<b>Abstract:</b>	<p><b>Abstract:</b> Nanocrystalline yttrium aluminium garnet (nYAG) powder has been synthesized via sol-gel and co-precipitation methods using nitrate precursors. Thermal evolution and crystallisation kinetics of both the methods were investigated. The optimised calcination condition for the formation of nYAG was also examined. It was found that a complete transformation to nYAG was observed at 925°C/2h and 1000°C/1h for the co-precipitation and sol-gel samples respectively. An intermediate YAIO<sub>3</sub> phase was formed at 900°C in all powders regardless of the synthesis methods. The powder morphologies obtained from TEM revealed very similar particle sizes for the two routes (20-30 nm); whilst the extent of agglomeration was higher for the sol-gel method. It was also observed that by controlling the pH in a narrow range, maintaining the precipitate processing temperature and dehydrating excess OH<sup>-</sup> ions in the precipitates using an n-butanol treatment, the extent of agglomeration was further reduced in the co-precipitated nYAG powder.</p>

### 1 Introduction

Ceramic powder processing within the  $Y_2O_3$ - $Al_2O_3$  system has largely been intended for optical and structural applications. In this system, three stable yttrium aluminates exist with different polymorphs, perovskite-based orthorhombic  $YAlO_3$  (YAP), monoclinic  $Y_4Al_2O_9$  (YAM) and garnet  $Y_3Al_5O_{12}$  (YAG) (Abell et al. 1974). The latter is rich in  $Al_2O_3$  and crystallises with cubic symmetry. It does not exhibit any birefringence effects at the grain boundaries and hence results in high in-line transparency. A hexagonal  $YAlO_3$  (YAH) has also been identified as an intermediate metastable phase during the processing of YAG (Tanner et al. 2003).

The choice of powder synthesis route has a significant effect on powder characteristics such as size, shape, distribution and the extent of agglomeration, each of which greatly influences the microstructural homogeneity of the resulting ceramics (Akio Ikeshue, Yan Lin Aung, Takunori Taira, Tomosumi Kamimura, Kunio Yoshida, Gary L. Messing 2006). Each factor has the potential to introduce an adverse effect on densification and microstructure of the ceramics. The presence of particle agglomeration, for example, is a well-known source of inhomogeneity, and hence defects, in the final microstructure of ceramic components (Lange 1989). Therefore, efforts have been made to produce high quality ceramic powders by a range of synthesis routes.

The conventional method for preparing YAG involves mixing  $Y_2O_3$  and  $Al_2O_3$  in a 3:5 molar ratio and then calcining at 1600°C for prolonged times together with repeated grinding (Li et al. 2007). Wet chemical routes such as sol-gel (Gowda 1986), co-precipitation (Li et al. 2004), solvo-thermal (Wang et al. 2006) and combustion (Devi et al. 2002, Ramanathan et al. 2003) routes are promising methods for synthesising high purity single phase YAG at relatively low temperatures, though there are some disadvantages. Solvo-thermal synthesis, for example, requires the use of an autoclave and pressures of about 70–175 MPa, whilst combustion synthesized powders result in chemical inhomogeneities and particle agglomeration due to the intense local

