ABSTRACT

Genomic technologies offer opportunities to gain a more global assessment of the health status of an organism through an understanding of the functional pathways that are responding to pollutant exposure. We have developed a 13,000 clone cDNA toxicogenomics microarray for *Platichthys flesus*, the European flounder (EU-GENIPOL Project). We aimed to distinguish the origins of flounder taken from six sampling sites of different pollution status in Northern Europe according to their hepatic gene expression profile using bioinformatic approaches. To determine which gene expression differences may relate to pollutant impact, we have completed complementary laboratory exposures of flounder to selected toxicants and determined the associated gene expression profiles. Using multivariate variable selection coupled with a statistical modelling procedure (GALGO) we can predict geographical site but the accuracy is limited to specific sites. The search space for a combination of genes that effectively predicts class membership is very large, however, by combining the signatures derived from acute laboratory exposure to individual chemicals to limit the search space, a very accurate model for classification of all the different environmental sites was achieved. The final model utilised the expression profiles of 16 clones and validation with a qPCR array comprising these genes correctly assigned the site of origin for fish obtained from three of the sites in an independent sampling. These data would imply that the gene expression fingerprints obtained with these arrays are primarily attributable to variations in chemical pollutant responses at the different sites, indicating their potential utility in environmental impact assessment.

1. Introduction

River estuaries often contain complex mixtures of xenobiotics derived from industrial and domestic effluents in high concentrations. Thus, organisms living in them are exposed to these compounds which may be detrimental to their health. The monitoring of both chemical content and biological responses in sentinel species play important roles in assessing the impact of such anthropogenic inputs. To achieve this, biomarkers have been employed as indicative or predictive of exposure to, or damage by, toxicants.

Such biomarkers include molecular, biochemical, histological, and morphological parameters (van der Oost et al., 2003). The measurement of expression of single biomarker genes cannot provide an integrated assessment of the effects of different chemical classes, however, with the advent of the “omic” technologies (Schena et al., 1995), interest has turned to the possibility of characterizing in more depth the health status of individual animals through a more complete analysis. Toxicogenomic studies in genetic model organisms have already shown the potential of this approach (McMillian et al., 2005) and there is great potential to apply such methods to environmentally relevant species (ecotoxicogenomics) (Neumann and Galvez, 2002; Snell et al., 2003; Snape et al., 2004; Denslow et al., 2007). Through a detailed characterisation of gene expression it is now possible to establish perturbation of biological pathways in a tissue of an organism and then to relate such pathways to toxic, stress or adaptive responses. Thus, microarrays have been used to determine expression profiles that may be diagnostic of exposure to certain classes of chemicals (Bartosiewicz et al., 2001; Waring et al., 2002; Hamadeh et al., 2002) and can allow class-prediction, where samples are classified according to a pre-existing database.

¹ Joint senior authors.

Current methodology and strategies in biomonitoring (e.g. use of histopathology) is likely to be efficient in the detection of a wide range of toxicities. However, the value of, and need for, a complementary suite of molecular biomarkers is in the provision of information on the mechanisms of toxicity and the additional detection of subtle changes that are adaptive or compensatory to exposure to the toxicant and may be predictive of potential toxicity. These markers, which may be obtained through the non-biased microarray approach, can thus act as sensitive, early warning sensors.

Our studies have focussed on the use of a flatfish, European flounder (*Platichthys flesus*) as a sentinel species. *P. flesus* is a teleost flatfish common in estuarine environments throughout north-west Europe, many of which are significantly impacted by toxicants including endocrine disrupters, heavy metals, polycyclic aromatic hydrocarbons (PAHs) and dioxins. These are usually present as complex mixtures closely associated with the sediment and flounder are exposed through feeding on associated invertebrates. It is a key sentinel species for biological effects monitoring in initiatives such as the OSPAR Joint Assessment and Monitoring Programme (OSPAR, 1997).

