## H I G H L I G H T S

- Integrated reduction reactions and sorption processes for $\mathrm{Cr}(\mathrm{VI})$ removal.
- $\mathrm{Cr}(\mathrm{VI})$ is reduced to $\mathrm{Cr}(\mathrm{III})$ by contact with electron-donor groups of biomass.
- The reduced $\mathrm{Cr}(\mathrm{III})$ remains in the aqueous phase or bound to the biomass.
- The oxidized biomass presents a higher number of carboxylic groups.
- Solution pH enhances the reduction reaction but inhibits the adsorption process.

#### Abstract

The main goal of this work was the valorization of seaweed Laminaria digitata, after acid pre-treatment, for the remediation of hexavalent chromium solutions. $\mathrm{The} \mathrm{Cr}(\mathrm{VI})$ removal efficiency by the protonated biomass was studied as a function of different parameters, such as contact time, pH , biomass and $\mathrm{Cr}(\mathrm{VI})$ concentration, and temperature. $\mathrm{Cr}(\mathrm{VI})$ removal is based on a complex mechanism that includes a reduction of $\mathrm{Cr}(\mathrm{VI})$ to $\mathrm{Cr}(\mathrm{III})$, through the oxidation of biomass at acidic medium, and further chemical binding of $\mathrm{Cr}(\mathrm{III})$ to the negatively charged binding groups, mainly carboxylic groups. The optimum pH for chromium removal, using protonated $L$. digitata algae, was 2.5. The maximum amount of $\mathrm{Cr}(\mathrm{VI})$ reduction by the algae was around $2.1 \mathrm{mmol} / \mathrm{g}$. The uptake capacity of $\mathrm{Cr}(\mathrm{III})$ by the oxidized biomass, after $\mathrm{Cr}(\mathrm{VI})$ reduction, was higher than by the algae in its original form (protonated algae). Results suggest that the oxidation of the biomass during $\mathrm{Cr}(\mathrm{VI})$ reduction, turns other active sites available for $\mathrm{Cr}(\mathrm{III})$ binding. Also, the $\mathrm{Cr}(\mathrm{III})$ binding from a solution of reduced $\mathrm{Cr}(\mathrm{VI})$ was much lower than from a pure $\mathrm{Cr}(\mathrm{III})$ solution. The result suggests the presence in solution of Cr (III) complexes with the organic matter released from the algae surface during $\mathrm{Cr}(\mathrm{VI})$ reduction. The activation energy obtained for the $\mathrm{Cr}(\mathrm{VI})$ reduction by $L$. digitata was $45 \pm 20 \mathrm{~kJ} \mathrm{~mol}^{-1}$. A kinetic model based on the redox reaction between $\mathrm{Cr}(\mathrm{VI})$ species and organic compounds from the biosorbent surface was able to fit well the hexavalent chromium concentration. Trivalent chromium equilibrium biosorption was well described at different chromium concentrations, considering the interaction between carboxylic groups present in the surface of the biomass and $\mathrm{Cr}(\mathrm{III})$ in solution.

| $T$ | solution temperature ( K ) |
| $X_{\text {OXI }}$ | fraction of organic compound oxidized |
| $\theta_{T, H}$ | total degree of protonation |

## 1. Introduction

Chromium can exist in eleven valence states ranging from -IV to +VI , however, only $\mathrm{Cr}(\mathrm{III})$ and $\mathrm{Cr}(\mathrm{VI})$ are sufficiently stable to occur in the natural environment [1]. $\mathrm{Cr}(\mathrm{III})$ is usually found bound to organic matter in soil and in aquatic environments and $\mathrm{Cr}(\mathrm{VI})$ is usually associate with oxygen, such as oxyanions chromate $\left(\mathrm{CrO}_{4}^{2-}\right)$ and dichromate $\left(\mathrm{Cr}_{2} \mathrm{O}_{7}^{2-}\right)$ [2]. These two divalent oxyanions are very water soluble and poorly adsorbed by soil and organic matter, making them mobile in soil and groundwater. Both chromate anions represent acute and chronic risks to animals and human health, since they are extremely toxic, mutagenic, carcinogenic, and teratogenic [3]. $\mathrm{Cr}(\mathrm{VI})$ oxyanions are readily reduced to trivalent forms, which are comparatively less toxic, when they come into contact with electron donors that are present in organic matter, or with reduced inorganic species present in soil, water and the atmosphere [4]. Most of the $\mathrm{Cr}(\mathrm{VI})$ found in the nature is the result of domestic and industrial emissions [5]. The nature and behavior of the various forms of chromium found in natural waters can be quite different from those found in wastewater, due to the variety of physical-chemical natures of the effluents discharged from various industrial sources. The presence and concentration of chromium in wastewaters is mainly dependent on the form of the chromium applied in industrial processes, the pH and the amount of organic and/or inorganic residues. $\mathrm{Cr}(\mathrm{VI})$ is present predominantly in wastewater effluents from heavy industrial processes, such as those derived from the metallurgical, metal finishing (hard chromium plating) and refractory industries and from the production and application of pigments (chromate color and corrosion inhibitors pigments) [4]. Chemical methods can be used for the treatment of $\mathrm{Cr}(\mathrm{VI})$ containing wastewaters, involving aqueous reduction of $\mathrm{Cr}(\mathrm{VI})$ to $\mathrm{Cr}(\mathrm{III})$, at acidic pH values, using various chemical reagents with subsequent pH adjustment (neutral pH values) leading to $\mathrm{Cr}(\mathrm{III})$ precipitation. However, these methods are considered undesirable due to the use of expensive and toxic reagents, low removal efficiency for low chromium concentrations and the production of large amounts of chemical waste [6]. Wastewaters that contains relatively low $\mathrm{Cr}(\mathrm{VI})$ concentrations are usually treated with ion exchange resins. This procedure offers the advantage of recovering chromic acid, however, it is an expensive technique due to the high cost of the resin [7]. In this scenario, the biosorption process, using low cost materials, appears to be a highly effective and economical alternative for the removal of $\mathrm{Cr}(\mathrm{VI})$ from wastewater [8]. It has been reported that $\mathrm{Cr}(\mathrm{VI})$ can be reduced to $\mathrm{Cr}(\mathrm{III})$ in aqueous solutions using different solid biomaterials, especially at acidic conditions [9-12]. Gardea-Torresdey
et al. [13] reported that $\mathrm{Cr}(\mathrm{VI})$ was easily reduced to $\mathrm{Cr}(\mathrm{III})$ using oat processing byproduct, and subsequently adsorbed by the available negatively charged carboxylic groups. During $\mathrm{Cr}(\mathrm{VI})$ reduction, a fraction of the organic carbon from the biosorbent, was completely oxidized into inorganic carbon, in the form of $\mathrm{HCO}_{3}^{-}$and $\mathrm{CO}_{2}$. The oxidation of the biomass supplies the electrons necessary for the $\mathrm{Cr}(\mathrm{VI})$ reduction reaction. For the $\mathrm{Cr}(\mathrm{VI})$ reduction to $\mathrm{Cr}(\mathrm{III})$, not only electrons, but also protons are necessary, meaning that the reaction rate depends on the solution pH , decreasing with the increment of pH . Sawalha et al. [14] studied the effect of pH on chromium binding employing native, esterified, and hydrolyzed saltbush (Atriplex canescens) biomass. X-ray absorption spectroscopy results showed that $\mathrm{Cr}(\mathrm{VI})$ was reduced in some extent to Cr (III) by the saltbush biomass at both pH 2.0 and pH 5.0 . Park et al. [15] reported the removal of $\mathrm{Cr}(\mathrm{VI})$ employing sixteen biomaterials and using XPS analysis to verify the oxidation state of the Cr bound to the biomaterials. Although, the chromium bound to the surface of these biomaterials was mostly or totally in the trivalent form in the final pH range of $2.17-2.50$, the reduction reaction of $\mathrm{Cr}(\mathrm{VI})$ to $\mathrm{Cr}(\mathrm{III})$ also occurred on the surface of the biomaterials.

Laminaria digitata is a large brown algae, found normally at the sub littoral zone of the northern Atlantic Ocean, reaching up to 4 m length, which was traditionally used as fertilizer and for the extraction of iodine [16]. Nowadays it has been used for the extraction of alginic acid, the manufacture of toothpastes and cosmetics, and in the food industry for binding, thickening and moulding [17,18]. In Portugal, big amounts of $L$. digitata can be found in the beaches, threaten the tourist industry by spoiling pristine environments. Turning macro-algae $L$. digitata into a resource for biosorption processes can be quite beneficial to some local economies.

The main objective of this work was to study the mechanism of hexavalent chromium removal in aqueous solutions using brown macro-algae L. digitata. The efficiency of the process was evaluated at different operational conditions, such as hexavalent chromium concentration, solution pH and temperature and biomass concentration. A kinetic model based on integrated reduction/oxidation reactions and sorption processes on the surface of the biomass was used to describe the behavior of hexavalent, trivalent and total chromium concentration in the aqueous and solid phase.

