenin complex

E-cadherin belongs to the family of calcium-dependent cell adhesion molecules and forms part of the adherens junction complex promoting tight adhesion of epithelial cells. Loss of E-cadherin occurs in several cancers and is associated with the development of invasive properties. E-cadherin expression was shown to be reduced in both Barrett's esophagus and esophageal adenocarcinoma and in the latter this was correlated with a greater frequency of lymph node metastasis and decreased patient survival [227,228]. Mutations of the E-cadherin gene were rare in adenocarcinomas [229]. However, epigenetic silencing via aberrant methylation of the E-cadherin promotor seemed to be a common cause of inactivation in adenocarcinomas [230].

β-Catenin is involved in cell-cell adhesion by its interaction with E-cadherin and with the cytoskeleton. A second function of β-catenin concerns cell-signaling. The β-catenin protein can translocate to the nucleus where it complexes with the transcription regulator proteins T-Cell factor 4/Lymphoid Enhancer-binding Factor 1 (TCF4/LEF1) to activate transcription of oncogenes including i.e. c-myc and cyclin D1. In general the APC gene product forms a complex with other proteins and targets β-catenin for degradation preventing β-catenin dependent transcription of oncogenes. However, activated Wnt signaling protects β-catenin from APC-mediated degradation and increases β-catenin-dependent transcription [231,232]. Nuclear and cytoplasmic instead of membranous β-catenin localization has been described to occur frequently in esophageal adenocarcinomas, however mutations in β-catenin or APC appeared to be very rare [233-236].

CD44 protein family

The CD44 gene produces a variety of glycosylated cell surface proteins by alternative splicing of its at least 20 exons. CD44 is involved in cell-cell adhesion and cell-matrix interactions. Expression of CD44 in APC and TCF mutant mice was described to implicate its regulation by the Wnt pathway [237]. Several reports focused on the expression of certain splice variants in esophageal adenocarcinoma. CD44V6 was detected by immunohistochemistry in 55% of Barrett's metaplasias and 63% of adenocarcinomas [238]. CD44V6 expression was related to an aggressive pathological feature in adenocarcinomas [239]. With RT-PCR and southern blot

analysis CD44V5 en CD44V6 were found to be frequently and similarly expressed in both Barrett's metaplasia and adenocarcinoma, thus not closely associated with development and progression of esophageal adenocarcinomas according to Menges et al. [240].

Cathepsin B

The cysteine protease cathepsin B (CTSB) gene is localized at chromosome 8p22 and codes for a lysosomal enzyme that has been shown to be overexpressed or exhibit altered localization in cancers [241]. Overexpression or altered localization of CTSB is thought to result in degradation of the basement membrane facilitating tumor invasion and metastasis. Characterization of an amplicon at chromosome 8p22-23 revealed that CTSB was both amplified and overexpressed in esophageal adenocarcinomas. Gene amplification was observed in 13% of tumors, mRNA overexpression was observed in 25% of tumors and protein staining was detected even in 75% of tumors, suggesting that CTSB overexpression could result from other mechanisms in addition to gene amplification [223]. These data support an important role for CTSB gene amplification and CTSB protein overexpression in esophageal adenocarcinomas.

SUMMARY AND FUTURE PERSPECTIVES

Concerning Barrett's metaplasia and its malignant potential there is still need for improved understanding of the molecular biology in order to develop a more scientific approach to cancer prevention in these patients. Since the annual incidence rate for developing esophageal adenocarcinoma in Barrett's esophagus is as low as 0.5-1%, a cancer preventive strategy needs to be cost effective and acceptable to a large number of patients at relatively low risk [76]. Despite ongoing efforts to characterize the molecular changes leading to esophageal adenocarcinoma, no clinically applicable biomarkers for prediction of prognosis and/or response to therapy came forward to date. Moreover, the proposed existence of intratumoral heterogeneity of genetic alterations has important implications for the development of such biomarkers. Using FISH analysis Walch et al. demonstrated intratumoral heterogeneity which they ascribe to a probable existence of many divergent neoplastic subpopulations [166]. This highlights one of the main problems associated with surveillance of Barrett's patients namely sampling error. LOH and gene amplification analysis at several gene loci of multiple tumor samples per patient elucidated marked intratumoral heterogeneity in Barrett's adenocarcinomas [242]. In studies of Galipeau et al., Prevo et al. and Barrett et al. the subject of clonal expansion of cells with certain alterations have been extensively studied [105,115,243]. It seems likely that the acquisition of 9p LOH and 17p LOH predisposes to the evolution of aneuploid cell populations and other genetic abnormalities that culminate in the development of cancer [105,115,243]. Maley et al. addressed the role of genetic instability and clonal expansion in Barrett's metaplasia using prospective data [244]. They measured the size of cell clones with p53

alterations, p16 alterations, aneuploidy and tetraploidy in serial endoscopy biopsy samples with a follow-up of 8 years [244]. They demonstrated that not the single presence of p53 LOH, aneuploidy or tetraploidy predict progression to adenocarcinoma, but the size of clones with these lesions [244]. Thus the combination of both genetic instability and clone size predicted progression to cancer in their prospective cohort study [244].

In conclusion, the search for molecular markers to predict which Barrett's patients are at high risk for neoplastic progression should be focused on early genetic events. Such early events concern loss of p16 and p53 with aneuploidy as a probable driving force. The value of various genetic alterations, amongst which p16 and p53, as molecular markers in GEJ adenocarcinogenesis was investigated in chapter 13 of this thesis.

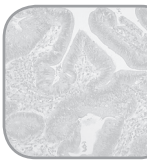
ABSTRACT

We aimed to investigate the contribution and possible prognostic role of the Wnt signaling pathway in gastro-esophageal junction (GEJ) adenocarcinomas. An immunohistochemical study of the diverse components of the Wnt pathway was undertaken in 164 GEJ adenocarcinomas and in 5 human GEJ adenocarcinoma cell lines, in which we formerly demonstrated that nuclear β-catenin expression correlates with enhanced TCF-mediated transcription of a reporter gene. Expression of β-catenin, phospho-β-catenin Ser33/37/Thr41, phospho-β-catenin Thr41/Ser45, dephosphorylated 'active' β-catenin, LEF1, TCF4, and the Wnt target genes CD44V6 and EphB2 was analysed in formalin-fixed, paraffin embedded tumor tissues and correlated to clinicopathological factors and survival. Thirty-five % of tumors expressed nuclear β-catenin in more than 10% of tumor cells, which correlated positively with elevated cytoplasmic (p=0.04) and reduced membranous (p=0.001) β-catenin as well as with elevated nuclear LEF1 expression (p=0.03). Membranous EphB2 as well as cytoplasmic EphB2 expression significantly correlated with better tumor differentiation grade (p=0.05 and p=0.04) and with better overall survival (p=0.04 and p=0.04 respectively), which was not substantiated in multivariable analysis. Activated Wnt signaling might probably be of less importance in GEJ adenocarcinomas than previously thought. However, expression of the Wnt target gene EphB2 correlated to prognosis of GEJ adenocarcinoma patients.

INTRODUCTION

Adenocarcinomas of the gastro-esophageal junction (GEJ) show a rapidly increasing incidence in the western world since the last three decades [1,2]. Little is known about the molecular mechanisms underlying the origin of these tumors. As in colorectal carcinomas the wingless-type (Wnt) pathway is suggested to play a key role in GEJ adenocarcinomas as well. Nuclear β-catenin expression, generally believed to indicate activated Wnt signaling, is reported in up to 60% of GEJ adenocarcinomas [3-7].



Wnt signaling has importance in a number of developmental processes in vertebrates and invertebrates, i.e. regulation of cell fate specification, proliferation and differentiation in various tissues [8]. Additionally, Wnt signaling is able to contribute to tumorigenesis by altering the state and activity of β-catenin [9], a protein that was first described in humans as a member of the cell membrane-bound adherens complex [10]. Later β-Catenin was found to participate also in cell-signaling which involves translocation of the protein from the cytoplasm to the nucleus through activated Wnt signaling [11,12]. β-Catenin levels are regulated by a protein complex containing the tumor suppressor gene product adenomatous polyposis coli (APC), serine/threonine protein kinase glycogen synthase kinase-3β (GSK3β) and Axin/conductin and by casein kinase Iα [13-19]. Degradation of free cytosolic β-catenin is consecutively promoted via phosphorylation of NH_2-terminal β-catenin sequences at Ser45 (by casein kinase Iα) and subsequently at Thr41, Ser37 and Ser33 (by the GSK3β/APC/Axin complex) followed by ubiquination and proteasomal degradation [20]. Upon Wnt signaling the degradation complex is inhibited. Non-phosphorylated β-catenin accumulates in the cytoplasm and translocates to the nucleus where it complexes with the transcription regulator proteins T-Cell factor 4/Lymphoid Enhancer-binding Factor 1 (TCF4/LEF1) [14,21]. TCF4/LEF1 proteins cooperate with β-catenin to activate transcription of target genes including i.e. c-myc, cyclin D1, immunoglobulin transcription factor-2 (ITF-2), although many of the target genes remain unknown [22-24]. CD44V6 and ephrin receptors B2 and B3 (EphB2, EphB3) also function as potential TCF4/LEF1 target genes [25,26].

In carcinogenesis, β-catenin signaling, besides Wnt induced, can also be the result of increased β-catenin levels caused by impaired β-catenin degradation due to lack of phosphorylation of β-catenin. In several tumor types mutations at phosphorylation sites in β-catenin or inactivating mutations in APC or Axin leading to inhibition of β-catenin phosphorylation and decreased degradation have been described [27-30]. However, in GEJ adenocarcinomas very few inactivating mutations leading to β-catenin stabilisation have been identified in APC or Axin, neither β-catenin phosphorylation residue mutations were identified and therefore the mechanism of Wnt activation in these tumors remains unknown [4,31-33]. Interestingly, Staal and colleagues showed Wnt signals to be transduced via N-terminally dephosphorylated β-catenin using an antibody specific for β-catenin non-phosphorylated at residues Ser37 and Thr41 [34,35]. To obtain more insight in a possible role of Wnt activation in GEJ adenocarcinomas

we investigated by immunohistochemistry the expression of total-, phosphorylated- and non-phosphorylated β-catenin, the β-catenin signaling partners TCF4 and LEF1 and the Wnt target genes CD44V6 and EphB2 in a large series GEJ adenocarcinomas. The results were compared with clinicopathological data and survival.

MATERIALS AND METHODS

Patients and Tissue Samples

Routine formalin-fixed and paraffin-embedded tissues derived from 164 patients with an adenocarcinoma of the gastro-esophageal junction were retrieved from the files of the Department of Pathology, Erasmus MC, Rotterdam, The Netherlands. All patients (141 men; 23 women) had received transhiatal resection of the tumor with restoration of continuity of the gastrointestinal tract by a gastric tube with cervical anastomosis between 1987 and 2002. Patient's mean age at the time of diagnosis was 64.7 year (range 44-84 years). Adenocarinomas arising from distal esophagus or gastric cardia, i.e. the gastro-esophageal junction, were included. Tumors arising from the fundus or corpus of the stomach and infiltrating the gastric cardia or distal esophagus were excluded. Histological diagnosis and staging were established following the TNM proposed by the International Union Against Cancer according to standard criteria classification (TNM-stage I, n=15; TNM-stage II, n=41; TNM-stage III, n=86; TNM-stage IV, n=22). Every tumor was examined histologically for differentiation (well differentiated, n=9; moderately differentiated, n=73; poorly differentiated, n=82).

Antibodies and immunohistochemical staining

To detect the localization of β-catenin, phospho-β-catenin (Ser33/37/Thr41), phospho-β-catenin (Thr41/Ser45), LEF1, TCF4, CD44V6 and EphB2, antibodies were used as described in Table 3.1. To detect dephosphorylated β-catenin, a monoclonal antibody active β-catenin, which recognises β-catenin when Ser37 and Thr41 are both non-phosphorylated, was used, as described by Van Noort et al., from here referred to as 'active β-catenin' [35]. Four-μm thick paraffin sections were mounted on 3-aminopropyl-triethoxysilane (APES)-coated glass slides. Immunohistochemical staining was carried out by a standard avidin biotin immunoperoxidase technique, using a commercially available kit (Labvision, Fremont, USA). Deparaffinized sections were treated with methanol containing 3% H_2O_2 for 20 minutes. After washing with phosphate-buffered saline (PBS), blocking serum was applied for 5 minutes. Then, primary antibodies were allowed to react as described in Table 3.1. After washing in PBS, biotin-conjugated secondary antibody was applied for 10 minutes followed by peroxidase-marked streptavidin. After rinsing in PBS, peroxidase was visualized by diaminobenzidine hydrochloride (Fluka, Neu-Ulm, Germany) with 0.03% H_2O_2 solution for 10 minutes. The slides were then counterstained with Mayer's Haematoxylin and dehydrated in alcohol before mounting. Ex-

Table 3.1. Primary antibodies used

Antibody	Manufacturer	Working dilution, incubation time	Validation
β-catenin (m)	Transduction Laboratories, Lexington, KY, USA	1:200, 30 minutes RT	Ougolkov et al. [61], Koch et al. [43]

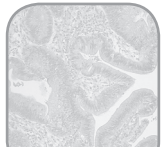
Ephrin B2 (m)	ITK Diagnostics, Uithoorn, The Netherlands	1:400, overnight 4°C	Battle et al. [52]

m: monoclonal antibody, p: polyclonal antibody, RT: room temperature



pression of antibodies was evaluated by highpower microscopic examination (400X) of the entire tissue section. As negative control we used normal mouse immunoglobulins and normal rabbit serum instead of the antibodies as described in Table 3.1. Normal gastric mucosas from the same resection specimens were used as internal positive controls.

Cell lines

As controls, sections of formalin fixed and paraffin embedded cultured cells were stained with β-catenin antibodies. In earlier experiments we performed a TCF/β-catenin reporter gene assay with pTOPGLOW and pFOPGLOW constructs [36]. Esophageal adenocarcinoma cell lines JROECL19 and JROECL33 showed 350- and 18-fold increase in transcriptional activity of the pTOPGLOW reporter as compared to the negative control pFOPGLOW. Esophageal adenocarcinoma cell lines SKGT-4, TE-7 and OACP4C showed no enhanced transcription of the pTOPGLOW reporter [36]. Sections of formalin fixed and paraffin embedded cultured cells were stained with β-catenin, phospho-β-catenin (Ser33/37/Thr41), phospho-β-catenin (Thr41/Ser45) and 'active β-catenin' antibodies. Moreover APC-mutant colon adenocarcinoma cell line SW480 with a 385-fold increase in transcriptional activity was immunohistochemically investigated.

Quantitation of immunostaining

Nuclear, cytoplasmic and membranous staining of antibodies was determined separately for each specimen. Concerning cytoplasmic and membranous staining, sections were considered negative when immunoreactive cells were absent and positive when immunoreactive cells, irrespective of the amount, were present. Nuclear expression levels of β-catenin, phospho-β-catenin (Thr41/Ser45), phospho-β-catenin (Ser33/37/Thr41), active β-catenin, LEF1, TCF4 and EphB2 were initially graded into 5 subgroups: (a) no detectable expression (0, negative); (b) expression detected in less than 10% of tumor cells (1+); expression detected in 10-30% of tumor cells (2+); expression detected in 30-80% of tumor cells (3+); expression detected in >80% of tumor cells (4+). Eventually, interpretation of staining score was defined as positive when >10% of tumor cells stained, and as negative when none or <10% of tumor cells stained.

Statistics

Significance testing for discrete variables was performed with the χ^2-test or the Fisher's exact test when appropriate. Reported P values are two-sided. $P<0.05$ was considered statistically significant. Follow-up was carried out until June 2003 for all patients. Survival rates were calculated according to the Kaplan-Meier method and differences in survival were assessed using the log rank test. Multivariate analysis using the Cox proportional hazards model was carried out to assess the independent prognostic significance of variables on overall survival.

RESULTS

Immunohistochemistry

Cell line JROECL19 (350-fold increase of transcriptional activity) expressed nuclear β-catenin, nuclear phospho-β-catenin (Thr41/Ser45) and nuclear active β-catenin, as did the APC mutant colon cancer cell line SW480 which served as a positive control (Table 3.2). Cell line JROECL33 (18-fold increase of transcriptional activity) showed nuclear β-catenin expression (weak) and nuclear phospho-β-catenin (Thr41/Ser45) expression (Table 3.2). Cell line OACP4C (no enhanced transcriptional activity) showed absence of nuclear β-catenin, nuclear phospho-β-catenin (Ser33/37/Thr41) and nuclear active β-catenin expression (Table 3.2).

Table 3.2. ß-catenin expression in GEJ adenocarcinoma-derived cell lines JROECL19, JROECL33, OACP4, TE7, KGT4 and in APC mutant colorectal cancer cell line SW480.

	ß-catenin	Phospho ß-catenin Ser33/37/Thr41	Phospho ß-catenin Thr41/Ser45[a]	Active ß-catenin
SW480 (APC mutation, signaling on[b])	+ nucleus + cytoplasm	- nucleus	+ nucleus	++ nucleus + cytoplasm
JROECL19 (signaling on[b])	+ nucleus + cytoplasm + membrane	- nucleus	+ nucleus	+/- nucleus
JROECL33 (signaling on[b], although weak)	+/- nucleus +/- cytoplasm +/- membrane	- nucleus	+ nucleus	- nucleus
OACP4 (signaling off[b])	- nucleus	- nucleus	No data	- nucleus
TE7 (signaling off[b])	No data	No data	No data	- nucleus + membrane
SKGT4 (signaling off[b])	No data	No data	No data	- nucleus + membrane

[a] Strongly expressed in dividing cells (M-phase of cell cycle); [b] Shown by a TCF/ ß-catenin reporter gene assay performed with pTOPGLOW and p FOPGLOW constructs in a former study (Koppert et al. [36])

Typical immunostaining patterns for the antibodies used are shown in Figure 3.1. In general, with all antibodies used we saw remarkable intratumor heterogeneity in staining. We noticed a very strong staining pattern of phospho-β-catenin (Thr41/Ser45) in mitotic cells (Figure 3.1G, H).

Using scoring criteria for nuclear staining as described in Materials and Methods, expression data are reported in Table 3.3. Fifty-eight out of 164 tumors (35%) expressed nuclear β-catenin in >10% of tumor cells. Nuclear β-catenin correlated positively with elevated cytoplasmic (p=0.04) and reduced membranous (p=0.001) β-catenin. Moreover, nuclear β-catenin correlated positively with elevated nuclear LEF1 expression (p=0.03, data not shown).

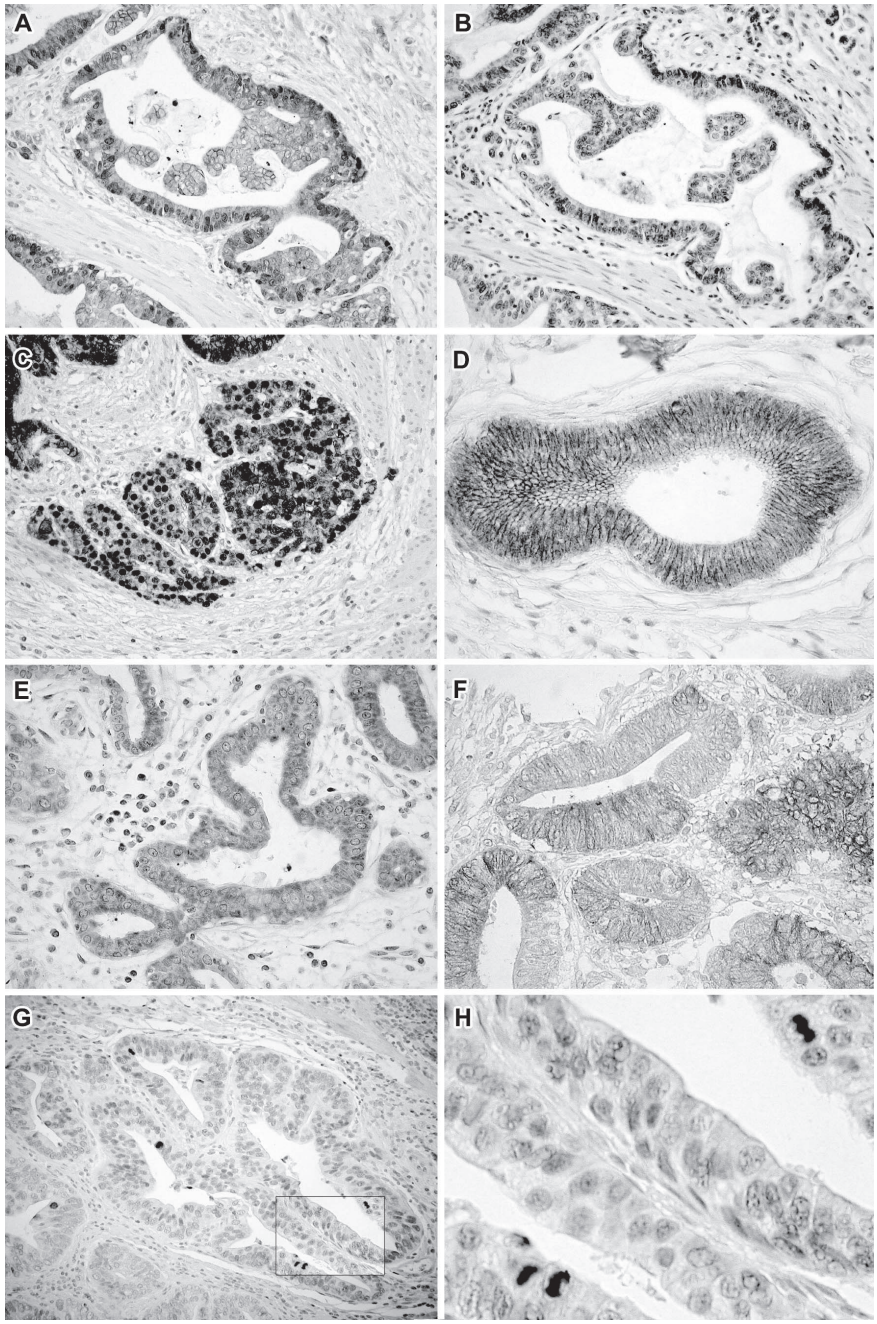


Figure 3.1. Immunohistochemistry of β-catenin in GEJ adenocarcinomas (Magnification x 200 (A., B., C., G.) and magnification x 400 (D., E., F., H.). A. Nuclear and cytoplasmic expression of β-catenin in the tumor cells. B. Nuclear active β-catenin staining in same GEJ tumor tissue as mentioned in A. C. Strong nuclear active β-catenin. D. Active β-catenin in membrane and cytoplasm of GEJ adenocarcinoma. E. EphB2 staining in cytoplasm of the tumor cells. F. Membranous EphB2 staining. G. Nuclear phospho β-catenin (Thr41/Ser45) with strong staining patterns in mitotic cells (insert H.). *Also see color figures page 291.*

Correlations with clinicopathological parameters and multivariate analysis

Absence of cytoplasmic LEF1 expression significantly correlated with unfavorable TNM stage (p=0.002, Table 3.3). Cytoplasmic EphB2 as well as membranous EphB2 expression significantly correlated with better tumor differentiation grade (p=0.04 and p=0.05 respectively, Table 3.3).

Survival Analysis

In univariate analysis, significantly better survival was shown for patients with membranous EphB2 staining as compared to patients without membranous EphB2 staining (p=0.04, Table 3.4, Figure 3.2). A significant better survival was also shown for patients with cytoplasmic EphB2 staining as compared to patients without cytoplasmic EphB2 staining (p=0.04, Table 3.4). These significant outcomes were not substantiated in multivariable analysis, with adjustments for age, gender, TNM stage and differentiation grade (Table 3.4). When patients with EphB2 cytoplasmic and/or membranous expression were pooled, EphB2 expression reached a Hazard Ratio of 0.6 (95% Confidence Interval 0.4-1.0, data not shown). Only TNM stage turned out to be an independent predictor of overall survival in multivariable Cox's proportional hazards analysis (p<0.001, Table 3.4).

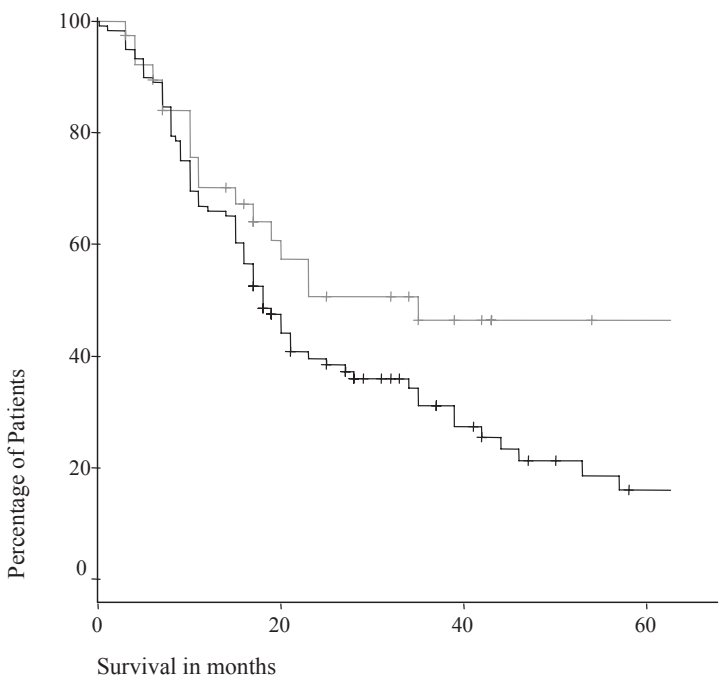

Figure 3.2. Overall survival of patients with membranous EphB2 staining (gray line n=39) versus patients with absence of membranous EphB2 staining (black line n=120), P logrank = 0.04. Five-year overall survival percentages were 46% and 16% respectively.

Table 3.4. Multivariable analysis of potential prognostic factors with overall survival in potentially curative resected GEJ adenocarcinomas. Multivariable analysis was performed using a Cox proportional hazards model.

Factor	Univariate 5-yr overall survival (%)	P-value	Hazard Ratio	95% Confidence Interval	P-value

[a] Age was included as a continous variable in the multivariable analysis. [b] Reference category.

DISCUSSION

Current models of Wnt signaling state that accumulation of nuclear β-catenin forms the key signaling event. In our series, 35% of GEJ adenocarcinomas (58/164) show nuclear β-catenin expression in >10% of tumor cells, being less than reported in literature [3-7]. This percentage increased to 56% when nuclear and/or cytoplasmic β-catenin expression was taken into account. Staal and collegues postulate that not the accumulation of β-catenin per se but the lack of phosphorylation at both Ser37 and Thr41 of this increased β-catenin forms the key signaling step [34]. They showed that Wnt signals are transduced via N-terminally dephosphorylated β-catenin using an antibody specific for β-catenin non-phosphorylated at residues Ser37 and Thr41 [34,35]. Only 16% of GEJ adenocarcinomas in our series express dephosphorylated β-catenin in >10% of tumor cells determined by the specific antibody for 'active' β-catenin which detects β-catenin when residues Ser37 and Thr41 are not phosphorylated both [35]. This percentage went up to 39 when nuclear and/or cytoplasmic expression was taken into account. According to the findings of Staal et al., this would imply that GEJ adenocarcinomas occasionally show activated Wnt signaling and that the conventional 'pan' β-catenin antibody does not represent the 'signal transducing' form of β-catenin.

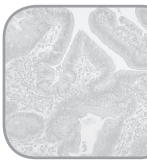
By using esophageal adenocarcinoma cell lines with available TCF reporter assay data, we aimed to affirm this assumption in an earlier study [36]. Nuclear β-catenin expression (as vi-

sualized by the conventional 'pan' β-catenin antibody) correlated with high TCF transcriptional activity (SW480, JROEC19, JROEC33). High TCF transcriptional activity in JROEC19 also correlated with nuclear 'active' β-catenin expression, though weak, as was the case in the control cell line SW480, known to have a homozygous inactivating APC mutation (Table 2). Also nuclear phospho-β-catenin (Thr41/Ser45) expression seemed to correlate with high TCF transcriptional activity in cell lines SW480, JROEC19, JROEC33. We hypothesize that casein kinase Iα still functions in these tumor cells, resulting in phosphorylation of β-catenin at position Ser45, but that these cells lack β-catenin phosphorylation by the GSK3β/APC/Axin complex, causing absence of phospho-β-catenin (Ser33/37/Thr41) expression. The immunohistochemical results in the colorectal cancer cell line SW480, with an inactive GSK3β/APC/Axin complex, support this assumption.

Notably, in 19 of 31 cases (61%) with nuclear phospho-β-catenin (Ser33/37/Thr41) none or less than 10% of tumor cells showed nuclear β-catenin, which could probably be due to antibody affinities. We could not establish an improved survival in patients with nuclear phospho-β-catenin (Ser33/37/Thr41), as reported in a large series of colorectal carcinoma patients [37]. Conversely, nuclear expression of phospho-β-catenin (Ser33/37/Thr41) in malignant melanomas has been described to correlate with poor outcome, lending evidence for differential behaviours in different tumors [38]. This could not be established in our series either.

To date only APC and β-catenin exon 3 mutation analysis in GEJ adenocarcinomas have been performed and very few mutations were found [4,7,31-33]. We investigated Axin1 mutations in all 10 exons in 17 GEJ adenocarcinomas with strong nuclear β-catenin expression and did not identify mutations [36]. Mutations in other components therefore should be considered, as well as activation of the canonical Wnt pathway or deregulated expression of pathway components responsible for Wnt pathway activation in these tumors [39,40]. A proper candidate for a mutation is β-transducing repeat-containing protein (β-TrCP), an F-box protein that is involved in β-catenin degradation. β-TrCP mutations are however rarely found in human tumors which are wild type for β-catenin and APC. β-TrCP mutations only have been described in two prostate cancer samples, of which one had nuclear β-catenin expression [41]. Despite the role of β-TrCP in β-catenin turnover, it is unlikely that β-TrCP might function as a tumor suppressor [42]. Within hepatoblastomas, increased expression of Wnt-inducible genes such as Axin2, Dkk-1, NKD-1 and β-TrCP was seen to be a common event [43]. These so called Wnt antagonists act as inhibitors of the Wnt pathway and their overexpression indicates Wnt pathway activation in hepatoblastomas, most likely because genetic alterations disrupt the multiprotein complex that controls β-catenin stability [43]. Epigenetic silencing of the phosphorylation complex might be another possibility for Wnt pathway activation. Methylation of APC has been described by Clément and colleagues during the neoplastic progression of Barrett's esophagus [44]. Additionally, it is possible that the Alzheimer's disease linked gene presenilin 1 (PS1) is deficient in these tumors. PS1 has been described as a negative regulator of the Wnt pathway [45]. Presinilin deficiency might reduce the pool of phospho-β-catenin

(Ser33/37/Thr41) available for ubiquitination by failing to target phospho-β-catenin (Ser45) for further phosphorylation and degradation [46]. Interestingly, Kang et al. also report extensive nuclear localization of phospho-β-catenin (Ser45) in tumors with either PS1 deficiency or activating β-catenin mutations and propose that Ser45-phosphorylated β-catenin might be signaling competent [46]. To our opinion rather the β-catenin mutation or PS1 deficiency than the presence of the phosphorylated protein seems responsible for Wnt-pathway activation in these tumors since phosphorylation means ubiquination and therefore degradation of β-catenin. In skin tumor tissues the absence of PS1 was associated with elevated nuclear β-catenin and upregulated β-catenin/LEF-dependent signaling [47].



We noticed a very strong staining pattern of phospho-β-catenin (Thr41/Ser45) in mitotic cells (Figure 3.1G, H). Interestingly, a third function of β-catenin, besides participation in cell-cell adhesion and Wnt-stimulated transcriptional activation, was recently described by Kaplan et al. [48]. They show evidence that β-catenin regulates the process of mitotic spindle formation by ensuring that components of the mitotic machinery are assembled in the correct place and at correct time for cell division to proceed efficiently [48].

The EphB2 receptor has a role in cell positioning in the intestine and has been described as a target gene of the β-catenin/TCF4 complex [26,49]. Moreover EphB2 is overexpressed in several human carcinomas, including tumors of the gastrointestinal tract, suggesting that this gene may indeed be involved in carcinogenesis [50,51]. Loss of EphB2 expression was recently described to be a critical step in colorectal cancer progression, including the onset of tumor invasion, dedifferentiation and metastasis [52,53]. Moreover EphB2 was identified as a prognostic factor in colorectal cancer with shorter mean duration of survival when EphB2 expression was lost [54]. Also in carcinomas of the small intestine and stomach EphB2 inactivation/downregulation may be relevant for tumor progression [55]. Loss of EphB2 membranous expression was also associated with poorer survival as well as with poorer tumor differentiation grade in our series. Since it is generally believed that localization on the cell membrane is necessary for the function of the ephrin receptor/ephrin system, cytoplasmic presence or absence of EphB2 is less likely to confer significance in tumor progression [51,56]. However, in our series cytoplasmic EphB2 staining was observed frequently, mostly apart from membranous EphB2 staining. And loss of cytoplasmic EphB2 staining was significantly correlated with poorer tumor differentiation grade as well as survival. Since membranous EphB2 is also expressed in the normal intestine, the observed better survival and tumor differentiation grade in patients with membranous expression could be the mere result of a proper functioning receptor instead of an activated Wnt pathway [52].

Cell surface glycoprotein CD44 expression is part of a genetic program controlled by the β-catenin/TCF4 signaling pathway and suggest a role for CD44 in the generation and turnover of epithelial cells [25]. CD44V6, a variant isoform of CD44, is considered to be implicated in carcinogenesis [57-59]. In Barrett's related adenocarcinoma CD44V6 expression is described to be correlated with aggressive pathological features [60]. In our series, 133 out of 163 tumors

had membranous CD44V6 expression, which was not correlated to either TNM-stage, tumor differentiation grade or patient survival. Membranous CD44V6 expression did not correlate with (any form, either phosphorylated or dephosphorylated) nuclear β-catenin expression. We therefore are not able to judge about a possible Wnt target gene function of CD44V6 in GEJ adenocarcinomas.

In summary, Wnt pathway activation, as classically represented by nuclear β-catenin expression, was present in 35% of our large series of GEJ adenocarcinomas. Moreover, since Wnt pathway activation might be caused exclusively by β-catenin which is dephosphorylated at Ser37 and Thr41, this pathway might be even far less important in GEJ adenocarcinomas than previously thought. However, immunohistochemical analysis of diverse contributors and targets of the Wnt pathway in a large series of GEJ adenocarcinomas showed loss of expression of the Wnt target gene EphB2 to be significantly correlated with worse survival and poor tumor differentiation grade.

ACKNOWLEDGMENTS

We would like to thank Paola Alberici for critical reading of the manuscript. We are grateful to Conny Vollebregt-Uiterwijk for kindly and dedicated assistance in collecting the data. We wish to thank Anke ter Brugge, Petra Lodder and Esther Hasper for technical assistance and Frank van der Panne for photographic work.

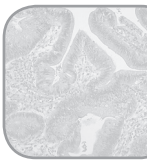
ABSTRACT

Up to 60% of gastro-esophageal junction (GEJ) adenocarcinomas show nuclear β-catenin expression, pointing to activated T-cell factor (TCF)/β-catenin driven gene transcription. We demonstrate in 5 human GEJ adenocarcinoma cell lines that nuclear β-catenin expression indeed correlates with enhanced TCF-mediated transcription of a reporter gene. In several tumor types, TCF/β-catenin activation is caused by mutations in either adenomatous polyposis coli (APC), β-catenin exon 3, AXIN1, AXIN2 or β-transducin repeat-containing protein (β-TrCP). In GEJ adenocarcinomas very few APC and β-catenin mutations have been found. Therefore the mechanism of Wnt pathway activation remains unclear. In the present study we did not find AXIN1 gene mutations in 17 GEJ tumors with nuclear β-catenin expression (without β-catenin exon 3 mutations). Six intragenic single nucleotide polymorphisms (SNPs) were identified. One of these, the AXIN1 gene T1942C SNP has a frequency of 21% but is only very recently described despite numerous AXIN1 gene mutational studies. We provide evidence why this SNP was missed in single strand conformation polymorphism (SSCP) analyses. The AXIN1 gene G2063A variation was previously described as a gene mutation but we demonstrate that this is a polymorphism. With these 6 SNPs loss of heterozygosity (LOH) was found in 11 of 15 (73%) informative tumors. To investigate a possible AXIN1 gene dosage effect in GEJ tumors expressing nuclear β-catenin, AXIN1 locus LOH was determined in 20 tumors expressing membranous and no nuclear β-catenin. LOH was found in 10 of 13 (77%) informative cases. AXIN1 protein immunohistochemistry revealed cytoplasmic expression in all tumors irrespective of the presence of AXIN1 locus LOH. These data indicate that nuclear β-catenin expression is indicative for activated Wnt signaling and that neither AXIN1 gene mutations nor AXIN1 locus LOH are involved in Wnt pathway activation in GEJ adenocarcinomas.

INTRODUCTION

The incidence of adenocarcinoma of the gastro-esophageal junction (GEJ), i.e. distal esophagus and gastric cardia, is rising in the Western world [1-3]. Patients with GEJ adenocarcinoma have a poor prognosis with 5-year survival rates of less than 25% [4]. Despite the common occurrence of this malignancy, relatively little is known about the molecular mechanisms underlying the genesis and the progression of these tumors.



Numerous studies focussed on cell-cell adhesion in GEJ adenocarcinomas since defective cell-cell adhesion is an important feature in epithelial tumor initiation and progression [5-10]. Aberrant expression of components of the E-cadherin-catenin complex, the prime mediator of epithelial cell-cell adhesion, has been found frequently in GEJ adenocarcinomas. In addition, E-cadherin-catenin complex aberrations appeared to have prognostic value in these tumors [11-16].

Recently, the E-cadherin-catenin complex component β-catenin has been demonstrated to play a dual role in the tumorigenic process [17-22]. β-Catenin, originally described to function in epithelial cell-cell adhesion, is implicated also in the Wnt signaling cascade as a transcriptional activator. In the absence of Wnt signals β-catenin is located at the plasma membrane, linked to E-cadherin, and functions in cell-cell adhesion. Excess cytoplasmic β-catenin is sequestered in a protein complex comprised of adenomatous polyposis coli (APC), glycogen synthase kinase 3β (GSK-3β) and AXIN1 or AXIN2. In this complex β-catenin is phosphorylated by GSK-3β and then targeted by β-transducin repeat-containing protein (β-TrCP) to proteasomal degradation. Activated Wnt signaling inhibits the phosphorylation of β-catenin, thereby preventing its degradation. The impaired β-catenin degradation leads to an increase in cytoplasmic β-catenin and its translocation to the nucleus. Nuclear β-catenin forms heterodimers with members of the T-cell factor (TCF) family of transcription factors and activates genes containing TCF-binding sites [19,20].

It has been demonstrated that β-catenin/TCF activated gene transcription can induce neoplastic transformation [23-25] and the β-catenin/TCF target genes comprise the oncogenes c-myc [26], cyclin D1 [27] and ITF-2 [23]. Impaired degradation of β-catenin in tumors has been reported to be caused by inactivating mutations in APC, AXIN1, AXIN2 or β-TrCP or oncogenic mutations in β-catenin exon 3 [5,19,20,28-33]. These mutations are in most cases mutually exclusive [28,29,31,34-36] .

Several studies have reported nuclear β-catenin expression in up to 60% of GEJ adenocarcinomas [11,12,15,16,37]. This nuclear expression of β-catenin can be regarded as an indication for activated, oncogenic, β-catenin/TCF transcription. However, mutation analysis of APC and β-catenin in GEJ adenocarcinomas revealed mutations in only less than 7 and 3% of cases respectively [12,38-40]. In accordance with these data, we recently did not find β-catenin exon 3 mutations in a series of 69 GEJ adenocarcinomas [37]. Inactivation of the AXIN1 gene has been demonstrated to induce β-catenin/TCF transcription and AXIN1 gene mutations have been described in hepatocellular carcinomas, hepatoblastomas, colorectal cancers, ovarian endo-

metrioid adenocarcinomas and in sporadic medulloblastomas [29,31,33,41-47]. In addition, reduced protein expression of AXIN1 has recently been reported to correlate with tumor progression in esophageal squamous cell carcinoma [48]. These results prompted us to search for genomic aberrations in the AXIN1 gene in GEJ adenocarcinomas. From the previously investigated series of 69 GEJ adenocarcinomas, 17 tumors with prominent nuclear β-catenin expression were selected for mutation and loss of heterozygosity (LOH) analysis. The entire coding region including the exon-intron boundaries of the AXIN1 gene was analysed for genetic alterations by single strand conformation polymorphism (SSCP) analysis. The presence of 6 intragenic single nucleotide polymorphisms (SNPs) was used to detect LOH. These 6 SNPs were also used to perform AXIN1 gene LOH analysis in 20 tumors with strong membranous β-catenin expression. In addition, AXIN1 protein expression was investigated by immunohistochemistry in all 37 tumor samples.

MATERIALS AND METHODS

TCF/β-catenin reporter gene assay

All cell lines, JROECL19, JROEL33, SKGT-4, TE-7, OACP4C and SW480 were cultured in RPMI 1640 supplemented with 10% fetal calf serum and antibiotics. Transcriptional activation mediated by TCF/β-catenin protein complexes was determined by transient transfection of the cell lines with either the pTOPGLOW or pFOPGLOW reporter constructs as described previously [49]. The pTOPGLOW and pFOPGLOW constructs contain a multimerized wildtype or mutant TCF binding motive, respectively, upstream of a luciferase gene. Cells were grown to 50-80% confluency in six-well plates and transfection was performed with 1μg of purified constructs each, using Fugene-6 (Boehringer, Mannheim, Germany). Transfection efficiencies were determined by cotransfection of a pRL-TK reporter construct (Promega, Madison, WI, USA) that contained the Renilla luciferase gene under control of the herpes simplex virus thymidine kinase promotor. Cells were harvested 24 h after transfection. Activity of both luciferases was measured sequentially in each sample using the Dual-Luciferase Reporter Assay System (Promega, Madison, WI, USA). TCF-mediated gene transcription was defined by the ratio of pTOPGLOW to pFOPGLOW luciferase activities. The luciferase activity of the internal control reporter was used to correct for differences in transfection efficiency.

Tumor and cell line DNA samples

In a previous study 69 GEJ adenocarcinoma samples, consisting of 54 primary tumors, 4 lymph node metastases, 9 xenografts and 2 in vitro cell lines were investigated for β-catenin expression and β-catenin exon 3 mutations [37]. From all cases tumor and normal DNA was isolated from frozen samples by standard proteinase K digestion and phenol/chloroform extraction. After β-catenin immunohistochemistry on 5μm paraffin sections parts of the tumor

with intense nuclear reactivity were isolated by microdissection from consecutive unstained sections. From the microdissected fragments DNA was isolated with standard proteinase K digestion followed by phenol/chloroform extraction and ethanol precipitation. No β-catenin exon 3 aberrations were found in these samples. For the present study the DNA from 17 tumors with strong nuclear β-catenin expression was used. Fifteen samples were originated from primary GEJ adenocarcinomas and 2 were from GEJ adenocarcinoma derived cell lines JROECL19 and JROECL33 [50]. In addition, the DNA's from 20 tumors with strong membranous β-catenin expression were investigated for LOH with the 6 SNPs. These 20 samples comprised 17 primary tumors and the established cell lines OACP4C, SKGT-4 and TE-7 [51-53]. Cell lines JROECL19 and 33 were obtained from the European Collection of Cell Cultures (ECACC, Wiltshire, United Kingdom), SKGT-4 and TE-7 were kind gifts from D. Schrump, NIH, Bethesda, USA and T. Kudo, Tohoku University, Sendai, Japan, respectively, OACP4C was established at our own institute. From cell lines JROECL19 and 33 patient's normal tissue was kindly provided by Dr. S.J. Darnton, Birmingham Heartlands Hospital, Birmingham, UK. From cell line OACP4C patient's normal tissue was obtained from our pathology archive and from cell lines SKGT-4 and TE-7 patient's normal tissue was not available. To determine SNP frequencies in the normal population we used DNA isolated from 161 healthy Caucasian blood donor volunteers.

Mutation analysis of the AXIN1 gene

The 17 pairs of tumor and normal DNA from tumors with nuclear β-catenin expression were screened for aberrations in the AXIN1 gene. The entire coding sequence, including the exon-intron boundaries was investigated by PCR-SSCP using the previously described 23 sets of primers with slight modifications [54]. All amplifications were performed in 15μL PCR containing 50-100ng DNA, 1.5mM $MgCl_2$, 0.02mM dATP, 0.2 mM dGTP, dCTP and dTTP each, 0.8μCi of [^{32}P]dATP (Amersham Biosciences, Buckinghamshire, UK), 20pmol of each primer and 0.3U AmpliTaq Gold polymerase (Perkin-Elmer Applied Biosystems, Foster City, CA, USA). AmpliTaq Gold polymerase was used because this enzyme is superior to other DNA polymerases with regard to amplification of DNA retrieved from routine formalin fixed and paraffin embedded tissues. To the PCRs with primer sets 4, 10, 12, 13, 14, 15, 18, 21 and 23 DMSO (5%) was added to increase the amplification efficiency. The PCRs were performed for 35 cycles of 95^{0}C for 30 sec, 55^{0}C (primer sets 10 and 14 at 58^{0}C and 60^{0}C, respectively) for 45 sec and 72^{0}C for 1 min. The PCR products were diluted 1:4 with loading buffer (95% formamide, 10mM EDTA, 0.05% bromophenol blue and 0.05% xylene cyanol), heated for 5 min, cooled on ice and electrophoresed in 6% polyacrylamide gels containing 10% glycerol at 7W overnight at room temperature, in 1x TBE running buffer. Gels were dried and exposed to X-ray films at –80^{0}C. Results were evaluated by visual inspection. With the used SSCP conditions the PCR products from primer sets 18, 19 and 21 resulted in simple banding patterns, inefficient for the detection of aberrations. To increase the DNA aberration detection efficiency these PCR products were electrophoresed without glycerol at 4^{0}C for 6 hours resulting in more complex

banding patterns. For each variant SSCP pattern identified by SSCP analysis, the genomic DNA samples were reamplified for bidirectional direct sequencing with the amplification primers. In 20 DNA samples from tumors with strong membranous β-catenin expression LOH was determined by SSCP analysis of 6 detected SNPs. These SNPs are at positions (according to GenBank accession no. AF009674) A94C, C874T, intron 4+17 G→A (nucleotide position identified from exon-intron boundary), G1396A, T1942C and G2063A. Amplification of these SNPs was performed with primer sets 1, 7, 11, 12 and 17, respectively.

β-catenin and AXIN1 immunohistochemistry

In all 37 tumor samples immunostaining for β-catenin and AXIN1 was performed on 5μm paraffin sections with a mouse anti-human β-catenin monoclonal antibody (Transduction Laboratories, Lexington, KY, USA; 1:200, 30 min, room temperature) [37] and a rabbit polyclonal anti-human AXIN1 antibody (Zymed Laboratories, San Francisco, CA, USA; 1:25, 30 min, room temperature), respectively. After deparaffinisation and treatment with methanol/H_2O_2, antigen retrieval was performed in citrate buffer for 15 min prior to incubation with the β-catenin antibody. No antigen retrieval was necessary for the AXIN1 immunohistochemistry. Immunoreactivity was made visible by a standard avidin biotin immunoperoxidase technique, using a commercially available kit (Labvision, Fremont, CA, USA) and diaminobenzidine hydrochloride (Fluka, Neu-Ulm, Germany). As negative controls normal mouse immunoglobulins and normal rabbit serum were used.

RESULTS

TCF/β-catenin reporter gene assay

The TCF/β-catenin reporter gene assay was performed with the pTOPGLOW and pFOPGLOW constructs. Cell lines JROECL19 and JROECL33, both with nuclear β-catenin expression (JROECL19, Figure 4.1c), showed 350- and 18-fold increase in transcriptional activity of the pTOPGLOW reporter as compared to the negative control pFOPGLOW (Figure 4.2). Cell lines SKGT-4, TE-7 and OACP4C, all with membranous β-catenin immunoreactivity (TE-7, Figure 4.1d), showed no enhanced transcription of the pTOPGLOW reporter (Figure 4.2).

Mutation analysis of the AXIN1 gene

SSCP analysis of the AXIN1 gene in 17 tumor/normal DNA pairs from tumors with strong nuclear β-catenin expression (Figure 4.1a, 4.1c) revealed 6 different aberration patterns. All these aberrations were also present in the corresponding normal DNA. Sequencing of the aberrant samples identified 6 different SNPs. These were at positions (according to GenBank accession no. AF009674) A94C, C874T, intron 4+17 G→A, G1396A, T1942C and G2063A (Figure 4.3).