One of the complications of using microarrays for the simultaneous measurement of expression of thousands of genes in tissues from animals taken from the environment is that the complex pattern of gene expression profiles will be determined by many factors such as genetic make-up, age, diet, salinity, temperature and reproductive state as well as being influenced by pollutant inputs. Moreover, inter-individual variability in gene expression profiles within organisms in the same environment can be substantial (e.g. Pritchard et al., 2001; George et al., 2004). Gene expression profiles will also vary depending on the doses of toxicants, by the length of exposure and the interval between exposure and sampling, as will many other toxicological parameters. In order to be able to interpret the expression profiles of fish in the environment, we have used a strategy within the present study to compare the gene expression of fish from different environmental sites with respect to a number of conventional biomarkers and also in relation to the “stress gene responses” observed in flounder exposed acutely to a range of different toxicants under controlled laboratory conditions (Williams et al., 2008 co-submission). Using a supervised classification procedure in combination with a multivariate gene selection procedure we have assessed the ability of subsets of genes to allow the prediction of the site at which fish were sourced. This approach has helped to establish stress genes that contribute to the differences in hepatic gene expression observed in flounder obtained from different sites. Integration of laboratory and field studies in this way should help to discriminate between pollutant mediated gene expression changes and those associated with other factors.

2. Materials and methods

2.1. Environmental fish samples

Adult gonadally quiescent male *P. flesus* of length 13–22 cm were caught at six North Sea sampling sites, our reference site, the Alde estuary ($n = 29$; latitude $52^{\circ}95'N$, longitude $1^{\circ}33'E$ Suffolk, UK), two sites on the Tyne estuary (Tyne and Wear, UK), Team ($n = 8$; latitude $54^{\circ}57'N$, longitude $1^{\circ}27'W$) and Howdon ($n = 10$; latitude $54^{\circ}57'N$, longitude $1^{\circ}38'W$), two sites on the Elbe estuary, Cuxhaven ($n = 4$; latitude $53^{\circ}53'N$, longitude $08^{\circ}15'-19'E$) and Brunsbuttel ($n = 21$; latitude $53^{\circ}52'N$, longitude $09^{\circ}09'-10'E$) and one site close to the island of Helgoland ($n = 5$; latitude $54^{\circ}06'N$, longitude $07^{\circ}15'-08^{\circ}00'E$) (Schleswig-Holstein, Germany), during statutory monitoring programs carried out in October 2002 and 2004, and in April 2005 and 2007 by CEFAS, Burnham laboratory and AWI, Bremerhaven. Fish were caught using beam trawls and held in tanks of

flowing sea water onboard ship and were sacrificed either onboard ship or immediately on return to shore. Livers were immediately removed and samples flash frozen in liquid nitrogen for RNA extraction. Each individual sample of liver was processed and arrayed individually as described previously (Williams et al., 2006).

2.2. Flounder laboratory exposures to which gene expression profiles were compared

Juvenile immature *P. flesus* of 50–120 g body wt. were previously exposed separately to six chemical substances (Sigma–Aldrich, Gillingham, UK) a pro-oxidant heavy metal salt, cadmium chloride ($50 \mu\text{g}/\text{kg}$ in saline), a polycyclic aromatic hydrocarbon, 3-methylcholanthrene ($25 \text{mg}/\text{kg}$ in olive oil), a technical PCB mixture Aroclor 1254 ($50 \text{mg}/\text{kg}$ in olive oil), an organic pro-oxidant, *tert*-butyl-hydroperoxide ($5 \text{mg}/\text{kg}$ in saline), a chlorinated hydrocarbon pesticide, lindane ($25 \text{mg}/\text{kg}$ in olive oil), a peroxisomal proliferative fatty acid analog, perfluoro-octanoic acid ($100 \text{mg}/\text{kg}$ in olive oil), or their carriers, olive oil ($1 \text{ml}/\text{kg}$) or saline (0.9%). The European flounder cDNA microarray was developed as part of the GENIPOL consortium and we have previously reported its construction and use in determining responses of flounder to disease, toxicant and hormone treatments (Williams et al., 2006, 2007; Diab et al., 2008). Details of the exposures and gene expression responses are given in detail in Williams et al. (2007 and co-submission) and Diab et al. (2008). Briefly, hepatic gene expression changes were determined 1, 2, 4, 8 and 16 days post-injection in comparison with time-matched carrier controls. Through gene ontology analyses, the key biological processes disturbed by the individual treatments were characterised.