## 2. Mathematical models

### 2.1. Quantification of functional groups

Since the algal surface is polyfunctional, each site of each functional group reacts with protons with different affinities. The
distribution of affinity defines the chemical heterogeneity of the active sites present at the surface of the biomass. The total degree of protonation, $\theta_{T, H}$, can be obtained from the Langmuir-Freundlich isotherms. Assuming a quasi-Gaussian distribution, the affinity constant suggested by Sips [19] can be described by Eq. (1):
$\theta_{T, H}=\frac{\left(K_{H}^{\prime} C_{H}\right)^{m_{H}}}{1+\left(K_{H}^{\prime} C_{H}\right)^{m_{H}}}$
where $K_{H}^{\prime}$ is the average of the affinity distribution of hydrogen ions, which determines the position of the affinity distributions along the axis $\log K_{i, H}^{\mathrm{int}}$ ( $K_{i, H}^{\mathrm{int}}$ is the intrinsic proton affinity constant at each binding site $i$ ), $C_{H}$ is the proton concentration in the solution and $m_{H}$ is related to the width of the Sips distribution, which can have values between 0 and 1 , representing an infinite width and a null width, respectively. It should be noted that the parameter $m_{H}$ is a measure of the overall heterogeneity, which includes the chemical heterogeneity. If the distribution of affinity displays more than one peak, then the charge of the acid surface, $Q_{H}$, is expressed as a weighted sum of the charge contributions of each active site:
$Q_{H}=\sum_{j} Q_{\max , j}\left(1-\left(\theta_{T, H}\right)_{j}\right)$

Assuming the presence of two different types of ligands, carboxyl ( $j=1$ ) and hydroxyl ( $j=2$ ), the equation of the continuous model [20,21] is obtained:
$Q_{H}=\frac{Q_{\max , 1}}{1+\left(K_{1, H}^{\prime} C_{H}\right)^{m_{H, 1}}}+\frac{Q_{\max , 2}}{1+\left(K_{2, H}^{\prime} C_{H}\right)^{m_{H, 2}}}$
where $Q_{\max , 1}$ and $Q_{\max , 2}$ are the maximum concentrations of carboxyl and hydroxyl groups, respectively.

The mathematical model was fitted to the experimental data using the Excel Solver (Quasi-Newton algorithm). In order to determine the errors associated with the parameters ( $K_{1, H}^{\prime}, K_{2, H}^{\prime}, Q_{\text {max, } 1}$, $Q_{\text {max }, 2}, m_{H, 1}, m_{H, 2}$ ), the matrix inversion approach [22] was used.

### 2.2. Kinetic modeling of $\operatorname{Cr}(V I)$ reduction

A good knowledge of hexavalent chromium speciation in solution is necessary to understand the chromium removal by integrated oxidation/reduction reactions and sorption processes. $\mathrm{Cr}(\mathrm{VI})$ exists in different ionic forms $\left(\mathrm{H}_{2} \mathrm{CrO}_{4}, \mathrm{HCrO}_{4}^{-}, \mathrm{CrO}_{4}^{2-}\right.$, $\mathrm{Cr}_{2} \mathrm{O}_{7}^{2-}$ and $\mathrm{HCr}_{2} \mathrm{O}_{7}^{-}$), depending on the solution pH and chromium concentration. Considering the pH working range and chromium concentration used in this work, two $\mathrm{Cr}(\mathrm{VI})$ speciation diagrams were constructed (Fig. A - Supplementary data file), for $\mathrm{Cr}(\mathrm{VI})$ concentrations of 0.2 mM and $6.0 \mathrm{mM}\left(T=25^{\circ} \mathrm{C}\right.$; Ionic strength $\left.=0 \mathrm{M}\right)$ [23]. For the lowest chromium concentration ( 0.2 mM ), and $1.0<\mathrm{pH}<4.0, \mathrm{HCrO}_{4}^{-}$anion is the predominant species, with a molar fraction above $92 \%\left(0<\left[\mathrm{H}_{2} \mathrm{CrO}_{4}\right]<7.6 \%\right)$. However, for higher total $\mathrm{Cr}(\mathrm{VI})$ concentrations, the molar fraction of $\mathrm{HCrO}_{4}^{-}$anion decreases and the molar fraction of $\mathrm{Cr}_{2} \mathrm{O}_{7}^{2-}$ anion increases. For a total $\mathrm{Cr}(\mathrm{VI})$ concentration of 6 mM , in the range of working pHs values (1-4) used in this work, the molar fractions for $\mathrm{HCrO}_{4}^{-}$, and $\mathrm{Cr}_{2} \mathrm{O}_{7}^{2-}$ anions are between $79-85 \%$ and $13-15 \%$, respectively ( $0<\left[\mathrm{H}_{2} \mathrm{CrO}_{4}\right]<6.5 \%$ ).

Hexavalent chromium species are also strong oxidants, which have the tendency to be reduced to trivalent chromium species, according to the following reactions ( $E^{\circ}$-standard potentials; $T=25^{\circ} \mathrm{C}$ ) [24], which is greatly influenced by the solution pH .
$\mathrm{Cr}_{2} \mathrm{O}_{7}^{2-}+14 \mathrm{H}^{+}+6 \mathrm{e}^{-} \leftrightarrow 2 \mathrm{Cr}^{3+}+7 \mathrm{H}_{2} \mathrm{O} \quad E^{\circ}=+1.33 \mathrm{~V}$
$\mathrm{HCr}_{2} \mathrm{O}_{7}^{-}+13 \mathrm{H}^{+}+6 \mathrm{e}^{-} \leftrightarrow 2 \mathrm{Cr}^{3+}+7 \mathrm{H}_{2} \mathrm{O} \quad E^{\circ}=+1.33 \mathrm{~V}$

$$
\begin{array}{ll}
\mathrm{CrO}_{4}^{2-}+8 \mathrm{H}^{+}+3 \mathrm{e}^{-} \leftrightarrow \mathrm{Cr}^{3+}+4 \mathrm{H}_{2} \mathrm{O} & E^{\circ}=+1.48 \mathrm{~V} \\
\mathrm{HCrO}_{4}^{-}+7 \mathrm{H}^{+}+3 \mathrm{e}^{-} \leftrightarrow \mathrm{Cr}^{3+}+4 \mathrm{H}_{2} \mathrm{O} & E^{\circ}=+1.35 \mathrm{~V} \\
\mathrm{H}_{2} \mathrm{CrO}_{4}+6 \mathrm{H}^{+}+3 \mathrm{e}^{-} \leftrightarrow \mathrm{Cr}^{3+}+4 \mathrm{H}_{2} \mathrm{O} & E^{\circ}=+1.33 \mathrm{~V} \tag{8}
\end{array}
$$

Depending on the type of hexavalent chromium species present in solution, different number of electrons and protons are requested to achieve total reduction to trivalent chromium. Increasing the total chromium concentration, the molar fraction of $\mathrm{Cr}_{2} \mathrm{O}_{7}^{2-}$ species increases, leading to a substantially increment in the number of electrons and protons necessary for the reduction process.

Park et al. [25-29] proposed a direct and/or indirect mechanism for $\mathrm{Cr}(\mathrm{VI})$ elimination by seaweed and fungal biomasses: (a) direct reduction mechanism, by which $\mathrm{Cr}(\mathrm{VI})$ is directly reduced to $\mathrm{Cr}(\mathrm{III})$ in the aqueous phase by contact with electron-donor groups of the biomass, and the reduced $\mathrm{Cr}(\mathrm{III})$ remains in the aqueous phase or bound to the negatively charged groups; and (b) indirect reduction mechanism that consists of three steps: (i) the binding of anionic $\mathrm{Cr}(\mathrm{VI})$ species to positively-charged groups present on the surface of the biomass, (ii) the reduction of $\mathrm{Cr}(\mathrm{VI})$ into $\mathrm{Cr}(\mathrm{III})$ by adjacent electron-donor groups and (iii) the release of Cr (III)-reduced ions into aqueous phase due to electrostatic repulsion between posi-tively-charged groups and $\mathrm{Cr}(\mathrm{III})$, or the reduced $-\mathrm{Cr}(\mathrm{III})$ complexation with adjacent negatively charged groups.

Considering that $L$. digitata presents mainly carboxylic (alginic acid) and sulfonic groups (fucoidan) [17,30], the binding of anionic $\mathrm{Cr}(\mathrm{VI})$ can be only possible at very low pH values, where the functional groups are completely protonated and can be positively charged. Low pH values increase the reduction reaction since the attraction of $\mathrm{Cr}(\mathrm{VI})$ species to the surface of the biomass is enhanced and protons are also available for the reduction reaction. Biomaterials are also electron-donors, mainly due to the oxidation of thiol and phenolic groups, as reported by several authors [31,32]. The cationic $\operatorname{Cr}(\mathrm{III})$ ions in the aqueous phase can bind to the negatively charged carboxylic and sulfonic groups. Low pH values favors the $\mathrm{Cr}(\mathrm{VI})$ reduction kinetics but decreases the total chromium removal, since functional groups are protonated or positively charged and protons compete with $\mathrm{Cr}(\mathrm{III})$ ions to the same binding sites.

Considering the aspects reported above, a kinetic model, as proposed by Park et al. [33,34], for the $\mathrm{Cr}(\mathrm{VI})$ reduction using biomaterials, was used to describe the $\mathrm{Cr}(\mathrm{VI})$ removal by L. digitata seaweed based on the redox reaction between $\operatorname{Cr}(\mathrm{VI})$ and the biomaterial:

Biomass $+\mathrm{Cr}(\mathrm{VI}) \xrightarrow{k}$ Biomass (oxidized) $+\mathrm{Cr}(\mathrm{III})$

The following assumptions are considered: (i) organic compounds in the biosorbent are responsible for reducing $\mathrm{Cr}(\mathrm{VI})$, (ii) only one kind of organic compound ( OC ) is capable of reducing $\mathrm{Cr}(\mathrm{VI})$, (iii) the equation rate for the $\mathrm{Cr}(\mathrm{VI})$ reduction is first-order (Eq. (9)) with respect to both the $\mathrm{Cr}(\mathrm{VI})$ concentration and the concentration of OC capable of reducing $\mathrm{Cr}(\mathrm{VI})$, (iv) no significant biomass loss during the oxidation process and (v) $1: 1$ stoichiometric ratio between $\mathrm{Cr}(\mathrm{VI})$ and $\mathrm{Cr}(\mathrm{III})$, considering that the predominant hexavalent chromium species in solution are hydrogen chromate $\left(\mathrm{HCrO}_{4}^{-}\right)$and chromic acid $\left(\mathrm{H}_{2} \mathrm{CrO}_{4}\right)\left(\mathrm{Cr}_{2} \mathrm{O}_{7}^{2-}\right.$ is below $\left.15 \%\right)$. When the pH and temperature are constant the rate of $\mathrm{Cr}(\mathrm{VI})$ reduction by an organic compound can be found as:
$\frac{d[\mathrm{Cr}(\mathrm{VI})]}{\mathrm{dt}}=-k[\mathrm{OC}][\mathrm{Cr}(\mathrm{VI})]$
where [OC] represents the equivalent organic compound concentration at time $t$ capable of reducing $\mathrm{Cr}(\mathrm{VI})\left(\mathrm{mmol} \mathrm{L}^{-1}\right),[\mathrm{Cr}(\mathrm{VI})]$ is the hexavalent chromium concentration ( $\mathrm{mmol} \mathrm{L}^{-1}$ ) at time $t$ and $k$ its rate coefficient ( $\mathrm{L} \mathrm{mmol}^{-1} \mathrm{~s}^{-1}$ ).