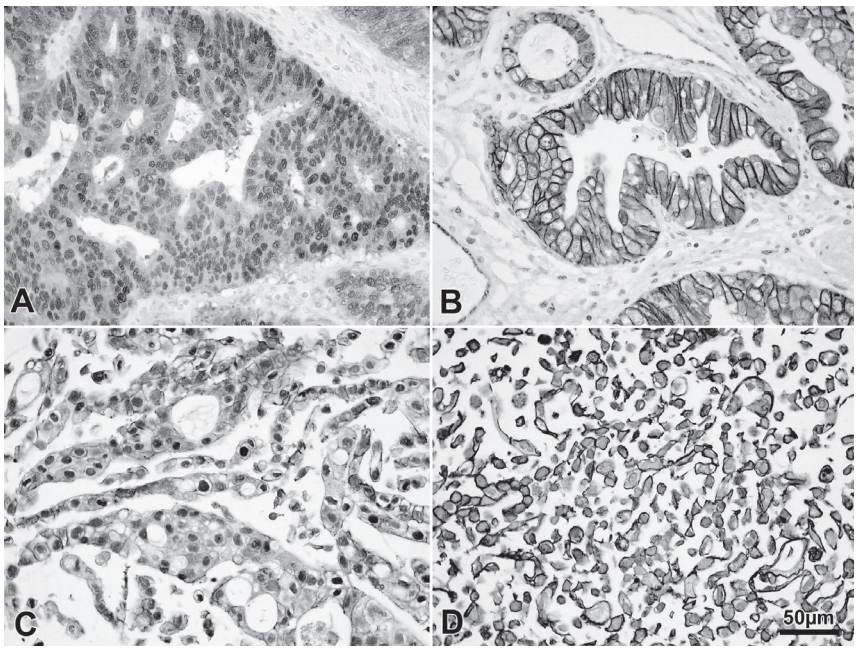


Figure 4.1 Immunohistochemistry of β-catenin in GEJ adenocarcinomas and cell lines. (β-catenin antibody, DAB and haematoxylin counterstain, magnification x 400). A. GEJ adenocarcinoma. Strong nuclear expression of β-catenin in the tumor cells. B. GEJ adenocarcinoma. Prominent membranous expression of β-catenin. C. Cell line JROECL19. Strong nuclear expression of β-catenin. D. Figure 4.2 TCF-mediated transcriptional activation in GEJ adenocarcinoma cell lines. Constitutive transcriptional activation was detected in cell line JROECL33 and JROECL19. APC mutant colorectal cancer cell line SW480 served as a positive control. TCF-mediated transcriptional activity was defined as the ratio of pTOPGLOW:pFOPGLOW luciferase activities, each corrected for pRL-TK luciferase activities and where no transactivation equals 1.

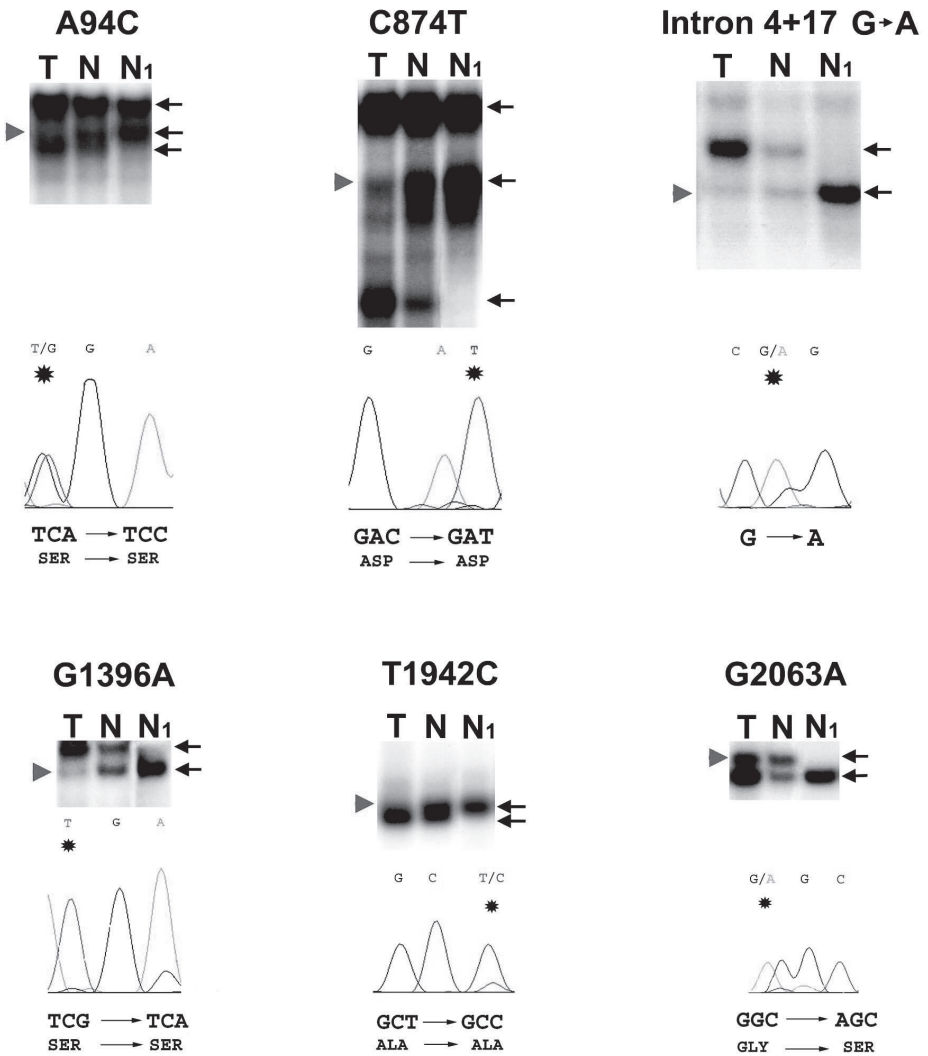

Figure 4.3 PCR-SSCP and sequencing analyses of the SNPs in tumors (T) and corresponding normal DNA (N), compared with DNA from individuals without SNPs (N1). Shown are informative cases with LOH. Black arrows point to allelic patterns. Red arrow heads point to deleted alleles in the tumor DNA. The sequencing chromatograms below each autoradiograph show the alterations (note the substituted nucleotide marked by an asterisk), which all represent SNPs. SNPs A94C and G1396A are annotated in the reverse complementary direction, whereas the SNPs C874, intron 4+17 G→A, T1942C and G2063A are annotated in forward direction. *Also see color figures page 291.*

ND (No Data)

Fifteen of the 17 cases appeared to be heterozygous for at least one polymorphism and LOH was observed in 11 (73%) cases (Table 4.1). The polymorphisms were used to investigate LOH in 20 GEJ adenocarcinoma cases with strong membranous β-catenin expression (Figure 4.1b, 4.1d). Also in this series all 6 polymorphisms were present and in 10 of 13 (77%) informative cases LOH was found (Table 4.2).

The T1942C and G2063A SNPs were found to have population frequencies of 21% and 3%, respectively (Tables 4.1 and 4.2). The relatively frequent SNP T1942C was only described very recently in two independent studies [46,47] and remained undetected in 10 AXIN1 gene mutation studies [29,31,43,44,48,54-58]. In most of these studies, as in ours, SSCP analyses were used. To determine whether the SSCP conditions have influence on the detection of the T1942C SNP we amplified DNA samples with AmpliTaq Gold and with Promega Taq DNA polymerases (Promega, Madison, WI, USA) in both AmpliTaq Gold and Promega Taq buffers. The AmpliTaq Gold buffer consists of 15 mM Tris-HCl (pH 8.0), 50 mM KCl and 1.5 mM $MgCl_2$ and the Promega buffer of 10 mM Tris-HCl (pH 9.0), 50 mM KCL, 1.5 mM $MgCl_2$ and 0.1%Triton X-100. As demonstrated in Figure 4 the T1942C SNP is only clearly visible after amplification with the AmpliTaq buffer.

β-catenin and AXIN1 immunohistochemistry

As mentioned before 37 GEJ adenocarcinoma samples were investigated, 17 with strong nuclear β-catenin expression and 20 cases with normal membranous reactivity (Figure 4.1). Eleven of the 15 (73%) informative cases with nuclear β-catenin expression and 10 of 13 (77%) informative cases with membranous β-catenin immunoreactivity showed loss of the AXIN1 gene locus. In all tumor samples AXIN1 protein expression was confined to the cytoplasm of the tumor cells exclusively (Figure 4.5). No consistent differences in AXIN1 protein expression were observed between tumors with and without AXIN1 locus loss, irrespective of nuclear or membranous β-catenin expression (Figure 4.5).

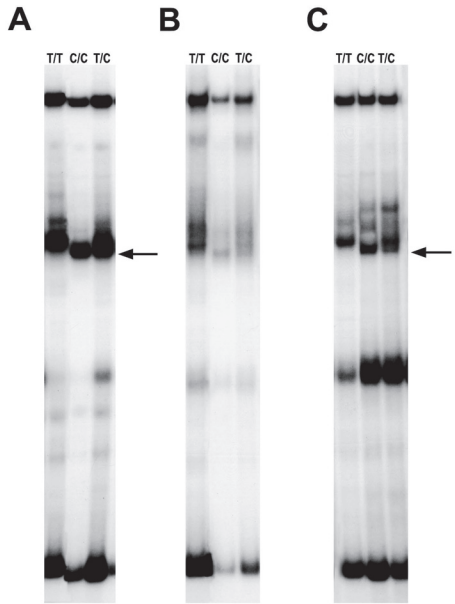

Figure 4.4 T1942C PCR-SSCP. Three DNA samples, 1942T/T (homozygous normal); 1942C/C (homozygous polymorphic); 1942T/C (heterozygous), were amplified with AmpliTaq Gold polymerase and AmpliTaq Gold buffer (panel A), Promega Taq and Promega buffer (panel B), Promega Taq and AmpliTaq Gold buffer (panel C) and with AmpliTaq Gold and Promega buffer (no PCR products obtained). All samples were amplified and SSCP-electrophoresed in the same experiment. Arrows point to the polymorphic SSCP fragment. Note that the polymorphic fragments are clearly visible only after amplification in AmpliTaq Gold buffer (panels A and C).

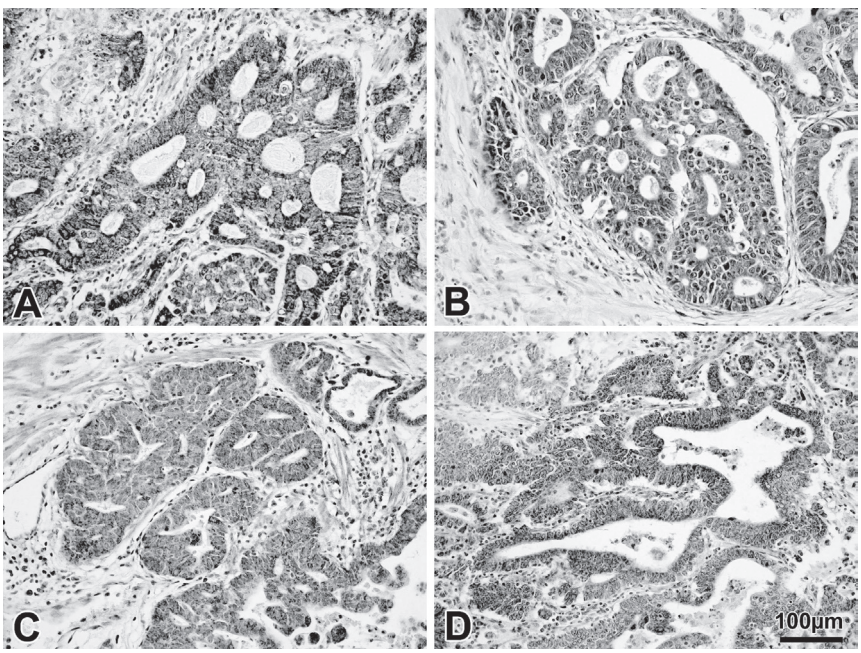

Figure 4.5 Immunohistochemistry of AXIN1 in GEJ adenocarcinomas. (AXIN1 antibody, DAB and haematoxylin counterstain, magnification x 200). A. and B. GEJ adenocarcinomas with nuclear β-catenin expression without (A.) and with (B.) AXIN1 locus LOH. C. and D. GEJ adenocarcinomas with membranous β-catenin expression without (C.) and with (D.) AXIN1 locus LOH. Note the strong cytoplasmic AXIN1 expression in the tumor cells in all 4 cases. *Also see color figures page 291.*

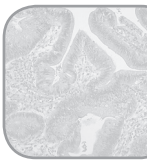
DISCUSSION

Nuclear β-catenin expression has been reported in up to 60% of GEJ adenocarcinomas [11,12,15,16,37]. In the present study we used the nuclear expression of β-catenin in GEJ adenocarcinomas as indication for activated Wnt signaling. This presupposition is substantiated by our finding of highly enhanced TCF-mediated transcriptional activity in the cell lines JROECL19 and JROECL33, both with nuclear β-catenin expression. None of the 3 cell lines without nuclear but with membranous β-catenin expression had increased transcription of the TOPGLOW reporter. Activated Wnt signaling in tumors is caused by increased levels of β-catenin which can be the result of mutations in APC, β-catenin, AXIN1, AXIN2 or β-TrCP [5,19,20,28-33]. To date only APC and β-catenin mutation analysis in GEJ adenocarcinomas has been performed and only few mutations were found [12,37-40]. Therefore, the mechanism of Wnt activation remains obscure in these tumors. These results prompted us to investigate GEJ adenocarcinoma samples with nuclear β-catenin expression for mutations in the AXIN1 gene. None of the tumors in the present study showed β-catenin exon 3 mutations [37]. In 17 GEJ adenocarcinoma samples no AXIN1 gene mutations were found. We therefore conclude that Wnt activation in GEJ tumors is not caused by AXIN1 gene mutations.

Six previously described polymorphisms in the AXIN1 gene were detected. All the detected DNA variations were also found in patients' constitutional DNAs indicating that they are truly polymorphisms and not somatic mutations. The G2063A SNP in exon 6 results in a substitution from glycine to serine. This polymorphism is described by Webster et al. [42] although these authors annotated the polymorphism to exon 7 and regarded it as a silent polymorphism. Furthermore, in a recent study by Taniguchi et al. [29] the G2063A polymorphism is found in one hepatocellular carcinoma and in one hepatoblastoma. Patients' normal tissues were not investigated and because the SNP was not found in their 147 control individuals they regarded it as an AXIN1 mutation. We found a G2063A allele frequency of 4% and 3% in GEJ adenocarcinoma patients and healthy controls, respectively, indicating that this AXIN1 gene variant is a SNP and not a mutation. In addition, we found a silent T1942C SNP (ala-ala) in exon 6 with an allele frequency of 18% and 21% in GEJ adenocarcinoma patients and healthy controls, respectively. This frequent SNP was only recently described, with comparable allele frequencies, in 2 independent studies [46,47] and remained undetected in 10 AXIN1 gene mutation investigations with in total 670 DNA samples [29,31,33,43,44,48,54,55,57,58]. We demonstrate that detection of the T1942C SNP by SSCP analysis is influenced by the PCR buffer characteristics. This finding suggests that also other SSCP parameters (gel composition, running buffer, running temperature, etc.) can have influence on the SNP detection.

The AXIN1 gene polymorphisms were used to determine LOH. Fifteen of 17 cases with nuclear β-catenin expression appeared to be heterozygous for at least one polymorphism and from these in 11 (73%) clear LOH was observed. This frequent loss of the AXIN1 gene could point to a dosage effect where the presence of 50% of the AXIN1 protein is insufficient

for proper β-catenin degradation and subsequently leads to Wnt-activation. To gather more information about this possibility we investigated AXIN1 gene LOH with the detected SNPs in a series of 20 tumors from our previous study with strong, normal membranous β-catenin expression. These included 3 cell lines (OACP4C, SKGT-4 and TE-7) without enhanced TCF-mediated transcriptional activity. In this series the T1942C and G2063A SNPs were detected in 4 and 2 samples, respectively. Thirteen cases were informative and in 10 (77%) clear LOH was observed.



By AXIN1 immunohistochemistry no differences were observed between tumors with and without AXIN1 locus loss. It's known that with the semiquantitative immunohistochemical method a twofold reduction in protein expression cannot be detected. In esophageal squamous cell carcinoma reduced protein and RNA expression has recently been described by Nakajima et al. [48]. These investigators suggest AXIN1 gene silencing by promotor methylation, in addition to allelic losses, as mechanism for AXIN1 downregulation. Our immunohistochemical results indicate that AXIN1 gene silencing does not occur in GEJ adenocarcinomas.

All the above-mentioned results indicate that AXIN1 gene haplo-insufficiency is not sufficient for Wnt-activation. This is in accordance with studies that demonstrated bi-allelic inactivation of the AXIN1 gene in several tumor types [29,31,33,41], although heterozygous AXIN1 gene inactivation has also been described [42,45]. Chromosome 16p loss has been reported in up to 40% in GEJ adenocarcinomas [59] and the presence of a tumor suppressor gene on 16p13.3 has been suggested by Takamochi et al. [60]. The frequent AXIN1 locus LOH in our study could point to a gene dosage effect independent of Wnt pathway activation. Furthermore, it cannot be excluded that an as yet to be defined tumor suppressor gene on 16p13.3 is the actual target for LOH in GEJ adenocarcinomas.

Since mutations in APC, β-catenin and AXIN1 do not play a major role in the frequent TCF/β-catenin activation in GEJ adenocarcinomas other components should be considered. AXIN2 gene mutations have been described in 11 colorectal cancers [32], one endometrioid ovarian adenocarcinoma [44] and two hepatocellular carcinomas [29]. Twelve of these 14 tumor samples had nuclear β-catenin expression indicating activated Wnt signaling. The AXIN2 gene mutations appear to be present exclusively in tumors with a microsatellite instable phenotype since all AXIN2 mutant colorectal carcinomas and the ovarian endometrioid adenocarcinoma were microsatellite instable [29,44]. The AXIN2 gene is an improbable candidate for Wnt activation in GEJ adenocarcinomas because microsatellite instability has been described in only less than 6% in these tumors [37,61]. Another candidate is β-TrCP, involved in β-catenin degradation. Recently, β-TrCP mutations have been described in two prostate cancer samples, of which one had nuclear β-catenin expression [28].

Activated Wnt signaling can also be the result of activation of the canonical Wnt pathway by secreted Wnts or by expression of the Wnt receptors frizzled [62,63]. In cell line cultures this would imply the presence of an autocrine Wnt/frizzled loop. Furthermore, tumor necrosis factor-α has recently been demonstrated to induce TCF/β-catenin mediated transcription in

a GEJ adenocarcinoma cell line [64]. These findings indicate that next to mutational activation of the Wnt pathway, gene expression alterations should be considered also as driving force behind Wnt activation in GEJ adenocarcinomas.

In summary, our results demonstrate that nuclear β-catenin expression in GEJ adenocarcinoma cell lines correlates with TCF-mediated transcription activation and so with activated Wnt signaling. The frequent nuclear localization of β-catenin in GEJ adenocarcinomas cannot be attributed by AXIN1 gene mutations. The mechanism of Wnt activation in these tumors remains to be established. In addition, the role of the frequent LOH of the AXIN1 locus in GEJ adenocarcinomas deserves further investigation.

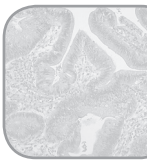
ABSTRACT

A recent evaluation by comparative genomic hybridization (CGH) demonstrated chromosome 14q31-32.1 to be frequently deleted in adenocarcinomas of the gastro-esophageal junction (GEJ). This suggests the presence of a tumor suppressor gene in the deleted region. In the present study we have performed a detailed loss of heterozygosity (LOH) analysis in 34 GEJ adenocarcinomas and one tumor-corresponding dysplastic Barrett's epithelium sample with 37 polymorphic microsatellite markers. Thirty-five markers are in the 14q24.3-32.33 region with a mean distance of 800 kilo base pairs. Fourteen of 34 tumor samples (41%) showed loss of 14q markers. We identified a minimal region of allelic loss of 7,105,440 base pairs between markers D14S1000 and D14S256 at cytogenetic location 14q31.1-32.11. Within this region markers D14S1035, D14S55, D14S1037, D14S1022, D14S1052, D14S974, D14S73, D14S1033, D14S67, D14S68 and D14S1058 showed loss in all informative tumors with 14q loss. The region between markers D14S1000 and D14S256 contains 7 known genes. The identification of this minimal deletion and the data base information on the genes present in this region facilitate the search for the candidate tumor suppressor gene(s).

INTRODUCTION

Adenocarcinomas arising from the lower esophagus or the gastric cardia are commonly referred to as adenocarcinoma of the gastro-esophageal junction (GEJ). As such, they can be regarded as a single entity [1,2]. These tumors have shown a rapid increase in incidence over the past decades [1,3]. The most important risk factor is gastro-esophageal reflux leading to the replacement of the normal stratified squamous epithelium by columnar epithelium. This condition is known as Barrett's esophagus. The prognosis for patients with adenocarcinoma of the GEJ is poor. Five-year survival after surgery with curative intent is approximately 20-25% [4,5]. Little is known about the genetic alterations involved in the progression of Barrett's epithelium towards dysplasia and invasive adenocarcinoma.



Recently, we and others identified chromosomal aberrations in GEJ tumors by comparative genomic hybridisation (CGH) [6,8]. Loss of chromosome 14q31-32.1 was detected in a significant number of cases, suggesting the presence of a tumor suppressor gene in that region [6]. Deletion of part of chromosome 14 has also been reported in other malignancies such as colorectal carcinoma [9,12], adenocarcinoma of the stomach [13,14], gastrointestinal tract stromal cell tumors [15], ovarian [16], bladder [17], pancreaticobiliary [18], breast [19], head and neck [20,21], renal cell carcinoma [22,23], malignant mesothelioma [24], neuroblastoma [25], meningioma [26], esophageal squamous cell carcinoma [27] and oligodendroglial and astrocytic tumors [28].

The goal of the present study was to define the common region of chromosome 14q31-32.1 loss in GEJ adenocarcinoma in more detail by loss of heterozygosity (LOH) analysis using 37 polymorphic microsatellite markers. From 34 patients 15 primary tumors, 15 xenografts from 10 primary tumors and 5 lymph node metastases, and 4 in vitro GEJ adenocarcinoma cell lines were used. From one patient in addition to a cell line derived from the primary tumor, a cell line established from a lymph node metastasis was investigated. Furthermore, from one patient the primary tumor and the dysplastic epithelium adjacent to the tumor were investigated. The xenografts and cell lines facilitate detection of homozygous deletions.

MATERIALS AND METHODS

Patients

We analyzed 36 tissue samples from 34 patients. All patients were diagnosed with adenocarcinoma of the gastro-esophageal junction, *i.e.* distal esophagus or the gastric cardia, and underwent transhiatal resection of the esophagus and the proximal stomach with curative intent as described [2].

Tumor samples: frozen tumor tissue, xenografts and cell lines

The tissue samples were obtained from the resection specimens and used according to the Code of Proper Secondary Use of Human Tissue in the Netherlands established by the Dutch Federation of Medical Scientific Societies (http://www.fmwv.nl/gedragcodes/goedgebruik/CodeProperSecondaryUseOfHumanTissue.pdf). Immediately after surgery small pieces of tumor, dysplasia and adjacent normal mucosa were taken, snap frozen and stored in liquid nitrogen until further analysis. Specimens included 15 primary tumors (coded Ba) and one dysplastic epithelium sample (Ba10d) adjacent to an adenocarcinoma, 10 primary tumor nude mouse xenografts (with code P-X), 5 xenografts from lymph node metastases (with code M-X) and 5 in vitro cell lines [29,30] (Figure 5.1). All xenografts were used in the first or second passage. Two of the in vitro cell lines are derived from a primary tumor (P4C) and a lymph node metastasis (M4C) from the same patient. Two human cell lines JROECL19 and -33, established by Rockett et al [30] were obtained from the European Collection of Animal Cell Cultures (ECACC) and 3 cell lines (P4C, M4C and M5C) were established in our laboratory [29]. Sixteen of the used tumors were previously investigated by CGH [6]. Eight samples showed 14q loss in the CGH study and all these 8 demonstrated 14q LOH. Of the 8 tumors with no 14q loss in CGH, two demonstrated partial 14q LOH. The remaining 6 tumors without CGH 14q loss did also not show 14q LOH. In our investigated cases there is a generally good concordance between 14q CGH and LOH results, with LOH analysis somewhat more sensitive in detecting DNA loss, as expected.

DNA extraction

DNA from cell lines was isolated according to standard procedures. Genomic DNA from xenografts and tumor samples was isolated from consecutive 5 μm cryostat tissue sections by overnight proteinase K digestion at 55 °C followed by phenol extraction and ethanol precipitation. DNA pellets were dissolved in TE (10 mM Tris/HCl pH 7.8; 1 mM EDTA). From the tumor and dysplastic tissue cryostat sections were microdissected to obtain tissue fragments containing at least 75% neoplastic cells. From all tumors and xenografts corresponding normal DNA was isolated from frozen normal lymph node, normal esophagus or normal stomach tissue. From cell lines JROECL19 and -33 corresponding normal DNA was isolated from formalin fixed and paraffin embedded normal tissue (kind gift of Dr. S.J. Darnton). From the in vitro cell lines P4C/M4C and from the xenografts M53X1, P35X1, M30X1 and M55X1 corresponding primary tumor DNA was isolated after microdissection of cryostat sections. Normal mouse DNA, isolated from mouse liver, was used as negative control for the xenograft samples.

Microsatellite marker selection

Thirty-seven polymorphic microsatellite markers with a high degree of heterozygosity were originally selected from the Généthon human genetic linkage map [31], from The Genome Database (http://www.gdb.org) and from the published complete chromosome 14 sequence

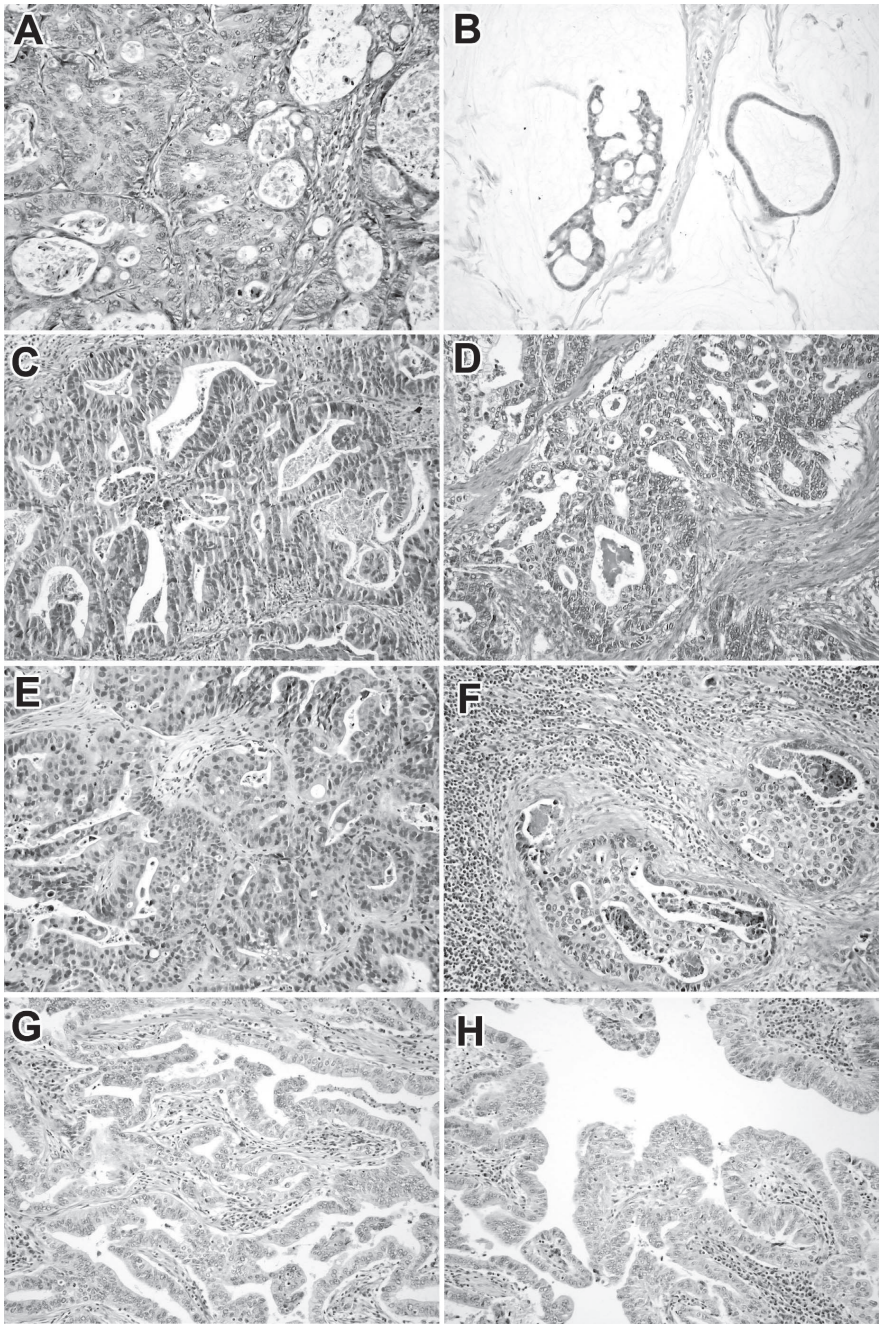


Figure 5.1 Histology (H&E stained sections) of investigated tumors. A: adenocarcinoma of the gastric cardia with 14q LOH (Ba7). B: adenocarcinoma of the gastro-esophageal junction without 14q LOH (Ba1). C and D: primary tumor derived xenograft P35X1 (C) and corresponding primary tumor (D). Note comparable tumor histology. E and F: lymphnode metastasis derived xenograft M55X1 (E) and corresponding lymphnode metastasis (F). Note comparable tumor histology. G and H: esophageal adenocarcinoma (G, Ba10) and from the same patient dysplastic Barrett's epithelium (H, Ba10d). Original magnifications x200.

(http://www.genoscope.cns.fr) [32]. The exact position of the markers was retrieved from the UCSC database (http://genome.ucsc.edu/; freeze May 2004, Build 35) [33]. Thirty-five markers are located in the region 14q24.1-32.33, spanning the region 14q31-32.1, and 2 markers are at 14q11.2. All 37 markers are CA/TG dinucleotide repeats and their location is indicated by the position of the first nucleotide of the CA/TG repeat (C or T) in the chromosome 14 sequence (http://genome.ucsc.edu/; freeze May 2004, Build 35; Figure 5.2). In the 14q24.1-32.33 region the marker distance varies between 13.7 kb (kilo base pairs; markers D14S250 and D14S78; Figure 5.2) and 2,157 kb (markers D14S985 and D14S293; Figure 5.2). We used the primers from the database for marker amplification, except for marker CCC1 for which we used the primers: 5'-GGCAGTTAAGAAGACACAGC-3' and 5'-GCCATAAGCCTGAAGATTGG-3'.

PCR amplification

PCR amplification was performed in a 15 μl reaction volume containing 0.1 μg of genomic DNA, 0.2 mM dCTP, 0.2 mM dGTP, 0.2 mM dTTP, 0.02 mM dATP and 0.8 μCi α-^{32}P-dATP (Amersham, Buckinghamshire, UK), 20 pmol of each primer, 0.4 U Taq polymerase (Promega, Madison, WI, USA) and 2-4 mM $MgCl_2$. Amplification proceeded during 35 cycles in a Biometra thermal cycler (Biometra, Göttingen, Germany) with the following parameters: denaturing at 95°C for 30 sec, annealing at either 50°C or 55°C for 45 sec and extension at 72°C for 60 sec. Reactions concluded with a final extension at 72°C for 10 min.

Electrophoresis and interpretation of loss of heterozygosity (LOH)

Just prior to gel electrophoresis 5 μl of the PCR amplification products were diluted with 5 μl of loading buffer (95% formamide, 10 mM EDTA, 0.025% bromophenol blue, 0.025% xylene cyanol, pH 8.0). Then the PCR products were denatured at 95°C for 5 min and loaded onto adjacent lanes of a 6% denaturing polyacrylamide gel containing 42% ureum. Electrophoresis was performed at 65 W for 2 to 3 hrs, depending on the size of the amplified DNA fragment. Gels were dried and exposed to X-ray films.

The signals derived from tumor and corresponding normal DNA were compared by visual inspection, independently performed by at least three investigators (W.N.M.D., D.A.D., M.A., H.F.B.M. and B.P.L.W.). DNA samples with controversial results were reamplified and in a number of cases we isolated and amplified DNA from a seperate part of the tumor. A case was classified as informative and having undergone allelic loss (LOH), informative and no LOH, not informative, or as having undergone an allelic shift (microsatellite instability, MSI).

RESULTS

From 34 patients 35 tumor samples and one dysplastic Barrett's epithelium were analyzed for LOH using 37 polymorphic microsatellite markers. Thirty-five markers cover chromosome

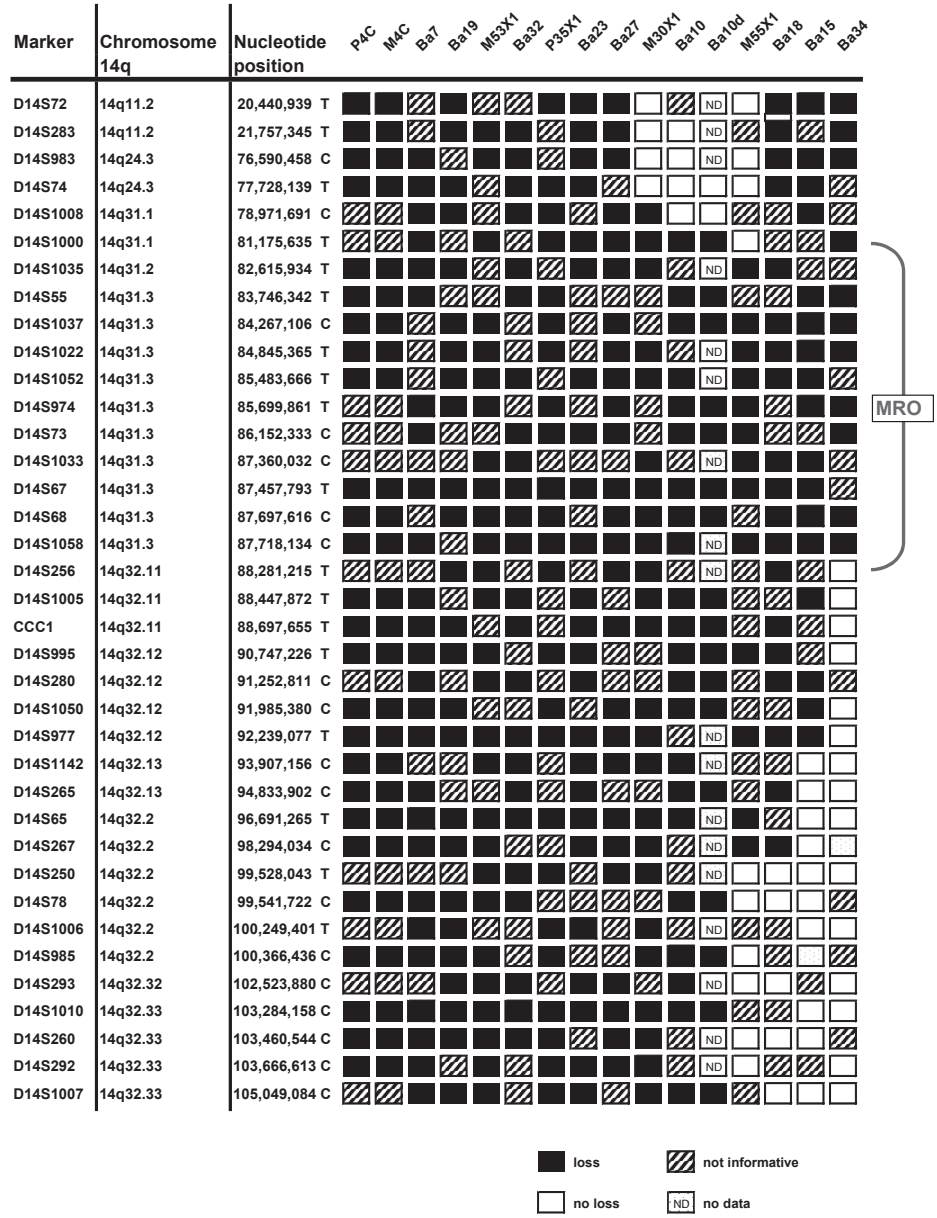

Figure 5.2 Chromosome 14 LOH results. All samples with loss of 14q markers are shown. P4C and M4C are in vitro cell lines from a primary tumor and a metastasis, respectively, from the same patient. P35X1 is a xenograft from a primary tumor and M30X1, M53X1 and M55X1 are xenografts from metastases. The Ba numbers are primary tumors and Ba10d is the dysplastic epithelium sample belonging to primary tumor Ba10. Nucleotide positions from the first nucleotide (C or T) of the CA or TG repeats are indicated by the position of the first nucleotide of the CA/TG repeat (C or T) in the chromosome 14 sequence (http://genome.ucsc.edu/; freeze May 2004, Build 35) [33]. White squares: no loss; black squares: loss; striped squares: not informative; ND: no data. The solid bar indicates the minimal region of overlapping deletion (MRO).

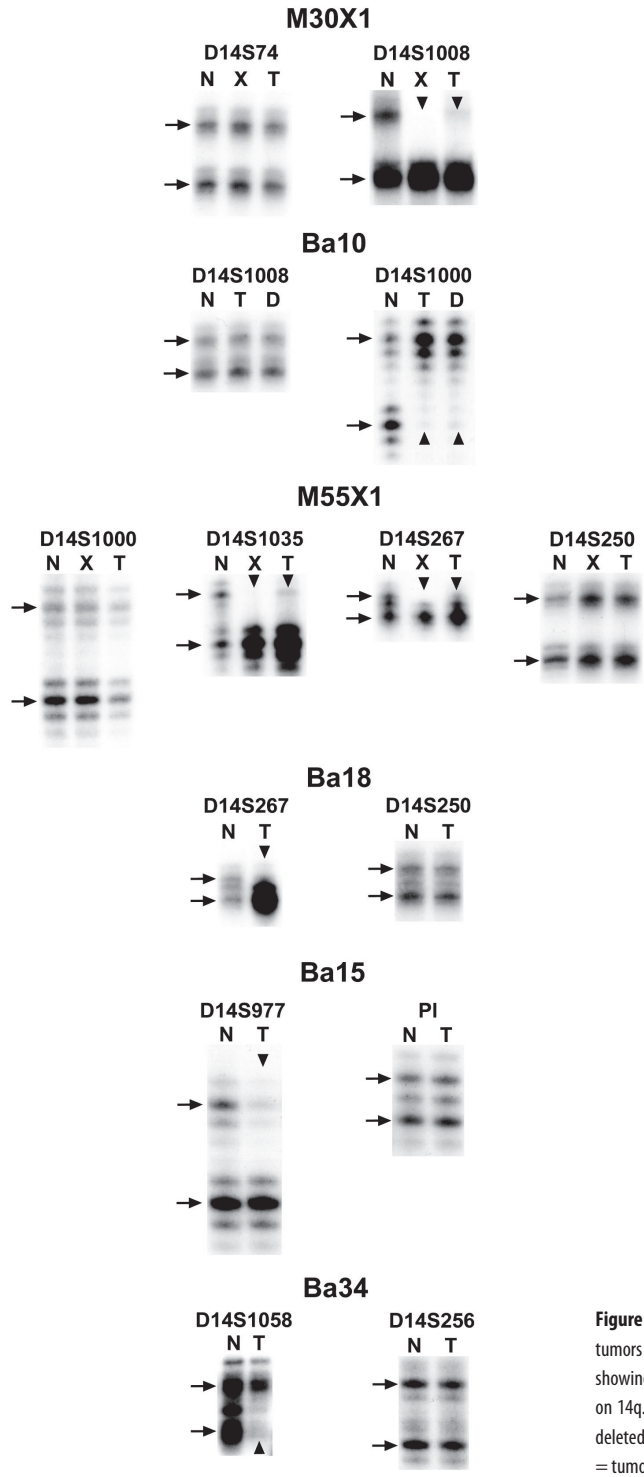

Figure 5.3 Autoradiograms from 6 representative tumors (M30X1, Ba10, M55X1, Ba18, Ba15 and Ba34) showing allelic band patterns from critical markers on 14q. Arrows indicate alleles; arrowheads point to deleted allele. N = normal DNA, X = xenograft DNA, T = tumor DNA and D = Barrett's dysplasia DNA.

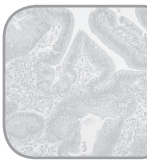
region 14q24.3-14q32.33. The relevant results are summarized in Figure 5.2. We regard cell lines P4C and M4C as one sample since they are derived from the same patient and since they showed identical results. No LOH was found in 18 tumors and 2 tumors showed widespread MSI. LOH of 14q was observed in 14 of 34 tumors (41%). Eight tumors (P4C/M4C, Ba7, Ba19, M53X1, Ba32, P35X1, Ba23 and Ba27) showed loss of all informative markers for the entire region 14q11-qter. In 6 tumors both loss and retention of heterozygosity was seen at informative markers. These patterns were used for defining the minimal region of overlapping deletion (MRO). With all xenograft and cell line DNA samples PCR products were obtained with all markers. Seven markers amplified also normal mouse DNA, but with a significant size difference from human DNA. The corresponding primary tumors from cell lines P4C and M4C and from xenografts M53X1, P35X1, M30X1 and M55X1 were investigated with the boundary determining markers D14S72, D14S74, D14S1008, D14S1000, D14S1035, D14S267, D14S250 and D14S292. The cell lines and xenografts and their corresponding primary tumors showed the same LOH pattern in all cases (Figure 5.3).



We defined a region of loss which was proximally bounded by marker D14S1000 and distally by marker D14S256, the size being maximally 7,105,440 base pairs (determined from the position of the first base down stream of the reverse D14S1000 primer (81, 175, 728) and the last base up stream of the forward D14S256 primer (88, 281, 168) (base positions from the 14q sequence at http://genome.ucsc.edu/; freeze May 2004, Build 35). Informative LOH results are shown in Figure 5.3. Xenograft M55X1, with an interstitial deletion, was critical for defining the centromeric boundary, whereas tumor Ba34 defined the telomeric boundary. This region has been cytogenetically assigned to 14q31.1-32.11 and it was deleted in all tumors that showed loss of 14q markers. Deletion of D14S1035, D14S55, D14S1037, D14S1022, D14S1052, D14S974, D14S73, D14S1033, D14S67, D14S68 and D14S1058 was found in all informative tumors with 14q loss. There was no correlation between LOH on 14q and the location of the tumor (esophagus or gastric cardia). GEJ tumors with 14q loss tended to have a higher tumor stage and more frequently distant metastases as compared to the tumors without 14q loss (χ^2 test $p = 0.13$ and $p = 0.076$, respectively).

DISCUSSION

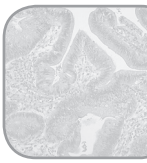
In this study we confirmed our previous finding that allelic loss on chromosome 14q31-32.1 occurs in more than 40% of all GEJ adenocarcinomas [6]. This strongly suggests that this region contains one or more tumor suppressor genes involved in GEJ tumorigenesis. Furthermore, we identified the commonly deleted region of allelic loss. This is located at cytogenetic location 14q31.1-32.11 between markers D14S1000 and marker D14S256, with a size of about 7.1 Mb. In the 15 xenografts and 5 cell lines we did not detect homozygous deletions, since with all markers tested PCR products were obtained. Two cell lines (from one patient) and 4 xeno-

grafts (1 from a primary tumor and 3 from metastases) showed 14q LOH. The corresponding primary tumors showed the same LOH patterns indicating that 14q LOH was not an ex vivo artefact.

Genome-wide allelic loss analysis in colorectal carcinomas reported an overall mean LOH frequency of about 20% which is regarded as non specific, "background", allelic loss [34,35]. The finding of more than 40% 14q311-32.11 allelic loss in adenocarcinomas of the GEJ points to possible involvement of this region in the genesis of these tumors. Furthermore, loss of 14q31-32 has been reported in several other carcinomas like colorectal adenocarcinoma [9-12], adenocarcinoma of the stomach [13,14], ovarian carcinoma [16], bladder carcinoma [17], pancreaticobiliary [18], breast [19] and head and neck carcinoma [20,21] and renal cell carcinoma [22,23]. Loss of 14q was reported to correlate with early age of onset, advanced stage, high grade and poor outcome of the disease [9,11,12,17,20-2]. In our series we also found a trend that loss of 14q is more common in advanced stage tumors and in tumors with distant metastases. These findings indicate that inactivation of the putative 14q31-32 tumor suppressor gene is involved in disease progression. Furthermore, in concordance with this is our finding of no 14q loss (with markers D14S1035, D14S1037, D14S1052, D14S67 and D14S1058) in 11 Barrett's dysplasia samples, including 6 high grades (data not shown). However, the 14q loss found in tumor Ba10 was also detected in the tumor-adjacent dysplastic Barrett's epithelium (Ba10d, Figures 5.2 and 5.3).

To our knowledge no clear candidate 14q31.1-32.11 tumor suppressor genes have been found to date. Seven known genes are present in the region between D14S1000 and D14S256 (derived from: http://genome.ucsc.edu/; freeze May 2004, Build 35) [33]. From centromeric to telomeric these are: fibronectin leucine rich transmembrane protein 2 (FLRT2), galactosylceramidase (GALC), G-protein-coupled receptor 65 (GPR65) or T-cell death-associated protein 8 (TDAG8), potassium channel subfamily K member 10 (KCNK10), spermatogenesis associated 7 (SPATA7), protein tyrosine phosphatase non receptor type 21 (PTPN21) and echinoderm microtubule associated protein like 5 (EML5 or EMAP-2). From current literature data it can be deduced that 3 of the genes have potential as tumor suppressor genes. The function of FLRT2 has been suggested to be in cell adhesion [36] and as such this protein could have a tumor suppressor activity. However, recently evidence has been obtained that FLRT2 has potential as an oncogene as the protein is involved in fibroblast growth factor (FGF) signaling [37]. GPR65/TDAG8 was originally described to function in activation-induced T-cell death [38]. However, recently GPR65/TDAG8 has been found to have oncogenic capacity and the protein is over-expressed in several human cancers [39]. PTPN21 is a tyrosine phosphatase and recently inactivating mutations in PTPN family members have been described in colorectal cancer although no mutations were found in PTPN21 [40]. From the other identified 14q31.1-32.11 genes GALC, KCNK10, SPATA7 and EML5/EMAP-2 no tumor suppressor function is known to date.

The relevance of all the abovementioned genes in GEJ adenocarcinogenesis has to be determined. In addition, it cannot be excluded that the region between markers D14S1000 and D14S256 contains other tumor suppressor genes yet to be discovered. Despite our data, it is also possible that the 14q GEJ adenocarcinoma tumor suppressor gene(s) reside outside the detected MRO. And finally it should be recognized that even frequent loss of a certain chromosomal region can be a bystander phenomenon and not causally related to the tumorigenic process.



In our previous CGH study we found that 14q loss occurred significantly more frequent in esophageal adenocarcinomas than in gastric cardia tumors [6]. In the present study this relationship was not confirmed. Also in a larger CGH study (van Dekken, unpublished results) and in a microsatellite study no relation was found between the location of the tumor and loss of 14q [41]. Besides phenotypical similarities, adenocarcinomas of the esophagus and gastric cardia apparently also have similar genotypes, as suggested by others [42,43].

In conclusion, our study has contributed to unravelling the complex molecular alterations present in adenocarcinomas of the GEJ. We have comprehensively mapped the deletions of chromosome 14q that were previously demonstrated in this disease. The reliability of our findings has been greatly enhanced by the use of xenografts and in vitro cell cultures. We have determined an overlapping region of LOH, possibly harboring a GEJ adenocarcinoma suppressor gene. This result in combination with the available data base information on the genes present in this region can facilitate the identification of the candidate tumor suppressor gene(s).

ABSTRACT

We estimated the prevalence and prognostic significance of neuroendocrine (NE) cells in a series of 208 resection specimens containing gastro-esophageal junction (GEJ) adenocarcinomas, with 56 specimens containing Barrett's mucosa. Immunohistochemically, chromogranin A (CGA) was positive in 49% (102/208) of GEJ adenocarcinomas and in 68% (38/56) of Barrett's mucosas. CGA in GEJ tumors correlated with pTNM stage. CGA in Barrett correlated with pTNM stage and tumor grade of the adjacent carcinoma. Patients with CGA in Barrett had better survival than patients without CGA in Barrett, with 5-year survival percentages of 56% and 9% respectively. In multivariate analysis, CGA in Barrett was an independent prognostic factor for survival after surgery. Therefore CGA in Barrett adjacent to GEJ adenocarcinoma might be helpful in the assessment of patient outcome.

INTRODUCTION

Neuroendocrine (NE) cells are defined as argentaffin and argyrophil cells that produce peptides or amines. They belong to the Diffuse Neuroendocrine System (DNES) and were previously known as amino-precursor-uptake-decarboxylation (APUD) cells. The neuroendocrine system of the normal gastro-intestinal tract might regulate proliferation and growth of epithelial and mesenchymal cells and probably function in sensation of hunger during fasting and food-intake [1]. Chromogranin A (CGA), a specific matrix component of endocrine granules, participates in vesicle aggregation, granulogenesis, and hormone secretion and serves as a precursor for bioactive peptides (prohormone function) in endocrine and NE cells [2-4]. CGA is stored in secretory granules of NE cells and is regarded as a general endocrine marker [5-7]. The presence of NE cells in carcinomas of the gastrointestinal tract is well documented but their role remains speculative [8-21]. In a number of immunohistochemical studies a prognostic relevance of NE cells in adenocarcinomas, mostly colorectal adenocarcinomas, has been reported, however, several other studies failed to demonstrate a relation between NE differentiation and biological behavior of colorectal adenocarcinomas [9-11,14-22]. Reports on the prevalence and prognostic significance of NE cells in adenocarcinomas of the esophagus and its precursor lesion, the Barrett's mucosa, have been scarce. Hamilton et al. did not find a significant correlation between the presence of chromogranin A (CGA) immunoreactive tumor cells and survival in patients with esophageal adenocarcinoma [23]. We analyzed the presence of NE cells in 208 resection specimens with adenocarcinoma of the gastro-esophageal junction (GEJ), i.e. gastric cardia or distal esophagus, and premalignant Barrett's mucosa and correlated immunostaining with tumor characteristics and patient survival in order to evaluate the possible application of NE cells as prognostic marker.