2.3. cDNA microarray analysis

Hepatic gene expression profiles were determined in environmentally sampled fish using the GENIPOL cDNA microarray which was fully described by Diab et al. (2008) following established protocols described earlier (loc. cit). Briefly, flounder hepatic total RNA was treated to remove contaminating genomic DNA with DNA-free (Ambion, Huntingdon, UK), reverse transcribed to cDNA with SuperscriptII (Invitrogen) using oligo-dT primers (Alta Biosciences, Birmingham, UK) then labelled with either Cy5-dCTP or Cy3-dCTP (Amersham, Amersham, UK) using Klenow polymerase (Invitrogen, Paisley, UK) before purification (Qiagen, Crawley, UK). All arrays utilised a synthetic reference DNA, labelled by a similar procedure. Each array consisted of labelled cDNA from one individual fish hybridized versus the differentially labelled synthetic reference. Hybridisations were carried out for 18 h, before stringent washing and scanning (Axon 4000B) (Molecular Devices, Wokingham, UK). Data were captured using Genepix software (Molecular Devices), and each slide was checked in detail, with spots showing poor morphology or arrays showing gross experimental artefacts being discarded. The data used in analyses consisted of local background-subtracted median intensities. MIAME-compliant data was input to Array-Express using maxdLoad2 (Hancock et al., 2005), accession number E-MAXD-40.

2.4. Microarray data analysis

2.4.1. Data normalisation

Each labelled cDNA sample was hybridized to one microarray slide (Williams et al., 2006; Diab et al., 2008). Quantile normalisation was applied to the raw intensities (\log_2 values) across the microarrays using the affy package (<http://www.bioconductor.org>) under the programming environment R (<http://cran.t-project.org>). The mean of the log intensities was then calculated for each gene

on the array. The expression of each gene was determined from average Cy5 intensities of at least two spots; where coefficients of variation were greater than 30% data were removed.

2.4.2. Gene expression and gene ontology

Individual samples from each site were considered as biological replicates. Differentially expressed genes were selected for each site by comparison with the Alde samples using a *t*-test with *P* < 0.05 and Benjamini and Hochberg multiple testing correction (Benjamini and Hochberg, 1995), resulting in a false discovery rate (FDR) of 0.05. These statistically significantly changing genes were filtered to remove those altered in expression in comparison with Alde samples by less than two-fold. Gene ontology (GO) analysis was carried out using Blast2GO (Conesa et al., 2005). The lists of differentially expressed genes were compared with all reliably detected genes using the Fisher’s Exact test within the Gossip package, which output the GO terms statistically significantly (FDR < 0.1) over-represented or under-represented in the test list.

2.4.3. Cluster analysis

Hierarchical clustering analysis (HCAs) was performed in R (<http://cran.t-project.org>). The degree of similarity of each pair of patterns was computed using Euclidean distance on standardized gene expression profiles.

2.4.4. Classification methods

To identify molecular signatures predictive of the geographical sampling site of the fish we have used two complementary approaches.

The first uses a univariate variable selection strategy where each gene is tested individually for its ability to discriminate between the sample groups. In this procedure genes were selected using an *F*-test. A predictive model was built using the smallest subset of most differentially expressed genes which gave the highest classification accuracy with a *K*-nearest-neighbor (KNN) classifier. In using this procedure we used the implementation available in the software application “Prophet” (Herrero et al., 2003).

A multivariate variable selection method was also used in combination with a KNN classifier for prediction of the sampling site based on the selection of gene sets. In this procedure combination of

genes are tested for their ability to discriminate between different sample groups. The GALGO package (Trevino and Falciani, 2006), running under the R language was employed. In short, GALGO incorporates a Genetic Algorithm procedure for selecting models with a fitness value above a given threshold. The supervised classification method was *k*-nearest neighbours algorithm (KNN) with *k* = 3. The classification efficiency (error estimation) was evaluated using a leave-one-out cross validation procedure. The models developed by GALGO were chosen to have a size of five “genes” (Trevino and Falciani, 2006). One thousand independent searches were performed and the best “chromosomes” of each run were selected. The genes represented in the model population were sorted accordingly to their frequency. A single representative model was built by applying a forward selection procedure to the sorted list using the criteria that maximized the average fitness.

2.5. Validation by quantitative PCR (qPCR) array

The validation of this microarray by real-time quantitative PCR was previously shown in experiments carried out with Cd and estradiol (Williams et al., 2006, 2007). Microarray and qPCR data for vitellogenin B, glutathione reductase, Cu/Zn superoxide dismutase and metallothionein correlated at *r*² = 0.95, 0.98, 0.79 and 0.89, respectively. In order to validate the results of the present experiment further qPCR was carried out using additional independently sampled and prepared flounder RNA.