Considering that electron-donors groups are oxidized during $\mathrm{Cr}(\mathrm{VI})$ reduction, which was confirmed by the release of organic carbon during the oxidation process (increment of dissolved organic carbon in solution), the equivalent organic compound concentration in the surface of the biomass decreases during the reaction and can be calculated as:
$[\mathrm{OC}]_{t}=C_{\mathrm{oC}}^{*}[B]\left(1-\frac{[\mathrm{Cr}(\mathrm{VI})]_{0}-[\mathrm{Cr}(\mathrm{VI})]_{t}}{C_{\mathrm{oc}}^{*}[B]}\right)$
where $[B]$ is the biomaterial concentration $\left(\mathrm{g} \mathrm{L}^{-1}\right),[\mathrm{Cr}(\mathrm{VI})]_{0}$ is the initial hexavalent chromium concentration ( $\mathrm{mmol} \mathrm{L}^{-1}$ ), $C_{\mathrm{oc}}^{*}$ is the concentration of equivalent organic compound per unit gram of biomaterial $\left(\mathrm{mmolg}^{-1}\right.$ ), i.e., the $C_{\mathrm{OC}}^{*}$ value for Laminaria is $2.1 \mathrm{mmol} \mathrm{g}^{-1}$, obtained by the biomass limited experiment. The product, $C_{\mathrm{OC}}^{*}[B]$, represents the initial concentration of OC and $\left([\mathrm{Cr}(\mathrm{VI})]_{0}-[\mathrm{Cr}(\mathrm{VI})]_{t}\right) /\left(C_{\mathrm{OC}}^{*}[B]\right)$ represents the fraction of OC oxidized ( $X_{\text {OXI }}$ ).

Substituting Eqs. (11) in (10), and integrating, results in:
$[\mathrm{Cr}(\mathrm{VI})]_{t}=\frac{C_{\mathrm{OC}}^{*}[B][\mathrm{Cr}(\mathrm{VI})]_{0}-[\mathrm{Cr}(\mathrm{VI})]_{0}^{2}}{\mathrm{C}_{\mathrm{oc}}^{*}[B] \exp \left\{k\left(C_{\mathrm{Oc}}^{*}[B]-[\mathrm{Cr}(\mathrm{VI})]_{0}\right) t\right\}-[\mathrm{Cr}(\mathrm{VI})]_{0}}$
where $k$ and $C_{\mathrm{oc}}^{*}$ are the model constant parameters and $t$ is the variable time ( $s$ ).

The mathematical model was fitted to the experimental data obtained from kinetic studies using the Excel Solver (Quasi-Newton algorithm). The errors associated with the parameters were determined using the matrix inversion approach [22].

## 2.3. $\operatorname{Cr}($ III ) biosorption

### 2.3.1. Equilibrium

In aqueous solutions, within the pH range used in this work ( $<4$ ), $\mathrm{Cr}^{3+}$ and $\mathrm{CrOH}^{2+}$ are the most abundant species, present in equal amounts at pH 3.55 [35]. In addition, the biosorption of trivalent chromium is qualitatively shown to involve a process of cationic exchange between chromium ions ( $\mathrm{Cr}^{3+}$ and/or $\mathrm{CrOH}^{2+}$ ) and the protons of the carboxylic groups of the biomass [36]. The biosorption of metal cations can be explained by the complexation with the negative charged groups present in the surface of the biomass. Considering the monovalent carboxylic groups (B) responsible for chromium binding, and initially saturated with hydrogen ions, and for a pH value of 2.5 , optimum pH for total chromium removal, $\mathrm{Cr}^{3+}$ represents $92 \%$ of the total trivalent chromium species [37], the binary complexation system can be described by the following reactions:
$\mathrm{Cr}_{(a q)}^{3+}+3 B_{(s)}^{-} \stackrel{K_{\mathrm{cr}}{ }^{3+}}{\leftrightarrows} 3 B \mathrm{Cr}_{1 / 3(s)}, K_{\mathrm{Cr}^{3+}}=\frac{\left[\mathrm{BCr}_{1 / 3}\right]^{3}}{\left[\mathrm{Cr}^{3+}\right]\left[\mathrm{B}^{-}\right]^{3}}\left(\frac{\mathrm{~L}}{\mathrm{~mol}}\right)$
$H_{(a q)}^{+}+B_{(s)}^{-} \stackrel{K_{H}}{\leftrightarrow} B H_{(s)}, K_{H}=\frac{[B H]}{\left[H^{+}\right]\left[B^{-}\right]}\left(\frac{\mathrm{L}}{\mathrm{mol}}\right)$
where $K_{H}$ and $K_{C^{3+}}$ are the equilibrium binding constants of $\mathrm{H}^{+}$and $\mathrm{Cr}^{3+}$ to the binding site $\left(\mathrm{L} \mathrm{mol}^{-1}\right)$, respectively, $\left[\mathrm{H}^{+}\right]$and $\left[\mathrm{Cr}^{3+}\right]$ are the equilibrium concentrations of $\mathrm{H}^{+}$and $\mathrm{Cr}^{3+}$ in the liquid phase, [ $B^{-}$] the number of free binding sites per unit mass of biomass ( $\mathrm{mmol} \mathrm{g}^{-1}$ ), $[\mathrm{BH}]$ and $\left[B C r_{1 / 3}\right]$ are the equilibrium concentrations of $\mathrm{H}^{+}$and $\mathrm{Cr}^{3+}$ in the solid phase ( $\mathrm{mmol} \mathrm{g}{ }^{-1}$ ), respectively.

Here, the metal-ligand binding sites were considered as $B C r_{1 / 3}$ instead of $B_{3} C r$, respectively, to emphasize that three bonds have to be broken in competitive binding or upon desorption of the metal, as formulated by [38].

When the biomass reacts with the metal in solution, the ligand sites become occupied by $\mathrm{Cr}^{3+}$ and $\mathrm{H}^{+}$or remain free. Therefore, the mass balance for the sites can be described as:
$[B]_{T}=\left[B^{-}\right]+[B H]+\left[B C r_{1 / 3}\right]$
where $[B]_{T}$ is the total number of binding sites $B$ per unit mass of biomass ( $\mathrm{mmol} \mathrm{g}^{-1}$ ). Substituting Eqs. (13) and (14) in (15), the concentration of free sites can be expressed as:

$$
\begin{equation*}
\left[B^{-}\right]=\frac{[B]_{T}}{1+K_{H}\left[H^{+}\right]+\sqrt{K_{C r^{3}}\left[\mathrm{Cr}^{3+}\right]}} \tag{16}
\end{equation*}
$$

The amount of chromium adsorbed $\left(q_{C r^{3+}}=\left[B C r_{1 / 3}\right] / 3\right)$ can be calculated combining Eqs. (13) and (16), which gives:
$q_{C r^{3+}}=\frac{\left([B]_{T} / 3\right) \sqrt[3]{K_{C r^{3+}}\left[\mathrm{Cr}^{3+}\right]}}{1+K_{H}\left[H^{+}\right]+\sqrt[3]{K_{C r^{3+}}\left[\mathrm{Cr}^{3+}\right]}}$
Considering that during the hexavalent chromium reduction, and consequently oxidation of the biomass, the number of negatively groups available for the trivalent chromium binding increases, Eq. (17) was rewritten as follows:
$q_{C^{3+}}=\frac{\left\{[B]_{T}\left(1+f X_{\text {OXI }}\right) / 3\right\} \sqrt[3]{K_{C r^{3+}}\left[\mathrm{Cr}^{3+}\right]}}{1+K_{H}\left[H^{+}\right]+\sqrt[3]{K_{\mathrm{Cr}^{3+}}\left[\mathrm{Cr}^{3+}\right]}}$
where $[B]_{T} \times f \times X_{O X I}$ represents the fraction of sites generated during the biomass oxidation. The experimental data obtained from equilibrium studies were fitted to the mathematical model using the Excel Solver (Quasi-Newton algorithm). In order to determine the errors associated with the parameters, the matrix inverse approach [22] has been used.

### 2.3.2. Kinetics

In order to determine the trivalent chromium concentration in the liquid and solid phase at a certain time, a mass balance to the total chromium can be made, since the sum of chromium present in aqueous solution and on the biomass is always constant:
$[\mathrm{Cr}(\mathrm{VI})]_{0}=[\mathrm{Cr}(\mathrm{VI})]_{t}+[\mathrm{Cr}(\mathrm{III})]_{t}+q_{\mathrm{Cr}^{3}}[B]$
Considering that the limit step of the integrated process is the hexavalent chromium reduction, and trivalent chromium sorption is instantaneous at the surface of the biomass (reduced $\mathrm{Cr}(\mathrm{III})$ remains in equilibrium state between the biomass and aqueous solution), for a certain time, the trivalent chromium concentration present in the aqueous solution, $[\mathrm{Cr}(\mathrm{III})]_{t}$, can be obtained solving the mass balance combining Eqs. (12), (18), and (19). The amount of trivalent chromium in the solid phase can be calculated by substituting the trivalent chromium concentration at each time, $[\mathrm{Cr}(\mathrm{III})]_{t}$, in Eq. (18).