MATERIALS AND METHODS

Tissues and Patients

Two hundred and eight patients (176 men; 32 women) with GEJ adenocarcinoma who underwent transhiatal resection of the tumor with restoration of continuity of the gastrointestinal tract by a gastric tube with cervical anastomosis were included in this study. Patients were operated between April 1987 and April 2002 at the Department of Surgery, Erasmus MC, Rotterdam. A standard dissection of the perigastric, left gastric and coeliac nodes was performed. Macroscopic tumor clearance was aimed at in all cases but no extended lymph node dissection was done. Seventeen patients received neoadjuvant chemotherapy and 2 patients received neoadjuvant chemoradiation. Patient's mean age was 63.6 year (range 39-84 years) at the time of diagnosis. All patients were followed up until April 2003 or until death if earlier. All 208 pathology records were reviewed. Barrett's mucosa was diagnosed by the GI-patholo-

gist and was defined as the presence of intestinal type epithelium with Goblet cells in the tubular esophagus [24]. In 73 patients Barrett's mucosa had been sampled prior to development of adenocarcinoma. Barrett's mucosa adjacent to tumor could be obtained in 56 out of these 73 resection specimens, whereas in 17 resection specimens the Barrett's mucosa could not be detected in the resection specimen. Barrett's mucosa showed no signs of dysplasia in 22, low grade dysplasia in 22 and high grade dysplasia in 12 resection specimens. A carcinoma was considered to arise from the distal esophagus when premalignant Barrett's mucosa was present and/or the epicenter of the mass was located in the tubular esophagus extending from the tracheal bifurcation to the gastro-esophageal junction including the intra-abdominal esophagus, according to the TNM classification (International Classification of Diseases for Oncology C15.5). The tumor was considered to be cardiac when the epicenter was immediately below the gastro-esophageal junction, extending approximately 2 cm downwards. The tumor was classified as a junction carcinoma when the epicenter was just at the GEJ, without predominance for distal esophagus or gastric cardia and no Barrett's mucosa was present. Tumors arising from the fundus or corpus of the stomach and infiltrating the gastric cardia or distal esophagus were excluded. Of the adenocarcinomas in our patient group, 112 arose from the distal esophagus and 73 arose from the cardia. The exact location of 23 GEJ adenocarcinomas could not be specified as either distal esophagus or gastric cardia and these were classified as junction carcinomas.

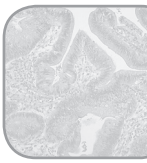
Immunohistochemical Analyses

From formalin-fixed paraffin-embedded tissue blocks of the primary tumor 4 μm thick sections were mounted on 3-aminopropyl-triethoxysilane (APES)-coated glass slides. For immunostaining a monoclonal antibody against CGA (Hybritech, San Diego, USA, at a dilution of 1:1250) was used. Staining was carried out by a standard avidin biotin immunoperoxidase technique, using a commercially available kit (Labvision, Fremont, USA). Deparaffinized sections were treated with methanol containing 3% H_2O_2 for 20 minutes. After washing with phosphate-buffered saline (PBS), blocking serum was applied for 5 minutes. Then, primary CGA antibodies were allowed to react at room temperature for 1 hour. After washing in PBS, biotin-conjugated secondary antibody was applied for 10 minutes followed by peroxidase-marked streptavidin. After rinsing in PBS, peroxidase was visualized by diaminobenzidine hydrochloride (Fluka, Neu-Ulm, Germany) with 0.03% H_2O_2 solution for 10 minutes. The slides were counterstained with Mayer's Haematoxylin and dehydrated in alcohol before mounting. Expression of CGA was evaluated by high power microscopic examination (400 X) of the entire tissue section. As negative controls normal mouse immunoglobulins and normal rabbit serum were applied on duplicate sections. Positive controls using normal colonic epithelium were also run with each batch, in addition to using non-involved normal gastric mucosa in the resection specimens, if present, as an internal positive control. Scoring of cytoplasmic CGA expression in adenocarcinomas was based on the percentage of positive cells: >20% of

cells with cytoplasmic staining (2+), 1-20% of cells with cytoplasmic staining (1+), no cells staining (0).

Statistical Analysis

Correlations between CGA immunoreactivity and patient and tumor characteristics were assessed by T-test and (a trend version of) χ^2 test. Survival rates were calculated according to the Kaplan-Meier method and differences in survival were assessed using the log rank test. $P<0.05$ was considered statistically significant. The Cox regression model was used to analyze the independent prognostic value of CGA expression after correction for possible confounding factors.



RESULTS

CGA expression was detected in 102/208 (49%) adenocarcinomas of the GEJ (Table 6.1). The CGA positive cells mostly presented diffusely scattered throughout the tissue or multifocally located in small nests, with just eight tumors having >20% (2+) CGA positive cells (Figure 6.1). For statistical comparison we hence combined the groups with 1+ and 2+ staining. Negative controls did not show staining and positive controls were positive. In 56 of the 208 resection specimens Barrett's mucosa adjacent to adenocarcinoma was detected. Positive staining for CGA was seen in 38/56 cases (68%). CGA immunoreactivity was absent in 18/38 (47%) tumors with CGA positive Barrett's mucosa (Table 6.1). There was no correlation between CGA immunoreactivity in Barrett's mucosas and CGA immunoreactivity in adenocarcinomas (P=0.57). In the patients with Barrett's mucosa adjacent to tumor, there was no correlation between CGA immunoreactivity in the Barrett and presence or degree of dysplasia (P=0.97 and P=0.65 respectively).

Table 6.1 CGA Expression in Adenocarcinomas of the GEJ and Barrett's Mucosa

	Non-Barrett	Barrett's mucosa		Total
		CGA positive	CGA negative	
Adenocarcinomas				
CGA positive	74	20	8	102
CGA negative	78	18	10	106
Total	152	38	18	208

CGA positive staining in GEJ tumors correlated with a more favorable pTNM stage (P=0.04, Table 6.2). CGA positive staining in Barrett's mucosas correlated with a more favorable pTNM stage and tumor grade (P=0.005 and P=0.024 respectively, Table 6.2). No difference in survival

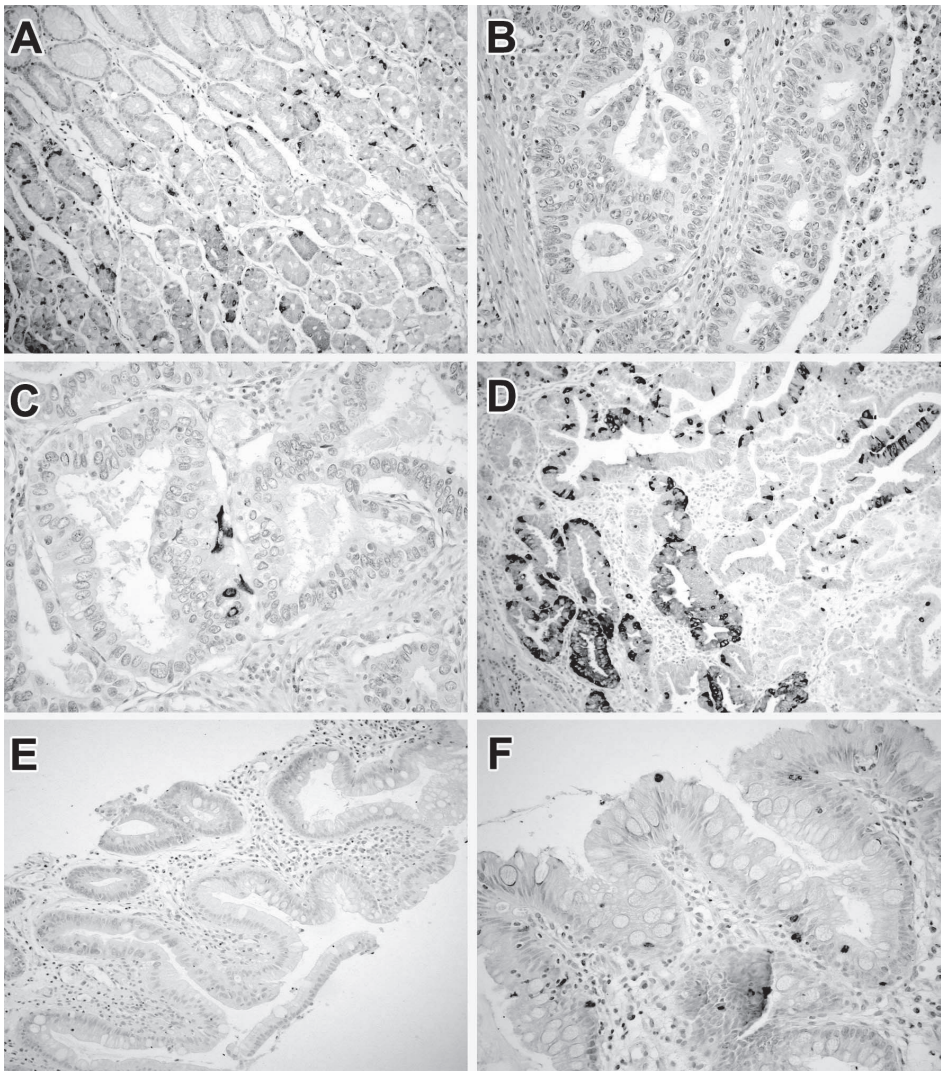


Fig. 6.1 CGA immunoreactivity in normal gastric epithelium (A), CGA negative adenocarcinoma (B). Scatters of individual tumor cells show CGA staining (1+) within a well-differentiated adenocarcinoma (C). Adenocarcinoma shows apparent cytoplasmic CGA staining in >20% (2+) of tumor cells (D). CGA negative Barrett's epithelium adjacent to adenocarcinoma (E), CGA positive cells in Barrett's epithelium most prominently located in the basal layer of the epithelium (F). *Also see color figures page 291.*

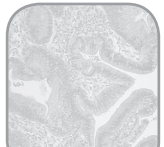

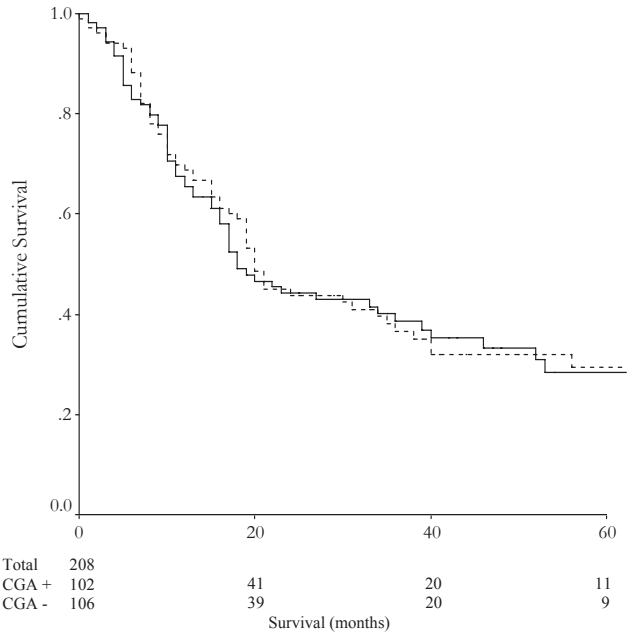

Fig. 6.2 Cumulative survival of patients with (n=102) and without (n=106) CGA immunoreactivity in adenocarcinomas of the GEJ (P=.69). Broken line represents CGA positive tumors, uninterrupted line represents CGA negative tumors.

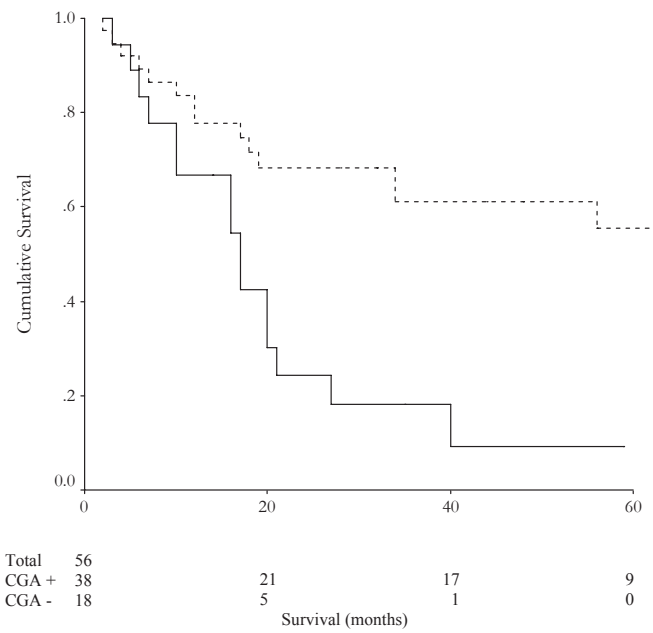

Fig. 6.3 Cumulative survival of patients with (n=38) and without (n=18) CGA immunoreactivity in Barrett's mucosa adjacent to adenocarcinoma (P=.0015). Broken line represents CGA positive Barrett's mucosas, uninterrupted line represents CGA negative Barrett's mucosas.

between patients with CGA positive and CGA negative adenocarcinomas was found (P=0.69, Figure 6.2). Five year survival percentages were 30% and 28% respectively. However, patients with CGA positive cells in Barrett's mucosa adjacent to the tumor had a better survival than patients without CGA positive cells in Barrett's mucosa (P=0.0015, Figure 6.3). Five year survival percentages were 56% and 9% for patients with and without CGA expression in Barrett respectively. Univariate analysis to identify prognostic variables in the total group showed pTNM stage, tumor grade and radicality of resection to be prognostic factors for survival (P=<0.001, P=0.012 and P=<0.001 respectively). In multivariate Cox regression analysis only pTNM-stage and radicality of resection turned out to be independent prognostic factors for survival in the total patient group (P=0.003 and P=0.006, Table 6.3A). However, in the group of patients with Barrett's mucosa, univariate analysis showed age, radicality of resection and CGA immunoreactivity in the Barrett's mucosa to be prognostic for survival (P=0.035, P=0.008 and P=0.003 respectively, Table 6.3B), which was substantiated by multivariate analysis (P=0.03, P=0.037 and P=0.003 respectively, Table 6.3B).

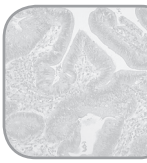

Table 6.3. Results of the Cox Regression Analyses in (A.) 208 GEJ Adenocarcinomas and in (B.) 56 Barrett's mucosas (adjacent to tumor), as part of the series of 208 GEJ adenocarcinomas

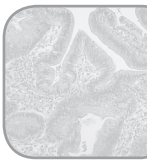
DISCUSSION

Our study, which showed that the presence of NE cells in GEJ tumors did not correlate with 5-year survival rate, is in concordance with the results reported by Hamilton et al. They investigated the expression of CGA in 52 patients with adenocarcinomas of the esophagus and did not find a correlation with survival [23]. We also confirm their findings of CGA positive Barrett's mucosas with adjacent CGA negative tumors (namely in 38% of their tumors and in 47% of our tumors). Obviously neuroendocrine differentiation common disappears in invasive adenocarcinomas. We likewise observed NE cells more often in Barrett's mucosa without dysplasia or with low grade dysplasia than in high grade dysplastic Barrett's mucosas, although this difference lacked statistical significance. Hamilton et al. found expression of CGA in 62% (21/34) of the Barrett's mucosas, as compared to our finding of 68% (38/56). In our study patients with CGA positive Barrett's mucosa had a better survival rate than patients with CGA negative Barrett's mucosa. Our study differs from the study of Hamilton et al. in several ways. The monoclonal CGA antibody we used differs from the antibody used by Hamilton et al. Our study encompasses 208 patients versus 52 patients in the study of Hamilton et al. Finally, their population contained 37 of 52 patients who underwent preoperative therapy, compared to 19 of our 208 patients, and this might influence CGA staining. However, when the 19 patients that received preoperative therapy were left out from the analyses, our results did not change. Moreover, Shia et al. suggested that the increased endocrine differentiation shown in rectal adenocarcinomas treated by chemo(radio)therapy could be related to therapy induced cytotoxity which is in contrast with the lower percentage of CGA positive patients although higher percentage of pretreated patients in the study of Hamilton et al. as compared to our study [25]. Since adenocarcinomas of the distal esophagus and the gastric cardia are regarded

as one clinical entity by some authors [26,27], we investigated the expression of NE markers in adenocarcinomas of the GEJ whereas in the study of Hamilton et al. only esophageal adenocarcinomas were included. Because the prevalence of NE differentiation in our series was about the same in esophageal and cardia adenocarcinomas, the different results cannot be ascribed to the fact that in our study cardia adenocarcinomas were included.

Several studies concerning colorectal carcinomas showed that the presence of CGA positive cells does not influence prognosis [14-19], whereas other studies indicate that CGA expression in tumor cells might distinguish a subgroup of colorectal carcinomas with poorer prognosis [10-12,21]. Swatek and Chibowski reported that endocrine cells were significantly more frequent in less advanced and better differentiated colorectal carcinomas, using immunostaining for CGA [13]. Two other studies showed a significantly better survival in patients with NE expression in pancreatic cancer and non small cell lung cancer [28,29].



In the current study we demonstrated that CGA expression in Barrett's mucosa adjacent to the tumor is an independent predictor of improved survival after surgery for GEJ adenocarcinomas. To our knowledge this is the first example that in the concurrent presence of a premalignant lesion and a carcinoma a characteristic of the premalignant lesion has prognostic significance. An explanation for this finding remains obscure. The presence of NE cells in Barrett's epithelium has been described by several authors [30-34], suggesting that it arises from a multipotent gastrointestinal stem cell probably responsible for the risk of adenocarcinoma [31,34]. Smith and Haggitt have described 4 explanations for the presence of NE cells in non-carcinoid adenocarcinomas of the gastrointestinal tract [14]: 1) entrapment of normal NE cells within the malignant tumor; 2) benign proliferation of NE cells within a malignant population of intestinal cells; 3) malignant transformation of 2 distinct stem cell lines (1 neuroendocrine and 1 endodermal); and 4) malignant transformation of 1 stem cell line capable of both endodermal and neuroendocrine differentiation. The last hypothesis has found support from several studies [20,35], including that by De Bruïne et al., who demonstrated mucin and CGA expression in the colorectal cell line H716 [36].

Since NE cells comprise an integral part of the intestinal epithelium, the presence of NE cells in Barrett's mucosa can be the mere result of the intestinal type differentiation. However, additional factors in NE differentiation can be involved. Duodeno-gastro-esophageal reflux is known to be a risk factor for the development of Barrett's mucosa. Reflux disease is often treated by acid-suppressive therapy. Sanduleanu et al. found that serum CGA increases during profound gastric acid inhibition [37]. Furthermore, Helicobacter pylori infection was associated with higher serum CGA levels [37]. It should therefore be addressed that both long-term acid-suppressive therapy and Helicobacter pylori status might play a role in CGA expression in Barrett's mucosa and adenocarcinomas of the GEJ. Unfortunately, we were not able to obtain reliable information on previous acid-suppressive therapy or Helicobacter pylori status in our patient population.

Colombo et al. investigated the effect of CGA on neoplastic growth and morphogenesis by use of mouse models [38]. They found slower progression of mouse mammary adenocarcinoma after transfection of CGA cDNA and suggested that CGA may contribute to regulate tumor growth in a negative manner. Given the fact that distal esophageal adenocarcinomas often develop from a precursor lesion, i.e. Barrett's mucosa, being present for years already prior to tumor formation, we were able to investigate the significance of CGA on tumor growth in 56 patients with Barrett available adjacent to tumor [39]. CGA expression in these Barrett's mucosas indeed correlated with less advanced pTNM stage and tumor grade of adjacent tumors as compared to Barrett related carcinomas without CGA in the precursor lesion. Furthermore, CGA expression in the Barrett's mucosa came forward as an independent predictor of survival in Cox regression analysis. Future experiments focussing on transfection of CGA cDNA in Barrett's metaplasia cell lines could possibly gain more insight in the role of CGA in GEJ adenocarcinoma development.

In summary, the current study demonstrates NE differentiation in Barrett's epithelium to be correlated with survival in patients with Barrett's associated adenocarcinomas of the GEJ. CGA immunoreactivity in Barrett's mucosa adjacent to tumor is an independent prognostic factor for better survival after surgery. It appears from these data, obtained in a large patient group, that CGA expression in Barrett's mucosa might be helpful in the prognostic assessment of patient outcome.

ABSTRACT

We investigated the distribution of serious comorbidity in patients with newly diagnosed esophageal and gastric cancer between 1993 and 2001. Our special interest was comparing distal esophageal and gastric cardia adenocarcinoma patients since a common origin of these tumors has been suggested. Data on comorbidity (previous cancers, Chronic Obstructive Pulmonary Diseases (COPD), cardiovascular and cerebrovascular diseases, hypertension, ulcerative digestive tract diseases, liver diseases and diabetes) were derived from a population-based database in the Netherlands to compare risk factor profiles for 479 esophageal squamous cell carcinomas, 339 distal esophageal adenocarcinomas, 570 cardia adenocarcinomas and 1965 subcardia cancers. Comparable age and gender distribution was shown in distal esophageal and cardia adenocarcinoma patients. After adjustment for age and gender, only the prevalence of previous cancers differed between adenocarcinomas of distal esophagus and cardia (more frequent in distal esophageal adenocarcinoma patients, odds ratio (OR)=1.84, p=0.01). Ulcerative and liver diseases were more prevalent in esophageal squamous cell carcinoma patients as compared to distal esophageal adenocarcinoma patients (OR=1.90, p=0.02; OR=8.82, p=0.04 respectively), whereas diabetes was more prevalent in the latter (OR=0.56, p=0.03). Cardia adenocarcinoma patients significantly more often had hypertension as compared to subcardia cancer patients (OR=1.53, p=0.001), whereas the latter more often suffered from previous cancers and ulcerative diseases (OR=0.54, p=0.0009; OR=0.25, p< 0.0001 respectively). In terms of comorbidity at diagnosis cardia adenocarcinoma patients resemble distal esophageal adenocarcinoma rather than gastric subcardia carcinoma patients with likewise equal age and gender distribution.

INTRODUCTION

Consistent with countries in Western Europe and the USA, the incidence of distal esophageal as well as gastric cardia, i.e. gastro-esophageal junction (GEJ), adenocarcinomas in the Netherlands has been increasing during the last decades, especially in males [1-5]. Causal factors underlying the upward trend in incidence in GEJ adenocarcinomas are not elucidated yet. In contrast, the incidence of squamous cell carcinoma of the esophagus has been stable or decreasing in males. Subcardia gastric cancer incidence has decreased since before the Second World War in industrialised countries, but remained the world's second leading cause of cancer mortality [6].

Although clear differences exist in risk factor profiles and epidemiological features between adenocarcinomas of the distal esophagus and cardia [7-11], similarities in epidemiological and histomorphological features as well as parallel, rising incidence rates have been shown by others [12-14]. Gastro-esophageal reflux disease is a known risk factor for distal esophageal adenocarcinomas, for which Barrett's esophagus, a columnar cell metaplasia of the native squamous cell epithelium, is a risk indicator [8,14,15]. A subgroup of cardia carcinomas may develop within short segments of intestinal metaplasia at the GEJ [14,16] although a causal role of gastro-esophageal reflux has been difficult to establish. Additionally, alcohol and/or tobacco use may confer risk for esophageal and for cardia adenocarcinomas [17-20] and they are also established risk factors for esophageal squamous cell carcinomas [18,21].

Esophageal squamous cell carcinomas and distal esophageal adenocarcinomas show marked differences in pathogenesis, tumor biology and patient characteristics [18,22].

Helicobacter Pylori infection plays an important role in the pathogenesis of not only persistent gastritis, but also of peptic ulcers and gastric subcardia carcinomas [23]. Diet rich in salted, smoked or poorly preserved food is another well-known risk factor for gastric cancer [23]. Gastric subcardia carcinomas are clearly distinct from cardia adenocarcinomas concerning epidemiology [13,19,24].

To gain more insight in variation of risk factor profiles of esophageal and gastric cancer, we investigated the prevalence of prognostically relevant comorbidity in newly diagnosed esophageal and gastric cancer patients in the South of the Netherlands.

METHODS

Study population

Data were derived from the population based Eindhoven Cancer Registry, which covers approximately 2 million inhabitants in the Southeast of the Netherlands [5]. They are served by 16 community hospitals and two large radiotherapy institutes that collaborate with the Cancer Registry within the framework of the Comprehensive Cancer Centre South, IKZ. Upon notifi-

cation by one of six pathological laboratories and the hospital medical records departments, registration clerks actively collect information (diagnosis, tumor stage, treatment, comorbidity) from the medical records. The Eindhoven Cancer Registry, at the request of clinicians, has been collecting data on clinically relevant comorbidity for new cancer patients since 1993 [25], according to a slightly adapted version of the list of Charlson et al. [26], Table 7.1. Information on comorbidity was extracted from previous admissions, letters of referral from and discharge to general practitioners, the medical history, current medication, and preoperative assessment. Cardiovascular, cerebrovascular and other vascular diseases were also included after a circulatory event or vascular surgery. Digestive tract diseases mainly consisted of major surgery for ulcerative diseases in the upper digestive tract. Previous cancers did not include basal cell skin cancer and cervix carcinoma in situ.

Table 7.1 Classification of comorbidity, according to an adapted list of Charlson et al. [26]

Comorbidity
Previous malignancies (except basal cell skin carcinoma and cervix carcinoma in situ)
Chronic Obstructive Pulmonary Diseases
Cardiovascular diseases:
Myocardial infarction
Heart failure
Angina pectoris
Intermittent claudication
Abdominal aneurysm
Cardiomyopathy
Valve prothesis (aorta or mitralis)
Cerebrovascular diseases:
Cerebrovascular accident
Hemiplegia
Hypertension
Digestive tract diseases:
Ulcerative disease (only registered since 1997)
Patients who underwent major surgery for ulcerative disease (Billroth I or II)

Selection of tumors

All primary tumors of the esophagus (N=952) and stomach (N=2581) that were newly diagnosed between 1 January 1993 and 31 December 2001 were included in our analysis.

Endoscopic, radiological, surgical and pathological data (if available) were taken into consideration for subsite assignment. Cancer of the esophagus was categorised into four groups based on the last ICD-O-3 digit: upper (codes C15.0 and C15.3), middle (C15.4), distal (C15.5) esophagus and other (overlapping and not otherwise specified (NOS); C15.8/9). Cancer of the stomach was classified: cardia (C16.0), midstomach (fundus, body or curvatures; C16.3/4/5/6 and C16.8), antrum/pylorus (C16.1/2) and other (unspecified; C16.9). Tumors were considered to be cardiac when the epicentre was at the gastric cardia, defined as the area at and immediately below the gastro-esophageal junction, extending approximately 2cm downwards. Tumors centred on the gastro-esophageal junction were considered to be of esophageal origin when Barrett's epithelium was present and as cardiac when Barrett's epithelium was absent, according to the advice of the International Union Against Cancer (UICC) [27]. Tumors arising from the fundus or corpus of the stomach and infiltrating the gastric cardia or distal esophagus were considered to be subcardiac. Esophageal tumors were classified as squamous cell carcinoma (codes 8050-8052 and 8047), adenocarcinoma (codes 8480-8490, 8140-8473 and 8500-8550) and all other morphology including unspecified cases and cases without histological confirmation (NOS). Gastric carcinomas were classified as adenocarcinomas, carcinomas with other morphology and NOS. Esophageal carcinomas were subdivided in squamous cell carcinomas, adenocarcinomas of the distal esophagus and other carcinomas. Gastric carcinomas were subdivided in cardia adenocarcinomas and subcardia carcinomas.

Statistical analysis

Multivariate (logistic regression) analyses, adjusted for gender and age (<55, 55-69, 70-84, ≥85 years) were performed for risk estimation of comorbidity in the different tumor groups. Odds ratios (OR) and 90% confidence intervals (90% CI) were computed.

RESULTS

Between 1993 and 2001, 952 esophageal cancer patients and 2581 gastric cancer patients were diagnosed. General characteristics are shown in Table 7.2. The age and gender distribution of patients with adenocarcinomas of the distal esophagus resembled that of patients with gastric cardia adenocarcinomas. In general, cardiovascular diseases, hypertension and previous malignancies were the most common associated concomitant diseases. Five patients with digestive diseases suffered from Crohn's disease. Below 70 years of age, 51% of males and 57% of females did not suffer from any serious comorbid condition, whereas this was true for only 29% and 42%, respectively, in the group over 70 years of age.

Table 3 shows the distribution of the various comorbidities according to subsite, gender and age. A rank order according to subsite is depicted in Figure 7.1.

[a] Tumors with other morphology than squamous cell (n=82) and adenocarcinomas of the upper 1/3 and middle 1/3 of the esophagus (n=52).

[b] Tumors of the gastric cardia with other than adenocarcinoma morphoplogy.

Esophageal squamous cell carcinoma patients most often presented with cardiovascular comorbidity (mainly in males over 70 years of age) and previous cancers, which mainly comprised skin cancer (16 patients), head and neck cancer (13 patients), or lung cancer (13 patients). Furthermore, hypertension (mainly elderly females), COPD (mainly in males) and ulcerative diseases (mainly in males) were also more common. Most obvious male preponderance was shown for COPD, cardiovascular and ulcerative diseases.

Distal esophageal adenocarcinoma patients most often presented with cardiovascular comorbidity (mainly in older males), hypertension (in older females and males), diabetes (mainly in older females and males), previous cancers, mainly comprising skin, prostate and breast cancer (11, 8, 5 patients) and COPD (mainly in older males). Evident male preponderance was shown for previous cancers, COPD, cardiovascular and ulcerative diseases.

Cardia adenocarcinoma patients presented with hypertension (mainly older females), cardiovascular disease (mainly in older males), diabetes (mainly in older females), COPD (mainly older males) and previous malignancies, mainly comprising colorectal cancer (9 patients), skin (6 patients), prostate (5 patients) and breast cancer (5 patients). Male preponderance was shown for COPD and cardiovascular diseases, whereas female preponderance was shown for hypertension and diabetes.

Gastric subcardia carcinoma patients presented with cardiovascular comorbidity (mainly older males), hypertension (mainly older females), ulcerative diseases (mainly older males), previous malignancies consisting of skin (55 patients), colorectal cancer (39 patients), prostate (33 patients) and breast cancer (31 patients) and diabetes (mainly older females). Obvious male preponderance in both cardia adenocarcinoma and subcardia cancer patients concerned COPD and cardiovascular comorbidity, whereas female preponderance was shown for

[a] More than one comorbid condition per patient possible.

hypertension and diabetes.

Patients with 'other esophageal carcinomas' consisted of 52 patients with adenocarcinomas in the upper or middle 1/3 of the esophagus and of 82 patients with 'mixed type epithelial carcinomas' or 'epithelial carcinomas, not otherwise specified', mainly due to advanced disease at diagnosis with, consequently, abandoned resection. Patients with 'other esophageal carcinomas' did not clearly resemble either squamous cell carcinoma or distal esophageal adenocarcinoma patients concerning comorbidity (results not shown) and were excluded for further analysis. Also cardia carcinomas with other morphology than adenocarcinomas were excluded for further analysis.

In age and gender adjusted multivariate analysis, only previous cancers were more prevalent among patients with distal esophageal adenocarcinoma patients than among cardia adenocarcinoma patients (OR=1.84, 90% CI 1.22-1.75, Table 7.4a).

Esophageal squamous cell cancer patients exhibited a lower male/female ratio and had a younger mean age in comparison with distal esophageal adenocarcinoma patients (Table 7.2). Ulcerative diseases and liver diseases were more prevalent among patients with esophageal squamous cell carcinomas than among patients with distant esophageal adenocarcinomas (OR=1.90, 90% CI 1.18-3.03; OR=8.82 90% CI 1.57-49.7 respectively, Table 7.4b), whereas patients with distal esophageal adenocarcinoma were more often diagnosed with diabetes (OR=0.56, 90% CI 0.36-0.87, Table 7.4b).

Cardia adenocarcinoma patients exhibited a higher male/female ratio and had a younger mean age in comparison with subcardia cancer patients (Table 7.2). Previous cancers and ulcerative diseases were less common among patients with cardia adenocarcinomas than among those with gastric subcardia tumors (OR=0.54, 90% CI 0.40 -0.73; OR=0.25, 90% CI 0.17-0.36, Table 7.4c), contrasting hypertension (OR=1.53, 90% CI 1.23-1.89, Table 7.4c).

The prevalence of patients who suffered from both COPD and cardiovascular comorbidity, as an indicator of tobacco use, was equally distributed between esophageal squamous cell cancer patients and distal esophageal adenocarcinoma patients, between distal esophageal adenocarcinoma and cardia adenocarcinoma patients, and between cardia adenocarcinoma and gastric subcardia patients in multivariate analysis.

DISCUSSION

We performed a population-based study of comorbidity prevalence in order to assess risk factor profiles of esophageal and gastric cancer. Patients with distal esophageal adenocarcinoma and gastric cardia adenocarcinoma had the same age and gender distribution as well as almost comparable comorbidity patterns. A common origin of these tumors is therefore likely [12-14], contrasting reports that described distal esophageal adenocarcinomas and gastric cardia carcinomas as separate entities [10,11]. Only previous cancers were more prevalent in dis-

tal esophageal adenocarcinoma patients as compared to cardia adenocarcinoma patients. These previous malignancies mainly comprised skin cancer, prostate cancer and breast cancer in both patients groups and colorectal cancer in cardia adenocarcinoma patients. Two previous studies have analysed a possible common aetiology of colorectal and esophageal cancer and showed conflicting results [28,29]. We could not establish a common aetiology between specific previous cancers and esophageal or gastric cardia cancer, since they form a mixed subset with consequently small patient numbers.

Adenocarcinomas of the distal esophagus versus adenocarcinomas of the gastric cardia

Ulcerative diseases were comparable prevalent in subjects with adenocarcinoma of the distal esophagus and subjects with gastric cardia adenocarcinoma. Lagergren et al. found a probable causal relationship between gastro-esophageal reflux and esophageal adenocarcinoma, and a relatively weak relation with adenocarcinoma of the gastric cardia [8]. Nevertheless, digestive tract diseases were even more strongly related to esophageal squamous cell carcinomas than to distal esophageal adenocarcinomas in our patient cohort, whatever the mechanism for this.

Case-control studies report discrepant findings about nicotine and alcohol consumption as risk factors for the development of esophageal and cardia adenocarcinomas [17-20]. COPD, largely resulting from nicotine abuse, may confer risk to esophageal or gastric cardia adenocarcinoma [30,31] through its contribution to gastro-esophageal reflux by an increased thoracoabdominal pressure gradient during COPD exacerbation, high hiatal hernia prevalence and altered crural diaphragm function [31-33]. Furthermore, asthma medication can worsen or cause reflux by relaxing the lower esophageal sphincter. However, in our study COPD prevalence did not differ between distal esophageal and cardia adenocarcinoma patients.

For registration and hence comparison of GEJ adenocarcinomas careful designation of cancer subsite is of vital importance. The necessity to distinctly determine gastro-esophageal junction tumor subsite led, as a consequence, to the introduction of a separate code for cardia cancer in the Netherlands as early as with the 8th revision of the ICD system (1978). However, since no separate code for gastro-esophageal junction tumors exists, the decision whether a tumor originates from the distal esophagus or the true gastric cardia is difficult. In concordance with Wayman et al. we feel that recognition of cancers at the gastro-esophageal junction as distinct from other esophageal and gastric subsites might improve the use of cancer registration data [34].

Esophageal squamous cell carcinomas versus adenocarcinomas of the distal esophagus

In our study, esophageal squamous cell carcinoma patients exhibited a lower male/female ratio and were younger than distal esophageal adenocarcinoma patients. The prevalence of the various comorbid conditions between these 2 patient groups differed somewhat less than expected, if one takes into account the marked contrasts in pathogenesis, tumor

biology, and patient characteristics [18,22]. The presence of concomitant ulcerative diseases provided an increased risk for esophageal squamous cell cancer patients as compared to distal esophageal adenocarcinoma patients. Patients aged 70-84 years mainly accounted for this difference (results not shown). Also liver diseases were more prevalent in squamous cell carcinoma patients, albeit small patient numbers. Impaired hepatic function in squamous cell cancer patients may result from increased alcohol consumption, which is known to be an important aetiological factor for squamous cell cancer of the esophagus [18,21]. In a preoperative risk analysis esophageal squamous cell cancer patients had considerably impaired liver function as well as impaired pulmonary function as compared to esophageal adenocarcinoma patients [35]. Pulmonary comorbidity largely results from nicotine abuse, which is another important risk factor for squamous cell cancer [18,21]. In our study COPD and also cardiovascular comorbidity prevalence did not differ between squamous cell carcinoma and distal esophageal adenocarcinoma patients. The higher prevalence of lung as well as head and neck cancer in esophageal squamous cell cancer patients nevertheless affirmed the role of alcohol and nicotine abuse in these patients. Diabetes was more prevalent in distal esophageal adenocarcinoma patients as compared to esophageal squamous cell carcinoma patients, for which the reason is not understood. One could speculate that this higher diabetes prevalence might be related to a higher obesity prevalence, which is described to be a risk factor for distal esophageal (and cardia) adenocarcinomas [18,36].

Adenocarcinomas of the gastric cardia versus subcardia carcinomas

In previous studies, risk factors as well as epidemiological features from cardia cancers have been reported to differ from subcardia cancers, which is also reflected in largely different comorbidity patterns in our data [13,19,24]. Cardia adenocarcinoma patients presented more often with hypertension as compared to subcardia cancer patients, especially in the age group of 70-84 years (results not shown). This is consistent with Zhang et al., who compared risk factors between esophageal plus cardia adenocarcinoma patients and distal stomach adenocarcinoma patients, speculating on a common cause [19]. Obesity, possibly related to hypertension, has emerged as a major risk factor for gastro-esophageal reflux disease [37] and (subsequent) esophageal and gastric cardia adenocarcinomas, by increasing intra-abdominal pressure [7,18,36]. The mounting evidence that obesity is associated with increased (distal esophageal as well as) cardia adenocarcinoma risk is supported by our finding of a higher hypertension prevalence in cardia adenocarcinoma as compared to subcardia adenocarcinoma patients. Data on body weight were unfortunately not available in our study. Moreover, nicotine and alcohol consumption might contribute to the development of both hypertension as to the development of (esophageal and) cardia cancer. Case-control studies report discrepant findings about nicotine and alcohol consumption as a risk factor for the development of cardia adenocarcinomas [18-20]. Previous ulcerative diseases occurred more frequently in gastric subcardia cancer patients as compared to cardia cancer patients, mainly in the age group of

55-84 years (results not shown). The higher frequency of previous ulcerative diseases in subcardia cancer patients might be explained by the probable carcinogenic potential of (gastric) ulcers and Helicobacter Pylori infections as possible underlying cause of ulcer development. Unfortunately, information on Helicobacter Pylori infection status in the patients was not available. Neither ulcer origin, whether duodenal or gastric, was recorded. In our data previous malignancies, mainly comprising skin cancers, colorectal cancers, prostate and breast cancers, were more common in gastric subcardia cancer as compared to cardia adenocarcinoma patients. Patients in the age of 55-69 years mainly accounted for this difference (results not shown). The mechanism how these previous malignancies could confer risk for subcardia cancer is unclear. Moreover, as these previous malignancies form a mixed subset, it is difficult to speculate on a probable common origin of these cancers. As mentioned earlier, 2 previous studies have analysed a possible association between colorectal cancer and esophageal, but not gastric carcinomas [28,29].

In conclusion, only the prevalence of previous malignancies differed between distal esophageal adenocarcinoma and cardia adenocarcinoma patients, with predominance in the first mentioned. Esophageal squamous cell cancer patients had more ulcerative as well as liver diseases in comparison with distal esophageal adenocarcinoma patients, whereas diabetes was more common in the latter patients. Cardia adenocarcinoma patients were apparently different from gastric subcardia cancer patients concerning age and gender distribution as well as concerning previous malignancies, hypertension and ulcerative diseases. Hence, cardia adenocarcinoma patients resembled distal esophageal adenocarcinoma patients considerably more than subcardia carcinoma patients concerning comorbidity, with likewise equal age and gender distribution.

ABSTRACT

We analysed the influence of comorbidity on treatment choice and survival in patients with newly diagnosed esophageal and gastric cancer between 1995 and 2002. Data on comorbidity (previous cancers, Chronic Obstructive Pulmonary Diseases (COPD), cardiovascular and cerebrovascular diseases, hypertension, ulcerative digestive tract diseases, liver diseases and diabetes) were derived from the population-based Eindhoven Cancer Registry for 430 esophageal squamous cell carcinomas, 392 distal esophageal adenocarcinomas, 494 cardia adenocarcinomas and 1708 subcardia cancers. Surgical resection with or without (neo)adjuvant therapy was applied in 76% of TNM stage I-III patients: in 49% of esophageal squamous cell carcinoma patients, 75% of distal esophageal adenocarcinoma, 83% of cardia adenocarcinoma and 83% of subcardia carcinoma patients. Surgery was less often applied in patients aged 70 years or older and in patients with ≥ 2 comorbidities at diagnosis. After adjustment for age, gender, tumor differentiation grade, TNM stage (I vs. II-III), tumor type, socio-economic status and type of hospital (non-teaching vs. teaching), the presence of ≥ 2 comorbidities independently lessened the chance of receiving surgery (p=0.006, OR 0.6) and formed a negative prognostic factor in multivariable survival analysis (p=0.02, HR 1.2). Since there was an adjustment for TNM stage and applied therapy (surgical resection or palliation) within multivariable survival analysis, the dismal prognosis for patients with ≥ 2 comorbidities at cancer diagnosis is likely to be a direct effect of the poor condition of the patient. Further refinement in perioperative care seems especially important in patients with ≥ 2 comorbidities. The exact role of comorbidity in therapy decision making and prognosis has to be addressed in prospective studies.

INTRODUCTION

Patients with esophageal or gastric carcinoma are often diagnosed at an advanced state due to late presentation of symptoms [1]. Surgery forms the only treatment with curative intent and is currently the preferred treatment if the tumor is considered to be resectable without evidence of distant metastases. Moreover, a patient needs to be fit enough to undergo surgery. Five-year overall survival after surgery is approximately 25% in esophageal and gastric cardia carcinoma patients and 30% in gastric carcinoma patients [2,3]. Unfortunately, around 40% of patients present with locally advanced or metastatic disease and receive palliative instead of curative therapy [3,4].

In the Netherlands, annually around 900 patients are newly diagnosed with esophageal cancer and 2050 with gastric cancer [5]. Patient's age and fitness might influence treatment outcome and, moreover, prior treatment decision making especially if comorbidity concerning vital organs is present.

The aim of this study was to analyse the influence of age and comorbidity on treatment choice in patients with esophageal or gastric cancer using the population-based database of the Eindhoven Cancer Registry. Moreover we analysed the influence of age and comorbidity on survival.

PATIENTS AND METHODS

All patients newly diagnosed with esophageal or gastric cancer between 1st of January 1995 and 31st of December 2002 in the registration area of the population-based Eindhoven Cancer Registry were included. This registry covers approximately 2.4 million inhabitants in the Southeast of the Netherlands [6]. There are no university hospitals in the registry area. Information on diagnosis, staging, treatment and comorbidity was extracted from the medical records by trained registrars [7]. Comorbidity was recorded, according to a slightly adapted version of the list of Charlson et al., Table 8.1 [8].

Only patients aged 40 years or older were included (872 patients with esophageal cancer and 2345 patients with gastric cancer).

Endoscopic, radiological, surgical and pathological data (if available) were taken into consideration for subsite assignment [9]. Cancer of the esophagus was categorized into four groups based on the last ICD-O-3 digit: upper (codes C15.0 and C15.3), middle (C15.4), distal (C15.5) esophagus and other (overlapping and not otherwise specified (NOS); C15.8/9). Cancer of the stomach was classified as: cardia (C16.0), midstomach (fundus, body or curvatures; C16.3/4/5/6 and C16.8), antrum/pylorus (C16.1/2) and other (unspecified; C16.9). Tumors were considered to be cardiac when the epicenter was at the gastric cardia, defined as the area at and immediately below the gastro-esophageal junction, extending approximately 2

Table 8.1. Classification of comorbidity, according to an adapted version of the list of Charlson et al. [8].

Comorbidity
Previous malignancies (except basal cell skin carcinoma and cervix carcinoma in situ)
Chronic Obstructive Pulmonary Diseases
Cardiovascular diseases:
Myocardial infarction
Heart failure
Angina pectoris
Intermittent claudication
Abdominal aneurysm
Cardiomyopathy
Valve prothesis (aorta or mitralis)
Cerebrovascular diseases:
Cerebrovascular accident
Hemiplegia
Hypertension
Digestive tract diseases:
Ulcerative disease (only registered since 1997)
Patients who underwent major surgery for ulcerative disease (Billroth I or II)
Chronic inflammatory diseases (M. Crohn, Colitis Ulcerosa except polyposis coli)
Liver disease (cirrhosis, hepatitis)
Diabetes Mellitus
Other:
Urinary tract diseases
Connective tissue diseases
Dementia
Chronic infections

cm downwards. Tumors centered on the gastro-esophageal junction were considered to be of esophageal origin when Barrett's epithelium was present and as cardiac when Barrett's epithelium was absent, according to the advice of the International Union Against Cancer (UICC) [10]. Tumors arising from the fundus or corpus of the stomach and infiltrating the gastric cardia or distal esophagus were considered to be subcardiac. Esophageal carcinomas were subdivided in squamous cell carcinomas (N=430), adenocarcinomas of the distal esophagus (N=392) and other carcinomas (N=50). Gastric carcinomas were subdivided in cardia adenocarcinomas (N=494), subcardia carcinomas (N=1708) and other carcinomas (N=143). Both esophageal and gastric 'other carcinomas' were left out for further analysis (N=193). Primary treatment of esophageal and gastric cancer patients was classified as surgery alone; surgery in combination with chemotherapy, radiotherapy, or in combination with chemotherapy and radiotherapy; chemotherapy alone; radiotherapy alone; chemotherapy in combination with radiotherapy; palliative therapy (i.e. flexible wallstent placement mostly); other therapy; and unknown therapy. Using the database, no discrimination could be made between neoadjuvant or adjuvant treatment within the group of surgically treated patients. For analysis, surgically treated patients (with or without (neo)adjuvant therapy) were regarded as treated with curative intent (potentially curative treatment) and were compared to patients that did not

receive therapy or received other therapy than surgery (palliative treatment). Importantly, in our retrospective study, surgery in patients with TNM stage IV or unknown stage could well have been palliative instead of potentially curative. To overcome this problem, patients with TNM stage IV or unknown were excluded from the analyses regarding application of potentially curative treatment.

TNM stage was calculated using pathological TNM data or, in case of unresected patients, using clinical TNM data.

Socio-economic status (SES) of the patients was defined at neighbourhood level (based on postal code of residence area, 17 households on average) combining mean household income (in 1998) and mean value of the house/apartment (in 2000), derived from individual fiscal data made available at an aggregated level. Postal codes were assigned to 3 SES categories: low (1st-3rd decile), intermediate (4th-7th decile), and high (8th-10th decile). Postal codes of institutions, such as nursing homes, were assigned to a separate category and left out of the analysis (198 patients, mentioned as unknown in Table 8.2). Another 39 patients had missing SES data and were left out of the analysis.

Type of hospital was defined as non-teaching hospital or teaching hospital.

For each tumor type the applied treatment was analysed, according to number of comorbid conditions and age (<70, 70+ years). Differences between groups were determined using the chi-square test. Logistic regression was applied to determine the independent effects of age, gender, tumor type, tumor differentiation grade, TNM-stage, SES, type of hospital and number of comorbid conditions on the application of curative treatment. Survival time was defined as the time from diagnosis until death (any cause). Vital status of all patients on January 1st, 2005 was assessed through merging with the database of the Central Bureau for Genealogy, that collects data on all deceased Dutch citizens via the civil municipal registries. In this way, information on patients who moved outside the registry area was also obtained. Crude survival rates were calculated according to age, gender, tumor type, tumor differentiation grade, TNM-stage, SES, applied treatment, type of hospital and comorbidity. In a multivariable Cox's proportional hazard regression analysis, independent hazard ratios (HR) were estimated for the variables mentioned, with either number of comorbid conditions, type of comorbid conditions or combinations of comorbidities (separate models). Patients with TNM stage IV or unknown were excluded from the analysis (N=1707). In order to analyse whether 'applied treatment' influenced differences in survival within age categories or within comorbidity categories, the model was first run without this variable. The SAS computer package (version 8.2) was used for all statistical analyses (SAS Institute Inc., Cary, North Carolina, USA, 1999).

[a] More concomitant diseases per patient possible. [b] Surgery with or without neoadjuvant or adjuvant therapy; [c] palliative therapy included chemotherapy and or radiotherapy, stent placement or no therapy.