Total RNA was extracted from liver samples obtained from fish collected from each of the Alde, Brunsbuttel and Tyne (Howdon) sites (*n* = 5 per site) obtained at a different sampling, using Tri reagent (Sigma) as above. Samples of 1 µg total RNA were reverse transcribed for 60 min at 42 °C using a Reverse-*iT* MAX™ first strand synthesis kit (Abgene, Epsom, UK) with 0.5 µM of a 3:1 mixture of random hexamers and anchored oligo-dT in a total volume of 20 µl. The reaction was terminated by heating to 75 °C for 10 min, diluted 20-fold with distilled water and then stored at –20 °C. PCR primers for the 15 “site diagnostic” and 3 “normalisation” genes (Table 1) were synthesized by MWG Biotech (London, UK), adjusted to 100 pmoles/µl with water and stocks stored at –20 °C. Quality control was assessed by product analysis of PCR reactions using agarose gel electrophoresis to verify formation of single products of

expected molecular size and examination of melting point analysis data during real time PCR to verify single peak dissociation profiles.

For qPCR array each forward and reverse primer pair were combined and diluted to yield enough mix for 100 reactions at a final primer concentration of 267 nM. 96-well plates were set up with three sub arrays containing 2 µl of each primer mix per well (15 wells with “diagnostic” genes, 4 wells with “normalisation” genes and 4 additional wells containing actin primers as “linearity” estimates), whilst 2 µl of water was added to 2 additional wells for no template and no transcriptase controls. For each subarray, 5 µl of the diluted cDNA reaction mixture was pipetted into the “diagnostic” and “normalization” wells, 5 µl of four decadal dilution cDNA samples were pipetted into the “actin linearity” wells and 5 µl water into the control wells. 10 µl SYBR Green PCR mix (ABgene Inc.) and 3 µl water were then added to each well and the plate subjected to real-time qPCR on a Quantica cyler (Techne Instruments, Stone, UK) using universal cycling conditions, activation at 95 °C for 15 min, cycling at 95 °C 15 s, 58 °C for 15 s and 72 °C for 30 s for 45 cycles and then melting at 75–95 °C. The cycle number (C_t) signals for each well were recorded and used for data analysis. C_t values for all samples across multiple plates were normalized to beta-actin, centered by median of gene, normalized to ±1, and ordered by hierarchical clustering (Unweighted pair-group average, 1 – Pearson r) using the analysis package Statistica (StatSoft, Bedford, UK).

3. Results

3.1. Gene expression changes

Comparison of gene expression with Alde samples resulted in 481 genes identifiable with known proteins that were statistically significantly differentially expressed ($P < 0.05$ t -test) and

with a greater than two-fold change in expression from Alde at one or more sites (Supplementary Table 1). Gene ontology analyses showed 167 statistically significantly altered GO terms (Supplementary Table 2).

3.2. Clustering

Unsupervised hierarchical clustering analysis resulted in imperfect aggregation based on the sites from which the samples of fish were collected. The hierarchical dendrogram revealed that no sample set perfectly segregates accordingly to its site apart from the highly impacted Brunsbützel samples (Fig. 1).

3.3. Class prediction

Initially, a univariate variable selection methodology to develop biomarkers predictive of the geographical site was used. This methodology ranks each individual clone based on its ability to discriminate among the geographical sites and then selects a final model that uses the smallest possible subset of clones that is most predictive. Initial analysis revealed that the classification accuracy was relatively high. However, this methodology does not take into account the fact that genes work in the context of integrated networks and pathways. To address this issue and identify genes that, in combination, are predictive of the geographical site, we used the statistical modelling (GALGO) system that implements a genetic algorithm as a multivariate variable selection method (Trevino and Falciani, 2006). The overall strategy is shown in Fig. 2.

First, the full microarray dataset was used to identify a subset of genes predictive of geographical site. In Table 2, the results of the multivariate analysis of the transcription dataset using GALGO are

Fig. 2. Flow diagram illustrating the procedure implemented to select the clones that were used to build the final statistical representative model based on the different chemical treatments.

The horizontal axis represents the individual samples grouped according to the geographical site classes whereas the vertical axis represents the predicted sites. The model was built using all microarray data. Classification accuracy of for each site prediction are marked in bold along the diagonal of the table.

presented. The prediction accuracy (Table 2A) is high (larger than 80%) for all sites except Tyne Howdon for which it is 70% as a result of the uncertainty in discriminating the geographically close Tyne Team site.