## 3. Material and methods

### 3.1. Biosorbent preparation

L. digitata seaweed biomass was collected at the Northern coast of Portugal, washed with tap water, sun-dried and cut into pieces of $0.5-1 \mathrm{~cm}$ length. The protonated biomass was prepared by washing $10 \mathrm{~g} \mathrm{~L}^{-1}$ of biomass with $0.2 \mathrm{M} \mathrm{HNO}_{3}$ in 2 cycles of 3 h each. The acid treatment is necessary to convert the insoluble alginate salts present in the cell walls into alginic acid [18]. This procedure was carried out using a 5-L capacity glass vessel and a mechanical shaker (VWR VOS 14) provided with a Teflon paddle.

The acid treated biomass was washed several times with distilled water until it reached pH 4.0 and then dried in an oven (Binder, WT ) at $45^{\circ} \mathrm{C}$ for 24 h . The material treated with the acid solution is referred to herein as the protonated algae.

### 3.2. Reactants

The chromium solutions were prepared from the salt $\mathrm{K}_{2} \mathrm{CrO}_{4}$ (Fluka). Solutions of diphenylcarbazide (Merck), NaOH and $\mathrm{HNO}_{3}$ were also used.

### 3.3. Analytical determinations

The total chromium concentration in aqueous solution was determined by atomic absorption spectrometry (AAS, GBC 932 Plus) with a nitrous oxide-acetylene flame, a spectral slit width of 0.2 nm , and working current/wavelength of $6.0 \mathrm{~mA} / 357.9 \mathrm{~nm}$, giving a detection limit of $0.08 \mathrm{mg} \mathrm{L}^{-1}$. The hexavalent chromium concentration was measured by molecular absorption spectrophotometry (UNICAM - HE $10 S$ spectrophotometer). The procedure followed is based on the formation of a pink complex of $\mathrm{Cr}(\mathrm{VI})$ with 1,5-diphenylcarbazide in acid solution which absorbs at 540 nm [39]. The trivalent chromium was determined by the difference between the measurements of total and hexavalent chromium.

Dissolved organic carbon (DOC) content was determined in a TC-TOC-TN analyzer equipped with an ASI-V autosampler (Shimadzu, model TOC-V $\mathrm{V}_{\mathrm{CSN}}$ ) and provided with a NDIR detector, calibrated with standard solutions of potassium hydrogen phthalate (total carbon) and a mixture of sodium hydrogen carbonate/carbonate (inorganic carbon). The total organic carbon of the solid samples was obtained using the same TC-TOC-TN analyzer coupled with a solid sample combustion unit (SSM-5000A).

To determine the amount of chromium present in the protonated and chromium loaded biomass, the samples were digested at $140^{\circ} \mathrm{C}$ during 2 h (G. Vittadini RECOD/6 Test), adding 5 mL distilled water, $12 \mathrm{~mL} \mathrm{HCl}(37 \%)$ and $4 \mathrm{~mL} \mathrm{HNO}_{3}$ ( $65 \%$ ) to 0.5 g of sample. After cooling, the metal concentration in the solution was determined by AAS after filtration through cellulose acetate membrane filters (Ref. Albet-CA-045-25-BI).

### 3.4. Fourier transform infrared (FTIR) analysis

The identification of the functional groups on the surface of the biosorbent was performed by infrared spectroscopy. The algal samples were ground and dried at $45^{\circ} \mathrm{C}$ for 24 h and analyzed by infrared spectrometry (Shimadzu FTIR IRAffinity with an EasiDiff diffuse reflectance accessory, Pike Technologies) in the solid form. Spectra were registered from 4000 to $400 \mathrm{~cm}^{-1}$.

### 3.5. Potentiometric titration

The potentiometric titration was performed using an automatic titration system (Metrohm, 702 SM Titrino) and a shaker module (Metrohm, 728 stirrer). The pH electrode was calibrated with buffer solutions of $\mathrm{pH} 1.00,4.01,7.00$ and 9.00 . For each titration, 0.25 g of protonated algal biomass was added to 50 mL of a $0.1 \mathrm{~mol} \mathrm{~L}^{-1} \mathrm{NaCl}$ solution and this suspension was then placed in a titration thermostatic cell at $25^{\circ} \mathrm{C}$. First of all, the suspension was acidified to $\mathrm{pH} 2.4-2.6$ by adding a specific volume of $0.1 \mathrm{~mol} \mathrm{~L}^{-1} \mathrm{HCl}$ solution and bubbled for 30 min with nitrogen gas to remove dissolved $\mathrm{CO}_{2}$ from the solution. Afterwards, the titration was performed with stepwise addition of 0.02 mL of a $0.1 \mathrm{~mol} \mathrm{~L}^{-1} \mathrm{NaOH}$ solution (Titrisol, Merck) to the cell until pH 10, while the suspension was stirred under nitrogen atmosphere. When the drift between each addition was less than
$0.5 \mathrm{mV} \mathrm{min}^{-1}$ or there was a 30 min break between each NaOH addition, it was considered that equilibrium had been reached. The data on the base volume added and the pH were continuously recorded.

## 3.6. $\operatorname{Cr}($ VI $)$ reduction kinetics

$\mathrm{Cr}(\mathrm{VI})$ reduction kinetic study was conducted in a 1000 mL glass reactor containing 800 mL of the metal solution, equipped with a cooling jacket to ensure a constant temperature during the experiments. Experiments were done at different solution $\mathrm{pH}(1.0,1.5$, $2.0,2.5,3.0,3.5$ and $4.0 ;[\mathrm{Cr}(\mathrm{VI})]=0.2 \mathrm{mM} ; 4 \mathrm{~g}$ biomass $\mathrm{L}^{-1}$; $T=20^{\circ} \mathrm{C}$ ), different initial $\mathrm{Cr}(\mathrm{VI})$ concentrations ( 0.2 ; 1.1 and $6.2 \mathrm{mM} ; \mathrm{pH}=2.5 ; 4 \mathrm{~g}$ biomass $\mathrm{L}^{-1} ; T=20^{\circ} \mathrm{C}$ ), different biomass concentrations ( $0.5,1.0,2.0,4.0$ and $6.0 \mathrm{~g} \mathrm{~L}^{-1} ;[\mathrm{Cr}(\mathrm{VI})]=0.2 \mathrm{mM}$; $\mathrm{pH}=2.5 ; T=20^{\circ} \mathrm{C}$ ), and different temperatures (10, 20, 30 and $40^{\circ} \mathrm{C} ;[\mathrm{Cr}(\mathrm{VI})]=0.2 \mathrm{mM} ; \mathrm{pH}=2.5 ; 4 \mathrm{~g}$ biomass $\left.\mathrm{L}^{-1}\right)$. The suspensions were mechanically stirred at 150 rpm (VWR VOS). The pH was adjusted using $\mathrm{HNO}_{3}$ solution since there was an increase in pH . The mass balance to the protons concentration includes: (i) proton consumption during the $\mathrm{Cr}(\mathrm{VI})$ reduction, according to reactions 5-9; (ii) proton release from biomass during $\operatorname{Cr}(\mathrm{III})$ binding via proton $-\mathrm{Cr}(\mathrm{III})$ ion exchange (since the biomass used has been protonated initially, the negatively charged groups responsible by Cr (III) binding are initially protonated); (iii) consumption of protons for the chromium hydrolysis reaction; and (iv) protonation of the binding sites generated during the biomass oxidation. Samples were collected at predetermined time intervals and filtered through cellulose acetate membrane filters (Sartorius Stedim).

To quantify the maximum $\mathrm{Cr}(\mathrm{VI})$ reducing capacity of $L$. digitata, a high concentration of $\mathrm{Cr}(\mathrm{VI}), 4.1 \mathrm{mM}$, was put into contact with a small amount ( $1.0 \mathrm{~g} / \mathrm{L}$ ) of biomass (biomass limiting experiment) under acid conditions ( $\mathrm{pH}=2.5$ ) and $T=20^{\circ} \mathrm{C}$. The suspension was maintained under constant agitation of 150 rpm in a shaker (VWR Advanced Digital Shaker) during 4 weeks, until achieve a constant $\mathrm{Cr}(\mathrm{VI})$ concentration, different from zero. To evaluated the influence of the presence of $\mathrm{Cr}(\mathrm{III})$ in $\mathrm{Cr}(\mathrm{VI})$ reduction kinetics, experiments with a solution of 1.8 mM of $\mathrm{Cr}(\mathrm{VI})$ concentration without and with 4.8 mM of $\mathrm{Cr}(\mathrm{III})$ concentration were performed (conditions: $V=250 \mathrm{~mL}, \mathrm{pH} 2.5$ and biomass concentration of $4 \mathrm{~g} \mathrm{~L}^{-1}$ ). To obtain a $\mathrm{Cr}(\mathrm{III})$ solution coming from the reduction process, a $\mathrm{Cr}(\mathrm{VI})$ reduction kinetic at high concentration ( 6.2 mM ) was carried out until total $\mathrm{Cr}(\mathrm{VI})$ reduction. The obtained $\mathrm{Cr}(\mathrm{III})$ solution with 1.2 mM was used for the adsorption kinetic at pH 4.0 using $2.0 \mathrm{~g} \mathrm{~L}^{-1}$ of fresh protonated biomass.