RESULTS

General characteristics of the patients are shown in Table 8.2. Median age was 69 years (range 40-100 years). The most common comorbid conditions were cardiovascular (22%), hypertension (18%), upper digestive tract ulcerative diseases (12%) and COPD (11%). Comorbidity was absent in 41% of patients <70 years of age and in 24% of patients 70+ years of age. Potentially curative treatment (i.e. surgery with or without (neo)adjuvant therapy) within patients stage I-III was offered to 76% of patients: 49% of squamous cell carcinoma patients, 75% of distal esophageal adenocarcinoma patients, 83% of cardia adenocarcinoma patients and 83% of subcardia gastric carcinoma patients. Surgery was applied less often in patients aged 70+ as compared to patients aged <70 concerning squamous cell and distal esophageal adenocarcinoma patients (Table 8.3). Within distal esophageal adenocarcinoma patients aged 70+ years the application of surgery was significantly decreased with increasing number of comorbidities (Table 8.3).

Surgical therapy was applied to 5% of squamous cell carcinoma patients, 4% of distal esophageal adenocarcinoma patients, 6% of cardia adenocarcinoma patients and 16% of subcardia gastric carcinoma patients with TNM stage IV tumors, which can explained by the possible application of palliative instead of curative surgery (bypass to ensure food passage) or to the fact that pathological TNM data instead of clinical data were analysed ('upstaging'). Upstaging was however seen in only 48 patients out of the total group. In logistic regression analysis with adjustment for age, gender, tumor type, tumor differentiation grade, TNM stage, SES and type of hospital the presence of 2 or more comorbid conditions was significantly associated with a lower probability of receiving curative treatment (p=0.006, OR 0.6, Table 8.4). When the different types of comorbid conditions (i.e. previous cancer, COPD, cardiovascular disease, cerebrovascular disease, hypertension, ulcerative disease, liver disease, diabetes) were entered into the multivariable models (instead of the number of comorbid conditions; a separate model for each condition), no specific comorbid condition came forward that conferred a lower chance for receiving curative treatment. Concerning combinations of comorbidity, three most common combinations were analysed in separate multivariate models (hypertension and diabetes n=19, cardiovascular and hypertension n=42, cardiovascular and COPD n=19). The combination hypertension and diabetes conferred a lower chance for receiving curative treatment (p=0.049, HR 0.3, data not shown). The combination cardiovascular and hypertension as well as cardiovascular and COPD did not show an effect. Apart from comorbidity also age, TNM-stage, tumor differentiation grade and tumor type were independently correlated with administration of curative treatment with lowest chance for squamous cell carcinoma patients and increasing chances for distal oesophageal adenocarcinoma, cardia adenocarcinoma and subcardia cancer patients (as compared to squamous cell carcinoma patients, Table 8.4).

to confer an independent prognostic role. When the model was run without 'applied therapy' as an independent variable, the presence of ≥ 2 comorbidities conferred an even stronger independent significant effect on overall survival (p=0.005, HR 1.3, data not shown). Apart from TNM-stage and tumor differentiation grade, also age 70+ and tumor type subcardia carcinoma came forward as independent prognostic factors (p=0.04, HR 1.2; p=0.003, HR 0.7 respectively, data not shown).

DISCUSSION

A surgical resection is currently the preferred treatment for esophageal and gastric cancer if the tumor is considered to be resectable without evidence of distant metastases (TNM stage I-III). Moreover a patient needs to be fit enough to undergo surgery. Intuitively, presence of comorbidities as well as increasing age might be associated with worse outcome of esophagectomy as well as gastrectomy. Curative therapy might be applied less often because of a subjective perception about life expectancy and ability to tolerate treatment. In this retrospective series from the area of the Eindhoven Cancer Registry 76% of patients with TNM stage I-III carcinomas received surgery. Within logistic regression analysis restricted to TNM stage I-III patients, age 70+ years as compared to age ≤ 70 significantly lowered the chance for application of curative treatment. Also the presence of ≥ 2 comorbidities clearly altered the chance for receiving curative therapy in multivariable analysis.

In retrospect, intuitions on possible worse outcome after surgery in elderly patients and in patients suffering from comorbidity seemed to be followed indeed. Only 49% of TNM stage I-III squamous cell carcinoma patients received surgery. Percentages for distal esophageal adenocarcinoma, cardia adenocarcinoma and subcardia carcinoma patients were 75%, 83% and 83% respectively. The question is whether this is good clinical practice, i.e. whether a higher percentage of patients should have received surgery instead of palliation. To answer this question, one might wonder whether decreased prognosis in palliatively treated patients is due to comorbidity or due to less aggressive treatment. In multivariable Cox proportional-hazard analysis restricted to TNM stage I-III patients, the presence of ≥ 2 comorbidities came forward as an independent prognostic factor. Since there was an adjustment for stage and applied therapy the dismal prognosis of patients with ≥ 2 comorbidities is likely an effect of the poor condition of the patient. Given the increasing age of the population and parallel increasing comorbidity and given the rising incidence of distal esophageal as well as cardia adenocarcinoma, weighing of risk becomes more and more important in clinical decision-making. Application of a tailor made therapy approach might be indicated to augment the patient's prognosis.

In the literature, a composite scoring system has been described with data on cardiovascular, pulmonary, hepatic and renal function as well as alcohol drinking habits and willingness to undergo major surgery [11,12]. Strict application of this scoring system led to a marked reduction of postoperative mortality after esophagectomy [11,13]. Data on comorbidity might add to data on detailed organ function in preoperative 'fitness' assessment.

Within a retrospective study in a tertiary medical center, comorbidity, as defined by the Charlson comorbidity index score, was univariately associated with increased mortality after esophagectomy, which effect disappeared in multivariable analysis [14]. In two recently performed studies concerning gastric cancer surgery in elderly patients, comorbidity not only was an independent prognostic factor for survival (Charlson index) but also formed a fre-

quent cause of death during follow-up [15,16]. Studies from the surgical literature on outcomes from colorectal carcinoma and from primary non-small cell lung cancer suggested that comorbidity, more than age, was a significant predictor for mortality [17,18].

Our data showed that the presence of ≥ 2 comorbidities had not only an effect on treatment choice, but also had an independent prognostic effect on overall survival. No specific type of comorbidity came forward (i.e. previous cancers, COPD, cardiovascular or cerebrovascular diseases, hypertension, ulcerative digestive tract diseases, liver diseases or diabetes) to confer a significant independent effect. Although patients with the combination of hypertension and diabetes at diagnosis had a independently lower chance for receiving surgery, this combination was not associated with worse survival in Cox proportional hazard analyses. Two other investigated combinations of comorbidity (cardiovascular and hypertension, cardiovascular and COPD) also did not confer significancy concerning survival. Noteworthy, patient numbers were very small. Multiple comorbidities in gastric cancer patients aged 80+ years involved much higher operative mortality in a retrospective study from Italy, however the presence of postoperative complications nor the number of comorbidities significantly influenced 5-year survival rate of curatively resected patients [19].

Concerning age, previous single-institution retrospective studies demonstrated that esophagectomy can be performed as safely in elderly patients as in younger patients with comparable long term survival [16,20-23]. Also surgery for gastric carcinoma has been reported to be relatively safe in patients aged 70+ years with survival that is comparable to younger patients [24]. In our multivariable survival analysis age 70+ years showed a trend to worse survival although not significant.

Limitations of our study exist in its retrospective nature. Some desirable information was not available, for instance data on performance status, scheme of (neo)adjuvant therapy and details about applied surgical technique. The Charlson's list was used to score prognostic comorbidity, without subdivision according to severity, because this was too complex for the registrars [25]. Misclassification of comorbidity is limited, because the comorbid diseases are recorded routinely by trained registry personnel and data are collected directly from the medical records of the patients, which is considered to be the most reliable source for comorbidity [26].

The fact that only 49% of squamous cell carcinoma patients received surgery as compared to 75% of distal esophageal adenocarcinomas, 83% of cardia carcinoma patients and 83% of subcardia carcinoma patients is reflected in univariable survival analysis with large differences in survival between tumor types. Within the multivariable analysis tumor type was not shown to be an independent prognostic factor which is in accordance with studies comparing squamous cell and adenocarcinomas of the esophagus [27,28]. This observation is in contrast with studies that show a markedly better prognosis for resected esophageal adenocarcinoma as compared to squamous cell carcinoma [29,30]. In the studies mentioned no adjustment was however applied for comorbidity.

We found a limited effect of socioeconomic status on choice of treatment or on overall survival in our population-based database, which did not change when a division was made between patients aged >70 and 70+ years. This is in contrast with Trivers and coworkers who found low income to be associated with shorter survival in esophageal and gastric cancer patients with exception of subcardia cancers [31]. The impact of socioeconomic status is most pronounced for cancers with relatively good survival, probably reflecting variations in access to quality health care [32,33].

In summary, this population-based study confirmed that surgery was applied less often in esophageal and gastric cancer patients (TNM stage I-III) than would be expected based on their TNM stage. This was most pronounced for esophageal squamous cell carcinoma patients and, to less extent, for distal esophageal adenocarcinoma patients. In retrospect, age 70+ years as well as presence of ≥ 2 comorbidities independently influenced chances for receiving surgery. No specific type of comorbidity came forward to confer this effect, unless the combination of hypertension and diabetes which independently lowered the chance for receiving surgery although patient numbers were small. The presence of ≥ 2 comorbidities was independently associated with worse survival, after adjustment for therapy. The balance between outcome of surgery on the one hand and the risk of withholding higher-risk patients any prospect of cure by not performing surgery on the other hand is a difficult dilemma for upper gastrointestinal surgeons. Further refinement in perioperative care seems especially important in patients with ≥ 2 comorbidities. The exact role of comorbidity in therapy decision making and prognosis has to be addressed in future prospective studies.

ACKNOWLEDGMENTS

We thank the registration team of the Eindhoven Cancer Registry for their dedicated data collection.

ABSTRACT

To contribute to therapeutic decision making we retrospectively analysed the outcome of transhiatal esophagectomy in 120 patients with pathologically proven high grade dysplasia (HGD; n=13) or T1-adenocarcinoma (n=107) of the distal esophagus or gastro-esophageal junction (GEJ). Adenocarcinoma of the esophagus or GEJ has a poor prognosis. Early lesions (*i.e.* HGD or T1-carcinoma) are pre-eminently the tumors which are potentially curable. Local endoscopic therapies are promising treatment options for superficial lesions, however for deeper lesions surgical resection is considered to be the treatment of choice. Tumors were subdivided into six different depths of invasion ('T1-mucosal' m1- m3, 'T1-submucosal' sm1-sm3), and the frequency of lymphatic dissemination and time to locoregional and/or distant recurrence were analysed. Only one of the 79 T1m1-3/sm1 tumors (1%) showed lymph node metastases as compared to 18 out of 41 T1sm2-3 tumors (44%). There was a significant difference in recurrence free period between T1m1-m3/sm1 versus T1sm2-sm3 tumor patients (p log rank < 0.0001), with 5-year recurrence free percentages of 97% and 57%, respectively. In multivariate analysis including age, gender, tumor differentiation grade and depth of invasion, only depth of invasion (T1sm2-3 versus T1m1-m3/sm1) was an independent prognostic factor for recurrence free period (hazard rate=7.5, 95% CI 2.0-27.7). These data indicate that T1m1-m3/sm1 adenocarcinomas of esophagus or GEJ show a very low risk of lymphatic dissemination and are therefore eligible for local endoscopic therapy. After transhiatal surgical resection almost half of the patients with T1sm2-sm3 lesions develop recurrent disease within 5 years, and therefore need additional therapy to improve survival.

INTRODUCTION

The incidence of adenocarcinomas of the esophagus or gastro-esophageal junction is rising [1-3]. As a result of the increased awareness of the malignant potential of Barrett's esophagus, the more generally applied endoscopic surveillance programmes, and the availability of more accurate endoscopic techniques (*e.g.* methylene blue staining, high resolution endoscopy, fluorescence endoscopy, optical coherence tomography and narrow band imaging),[4,5] high grade dysplasia (HGD) and early esophageal adenocarcinoma are being diagnosed with increasing frequency in the Western world [6-8] . Early carcinoma is defined as a tumor limited to the mucosa or submucosa irrespective of the presence of lymph node metastases [9].

Many institutions favor radical esophagectomy with lymphadenectomy as standard therapy for esophageal carcinoma. As this procedure is associated with substantial morbidity and mortality,[10] the question rises if this extensive resection is also necessary in patients with early malignancies of the esophagus [11,12] . Presently, various techniques have been applied for the treatment of early esophageal carcinoma, *i.e.* local endoscopic, organ-preserving treatment modalities (*e.g.* endoscopic mucosal resection (EMR) or photodynamic therapy (PDT)),[13-15] limited surgical resection (*e.g.* Merendino operation or vagal-sparing esophagectomy)[16,17] and radical esophagectomy with or without systematic lymphadenectomy (transthoracic or transhiatal).

In this study we retrospectively evaluated the outcome of transhiatal esophagectomy in 120 patients with early adenocarcinoma of the esophagus or gastro-esophageal junction. In order to precisely subclassify this series of early cancers we subdivided the mucosa and submucosa into six successive layers (m1, m2, m3, sm1, sm2, sm3), as previously has been described for early squamous cell carcinoma of the esophagus by the Japanese Society for Esophageal Diseases (1999) [18]. Subsequently, we analysed whether a possible correlation between the depth of tumor infiltration on the one hand, and lymphatic dissemination and recurrence free period on the other hand, was present.

MATERIALS AND METHODS

Patient materials

Data from all patients operated for carcinoma of the esophagus or gastro-esophageal junction (GEJ) in the Erasmus University Medical Center in Rotterdam and the Academic Medical Center at the University of Amsterdam, The Netherlands, are continuously collected in prospective databases since 1980 and 1993, respectively. A cancer was termed esophageal adenocarcinoma, if the centre was clearly situated in the distal esophagus with or without specialised Barrett's epithelium. Also cancers at the GEJ in the presence of Barrett's epithelium were considered esophageal adenocarcinoma. A tumor was designated GEJ adenocar-

cinoma, if the centre was located at the junction in the absence of Barrett's mucosa, or if the centre of the tumor was seen in the proximal stomach. Between January 1980 and July 2002, 702 patients underwent subtotal esophageal resection with proximal gastrectomy for HGD or adenocarcinoma in Rotterdam; between January 1993 and July 2002, 398 patients underwent this same procedure in Amsterdam. All patients with a pathologically proven HGD (n=13) or pT1 invasive adenocarcinoma (n=107), who underwent a transhiatal resection, were included in the present study. All 13 HGD lesions were situated in Barrett's mucosa. The 107 pT1 carcinomas included 94 early cancers of the distal esophagus, 13 were classified as GEJ adenocarcinomas. None of the patients received (neo)adjuvant chemo- and/or radiotherapy.

Histopathologic assessment

The resection specimens of all included patients were reviewed by two experienced pathologists (FJWtK, HvD) to determine size and location of the primary tumor, the number of resected and involved lymph nodes, and the radicality of resection. All tumors were graded, staging was performed according to the 2002 UICC TNM classification [9]. The depth of tumor invasion was measured and subclassified based on the criteria proposed by the Japanese Society for Esophageal Diseases [18]. High-grade dysplasia (carcinoma *in situ*) arising in a Barrett segment was defined by the lack of obvious invasion through the basement membrane (HGD, m1). Intramucosal carcinoma was defined as tumor cells extending beyond the basement membrane into the lamina propria (m2), or as carcinomas with deepest invasion into the muscularis mucosae (m3). In the presence of a double muscularis mucosae (*i.e.* a superficial and a deep one in Barrett's mucosa), we considered the deep one as the pre-existing muscularis mucosae and the superficial one as newly formed [19]. Consequently, a carcinoma invading into the superficial, *i.e.* newly formed, muscularis mucosae was defined as m2 and invasion into the deeper (pre-existing) muscularis mucosae was defined as m3. Carcinomas infiltrating into the submucosa without invasion of the muscularis propria were further subclassified as invasion limited to the upper third (sm1), intermediate third (sm2), or lower third part of the submucosal layer (sm3).

Follow-up

Patients were followed until death or until April 2003 with a median follow-up time of 44 months (range, 1 day to 13.6 years). They were seen on a regular basis for 5 years in the outpatient clinic (at 3- to 4-month intervals for the first 2 years and at 6-month intervals thereafter). For the present study, patients and/or their family practitioners were contacted by telephone to assess their current status when the patient had been discharged after 5 years. No patients were lost to follow-up.

Statistical analysis

All statistical analyses were performed using the Statistical Software Package version 11.5 (SPSS INC., Chicago, IL, USA). Recurrence free periods were calculated according to the Kaplan-Meier method and differences in recurrence free period were assessed using the log-rank test. P-values of <0.05 were considered statistically significant. The Cox regression model was used to analyse the independent prognostic value of different variables.

RESULTS

Pathological findings in the esophagectomy specimens

Of the 1100 patients operated upon for HGD or adenocarcinoma in both institutions, 120 patients were found to have an early lesion and underwent a transhiatal resection. There were 103 men (85%) and 17 women (15%), with a median age of 65.4 years (range 31-83 years). Hundred and seven patients had an early lesion of the distal esophagus (94 adenocarcinomas, 13 HGD's), in all but 2 cases associated with specialised intestinal metaplasia (Barrett's epithelium). Thirteen patients had a GEJ carcinoma (including 9 gastric cardia adenocarcinomas). All the 13 HGD cases were associated with Barrett's mucosa. Of the 107 invasive adenocarcinomas 26 were classified as well differentiated, 58 as moderately differentiated, whereas the remaining 23 tumors showed a poor differentiation grade.

Thirteen patients (11%) had a T1m1 tumor without clear invasion into the deeper layers (HGD, carcinoma in situ, Table 9.1). In 18 patients invasion was limited to the lamina propria (T1m2, 15%), 23 patients had the deepest tumor infiltration into the (deeper, pre-existent) muscularis mucosae (T1m3, 19%). In 25 patients the tumor extended into the upper third of the submucosal layer (T1sm1, 21%), 23 of the patients had a cancer infiltrating into the intermediate one-third (T1sm2, 19%), and in 18 patients the carcinoma infiltrated into the lower third part of the submucosal layer (T1sm3, 15%). Examples of each T1-substage are depicted in Figure 9.1. Of the 79 patients with T1m1-m3 or sm1 cancers, only one patient (T1m3) showed lymph node metastasis (1%), whereas 18 out of 41 patients with T1sm2-sm3 tumors (44%) had lymph node metastases (Table 9.1). The 19 cases with lymph node involvement included 18 distal esophageal adenocarcinomas and 1 GEJ cancer. The mean number of resected lymph nodes was 8.6 (range 1-40). The ratio of infiltrated to removed lymph nodes in these 19 pN+ cases was 0.21, the mean number of resected nodes was 10.0 (range 3-20). In 16 patients only regional lymph node metastases were present (paraesophageal, paracardial and/or along the lesser curvature), in 3 patients lymph nodes at the origin of the left gastric artery contained metastatic tumor (M1a).

Table 9.1 Histopathological features in 120 transhiatal esophagectomy specimens with high grade dysplasia (m1) or early invasive adenocarcinoma of the esophagus or gastro-esophageal junction.

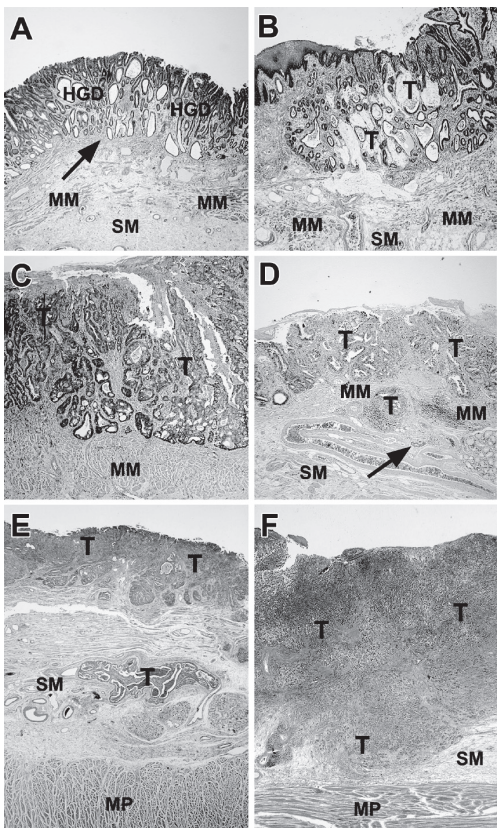

Figure 9.1. Hematoxylin-eosin stained histological sections of examples of the six different subgroups for depth of tumor invasion. A. T1m1, HGD; note the newly formed Barrett-associated muscularis mucosae (arrow) in relation to the pre-existent muscularis mucosae. B. T1m2, a mucinous, well differentiated, intra-mucosal adenocarcinoma. C. T1m3, adenocarcinoma reaches into the (pre-existent) muscularis mucosae. D. T1sm1, a small group of tumor cells is present in the superficial submucosa (arrow). E. T1sm2, carcinoma can be seen in the middle part of the submucosa, surrounded by vessels and esophageal salivary glands. F. T1sm3, a poorly differentiated adenocarcinoma infiltrates the deep submucosa. A-C, 4X objective, D-F, 2X objective. Abbreviations: HGD, high grade dysplasia; MP, muscularis propria; MM, muscularis mucosae; SM, submucosa; T, tumor.

Outcome after surgical resection

In all patients microscopically complete resection (R0) of the tumor was achieved. Five patients died in the hospital (mortality = 4%). Overall, the 120 patients with early lesions had a 5-year disease free survival of 68%. During follow-up 37 patients died. The proportions of patients without recurrence, per subgroup of depth of tumor invasion, are shown in Figure 9.2. Recurrence free period of patients with T1sm1 tumors did not differ from that of patients with T1m1, nor from that of patients with T1m2, or from that of patients with T1m3 tumors. However, recurrence free period did significantly differ from that of patients with T1sm2 and T1sm3 tumors (Figure 9.2). We, therefore, redefined depth of invasion into two subclasses, *i.e.* group I (T1m1, T1m2, T1m3 and T1sm1) and group II (T1sm2 and T1sm3), and subsequently compared recurrence free periods in both groups. A significant difference in recurrence free period was found between group I and group II (p logrank < 0.0001, Figure 9.3), with

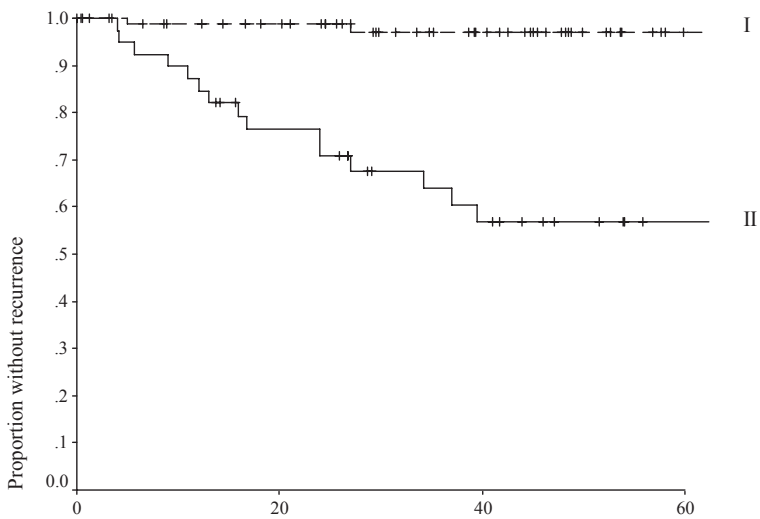
[a] In multivariable analysis correction was carried out for the prognostic variables age, gender, tumor differentiation grade and depth of tumor invasion; variables are mentioned in the column 'Prognostic factors'. [b] Hazard Rate. [c] CI: 95% Confidence Interval. [d] In the multivariable analysis, age is included as a continuous variable. [e] Reference category.



No at risk

Total	120	94	64	34
Group I	79	67	48	27
Group II	41	27	16	7

Figure 9.3. Proportion of patients without recurrence, T1m1, T1m2, T1m3, T1sm1 (group I, broken line, n=79) versus T1sm2 or T1sm3 (group II, uninterrupted line, n=41). A clear difference can be seen between the two groups (p logrank < 0.0001). Five-year recurrence free percentages for group I and group II were 97% (95% CI 93%-100%) and 57% (95% CI 40%-74%), respectively. Tick marks represent censored patients, i.e. end of follow-up.

5- year recurrence free percentages of 97% (95% CI 93%-100%) and 57% (95% CI 40%-74%), respectively. Importantly, when patients with HGD were left out of analysis, the difference in recurrence free period remained significant between T1m2, T1m3, T1sm1 (group I minus T1m1) and T1sm2, T1sm3 (group II) patients (p logrank < 0.0001), with 5-year recurrence free percentages of 96% (95% CI 92%-100%) and 57% (95% CI 40%-74%), respectively. Univariate Cox regression analysis to identify prognostic variables in the total group showed tumor differentiation grade and depth of tumor invasion to be prognostic factors for recurrence free period (p = 0.001 and p < 0.0001, respectively; Table 9.2). In multivariate analysis only depth of tumor invasion was an independent prognostic factor (HR 7.5, 95% CI=2.0-27.7, p=0.002). Alternatively, when recurrence free survival instead of recurrence free period was analysed, the significant difference between group I (T1m1, T1m2, T1m3, T1sm1) and group II (T1sm2, T1sm3) remained intact (p logrank=0.0001) with 5-year recurrence free survival percentages of 83 % (95% CI 65%-92%) and 42% (95% CI 25%-59%), respectively. Again, when patients with HGD were left out of this analysis a significant difference in recurrence free survival remained (p logrank=0.0008) with 5-year recurrence free survival percentages of 80% (95% CI 68%-91%) and 42% (95% CI 25%-59%), respectively.

Table 9.3 Tumor recurrence; of the 18 patients, some patients had recurrence at more than one site.

Recurrence	Number of patients
Locoregional	7
Distant	8
Bone	2
Pleural	3
Peritoneal	1
Liver	3
Truncal region	1
Both locoregional and distant	3
Truncal region	1
Bone	1
Supraclav lymph node	1

During the follow-up period 18 patients developed tumor recurrence (Table 9.3). The mean interval between operation and recurrence was 16 months (range 4-85 months). Seven patients died because of locoregional tumor recurrence without evidence of distant disease, eight patients developed only distant recurrence (of whom one patient was still alive at the end of follow-up), and three patients died because of both locoregional and distant recurrence. One patient died because of a second primary carcinoma in the lung (Table 9.4). Twelve out of eighteen patients, who died of locoregional recurrence and/or distant metastases, already had lymph node metastases at the time of resection. Recurrence free period differed significantly between patients with N0 (n=101) and N+ (n=19) tumors (p logrank < 0.0001,

Figure 9.4) with 5-year recurrence free percentages of 94% (95% CI 89%-99%) and 33% (95% CI 12%-55%), respectively.

Table 9.4 Distribution of patients at the end of follow-up.

Distribution	Number of patients
In-hospital mortality	5
Intercurrent death without disease	14

N+	19	10	6	1

Figure 9.4. Proportion of patients without recurrence, N0 (broken line, n=101) versus N+ (uninterrupted line, n=19). Patients with positive lymph nodes display a strikingly higher frequency of recurrence (p logrank < 0.0001). Five-year recurrence free percentages for N0 and N+ patients were 94% (95% CI 89%-99%) and 33% (95% CI 12%-55%), respectively. Tick marks represent censored patients, i.e. end of follow-up.

DISCUSSION

We have created a detailed map of T1-substages of early Barrett's and GEJ cancers in relation to lymphatic dissemination and tumor recurrence. A favorable outcome was characterised by vertical tumor growth into, but not deeper than the upper layer of the submucosa. In contrast, cancers proliferating into the middle and deeper layers of the submucosa showed an unfavorable outcome with a high rate of recurrence after surgical resection. In our study the overall 5-year disease free survival was 68%, which is comparable to the sparse literature on this subject [20-23] . In the literature 5-year overall survival rates of 100% have been reported for T1 tumors limited to the mucosa, and rates declining to 63-100% for T1 tumors invading into the submucosa.

The group of T1m1-m3/sm1 tumors had lymph node metastases in only 1% as compared to 44% in the group of T1sm2-sm3 carcinomas. The very low frequency of lymphatic dissemination in the first group could not be attributed to the inclusion of 13 HGDs, as the recurrence free period did not alter by excluding them from analysis. In a previous study of our group the correlation between vertical cancer growth, angio-lymphatic permeation and the presence of lymph node metastasis has already been investigated. However, this concerns only a subset of the present cohort that was operated on with various procedures.

The histopathological examination of endoscopically removed T1 adenocarcinomas in Barrett's esophagus can be difficult due to the presence of a double muscularis mucosae [19]. In Barrett's esophagus the mucosa consists of columnar epithelium, a superficial lamina propria, a superficial (newly formed) muscularis mucosae, a deep (pre-existent) lamina propria and a deep (pre-existent) muscularis mucosae. Precise classification of T1m2, T1m3 or T1sm1 cancer can be hampered, if there is doubt concerning the presence of the deep muscularis mucosae in the endomucosal resection specimen. Another, likely more important issue, is the correct classification of superficial tumor invasion of the submucosa in EMR specimens, because the deep (pre-existent) muscularis mucosae is not always a continuous structure [24]. However, our data indicate that this probably has no therapeutic consequences, since there is no difference in prognosis between T1m3 and T1sm1.

The 5-year recurrence free percentage of the patients with early tumors with lymph node invasion after transhiatal resection is disappointing (33%) and comparable to the prognosis of tumors with a more advanced T-stage and lymph node invasion [25]. The potential, particularly of the T1sm2-sm3 tumors, for both lymphatic and hematogenous dissemination already in an early stage is an indication of their aggressiveness. This might justify a more radical treatment, *i.e.* transthoracic esophagectomy with extended lymphadenectomy of the posterior mediastinum, upper abdomen and perhaps even the neck [26]. Moreover, the unordered pattern of lymphatic dissemination in esophageal cancer, resulting in the frequent presence of tumor cells at a relatively large distance from the primary lesion, [27] is once more a reason for extensive procedures. Extended resection is believed to reduce the rate of locoregional re-

currence, thereby increasing the quality of life and prolonging the recurrence free period and perhaps even survival. However, a more extensive resection for patients with early carcinomas could only be legitimated if it leads to a higher chance for cure. The possible advantages should be weighed against the increased risk of postoperative morbidity and mortality, since these patients are exposed to the higher risk of surgical complications [28].

To improve long term outcome, many institutes apply neoadjuvant chemoradiotherapy for advanced esophageal carcinoma, especially after the recent publication of favorable long term results of a randomized MRC-trial comparing neoadjuvant chemotherapy followed by surgery versus surgery alone [29]. However, the poor prognosis of submucosal T1 tumors, and the high frequency of lymphatic dissemination indicate that these patients could also benefit from neoadjuvant chemoradiotherapy.

In conclusion, based on these results we suggest that the combined group of mucosal (T1m1-m3) and superficial submucosal (T1sm1) adenocarcinomas are eligible for local endoscopic treatment, since they carry only a 1% risk of lymphatic dissemination in combination with a 5-year recurrence free period of 97%. For the T1sm2-sm3 adenocarcinoma group, which showed lymph node metastases in 44% and a recurrence free period of 57%, surgical resection should be the treatment of choice. The substantial locoregional recurrence with or without distant dissemination after limited transhiatal resection is an argument in favor of more extensive surgery, and/or neoadjuvant chemoradiation.

ABSTRACT

Surgery has curative potential in a proportion of patients with esophageal cancer, but is associated with considerable peri-operative risks. We aimed to develop and validate a simple risk score for surgical mortality that could be applied to administrative data. We analyzed 3592 esophagectomy patient from 4 cohorts. We applied logistic regression analysis to predict mortality occurring within 30 days after esophagectomy for 1327 esophageal cancer patients over 65 years of age, diagnosed between 1991 and 1996 in the linked Surveillance, Epidemiology, and End Results (SEER) - Medicare database. A simple score chart for preoperative risk assessment of surgical mortality was developed and validated on 3 other cohorts, including 714 SEER-Medicare patients diagnosed between 1997 and 1999, 349 patients from a population-based registry in the Netherlands diagnosed between 1993 and 2001, and 1202 patients from a referral hospital in the Netherlands diagnosed between 1980 and 2002. Surgical mortality in the 4 cohorts was 11% (147/1327), 10% (74/714), 7% (25/349) and 4% (45/1202) respectively. Predictive patient characteristics included age, comorbidity (cardiac, pulmonary, renal, hepatic, and diabetes), preoperative radiotherapy or combined chemoradiotherapy, and a relatively low hospital volume. At validation, the simple score showed good agreement of predicted risks with observed mortality rates (calibration), but low discrimination (area under the ROC curve 0.58 to 0.66). A simple risk score combining clinical characteristics along with hospital volume to predict surgical mortality after esophagectomy from administrative data may form a basis for risk adjustment in quality of care assessment.

INTRODUCTION

Surgical resection offers a chance of long-term survival in patients with esophageal cancer [1]. However, even after careful staging, survival remains disappointing with less than 25% of patients surviving at 5 years after esophagectomy [2]. Better results may be achieved with the concomitant use of preoperative (neoadjuvant) chemotherapy and radiotherapy, although the benefits may be small [3-5]. The surgical risk in the short-term and the potential loss in quality of life have to be weighed against the long-term benefit, such as a longer survival [6 7].

Accurate prediction of surgical mortality is important not only for appropriate selection of candidates for esophagectomy [8], but also for evaluation of quality of care and policy decisions. Risk-adjustment is particularly necessary when comparing surgical mortality rates between institutions [9-11]. It is well known that the short-term surgical risk of esophagectomy varies by clinical characteristics, such as age [12] and presence of concomitant diseases (comorbidity) [8, 13]. Further, esophagectomy is among the procedures where physician and hospital characteristics, especially volume, have been found to be strongly related to the surgical outcome [14-18]. Hence, patients at higher risk may most appropriately undergo surgery at high volume centers [18-20].

Patient characteristics have been combined in multivariable prediction models for short-term mortality after esophagectomy. However, these models were often based on selected patient groups in specialized centers [8, 21], thus limiting the generalizability of the results. Furthermore, validation on new patients was often not performed, or showed unsatisfactory results [22]. The aim of the present study was to develop a simple and robust prediction model for surgical mortality in esophageal cancer patients. We first analyzed several previously identified predictive characteristics in a large population-based cohort, then developed a simple risk score, and finally validated this score in 3 other cohorts.

METHODS

We analyzed 4 cohorts: two population-based series of 1327 and 714 patients from the linked Surveillance, Epidemiology, and End Results (SEER) - Medicare database [23], another population-based series of 349 patients from the Netherlands ('Eindhoven') [24], and 1202 patients from a referral hospital in the Netherlands ('Rotterdam') [25, 26]. The larger SEER–Medicare cohort served as the model development set and the other three as validation sets.

Patients: SEER-Medicare

The SEER database is made up of 11 tumor registries covering approximately 14% of the United States population. It has been linked to the Centers for Medicare and Medicaid services Medicare database through the end of 2001. We identified 2 sets of patients diagnosed with

pathologically confirmed esophageal cancer. The first set ('SEER 91-96') included patients diagnosed between January 1, 1991 and December 31, 1996. It was used for development of the prediction model. The second set included patients diagnosed between January 1, 1997 and December 31, 1999 ('SEER 97-99'), for validation of the developed model. The selection criteria and definitions of variables were identical in both sets. We excluded patients for whom the date of death differed by more than three months between the SEER and Medicare database, patients who were diagnosed from death certificate or autopsy, and patients for whom the month of diagnosis was not available. We also excluded patients who were only eligible for Medicare on the basis of end-stage renal failure or disability; therefore, all patients were 65 years or older.

We considered combinations of surgery, radiation, and chemotherapy [27]. Surgery was identified from the Medicare database using the International Classification of Diseases, 9th revision (ICD-9 codes 42.0 to 43.99) [28]. Information on radiation use was based on SEER records and Medicare data [29]. Information on chemotherapy was based on Medicare data only [30].

Comorbidity was determined based on Medicare claims between 13 months and 1 month before diagnosis [31]. Missing values were assigned to patients without Medicare data from this time window if no comorbidity was registered. Missing values were statistically imputed to allow for analysis of the available information from other predictors [32]. Exclusion of these patients in a sensitivity analysis did not affect results (data not shown). ICD-9 codes of both inpatient and outpatient bills were analyzed [33, 34]. Comorbidities were grouped as cardiovascular (previous myocardial infarction, heart failure, peripheral arterial disease, cerebrovascular disease), diabetes (with or without complications), pulmonary (COPD), renal (mild to severe), and hepatic (mild to severe) [8, 35]. We created a simple comorbidity score based on the presence of cardiac, pulmonary, renal, or hepatic comorbidity, or diabetes. For simplicity, each comorbidity was counted as one point, based on similar regression coefficients [36]. Patients were classified as having surgery performed in a teaching hospital versus not in a teaching hospital. Further hospital characteristics included the hospital volume, based on the sum of esophagectomies per hospital using the unique hospital provider number in the Medicare data [37]. Low, intermediate and high volumes were defined by tertile of patients.

Patients: Eindhoven

As a second validation cohort, we considered 349 patients who underwent surgical resection for a primary tumor of the esophagus, diagnosed between January 1, 1993 and December 31, 2001 in the Southeast of the Netherlands [24]. The Eindhoven Cancer Registry covers approximately 2 million inhabitants who are served by 16 community hospitals and two large radiotherapy institutes (16% of the Netherlands). Upon notification by one of six pathological laboratories and the hospital medical records departments, registration clerks actively collect information on diagnosis, tumor stage, treatment, and comorbidities from the medical re-

cords. The Eindhoven Cancer Registry has been collecting detailed data on clinically relevant comorbidity for new cancer patients since 1993 [35].

Patients: Rotterdam

As a third validation cohort, we considered 1202 patients who underwent surgical resection for a primary tumor of the esophagus at the University Hospital Rotterdam, between January 1, 1980 and December 31, 2002. This hospital serves as a referral center for the Southwest of the Netherlands. A database system is maintained with detailed information on diagnosis, tumor stage, treatment, and comorbidity [25, 26]. Information on hepatic and renal disease was not available for these patients.

Statistical analysis

Descriptive statistics were used for univariate analyses, with cells with fewer than 5 patients in the SEER cohorts indicated as '<5'. We applied logistic regression analysis to relate patient and treatment characteristics to mortality within 30 days after surgery. Mortality was considered irrespective of the cause. Odds ratios (ORs) were calculated with 95% confidence intervals (95%CI). Potential predictive characteristics were chosen from the clinical literature and expert opinion [38]. The performance of the model was assessed with respect to calibration and discrimination [39]. Calibration refers to the agreement between observed outcomes and predicted probabilities and is the most important quality when trying to predict the expected mortality rate for a group of patients. Calibration was assessed graphically, and tested with the Hosmer-Lemeshow goodness of fit test [40]. Discrimination refers to the ability to distinguish patients who will die from those who will survive. Discrimination was quantified by the Area Under the Receiver Operating Characteristic Curve (AUC), which is identical to the concordance (c) statistic [39]. An AUC of 0.5 indicates no discriminative ability at all, i.e. a coin flip, while an AUC of 1 indicates perfect discrimination, i.e. a test with 100% sensitivity and 100% specificity. Prediction models with an AUC exceeding 0.8 have often been labeled as good to excellent, those with AUC between 0.7 and 0.8 as moderate, and those with AUC between 0.6 and 0.7 as providing low discrimination.

Multivariable models were internally and externally validated. Internal validation was performed with a standard bootstrap procedure [38, 39]. Bootstrap samples were drawn with replacement, of the same size as the original sample. Predictions from each bootstrap model were evaluated in the original sample. The difference in performance in the bootstrap sample and in the original sample quantifies the optimism that may be expected when the multivariable model is applied to new, but similar, patients. A score chart was derived from the multivariable regression coefficients. For simple application, the coefficients were multiplied by two and rounded.

For external validation, we constructed logistic regression models for each cohort, containing the same predictors as the multivariable model based on SEER 1991-96. We studied whether

the predictors had similar effects. Subsequently, we derived a combined model based on all patient data, with stratification for study.

RESULTS

The SEER-Medicare patients were on average 73 and 74 years of age (Table 10.1). The patients in the Eindhoven and Rotterdam series were approximately 10 years younger on average (64 and 62 years respectively), since these series included patients of all ages, not just over 65 or older. The majority of patients was male. Comorbidity was found in around 20% of the SEER-Medicare patients (19% and 23%, respectively, especially pulmonary (9% and 9%), cardiovascular (9% and 9%), and diabetes (8% and 10%)). Pulmonary and cardiovascular comorbidities were more often registered for the Rotterdam patients (15% and 16% respectively), while cardiovascular comorbidity was more common in the Eindhoven patients (18%). Most patients had adenocarcinoma, and pathologically confirmed locoregional disease. Neoadjuvant treatment was given in around 20% of the SEER-Medicare patients, 7% of the Eindhoven patients and 38% of the Rotterdam patients. Most SEER-Medicare patients were treated in teaching hospitals, though the annual volumes of esophagectomies were relatively small. This information was not reliably available for the Eindhoven patients. The Rotterdam center is a referral hospital with over 50 esophagectomies per year.
Of the 1317 and 714 SEER-Medicare patients undergoing surgery, 147 (11%) and 74 (10%) died within 30 days after surgery, respectively. Mortality was lower among the Eindhoven and Rotterdam patients (7% and 4% respectively).

Univariate analyses

In univariate analysis of the 1317 SEER 91-96 patients, characteristics that were statistically significantly associated with mortality included age and comorbidity (pulmonary, diabetes) (Table 10.2). Neoadjuvant treatment with radiotherapy was associated with a substantially higher surgical mortality risk (23%), as was neoadjuvant chemoradiotherapy (16%). In contrast, neoadjuvant chemotherapy alone was associated with a somewhat lower risk of mortality (6%). For robust further analyses we combined the patients without any neoadjuvant treatment with those with neoadjuvant chemotherapy. Finally, higher hospital volume was clearly associated with lower surgical mortality (p-value for trend 0.003).
Similar relationships were observed in the other 3 cohorts, with higher mortality among older patients, those with comorbidity, and those who had neoadjuvant radiotherapy or chemoradiotherapy (Table 10.2).

1.1–2.5 / yr	42	12%	30	18%				
>= 2.6 /yr	39	8%	17	5%				

Multivariable analyses

Neoadjuvant treatment remained associated with an increased risk of surgical mortality in multivariable logistic regression analysis of the 1317 SEER 91-96 patients, with adjusted ORs of 2.5 and 1.9 for radiotherapy and chemoradiotherapy respectively (Table 10.3). Comorbi-

dity and age were also highly predictive, with an OR of 1.6 per comorbid condition, and an OR 1.6 per decade of age. Higher volume hospitals exhibited close to half the mortality of lower volume hospitals (OR 0.59).

The effects of age, comorbidity, and neoadjuvant therapy were very similar for the 714 SEER 97-99 patients. For the Eindhoven patients, comorbidity was associated with a higher mortality (OR 1.5 per condition), while age had no effect (OR close to 1). For the Rotterdam patients, predictive effects of age, comorbidity and neoadjuvant therapy were largely similar to those for the SEER-Medicare patients. When we combined all 4 cohorts (n=3592), the predictive effects were similar to those observed in the SEER 91-96 patients that were initially used for model development. For hospital volume, we found that mortality in 'high volume' centers was about half that in 'low volume' centers. For a 'very high' volume center such as Rotterdam the mortality was only a third of that in 'low volume' centers (Table 10.3).

Table 10.3 Multivariable logistic regression analyses in 4 cohorts. The combined data set contained 3592 patients, of whom 291 had died by 30 days.

Characteristic	SEER 91-96	SEER 97-99	Eindhoven	Rotterdam	Combined
Age per decade	1.6 [1.2-2.0]	1.5 [1.0-2.2]	0.94 [0.6-1.4]	1.4 [1.0-2.0]	1.4 [1.2-1.7]
Comorbidity count	1.6 [1.2-2.1]	1.3 [.91-1.9]	1.5 [0.8-2.9]	1.5 [1.0-2.3]	1.5 [1.2-1.8]

* Estimate for Rotterdam, a very high volume referral center

Model performance and risk score

The multivariable model based on the 1317 SEER 91-96 patients showed low discrimination (AUC 0.66). Internal validation of this model indicated a slight decrease in discriminative ability (AUC 0.65). The multivariable model performed similarly in the 714 SEER 97-99 patients (AUC 0.70) and Rotterdam patients (AUC 0.66), but poor in the Eindhoven patients (AUC 0.56).

A simple chart assigned 1 point per 15 years of age, 1 point per comorbidity, 1 point for neoadjuvant chemoradiotherapy, and 1.5 points for radiotherapy (Table 10.4). Hospital volume was scored as 0, –0.5, –1.5 and –2 for low, intermediate, high and very high volume respectively, based on the multivariable effects from Table 10.3. A summary score corresponds to

Table 10.4 Score chart to estimate 30-day mortality after cancer-directed surgery for esophageal cancer.

Characteristic	Value	Score
Age (years)	50	-1
	65	0
	80	1
Comorbidity	Pulmonary	1
	Cardiovascular	1
	Diabetes	1
	Hepatic	1
	Renal	1
Neoadjuvant therapy	Radiotherapy	1.5
	Chemoradiotherapy	1
Hospital volume	Low (<1/ yr)	0
	Intermediate (1.1-2.5/ yr)	-0.5
	High (>2.6/yr)	-1.5
	Very high (±50/yr)	-2
Sum score (add scores)		

Intermediate scores for age can be approximated by linear interpolation, e.g. age 72 corresponds to a score of +0.5.
The formula to calculate the predicted probability of surgical mortality is
P(mort) = 1 / [1+exp(2.41 – 0.32 * score)].

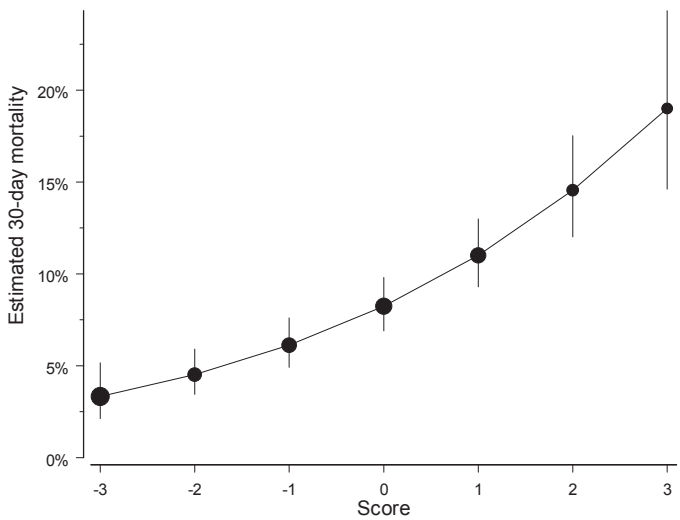

Figure 10.1 Estimated surgical mortality in relation to the sum score that can be obtained from Table 10. 4. The 95% confidence intervals are based on analysis of 4 cohorts, containing 3592 patients undergoing surgery for esophageal cancer. Dot size is proportional to number of patients.