These results demonstrated that it was possible to identify gene signatures that are highly predictive of geographical site. We postulated that these complex signatures may be, in part, the result of a combined cellular response to the individual chemicals that are present in the environment; however, this model does not include

many of the known classical pollutant responsive biomarker genes. This may be artefactual or a reflection of the fact that our procedure is somehow identifying a set of alternative, and perhaps better, predictors. In order to test this hypothesis another model was developed which was specifically designed to represent the response of a set of chosen “classical” biomarker genes (listed in Table 3B). The classification accuracy of the representative model obtained using GALGO is shown in Table 3A. Whilst the model is accurate in predicting some of the sites such as Alde, Elbe Brunsbüttel and to some

Each row shows the sensitivity values of the representative models that were built using only the most statistically significantly changing clones after the administration of the six specific chemical treatments.

extent the Tyne Team site, it shows a rather poor accuracy for all the other sites.

We then hypothesized that a wider selection of stress-responsive genes should improve predictivity. In order to test this hypothesis, the predictive power of hepatic gene signatures identified from laboratory exposure of flounder to the model xenobiotics, cadmium, *tert*-butyl hydroperoxide, perfluorooctanoic acid, 3-methylcholanthrene, Aroclor and lindane (Williams et al., 2008 co-submission) was assessed. Models were developed from the 200 most statistically significantly differentially expressed clones for each chemical treatment (Supplementary Table 3). Table 4 shows the classification accuracy of the models developed using these gene lists. It can be seen that some gene signatures such as those found following cadmium treatment, were predictive of some geographical locations with an average weighted sensitivity of the model of 84%, but its overall accuracy compared to the use of the entire gene pool analyzed above, was decreased. Similar findings were obtained with the other gene signatures and the average weighted sensitivity of the representative models were in the range from 49% to 86%.

Each column corresponds to one of the six different environmental conditions. Classification accuracy of for each site prediction are marked in bold along the diagonal of the table.

On the basis that a larger pool of “stress-related” genes are more likely to be able to have a predictive capacity, all the clones that were selected in the representative models developed from the gene signatures of each chemical treatment (Table 4) and the set of selected ‘biomarker’ genes (Table 3) were merged to develop a representative model based on this list. We found that this statistical model greatly improved our prediction of the geographical sites compared to the use of individual stressors (Table 5A) and that the average weighted sensitivity of the model improved to 92.5%. To ensure that this solution was not discovered by random chance we tested the probability of finding a model with given accuracy based on selecting a random list of 100 clones from the full environmental sites dataset. The distribution of average weighted sensitivity of these models is in the range 68–78%. Principal components analysis was then used to illustrate the overall differences in response between sampling sites, based on the expression of genes incorporated into the final representative model (Fig. 3). The test-site fish are clearly separated from those sampled at our reference site, the Alde. The fish from Helgoland and Cuxhaven are well separated from other samples but show some overlap with each other. There is an overlap between some individuals from Tyne Howdon, and Brunsbüttel with Tyne Team fish, whilst the remainder of Tyne Howdon and Brunsbüttel fish fall into well defined areas.

3.4. Verification of predictive gene set by qPCR array

PCR primers were designed to each of the 17 diagnostic clones used in the final genetic model, serial dilutions of input cDNA confirmed near 100% yield for all primer sets with one exception where more than one product was obtained and this was omitted from the final qPCR array assembly. No-template and no-transcriptase controls were used as contamination checks. Serial dilutions of

Fig. 3. Principal components analysis of environmentally sampled flounder using the expression of clones shown in Table 5.

input cDNA were utilised with actin primers to confirm linearity of response under the conditions used and the amount of input cDNA to use was optimised by using the beta-actin gene primers so that a C_t value of around 20 was obtained. RNA extracted from five fish from the reference Alde and two polluted sites, Tyne (Howdon) and Elbe (Brunsbuttel) were obtained from an independent sampling and analyzed using the PCR array. C_t values for actin differed by less than ± 1 , therefore in this study only beta-actin expression was used for normalisation. Cluster analysis (Fig. 4) showed that all samples were segregated by site of origin.