heating. In contrast, sol-gel and co-precipitation synthesis can be low cost and are more likely to yield homogenous YAG powders. The use of alkoxide precursors (Veith et al. 1999) leads to crystallisation from 700 - 1000°C and the resultant powder consequently exhibits particle sizes of about 60-80 nm with heavy agglomeration. In contrast, nitrate (Hou et al. 2009) and chloride (Tachiwaki et al. 2001) precursors lead to crystallisation at about 950°C, although chlorine ions are more difficult to rinse from the hydroxide precipitate, even with washing. The presence of chlorine ions results in hard agglomerates in the nanopowder (Wang et al. 2010) and hence has negative effects on the mechanical properties of the subsequent ceramic. To reduce the level of agglomeration, several complexing and precipitating agents have been examined for both sol-gel and co-precipitation methods using nitrate precursors. Nanocrystalline YAG was synthesised using citric acid as a chelating ligand in sol-gel method, (Vaquero and Arturo Lopez-quintela 1998). This resulted in rod shaped particle morphology with particle sizes in the range of 20-70 nm and significant agglomeration was still observed. Recently, Yang (2010) optimised the solvent concentration and calcination conditions to achieve nano YAG with soft agglomerates using a sol-gel method. This work also confirmed that the molar concentration ratio of the  $Y^{3+}$  and  $Al^{3+}$  ions in the precursor solution has a significant effect on particle size. Wang (2000) also studied the effect of different concentrations of precursor solution for the co-precipitation synthesis of YAG nano powder. They achieved 20-30 nm particles using a precursor solution ratio of <1 and calcination for 2 hours at 900°C. The uses of different precipitants (Li et al. 2000) and pH conditions (Apte et al. 1992, Palmero et al. 2005) have also been studied; these are also considered to be very important factors governing particle morphology with the co-precipitation method. Li (2000) studied the effect of precipitants using ammonium hydroxide and ammonium hydrogen carbonate (AHC) with a precursor solution ratio of about 1.5 at pH 9. Their comparative study suggests that the YAG powder synthesized using AHC resulted in less agglomeration with crystallite size of about 52 nm. However, neither the precursor concentration, nor the control over the pH was optimized. Apte and Vrolijk (1992, 1990) investigated the best pH range for the precipitating YAG using ammonium hydroxide was investigated and suggested that it was pH 7 – 9. Palmero (2005) investigated the influence of calcination temperature on the phase evaluation of YAG from 800 - 1100°C, but omitted 950 and 1000°C/1h, the powders were over calcined at 1100°C and resulted in large particles with heavy agglomeration. These results suggest that identification of the most suitable processing conditions is still required for the production of fine, nanocrystalline YAG displaying little agglomeration. In the present work, the syntheses of nano YAG by sol-gel and co-precipitation methods are compared with a view to optimising the processing conditions and determining the formation mechanisms.

## 2 Experimental

### 2.1 Materials

99.9%  $\text{Y}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$  and  $\geq 98\%$   $\text{Al}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ , both from Sigma Aldrich, Dorset, UK were used as the source of  $\text{Y}^{3+}$  and  $\text{Al}^{3+}$  ions. 99.9% citric acid, also from Sigma Aldrich, was used as the complexing agent for the sol-gel synthesis. 35% ammonium hydroxide and 99% *n*-butanol, both from Fisher Chemicals, Loughborough, UK were used as the precipitating agent for the cations and for dehydrating them in the co-precipitation method, respectively.

### 2.2 Synthesis

#### 2.2.1 Sol-gel

A solution containing the stoichiometric ratio of 3:5 (Y:Al) was prepared by mixing calculated amounts of 0.6M  $\text{Y}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$  and 1M  $\text{Al}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$  aqueous solutions in 1M citric acid solution. The schematic representation of the sol-gel process is shown in figure 1a. Homogenous mixing was achieved in a round bottom (RB) flask equipped with a magnetic stirrer and a refluxing condenser. The reaction flask was immersed in a thermostatic oil bath and refluxed at  $90 \pm 10^\circ\text{C}$  for 24 hours. During mixing, the transparent precursor sol underwent substitution and polymerization reactions to form a transparent gel, which was then dried in an oven at  $100^\circ\text{C}$  for 24 hours. The fluffy mass obtained after drying was subsequently ground using an agate pestle and mortar for further characterisation.