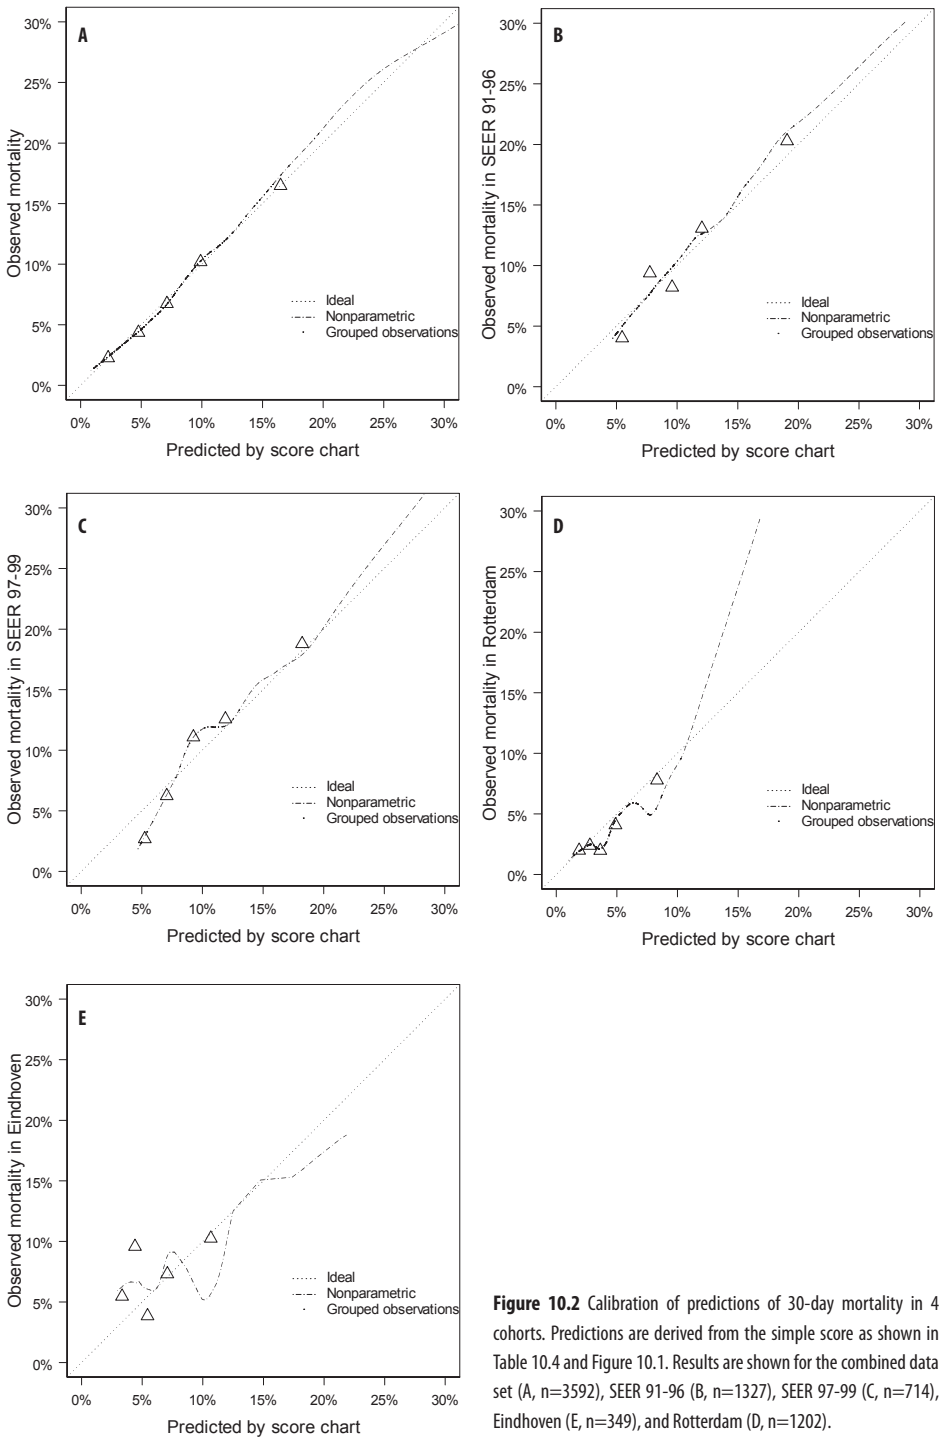

Figure 10.2 Calibration of predictions of 30-day mortality in 4 cohorts. Predictions are derived from the simple score as shown in Table 10.4 and Figure 10.1. Results are shown for the combined data set (A, n=3592), SEER 91-96 (B, n=1327), SEER 97-99 (C, n=714), Eindhoven (E, n=349), and Rotterdam (D, n=1202).

a predicted probability of 30-day mortality (Figure 10.1). For example, a 65-year-old patient, who has pulmonary and cardiovascular comorbidity, has not received neoadjuvant treatment, and undergoes surgery in a low volume hospital has a score of 0 + 2 + 0 + 0 = 2 points. This score corresponds to a predicted mortality of 17% [95%CI 14 – 21%]. If this patient were to be treated in a very high volume hospital (score –2, sum score=0), the predicted mortality would be 7% [5.7 – 8.5%]. The performance of the risk score was similar to the original model for each cohort (Table 10.3).

In Figure 10.2 we show the calibration of the predictions corresponding the risk scores. Predictions were above 19% for only 5% of the patients, consistent with the low discrimination. Calibration was excellent for all patients combined (Fig 10.2 A), and for the 2 series of SEER patients (Fig 10.2 B-C). Calibration was modest for Eindhoven and reasonable for Rotterdam (Figures 10.2 D-E).

DISCUSSION

Surgical mortality after esophagectomy is an important quality of care measure, but is only predictable to a certain extent with a limited set of patient, treatment and hospital characteristics. Using data from 3 different settings we found, as expected, that age and comorbidity were strongly related to outcome. Also, preoperative radiotherapy and chemoradiotherapy were clearly associated with 30-day mortality, as was a lower hospital volume. The discriminative ability of a simple risk score that combined these characteristics was however low.

Age predicts surgical risk for a wide range of procedures. For esophagectomy, one major study found that 30-day mortality increased from 10.7% for patients between 65 and 69 years of age to over 20% for those over 80 years [12]. We confirmed this trend in our data, especially in the SEER-Medicare cohorts, where we observed a relative increase in mortality of 40% per decade in adjusted analysis. The presence of comorbidity is known to affect outcome in many cancers. A number of scoring systems have been developed to measure it, including the Charlson score [41] and the ACE-27 [13]. We used a simple count of comorbid cardiovascular, pulmonary, renal, hepatic conditions, and diabetes, and found that each point was on average associated with a 50% increase in surgical risk (OR 1.5). Comorbidity scoring was claims-based in the SEER-Medicare data, and chart-based in the other 2 cohorts. Despite these and other differences in definitions, the comorbidity-mortality relationship was similar across the 4 study cohorts, in line with findings in a previous study [42].

Preoperative unimodality radiotherapy was clearly associated with higher surgical mortality. This treatment strategy has largely been abandoned in recent years [43], so a more relevant finding is that neoadjuvant chemoradiotherapy nearly doubled mortality compared to no neoadjuvant treatment or neoadjuvant chemotherapy alone. It is possible that these results may be somewhat confounded by selection of patients with more advanced tumors for

neoadjuvant treatment. However, our findings are consistent with recent meta-analyses of randomized trials, showing that neoadjuvant chemoradiotherapy was associated with a 1.72 fold higher surgical mortality (95%CI 0.96 – 3.1, p = 0.07) [3], while neoadjuvant chemotherapy alone was not (OR 1.08 [95%CI 0.45 – 2.6]; p=0.87) [44]. This implies that part of the benefit of neoadjuvant chemoradiotherapy (e.g. on small metastases which would not be resected by surgery) may be offset by higher surgical mortality. This issue requires further detailed evaluation in randomized trials. Our results suggest that measures to reduce surgical risk should especially be considered for patients with neoadjuvant chemoradiotherapy.

Reported surgical risks vary widely in the literature. Much of this variation can be explained by differences in hospital volume [14-19, 45, 46]. Hospital volume remained important after adjustment for case-mix, which is generally an important methodological consideration in such analyses of observational data [9-11]. Many authors suggest that a policy of concentrating care in high-volume centers should be considered especially for esophagectomy, where outcome varies substantially between low-volume and high-volume providers [20, 47]. As illustrated, a patient could have a 17% or 7% predicted mortality risk depending on surgery in a low volume or in a high volume center.

Our study has some limitations. Our 4 cohorts were of considerable size, but the Eindhoven and Rotterdam series had only few events, which makes firm conclusions on external validity difficult [48]. We included all patients undergoing esophagectomy. Around 10% had pathologically distant disease, and we cannot exclude that a few patients had clinically known distant disease before surgery. The inclusion of these patients may have led us to overestimate risk for patients with true locoregional disease. On the other hand, we considered 30-day mortality, and in-hospital mortality can be substantially higher. We further note that the model was mainly based on patients over 65 years of age; validity may be best for this patient category. Next, the exact limits to define low, medium and high volume centers are hard to determine. We used rather low annual volumes (<1, 1-2.5, >=2.6 per year), based on tertiles of patients, while higher limits may be better defendable. Finally, we did not have information on physiologic variables such as performance status or ASA score which have been used in clinical models [45, 49]. Our risk model hence had only a low discriminative ability, and can therefore only be a relatively rough, though evidence-based, basis for the surgical risk of individual patients. Our score is easy to calculate from existing, readily available data, however, and so could well serve for case-mix adjustment when comparing surgical mortality rates between institutions.

In conclusion, we found substantial mortality after esophagectomy, which was related to patient, neoadjuvant therapy, and hospital characteristics. We developed and externally validated a simple risk score, which provides an admittedly rough estimate of surgical mortality with which to compare actual outcomes. Further validation and extension of this score is mandatory.

Chapter 11

The CHEK2*1100delC mutation has no major contribution in esophageal carcinogenesis

British Journal of Cancer, 2004 Feb 23;90(4):888-891

ABSTRACT

In response to DNA damage, the cell cycle checkpoint kinase 2 (CHEK2) may phosphorylate p53, Cdc25A and Cdc25C, and regulate BRCA1 function, leading to cell cycle arrest and DNA repair. The truncating germline mutation CHEK2*1100delC abrogates kinase activity and confers low-penetrance susceptibility to breast cancer. We found CHEK2*1100delC in 0.5% of 190 esophageal squamous cell carcinomas and in 1.5% of 196 esophageal adenocarcinomas. In addition we observed the mutation in 3.0% of 99 Barrett's metaplasias and 1.5% of 66 dysplastic Barrett's epithelia, both known precursor lesions of esophageal adenocarcinoma. Since CHEK2*1100delC mutation frequencies did not significantly differ among esophageal squamous cell carcinomas, adenocarcinomas and (dysplastic) Barrett's epithelia as compared to healthy individuals, we conclude that the CHEK2*1100delC mutation has no major contribution in esophageal carcinogenesis.

INTRODUCTION

Esophageal carcinoma is the ninth most common tumor type worldwide. Despite surgical intervention, 5-year overall survival is less then 20%, mainly due to the fact that patients often present with an advanced tumor stage. Alcohol and tobacco use are established risk factors for the development of esophageal squamous cell carcinomas [1]. The presence of Barrett's esophagus is the main risk factor for adenocarcinoma formation, being 30-125 times higher in patients with Barrett's esophagus as compared to the general population. Barrett's esophagus is defined as a columnar cell metaplasia of the native distal esophageal squamous cell epithelium [2], accompanied by the presence of Goblet cells, as a result of chronic gastro-esophageal reflux. Barrett's metaplasia can progress to low and high grade dysplasia and ultimately to invasive and metastasising adenocarcinoma. Patients with Barrett's esophagus receive endoscopic surveillance to detect dysplasia and to diagnose carcinoma at an early and possibly treatable stage. The identification of genes that confer susceptibility for adenocarcinoma formation in Barrett's esophagus would imply improved manageability of patients with Barrett's esophagus. Familial cases of esophageal cancer are however rare, and susceptibility genes for esophageal cancer are thus unlikely to be found by linkage analysis. Consequently, screening of candidate susceptibility genes may be a more feasible approach for esophageal cancer.

CHEK2 (also known as CHK2) is the mammalian homologue of Saccharomyces cerevisiae Rad53 and Schizosaccharomyces pombe Cds1 genes [3,4]. The CHEK2 gene, located on human chromosome 22q12, encodes a cell cycle checkpoint kinase that is implicated in DNA damage responses. Phosphorylation of the p53, Cdc25A and Cdc25C protein results in arrests in various phases of the cell cycle [5,6]. In addition, CHEK2 has been implicated in the regulation of DNA repair by the BRCA1 protein [5,6]. CHEK2*1100delC is a truncating germline variant of CHEK2 that abrogates kinase activity [7,8] and has initially been reported in families suffering from the Li-Fraumeni syndrome without p53 mutations [9]. In familial gastric cancers, which are known to cluster in Li-Fraumeni families, germline CHEK2 mutations were absent [10]. In sporadic (osteo)sarcomas, lung cancers, breast cancers, ovarian cancers, colon cancers and hematopoietic neoplasms, CHEK2 was found to be rarely mutated [9,11-17]. From recent publications it appeared that the germline CHEK2*1100delC mutation in fact confers low-penetrance susceptibility to breast cancer [18,19]. An increased frequency of CHEK2*1100delC was found among breast carcinoma families without BRCA1 or BRCA2 mutations, associated with an approximately twofold increase of breast cancer risk in female carriers [18].

The p53 protein is one of the downstream targets of CHEK2 kinase. Mutations of the p53 gene result in a variety of disturbances in growth control involving DNA replication, DNA repair and apoptosis. Like in breast carcinoma, mutations of the p53 gene appear to play an important role in the development of esophageal squamous cell carcinoma, dysplastic Barrett's epithelium and the progression to esophageal adenocarcinoma [20-22]. Ample studies have re-

ported mutations in p53 in esophageal carcinomas, with mutation frequencies varying from 40-90% [23-26]. As CHEK2 and p53 are thought to be participants of the same biological pathway we aimed to establish whether CHEK2*1100delC confers susceptibility to esophageal cancer by determining the frequency of the mutation among an unselected series of esophageal cancers and precursor lesions.

MATERIALS AND METHODS

Tissue specimens and controls

We investigated a cohort of 190 esophageal squamous cell cancer patients, 196 esophageal adenocarcinoma patients, 99 patients with Barrett's metaplasia and 66 patients with dysplastic Barrett's epithelium. Tissue samples were obtained from resection specimens (carcinomas) or endoscopic biopsies (Barrett's metaplasia and dysplasia), all derived from different patients. We microscopically confirmed that the endoscopic biopsy specimens did not exhibit any tumor cell invasion. Tissue fragments were digested from routine formalin-fixed, paraffin-embedded tissue blocks, without deparaffinization, in 180μL of 50mM/L Tris/HCl (pH=8.0), and 20μL of Proteinase K (20mg/μL) was added. After overnight incubation at 56°C, the lysates were boiled for ten minutes and subsequently centrifuged. Two series of Dutch control individuals consisted of (A) 184 spouses of individuals heterozygous with respect to cystic fibrosis from the Southwest Netherlands, and (B) 460 individuals at ages 55 and older ascertained through the Erasmus Rotterdam Health and the Elderly Study (ERGO) [18].

Allele-specific oligonucleotide hybridisation assay

CHEK2 exon 10 was amplified using forward CHEK2 primer (5'-CAACATTATTCCCTTTTG-TACTG-3') and reverse CHEK2 primer (5'-GTTCCACATAAGGTTCTCATG-3'). DNA samples (1μL) were subjected to PCR analysis in a total volume of 50 μL containing 1x Promega buffer, 1.5 mM $MgCl_2$-solution, 4 μM dGTP, dTTP, dCTP and dATP, 3U Taq DNA polymerase (Promega, Madison, USA), and 0.2μg of forward and reverse CHEK2 primer. PCR amplification consisted of 35 cycles (95°C for 30 sec, 55°C for 45 sec and 72°C for 45 sec) followed by a final extension at 72°C for 10 minutes. We detected the CHEK2*1100delC mutation by application of diluted PCR products to nylon filters and hybridisation under high stringency of [^{32}P]-labelled oligonucleotides complementary to CHEK2*1100delC and the wild-type sequence (5'-TTAG-ATTATGATTTTGGG-3' and 5'-TTAGATTACTGATTTTGG-3' respectively).

Polymorphic marker analysis

DNA was radioactively amplified essentially as described above, using forward primer (5'-TAAGGTGGGAGGTTCACTTG-3') and reverse primer (5'-ACCCATCCTCCTGCCTTAG-3') for the D22S275 locus. PCR products were separated on a 6% polyacrylamide denaturing gel. After

electrophoresis, gels were dried on blotting paper and exposed to X-ray films. Films were evaluated by visual inspection.

Immunohistochemistry

From formalin-fixed paraffin-embedded tissue blocks, 4-μm thick sections were mounted on 3-aminopropyl-triethoxysilane (APES)-coated glass slides. The sections were incubated with a mouse monoclonal antibody DCS 270.1 against the human CHEK2 protein (Novocastra Laboratories, Newcastle, UK; at a dilution of 1:50). Immunoreactivity was visualised by a standard avidin biotin immunoperoxidase technique, using a commercially available kit (Labvision, Fremont, USA)[27,28].

Statistics

Differences of the CHEK2*1100delC mutation frequency between patients and controls were expressed in terms of odds ratios (OR) and 95% confidence intervals (95% CI), and tested with the χ^2-test.

RESULTS AND DISCUSSION

We analysed tumor and biopsy samples obtained from 551 Dutch patients by a CHEK2*1100delC allele-specific oligonucleotide hybridisation assay. CHEK2*1100delC mutations were detected in 0.5% of 190 squamous cell carcinomas, 1.5% of 196 adenocarcinomas, 3.0% of 99 Barrett's metaplasias and in 1.5% of 66 dysplasias (Table 11.1). Chi-square analysis revealed no significant differences between patient groups and the CHEK2*1100delC mutation frequency of 1.4% among 644 control individuals (p=.94) and the Odds Ratio of the total patient group compared to the controls was 1.04 (95%CI 0.35-3.06, Table 11.1). These results suggest that CHEK2*1100delC does not substantially contribute to the development of esophageal carcinoma. CHEK2*1100delC could still confer a three-fold risk, which is greater than the estimated two-fold risk associated with breast cancer and CHEK2*1100delC thus may still be a low-penetrance susceptibility gene to esophageal cancer. Given the low frequency of the mutation, however, even the maximal possible three-fold risk conferred by CHEK2*1100delC would only marginally contribute to the overall incidence of esophageal cancer.

Examples of the hybridisation assay are shown in Figure 11.1. Median ages of patient groups at diagnosis were 59.6, range 14-86 years (Barrett's metaplasias), 60.3, range 32-84 years (dysplasias), 63.9, range 36-84 years (adenocarcinomas) and 60.9, range 31-79 years (squamous cell carcinomas). Ages at diagnosis of CHEK2*1100delC mutation carriers were 48, 73 and 77 years (Barrett's metaplasias), 59 years (dysplasia), 44, 50 and 63 years (adenocarcinomas) and 73 years (squamous cell carcinoma), which was not different from non-carriers and again not supporting a major role of CHEK2*1100delC in esophageal cancer predisposition.

Table 11. 1 CHEK2*1100delC mutation frequencies.

CHEK2*1100delC mutation					
	number tested	carriers	percentage	OR (95%CI)[a]	P-value[a]
Controls					
Netherlands (A)[b]	184	3	1.6		
Netherlands (B-ERGO)[b]	460	6	1.3		
Total	644	9	1.4		
Barrett's metaplasias	99	3	3.0	2.20 (0.38-9.04)	.23
Dysplasias	66	1	1.5	1.09 (0.02-8.05)	.93
Adenocarcinomas	196	3	1.5	1.10 (0.19-4.45)	.89
Squamous cell carcinomas	190	1	0.5	0.37 (0.01-2.73)	.33
Total	551	8	1.5	1.04 (0.35-3.06)	.94

[a]OR: Odds Ratio, 95%CI: 95% Confidence Interval, and P-values are determined by χ^2-test, as compared to frequency in controls. [b]CHEK2*1100delC frequency in Dutch control cohorts A and B by Meijers-Heijboer et al., 2002.

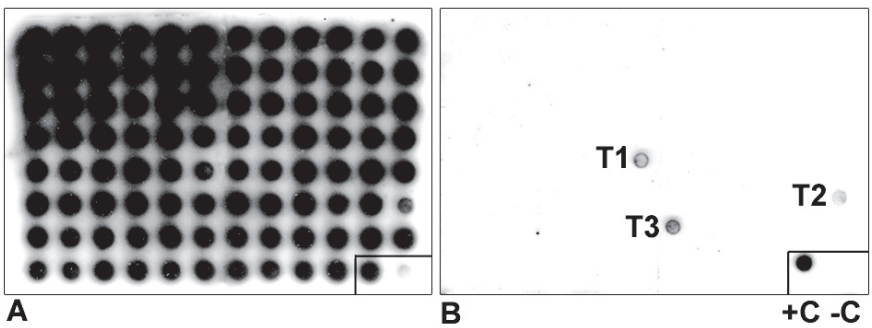

Figure 11.1 Allele-specific oligonucleotide hybridisation assay of 94 adenocarcinomas. Blot A, hybridisation with wild-type oligonucleotide. Blot B, hybridisation with mutant oligonucleotide. Adenocarcinoma samples T1, T2 and T3 are positive for the CHEK2*1100delC mutation, sample '+C' represents a control individual with CHEK2*1100delC, and sample '-C' represents a control individual negative for CHEK2*1100delC.

All mutations were confirmed and proven to be germline-derived by investigating patients' normal tissue. Only paraffin embedded samples of tumor negative lymph nodes were available, precluding confirmation of mutations by sequencing of long range PCR products [29]. The CHEK2*1100delC germline mutation has however been found to be linked to one specific allele of the D22S275 polymorphic marker, that is located in intron 4 of CHEK2, which is present in 13% of the Dutch population [18]. All eight mutation-positive cases were demonstrated to carry the D22S275 allele linked to the CHEK2 mutation, which supports the detected mutations (Figure 11.2). Comparison of allele patterns in mutated tumors with their normal tissues revealed LOH in only one of the three informative carcinomas (T1 without LOH in Figure 11.2B, T4 with LOH in Figure 11.2C). LOH was also observed in three out of 14 informative non-mutated tumor samples. Limited data are however available on LOH of CHEK2 in tumors and the possible tumor suppressing role of CHEK2 therefore awaits further studies.

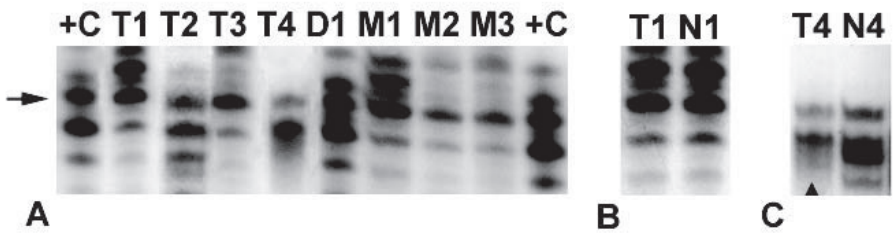

Figure 11.2 D22S275 polymorphic marker analysis in samples with CHEK2*1100delC. A, the allele (arrow), known to be present in all carriers of CHEK2*1100delC[18], is present in all samples with the CHEK2*1100delC mutation (T1-T3 mutated adenocarcinoma samples, T4 mutated squamous cell carcinoma, D1 mutated dysplastic tissue, M1-M3 mutated metaplastic tissue), '+C' represents a control individual with CHEK2*1100delC. B, C, LOH patterns from 2 mutated tumors (T1 adenocarcinoma and T4 squamous cell carcinoma) compared with corresponding normal tissues (N1 and N4) are shown. Arrowhead points to the deleted allele in T4.

Immunohistochemistry using monoclonal antibody DCS 270.1 on a series of mutated and non-mutated tumor tissues showed clear nuclear staining in all cases (Figure 11.3). Since the DCS 270.1 epitope lies within the N-terminus of CHEK2, staining of both wild type and mutant protein may be expected. We observed no differences in CHEK2 protein levels, i.e. no lower intensity nor a lower percentage of CHEK2-positive cells, between CHEK2*1100delC mutated and non-mutated cancers. This was also true for the single mutated tumor with LOH (T4 in Figure 11.3F), suggesting that a theoretical two-fold reduction in CHEK2 protein level can not be detected by the applied immunohistochemistry method. This appears to contrast results of Vahteristo et al. who reported loss of expression in three of the four CHEK2*1100delC tumors and reduction of CHEK2 protein expression in the fourth, using the same antibody [19]. Comparison of the two studies is however difficult, as they did not indicate the precise level of reduction in protein expression [19]. Since only few CHEK2*1100delC tumors have currently been reported, both the data of Vahteristo et al. and the present data should be interpreted with caution.
In summary, our study of a large and unselected series of Barrett's metaplasias and dysplasias, esophageal adenocarcinomas and squamous cell carcinomas suggests that the germline CHEK2*1100delC mutation has no major contribution in esophageal carcinogenesis.

ACKNOWLEDGMENTS

We are grateful to Dr. Anneke van der Wurff (Department of Pathology, Elisabeth Hospital Tilburg) for kindly providing biopsy samples and to Dr. Wim van Putten (Department of Statistics, Daniël den Hoed Cancer Clinic, Rotterdam) for statistical analyses. We wish to thank Marijke Wasielewski, Antoinette Hollestelle and Fons Elstrodt for technical assistance, Frieda van der Ham for performing immunohistochemistry and Frank van der Panne for photographic work.

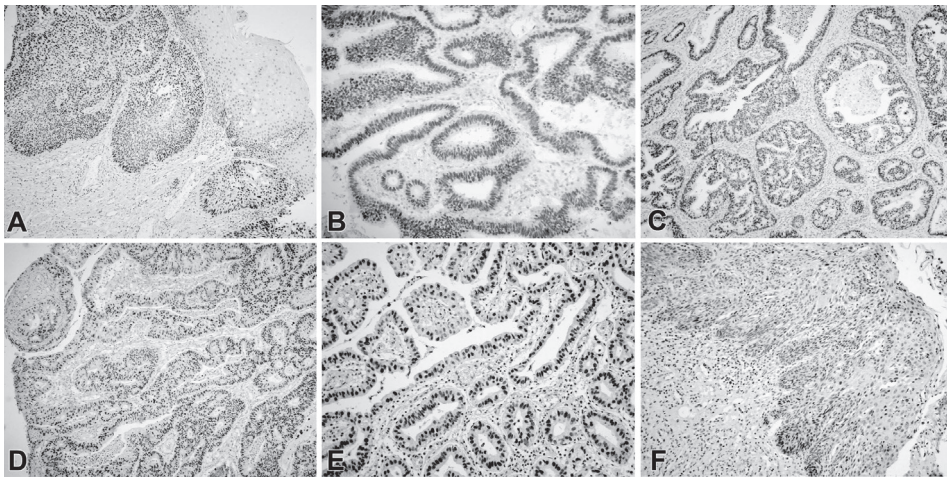

Figure 11.3 CHEK2 protein expression. Non-mutated squamous cell carcinoma in A, non-mutated adenocarcinoma in B. Remaining samples are from the 4 mutated tumors: adenocarcinomas T1, T2 and T3 shown in C, D, E, squamous cell carcinoma T4 shown in F. Magnification 100 x B, E 50 x A, C, D, F. Note: the strong nuclear CHEK2 immunoreactivity in the tumor cells. *Also see color figures page 291.*

ABSTRACT

Research has begun to identify common genetic variants, so called Single Nucleotide Polymorphisms (SNPs), that confer susceptibility to cancer. The aim of the present study was to analyse the relationship between SNPs and the susceptibility for cancer of the esophagus and gastro-esophageal junction (GEJ). SNPs were selected from the literature upon association with cancer predisposition in various other types of cancer. SNPs were genotyped in DNA from 254 GEJ adenocarcinomas and 189 esophageal squamous cell carcinomas obtained from resection specimens and in a control group of 235 healthy blood donors. The SNPs in p53 (exon 4 G72C and intron 6), Her-2/neu (exon 17 A655G), Cyclin D1 (exon 4 A870G) and STK15 (exon 5 T31A) were genotyped by PCR-restriction fragment length polymorphism (PCR-RFLP) analysis. SNPs in p53 intron 3 (16 bp duplication), TGF β receptor 1*6A and E-cadherin (-347 G/GA) were visualized on agarose gels or denaturing gels. SNPs in E-cadherin (-160 C/A), TGF β (-509 G/A), p16 (exon 3 C540G), p73 (exon 2 G4C14-A4T14) and PPAR γ (exon 7 C34G) were analysed with the Taqman allelic discrimination assay. Significant differences between cases and controls were validated in separate validation cohorts of 326 GEJ adenocarcinomas and 209 squamous cell carcinomas. Subjects with the p16 exon 3 C/C genotype were at 1.5-fold reduced risk for squamous cell carcinoma as compared to those with C/G and G/G genotypes. Genotype frequencies were 51% (CC), 46% (CG) and 3% (GG) as compared to 75% , 23% and 2% GG in controls ($p<0.001$). Subjects with the Cyclin D1 exon 4 A/A genotype were at 1.3-fold reduced risk for squamous cell carcinoma as compared to the other genotypes. P73 exon 2 GC/GC genotype conferred a 1.2-fold increased risk for adenocarcinoma whereas the AT/AT genotype conferred a 1.99-fold increased risk for squamous cell carcinoma. These data suggest that the p16 exon 3 C/C wildtype genotype and the Cyclin D1 exon 4 A/A variant genotype might be protective for the development of squamous cell carcinoma. The p73 exon 2 SNP may be a genetic susceptibility factor for the onset of esophageal squamous cell carcinoma (AT/AT) and GEJ adenocarcinoma (GC/GC).

INTRODUCTION

Under current therapy modalities esophageal cancer remains a disease with poor prognosis. Alcohol and tobacco use are established risk factors for the development of esophageal squamous cell carcinomas [1]. Gastro-esophageal reflux disease (GERD) with formation of Barrett's esophagus is a well established risk factor for adenocarcinomas of the distal esophagus and the gastric cardia, the gastro-esophageal junction (GEJ) [2,3]. Despite these etiological conditions only a small group of patients suffering from predisposing disease or environmental exposure will ever develop cancer. It seems likely that progress with this cancer will be made only with early detection, prevention and a clearer understanding of its aetiology and tumor biology.

The number of known genetic mutations that are associated with cancer susceptibility is growing at an exponential rate [4]. With completion of the Human Genome project physicians are provided with an arsenal of genetic information that will hopefully lead to better understanding and treatment of approximately 4000 genetic diseases. An important example is the discovery of single nucleotide polymorphisms (SNPs) that occur about once every 1000 bases along the 3-billion base human genome. Individual variations in cancer risk have been associated with specific variant alleles of different genes, SNPs, that are present in a significant proportion of the normal population. The aetiology of specific cancers might therefore be associated with a set of SNPs, many of which could adversely interact with environmental factors. SNPs are thought to serve as genetic markers for identifying disease genes by linkage studies in families. Familial cases of esophageal cancer are however rare, and susceptibility genes for esophageal cancer are thus unlikely to be found by linkage analysis. Consequently, screening of candidate susceptibility genes may be a more feasible approach. Genes directly involved in tumor mutagenesis form the most interesting candidate susceptibility genes, i.e. tumor suppressor and proto-oncogenes. In this study SNPs with known susceptibility in several types of cancer were analysed in esophageal squamous cell carcinomas and GEJ adenocarcinomas. Selected SNPs concerned the tumor suppressor or proto-oncogenes p53 [5-21], p16 [22-24], Cyclin D1 [25-39], p73 [16,40-50], Transforming Growth Factor β (TGF β) receptor 1 [51-54], TGF β [55,56], E-cadherin [33,57-62], Peroxisome Proliferator-Activator Receptor-γ (PPAR-γ) [63-67], Serine/Threonine protein Kinase 15 (STK15) [68-71] and Her-2/neu [72-74] (Table 12.1).

MATERIALS AND METHODS

Study subjects

Cases included 254 GEJ adenocarcinoma patients and 189 esophageal squamous cell carcinoma patients who underwent esophagectomy at the Erasmus Medical Center (Rotterdam). Tissue was obtained from resection specimens. Validation cohorts of 326 adenocarcinomas and 209 squamous cell carcinomas were obtained from the archives of the Academic Medical

Centers (Amsterdam, Maastricht) and non-academic hospitals Medisch Centrum Rijnmond Zuid (Rotterdam), Reinier de Graaf Gasthuis (Delft) and analysed when significant differences were found between cases (Rotterdam) and controls. All control cohorts consisted of Dutch healthy blood donors. To compare frequencies of the 3 investigated p53 polymorphisms control cohort 1 was analysed (N=166). For the TGF β receptor 1 polymorphism a control cohort was used described in the literature (control cohort 2, N=183) [75]. For the other investigated polymorphisms control cohort 3 was used (N=235). A fourth control cohort was used when the genotype distribution was not in agreement with Hardy-Weinberg equilibrium (N=360).

SNP genotyping

Genomic DNA was extracted from frozen or paraffin-embedded formalin fixed normal (not tumor) tissues (patients) or from whole blood samples (controls). PCR-primer sequences are shown in Table 12.2. Used technique per SNP, flanking sequences, genotype and dbSNP ID rs number are mentioned in Table 12.3. For SNPs in E-cadherin promotor -347, p53 (exon 4 G72C, intron 3 and intron 6), Her-2/Neu (exon 17 A655G), Cyclin D1 (exon 4 A870G) and STK15 (exon 5 T31A) PCR conditions were standardised at 35 cycles of 95°C for 30 sec, 55°C for 45 sec, 72°C for 45 sec and 72°C for 10 min. Amplified PCR products using p53 intron 3 primers were visualized on 1.5% agarose gels. E-cadherin (promotor -347 G/GA) SNP was visualized on denaturing polyacrylamide gels (acrylamide/bisacrylamide 19:1). PCR-Restriction Fragment Length Polymorphism (PCR-RFLP) analysis was performed for determining genotypes of p53 (exon 4 and intron 6), Her-2/neu (exon 17 A655G), Cyclin D1 (exon 4 A870G), and STK15 (exon 5 T31A). Ten units of restriction enzym (BstU, MspI, APOI or BsmAI) were added to PCR products with 16 hours of incubation at 60°C (BstU), 37°C (MspI), 50°C (APOI) or 55°C (BsmAI) with a final inactivation at 80°C for 20 min. Digested products were visualized on 3% agarose gels.

[a] dbSNP http://www.ncbi.nlm.nih.gov/SNP

A touchdown PCR was performed for the TGF β receptor 1*6A (deletion of three alanines (6A) from a nine-alanine stretch (9A)) SNP for 27 cycles of 95°C for 30 sec, 68°C (-0,5°C per cycle) for 30 sec, 72°C for 30 sec, 10 cycles of 95°C for 30 sec, 55°C for 30 sec, 72°C for 30 sec and 72°C for 10 min. Amplified products were analysed on 3% agarose gels.

E-cadherin (promotor -160 C/A), TGF β (promotor -509 G/A), p16 (exon 3 C540G), p73 (exon 2 G4C14-A4T14) and PPAR γ (exon 7 C34G) were genotyped in 5-ng genomic DNA with the Taqman allelic discrimination assay (Applied Biosystems, Foster City, Calif). PCR conditions were standardised at 95°C for 10 min, 40 cycli of 92°C for 15 sec and 60°C for 1 min. Reactions were performed with the Taqman Prism 7900HT 384 wells format. Primer sequences are reported in Table 12.2, probe sequences corresponded to wildtype or SNP sequence mentioned in Table 12.3. Examples of Taqman allelic discrimination analysis and PCR-RFLP analysis are shown in Figures 12.1 and 12.2.

Statistics

The χ^2 test was used to compare genotype frequencies between cases and controls and to compute deviations from Hardy-Weinberg equilibrium. The association between the variant genotypes and risk of esophageal and GEJ cancer was estimated by computing odds ratios (ORs) and their 95% confidence interval (CIs). Statistical significance was set at $p<0.05$. All analyses were 2-sided and conducted using SPSS software (version 11.0; SPSS, Inc., Chicago, IL).

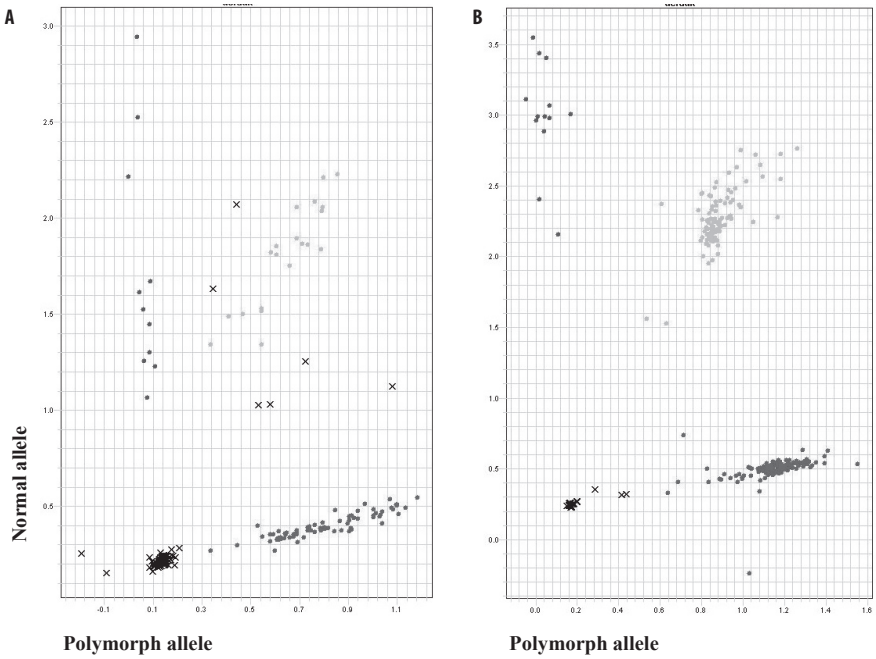

Figure 12.1. Taqman allelic discrimination assay concerning p73 exon 2 G4C14-A4T14 of 191 GEJ adenocarcinomas (A.) and 232 controls (B.). Distribution of homozygous normal (blue dots), heterozygous (green dots) and homozygous polymorphism (red dots). *Also see color figures page 291.*

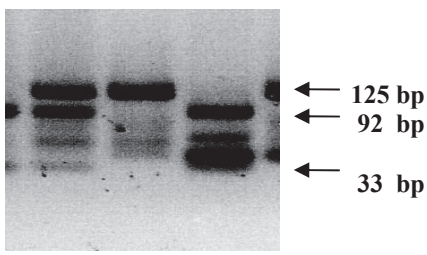

Figure 12.2. Example of PCR-RFLP analysis concerning Cyclin D1 exon 4 A870G. The polymorphic allele contains a restriction site resulting in two bands, 92 basepairs and 33 basepairs respectively (arrows). The normal allele, without a restriction site has a length of 125 basepairs. Examples shown are heterozygous (lane 1), homozygous normal (lane 2) and homozygous polymorphic (lane 3).

RESULTS

Mean age ± standard deviation (cases) and gender (cases and controls) are shown in Table 12.4. The distributions of genotype frequencies of the 13 investigated SNPs between the cases and controls are summarized in Table 12.5. Only informative samples were mentioned. For the p16 exon 3 C540G SNP in squamous cell carcinomas the frequencies of CC, CG and GG genotypes were 51%, 46% and 3% respectively which were significantly different from the frequencies in controls (75%, 23% and 2%, $p<0.001$, Table 12.5). After significant results in the cases in the first cohort, results were validated using a validation cohort with substantiation

Table 12.4. Characteristics of patients and controls.

Cohort	Age, years (mean ± SD[a])	Gender (M:F)
Adenocarcinomas

[a]Standard deviation; [b]Unknown

of significancy. Pooled results are depicted in Table 12.5. The odds ratio (OR) for development of squamous cell carcinoma in C/C homozygotes compared to the other genotypes was 0.68 (95% CI 0.60-0.77), corresponding to a 1.5-fold reduced risk in these individuals and therefore a protective effect of the C/C homozygote genotype. The OR in C/G heterozygotes as compared to the other genotypes was 1.99 (95% CI 1.53-2.59), corresponding to a 1.99-fold increased risk.

For the Cyclin D1 exon 4 A870G SNP in squamous cell carcinomas the frequencies of A/A, A/G and G/G genotypes were 18%, 52% and 30% respectively which were different from the frequencies in controls (23%, 52% and 25%, p=0.048, Table 12.5). The OR for development of squamous cell carcinoma in G/G homozygotes compared to the other genotypes was 1.21 (95% CI 0.99-1.49, p=0.07), corresponding to a 1.21-fold increased risk in these individuals or a 1.3-fold reduced risk for A/A homozygotes (OR 0.75 (95% CI 0.58-0.98, p=0.03). Examples of Cyclin D1 exon 4 A870G PCR-RFLP analysis are shown in Figure 12.2.

SNPs in the same chromosomal region are not inherited randomly, but as combinations of alleles which form haploblocks. The p73 exon 2 G4C14-A4T14 SNP is such an example. For this SNP in adenocarcinomas and squamous cell carcinomas frequencies of GC/GC, GC/AT, AT/AT genotypes were 70% and 65% respectively, 25% and 24% respectively and 5% and 10% respectively as compared to 57%, 37% and 5% in healthy blood donors which significantly differed (p=0.003 and p=0.003, Table 12.5). The OR for development of adenocarcinoma in GC/GC homozygotes compared to the other genotypes was 1.21 (95% CI 1.07-1.37). The OR for development of squamous cell carcinoma in AT/AT homozygotes compared to the other genotypes was 1.99 (95% CI 1.03-3.84).

[a]P-value as compared to controls by χ^2 test. AC: Adenocarcinoma. SCC: Squamous cell carcinoma.

The distribution of none of the other genotypes was associated with risk of esophageal squamous cell carcinoma or adenocarcinoma. Examples of the p73 exon 2 G4C14-A4T14 Taqman allelic discrimination assay in GEJ adenocarcinomas and controls is shown in Figure 12.1.
All genotype frequencies of controls were in Hardy-Weinberg equilibrium ($p>0.05$), except for Cyclin D1 exon 4 A870G and Her-2/neu exon 17 A655G (control cohort 1, $p=0.01$ and $p=0.005$ respectively). There could have been an influence from control selection. To overcome this problem a second control cohort was used, which was in agreement with the Hardy-Weinberg equilibrium ($p=0.6$ and $p=0.8$ respectively). When the two control cohorts were pooled it was in Hardy-Weinberg equilibrium (Table 12.5, $p=0.4$ and $p=0.1$ respectively). All genotype frequencies of the cases were in Hardy-Weinberg equilibrium except for the p16 exon 3 polymorphism (squamous cell carcinomas, $p<0.001$) and the p73 (squamous cell carcinomas and adenocarcinomas, $p=0.002$ and $p<0.001$ respectively), which gave significant results when distribution of genotypes were compared between cases and controls (Table 12.5).

DISCUSSION

The current study analysed the possible influence of common genetic variants, Single Nucleotide Polymorphisms (SNPs), for risk of esophageal squamous cell carcinoma and GEJ adenocarcinoma. Most SNPs are 'silent', i.e. do not alter the function or expression of a gene. The term 'mutation' is reserved for rare variants with a particularly high penetrance, usually associated with a detrimental phenotype, such as Hereditary Breast and Ovarian Cancer (BRCA1, BRCA2), Hereditary Non-Polyposis Colorectal cancer (MSH2, MSH6, MLH2, PMS1, PMS2) and Familial Adenomatous Polyposis (APC) amongst others. As classically thought, changes in either tumor suppressor or oncogenes sort 100% effect, in an on/off way. SNPs are associated with low penetrance and variable effects on wildtype activity. Interestingly, all SNPs with a significant effect on esophageal cancer susceptibility in this study (p16 exon 3 C540G, Cyclin D1 exon 4 A870G, p73 exon 2 G4C14-A4T14) did not lead to an amino acid sequence change. SNPs are, however, thought to be able to sort their effect by influence on splicing, by linkage with other SNPs (on the same or on a different gene) with functional effects or by mere coincidence. Even intronic SNPs, within non-coding regions of the corresponding genes, are

described to confer functional relevance without a proven explanation. It becomes increasingly apparent that cancer susceptibility might be related to polymorphic variations in the DNA sequence [76].

In the current study, healthy blood donors were chosen as controls. Although it is not clear if blood donors exactly mirror the genotypes of a population, e.g. due to ethnic asymmetries, blood donors are generally accepted as controls for SNP studies for practicability reasons [77]. However, as blood donors tend to be younger than cancer patients, no perfect match between patients and controls was gained in our study.

A 1.5-fold reduced risk was shown for squamous cell carcinoma subjects with the p16 exon 3 C540G C/C genotype as compared to those with C/G and G/G genotypes. This suggests a protective role for the C/C genotype in the development of squamous cell carcinoma. P16 regulates function in G1 cell cycle arrest and is therefore important in carcinogenesis. P16 exon 3 C540G SNP does not lead to an amino acid sequence change but has, however, been associated with tumor susceptibility in a number of studies [22-24]. The SNP has been associated with low expression of p53 [24]. In our series not the variant G/G genotype but the heterozygous C/G genotype was increased prevalent in squamous cell carcinoma cases, with an OR 1.99 (95% CI 1.53-2.59), corresponding to a 1.99-fold increased risk for squamous cell carcinomas as compared to the other genotypes. We were not able to test for linkage disequilibrium, described for melanomas in the literature, since we did not analyse the described p16 intronic SNP [24]. Analogous to Geddert and colleagues, who did not find an association of p16 exon 3 C540G SNP with esophageal adenocarcinomas, cardia adenocarcinomas and subcardia adenocarcinomas, we could also not find an association between this SNP and GEJ adenocarcinomas in our series [78].

Subjects with the Cyclin D1 exon 4 G/G genotype were at 1.21-fold increased risk for squamous cell carcinoma as compared to the other genotypes. The control cohort used (control cohort 3) was not in agreement with the Hardy-Weinberg equilibrium (HWE) and therefore was supplemented with a second control cohort (n=581 in total, HWE p=0.4). Cyclin D1 is a key protein for the regulation of cell cycle G1-S-transition. The Cyclin D1 exon 4 A870G SNP does not lead to an amino acid sequence change but it creates an alternative splice site in its mRNA, encoding a protein with an altered C-terminal domain. It has been suggested that DNA damage in cells with the A allele bypasses the G(1)/S checkpoint of the cell cycle more easily than damage in cells without the A allele. Several studies have suggested a significant association between the Cyclin D1 genotype and onset or progression of various cancers [25-39]. Interestingly, this SNP is in the literature contradictory reported as A>G and G>A. Within the dbSNP (http://www.ncbi.nlm.nih.gov/SNP) this SNP is reported as A870G, which was followed in our study. Concerning squamous cell carcinomas of head and neck and of esophagus, having comparable risk factors, significant associations between the A/A genotype and cancer risk were described, which is not in agreement with our data which show a protective role of the A/A genotype instead of susceptibility for esophageal squamous cell

carcinoma [38,39]. In these studies there was an adjustment for smoking habits within multivariable analyses. Unfortunately, since our study was not designed as a prospective case-control study, data on life style riskfactors were not available for cases or for controls. Interestingly, in a recently performed study the A/A genotype was shown to confer increased risk for GERD, Barrett's esophagus and esophageal adenocarcinoma [25]. In a northern Chinese population the A/A genotype conferred an increased risk for gastric cardia adenocarcinoma [38]. In our study, distribution of Cyclin D1 genotypes within 253 GEJ adenocarcinomas as compared to 587 controls did significantly differ (A/A 29% vs. 23%, p=0.01), but when a validation cohort existing of 299 adenocarcinomas was analysed, this significancy disappeared (22% vs. 23%, p=0.7; total group 26% vs. 23% p=0.1). Cyclin D1 exon 4 A870G therefore did not function as a genetic susceptibility factor in GEJ adenocarcinomas in our study.

P73 is a gene that is structurally similar to the p53 tumor suppressor gene and can inhibit cell growth and induce apoptosis. Two common SNPs in position 4 (G/A) and 14 (C/T) in the uncoding region of exon 2 of the p73 gene are in complete linkage disequilibrium with one another and form a haplotype block. The AT allele is described to possibly affect p73 function by altering the efficiency of translation initiation [79]. P73 exon 2 G4C14-A4T14 has been associated with several cancer types [16,40-50]. In our current study, p73 exon 2 GC/GC genotype conferred a 1.2-fold increased risk for adenocarcinoma whereas the AT/AT variant genotype conferred a 1.99-fold increased risk for squamous cell carcinoma. Analysing esophageal squamous cell and adenocarinomas (n=25 and n=59), Ryan et al. reported less prevalent AT/AT in the total group of patients as compared to controls (1.2% vs. 4%, p<0.02) [50]. When squamous cell carcinomas and adenocarcinomas were separately analysed genotype frequencies were 48% and 50.8% (GC/GC), 48% and 49.1% (GC/AT) and 4% and 0% (AT/AT) respectively [50]. In our study, using large patient numbers, genotype frequencies were 65% and 70% (GC/GC), 24% and 25% (GC/AT) and 10% and 5% (AT/AT) in squamous cell and adenocarcinomas respectively. AT/AT was increased prevalent in squamous cell carcinomas as compared to controls, in contrast to the Ryan-study. GC/GC was increased prevalent in GEJ adenocarcinomas. Since esophageal squamous cell and adenocarcinomas concern different tumortypes, harbouring different genetic alterations, we analysed them separately, with different outcomes concerning p73 (amongst others). Different results in the Ryan-study and our study might perhaps be explained by different ethnic background, although the control group used by Ryan et al. is a Caucasian one (homogeneous Irish) as are the control groups used in our study. Ethnicity is known to be an important confounding factor in epidemiologic studies involving genetic polymorphisms [80]. Interestingly, in the study performed by Ryan et al., LOH of p73 was shown in 37.8% of 37 heterozygote tumor tissues being exclusive loss of the AT allele, suggesting a specific functional role for the AT allele [50]. They speculate that the p73 AT allele might modulate the inflammatory response to GERD and its subsequent evolution of Barrett's esophagus, dysplasia and cancer because it may lead to difference in p73 function, perhaps due to splice variant expression [50]. We did not perform LOH analysis in our cases, which might be very

interesting. It could well be that this allele is lost in tumors of part of the patients harbouring the allele in their normal DNA. Since it could also be that the p73 SNP is in linkage disequilibrium with other functional polymorphisms, thereby altering the function of p73 or involving adjacent susceptibility loci, it would also be interesting to study multigenetic effects of variant alleles, for example from p53 exon 4, introns 3 and 6, and p73.