## 4. Results and discussion

### 4.1. FTIR analysis

The FTIR spectra for the protonated biomass before and after oxidation in the presence of hexavalent chromium solution $\left([\mathrm{Cr}(\mathrm{VI})]_{0}=6.2 \mathrm{mM},[B]=4 \mathrm{~g} \mathrm{~L}^{-1}\right.$, contact time $=143 \mathrm{~h}, \mathrm{pH}=2.5$, $X_{O X I}=0.74 ;[\mathrm{Cr}(\mathrm{VI})]_{0}=5.3 \mathrm{mM},[B]=4 \mathrm{~g} \mathrm{~L}^{-1}$, contact time $=47 \mathrm{~h}$, $\mathrm{pH}=1.0, X_{O X I}=0.63$ ) and, trivalent chromium loaded biomass $\left([\mathrm{Cr}(\mathrm{III})]_{0}=1.2 \mathrm{mM},[B]=2 \mathrm{~g} \mathrm{~L}^{-1}\right.$, contact time $=120 \mathrm{~h}, \mathrm{pH}=4.0$, $\left(q_{C^{3+}}=0.4 \mathrm{mmol} \mathrm{g}^{-1}\right)$, using the chromium solution after complete reduction of $\mathrm{Cr}(\mathrm{VI})$ to $\mathrm{Cr}(\mathrm{III})$ and protonated biomass without suffering any oxidation in a $\mathrm{Cr}(\mathrm{VI})$ solution, were used to determine the vibration frequency changes in the functional groups of the biosorbent (Fig. 1).

The region of $3400 \mathrm{~cm}^{-1}$ can be related to $\mathrm{O}-\mathrm{H}$ and $\mathrm{N}-\mathrm{H}$ stretching indicating the presence of hydroxyl and amino groups [40]. The peak at $2929 \mathrm{~cm}^{-1}$ represents the $\mathrm{C}-\mathrm{H}$ stretching.

Changes in the peaks of the spectra are visible at wavenumbers below $1740 \mathrm{~cm}^{-1}$ (Fig. 1b). The peak at $1740 \mathrm{~cm}^{-1}$ decreases considerably for the biomass after $\mathrm{Cr}(\mathrm{VI})$ reduction at pH 2.5 and disappears for the $\mathrm{Cr}(\mathrm{III})$ loaded biomass. This suggests that there is interaction between $\mathrm{Cr}(\mathrm{III})$ produced from the reduction of $\mathrm{Cr}(\mathrm{VI})$ and the group which adsorbs in this region, i.e., carboxyl group [41]. For the reduction experiment at $\mathrm{pH}=1$, the amount of $\mathrm{Cr}($ III $)$ sorbed in the carboxyl group is low and no modification in the FTIR spectra is observed. The peak at $1532 \mathrm{~cm}^{-1}$, attributed to $\mathrm{N}-\mathrm{H}$ groups [40], is suppressed for the biomass after $\mathrm{Cr}(\mathrm{VI})$ reduction at pH 2.5 and $\mathrm{Cr}(\mathrm{III})$ loaded biomass, indicating interaction of the metal with this group. The peak at around $1440 \mathrm{~cm}^{-1}$, attributed to $\mathrm{C}=\mathrm{O}$ symmetric stretching [41], is shifter to a shorter wavelength, for the $\mathrm{Cr}(\mathrm{III})$ loaded algae. $\mathrm{Cr}(\mathrm{VI})$ is a powerful oxidizing agent, which can oxidize primary and secondary alcohols to the corresponding ketones, and carboxylic acids and other compounds with "benzyl" hydrogen to benzoic acids, while $\mathrm{Cr}(\mathrm{VI})$ is reduced to $\mathrm{Cr}(\mathrm{III})$ [32]. For the reduction at pH 1.0 there is an increase in the peak at $1743 \mathrm{~cm}^{-1}$. The biomass after $\mathrm{Cr}(\mathrm{VI})$ reduction was dried and it was observed a decolorization resulting from the biomass

Fig. 1. (a) Fourier transform infrared spectra of different algae samples; (b) high resolution graph: 1 - protonated biomass, 2 - protonated biomass after $\mathrm{Cr}(\mathrm{VI})$ reduction at $\mathrm{pH} 1.0\left(X_{\text {OXI }}=0.63 ;[\mathrm{Cr}(\mathrm{VI})]_{0}=5.3 \mathrm{mM} ;[\mathrm{Cr}(\mathrm{VI})]_{\text {final }}=0.003 \mathrm{mM}\right.$; $q_{\mathrm{Cr}^{3+}}=0.14 \mathrm{mmol} \mathrm{g}^{-1} ; 3$ - protonated biomass after $\mathrm{Cr}(\mathrm{VI})$ reduction at pH 2.5 $\left(X_{\text {OXI }}=0.74 ;[\mathrm{Cr}(\mathrm{VI})]_{0}=6.2 \mathrm{mM} ;[\mathrm{Cr}(\mathrm{VI})]_{\mathrm{final}}=0.02 \mathrm{mM} ; q_{\mathrm{Cr}^{3+}}=1.2 \mathrm{mmol}^{-1}\right) ; 4-$ $\mathrm{Cr}(\mathrm{III})$-loaded biomass (fresh protonated biomass was equilibrated with a $\mathrm{Cr}(\mathrm{III})$ solution $\left([\mathrm{Cr}(\mathrm{III})]_{0}=1.2 \mathrm{mmol} \mathrm{L}^{-1}\right)$ at $\mathrm{pH}=4.0$ obtained by reduction of a $\mathrm{Cr}(\mathrm{VI})$ solution, $\left.q_{\mathrm{Cr}^{3+}}=0.4 \mathrm{mmol} \mathrm{g}^{-1}\right)$.
oxidation. This indicates that the algae pigments are the main electron-donors groups responsible by the reduction of hexavalent to trivalent chromium.

### 4.2. Potentiometric titration

To examine the number of negatively functional groups responsible for trivalent chromium binding, a potentiometric titration of the protonated biomass before and after oxidation in the presence of an hexavalent chromium solution $\left([\mathrm{Cr}(\mathrm{VI})]_{0}=6.2 \mathrm{mM}\right.$, $[B]=4 \mathrm{~g} \mathrm{~L}^{-1}, \quad$ contact $\quad$ time $=143 \mathrm{~h}, \quad \mathrm{pH}=2.5, \quad X_{\text {OXI }}=0.74$, $q_{\mathrm{Cr}^{3+}}=1.2 \mathrm{mmol} \mathrm{g}{ }^{-1}$ ) was performed (Fig. 2). Fig. 2 shows that the continuous model fits well the experimental data, where two peaks can be observed, and according to the $p K_{i, H}^{\prime}$ values can be associated to carboxylic and hydroxyl groups [36]. Fig. 2 also shows the distribution function $F=\sum_{i} f_{i}\left(\log K_{i, H}^{\text {int }}\right) Q_{\text {max }, i}$ versus $\log K_{i, H}^{\text {int }}$ where $f_{i}\left(\log K_{i, H}^{\text {int }}\right)$ represents the Sips distribution function for the carboxylic and hydroxyl groups with total charges $Q_{\text {max, } 1}$ and $Q_{m a x, 2}$, respectively [36]. Alginate, mannitol, laminaram and cellulose are the main constituents of the cell wall of brown seaweed Laminaria, which contains many carboxyl and hydroxyl groups [42].

Table 1 shows that for $L$. digitata the carboxylic groups are more abundant than the hydroxyl ones ( $Q_{\max , 1}=2.06 \pm 0.01 \mathrm{mmol} \mathrm{g}^{-1}$ and $Q_{\max , 2}=1.4 \pm 0.7 \mathrm{mmol} \mathrm{g}^{-1}$, respectively). Through the heterogeneity distribution parameter $m_{H, i}$, low $m_{H, i}$ values correspond to a wider distribution and also a greater heterogeneity of the groups, it can be observed that the hydroxyl groups are more heterogeneous than carboxylic groups. A high increase of carboxylic groups ( $0.91 \mathrm{mmol} \mathrm{g}^{-1}$ ) was obtained for the oxidized biomass after $\mathrm{Cr}(\mathrm{VI})$ reduction. Considering that the amount of trivalent chromium sorbed on the oxidized biomass, $q_{C_{r}{ }^{3+}}$, is $1.2 \mathrm{mmol} \mathrm{g}^{-1}$ (assuming as negligible the loss of biomass during the biomass oxidation), the number of carboxylic groups generated during the oxidation process is $\sim 4.5 \mathrm{mmol}$ per gram of biomass (total binding groups of $6.57 \mathrm{mmol} \mathrm{g}^{-1}$ for $X_{O X I}=0.74$, assuming that each mmol of $\mathrm{Cr}^{3+}$ occupies three mmol of carboxylic groups). Similar results were obtained by Dupont and Guillon [31] who studied the removal of $\mathrm{Cr}(\mathrm{VI})$ by a lignocellulosic substrate extracted from wheat bran. They reported that the oxidation of lignin moieties occurred concomitantly with the $\mathrm{Cr}(\mathrm{VI})$ reduction and led to the formation of carboxyl and hydroxyl groups.

### 4.3. Kinetic modeling of $\mathrm{Cr}(\mathrm{VI})$ reduction to $\mathrm{Cr}(\mathrm{III})$

### 4.3.1. Influence of pH

Fig. 3a shows that the kinetic model, presented in Section 2.2, is able to fit well the $\mathrm{Cr}(\mathrm{VI})$ reduction for all the pH values tested. Fig. 3a also confirms the important role played by solution pH in $\mathrm{Cr}(\mathrm{VI})$ reduction, in which strongly acidic conditions favor the reduction rates (Table 2). Although $\mathrm{Cr}(\mathrm{VI})$ reduction is observed in the all range of pH tested, the reaction rate at $\mathrm{pH}=1.0$ is more than 100 times higher than at pH 4.0 , since protons are needed for the reduction of hexavalent chromium to trivalent chromium, according to Eqs. (4)-(8). At pH 1.0, only 8 h are required for complete $\mathrm{Cr}(\mathrm{VI})$ removal considering the detection limit of the analytical method ( $<10 \mu \mathrm{~L} \mathrm{~L}^{-1}$ ).