#### 2.2.2 Co-precipitation

The reverse strike co-precipitation method used involved mixing the same 0.6M  $\text{Y}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$  and 1M  $\text{Al}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$  aqueous solutions for 2 hours. The schematic representation of the co-precipitation process is shown in figure 1b. This precursor solution was placed in a burette and added drop-wise to 200 ml of the aqueous  $\text{NH}_4\text{OH}$  precipitant solution whilst simultaneously stirring and maintaining the pH at  $8.20 \pm 0.05$ . The first few drops of the precursor solution were found to decrease the pH rapidly to 4; therefore excess ammonia solution of 5M concentration was added concurrently to maintain the pH. Continuous monitoring of the pH allowed it to be controlled to  $\pm 0.05$  pH units. The resultant precipitate was filtered, washed three times with dilute ammonia solution of pH 8.2 to remove nitrate residues, and then the filtered precipitate was dispersed

with 20 ml of *n*-butanol using ultrasound for two minutes. The dispersed precipitate was dried at 100°C for 24 hours and ground using the pestle and mortar.

The precursor powders from the sol-gel (SG-nYAG) and co-precipitation (CP-nYAG) routes were then calcined for 1 or 2 h in a silica crucible at temperatures in the range 900 - 1000°C in an air atmosphere, using a heating and cooling rate of 10°C/min.

### **2.3 Powder characterisation**

Thermal analysis of the dried SG-nYAG and CP-nYAG precursor powders was performed using simultaneous TGA/DSC (SDT 2960, TA Instruments, USA). The precursors were weighed to 25 mg and placed into an alumina sample pan with a clean, empty alumina pan used as a reference. All TGA/DSC traces were recorded between 25°C and 1000°C at a ramp rate of 10°C min<sup>-1</sup> under flowing air. Fourier transform-infrared spectroscopy (FT-IR 8400S, Shimadzu, Maryland, USA) was used to identify structural features in the precursors and heat-treated powders. Transmission FTIR was carried out over the wavenumber range of 4000 – 400 cm<sup>-1</sup>. All samples for FTIR measurement were well mixed with KBr in a weight ratio of 1:20 and then pressed into translucent pellets. The crystalline structure of the calcined nano powders was characterised using X-ray diffraction (Bruker D8, Bruker AXS GmbH, Karlsruhe, Germany, fitted with a quarter-circle Eulerian cradle). All the powder samples were analysed at a step size of 0.02° whilst the XRD patterns were recorded from 20° to 90°. TEM, (JEOL JEM 2000FX, JEOL Ltd. Tokyo, Japan) was used to study the particle size of the powders. The samples for TEM were prepared by dispersing the powders in an alcohol medium using ultrasound and then a drop of the suspension was deposited on a carbon film, from Agar Scientific, Stansted, UK. The TEM samples were dried in a laboratory oven at 60°C for 15 minutes and loaded into a single tilt holder. The TEM was operated at 200 kV and the images were obtained at different magnifications.

## **3 Results and Discussion**

### **3.1 TGA/DSC**

The thermal analysis curves for the dried SG-nYAG and CP-nYAG precursor powders are shown in figures 2a and 2b. The curves show 45 wt% and 35 wt% total weight loss for the dried SG-nYAG and CP-nYAG precursor powders respectively. The difference in the weight loss for the co-precipitation route is due the removal of ~10% of the organics in the precipitates during filtering and washing before the heat treatment. Nevertheless,

these results match with the conversion yield of the YAG powders, 19.6 wt %, after thermal decomposition of the precursors from both the methods. The substantial weight loss from 100–600°C is associated with the decomposition of the organics in the precursors. The difference in total weight loss between the powders and the crystallisation kinetics are described with the endotherms and exotherms provided by the DSC analyses.

For the SG-nYAG powder, figure 2a, an endothermic peak near 390°C corresponds to the decomposition of  $\text{NO}_3^-$  and  $\text{CO}_2$  (Lu et al. 2002) due to the redox reaction between them, where citrate acts as a reductant and the nitrate as an oxidant (Li et al. 2008). The second endothermic peak at 450°C is attributed to the oxidation of free carbon from the incomplete combustion of carboxylate groups in the citric acid (Li et al. 2008). As the temperature exceeded 600°C, the weight loss became insignificant and the transition of the crystalline phase proceeded with the change in heat capacity. An exothermic peak observed near 917°C indicates the onset crystallization temperature,  $T_c$ .