Over the past decades, there has been an increasing incidence of GEJ adenocarcinomas in developed countries. GEJ adenocarcinoma now exceeds the incidence of esophageal squamous cell carcinoma. GERD and Barrett's esophagus, the precursorlesion of GEJ adenocarcinoma, are highly prevalent in the population. Only a fraction of individuals show progression to adenocarcinoma. Endoscopic surveillance of Barrett's esophagus patients is a widely accepted and utilized strategy to detect early carcinoma, which is potentially curable. Most Barrett's patients however never develop carcinoma. It is likely that interactions between molecular and lifestyle risk factors confer individual susceptibility for neoplastic progression. SNPs may modify the effect of environmental exposures and therefore susceptibility for cancer [81]. As published previously for breast cancer, microarray technique allowing for the simultaneous detection of a high number of mutations and SNPs might provide prognostic information in addition to established clinical parameters [82]. Analysis of SNPs can be performed conveniently from a simple blood test. This might be of help to define subsets of Barrett's esophagus patients or patients suffering from GERD, who are at increased risk for adenocarcinoma and therefore to further stratify surveillance. There is no known precursor lesion of squamous cell carcinoma, although chronic irritation and inflammation of the esophagus in response to environmental factors such as alcohol or nicotine is thought to play a role in the development of cancer. Also in these patients at risk SNPs analysis might be helpful in the future. Our data confirm that SNPs confer risk for esophageal squamous cell carcinoma (p16 exon 2 C540G, Cyclin D1 exon 4 A870G and p73 exon 2 G4C14-A4T14) and for GEJ adenocarcinoma (p73 exon 2 G4C14-A4T14). Currently a large cohort of Barrett's esophagus patients, who did not develop cancer yet, is being analysed for p73 exon 2 G4C14-A4T14 genotype frequencies as well as for the other SNPs described in this study to reveal whether SNPs could be helpful to stratify surveillance.

ABSTRACT

Barrett's metaplasia (MET) or intestinal differentiation in columnar lined esophagus can progress to low grade dysplasia (LGD), high grade dysplasia (HGD) and ultimately to invasive carcinoma (CA). Since the genetic abnormalities involved in this multistep process are still poorly understood, we aimed to identify molecular markers that predict progression to malignancy in Barrett's patients. We investigated first whether gastro-esophageal (GEJ) adenocarcinomas are monoclonal or polyclonal proliferations. To this end, multiple biopsies per carcinoma were selected from 14 GEJ adenocarcinoma resection specimens. These were investigated for loss of heterozygosity (LOH) of chromosomal loci 17p (p53), 9p (p16), 5q (APC, MCC), 13q (Rb) and 18q (DCC, DPC4/SMAD4), for p53 mutations (exon 5 to 8) and for mutations in the homopolymeric C-stretch (D310) within the mitochondrial DNA (mtDNA) displacement loop. We then investigated the usefulness of these aberrations as molecular progression markers in the MET-LGD-HGD-CA sequence in Barrett's esophagus from 31 GEJ resection specimens. Results of the genetic analyses were compared to the histology of the specimens. Identical 17p LOH patterns in multiple biopsies from one tumor were seen in 10 out of 11 informative tumors and, especially, identical intratumor p53 mutations in all nine tumors with a p53 mutation indicated monoclonality of GEJ adenocarcinomas. LOH of 9p was detected in 76% of MET, p53 aberrations appeared in around 60% of LGD, 13q LOH and 18q (DCC and DPC4) LOH appeared in around 45% of LGD adjacent to carcinoma. Consistent LOH and mutation patterns, i.e. loss of the same allele or identical mutations, were found in the majority of cases within the MET-LGD-HGD-CA sequence. A combination of the investigated markers, especially p53 mutations, 17p LOH, 9p LOH, 13q LOH and 18q LOH may be used in conjunction with the histopathological diagnosis for detection of neoplastic progression in Barrett's esophagus.

INTRODUCTION

Chronic gastro-esophageal reflux disease leads to Barrett's esophagus (BE) in around 10% of the patients suffering from this common disease. BE is characterized by columnar metaplasia with intestinal differentiation that has replaced the normally present stratified squamous epithelium in the lower third of the esophagus. BE harbors the risk of progression to dysplasia and adenocarcinoma, with 0.2-2% of patients with Barrett's metaplasia eventually developing a carcinoma [1]. Progression is considered to follow the 'metaplasia (MET)-low grade dysplasia (LGD)-high grade dysplasia (HGD)-carcinoma (CA) sequence', characterized by accumulation of cell cycle abnormalities, genetic abnormalities and aneuploidy [2-4]. Patients with BE are mostly subjected to intensive endoscopic surveillance with biopsy sampling to identify those with neoplastic progression. The histological identification of dysplasia in tissue biopsies is of major importance in determining the intensity of both surveillance and treatment [5]. The histological diagnosis of the grade of dysplasia, however, is characterized by problems concerning biopsy sampling error and intra- and interobserver variation [6].

Preferably, BE patients at high risk for neoplastic progression should be identified before histologic presence of dysplasia. From the literature it is known that aneuploidy as well as genetic abnormalities could be predictors of neoplastic progression, demonstrating a clinical application of early tumor markers in BE surveillance programs [7,8]. From this perspective, it is important to know whether GEJ cancer develops via a process of monoclonal or polyclonal expansion. Monoclonal development would enhance the reliability of molecular markers, since the genetic aberrant clone that represents a possible developing tumor could then be harvested from the premalignant Barrett's epithelium. If we assume that progression from premalignant Barrett's epithelium to carcinoma is a monoclonal process, we expect intratumor homogeneity of early genetic alterations.

In the current study we investigated whether GEJ adenocarcinomas are monoclonal or polyclonal proliferations. Furthermore we investigated the value of several candidate molecular markers as predictors of neoplastic progression from Barrett's metaplasia to adenocarcinoma. We hypothesized that genetic alterations may occur before phenotypic changes in Barrett's epithelium take place. The most promising candidate markers are genetic alterations that are known to occur early in GEJ carcinogenesis as shown by Loss of Heterozygosity (LOH) studies and Comparative Genomic Hybridization (CGH) studies reported in the literature [2,9-28]. In addition, mitochondrial DNA (mtDNA) mutation analyses were performed of a homopolymeric C stretch (D310), a mutational hotspot in the mitochondrial genome. MtDNA mutations have been suggested to be indicators of clonal expansion and as such can be considered as cancer biomarkers [29,30]. The molecular aberrations detected were evaluated for their use as early tumor markers in 31 GEJ resection specimens containing several combinations of MET-LGD-HGD and adenocarcinoma.

MATERIALS AND METHODS

Patients and specimens

Resection specimens of patients with GEJ adenocarcinomas were obtained from 35 patients (33 male, 2 female, mean age at the time of cancer diagnosis 65.4 ± 8.4 years, age range 50-80 years) treated between July 1999 and April 2002 at the Erasmus MC, Rotterdam. All patients underwent a transhiatal resection of the tumor with restoration of the continuity of the gastrointestinal tract by a gastric tube with cervical anastomosis. In thirty-one patients Barrett's epithelium was present. In one patient high grade dysplastic Barrett's epithelium without invasive carcinoma was present. In 4 patients no Barrett's epithelium was found. Thirty-one tumors were located at the distal esophagus, 2 were located at the GEJ and 2 carcinomas were located at the gastric cardia.

Tissue samples and DNA isolation

Tissue biopsies were derived from premalignant and malignant tissue from the 35 GEJ adenocarcinoma resection specimens who were all embedded in paraffin. From 14 GEJ adenocarcinomas multiple, macroscopically separated, tumor biopsies were collected (Figure 13.1). From 31 GEJ resection specimens, 10 of which were also used for the analysis of multiple tumor samples, both premaligant and malignant tissue was present and collected (11 cases MET-LGD-HGD-CA, 6 cases LGD-HGD-CA, 4 cases HGD-CA, 3 cases MET-LGD-CA, 2 cases MET-HGD-CA, 3 cases MET-CA, 1 case LGD-CA, 1 case MET-LGD-HGD). Five-μm thick sections of the paraffine embedded tissue biopsies were mounted on uncoated glass-slides. After deparaffinisation, the sections were stained with eosine and Mayer's haematoxylin solution, analysed by an experienced GI-pathologist (HvD) and finally areas of interest were isolated by Laser Capture Microdissection (LCM, Figure 13.2). In all 35 cases tumor-negative lymph nodes were used as normal non-cancerous tissue. Microdissected tissues and multiple sections of normal tissue were incubated in 50μl of lysis buffer (10 mmol/L Tris-HCl, 1mmol/L EDTA and 1% Tween 20 pH 8.0) plus 1μl proteinase K (20μg/ml) for at least 48 hours. Every 24 hours, 1 μl of proteinase K was added to the samples. Thereafter samples were heated for 10 minutes at 95 °C to inactivate proteinase K.

PCR amplification

DNA was amplified by a radioactive 15μl Polymerase Chain Reaction (PCR). The PCR mix per sample consisted of 10μl distilled H_2O, 1.5μl goldbuffer, 1.5μl 25 mM $MgCl_2$-solution, 0.3μl 10mM dGTP, dTTP, dCTP, 0.3μl 1mM dATP, 0.9 Units (5U/μl x 0.18μl) Amplitaq polymerase (Perkin-Elmer, Wellesley, MA, USA), 30 ng (0.1μg/μl x 0.3μl) of forward and reverse primer, 0.075μl αP^{32}-dATP and 1μl DNA sample. Before amplification, the PCR-mix was heated at 95°C for 5 minutes to activate the Amplitaq polymerase. The temperatures for amplification were 95°C for 30 seconds, 55°C for 45 seconds and 72°C for 45 seconds. These steps were repeated

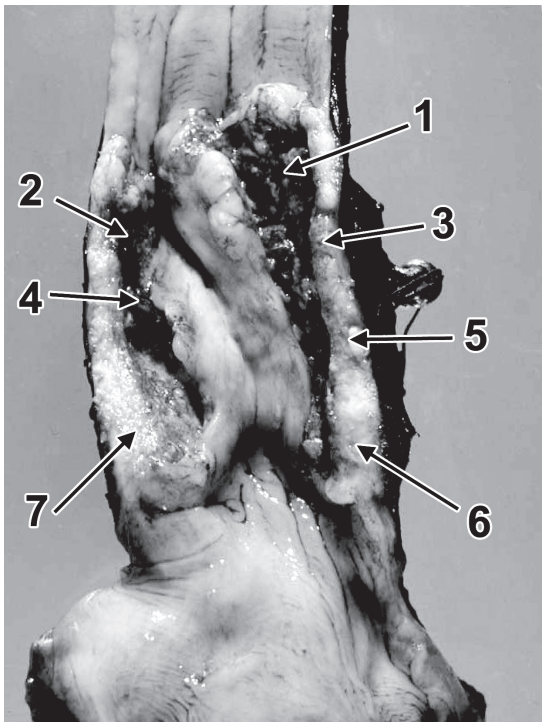

Figure 13.1 Collection of macroscopically separated tumor biopsies from a distal esophageal adenocarcinoma.

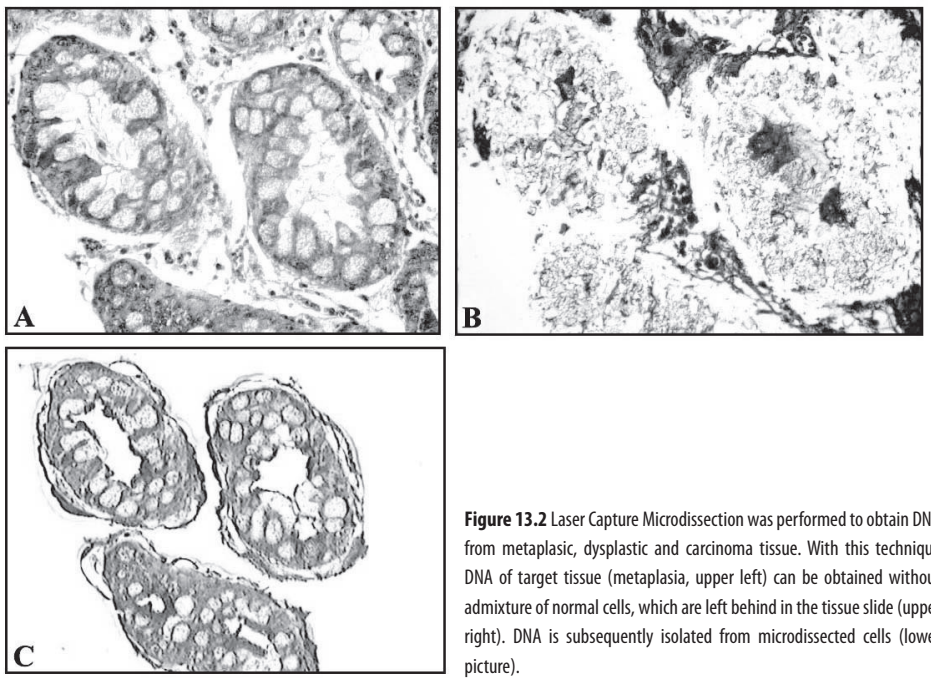

Figure 13.2 Laser Capture Microdissection was performed to obtain DNA from metaplasic, dysplastic and carcinoma tissue. With this technique DNA of target tissue (metaplasia, upper left) can be obtained without admixture of normal cells, which are left behind in the tissue slide (upper right). DNA is subsequently isolated from microdissected cells (lower picture).

for 35 cycles followed by a final extension at 72°C for 10 minutes.

LOH and Single Strand Conformation Polymorphism (SSCP) analysis

For LOH analysis, highly polymorphic dinucleotide repeat markers were amplified. The markers used were located at chromosomal regions known to be frequently deleted in GEJ adenocarcinomas [2,9-28]. The chromosome loci selected harbor the tumor suppressor genes p53 (17p), p16 (9p), Adenomatous Polyposis Coli (APC, 5q), Mutated in Colorectal Cancer (MCC, 5q), Retinoblastoma (Rb, 13q), Deleted in Colorectal Cancer (DCC, 18q), and Deleted in Pancreatic Cancer (DPC4/SMAD4, 18q). Exons 5 to 8 of the p53 gene were investigated by SSCP analysis. Each exon was amplified in 2 overlapping fragments. In addition, deletion/insertion mutations in the mitochondrial D310 fragment were investigated according to the revised human mitochondrial DNA Cambridge sequence [31]. For the mtDNA experiments DNA samples from the mtDNA-less 143B206 ρ° cells and parental 143B206 cells were used as negative and positive controls (cell lines were kind gifts of Dr. G.P. Comi, Milan, Italy, and Dr. D.M. Turnbull, Newcastle upon Tyne, United Kingdom). All primers used are listed in Table 1. PCR products (15μl) were diluted with 14μl loading buffer (95% formamide, 10 mM EDTA pH 8, 0.05% bromophenol blue and 0.05% xylene cyanol) and denaturated at 95°C for 5 minutes. Solutions were chilled on ice and, per sample, 4μl was loaded on a 15% polyacrylamide gel (acrylamide to bisacrylamide 19:1) for LOH analysis, or on an 8% polyacrylamide gel (acrylamide to bisacrylamide 49:1) containing 10% of glycerol for SSCP analysis. Electrophoresis was performed at 65W at room temperature for 1.5-2 hours for LOH analysis, and at 8W overnight at room temperature for SSCP analysis. The gels were vacuum dried at 80°C and exposed to X-ray films. For LOH as well as for SSCP analyses, tumor DNA was always compared with normal DNA from the same patient.

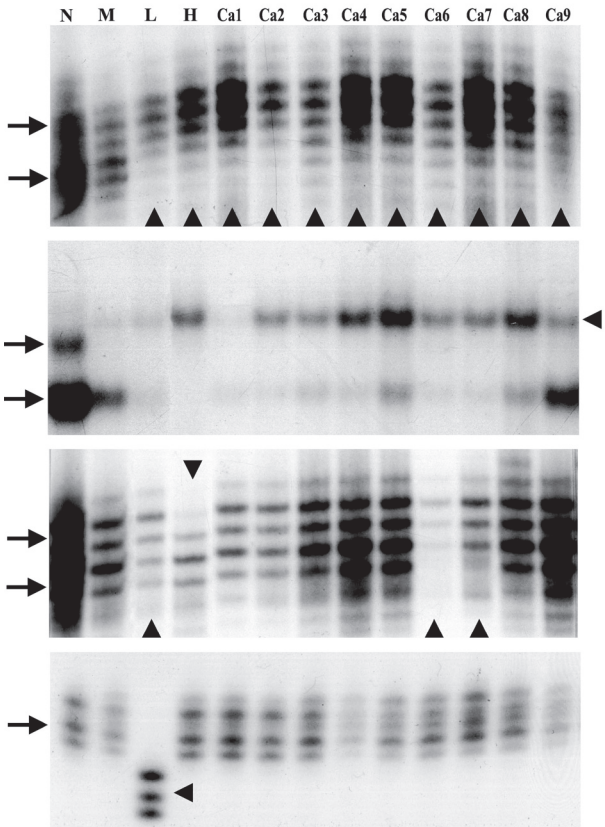

Figure 13.3 PCR-LOH 17p (p53, marker TP53CA), PCR-SSCP p53 (exon 7), PCR-LOH 9p (p16, marker D9S1748) and PCR-SSCP MtDNA (marker D310) analyses of GEJ adenocarcinoma with MET-LGD-HGD and 9 carcinoma samples (see also Table 13.2, Table 13.3 patient 12). Black arrows at the left side point to allelic patterns. The upper picture demonstrates loss of the lower allele (arrow heads) in LGD, HGD and in all carcinoma (Ca) samples as compared to corresponding Normal DNA (N). The second picture demonstrates an identical p53 mutation in MET (M), LGD (L), HGD (H) and all Ca samples (arrow head points to mutation pattern). The third picture demonstrates loss of the lower allele in L, Ca6 and Ca7 (arrow heads) and loss of the upper allele in H (arrow head) as compared to N. The fourth picture demonstrates a MtDNA mutation in L (arrow head).

Sequencing

P53 mutations indicated by SSCP analysis were identified by direct sequencing (Figure 13.4). PCR products were used for cycle sequencing using a Dye Terminator Cycle Sequencing Ready Reaction and analysed on an ABI Prism 3100 genetic analyser according to the instructions of the manufacturer (PE Biosystems, Foster City, CA).

Statistics

The mean number of molecular aberrations was compared between the total groups of MET and LGD, between total groups of LGD and HGD, between total groups of HGD and carcinoma and between MET/LGD and HGD/carcinoma using the independent samples T-test. The number of molecular aberrations was calculated as the sum of p53 mutation, LOH at 7 investigated loci (wit maximum count of 7) and D310 mutation.

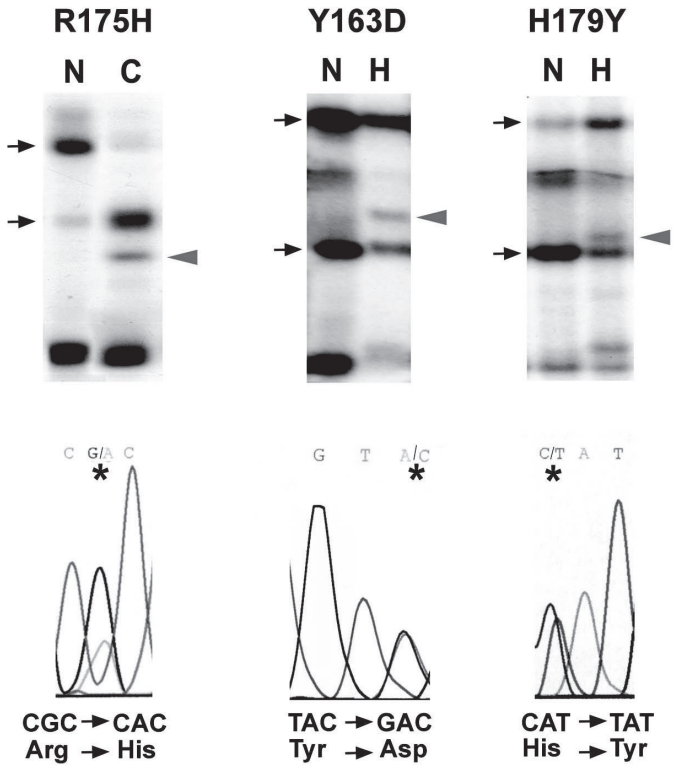

Figure 13.4 PCR-SSCP and sequencing analyses of three p53 mutations in High grade dysplasia (H), Carcinoma (C) and corresponding normal DNA (N). Black arrows point to allelic patterns. Red arrow heads point to mutated alleles. The sequencing chromatograms below each autoradiograph show the alterations (note the substituted nucleotide marked by an asterisk), which all represent p53 mutations. *Also see color figures page 291.*

RESULTS

Clonal analysis

A mean number of six biopsies (range 2-10) was taken from different areas within the tumor. LOH (17p, 9p, 5q, 13q and 18q), p53 exon 5 to 8 and D310 mutation analyses were thus investigated in a total number of 78 samples from 14 tumors. The LOH and mutation data of 1 of the 14 tumors are shown in Table 13.2 and Figure 13.3.

In 9 out of 14 tumors, p53 mutation analysis showed complete intratumor homogeneity, i.e. all biopsies from one tumor harbored an identical p53 mutation. In 5 out of 14 tumors no p53 mutation could be detected in all tumor biopsies (Table 13.3). With regard to the intratumor clonality of 17p LOH (p53), 11 patients had an informative LOH pattern for at least one of the microsatellite markers and 10 of the tumors demonstrated LOH with intratumor homogeneity (Table 13.3). In the remaining informative tumor, no p53 locus LOH was detected in all tumor biopsies. Thirteen tumors showed LOH of the p16 locus with 9 tumors demonstrating intratumor homogeneity and 4 tumors heterogeneity of 9p LOH (Table 13.3). Of the 14 informative tumors for the 5q (APC) locus, 10 showed LOH, with 6 tumors intratumor homogene-

ity (14/10/6, Table 13.3). For the 5q (MCC) locus these Figures were 14/10/5, for 13q 13/8/3, for 18q (DCC) 11/9/4, and for the 18q (DPC4/SMAD4) locus 13/11/4 (Table 13.3). Intratumor consistent LOH patterns were detected in all 14 tumors for at least one microsatellite marker. In 6 tumors mtDNA D310 mutations were found. In 3 of these tumors there was intratumor homogeneity with regard to the D310 mutations and in 3 tumors with D310 mutation heterogeneity was observed (Table 13.3).

Molecular analysis in MET-LGD-HGD-CA

Table 13.4 summarizes the LOH analysis and mutation data for the 31 patients with GEJ adenocarcinoma and adjacent premalignant lesions. In 25 of the 31 investigated cases one or more p53 mutation was found, in 21 cases in the CA sample. Examples of PCR-SSCP and sequencing analyses are shown in Figure 13.4. In 11 resection specimens from which MET, LGD, HGD and CA were microdissected, we found 9 p53 mutations. In one case the same p53

m=monoclonal; p=polyclonal; -=no mutations in carcinoma samples; ni=not informative.

mutation was present in MET, LGD, HGD and CA, and in 6 cases an identical p53 mutation was found in LGD, HGD and CA with no mutation in the MET samples. In 2 cases the same mutation was found only in the HGD and CA samples, with no mutation in MET and LGD. In addition, in 6 cases from which we had only LGD, HGD and CA 2 cases had an identical mutation in the LGD, HGD and CA samples, 2 cases had no p53 mutation, one case had a p53 mutation only in the LGD and one case only in the HGD sample.

In 19 of 21 MET samples, at least one molecular aberration was found (p53 mutation, LOH of one of 7 investigated loci, D310 mutation). In 13 of these cases at least one aberration in the MET was also found in all of the more advanced stages.

As shown in Table 13.4, p53 mutations were found in 10% (MET), 59% (LGD), 68% (HGD) and 71% (CA). P53 allelic loss increased from 0% (MET), to 67% (LGD), to 76% (HGD) and to 93% (CA). P16 allelic loss increased from 76% (MET), to 91% (LGD), 91% (HGD) and 91% (CA). For APC and MCC allelic loss percentages were: 16% and 29% (MET), 23% and 32% (LGD), 48% and 59% (HGD) and 50% and 51% (CA) respectively. Rb allelic loss was detected in 26% (MET), 45% (LGD), 50% (HGD) and 52% (CA). Finally, DCC and DPC4/SMAD4 allelic loss increased with 5% and 26% (MET), 48% and 43% (LGD), 45% and 62% (HGD) to 63% and 65% (CA) respectively.

Table 13.4 Results of LOH and mutation analysis in 31 patients within Metaplasia-Dysplasia-Carcinoma sequence.

[a] Number of patients with LOH out of total number of informative patients.

Of 30 cases from which we obtained D310 mutation data, 12 cases had one or more D310 insertion/deletion mutation. Four of 18 MET, 6 of 22 LGD, 6 of 19 HGD and 11 of 30 CA samples had D310 mutations. In 3 of the 4 MET samples with the D310 mutation, the same mutation was also found in the more advanced histological stages. In 5 cases with a D310 mutation in LGD, and without a MET sample or with a MET sample without D310 mutation, 3 mutations were also found in more advanced lesions from the same cases.

Within MET, a mean number of 1.95 ± 1.28 molecular aberrations (p53 mutation, LOH of one of 7 investigated loci, D310 mutation) was found. Within LGD a mean number of 4.0 ± 1.54, within HGD 4.91 ± 1.69 and within CA a mean number of 5.03 ± 1.74 molecular aberrations

was found. This number differed significantly between MET and LGD ($p<0.001$). No significant differences in mean number of molecular aberrations were found when LGD and HGD were compared or when HGD and CA were compared ($p=0.07$ and $p=0.8$ respectively). The mean number of molecular aberrations was significantly lower in the combined group MET and LGD (3.0 ± 1.74) as compared to the combined group HGD and CA (5.0 ± 1.71, $p<0.001$).

DISCUSSION

Currently the histological diagnosis of dysplasia is still the gold standard for the risk stratification for malignant progression in patients with BE. In recent years, many studies have reported that (combinations of) molecular markers could be of additional value in predicting neoplastic progression. In this respect, a monoclonal development of adenocarcinoma in BE would be a prerequisite to find molecular markers that predict progression. Monoclonality in human cancers has been reported for several cancers, amongst which endometrial cancer, head and neck cancer, and bladder cancer [32-34]. To investigate whether GEJ adenocarcinomas are monoclonal or polyclonal proliferations, we performed p53 exon 5 to 8 mutation analyses, LOH analyses of 7 loci with 19 microsatellite markers and mtDNA D310 mutation analyses on a total of 78 samples from 14 GEJ adenocarcinomas. Nine of 14 GEJ adenocarcinomas showed identical p53 mutations in multiple carcinoma biopsies within each tumor, whereas the other 5 carcinomas had no p53 mutation in their carcinoma biopsies. All 5 carcinomas without p53 mutations demonstrated however homogeneity for p53 locus LOH and/or p16 locus LOH. From 13 tumors with LOH at the p16 locus, 9 showed intratumor homogeneity and 4 intratumor heterogeneity. Three of these latter 4 had homogeneous p53 mutations in all tumor biopsies per case. The fourth tumor without p53 mutation demonstrated homogeneous p53 locus LOH. These results strongly indicate that GEJ adenocarcinomas are monoclonal in origin and that p53 and p16 genomic aberrations are early events in GEJ adenocarcinogenesis, as has been proposed by other investigators [2,3,9,11,14,21,25,26,35-37]. The patterns of allelic loss of MCC, Rb, DCC and DPC4/SMAD4 showed higher percentages of heterogeneity in different carcinoma samples (Table 13.2A and 13.3), and might therefore be later events in GEJ adenocarcinogenesis. Miyazono et al. investigated mtDNA D310 mutations in 20 Barrett's adenocarcinomas and adjacent Barrett's epithelium [30]. They found two D310 c-track mutations (10%), both one nucleotide deletions, in only two carcinoma samples [30]. We found D310 c-track mutations in six of 14 (43%) GEJ adenocarcinomas. Three tumors with D310 mutations showed intratumor homogeneity and three heterogeneity. This indicates that D310 c-track mutations have limited value as clonality marker in GEJ adenocarcinomas.

Our finding that GEJ adenocarcinomas are monoclonal in origin is in agreement with several other studies. Nowell et al. proposed that tumors may be monoclonal in origin and share, common, early genetic abnormalities predisposing to the evolution of clones with accumu-

lated, different, late genetic abnormalities [38,39]. Several studies on GEJ adenocarcinomas with or without metaplastic areas and studies on high grade dysplasia without carcinoma show evidence for a monoclonal origin of these lesions by use of comparative genomic hybridisation (CGH), LOH analysis, mutation analysis, X-chromosome inactivation analysis as well as methylation analysis [27,40-46].

Supported by this evidence for monoclonality of GEJ adenocarcinomas, molecular tumor markers can potentially be found which identify BE patients at increased or decreased risk for neoplastic progression. Due to good accessibility of the distal esophagus, tissue biopsies and thus DNA from Barrett's epithelium can readily become available for molecular investigation. DNA in our study was derived from routine formalin fixed and paraffin embedded tissue specimens after LCM. We were able to perform genetic analyses on isolated epithelium from MET, LGD, HGD and CA with minimal contamination of stromal cells (Figure 13.2).

Next to the molecular clonality analyses in 14 GEJ adenocarcinomas molecular aberrations were determined in 31 cases of different combinations of the MET-LGD-HGD-CA sequence. LOH as well as p53 mutations were found in premalignant lesions already. 9p LOH was found in 76% of MET. Within LGD 9p LOH and p53 alterations comprised 91% and about 60%, respectively. LOH of 13q, 18q (DCC) and 18q (DPC4/SMAD4) was also found in LGD in about 45% of cases. We found consistent LOH and p53 mutation patterns, i.e. loss of the same allele or identical mutations, in the majority of cases within the MET-LGD-HGD-CA sequence. This in accordance with Zhuang et al. who found identical allelic loss patterns of the APC gene in metaplasia, dysplasia and adjacent carcinoma as well as the same X-chromosome inactivation patterns in female cases [41]. In that study, metaplasia distant from dysplasia, however, did not show identical LOH patterns as compared to dysplasia and carcinoma [41]. Wu et al. report the same allelic losses of 17p, 18q and 5q in Barrett's metaplasia and carcinoma in 59%, 62% and 27%, respectively [11]. After flow cytometric cell sorting, the same p53 mutations were found in both carcinoma and surrounding HGD in their study as well as in diploid and aneuploid cell populations in another study [11,27]. Walch et al. used CGH analysis and found a high concordance between specific aberration patterns in the MET-LGD-HGD-CA sequence within several samples [9]. Gleeson et al. showed dysplastic Barrett's epithelium and adjacent carcinoma to have the same pattern of novel microsatellite alleles at a number of loci in three cases [14]. In a CGH study by Riegman et al. about one-third of the aberrations present in the dysplasias was also found in the adjacent carcinomas [2]. Identical 18q (DCC), 5q (APC) and 17p (p53) LOH was detected in premalignant and malignant tissues in 4 of 17 patients by Dolan et al. [13]. In contrast to our findings and that of others, Raja et al. found that the genotype of dysplastic Barrett crypts did not necessarily mirror that of the adjacent adenocarcinoma [36]. Finally, Galipeau et al. reported different 9p and 17p LOH patterns in patients with HGD using purified cell fractions by flow cytometry [35]. Flow cytometric cell sorting selects cells with aberrant DNA content, whereas in our study cells were selected by histology.

Our results and literature data demonstrate that part of the DNA aberrations present in the GEJ adenocarcinomas are also present in the tumor adjacent precursor lesions. These molecular results provide evidence that in the investigated GEJ adenocarcinoma resection specimens the precursor lesions progressed to malignancy. This implies that molecular aberrations present in premalignant lesions potentially can predict disease progression. In the current study all resection specimens contained next to premalignant lesions, HGD or adenocarcinoma, indicating that progression had occurred. In the literature few studies have reported on LOH or p53 mutations in premalignant Barrett's epithelium without simultaneous, or in follow up, HGD or cancer. Also in these studies on premalignant Barrett's epithelia without evidence of progression the number of molecular aberrations increases with increasing histological grade [21,25,26,37,47].

Interestingly, in a few cases the premalignant lesions and the adjacent CA samples did show both LOH of a specific locus, though with different allelic loss (i.e. upper allele could be lost in MET whereas lower allele was lost in LGD, HGD and/or CA (Figure 13.3). However, consistent patterns of LOH or absence of LOH in all premalignant lesions and carcinoma were demonstrated in 84% of p53 LOH informative patients (16/19), in 75% of p53 mutation patients (12/16), in 63% of p16 LOH informative patients (17/27), in 61% and 62% of APC and MCC LOH informative patients (14/23 and 16/26), in 68% of Rb LOH informative patients (17/25) and in 57% and 62% of DCC and DPC4 LOH informative patients (12/21 and 13/21). In the cases with slightly different locus LOH patterns clonal expansion may have occurred from a different cell population than the sampled precursor lesion, as suggested by Gleeson et al. [14]. Hypothetically, Barrett's epithelium may comprise multiple genetically different clones while one of these clones progresses, representing the genetic alterations of the tumor. Such a development is known in polyclonal colorectal adenoma and the eventually monoclonal adenocarcinoma [48]. In our study we provided evidence for a monoclonal origin of Barrett's adenocarcinoma, thus minimizing 'genetic sampling error'.

In summary, the MET-LGD-HGD-CA sequence is complex from a molecular point of view. We presented molecular evidence that GEJ adenocarcinomas are monoclonal in orgin. Most likely, a monoclonal tumor harbors clonal diversity concerning later genetic events. Supported by evidence for monoclonality by this current study, we think that tumor markers potentially can be applied in conjunction with histopathology to identify Barrett patients at risk for neoplastic progression. Since the mean number of molecular aberrations (p53 mutation, LOH of one of 7 investigated loci, D310 mutation) significantly differed between MET/LGD as compared to HGD/CA these aberrations potentially can be used as diagnostic markers in tissue biopsies showing indefinite for dysplasia. Importantly, we have to test this hypothesis in a cohort of non-progressive versus progressive BE patients. To date, 17p LOH and DNA content as measured by flow cytometry represent markers which might be prospectively predictive of progression, although routine clinical use is not recommended yet [7,8,49]. In general, a 'multimarker' approach seems more promising than a 'single marker' approach.

Fearon and Vogelstein proposed 'accumulation of changes, rather than order, to be most important in (colorectal) tumor progression' [50]. The development of a 'combined histological and molecular staging system' seems to be a realistic aim to classify patients into various risk groups very early on in the development of malignancy, allowing a tailor-made program for follow-up, screening and therapeutic interventions [51]. The burden of proof lies in prospective future studies. An eventual management strategy could be proposed restricting endoscopic surveillance for neoplastic progression of BE to BE patients with more than a certain number of genetic aberrations in a panel of markers [52]. We suggest that a combination of the investigated markers, especially p53 mutations, 17p LOH, 9p LOH, 13q LOH and 18q LOH might be part of the panel of markers, in conjunction with histopathological diagnosis.

Summary, Conclusions and Epilogue

Part VI

Chapter 14

Summary and Conclusions
Samenvatting en Conclusies

SUMMARY

Adenocarcinoma of the distal esophagus or gastric cardia, the gastro-esophageal junction, is an aggressive disease with an extremely poor prognosis as reflected by a 5-year survival rate of less than 25% after surgery. Most of these cancers are detected at an advanced stage when they cannot be cured surgically. Barrett's esophagus is the only known precursor to adenocarcinoma. Barrett's esophagus is an acquired metaplastic change that occurs in the distal esophagus secondary to chronic gastro-esophageal reflux. The progression towards adenocarcinoma is believed to follow the 'metaplasia-low grade dysplasia-high grade dysplasia-carcinoma sequence'. This neoplastic progression involves an accumulation of genetic and cell cycle abnormalities. Actual knowledge on these genetic pathways remains limited, especially in relation to clinicopathologic characteristics. The interest of the studies described in this thesis was to analyze genetic alterations within GEJ adenocarcinomas and Barrett's esophagus in order to develop molecular markers that in the end could predict which Barrett's patients are at high risk for adenocarcinoma formation and which patients are not. Genetic alterations were related to tumor and patient characteristics as well as to patient outcome. Moreover epidemiological and treatment aspects were highlighted.

The current literature on the molecular biology of esophageal adenocarcinoma was reviewed in **Chapter 2**. Findings on proto-oncogenes, tumor suppressor genes, mismatch repair genes and mitotic checkpoint genes, as the targets of genomic instability, were summarized. From Chapter 2 it was concluded that within the multistep process of esophageal adenocarcinogenesis, no single molecular marker came forward yet able to predict who will and who will not develop cancer in the setting of Barrett's esophagus. Instead, combinations of markers will perhaps lead to a further differentiation in the prediction of neoplastic risk.

Part II concerns molecular biological studies in GEJ adenocarcinomas. The contribution of the Wnt signaling pathway in GEJ adenocarcinomas was studied in **Chapter 3 and 4.** As in colorectal carcinomas the Wnt pathway is suggested to play a key role in GEJ adenocarcinomas. Nuclear β-catenin expression is generally believed to indicate activated Wnt signaling. In chapter 4 it was demonstrated that nuclear β-catenin expression in GEJ adenocarcinoma cell lines indeed correlated with T-cell factor 4 (TCF4)-mediated transcription activation and therefore with activated Wnt signaling. In several tumor types, TCF/β-catenin activation is caused by mutations in either Adenomatous Polyposis Coli (APC), β-catenin exon 3, AXIN1, AXIN2 or β-Transducin repeat-Containing Protein (β-TrCP). In GEJ adenocarcinomas very few APC and β-catenin mutations have been described in the literature. As described in chapter 4 we did not find AXIN1 gene mutations in 17 GEJ tumors with nuclear β-catenin expression (without β-catenin exon 3 mutations). Therefore the mechanism of Wnt pathway activation in GEJ adenocarcinomas still remains unclear. To elucidate a possible prognostic role of the diverse components of the Wnt pathway, an immunohistochemical study was undertaken

in 164 GEJ adenocarcinomas and in 5 human GEJ adenocarcinoma cell lines (chapter 3). Expression of β-catenin, phospho-β-catenin Ser33/37/Thr41, phospho-β-catenin Thr41/Ser45, dephosphorylated 'active' β-catenin, Lymphoid Enhancer-binding Factor 1 (LEF1), TCF4, and the Wnt target genes CD44V6 and Ephrin receptor B2 (EphB2) was analysed in formalin-fixed, paraffin embedded tumor tissues. Thirty-five % of tumors expressed nuclear β-catenin in more than 10% of tumor cells, which indicated that activated Wnt signaling might probably be of less importance in GEJ adenocarcinomas than previously thought. However, loss of expression of the Wnt target gene EphB2 in the membrane or the cytoplasm correlated with worse tumor differentiation grade (p=0.05 and p=0.04) and with worse overall survival (p=0.04 and p=0.04 respectively).

Within the search for genetic alterations that play a role in GEJ adenocarcinogenesis, recent work demonstrated chromosome 14q31-32.1 to be frequently deleted in GEJ adenocarcinomas, suggesting the presence of a tumor suppressor gene in the deleted region. In **Chapter 5** a detailed Loss of Heterozygosity (LOH) analysis was performed in 34 GEJ adenocarcinomas and one tumor-corresponding dysplastic Barrett's epithelium sample with 37 polymorphic microsatellite markers. Fourteen of 34 tumor samples (41%) showed loss of 14q markers. A minimal region of allelic loss of 7,105,440 base pairs was identified between markers D14S1000 and D14S256 at cytogenetic location 14q31.1-32.11 containing 7 known genes. The identification of this minimal deletion and the data base information on the genes present in this region facilitate the search for the candidate GEJ adenocarcinoma suppressor gene(s).

In **Chapter 6** the prevalence and prognostic significance of neuroendocrine (NE) cells was estimated in a series of 208 GEJ adenocarcinomas and 56 Barrett's mucosas adjacent to carcinoma, using immunohistochemistry with chromogranin A (CGA) antibodies. CGA was positive in 49% (102/208) of GEJ adenocarcinomas and in 68% (38/56) of Barrett's mucosas. In multivariate analysis, CGA in Barrett adjacent to carcinoma was an independent prognostic factor for better survival after surgery. To our knowledge this is the first example that in the concurrent presence of a premalignant lesion and a carcinoma a characteristic of the premalignant lesion has prognostic significance. An explanation for this finding remains obscure. Although, its finding might be helpful in the prognostic assessment of patient outcome.

In **Part III** of the thesis epidemiological aspects of GEJ adenocarcinomas as well as gastric carcinomas are discussed. Similarities in epidemiological and histomorphological features haven been described between patients with adenocarcinomas of the distal esophagus and patients with adenocarcinomas of the gastric cardia as well as parallel, rising incidence rates. This formed the assumption for pooling adenocarcinomas of the GEJ within the studies described in this thesis. In **Chapter 7** it was questionized whether distal esophageal adenocarcinoma patients and gastric cardia carcinoma patients were comparable concerning comorbidity. Data on comorbidity at diagnosis (previous cancers, Chronic Obstructive Pulmonary

Diseases (COPD), cardiovascular and cerebrovascular diseases, hypertension, ulcerative digestive tract diseases, liver diseases and diabetes) were derived from a population-based database in the Netherlands (Eindhoven Cancer Registry/IKZ) to compare comorbidity profiles for 479 esophageal squamous cell carcinomas, 339 distal esophageal adenocarcinomas, 570 cardia adenocarcinomas and 1965 subcardia cancers. In terms of comorbidity at diagnosis, cardia adenocarcinoma patients resembled distal esophageal adenocarcinoma patients with likewise equal age and gender distribution.
Additionally, the influence of comorbidity on treatment choice (either curative (surgery) or palliative) and its prognostic value was analyzed within 430 esophageal squamous cell carcinomas, 392 distal esophageal adenocarcinomas, 494 cardia adenocarcinomas and 1708 subcardia cancers in a retrospective study described in **Chapter 8**. It was concluded from multivariable analyses with adjustment for TNM stage and applied therapy that esophageal and gastric carcinoma patients with ≥2 comorbidities had a lower chance of receiving surgery as well as worse overall survival. The dismal prognosis for patients with ≥ 2 comorbidities at cancer diagnosis was likely to be a direct effect of the poor condition of the patient stressing importance of further refinement in perioperative care.

Part IV of the thesis describes several aspects of surgery. Since surgical resection of cancers of the GEJ is associated with substantial morbidity and mortality, one might wonder if this is also necessary in patients with early malignancies, i.e. high grade dysplasias, and intramucosal or submucosal (T1) tumors. Local endoscopic techniques seem to offer a safe alternative to surgery in these patients. A retrospective study described in **Chapter 9** evaluated the outcome of transhiatal esophagectomy in 120 patients with early GEJ adenocarcinoma (13 high grade dysplasias and 107 T1 tumors). Tumors were subdivided into six different depths of invasion ('T1-mucosal' m1- m3, 'T1-submucosal' sm1-sm3). T1m1-m3/sm1 GEJ adenocarcinomas showed a very low risk of lymphatic dissemination and are therefore eligible for local endoscopic therapy. In contrast, almost half of the patients with T1sm2-sm3 lesions developed recurrent disease within 5 years, and therefore need aggressive therapy to improve survival.
With less than 25% of patients surviving at 5 years after surgical resection, the risk in the short-term and the potential loss in quality of life have to be weighed against the long-term benefit. It is well known that the short-term surgical risk varies by clinical characteristics, such as age and comorbidity. In **Chapter 10** 3592 esophagectomy patients from 4 cohorts were analyzed to develop and validate a risk score able to predict mortality occurring within 30 days after esophagectomy. The risk score combines age, comorbidity (cardiac, pulmonary, renal, hepatic, and diabetes), preoperative radiotherapy or combined chemoradiotherapy along with hospital volume.

In **Part V** of the thesis it was aimed to identify Barrett's patients at high risk for developing GEJ adenocarcinoma using molecular biology. The identification of genetic alterations that

confer susceptibility for adenocarcinoma formation in Barrett's esophagus would imply improved manageability of patients with Barrett's esophagus. CHEK2 was investigated as a candidate susceptibility gene within a cohort of adenocarcinomas and (dysplastic) Barrett's epithelia as well as in esophageal squamous cell carcinomas in **Chapter 11**. CHEK2*1100delC is a truncating germline variant of CHEK2 that abrogates kinase activity and confers low-penetrance susceptibility to breast cancer. CHEK2*1100delC was found in 1.5% of 196 esophageal adenocarcinomas, 3.0% of 99 Barrett's metaplasias, 1.5% of 66 dysplastic Barrett's epithelia and in 0.5% of 190 esophageal squamous cell carcinomas. Since these CHEK2*1100delC mutation frequencies did not significantly differ as compared to healthy individuals it was concluded that the mutation has no major contribution in esophageal carcinogenesis. Therefore CHEK2*1100delC is not suitable for risk prediction of neoplastic progression in Barrett's patients.

Individual variations in cancer risk have been associated with specific variant alleles of different genes, Single Nucleotide Polymorphisms (SNPs). SNPs are present in a significant proportion of the normal population. **Chapter 12** investigated the distribution of various SNPs in GEJ adenocarcinoma and esophageal squamous cell carcinoma patients. Frequencies were compared between patients (cases) and healthy blood donors (controls), in order to investigate a possible significance for cancer susceptibility. Selected SNPs concerned the tumor suppressor or proto-oncogenes p53, p16, Cyclin D1, p73, Transforming Growth Factor β (TGF β) receptor 1, TGF β, E-cadherin, Peroxisome Proliferator-Activator Receptor-γ (PPAR-γ), Serine/Threonine protein Kinase 15 (STK15) and Her-2/neu. The value of several candidate molecular markers as predictors of neoplastic progression in Barrett's metaplasia was investigated in **Chapter 13**. Application of such markers in the future would be favoured by a monoclonal growth pattern from the Barrett's esophagus towards adenocarcinoma. A monoclonal growth pattern would enhance the reliability of molecular markers, since the genetic aberrant clone that represents a possible developing tumor could then be harvested from the premalignant Barrett's epithelium. Multiple biopsies per carcinoma were selected from 14 GEJ adenocarcinoma resection specimens and obtained by Laser Capture Microdissection (LCM). LCM allows isolation of target cells without admixture of normal cells. DNA was investigated for LOH of several chromosomal loci (17p (p53), 9p (p16), 5q (APC, Mutated in Colorectal Cancer (MCC)), 13q (Retinoblastoma (Rb)) and 18q (Deleted in Colorectal Cancer (DCC), Deleted in Pancreatic Cancer (DPC4/SMAD4)), for p53 mutations (exon 5 to 8) and for mutations in the homopolymeric C-stretch (D310) within the mitochondrial DNA (mtDNA) displacement loop. In 9 out of 14 tumors, p53 mutation analysis showed complete intratumor homogeneity, i.e. all biopsies from one tumor harbored an identical p53 mutation and therefore evidence for a monoclonal origin of GEJ adenocarcinomas was provided. Next to the clonality analyses, the mentioned molecular aberrations were determined in 31 cases of different combinations of the 'metasplasia-low grade dysplasia-high grade dysplasia-carcinoma sequence', again isolated by LCM. Part of the DNA aberrations present in the GEJ adenocarci-

nomas was also present in the tumor adjacent precursor lesions and therefore could be able to predict adenocarcinoma formation. A combination of the investigated markers, especially p53 mutations, 17p LOH, 9p LOH, 13q LOH and 18q LOH might be part of a future panel of molecular markers, in conjunction with histopathological diagnosis.

SAMENVATTING

Klierbuisvormende tumoren (adenocarcinomen) van het onderste gedeelte van de slokdarm of van het bovenste gedeelte van de maag, de slokdarm-maag overgang (SMO), zijn agressieve tumoren met een zeer slechte prognose. De 5-jaarsoverleving bedraagt <25% na chirurgie. De meeste van deze tumoren worden pas in een vergevorderd stadium gediagnostiseerd als er geen mogelijkheden meer zijn om te opereren. Het enige bekende voorloperstadium van deze tumoren vormt de zogenaamde Barrett slokdarm. Dit is een verworven weefselverandering (metaplasie) in het onderste gedeelte van de slokdarm die ontstaat na langdurige expositie aan zure reflux ('zuurbranden'). Eventuele progressie naar kanker vindt plaats volgens de 'Barrett metaplasie-laaggradige dysplasie-hooggradige dysplasie-carcinoom sequentie'. Deze maligne ontaarding gaat gepaard met een opeenstapeling van genetische afwijkingen en disregulatie van de celcyclus. Gedetailleerde kennis over deze cascade van moleculair genetische gebeurtenissen is beperkt en met name kennis over het verband tussen genetische afwijkingen en patiënt- en tumorkenmerken ontbreekt. De studies in dit proefschrift hadden tot doel moleculair genetische afwijkingen in SMO adenocarcinomen en Barrett slokdarm te analyseren om zodoende moleculaire markers te vinden. In de toekomst zouden moleculaire markers wellicht behulpzaam kunnen zijn in het voorspellen welke Barrett patiënten een hoog risico lopen op het krijgen van kanker en welke Barrett patiënten niet. De gevonden genetische afwijkingen werden gecorreleerd aan patiënt- en tumorkenmerken en overleving. Tevens werden epidemiologische aspecten en aspecten van de behandeling van SMO adenocarcinomen belicht.

In een review in **Hoofdstuk 2** werd de bestaande literatuur over de moleculaire biologie van slokdarm adenocarcinomen samengevat. Afwijkingen in proto-oncogenen, tumorsuppressor genen, mismatch repair genen en mitotische checkpoint genen resulteren in genomische instabiliteit. Gevonden afwijkingen in deze groepen genen in slokdarm adenocarcinomen werden beschreven. De conclusie luidde dat in het uitgebreide proces van slokdarm adenocarcinogenese nog geen unieke moleculaire marker is gevonden die kan voorspellen welke Barrett patiënt een hoog risico heeft op het krijgen van kanker en welke patiënt niet. In plaats daarvan zullen naar verwachting combinaties van moleculaire markers in de toekomst bijdragen aan risico predictie.