Park et al. [33] also demonstrated that the reaction rate constant is strongly pH dependent, and that a linear correlation exists between the reaction rate logarithm and the pH value, according to Eq. (20):
$k=f\left(\left[H^{+}\right]\right)=a\left[H^{+}\right]^{n}, \quad \log k=\log a-n \times p H$
where $n$ is the order of the reaction with respect to proton concentration and $a$ is an empirical constant. Eq. (20) fits well to experimental data (Fig. B - Supplementary data file), yielding $n$ and $a$ values of $0.72 \pm 0.08$ and $400 \pm 200 \mathrm{~L}^{n+1} \mathrm{~mol}^{-(n+1)} \mathrm{h}^{-1}$, respectively. This indicates that the hexavalent chromium reduction reaction is approximately a first order reaction with respect to protons concentration ( $n \sim 1$ ). Park et al. [33] obtained the same value, $n=0.714$, for the $\mathrm{Cr}(\mathrm{VI})$ reduction using the brown seaweed Ecklonia $s p$.

Fig. 3b shows that $\mathrm{Cr}(\mathrm{VI})$ concentration decreases with time and is completely removed, below the detection limit, from the aqueous phase, after 52 h at $\mathrm{pH}=2.5$. In other hand, $\mathrm{Cr}(\mathrm{III})$, which was not initially present neither in the aqueous solution or in solid phase (biomaterial), appears in the aqueous phase and its concentration increases until all $\mathrm{Cr}(\mathrm{VI})$ is removed. However, this increase is not proportional to the $\mathrm{Cr}(\mathrm{VI})$ disappearance, as part of the $\mathrm{Cr}(\mathrm{III})$ sorbs onto the surface of the biosorbent. This indicates that $\mathrm{Cr}(\mathrm{VI})$ was directly reduced to Cr (III) in the aqueous phase by contact with electron-donor groups of the biomass, and the reduced Cr (III) established an equilibrium between the liquid and solid phase, in which Cr (III) binds to the negatively charged groups present in the surface of the biomaterial. Park et al. [15] showed that chromium bound on fifteen biomaterials (Sargassum, Ecklonia, pine bark, pine cone, banana skin, pine needle, walnut shell, rice straw, Rhizopus, etc.) was mostly or totally in trivalent form, for an initial pH of 2.2, using high-resolution XPS technique.

A significant amount of dissolved organic matter was released into the system, confirmed by the DOC analysis in the aqueous solution, mainly due to the biomass oxidation during $\mathrm{Cr}(\mathrm{VI})$ reduction. At the end of the $\mathrm{Cr}(\mathrm{VI})$ reduction reactions DOC values of $232.6 \mathrm{mg} \mathrm{L}^{-1}$ (reaction time $=143 \mathrm{~h},[\mathrm{Cr}(\mathrm{VI})]_{0}=321 \mathrm{mg} \mathrm{L}^{-1}$, $\left.[\mathrm{Cr}(\mathrm{VI})]_{\text {final }}=1.2 \mathrm{mg} \mathrm{L}^{-1}, X_{\text {OXI }}=0.74, T=25^{\circ} \mathrm{C},[B]=4 \mathrm{~g} \mathrm{~L}^{-1}\right)$ and $345 \mathrm{mg} \mathrm{L}^{-1} \quad$ (reaction time $=47 \mathrm{~h}, \quad[\mathrm{Cr}(\mathrm{VI})]_{0}=278 \mathrm{mg} \mathrm{L}^{-1}$, $[\mathrm{Cr}(\mathrm{VI})]_{\text {final }}=0.029 \mathrm{mg} \mathrm{L}^{-1}, X_{\text {OXI }}=0.63, T=25^{\circ} \mathrm{C},[B]=4 \mathrm{~g} \mathrm{~L}^{-1}$ ) were achieved for the experiments performed at pH 2.5 and 1.0 , respectively. Turbidity in the solution was observed after longer contact
times, $>120 \mathrm{~h}$, and principally for $\mathrm{pH}>3.0$, associated to the release of organic compounds from the biomass by oxidation and dissolution of some algae extracts [43]. Table 3 summarizes the values for the volatile matter, TOC and Cr present in the solid matter after $\mathrm{Cr}(\mathrm{VI})$ reduction at pH 2.5 and 1.0 with an initial $\mathrm{Cr}(\mathrm{VI})$ concentration of 6.2 mM and 5.3 mM , respectively ( $T=20^{\circ} \mathrm{C},[B]=4 \mathrm{~g} \mathrm{~L}^{-1}$ ) and compares with the values for the protonated algae. This shows that even for the most severe conditions ( pH 1.0 ) the oxidation process does not achieve significant mineralization of biomass organic matter. The algae sample, oxidized at pH 2.5 , showed a high percentage of ash ( $9.8 \%$ ) when compared with the protonated algae ( $0.5 \%$ ) [37], which can be attributed to the high level of chromium adsorbed during the reduction process. After the reduction at pH 1.0, the algae had low ash content (1.9\%) due to the small amount of chromium adsorbed at this pH value. The results presented for Cr adsorbed at pH 2.5 and 1.0 are slightly lower than those obtained from the material balance in the reactor during the kinetic studies ( $66.4 \mathrm{mg} \mathrm{g}^{-1}$ and $5.5 \mathrm{mg} \mathrm{g}^{-1}$, respectively), suggesting a partial loss of chromium during the biomass digestion procedure.

In the biomass limited experiment $\left([\mathrm{Cr}(\mathrm{VI})]_{0}=4.2 \mathrm{mmol} \mathrm{L}^{-1}\right.$, $[\mathrm{Cr}(\mathrm{VI})]_{\mathrm{final}}=1.9 \mathrm{mmol} \mathrm{L}^{-1}, \quad[B]=1.1 \mathrm{~g} \mathrm{~L}^{-1}, \quad T=20^{\circ} \mathrm{C}, \quad$ contact time $=42$ days), 1 g of the biomass was able to reduce 2.1 mmol of $\mathrm{Cr}(\mathrm{VI})(109.2 \mathrm{mg})$ at pH 2.5 . Considering that at pH 2.5 , and in the range of hexavalent chromium concentrations used, the molar fractions of $\mathrm{HCrO}_{4}^{-}, \mathrm{CrO}_{7}^{2-}$ and $\mathrm{H}_{2} \mathrm{CrO}_{4}$ are $84.5 \%, 15.2 \%$ and $0.2 \%$, respectively, and since 3,6 and 3 mmol of electrons are required for the reduction of 1 mmol of $\mathrm{Cr}(\mathrm{VI})$ to $\mathrm{Cr}(\mathrm{III})$, respectively for $\mathrm{HCrO}_{4}^{-}, \mathrm{CrO}_{7}^{2-}$ and $\mathrm{H}_{2} \mathrm{CrO}_{4}$ species, it can be suggested that 1 g of biomass has 7.25 mmol of available electrons. Considering that, in theory, 1 g of $\mathrm{FeSO}_{4} \cdot 7 \mathrm{H}_{2} \mathrm{O}$ can reduce 62.4 mg of $\mathrm{Cr}(\mathrm{VI})$ ( 1.2 mmol ), the $\mathrm{Cr}(\mathrm{VI})$-reducing capacity of algae $L$. digitata is almost two times higher than that of the common chemical $\mathrm{Cr}(\mathrm{VI})-$ reductant. Table 4 compares the reducing capacities for different biomaterials tested, and it can be seen that algae $L$. digitata shows to be an interesting biomaterial for these kinds of applications.

Although the $\mathrm{Cr}(\mathrm{VI})$ reduction rates increases sharply with the decrease of solution pH , the removal of total chromium has an optimum pH value for a fixed contact time, as it can be observed in Fig. 3c. The removal efficiency of total chromium was calculated from the mass balance for total Cr in the aqueous phase. Fig. 3c shows that the optimum pH for total Cr removal increases with the contact time until pH 3.0. This observation can be attributed to three main factors: (i) at a high $\mathrm{pH}, \mathrm{Cr}(\mathrm{VI})$ reduction rate is very slow, and can be considered the rate limiting step mainly due to the protons limitation, and as the contact time increases, $\mathrm{Cr}(\mathrm{VI})$ can be completely reduced to $\mathrm{Cr}(\mathrm{III})$, which is then bound to the negatively charged functional groups present on the surface of the biomaterial; (ii) increasing the solution pH , sorption of $\mathrm{Cr}(\mathrm{III})$ is favored since more deprotonated negatively charged groups are available and the competition between protons and trivalent chromium ions for actives sites decreases, (iii) at pH above 3.0 the protons in solution are not sufficient for the reduction reaction to occur, during the reaction period tested, and low amount of trivalent chromium are generated, decreasing the total Cr removal efficiency. Park et al. [6] also observed the same phenomenon for $\mathrm{Cr}(\mathrm{VI})$ removal using the brown seaweed Ecklonia, obtaining an

Fig. 3. (a) Evolution of $\mathrm{Cr}(\mathrm{VI})$ concentration as a function of time at various pH values: $(\boldsymbol{\square})-\mathrm{pH}=1.0,(\bigcirc)-\mathrm{pH}=1.5,(\boldsymbol{\Delta})-\mathrm{pH}=2.0,(\nabla)-\mathrm{pH}=2.5,(\star)-\mathrm{pH}=3.0$, $(\star)-\mathrm{pH}=3.5,(\varangle)-\mathrm{pH}=4.0$; Symbols: experimental data; Line: predicted data. (b) Evolution of $\mathrm{Cr}(\mathrm{VI}), \mathrm{Cr}(\mathrm{III})$ and total Cr concentrations and trivalent chromium uptake over time at controlled $\mathrm{pH}(2.5):(\hat{\alpha}): \mathrm{pH} ;(\square, \square): C_{\mathrm{Cr}(\mathrm{VI)})} ;(\triangle, \Delta): C_{\mathrm{Cr}(\mathrm{III})} ;(\bigcirc$, ○): $C_{\mathrm{Cr}(\text { total })} ;(\nabla, \nabla): q_{\mathrm{Cr}(I I I)} ;$ Conditions: $[\mathrm{Cr}(\mathrm{VI})]_{0}=0.2 \mathrm{mmol}^{-1},[B]=4 \mathrm{~g} \mathrm{~L}^{-1}$, $T=20^{\circ} \mathrm{C}$; Open symbols: experimental data; Closed symbols: predicted data. (c) Optimum pH for the removal efficiency of total Cr according to the reaction time; Symbols: (■) - $4 \mathrm{~h},(\boldsymbol{(})-9 \mathrm{~h},(\boldsymbol{\Delta})-24 \mathrm{~h},(\star)-32 \mathrm{~h},(\nabla)-48 \mathrm{~h},(\boldsymbol{(})-120 \mathrm{~h}$; Conditions: $[\mathrm{Cr}(\mathrm{VI})]_{0}=0.2 \mathrm{mmol} \mathrm{L}^{-1},[B]=4 \mathrm{~g} \mathrm{~L}^{-1}, T=20^{\circ} \mathrm{C}$.
optimum pH value according to the reaction time. For reaction times of 48 h and 480 h , the optimum pH value was 3.0 and 4.0 , respectively.