4. Discussion

In the present study, we have investigated by cDNA microarray the gene expression profiles of 77 hepatic samples of *P. flesus* collected from six different environmental sites around north-west European estuaries. Heavy metal, petroleum hydrocarbon, carcinogenic polyaromatic hydrocarbon and polychlorinated biphenyl concentrations in the sediments of the highly industrialized sites

Table 6

Concentrations of major pollutant classes in sediments from UK and German estuaries where flounder were sampled

Analyte	Alde	Tyne (Howdon)	Elbe (Brunsbuttel)

in the Tyne and Elbe estuaries are generally one to two orders of magnitude greater than in the Alde estuary (Table 6) and residue analysis has shown detectable levels of these pollutants in tissues of fish from these sites (ICES data, not shown), thus it is to be expected that fish from these sites will display transcriptomic responses to these pollutant classes. The sites at Cuxhaven and Helgoland were of intermediate contamination (data not shown).

4.1. Gene expression and gene ontology

The Alde site has low anthropogenic impact (Lyons et al., 2004) and is regarded as a non-polluted reference site due to consistently low plasma vitellogenin and hepatic ethoxyresorufin-*o*-deethylase (EROD) activity in flounder from this site (George et al., 2004; Kirby et al., 2004a,b). In comparison with the Alde fish, the expression of many genes was altered in livers of fish from one or more of the other sampling sites. Of these changes a majority showed repression in comparison with the Alde, however, there was an upregulation of many genes coding for xenobiotic metabolism and detoxification proteins.

The functionally related groups of genes showing clearest overall induction in the highly impacted Brunsbuttel and Tyne Howdon sites were those encoding the phases I and II metabolic enzymes. Of these the most prominent was the well-known biomarker cytochrome P450 1A (CYP1A), which was induced at all sites in comparison with the Alde and induced most highly (greater than

Fig. 4. Hierarchical dendrogram of cluster analysis of gene expression of clones shown in Table 5 determined by qPCR array with an independent sample set to Figure 3. Sampling locations are A, Alde; B, Brunsbuttel and T, Tyne Howdon.

seven-fold) at the Brunsbützel site. CYP1A is inducible by aromatic hydrocarbon receptor (AhR) ligands such as polycyclic aromatic hydrocarbons (PAH) and halogenated aromatic compounds such as PCB's and its mRNA and enzyme activity (EROD) have previously been shown to be induced at pollutant-impacted sites including the Tyne (George et al., 2004; Kirby et al., 2004b; Williams et al., 2003). Hepatic neoplasia have been found to be more frequent in flounder sampled from the Tyne in comparison with the Alde (Stentiford et al., 2003) and in the Elbe estuary in comparison with Helgoland (Koehler, 2004) and this is believed to be due to PAH impact. Aldehyde dehydrogenase (ADH) activity has been reported to be induced in flounder treated with polycyclic aromatic hydrocarbons (Koehler et al., 1998) and ADH mRNA was found to be induced in Tyne fish (Williams et al., 2003). In the present study, a transcript with homology to aldehyde dehydrogenase 9A1 (originally associated with gamma-amino butyraldehyde dehydrogenase activity, Kikonyogo and Pietruszko, 1996) was induced in fish from all sites compared with the Alde. Cytochrome P450 8B1, a bile acid synthetic enzyme (Eloranta and Kullak-Ublick, 2005), is upregulated at all Elbe sites but not in Tyne samples. The induction of such genes at the Helgoland site, which was previously relatively uncontaminated, may in part be due to deposition of contaminants by the severe floods of 2002 which carried much estuarine sediment from the Elbe into the German Bight (Einsporn et al., 2005). At the Tyne Team site there is induction of glutathione-S-transferases which detoxify lipid peroxides produced by oxidative stress, and this response is further supported by the induction of other oxidative stress-responsive genes, catalase and glutathione peroxidase 1. Only one oxidative stress responsive transcript was induced at all sites, peroxiredoxin 6, with selenium-binding protein 1 displaying induction at the Cuxhaven and the Tyne sites. Additionally, cytochrome P450 2 and 3 family transcripts were induced at the Tyne Team site, with the GO term mono-oxygenase activity being over-represented.

Surprisingly, a number of chaperones and heat-shock proteins, which we previously found to be very highly induced by acute heavy metal and organic xenobiotic exposures in the laboratory (Williams et al. (2008) co-submission), were broadly repressed in fish from the polluted sites. Such a lack of induction may reflect the differences between acute laboratory exposures and long-term environmental exposure where a degree of adaptation has occurred.