Deel II betreft moleculair biologische studies in SMO adenocarcinomen. Het aandeel van de zogenaamde 'Wnt pathway' in SMO adenocarcinomen werd onderzocht in **Hoofdstuk 3** en **4**. De Wnt pathway of, beter gezegd, afwijkingen in de Wnt pathway waardoor de pathway wordt geactiveerd, spelen een sleutelrol in dikke darm tumoren (colon en rectum). De aanwezigheid van ß-catenine in de kern van tumorcellen wordt in het algemeen beschouwd als uiting van een geactiveerde pathway en daarmee als tumorigeen. In **Hoofdstuk 4** werd aangetoond dat kernexpressie van ß-catenine correleert met T-cell factor 4 (TCF-4) geme-

dieerde transcriptie activatie en daardoor met een geactiveerde pathway. In verscheidene typen tumoren wordt TCF-4/ ß-catenine activatie veroorzaakt door mutaties in Adenomatous Polyposis Coli (APC), ß-catenine exon 3, AXIN1, AXIN2 of ß-Transducin repeat-Containing Protein (ß-TrCP). In SMO adenocarcinomen zijn in de literatuur slechts enkele gevallen beschreven van APC en ß-catenine mutante tumoren en daarom lijken mutaties in APC en ß-catenine geen verklaring voor activatie van de Wnt pathway in SMO adenocarcinomen met nucleair ß-catenine. Zoals in **Hoofdstuk 4** beschreven werden in een serie van 17 SMO adenocarcinomen met ß-catenine kernexpressie (en zonder ß-catenine exon 3 mutatie) geen AXIN1 mutaties gevonden. Het Wnt pathway mechanisme in SMO adenocarcinomen is dus nog altijd onduidelijk. In **Hoofdstuk 3** werd een immunohistochemische studie verricht met de vraagstelling of componenten van de Wnt pathway een prognostische betekenis hebben in SMO adenocarcinomen. Expressie van verschillende eiwitten werd onderzocht in formaline gefixeerd paraffine materiaal van 164 SMO adenocarcinomen en 5 SMO tumor cellijnen. De onderzochte eiwitten waren: ß-catenine, phospho-ß-catenine Ser33/37/Thr41, phospho-ß-catenine Thr41/Ser45, gedefosforyleerd 'active' ß-catenine, Lymphoid Enhancer-binding Factor 1 (LEF1), TCF4 en de Wnt target genen CD44V6 en Ephrin receptor B2 (EphB2). In 35% van de tumoren werd kernexpressie van ß-catenine aangetoond in de kern in >10% van de tumorcellen, erop duidend dat de Wnt pathway mogelijk een minder belangrijke rol speelt in SMO adenocarcinomen dan aanvankelijk gedacht. Desalniettemin correleerde afwezigheid van EphB2 in celmembraan of het cytoplasma met een slechtere tumor differentiatiegraad (p=0.05 en p=0.04) en slechtere survival (p=0.04 en p=0.04).

In de zoektocht naar genetische afwijkingen welke een rol spelen in SMO adenocarcinogenese werd recent gevonden dat een gebied op de lange arm van chromosoom 14 frequent verloren was in SMO adenocarcinomen. Dit zou kunnen duiden op de lokalisatie van een tumorsuppressor gen in dat gebied. In **Hoofdstuk 5** werd een gedetailleerde Loss of Heterozygosity (LOH) analyse verricht in 34 SMO adenocarcinomen en 1 dysplastisch Barrett epitheel gelegen naast een SMO adenocarcinoom, met behulp van 37 polymorfe microsatelliet markers. In 14 van de 34 samples (41%) werd 14q LOH aangetoond. Tussen de markers D14S1000 en D14S256 werd een minimale regio van verlies gevonden van 7105440 baseparen (14q31.1-32.11), een gebied waar zich 7 bekende genen bevinden. Identificatie van deze regio in combinatie met database informatie over de genen in de minimale verlies regio vergemakkelijken de zoektocht naar een kandidaat SMO adenocarcinoom tumorsuppressor gen/genen.

In **Hoofdstuk 6** werd de prevalentie en eventueel prognostische betekenis van neuroendocriene cellen onderzocht in 208 SMO adenocarcinomen en 56 Barrett epithelia gelegen naast tumor. Hiertoe werd Chromogranine A (CGA) immunohistochemie verricht. CGA werd aangetoond in 49% (102/108) van de tumoren en in 68% (38/56) van de Barrett epithelia. In multivariate analyse bleek CGA in Barrett epitheel gelegen naast tumor een onafhankelijke prognostische factor voor betere overleving na chirurgie. Dat een kenmerk van een prema-

ligne lesie, gelegen naast tumor, prognostische betekenis heeft, is niet eerder aangetoond. Een mogelijke verklaring voor deze bevinding hebben we vooralsnog niet gevonden. Toch zou deze uitkomst van prognostische betekenis kunnen zijn in patiënten met SMO adenocarcinomen.

In **Deel III** van dit proefschrift werden epidemiologische aspecten bediscussieerd. In de literatuur worden overeenkomsten in epidemiologische factoren en histomorfologische kenmerken beschreven tussen patiënten met adenocarcinomen van het onderste deel van de slokdarm en patiënten met adenocarcinomen van het bovenste gedeelte van de maag, de cardia. Ook wordt een vergelijkbare, parallel stijgende incidentie van deze tumoren beschreven. Dit vormde de aanname om in de studies beschreven in dit proefschrift de tumoren van onderste gedeelte van slokdarm en bovenste gedeelte van maag als één klinische entiteit te beschouwen en als zodanig te analyseren.
In **Hoofdstuk 7** werd onderzocht of de aanwezigheid van comorbiditeit verschilde tussen patiënten met adenocarcinomen van het onderste deel van de slokdarm en patiënten met adenocarcinomen van de cardia. Gegevens over aanwezige comorbiditeit ten tijde van diagnose (eerdere maligniteit, Chronic Obstructive Pulmonary Disease (COPD), cardiovasculaire en cerebrovasculaire ziekten, hypertensie, ulcuslijden van het maagdarmstelsel, leverziekten en diabetes) werden verkregen uit een Nederlandse populatie database (Kankerregistratie Eindhoven/IKZ). Comorbiditeitsprofielen van 479 slokdarm plaveiselcelcarcinomen, 339 slokdarm adenocaricnomen, 570 cardia adenocarcinomen en 1965 subcardia carcinomen werden met elkaar vergeleken. Patiënten met cardia adenocarcinomen waren qua comorbiditeitspatroon vergelijkbaar met patiënten met onderste slokdarm adenocarcinomen, met eveneens vergelijkbare leeftijds- en geslachtsverdeling.
Vervolgens werd de invloed van comorbiditeit op keuze van therapie (curatief (chirurgie) of palliatief) onderzocht in 430 slokdarm plaveiselcelcarcinomen, 392 slokdarm adenocarcinomen, 494 cardia adenocarcinomen en 1708 subcardia carcinomen in een retrospectieve studie in **Hoofdstuk 8**. Multivariate analyse met correctie voor TNM stadium en therapie wees uit dat patiënten met slokdarm- of maagtumoren bij aanwezigheid van ≥2 comorbiditeiten een kleinere kans hadden op het krijgen van chirurgie. Tevens was er een slechtere overleving. De slechtere prognose van patiënten met ≥2 comorbiditeiten leek een direct effect te zijn van hun slechtere conditie. Dit legt de nadruk op het belang van zorgvuldige perioperatieve zorg.

In **Deel IV** van het proefschrift werden aspecten van chirurgie belicht. Chirurgische resectie van SMO tumoren is geassocieerd met substantiële morbiditeit en mortaliteit. Mogelijk zou dit met een minder invasieve behandeling bij patiënten met vroege tumoren bespaard kunnen blijven. Vroege tumoren zijn hooggradige dysplasie en intramucosale en submucosale tumoren (T1 tumoren). Lokale endoscopische technieken lijken een veilig alternatief voor

chirurgie in deze patiënten. In **Hoofdstuk 9** werd een retrospectieve studie beschreven waarin de uitkomsten na chirurgie werden geanalyseerd in 120 patiënten met vroege SMO tumoren (13 hooggradige dysplasiëen en 107 intramucosale of submucosale tumoren). Deze groep werd onderverdeeld in 6 verschillende niveaus van invasie ('T1-mucosaal' m1-m3 en 'T1-submucosaal' sm1-sm3). T1m1-m3/sm1 SMO tumoren hadden een laag risico op lymfkliermetastasering en lijken daardoor veilig toegankelijk voor locale endoscopische therapie. Daarentegen bijna de helft van de patiënten met T1sm2-sm3 tumoren ontwikkelde tumorrecidief binnen 5 jaar en deze tumoren lijken agressief te moeten worden behandeld om overleving te verbeteren.
Met <25% 5-jaars overleving na chirurgie moeten de risico's van chirurgie op korte termijn en de daardoor potentieel verminderde kwaliteit van leven worden afgewogen tegen de baten op lange termijn. De risico's van chirurgie worden beïnvloed door patiënt kenmerken zoals leeftijd en comorbiditeit. In **Hoofdstuk 10** werden 3592 patiënten uit 4 verschillende cohorten na chirurgie geanalyseerd en werd een risico score model ontwikkeld en gevalideerd waarmee 30-dagen mortaliteit na chirurgie kon worden voorspeld. De score combineert gegevens van leeftijd, comorbiditeit (cardiaal, pulmonaal, renaal, leverziekten en diabetes), preoperatieve radiotherapie of gecombineerde chemoradiotherapie en ziekenhuisvolume.

In **Deel V** van het proefschrift werd geprobeerd moleculaire biologie te gebruiken voor het identificeren van Barrett patiënten met een hoog risico op het krijgen van kanker. Met het identificeren van genetische afwijkingen, geassocieerd met een verhoogde kans op het ontstaan van kanker in Barrett epitheel, zou surveillance kunnen worden verbeterd als ook behandeling en informatievoorziening van Barrett patiënten. In **Hoofdstuk 11** werd het CHEK2 gen onderzocht als mogelijk kandidaatgen voor deze toepassing in een cohort van adenocarcinomen, (dysplastische) Barrett epithelia en slokdarm plaveiselcelcarcinomen. CHEK2*1100delC is een truncerende kiembaanmutatie die kinase activiteit blokkeert. Deze mutatie is geassocieerd met een hogere kans op borstkanker (lage penetrantie). CHEK2*1100delC was aanwezig in 1.5% van 196 adenocarcinomen, 3.0% van 99 Barrett's metaplasieën, 1.5% van 66 dysplastische Barrett epithelia en 0.5% van 190 plaveiselcelcarcinomen. Aangezien deze CHEK2*1100delC mutatiefrequenties niet significant verschilden met de mutatiefrequentie in een cohort gezonde vrijwilligers luidde de conclusie van **Hoofdstuk 11** dat CHEK2*1100delC geen grote bijdrage levert aan het ontstaan van slokdarmkanker. CHEK2*1100delC is daarom geen geschikte kandidaat voor het identificeren van hoog risico patiënten. In de recente literatuur komt naar voren dat Single Nucleotide Polymorfismen (SNPs) geassocieerd zijn met het risico op het ontwikkelen van verschillende tumoren. Een genpolymorphisme is een variante sequentie van kiembaan DNA die frequent voorkomt in de populatie. In **hoofdstuk 12** werd de frequentie van verschillende SNPs onderzocht in patiënten met adenocarcinoom en plaveiselcelcarcinoom van de slokdarm. De frequentie van SNPs werd vergeleken met de frequentie in controles (gezonde bloeddonoren) om zodoende vast

te stellen of een of meerdere van de onderzochte SNPs geassocieerd waren met het krijgen van slokdarmcarcinoom. De onderzochte genen betroffen de tumorsuppressorgenen of proto-oncogenen p53, p16, Cycline D1, p73, Transforming Growth Factor β (TGF β) receptor 1, TGF β, E-cadherine, Peroxisome Proliferator-Activator Receptor-γ (PPAR-γ), Serine/Threonine proteïne Kinase 15 (STK15) en Her-2/neu. In **Hoofdstuk 13** werd de waarde van verscheidene kandidaat moleculaire markers onderzocht als voorspellers van neoplastische progressie in Barrett epitheel. Eventuele toepasbaarheid van moleculaire markers in de toekomst zou aangemoedigd worden als er een monoclonaal groeipatroon van Barrett metaplasie richting tumor zou bestaan. Dit betekent dat de voorlopercellen waaruit kanker ontstaat dezelfde genetische afwijkingen hebben als de uiteindelijke tumor. Een monoclonaal groeipatroon zou de betrouwbaarheid van moleculaire markers verhogen omdat de genetisch afwijkende cel welke een mogelijk ontwikkelende tumor representeert dan geoogst zou kunnen worden uit Barrett epitheel. Om dit te onderzoeken werden van 14 SMO adenocarcinomen per tumor meerdere biopten verzameld waarna DNA werd geïsoleerd na Laser Capture Microdissection (LCM). Met de LCM techniek werden selectief de cellen van interesse verkregen voor het isoleren van DNA zonder bijmenging van normale cellen. Vervolgens werd LOH analyse verricht van verscheidende chromosoom loci (17p (p53), 9p (p16), 5q (APC, Mutated in Colorectal Cancer (MCC)), 13q (Retinoblastoma (Rb)) en 18q (Deleted in Colorectal Cancer (DCC), Deleted in Pancreatic Cancer (DPC4/SMAD4)), werd mutatie analyse van p53 (exon 5 tot en met 8) verricht en werd mutatie analyse verricht van mitochondriaal DNA (mtDNA, D310). In 9 van de 14 tumoren liet p53 mutatie analyse complete intratumor homogeniteit zien, dat wil zeggen alle biopten van dezelfde tumor hadden dezelfde, identieke, p53 mutatie waarmee een bewijs werd geleverd voor het monoclonaal ontstaan van SMO adenocarcinomen. Vervolgens werden de LOH en mutatie analyses verricht in 31 verschillende combinaties van de 'metaplasie-laaggradige dyplasie-hooggradige dysplasie-carcinoom sequentie'. Een deel van de genetische afwijkingen aanwezig in de SMO adenocarcinomen was ook aanwezig in de, naast de tumor gelegen, voorloperstadia en zou daarmee geschikt zijn voor het voorspellen van adenocarcinoomvorming in Barrett patiënten. Een combinatie van de onderzochte moleculaire markers, met name p53 mutaties, 17p LOH, 9p LOH, 13q LOH, en 18q LOH zou in de toekomst deel uit kunnen maken van een set van moleculaire markers in Barrett patiënten in combinatie met histopathologie.

Chapter 15

Epilogue: general discussion, clinical implications and future research

Adenocarcinomas of the GEJ are often diagnosed at an advanced disease state and associated with a poor prognosis. These carcinomas are thought to arise within the 'Barrett's metaplasia-low grade dysplasia-high grade dysplasia-carcinoma sequence'. Therefore the detection of preneoplastic lesions is important to ensure early and appropriate treatment. Presently, the histological detection of dysplasia is the best available marker for cancer risk. Intensive endoscopic surveillance, including tissue biopsies, is aiming at early detection of high-grade dysplasia and early adenocarcinoma. Probably, molecular genetic analysis could be of help to identify high risk patients. This assumption formed the aim of this thesis. Genetic and clinical studies were performed and, as described in part V of the thesis, combined in order to build a bridge from Laboratory to Clinic.

MOLECULAR BIOLOGY

The formation of adenocarcinoma in Barrett's esophagus is complex from a molecular point of view and in this thesis it was aimed to further unravel the complex molecular alterations present in GEJ adenocarcinomas and its precursor lesions. Moreover it was aimed to correlate these molecular changes to clinicopathologic characteristics.

Many questions still exist and could not be answered in this thesis. Wnt signaling, having importance in a number of developmental processes, is able to contribute to tumorigenesis by altering the state and activity of β-catenin, and as such plays an important role in colorectal adenocarcinoma formation, amongst others. In the absence of Wnt signals β-catenin is located at the plasma membrane, linked to E-cadherin, and functions in cell-cell adhesion. Excess cytoplasmic β-catenin is sequestered, phosphorylated and eventually targeted to degradation in a protein complex comprised of adenomatous polyposis coli (APC), glycogen synthase kinase 3β (GSK-3β) and AXIN1 or AXIN2. Activated Wnt signaling inhibits the phosphorylation and therefore degradation of β-catenin, which translocates to the nucleus where it activates genes containing T-cell factor (TCF)-binding sites, a family of transcription factors. In addition to work from others, who did not find mutations in β-catenin nor in APC to be responsible for Wnt signaling in GEJ adenocarcinomas [1-4], neither AXIN1 mutations nor AXIN1 LOH were shown to be responsible for Wnt signaling. Therefore, the mechanism of Wnt activation remains obscure in these tumors. We did show however that loss of expression of the recently identified Wnt target gene EphB2 was shown to be significantly correlated with worse survival and poor tumor differentiation grade.

We identified the commonly deleted region of allelic loss of chromosome 14q31-32.1, occurring in more than 40% of all GEJ adenocarcinomas, and determined an overlapping region of LOH with a size of about 7.1 Mb. This suggests that this region contains one or more tumor suppressor genes involved in GEJ tumorigenesis.

The presence of neuroendocrine cells, as shown by chromogranin immunohistochemistry, in Barrett's epithelium adjacent to tumor was an independent prognostic factor for better survival after surgery. Using mouse models and transfection of chromogranin cDNA a slower progression of tumor growth was demonstrated in the literature, probably being an explanation for the findings in this thesis [5]. Future experiments focusing on transfection of chromogranin cDNA in Barrett's metaplasia cell lines could possibly gain more insight in the role of CGA in GEJ adenocarcinoma development. It also needs to be established which kind of hormone(s) is/are being secreted by the neuroendocrine cells in Barrett and GEJ adenocarcinomas to unravel their function. A large panel of candidate hormones has being tested already at the Department of Pathology of the Erasmus MC but none of these has provided a firm conclusion yet.

EPIDEMIOLOGY

Concerning the epidemiology of esophageal cancer, remarkable changes have taken place over the past decades. About 50 years ago, the incidence of esophageal adenocarcinoma was lower than the incidence of squamous cell carcinoma [6]. To date, adenocarcinoma is the most common esophageal carcinoma and moreover, carcinomas from the gastric cardia show a parallel increasing incidence. Both esophageal and cardia adenocarcinomas occur mainly in Caucasian men. The risk of both esophageal and cardia adenocarcinomas is increased in people with Gastro-Esophageal Reflux Disease. Although studies concerning molecular biology produced conflicting results, many have demonstrated the similarity of these tumors [7-11]. In this thesis it was investigated whether distribution of comorbidity (previous cancers, Chronic Obstructive Pulmonary Diseases (COPD), cardiovascular and cerebrovascular diseases, hypertension, ulcerative digestive tract diseases, liver diseases and diabetes) differed between esophageal squamous cell carcinoma, distal esophageal adenocarcinoma, cardia adenocarcinoma and subcardia carcinoma patients within a large population based database (Eindhoven Cancer Registry). Cardia adenocarcinoma patients resembled distal esophageal adenocarcinoma patients considerably more than subcardia carcinoma patients concerning comorbidity, with likewise equal age and gender distribution and therefore again it seems justified to evaluate these tumors similarly.

Importantly, there is evidence that the likelihood and pattern of lymph node metastases as well as overall survival are similar in esophageal and cardia adenocarcinoma patients [12-14]. Therefore treatment should also be similar. In a retrospective study it was shown that the presence of comorbidity influenced the choice of treatment in patients with esophageal and gastric carcinoma.

TREATMENT

Surgery

Esophageal resection with extensive lymph node dissection is still considered the standard therapy for early GEJ lesions, i.e. high grade dysplasia or T1 adenocarcinoma, at many institutions. We showed lymph node metastases in only one out of 79 T1 tumors (1%) with location in the mucosa or superficial submucosa as compared to 18 out of 41 T1 tumors (44%) with location in the deep submucosa. Moreover, recurrence free period differed significantly between these two groups (p log rank < 0.0001, with 5-year recurrence free percentages of 97% and 57% respectively). Less invasive and more limited surgical procedures and endoscopic procedures might therefore be appropriate alternatives for high grade dysplasia and T1 tumors (intramucosal or superficial submucosa). Hence, an individualized treatment strategy should be employed based on depth of tumor penetration into the mucosa or submucosa, presence of lymph node metastases, endoscopic appearance concerning multicentricity of tumor growth and length of the underlying Barrett's mucosa and comorbidity of the affected patient. Esophageal resection is associated with substantial morbidity and compromised postoperative quality of life. Moreover, the average reported mortality nowadays varies from 4% in specialized centres to more than 10% in low volume hospitals [15,16]. We attempted to develop a simple and robust prediction model for surgical mortality in esophageal cancer patients. Mortality after esophagectomy was found to be related to patient characteristics (age and comorbidity (pulmonary, diabetes)), neoadjuvant therapy and hospital volume. Interestingly, neoadjuvant treatment with radiotherapy was associated with a substantially higher surgical mortality risk, as was neoadjuvant chemoradiotherapy.

Neoadjuvant therapy

In the literature, irradical resections are reported to occur frequently after esophageal resection, varying from 25-41% [17-19]. Adequate loco-regional control is an important issue and might be improved by neoadjuvant therapy. Concerning neoadjuvant chemotherapy, available randomised phase III studies and reviews show that the possible benefit, if any, is considered to be small and it is uncertain whether such a potential survival benefit outweighs the morbidity caused by such a treatment [17,19-26]. From several studies on neoadjuvant radiotherapy it was learned that concurrent chemoradiotherapy is recommended compared to radiotherapy alone since chemotherapy and radiotherapy can interact in several ways. [27-33]. To date several randomized controlled trials have been reported in which neoadjuvant chemoradiotherapy was applied [24,34-39]. Only one trial could show a survival benefit for the chemoradiotherapy-followed-by-surgery-arm and the reliability of the results in this study have been debated [6,39]. Complete pathologic response rate seems to be crucial for a beneficial effect of neoadjuvant chemoradiotherapy. A phase II study has recently been performed at the Erasmus MC, studying neoadjuvant paclitaxel and carboplatin in combination with radiotherapy prior to

surgery within 50 patients having resectable adenocarcinomas or squamous cell carcinomas of the esophagus. All patients received 100% of the planned dose of chemotherapy and radiotherapy with mild adverse effects. All but one patient had a radical surgical resection (R0-resection). Approximately 25% of patients had a complete pathological response. All but one had negative lymphnodes. The concept that this regimen of preoperative chemoradiotherapy improves the overall survival has, however, to be proven in a randomized phase III prospective trial, which is currently being performed in a multicenter setting.

Evidence is mounting that patients who do not respond to chemoradiotherapy may have worse survival due to delay of surgery. Molecular genetic analysis might be helpful in the identification of patients who are most likely to achieve a complete response before initiation of neoadjuvant chemoradiotherapy. Currently, GEJ adenocarcinoma cell lines as well as esophageal squamous cell carcinoma cell lines are being treated with chemoradiotherapy at the Department of Pathology to reveal genetic alterations that can predict therapy resistance/response.

SUSCEPTIBILITY

The identification of genes that confer susceptibility for adenocarcinoma formation in Barrett's esophagus would imply improved manageability of patients with Barrett's esophagus. However, familial cases of esophageal cancer are rare, and susceptibility genes are thus unlikely to be found by linkage analysis. Consequently, screening of candidate susceptibility genes may be a more feasible approach. A study of a large and unselected series of Barrett's metaplasias and dysplasias, esophageal adenocarcinomas and squamous cell carcinomas was performed in which the candidate susceptibility germline CHEK2*1100delC mutation was screened. This mutation had no major contribution in esophageal carcinogenesis. Genetic polymorphisms may play a significant role in person-to-person variability in cancer susceptibility. In this thesis the distribution of numerous Single Nucleotide Polymorphisms (SNPs) was screened in GEJ adenocarcinomas and squamous cell carcinomas and compared to a cohort of healthy blood donors. Interestingly, data confirm that SNPs influence risk for esophageal squamous cell carcinoma (p16 exon 2 C540G, Cyclin D1 exon 4 A870G and p73 exon 2 G4C14-A4T14) and for GEJ adenocarcinoma (p73 exon 2 G4C14-A4T14). SNPs might be used in the setting of surveillance of patients with Barrett's esophagus. Currently a large cohort of Barrett's esophagus patients, who did not develop cancer yet, is being analysed for p73 exon 2 G4C14-A4T14 genotype frequencies as well as for the other SNPs described in this study to reveal whether SNPs could be helpful to stratify surveillance.

FROM BARRETT'S ESOPHAGUS TOWARDS ADENOCARCINOMA: FROM LABORATORY TO CLINIC

At the Erasmus MC, patients with Barrett's metaplasia undergo surveillance endoscopy with tissue biopsies once in two years and patients with low grade dysplasia once a year. Importantly, high grade dysplasia harbors areas of invasive carcinoma in 30-60% already, which is a reason for surgical resection in many institutions. An alternative option for patients with high grade dysplasia forms intensive endoscopic follow-up (once in 3 months) until invasion is observed. Patients with high grade dysplasia or early adenocarcinoma have a survival rate of 80% after surgical resection as compared to 20% after surgery for invasive adenocarcinoma. This stresses the importance of early detection.

Interestingly, new endoscopic ablative techniques have emerged over the past two decades. These techniques have been developed primarily to treat dysplasia and early carcinoma. New techniques include endoscopic mucosal resection, photodynamic therapy, laser therapy, multipolar electrocoagulation, argon plasma coagulation, radiofrequency ablation and cryotherapy [40]. It has yet to be determined whether the risks associated with ablation therapy are less than the risk of Barrett's esophagus progressing to cancer. Whether ablation therapy eliminates or significantly reduces the risk of cancer is subject of currently performed comparative trials.

Endoscopic recognition of preneoplastic lesions might be difficult. The same holds for the histological classification of dyplasia. Significant intra- and interobserver variation exists in classifying dysplasia whereas the decision to treat or to follow-up largely depends on this diagnosis. New developments in both endoscopy technique and tissue sampling aim to improve diagnosis of high grade dysplasia and early cancer [41].

To date it is not possible to predict which patients with Barrett's esophagus will progress to invasive carcinoma. Stratification of patients with Barrett's esophagus who are at risk of esophageal adenocarcinoma and those who are not, is therefore urgently needed. This would allow more aggressive or preventative treatment of the people at risk, but also release the vast majority of people that are not at risk from years of unnecessary endoscopic surveillance.

Molecular genetic analysis might be helpful for two reasons:

1. The histological classification of dysplasia could be supplemented by the screening for genetic alterations to ensure accurate diagnosis. In this thesis areas of Barrett's metaplasia, low and high grade dysplasia and carcinoma were selected in H&E stained slides by a specialised GE pathologist. However, a major obstacle to apply molecular biologic techniques effectively to the genetic analysis of (pre)neoplastic tissue is the presence of abundant nonneoplastic elements in the analyzed specimen. These nonneoplastic elements, including reactive fibrous cells, vascular cells, and a variety of infiltrating white blood cells, may mask

genetic alterations that otherwise would be easily detectable if the (pre)neoplastic cells were procured selectively. In chapter 13 DNA from (pre)neoplastic areas was obtained after Laser Capture Microdissection technique. This technique allows to selectively procure and genetically analyze small populations of (pre)neoplastic cells from the glass slides. We compared the mean number of investigated molecular aberrations (i.e. LOH at p53 (17p), p16 (9p), Adenomatous Polyposis Coli (APC, 5q), Mutated in Colorectal Cancer (MCC, 5q), Retinoblastoma (Rb, 13q), Deleted in Colorectal Cancer (DCC, 18q), Deleted in Pancreatic Cancer (DPC4/SMAD4, 18q), mutation of the p53 gene, and mutation of mitochondrial DNA). The mean number was significantly lower in the combined group metaplasia/low grade dysplasia (3.0 ± 1.74) as compared to the combined group high grade dysplasia/carcinoma (5.0 ± 1.71, $p<0.001$). Screening for molecular aberrations might therefore indeed be valuable and add to histology within patients with difficulty to diagnose grade of dysplasia.

2. Endoscopic biopsy samples of Barrett's esophagus that histologically appear as low risk for neoplastic progression might in fact harbor genetic alterations that are indicative for a high risk profile (Figure 15.1). Therefore genetic alterations should perhaps also be investigated within evident metaplastic or low grade dysplastic lesions. A more intense surveillance should perhaps be offered to the patients harboring genetic alterations in their histologically unsuspected metaplasia or low grade dysplasia. It has been estimated that at least 1% of the Caucasian population may have Barrett's metaplasia and that from the patients with Barrett's esophagus 0.5-1% will develop adenocarcinoma [42]. It would be of great importance to be able to discriminate at an early stage which metaplasia- or low grade dysplasia patients will develop invasive disease and which will not.

Numerous genetic aberrations are known to frequently occur in esophageal adenocarcinoma. However, knowledge of the timing of these genetic events during esophageal adenocarcinogenesis is limited. In particular, few studies have analysed genetic aberrations in Barrett's epithelia that did not progress to esophageal adenocarcinoma. At the Erasmus MC, there is access to longitudinal esophageal biopsies from a cohort of at least 550 patients with Barrett's esophagus who underwent annual endoscopic surveillance since 1973. The cohort includes patients that have developed esophageal adenocarcinoma as well as patients that are still disease-free for more than 5 years. This collection of biopsies provides an unique opportunity to compare genetic aberrations in lesions from patients with Barrett's esophagus that are at risk of esophageal adenocarcinoma and those that are not at risk. Within a present study performed at the Departments of Pathology, Gastroenterology, Surgery and Epidemiology it is aimed to identify genetic markers that distinguish Barrett's epithelia that will progress to esophageal adenocarcinoma from those that will not progress to malignancy.

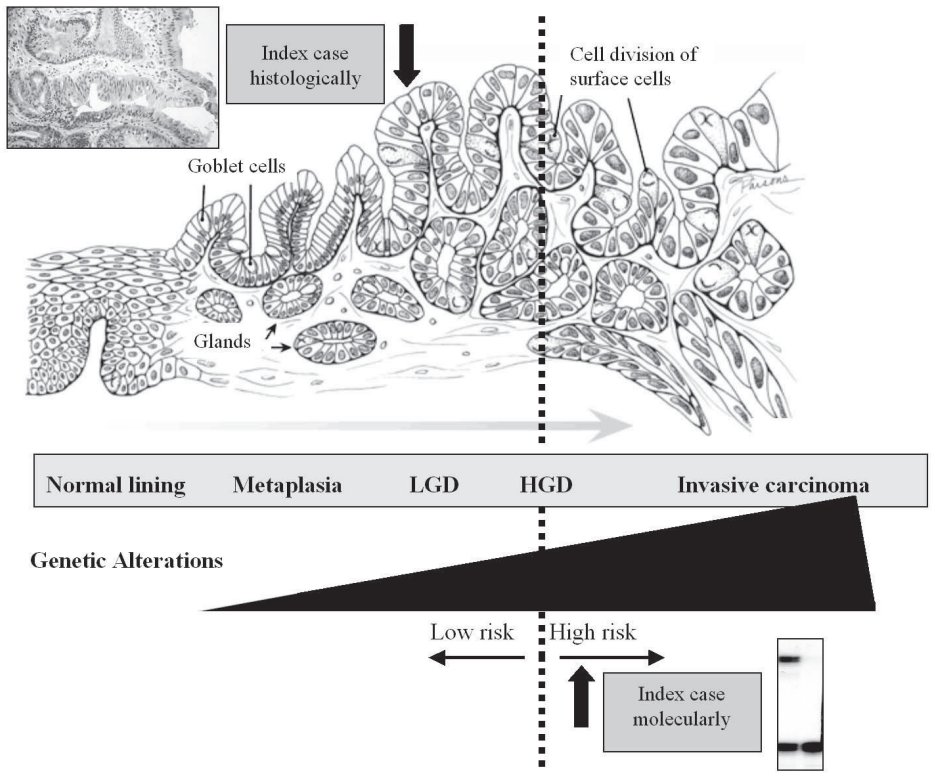

Figure 15.1 Metaplasia-Dysplasia-Carcinoma sequence. Index case is histologically at low risk for neoplastic progression, however genetic alterations are indicative for high risk profile. *Also see color figures page 291.*

FUTURE PERSPECTIVES

Targeted therapy

The sequence of the human genome has enabled systematic approaches to identify cancer genome alterations including point mutations, copy number increases and decreases, loss of allelic heterozygosity and chromosome translocations [43]. Molecular targets for therapy are becoming more widely known and include epidermal growth factors, tyrosine kinases, vascular endothelial growth factor and intracellular signaling pathways. With further development of targeted cancer therapies and improvement in genome analysis technology, genome-wide surveys of cancer will likely become tools for diagnosis as well as discovery [43-45]. Microarray analysis to study gene expression is able to rapidly identify genes which can function as a guide for tailored (neoadjuvant chemoradiation) therapy [46,47]. Examples of cancer-targeted therapy are the drugs Herceptin, used to treat c-erbB2 overexpressing breast cancer, Gleevec, used to treat a type of leukemia and certain rare cancers, and Gefitinib (Iressa), used to treat

lung cancers with EGFR mutations and probably other epithelial cancers with similar mutations in the near future. Intervention trials are underway in which neoadjuvant chemoradiotherapy is combined with EGFR-inhibitor Iressa prior to surgery for resectable esophageal cancer [48]. The concept of a cancer stem cell population as described in the literature gives hope that the isolation of these cells, coupled with the knowledge of the mutations causing cancer, will result in ways to eliminate cancer cells while sparing normal tissues [49]. In search for the Achilles' heel for cancer, future targeted cancer therapies will become available, although the pace at which molecular developments have been translated in clinical applications have been slow to date.

Molecular markers

Concerning Barrett's metaplasia and its malignant potential there is still need for improved understanding of the molecular biology in order to develop a more scientific approach to cancer prevention in these patients. Biopsy samples from patients with Barrett's esophagus might histologically appear as low risk for neoplastic progression whereas genetic alterations might be indicative for a high risk profile (Figure 15.1). Since the annual incidence rate for developing esophageal adenocarcinoma in Barrett's esophagus is as low as 0.5-1%, a cancer preventive strategy needs to be cost effective and acceptable to a large number of patients at relatively low risk [50]. It has been propagated that endoscopic cancer surveillance should therefore be limited to patients with increased cancer risk (for example Caucasian men, 55-70 years age, people with GERD) [51]. Perhaps it may someday be possible to identify a molecular marker that identifies GERD patients at high risk for Barrett's esophagus who might benefit from endoscopic surveillance [52]. Despite ongoing efforts to characterize the molecular changes leading to esophageal adenocarcinoma, no clinically applicable molecular markers for prediction of prognosis and/or response to therapy came forward to date. Several studies performed and described in this thesis intended to identify genetic alterations in GEJ adenocarcinogenesis and to develop molecular markers applicable in Barrett's patients. Unfortunately many patients with GEJ adenocarcinoma present with advanced stage of disease since they were not known to harbor Barrett's esophagus. Having realized this, one of the other main concerns in the finding of molecular markers forms the suspected existence of intralesional heterogeneity of genetic alterations in Barrett's epithelium. In the literature, FISH analysis, LOH and gene amplification analysis showed intratumoral heterogeneity in Barrett's adenocarcinomas [53,54]. This highlights one of the main problems associated with surveillance of Barrett's patients namely sampling error. From other studies it seemed likely that the acquisition of 9p LOH and 17p LOH predisposes to the evolution of aneuploid cell populations and other genetic abnormalities that culminate in the development of cancer [55-57]. Tumors may be monoclonal in origin and share, common, early genetic abnormalities predisposing to the evolution of clones with accumulated, different, late genetic abnormalities [58,59]. Several studies on GEJ adenocarcinomas with or without metaplastic areas and studies on high

grade dysplasia without carcinoma indeed show evidence for a monoclonal origin of these lesions by use of comparative genomic hybridisation (CGH), LOH analysis, mutation analysis, X-chromosome inactivation analysis as well as methylation analysis [54,56,60-65].

This issue of clonality of genetic alterations was investigated in this thesis. We presented molecular evidence that GEJ adenocarcinomas are monoclonal in orgin concerning early genetic alterations, i.e. especially p53 mutations, 17p LOH, 9p LOH, 13q LOH and 18q LOH. Mitochondrial DNA mutations have been suggested to be indicators of clonal expansion [66,67] and were also analyzed but they seemed to have limited value as clonality marker in GEJ adenocarcinomas. Most likely, a *monoclonal* tumor concerning *early genetic alterations* harbors *clonal diversity* concerning *later genetic alterations*. Such early genetic events in the neoplastic progression of Barrett's metaplasia concern loss of p16 and p53 but also loss of APC, Rb and DCC with aneuploidy as a probable driving force; additional genetic alterations superpose. Since this thesis provided evidence for monoclonality concerning early genetic alterations, molecular markers potentially can be applied in conjunction with histopathology to identify Barrett's patients at risk for neoplastic progression.

Most probably no single 'universal' genetic marker is sufficient to enable prediction of which patient will and which patient will not develop cancer in the setting of Barrett's esophagus. Thus a 'multimarker' approach seems more promising than a 'single marker' approach. A combination of the investigated markers, especially p53 mutations, 17p LOH, 9p LOH, 13q LOH and 18q LOH might be part of a future panel of markers, in conjunction with histopathological diagnosis. Early genetic alterations should be given highest priority in the ongoing search for molecular markers both for diagnostic and prognostic use. This will hopefully lead to a further differentiation in the prediction of neoplastic risk in Barrett's esophagus patients with early intervention and individualized treatment as ultimate goal.

ACKNOWLEDGMENTS/ DANKWOORD

Graag besluit ik mijn proefschrift met het bedanken van de mensen zonder wiens hulp en betrokkenheid mijn promotie niet tot stand was gekomen. Ik streef niet naar volledigheid, mijn dank gaat uit naar iedereen met wie ik op enig moment mocht samenwerken. Een aantal mensen wil ik echter bij name noemen.

Beste Winand Dinjens, "Chief", niemand kan een vriendelijker en kundiger copromotor hebben getroffen dan ik. Voor de manier waarop je in het leven staat, samen met Wil, heb ik diep respect. Het was en is een groot voorrecht met je te mogen samenwerken.
Beste Professor Tilanus, zeer gewaardeerde eerste promotor, als student kreeg ik de kans het studententeam Levertransplantaties te bemannen. De momenten, vaak in het holst van de nacht, waarop ik achter of naast u aan tafel mocht staan, maakten me enthousiast voor de chirurgie. U speelde de hoofdrol in het vormgeven van mijn wetenschappelijke ambities en u was niet teleurgesteld toen ik de mogelijkheid bij u op het leverlab te promoveren afsloeg… de oncologische chirurgie -prachtig!-, dáár had u ook nog een plaats vrij! Mijn dank is groot. Mag ik binnenkort weer van u leren aan tafel?
Geachte Professor Oosterhuis, tweede promotor, dank voor het onderdak dat u me bood op het Laboratorium Moleculaire Diagnostiek in het Josephine Nefkens Instituut. Ik vind het een eer bij u te promoveren en dank u voor de bereidheid mijn tweede promotor te willen zijn.

De kleine commissie
Dr. van Dekken, beste Herman, als coauteur op een aantal van mijn stukken gaf je me immer je eerlijke, kritische commentaar waarvoor veel dank. Het lijkt me leuk in de nabije toekomst casusgericht verder te discussiëren hóe moleculaire kennis te implementeren in de kliniek. Dank voor je zitting in de kleine commissie.
Hartelijk dank Professor Coebergh, beste Jan-Willem. Een voorrecht om met je te hebben mogen samenwerken en gebruik te mogen maken van de waardevolle schat aan data van de Kankerregistratie Eindhoven/IKZ. Aanstekelijk enthousiasme van jou en je team maakt hongerig naar epidemiologische antwoorden op klinische vraagstukken. Chirurgen kunnen niet zo goed registeren en jouw tijd is kostbaar…, maar de discussie gaat misschien toch verder?
Professor Kuipers, beste Ernst, dank voor je bereidheid plaats te nemen in de kleine commissie. Het inzetten van moleculaire kennis in de kliniek maakt nu al deel uit van je dagelijks werk en de toekomst wordt volgens mij des te interessanter. Leuk dat je er de 16e bij wilt zijn!

De grote commissie
Beste Professor Obertop, dank voor uw bereidheid plaats te nemen achter de tafel als Rotterdams lid van de grote commissie.

Dank Professor van Lanschot uit het AMC Amsterdam voor de prettige samenwerking met uw onderzoeksgroep (ik noem met name Marinke Westerterp en Christianne Buskens) en de mogelijkheid een grote serie materiaal te gebruiken voor de validatie van onze onderzoeksresultaten.
Geachte Professor Lerut, Universiteitsziekenhuis Gasthuisberg te Leuven, na met u een boekhoofdstuk te hebben geschreven bent u nu commissielid op mijn promotie. Hartelijk dank hiervoor en voor uw bereidheid naar Rotterdam te komen. Ik vind het een eer dat u wilt plaatsnemen in de commissie.
Dr. Mieke Schutte, wetenschapper Interne Oncologie pur sang, het was fantastisch het CHEK2 artikel met je te mogen schrijven. Ik ben onder de indruk van de manier waarop je wetenschap bedrijft en bediscussieert (en brieven schrijft!). Dank dat je als deskundige wilt opponeren.
Dr. Peter Siersema van de MDL, ik heb je leren kennen als zeer gedreven wetenschapper. Dank dat je zitting neemt in de kleine commissie!
Dr. Laurents Stassen, zeer gewaardeerde opleider te Delft, op 16 juni verruilen we de meester-gezel relatie eventjes voor die van opponent-promovendus, maar wel met een tafel ertussenin. Hartelijk dank voor je aanwezigheid.

Beste Bas Wijnhoven, eigenlijk baande jij voor dit proefschrift en daarmee voor mij de weg. Ik had het me niet beter kunnen wensen. Dank voor je betrokkenheid en de manier waarop je zowel in het hanteren van de pipet als van het mes voor mij een voorbeeld bent.

Mijn collega's van het Laboratorium Moleculaire Diagnostiek wil ik bedanken voor de gezellige samenwerking en opperbeste werksfeer. Jullie leerden me de verschillende technieken en wijdden me in in jullie jargon… Dank jullie wel Mustaffa Abbou (inmiddels commercieelga d'r voor Mus!), Albertina van der Velden (volg je hart lief mens), Monique Hoogmans (d'r komt weer een feessie aan…!), Hein Sleddens (gezelliger kan bijna niet), Erwin Beerens (wel ff checken of het in evenwicht is), Peter Riegman & Monique Oomen (tissue is the issue), Alex Nigg (mogen we flèèèètscreens Ááál ââh?), Frank van der Panne (kwaliteit is de naam), Ludo Uitdenwilligen (turbosnijder).
Tot ziens lieve collega's van het Josephine Nefkens Instituut (verdieping 2, 3 & 4), allemaal hartelijk bedankt voor de prettige samenwerking.
Op het lab heb ik veel mogen werken met stagiaires. Hartelijk dank voor jullie inzet Henk van de Meerendonk, Laura Piket, Taco van der Wel, Sita Ramcharan, Anke van Bruggen, Petra Lodder, Jolanda van Velzen, Laura Willemsteijn en Esther Hasper.

Dank aan de onderzoekers en het registratieteam van de Eindhoven Kankerregistratie/ IKZ. Beste Valery Lemmens, dank voor de zeer prettige samenwerking, op jou kon ik altijd bouwen. Ik wens je een succesvolle toekomst en een geweldige promotie! Beste Maryska Janssen-Heijnen, dank voor je intensieve begeleiding en je hartelijkheid. Bedankt voor de

prettige samenwerking Marieke Louwman. Conny Vollebregt wil ik hartelijk bedanken voor het datamanagement en het gezellige contact. Ewout Steyerberg, dankjewel voor je inzet op vele fronten! Jouw enthousiasme voor je vak en je werklust zijn aanstekelijk. Heel graag werk ik in de toekomst nog eens samen met je aan een project. Beste Khe Tran, n= heel veel buismagen inmiddels. Tussendoor misschien tijd voor nog een slokdarmcongres? Beste Marc van de Wetering, hartelijk dank voor je hulp bij de siRNA experimenten in de cellijnen. Ik voelde me erg welkom op het Utrechtse lab. Helaas waren we met de opzet van ons experiment uiteindelijk niet succesvol.

Ate van der Gaast, dank voor de prettige samenwerking bij het opzetten van de fase III trial. Lieve Marijke Smits-Schouten, dank voor al je hulp en gezelligheid!

Mijn interesse voor wetenschappelijk onderzoek kwam naar voren in de periode binnen het studententeam Levertransplantaties. Degenen die daar een rol bij speelden wil ik in dit dankwoord noemen: Gerda Bouma, Michiel Warlé, Pieter Zondervan (en Monica Seijbel, gezellig dat je inmiddels op de afdeling Heelkunde werkt!), Jaap Kwekkeboom, Herold Metselaar, Jan IJzermans, Geert Kazemier, Hans Brouwer, Rob de Man en Jeroen de Jonge.

Een aantal van de artikelen uit dit proefschrift heb ik geschreven tijdens mijn opleidingstijd in Delft. Van verschillende kanten werd regelmatig interesse getoond en- niet te vergeten- de 'herkenning' gedeeld. Bedankt voor de support en de prettige werksfeer chirurgen en collega arts-assistenten, verpleegkundigen van afdelingen 4.I GE, 4.I Vaat, en 4.II Trauma, collega's van de IC, de OK, de poli en de SEH en secretaresses Heelkunde.

Vanuit mijn vriendenkring was er de afgelopen tijd veel begrip voor mijn drukke agenda. Daar komt dus binnenkort verandering in… in de agenda bedoel ik. Dank voor al jullie belangstelling, support en bemoediging. Lieve Jan & Léanne, pappa en mamma van Sven, Roos en kleine Tess, bedankt voor jullie vriendschap, wat mij betreft 'for life'! Lieve Hester, praten over het leven is met jou zo leuk! Enneke, jij verstaat de kunst van vriendschap als geen ander. Stoere vriendin Marijke de Jong in Kaapstad, ik ben trots op je! Karo & Corné, pappa en mama van Roos en Stijn, Oud-Beijerland is inderdaad dichtbij, tot snel. Lieve Annemieke (& Marcel), dank voor warme vriendschap, … ooit samen aan tafel? Kinderdok Marijke (& Martin), binnenkort jij?! Andréa (& Michel), lieve chica, dank voor je meeleven... en niet alleen met de promotieperikelen! Beste Bart, komt mijn boek in 1 van jouw boekenkasten? Miriam & Erik, pappa en mamma van Sebastiaan en Olivier, dank voor jullie betrokkenheid en vriendschap. Doctor Hilde, je ging me voor maar we zijn tegelijk klaar met de opleiding.. zelfde maatschap misschien?.. Ik zeg <ja!>. Lieve Vera, jij leeft met mij mee, en ik met jou, zet hem op! Bedankt voor jullie warme betrokkenheid Ingrid & Michiel (Donna, Bo en Jim), Hans & Frieda, Merel, Jelle & Joke, Annemien, Ankie Meyran, Jannie & Leen Tanis, Olaf Schouten.

Bedankt lieve ouders van Niels, Thijs en Betty Kok voor jullie gastvrijheid en niet aflatende support in alle betekenissen van het woord. Bedankt Diederik, Eline en Roelof voor het toevoegen van die nieuwe dimensie: ADHD! Tijd voor nog een feestje?

Hartstikke trots ben ik op mijn paranimfen Madelon & Sabine. Lieve roommie, wat hadden we het gezellig op kamer Be332. Ruim tweeëneenhalf jaar lang gingen we dagelijks met elkaar om, ik mis het. Met jou als close friend is het leven aangenaam, dank voor wie je bent. Lieve sis, ondanks je drukke leventje ben je er altijd voor mij. Top dat ook jij naast me wilt staan op de 16e!

Sabine en Marjolein, zusjes, weer een hoogtepunt in ons leven, na jullie bruiloften nu mijn promotie. Wat een bijzondere tijd. Gelukkig weten we alledrie wie we mogen bedanken!... En dat geeft een hele bijzondere band. Dat we nog maar veel mooie momenten mogen beleven, samen met pap en mam én de mannen. Lieve Pim en Han, dank voor mannelijke gezelligheid in gezin Koppert én voor het feit dat jullie mijn zusjes gelukkig maken!

Lieve Niels, dank voor jouw liefde voor mij. Je hebt me ontzettend gesteund en bovenal aangemoedigd te genieten van deze unieke tijd. Jouw tomeloze energie is aanstekelijk. Ik heb er alle vertrouwen in dat jij binnenkort ook promoveert en zal je steunen waar ik kan. Op een mooie toekomst samen, ik hou van jou!

Lieve pappa en mamma, jullie hebben me geleerd te geloven, te hopen en lief te hebben. Jullie onvoorwaardelijke steun en liefde zijn overweldigend. Ik ben ontzettend trots op je pap, op de manier waarop je in het leven staat en dat ook volop uit in je vak. Jij bent mijn voorbeeld. Lieve mam, je bent hartsvriendin en moeder tegelijk… en tegenwoordig ook m'n golfmaatje! Ik ben jullie innig dankbaar. Mijn proefschrift draag ik dan ook aan jullie op.

Dank U Vader God, bron van levend water, dank voor wie U bent voor mij.