The DSC result for the CP-nYAG powder, figure 2b, confirms that the loss of organics during heat treatment is less than for the SG-nYAG powder and the reaction mechanism is simpler. The first endothermic peak near 170°C can be attributed to the removal of butanol; this is due to the substitution of surface hydroxyl groups by the butoxyl groups in the precipitates (Qiu et al. 1995). The small endothermic peaks from 300 - 500°C are due to the decomposition of residual  $\text{CO}_2$ ,  $\text{NO}_2$  and  $\text{NH}_4$  in the powder. These endotherms explain the difference in weight loss in the TGA curves between the two powders. The excess hydroxyl molecules and  $\text{NO}_3^-$  ions will be removed during the filtering stage in the co-precipitation process. The exotherm observed near 916°C corresponds to the onset crystallisation temperature for YAG (similar to the SG-nYAG powder).

### 3.2 FT-IR analysis

Further investigation of the crystalline transition and the decomposition pathways of the two powders were performed using FT-IR spectroscopy. The goal was to obtain an improved understanding of the crystallisation kinetics and the relevant formation mechanisms.

FT-IR spectra from 4000 - 400  $\text{cm}^{-1}$  for the two powders after heat treatment at different temperatures are shown in figures 3a and 3b. The broad absorption bands near  $\sim 3450 \text{ cm}^{-1}$  and  $\sim 1630 \text{ cm}^{-1}$  in both powders at 100°C are associated with the O-H stretching vibrations of coordinated water molecules and the characteristics of H–O–H bending modes of molecular water (Su et al. 2005, Tanner et al. 2003).

The COOH functional groups, chelating ligands, near  $\sim 1729$ ,  $\sim 1450$  and  $\sim 1323$   $\text{cm}^{-1}$  in the SG-nYAG curve, figure 3a, after drying at  $100^\circ\text{C}$  are associated with the carboxyl vibrations of the citric acid. The weak band near  $\sim 1729$   $\text{cm}^{-1}$  coincides with  $\nu(\text{C}=\text{O})$  stretching (Ojamäe et al. 2006), which suggests that not all the carboxyl groups are bonding with the metal cations or free  $\nu(\text{C}=\text{O})$  exists. The other two bands near  $\sim 1450$   $\text{cm}^{-1}$  and  $\sim 1323$   $\text{cm}^{-1}$  are associated with the symmetric  $\nu_s(\text{C}=\text{O})$  and asymmetric  $\nu_{as}(\text{C}=\text{O})$  vibrations (Rajendran and Rao 1994, Xia et al. 2005), which implies that the dissociated carboxylic ions from the citric acid react to form bonds with the  $\text{Al}^{3+}$  and  $\text{Y}^{3+}$  ions, forming a coordinative complex structure between the ligands and the metal ions (Motta et al. 2008, Tanner et al. 2003). The nitrate groups were also observed at  $\sim 1380$   $\text{cm}^{-1}$  and  $\sim 825$   $\text{cm}^{-1}$ , which corresponds to  $\nu(\text{NO}_2)$  and  $\nu(\text{NO}_3)$ , respectively (Li et al. 2008). After heat treatment at  $600^\circ\text{C}$ , the unreacted  $\nu(\text{C}=\text{O})$ ,  $\nu(\text{NO}_3)$  and  $\delta(\text{CO})$  scissoring band ( $\sim 1037$   $\text{cm}^{-1}$ ) disappear and some traces of the  $\nu_{as}$  and  $\nu_s$  of  $\text{C}=\text{O}$ , along with  $\nu(\text{NO}_2)$  vibrations, are still present in the SG-nYAG curve. This demonstrates that  $\nu_{as}$  and  $\nu_s$  ( $\text{C}=\text{O}$ ) and  $\nu(\text{NO}_2)$  were involved in the redox reaction (Li et al. 2008) and also supplements the thermal analysis results for the SG-nYAG powder. After heat treating at  $925^\circ\text{C}$ , the new bands near  $\sim 783$ ,  $\sim 713$  and  $\sim 680$   $\text{cm}^{-1}$ , associated with the metal–oxygen vibration characteristics of  $\text{Al}-\text{O}$ ,  $\text{Y}-\text{O}$ , and  $\text{Y}-\text{O}-\text{Al}$  stretching confirms the formation of the YAG phase<sup>(15)</sup> and also coincides with the onset crystallisation peak observed from the DSC results. Nevertheless, the  $\nu(\text{NO}_2)$  vibration is still present in the SG-nYAG powder after heat treatment at  $1000^\circ\text{C}$  for 1h, which suggest that some traces of nitrate persists, even after calcination with the sol-gel route.