There was little evidence of a co-ordinated induction of protein synthetic genes such as those encoding ribosomal proteins, again in contrast to laboratory exposures. Indeed certain translation initiation factors were repressed at our test sites, as previously found in Tyne fish (Williams et al., 2003). There were, however, a number of inductions of amino-acid metabolic genes, with additional support from the over-representation of related GO terms in Tyne Howdon and Brunsbützel samples. The lipid transporters cholesteryl ester transfer protein and fatty acid-binding protein were induced at all Elbe sites, whereas other lipid transporters such as apolipoprotein E and vigilin were repressed. This disruption of lipid transport may reflect that flounder from this area have shown hepatic steatosis as reported in a histopathology study by Koehler (2004). The alteration of expression in these gene classes and those of carbohydrate and lipid metabolism, as well as those of energy generation pathways, may be due to pollution effects or to differences in nutritional status between the groups of fish. Vigilin has been shown to stabilise vitellogenin mRNA in *Xenopus* (Cunningham et al., 2000). The suppression of vigilin gene expression noted at Brunsbützel, Cuxhaven and Helgoland may therefore have reduced any apparent induction of vitellogenin transcript, however, it is not currently known if this mechanism is conserved in flounder.

No clear conclusions could be made as to whether gene expression responses favoured apoptosis or cell survival since

mixed responses were observed. Expression of cytochrome C, programmed cell death 2 and 6 were repressed at most sites compared with the Alde. At the Brunsbützel site there was induction of the diablo gene (Verhagen and Vaux, 2002) and associated transcripts, at the Tyne sites the expression of survival motor neuron domain containing 1 (Talbot et al., 1998) and programmed cell death 4 were induced, whilst that of survivin, the anti-apoptotic gene was suppressed. These responses would indicate that the fish have been affected by a mixture of pro- and anti-apoptotic stimuli, including toxicants.

Fish from all sites showed an unexpected repression of transcription of DNA repair enzymes such as alkylated DNA repair protein AlkB and aprataxin, a repair enzyme of single strand breaks (Takahashi et al., 2007) when compared with the Alde fish. It may be possible that this repression contributes to the increased prevalence of DNA adducts reported in flounder from the Tyne (Lyons et al., 1999). Cell cycle genes apart from cyclin G and geminin, a DNA replication inhibitor, are generally repressed at all sites. Such cell cycle transcriptional disruption may also contribute to the pro- and anti-apoptotic gene expression responses observed.

Haemoglobin transcripts were induced and associated GO terms were over-represented in Tyne Howdon and Brunsbützel fish which may be consistent with tissue damage allowing erythrocyte infiltration into the liver at these two sites, a condition confirmed by histopathology analysis (results not shown). Significant induction of hepatic metallothionein gene expression was only observed in the Cuxhaven fish, which is consistent with the elevated protein levels found in a caging study with cod (*Gadus morhua*) in this area (Chesman et al., 2007). qPCR analysis of metallothionein mRNA and analysis of Cd/Zn metallothionein protein of these and other flounder from the Alde and Tyne did not show significantly different levels between sites (George et al., 2004).

Inflammatory and immune system genes displayed mixed responses. Whilst expression of the antimicrobial proteins hepcidin, lysozyme and pleurocidin were elevated at most sites, a variety of other transcripts were repressed in the Helgoland and Cuxhaven samples compared with the Tyne and Brunsbützel samples. Disruption of immune function has previously been shown in flounder from the Elbe estuary (Broeg et al., 2005). Tyne Team and Howdon samples showed induction of complement component C3 and Tyne Howdon induction of nuclear factor kappa B, with over-representation of the GO term inflammatory response.

Although, historically, high plasma vitellogenin levels have been reported in flounder from the Tyne (Allen et al., 1999), a more recent study reported a decline towards levels found at the Alde which was attributed to the installation of secondary treatment facilities in 2000 (Kirby et al., 2004a). In the present study where sampling was carried out in 2002, significant induction of vitellogenin mRNA in comparison with Alde fish was apparent only at the Tyne Howdon site, and physiological anchoring by measurement of plasma vitellogenin levels confirmed these findings (George et al., 2004), however, in common with results obtained in fish from other polluted sites there was a high inter-individual variability (George et al., 2004 and unpublished). Although there is previous evidence of induced vitellogenesis in bream (*Abramis brama*) from the Elbe, this was relatively low in flounder from the Elbe estuary (Hecker et al., 2002) and plasma vitellogenin analysis of three of the fish subjected to microarray analysis in the present study also showed no induction (unpublished results).