Zegen op jullie wegen,
Linetta

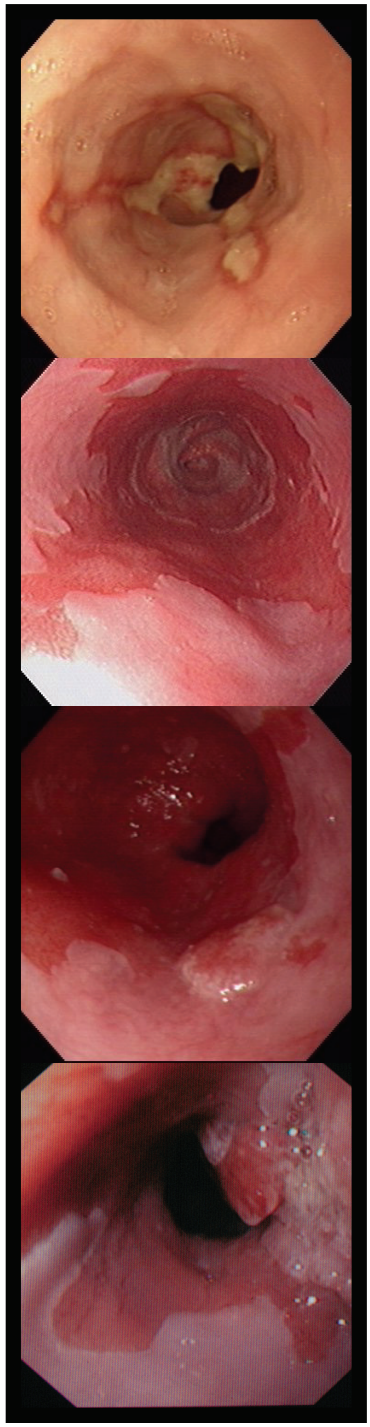

Figure 1.1 Endoscopy images

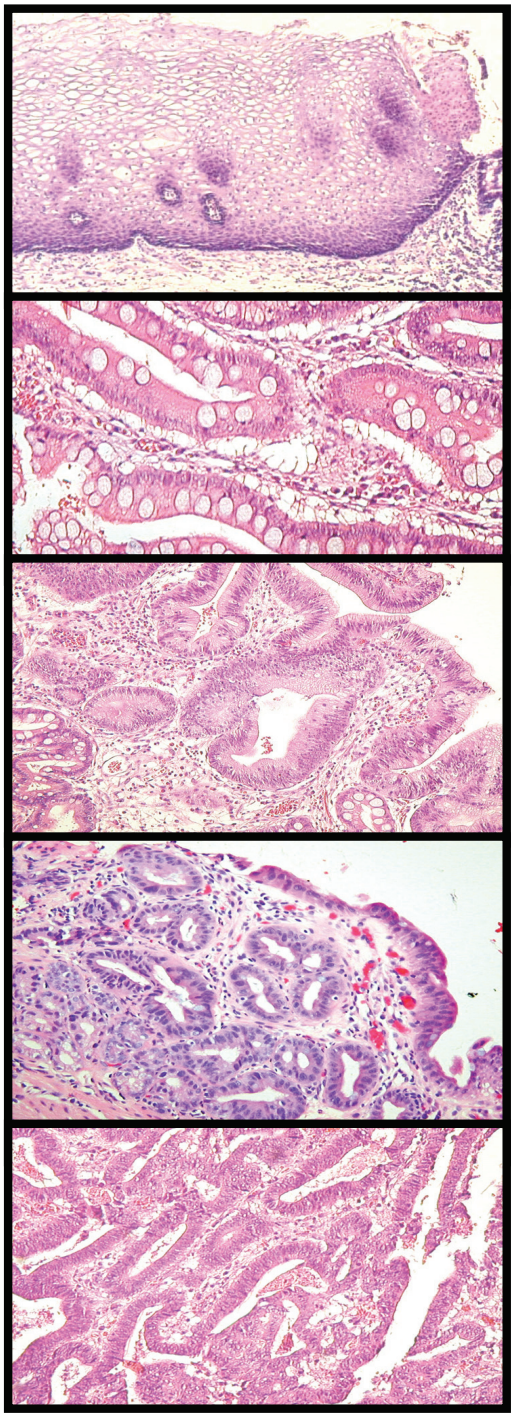

Figure 1.2 Histology of 'metaplasia-low grade dysplasia-high grade dysplasia-carcinoma sequence'

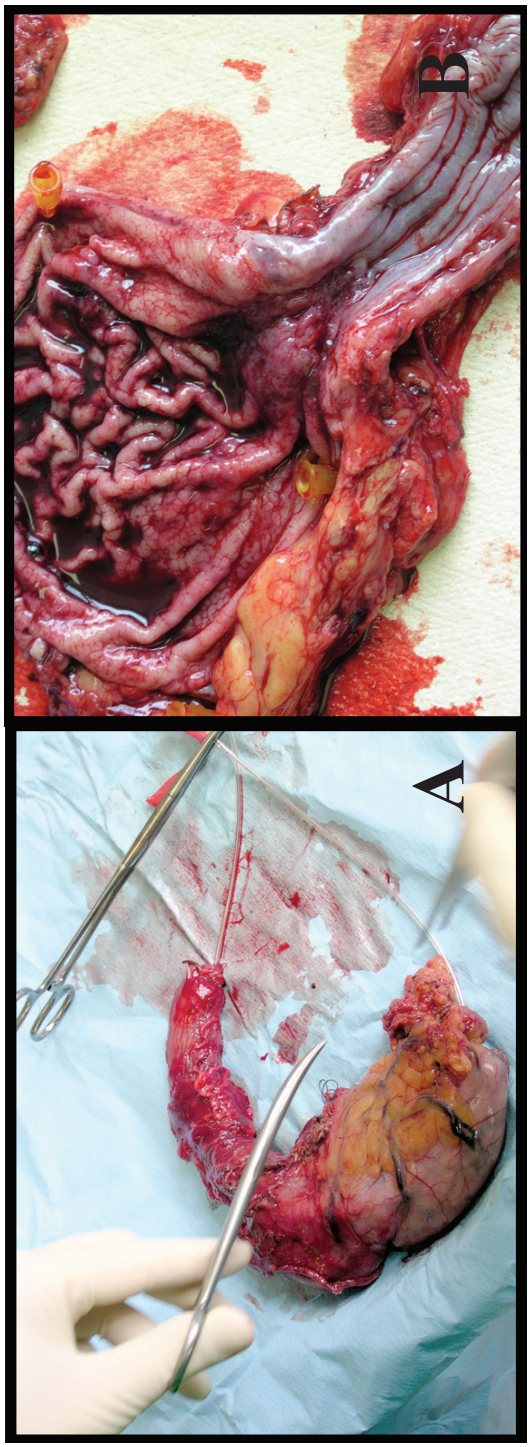

Figure 1.3 Resection specimen with GEJ adenocarcinoma

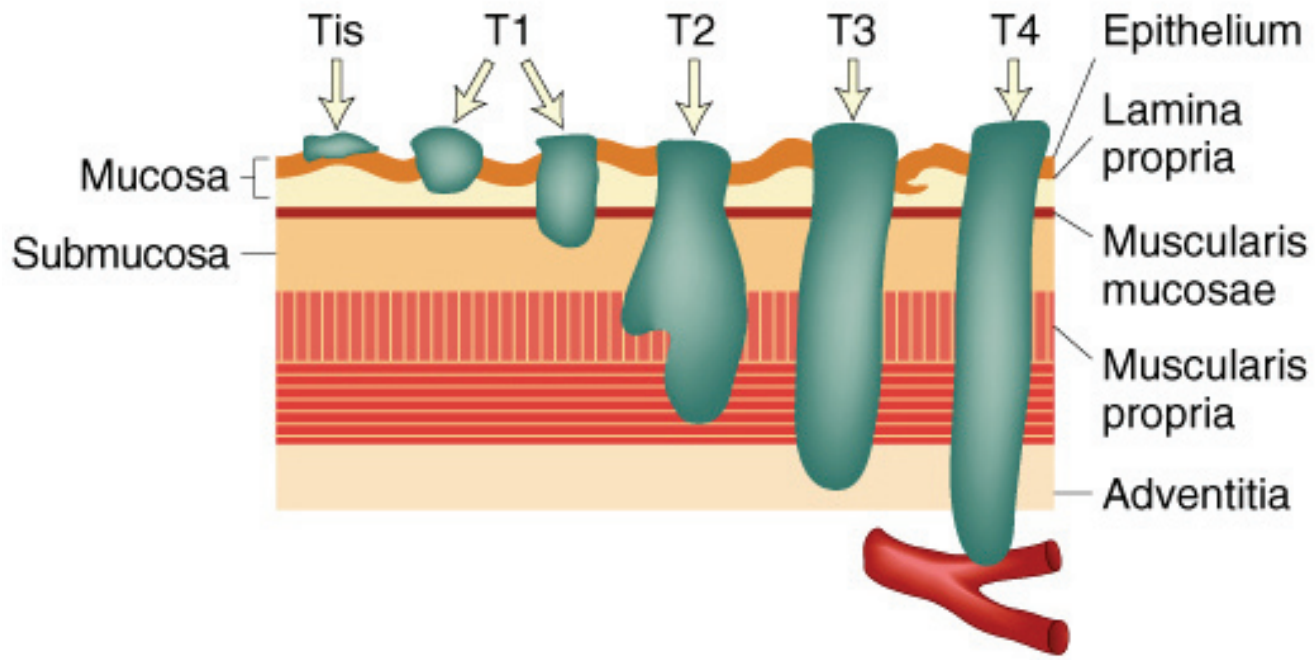

Figure 1.5 TNM classification (T-stage)

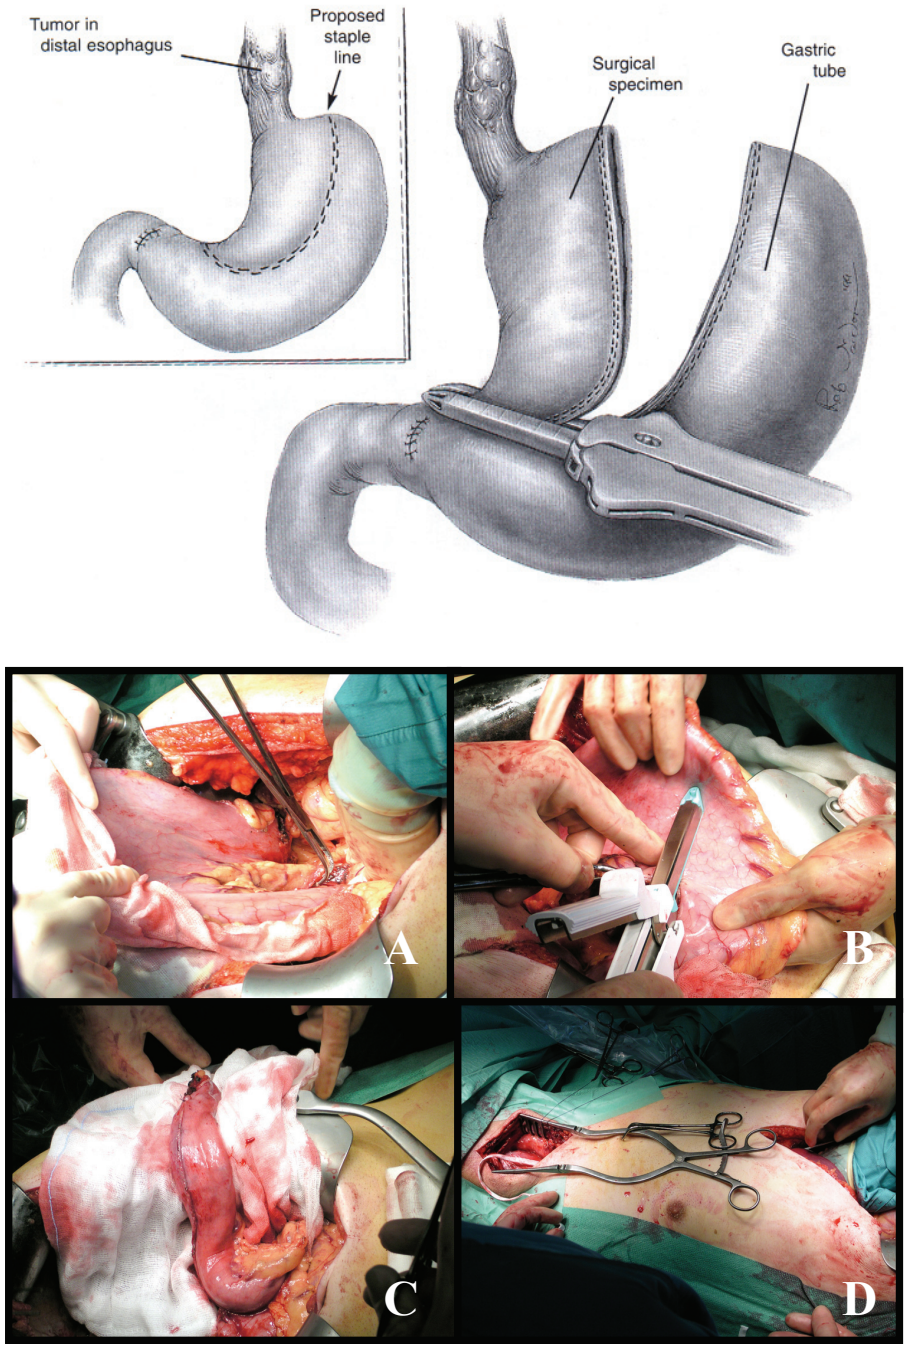

Figure 1.6 Schematic overview of surgical resection of GEJ adenocarcinoma. Photographs below the scheme show upper abdominal incision (A.), and creation of the gastric tube (A. B. C.) to restore continuation of the gastrointestinal tract after transhiatal en-bloc removal of esophagus and gastric cardia including tumor and adjacent lymph nodes (D.). Esophagogastrostomy will be performed in the neck (smaller incision left side of picture D.)

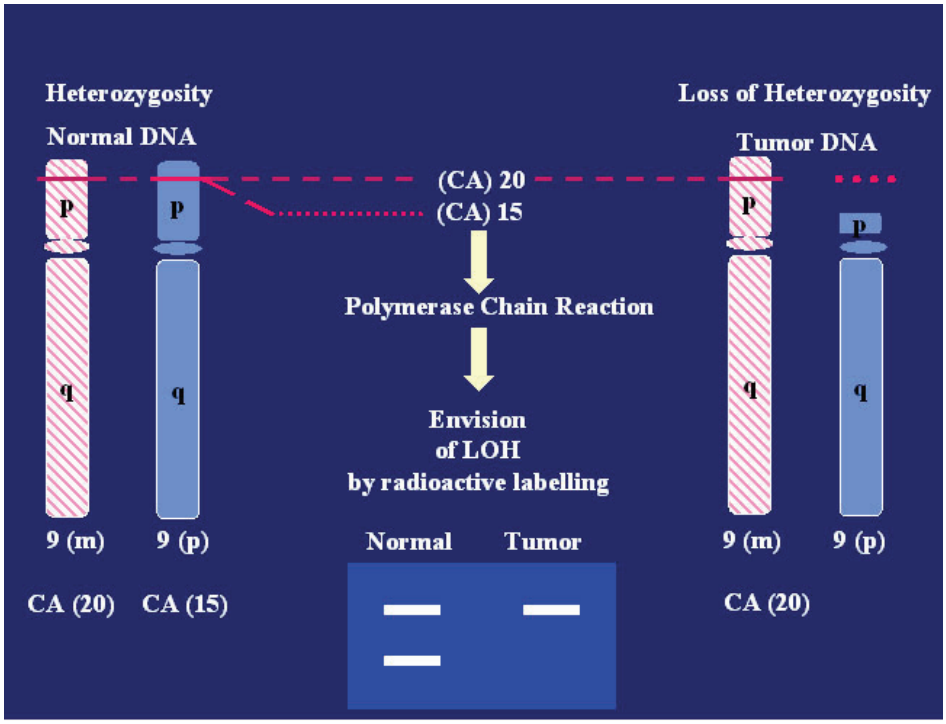

Figure 1.7 Schematic overview of Loss of Heterozygosity (LOH) analysis. Amplified fragments of maternal and paternal DNA of chromosome 9 are compared between normal and tumor DNA of a patient. Length of CA repeats within the fragments differs in the normal DNA, i.e. there is heterozygosity (maternal contains 20 CA repeats and paternal contains 15 CA repeats). In patients tumor DNA part of the short arm of paternal chromosome 9, containing the 15 CA repeat, is lost and therefore the heterozygosity is lost. This is visualized on a gel after radioactive labeling. Only the maternal 20 CA repeat is visualized in the tumor as compared to the normal DNA in which both fragments are shown and therefore this tumor shows LOH. Within LOH analysis, a separation of fragments takes place through difference in length, whereas Single Strand Conformation Polymorphism (SSCP) analysis separates fragments by a different conformation between normal and mutated DNA.

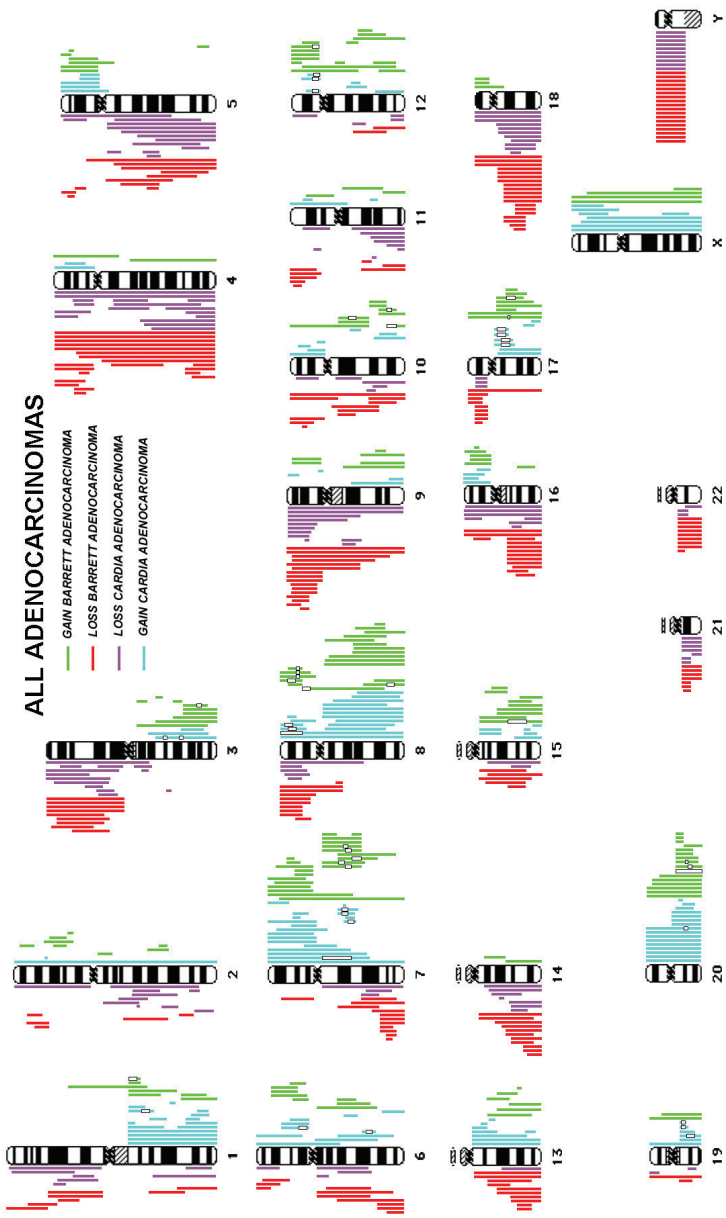

Figure 2.1 Combined CGH data from Van Dekken et al. (20 gastric cardia adenocarcinomas) and from Riegman et al. (30 Barrett adenocarcinomas) [167,171]. Boxes indicate regions of high-level amplification.

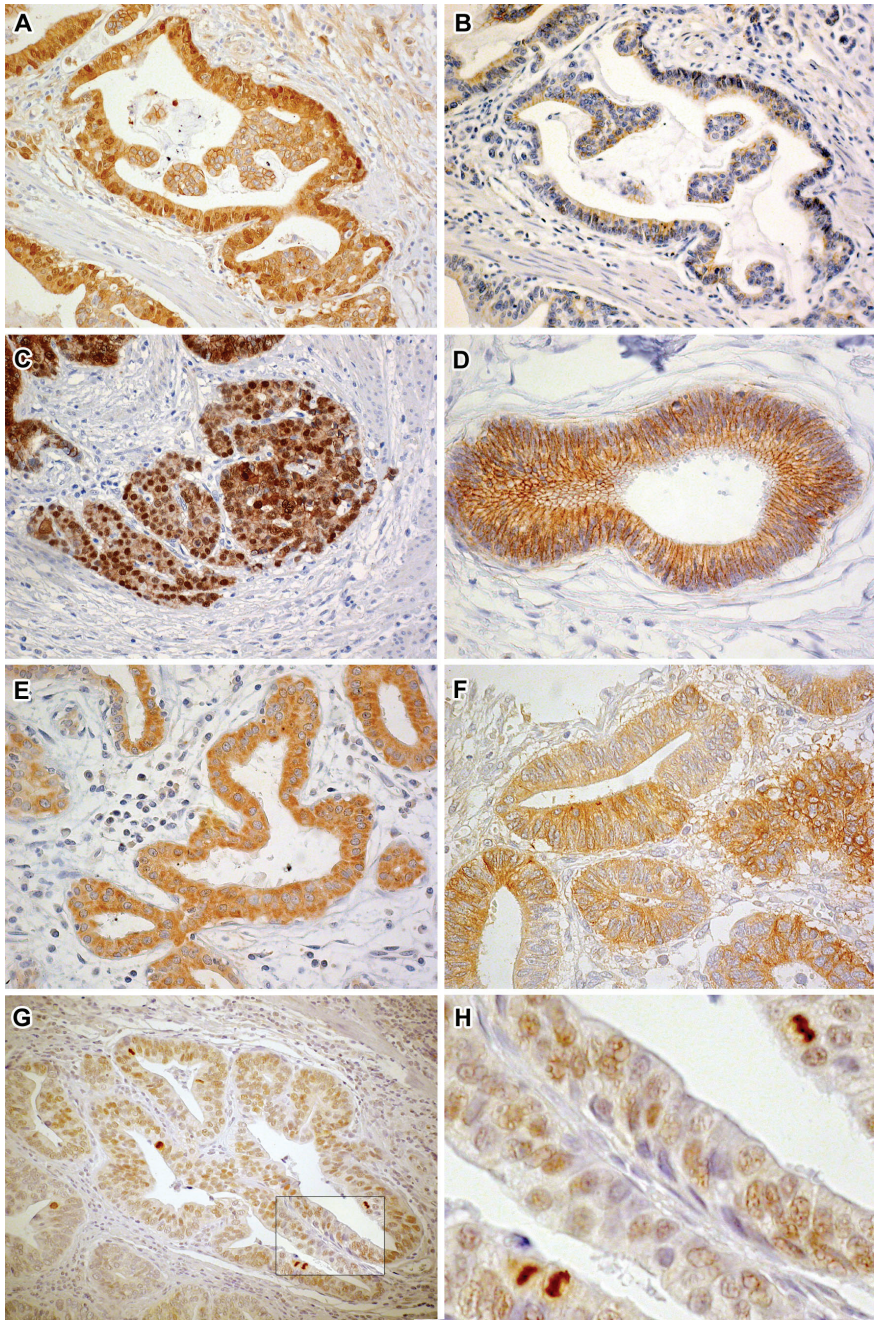

Figure 3.1. Immunohistochemistry of β-catenin in GEJ adenocarcinomas (Magnification x 200 (A., B., C., G.) and magnification x 400 (D., E., F., H.). A. Nuclear and cytoplasmic expression of β-catenin in the tumor cells. B. Nuclear active β-catenin staining in same GEJ tumor tissue as mentioned in A. C. Strong nuclear active β-catenin. D. Active β-catenin in membrane and cytoplasm of GEJ adenocarcinoma. E. EphB2 staining in cytoplasm of the tumor cells. F. Membranous EphB2 staining. G. Nuclear phospho β-catenin (Thr41/Ser45) with strong staining patterns in mitotic cells (insert H.).

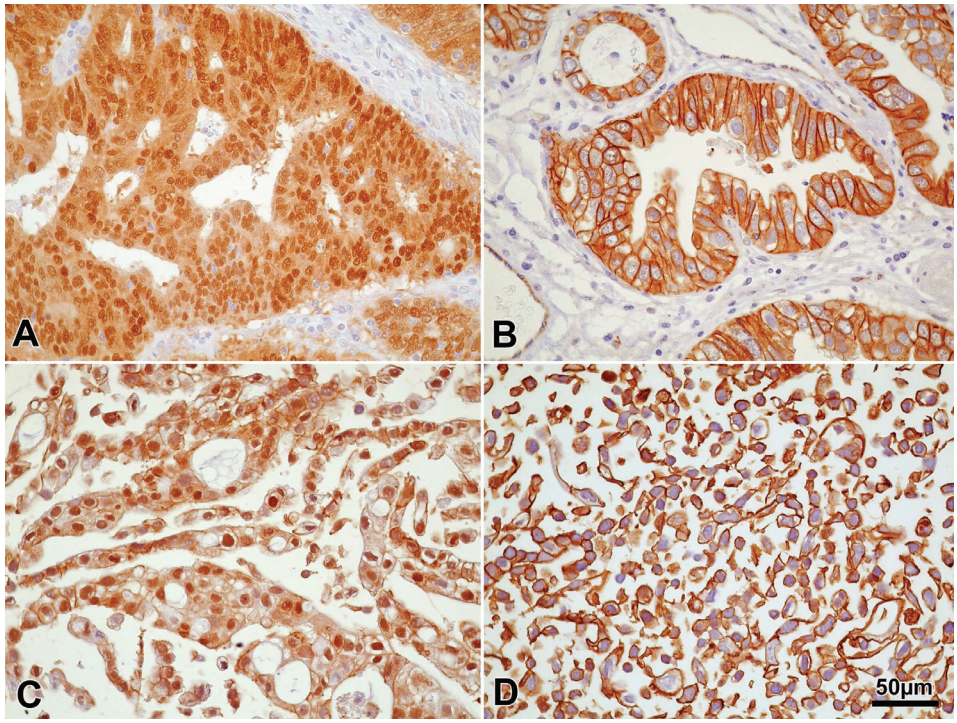

Figure 4.1 Immunohistochemistry of β-catenin in GEJ adenocarcinomas and cell lines. (β-catenin antibody, DAB and haematoxylin counterstain, magnification x 400). A. GEJ adenocarcinoma. Strong nuclear expression of β-catenin in the tumor cells. B. GEJ adenocarcinoma. Prominent membranous expression of β-catenin. C. Cell line JROECL19. Strong nuclear expression of β-catenin. D. Cell line TE-7. Membranous expression of β-catenin.

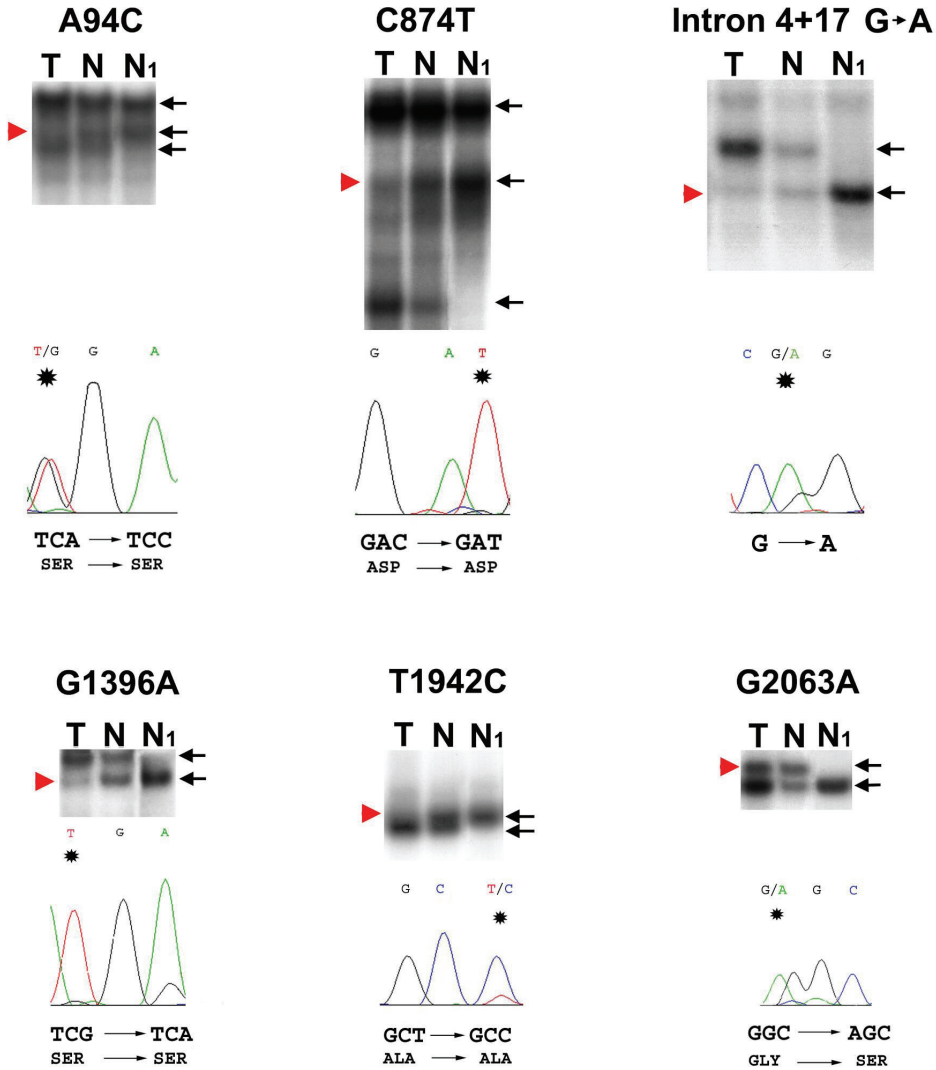

Figure 4.3 PCR-SSCP and sequencing analyses of the SNPs in tumors (T) and corresponding normal DNA (N), compared with DNA from individuals without SNPs (N1). Shown are informative cases with LOH. Black arrows point to allelic patterns. Red arrow heads point to deleted alleles in the tumor DNA. The sequencing chromatograms below each autoradiograph show the alterations (note the substituted nucleotide marked by an asterisk), which all represent SNPs. SNPs A94C and G1396A are annotated in the reverse complementary direction, whereas the SNPs C874, intron 4+17 G→A, T1942C and G2063A are annotated in forward direction.

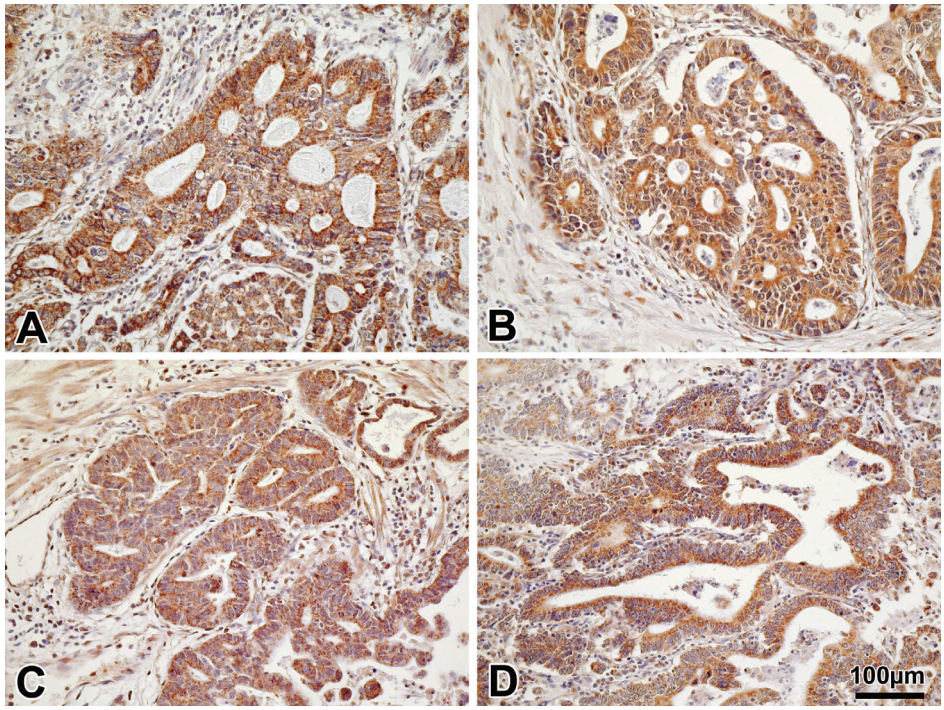

Figure 4.5 Immunohistochemistry of AXIN1 in GEJ adenocarcinomas. (AXIN1 antibody, DAB and haematoxylin counterstain, magnification x 200). A. and B. GEJ adenocarcinomas with nuclear β-catenin expression without (A.) and with (B.) AXIN1 locus LOH. C. and D. GEJ adenocarcinomas with membranous β-catenin expression without (C.) and with (D.) AXIN1 locus LOH. Note the strong cytoplasmic AXIN1 expression in the tumor cells in all 4 cases.

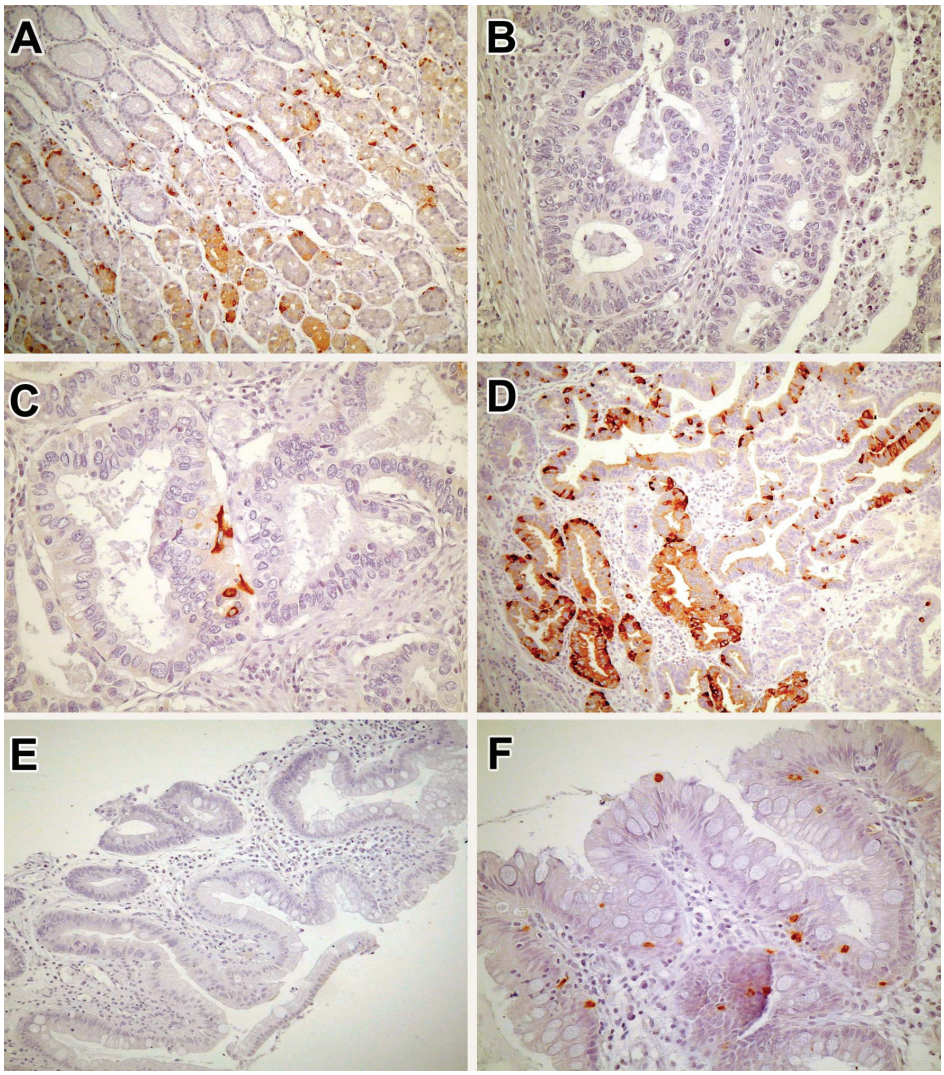

Fig. 6.1 CGA immunoreactivity in normal gastric epithelium (A), CGA negative adenocarcinoma (B). Scatters of individual tumor cells show CGA staining (1+) within a well-differentiated adenocarcinoma (C). Adenocarcinoma shows apparent cytoplasmic CGA staining in >20% (2+) of tumor cells (D). CGA negative Barrett's epithelium adjacent to adenocarcinoma (E), CGA positive cells in Barrett's epithelium most prominently located in the basal layer of the epithelium (F).

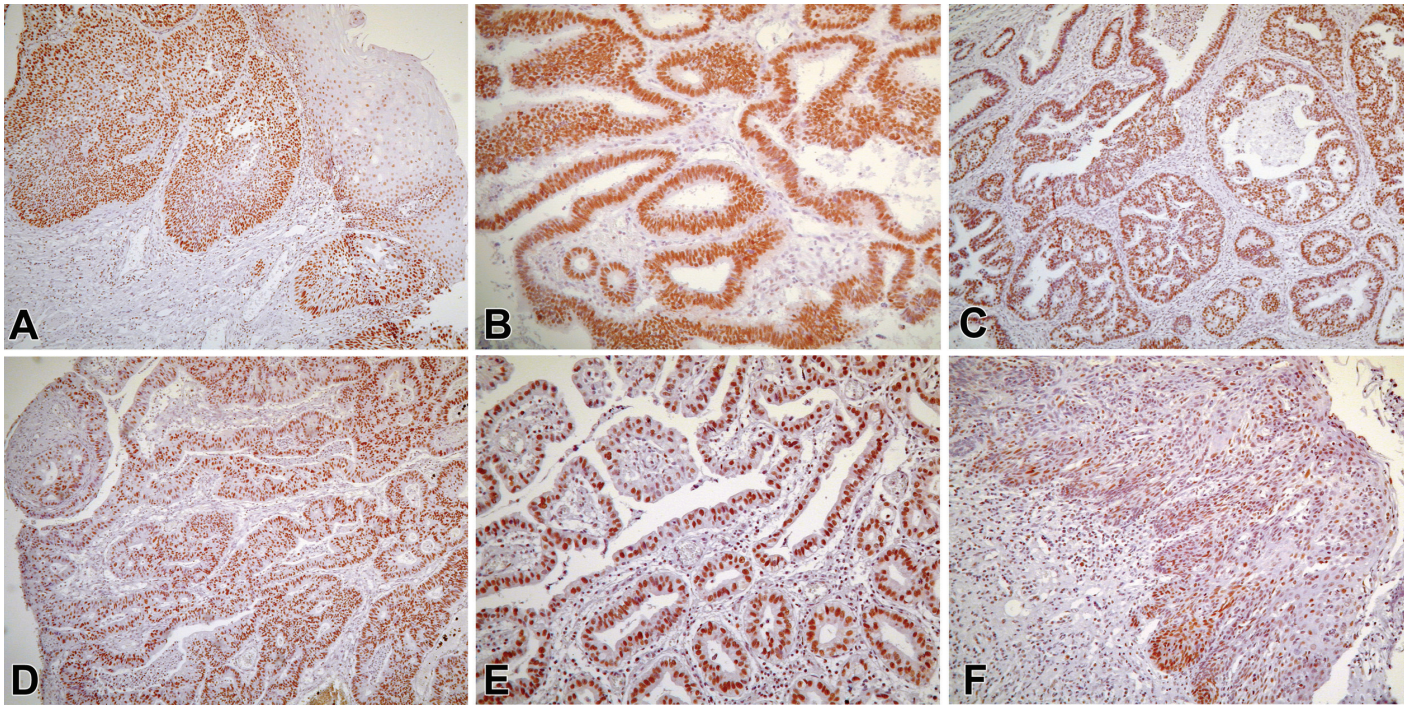

Figure 11.3 CHEK2 protein expression. Non-mutated squamous cell carcinoma in A, non-mutated adenocarcinoma in B. Remaining samples are from the 4 mutated tumors: adenocarcinomas T1, T2 and T3 shown in C, D, E, squamous cell carcinoma T4 shown in F. Magnification 100 x B, E 50 x A, C, D, F. Note: the strong nuclear CHEK2 immunoreactivity in the tumor cells.

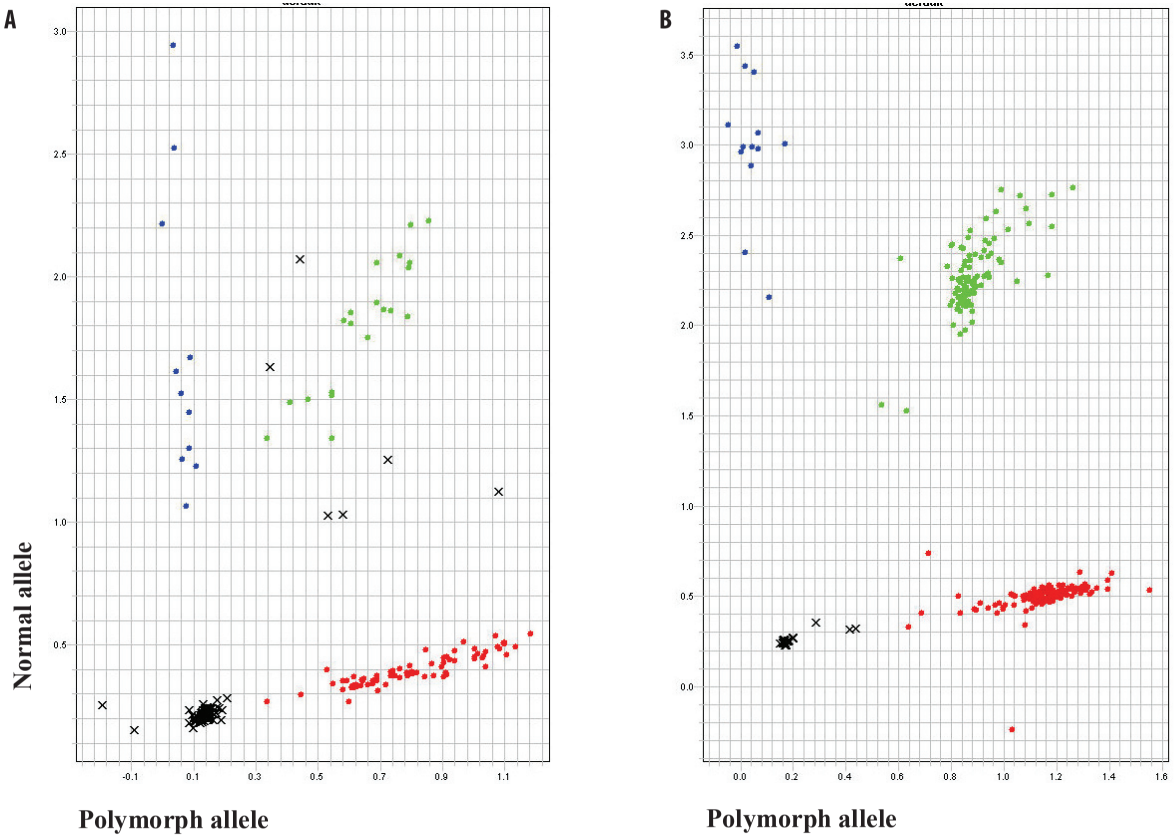

Figure 12.1. Taqman allelic discrimination assay concerning p73 exon 2 G4C14-A4T14 of 191 GEJ adenocarcinomas (A.) and 232 controls (B.). Distribution of homozygous normal (blue dots), heterozygous (green dots) and homozygous polymorphism (red dots).

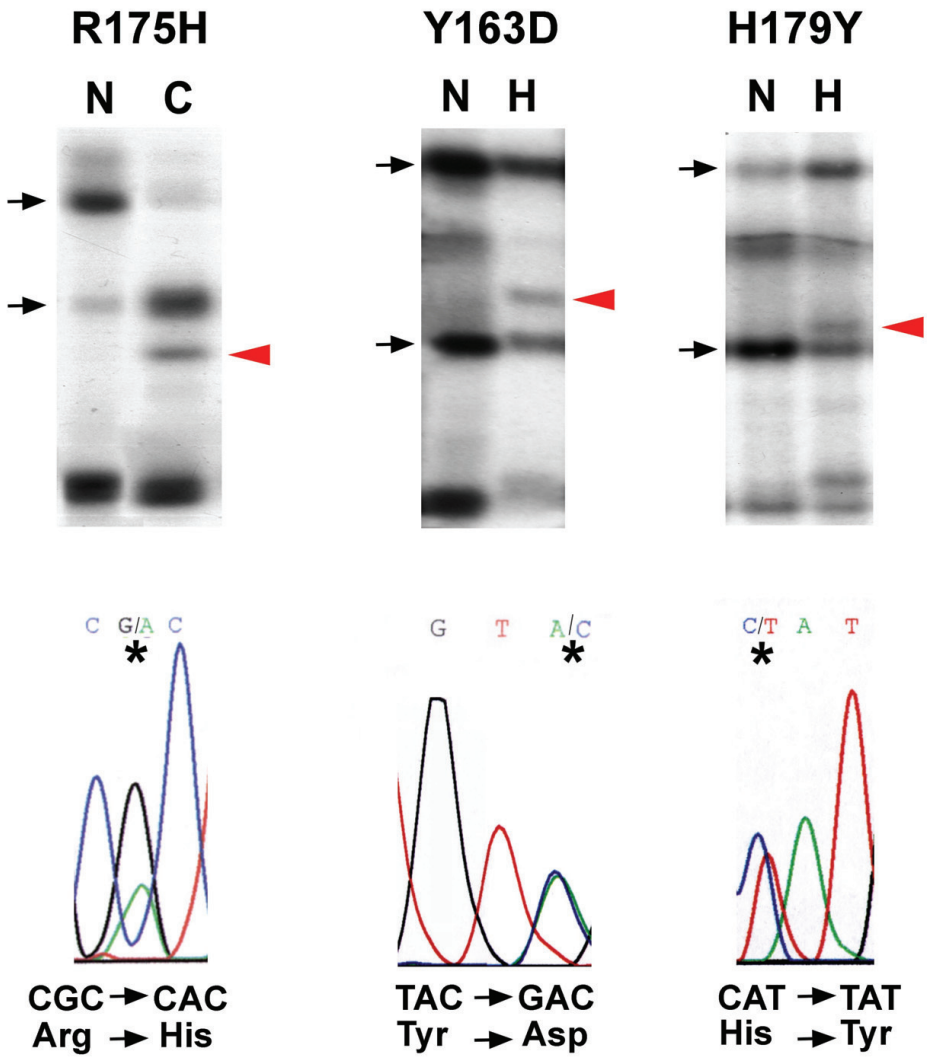

Figure 13.4 PCR-SSCP and sequencing analyses of three p53 mutations in High grade dysplasia (H), Carcinoma (C) and corresponding normal DNA (N). Black arrows point to allelic patterns. Red arrow heads point to mutated alleles. The sequencing chromatograms below each autoradiograph show the alterations (note the substituted nucleotide marked by an asterisk), which all represent p53 mutations.

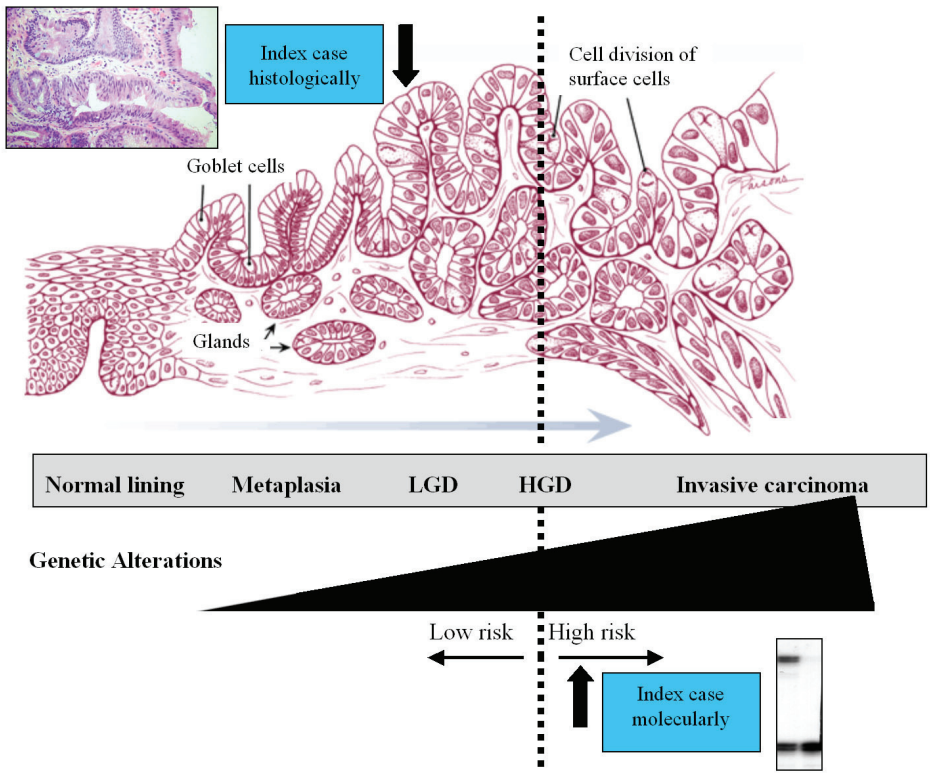

Figure 15.1 Metaplasia-Dysplasia-Carcinoma sequence. Index case is histologically at low risk for neoplastic progression, however genetic alterations are indicative for high risk profile.