### 4.3.2. Effect of initial $\operatorname{Cr}(V I)$ concentration

Fig. 4a shows that higher initial $\mathrm{Cr}(\mathrm{VI})$ concentrations requires longer contact times, ranging from 40 to 140 h , respectively for the lowest and highest initial $\mathrm{Cr}(\mathrm{VI})$ concentrations tested, to achieve final $\mathrm{Cr}(\mathrm{VI})$ concentrations below the analytical detection limit ( $<10 \mu \mathrm{~g} \mathrm{~L}^{-1}$ ). However, the initial $\mathrm{Cr}(\mathrm{VI})$ concentration, considering the concentration range between 0.2 and 6.2 mM , had little influence on the $\mathrm{Cr}(\mathrm{VI})$ removal rate (Table 2), and the obtained results shows that $\mathrm{Cr}(\mathrm{VI})$ reduction is a first-order reaction with respect to the $\mathrm{Cr}(\mathrm{VI})$ concentration. On the other hand, considering that the biomaterial has a limited number of organic compounds with capacity to reduce $\mathrm{Cr}(\mathrm{VI})$, which means a limited number of electrons for $\mathrm{Cr}(\mathrm{VI})$ doses higher than 2.1 mmol per gram of biomaterial, insufficient electrons will be available for total $\mathrm{Cr}(\mathrm{VI})$ conversion into Cr (III).

Higher initial $\mathrm{Cr}(\mathrm{VI})$ concentrations results in higher $\mathrm{Cr}(\mathrm{III})$ concentrations released to the solution, leading to higher amounts of Cr (III) accumulated in the biomaterial. Considering that the sorption rate of the reduced $\mathrm{Cr}(\mathrm{III})$ might be faster than the reduction rate of $\mathrm{Cr}(\mathrm{VI})$ for pH values above 2.0 , as observed in a previous work using pure solutions of Cr (III) [36], where the equilibrium is achieved after 10 h , it can be assumed that the reduced $\mathrm{Cr}(\mathrm{III})$ remains in equilibrium between the liquid and solid phase. Fig. 5 shows the $\mathrm{Cr}(\mathrm{III})$ equilibrium data points obtained during $\mathrm{Cr}(\mathrm{VI})$ reduction (the biomass is oxidized during the $\mathrm{Cr}(\mathrm{VI})$ reduction to $\mathrm{Cr}(\mathrm{III})$ ) (experimental and model prediction using Eq. (18)) and using pure $\mathrm{Cr}(\mathrm{III})$ solutions (in contact with fresh protonated biomass). Considering the equilibrium data obtained at pH 2.5 , the uptake capacity of $\mathrm{Cr}(\mathrm{III})$ is four times higher for the reduced $\mathrm{Cr}(\mathrm{III})$ solution (the oxidation of the biomass during $\mathrm{Cr}(\mathrm{VI})$ reduction was $73 \%$ ), than for pure Cr (III) solutions. These results are in agreement with the potentiometric titration data, where it was concluded an increment of carboxylic groups during the oxidation of the biomass.

Fig. 4b shows that the kinetic model, considering integrated reduction reactions and sorption processes is able to fit well the concentration profiles of $\mathrm{Cr}(\mathrm{VI}), \mathrm{Cr}(\mathrm{III})$, total Cr and trivalent chromium uptake over time. The pH was not modeled, since pH was controlled during the reaction.

### 4.3.3. Effect of biomass concentration

Fig. 6 shows the $\mathrm{Cr}(\mathrm{VI})$ reduction kinetics using different biomass concentration in the range of $0.5-6.0 \mathrm{~g} \mathrm{~L}^{-1}$, for an initial $\mathrm{Cr}(\mathrm{VI})$ concentration of $0.2 \mathrm{mM}, \mathrm{pH}$ controlled at 2.5 and a temperature of $20^{\circ} \mathrm{C}$. The kinetic model fits well the $\mathrm{Cr}(\mathrm{VI})$ reduction kinetics for all tested biomass concentrations. Although $\mathrm{Cr}(\mathrm{VI})$ removal rates increases with increasing biosorbent dose, since more electrons are available for the reduction reaction, for biomass concentrations higher than $4 \mathrm{~g} \mathrm{~L}^{-1}$, the reaction rate decreases slightly mainly associated to high density of solids that difficult the interaction of $\mathrm{Cr}(\mathrm{VI})$ anions with the biomass surface. For lower biomass doses, the limiting reaction step is the availability of electrons. Although total chromium removal is similar ( $\sim 81 \%$ ) for all biomass concentrations tested, lower reaction times are necessary when using higher biomass doses.

### 4.3.4. Temperature effect

Fig. 7 shows the temperature dependency of $\mathrm{Cr}(\mathrm{VI})$ reduction reaction, in the range of $10-40^{\circ} \mathrm{C}$, at a fixed pH value and biomass concentration of 2.5 and $4 \mathrm{~g} \mathrm{~L}^{-1}$, respectively. $\mathrm{The} \mathrm{Cr}(\mathrm{VI})$ reduction reaction was greatly dependent on the solution temperature, leading to a substantial reduction of contact time, necessary to

achieve complete removal of $\mathrm{Cr}(\mathrm{VI})$ below the detection limit of the analytical method, as the solution temperature increases. This can be mainly attributed to two main factors: (i) the increase of the solution reduction potential with temperature [44]; (ii) the increase of diffusion rate of ions from the bulk solution to the surface of biosorbent with temperature [45].

The kinetic model was able to fit well the experimental data at different temperatures, showing an increase of the kinetic rate constant of about five times from $20^{\circ} \mathrm{C}$ to $40^{\circ} \mathrm{C}$ (Table 2). The percentage of total Cr removal was similar for all kinetics performed at different temperatures ( $\sim 80 \%$ ), which means that the increase in temperature does not enhance the adsorption capacity (in all experiments almost complete reduction of $\mathrm{Cr}(\mathrm{VI})$ to $\mathrm{Cr}(\mathrm{III})$ was achieved, meaning that the same concentration of trivalent chromium was equilibrated with the biomass).

The influence of the temperature on the reaction rate can be expressed mathematically by the Arrhenius equation [46]:
$k=A e^{-\frac{E a}{K l}}$ or $\ln k=\ln A-\frac{E_{a}}{R} \frac{1}{T}$
where $A, E_{a}, R, T$ and $k$ are the frequency factor, activation energy ( $\mathrm{J} \mathrm{mol}^{-1}$ ), gas constant ( $8.314 \mathrm{~J} \mathrm{~mol}^{-1} \mathrm{~K}^{-1}$ ), temperature in Kelvin
(K) and kinetic constant ( $\mathrm{L} \mathrm{mol}^{-1} \mathrm{~h}^{-1}$ ), respectively. The activation energy obtained for the removal of $\mathrm{Cr}(\mathrm{VI})$ by $L$. digitata was $45 \pm 20 \mathrm{~kJ} \mathrm{~mol}^{-1}$ (Fig. C - Supplementary data file). The value for $\ln A\left(\mathrm{~L} \mathrm{~mol}^{-1} \mathrm{~h}^{-1}\right)$ was $20 \pm 8$. The values obtained were in the same order of magnitude as those reported by Park et al. [34] in the $\mathrm{Cr}(\mathrm{VI})$ removal using the biomaterial pine needle.