The numbers of gene ontology terms whose representation was statistically significantly changed in comparison with the Alde reference site may be useful as a rough indicator of impact. These were, Tyne Howdon 106, Brunsbützel 91, Tyne Team 73, Cuxhaven 46 and Helgoland 35. Comparing Brunsbützel and Tyne Howdon

fish, from the GO classes affected it appeared that the additional changes at the Tyne Howdon site were related to inflammation and haem proteins, whilst both sites showed alterations in classes indicative of contamination with organic compounds such as PAHs and PCBs compared with the other sites.

4.2. Class prediction

Using a hierarchical clustering method, we inferred that samples of each geographical site do not display a unique expression pattern. Although the cluster analysis demonstrated that the molecular profile of fish liver cells could be associated with the geographical site in some cases, it suffered from several limitations. First, it did not identify genes which are associated strongly with any specific site and secondly it did not provide any indication of how useful a gene (or a set of genes) would be as biomarkers either for discriminating between sampling sites or as an indicator of exposure to different forms of stress.

In this study, we merged the results of acute stress responsive genes derived from controlled laboratory exposure of fish to individual toxicants with the gene expression profiles that were generated by long-term exposure in different environmental conditions. To integrate both types of analysis we built a series of representative statistical models using a multivariate analysis approach. Neither the use of any of the representative models derived from single chemical treatments or the use of a battery of conventional biomarker genes were capable at efficiently summarizing the complexity measured in the environmental samples. However, by merging the clones selected from each representative stressor model we acquired a representative model that showed a comprehensive prediction of the site of origin of fish based on the gene expression generated in each of the environmental conditions. We emphasize that this type of analysis does not negate the use of specific biomarkers of stressors, the conventional biomarkers employed were efficient at site prediction of Brunsbittel fish and CYP1A, for example, gave marked differences between the clean Alde site and the more polluted sites of Tyne and Brunsbittel. However, the statistical model has been successful in the use of a battery of stress-related genes for site prediction. This implies that one of the distinguishing features of the expression profiles between the different sites is the influence of stress genes. Since the models developed using a combination of all signatures developed from the individual chemical exposures are even more accurate in predicting geographical location it is suggested that it is a combination of different stressors that contribute to the molecular profile of liver tissue chronically exposed in the environment.

The genes that were identified by modeling as efficiently predicting sampling sites included those encoding ribosomal proteins, haemoglobin and aldehyde dehydrogenase discussed above. Other predictive transcripts are indicative of an oxidative stress response in polluted environments, including an aldo-keto reductase and copper/zinc superoxide dismutase. The glutamate carbonylpeptidase-like clone, which is associated with folate and homocysteine levels and is similar to anserinase (Yamada et al., 2005) also contributed to prediction, warranting further study on its function and regulation. The well documented biomarkers CYP1A, choriogenin and metallothionein were also strong predictors. Induction of the innate immune response gene, liver expressed antimicrobial peptide (LEAP-2) may indicate increased bacterial exposure of pollutant-impacted fish. The unidentified expressed sequence tags (ESTs) present opportunities for novel biomarker gene discovery, indeed, one was isolated by suppressive, subtractive hybridisation between flatfish from reference and polluted estuaries (Straub et al., 2004).

5. Conclusions

Using a multivariate variable selection coupled with a statistical modelling procedure (GALGO) we demonstrated that gene expression signatures in livers of flounder can predict their geographical site of origin but that the accuracy is limited to specific sites. The search space for a combination of genes that effectively predict sample origin is very large and since the selected sites contained varying levels of complex mixtures of pollutants we limited the search space by incorporating prior knowledge and data from laboratory exposures to prototypical pollutants. This produced a very accurate model utilising the expression profiles of only 17 genes for classification of all the different environmental sites. This model was further verified by use of a qPCR array to determine the expression of 16 clones which predicted with 100% accuracy the site of origin of an independent sample of 15 fish from 3 of the sites. This indicates that expression changes derived from short-term exposures can, in some cases, be used to infer longer term exposures accumulated over months or years of exposure. These gene expression changes combine recent and longer term responses to the environment. We aim, in future experiments, to define the bases of individual and population susceptibility and adaptation to environmental pollutants in fish, using a combination of 'omic technologies and genetic analyses.