### 4.4. Total chromium concentration modeling

Total and trivalent concentration profiles can be only predicted if trivalent chromium equilibrium is known. Considering that carboxylic groups are the main responsible for $\mathrm{Cr}(\mathrm{III})$ binding, and that during the hexavalent chromium reduction, and consequently oxidation of the biomass, the number of negatively groups available for the trivalent chromium binding increases, the equilibrium model proposed is described by Eq. (18). Although the equilibrium equation fits well the experimental data obtained at different $\mathrm{Cr}(\mathrm{III})$ equilibrium concentrations ( $\mathrm{pH}=2.5$ ) (Fig. 5) and at different biomass concentrations (data not presented), the model overestimated the $\mathrm{Cr}(\mathrm{III})$ uptake capacity at pH values higher than 2.5. This can be attributed to the fact, that in those situations, the equilibrium time $(\mathrm{Cr}(\mathrm{VI})$ reaction time) was not sufficient to reach the $\mathrm{Cr}(\mathrm{III})$ equilibrium between the solid and liquid phase. The estimated model equilibrium parameters for trivalent chromium biosorption are shown in Table 5. The $p K_{H}$ and $p K_{C r}$ values are lower than those obtained for the $\mathrm{Cr}(\mathrm{III})$ biosorption using pure $\mathrm{Cr}(\mathrm{III})$ solutions [36], which indicates that protons and $\mathrm{Cr}(\mathrm{III})$ ions may be complexed with the organic matter released during $\mathrm{Cr}(\mathrm{VI})$ reduction and the overall affinity of the organic-metal complex to the binding groups decreases. The same conclusions were obtained from the experiment, in which an amount of protonated biomass was in contact with a $\mathrm{Cr}(\mathrm{III})$ solution obtained from $\mathrm{Cr}(\mathrm{VI})$ solution, and the uptake capacity of Cr (III) was lower than that observed

Fig. 4. (a) Evolution of $\mathrm{Cr}(\mathrm{VI})$ concentration as a function of time at various $[\mathrm{Cr}(\mathrm{VI})]_{0}:(\boldsymbol{\square})-[\mathrm{Cr}(\mathrm{VI})]_{0}=0.21 \mathrm{mmol} \mathrm{L}^{-1},(\mathbf{(})-[\mathrm{Cr}(\mathrm{VI})]_{0}=0.98 \mathrm{mmol} \mathrm{L}^{-1}$, (○) $-[\mathrm{Cr}(\mathrm{VI})]_{0}=6.19 \mathrm{mmol} \mathrm{L}^{-1}$; Conditions: $[\mathrm{Cr}(\mathrm{VI})]_{0}=0.2 \mathrm{mmol} \mathrm{L}^{-1},[B]=4 \mathrm{~g} \mathrm{~L}^{-1}$, $T=20^{\circ} \mathrm{C}$; Symbols: experimental data; Line: predicted data. (b) Evolution of $\mathrm{Cr}(\mathrm{VI})$, $\mathrm{Cr}($ III ) and total Cr concentrations and trivalent chromium uptake capacity over time at controlled $\mathrm{pH}(2.5):(\hat{\wedge}): \mathrm{pH}$; ( $\square, \square): C_{\mathrm{Cr}(\mathrm{VI})} ;(\triangle, \Delta): C_{\mathrm{Cr}(\mathrm{III})} ;(\bigcirc, \bigcirc): C_{\mathrm{Cr}(\text { total })}$; $(\nabla, \nabla): q_{\mathrm{Cr}(\mathrm{III})}$; Conditions: $[\mathrm{Cr}(\mathrm{VI})]_{0}=6.19 \mathrm{mmol} \mathrm{L}^{-1} ;[B]=4 \mathrm{~g} \mathrm{~L}^{-1}, T=20^{\circ} \mathrm{C}$; Open symbols: experimental data; Closed symbols: predicted data.
during the $\mathrm{Cr}(\mathrm{VI})$ reduction. This also indicates, that during the $\mathrm{Cr}(\mathrm{VI})$ reduction, a faction of $\mathrm{Cr}(\mathrm{III})$ ions bounds to the functional groups immediately without interaction of the organic matter released to the solution. Another important aspect is that the $f$ value is higher than one, meaning that new negatively charged binding sites are generated during $\mathrm{Cr}(\mathrm{VI})$ reduction, and it depends on the degree of biomass oxidation. A higher biomass oxidation leads to higher amount of negatively charged binding groups.

Figs. 3b and 4b shows that the mass balance to the total chromium is well predicted, as well the trivalent chromium concentration in the solid and liquid phase.

The $\mathrm{Cr}(\mathrm{III})$ interference on $\mathrm{Cr}(\mathrm{VI})$ reduction was also evaluated (Fig. D - Supplementary data file). The reaction rate for $\mathrm{Cr}(\mathrm{VI})$ removal is not influenced by $\mathrm{Cr}(\mathrm{III})$ concentration in the solution. Park et al. [6] demonstrated the irreversibility of the reaction of $\mathrm{Cr}(\mathrm{VI})$, considering the effect of $\mathrm{Cr}(\mathrm{III})$ concentration ( 0,50 and $100 \mathrm{mg} \mathrm{L}^{-1}$ ) in the $\mathrm{Cr}(\mathrm{VI})$ reduction at pH 1.0 .

## 5. Conclusion

The protonated brown seaweed L. digitata showed to be an effective biomass for the reduction of hexavalent chromium from

Fig. 5. Equilibrium isotherms of trivalent chromium sorption: reduced $\mathrm{Cr}(\mathrm{III})$ solution during $\mathrm{Cr}(\mathrm{VI})$ reduction at $\mathrm{pH} \sim 2.6$ ( $\boldsymbol{\Delta}$ - experimental data; $\Delta$ equilibrium model); pure $\mathrm{Cr}(\mathrm{III})$ solutions at $\mathrm{pH} 4.0(\bullet)$ and 2.5 (■) using fresh protonated biomass [36].

Fig. 6. Evolution of $\mathrm{Cr}(\mathrm{VI})$ concentration as a function of time at different biomass concentrations: (■) $-0.5 \mathrm{~g} \mathrm{~L}^{-1}$, ( $)-1.0 \mathrm{~g} \mathrm{~L}^{-1}$, ( $\left.\mathbf{(}\right)-2.0 \mathrm{~g} \mathrm{~L}^{-1}$, ( $\star$ ) $-4.0 \mathrm{~g} \mathrm{~L}^{-1}$, ( $\left\langle\right.$ ) $-6.0 \mathrm{~g} \mathrm{~L}^{-1}$; Conditions: $[\mathrm{Cr}(\mathrm{VI})]_{0}=0.2 \mathrm{mmol} \mathrm{L}^{-1}, \mathrm{pH}=2.5, T=20^{\circ} \mathrm{C}$; Symbols: experimental data; Line: predicted data.
aqueous solutions and trivalent chromium sorption. The FTIR spectra showed that the biomass oxidation during the $\mathrm{Cr}(\mathrm{VI})$ reduction and Cr (III) accumulation in the biomass, changes the absorption frequencies of the various functional groups present in the surface of the biomass. The potentiometric titration revealed a substantial increase on the number of carboxylic groups during the biomass oxidation, which was later correlated with the increase on the $\mathrm{Cr}(\mathrm{III})$ uptake capacity. $\mathrm{Cr}(\mathrm{VI})$ elimination by protonated Laminaria was mainly associated to the direct reduction mechanism, in which $\mathrm{Cr}(\mathrm{VI})$ was directly reduced to $\mathrm{Cr}(\mathrm{III})$ in the aqueous phase by contact with electron-donor groups of the biomass, and the reduced $\mathrm{Cr}($ III $)$ remained in the aqueous phase or bounded to the negatively charged carboxylic groups. The concentration of equivalent organic compounds, per unit gram of biomaterial, with capacity to reduce

Fig. 7. Evolution of $\mathrm{Cr}(\mathrm{VI})$ concentration as a function of time at different temperatures: (■) $-T=10^{\circ} \mathrm{C},(\bigcirc)-T=20^{\circ} \mathrm{C},(\mathbf{\Delta})-T=30^{\circ} \mathrm{C}$, ( $\left.\stackrel{\rightharpoonup}{ }\right)-T=40^{\circ} \mathrm{C}$; Conditions: $[\mathrm{Cr}(\mathrm{VI})]_{0}=0.2 \mathrm{mmol} \mathrm{L}^{-1},[B]=4 \mathrm{~g} \mathrm{~L}^{-1}, \mathrm{pH}=2.5$; Symbols: experimental data; Line: predicted data.

| $p K_{C^{3+}}^{\prime}$ | $p K_{H}^{\prime}$ | $f$ | $R^{2}$ | $S_{R}^{2}\left(\mathrm{mmol} \mathrm{g}^{-1}\right)^{2}$ |
| :--- | :--- | :--- | :--- | :--- |
| $3 \pm 1$ | $2 \pm 1$ | $6 \pm 4$ | 0.987 | $3.8 \times 10^{-4}$ |
| $[B]_{\mathrm{T}}=Q_{\text {max }, 1}=2.06 \mathrm{mmol} \mathrm{g}^{-1} ; C_{\mathrm{OC}}^{*}=2.1 \mathrm{mmol} \mathrm{g}^{-1} ; K_{H}^{\prime}=1 / K_{H} ; K_{\mathrm{Cr}^{3+}}^{\prime}=1 / K_{\mathrm{Cr}^{3+}}$. |  |  |  |  |

$\mathrm{Cr}(\mathrm{VI})$, is $2.1 \mathrm{mmol} \mathrm{g}^{-1}$. Considering the molar fractions of $\mathrm{Cr}(\mathrm{VI})$ species and the required number of electrons for each species, 1 g of biomass has 7.25 mmol of available electrons, indicating that the $\mathrm{Cr}(\mathrm{VI})$-reducing capacity of algae $L$. digitata is almost two times higher than that of the common chemical $\mathrm{Cr}(\mathrm{VI})$-reductant (ferrous sulfate). The rate of $\mathrm{Cr}(\mathrm{VI})$ reduction was highly pH dependent since protons are involved in the redox reaction. Although low pH values enhance significantly the $\mathrm{Cr}(\mathrm{VI})$ reduction rate, $\mathrm{Cr}(\mathrm{III})$ sorption is drastically reduced since the functional groups become protonated, leading to low total chromium removal efficiency. The optimum pH value for total chromium removal was 2.5 and 3.0 for reaction times of 48 h and 140 h , respectively, indicating that the reduction reaction is the limiting step of the overall process. The solution temperature enhances significantly the $\mathrm{Cr}(\mathrm{VI})$ reduction rate, achieving a five holder increase from $10^{\circ} \mathrm{C}$ to $40^{\circ} \mathrm{C}$, leading to an activation energy of $45 \pm 20 \mathrm{~kJ} \mathrm{~mol}^{-1}$.

The kinetic model fitted well all the experimental data at different conditions of pH , temperature, biomass concentration and $\mathrm{Cr}(\mathrm{VI})$ concentration. This indicates that the hexavalent chromium reduction reaction is approximately first order with respect to $\mathrm{Cr}(\mathrm{VI})$ and concentration of OC with capacity to reduce $\mathrm{Cr}(\mathrm{VI})$ to $\mathrm{Cr}(\mathrm{III})$.