The FT-IR spectra for the as-dried CP-nYAG powder, figure 3b, displayed very few functional groups when compared to the dried SG-nYAG powder. This also confirms the reaction mechanism between the precipitations is simple and most of the organics were removed during the washing process. The bands near  $\sim 1460$   $\text{cm}^{-1}$  and  $\sim 1380$   $\text{cm}^{-1}$  are associated with the vibrations of  $\nu(\text{NH})$  and  $\nu(\text{NO}_2)$  (Chen et al. 2007), whilst the peak intensities of the  $\text{H}-\text{O}-\text{H}$  bending modes ( $\sim 1630$   $\text{cm}^{-1}$ ) and  $\nu(\text{NO}_2)$  were apparently low and the  $\nu(\text{NO}_3)$  vibrations present in the SG-nYAG ( $100^\circ\text{C}$ ) trace were absent in the equivalent CP-nYAG curve. This could be due to the effect of ammonia washing and the dehydration effect of the *n*-butanol treatment on the precipitates. The intensities of these bands were further reduced in the CP-nYAG curve after heat treatment at  $600^\circ\text{C}$  and there was also agreement with the thermal decomposition results. On further heat treatment at  $925^\circ\text{C}$ , the triplet bands formed between  $800 - 600$   $\text{cm}^{-1}$  correspond to the vibrations of  $\text{Al}-\text{O}$ ,  $\text{Y}-\text{O}$  and  $\text{Y}-\text{O}-\text{Al}$  stretching, which coincides with the crystallisation peak of the DSC analysis. Moreover, the  $\nu(\text{NO}_2)$  band present in the SG-nYAG after calcination at  $1000^\circ\text{C}$  for 1 hour is absent in the equivalent curve for the CP-nYAG powder, which confirms that the nitrate ions are removed during the co-precipitation synthesis method.

### 3.3 XRD - YAG formation

Figures 4a and 4b show the phase evolution as a function of temperature and time for the SG-nYAG and CP-nYAG powders respectively. The obtained peaks are compared with the standard JCPDS card no: 33-0040.

After being heat-treated at 900°C for 2 h and 925°C for 1 h, some traces of the metastable hexagonal h-YAlO<sub>3</sub> (YAH) phase was observed for both the SG-nYAG and CP-nYAG powders. However, after heat treating at 925°C for 2 h, no detectable YAH phase was observed for the CP-nYAG powder; whilst the SG-nYAG powder still displayed characteristic peaks of the YAH phase. These peaks were still present after 1 h at 950°C, but disappeared after heat treating for 1 h at 1000°C for the SG-nYAG powders. Thus, after heat treatments of 2 h at 925°C (CP-nYAG) and 1 h at 1000°C (SG-nYAG), all the peak positions matched with the standard YAG diffraction reference pattern and no intermediate phases such as YAM or YAP were observed. Only the metastable YAH formed as an intermediate, which subsequently transformed to YAG at elevated temperatures.

### 3.4 Mechanisms of YAG formation

Possible mechanisms for YAG formation via the sol-gel and co-precipitation routes are proposed based on the analytical evidence obtained from the thermal analysis, FT-IR spectroscopy and XRD of the precursor powders after heat treatment at different temperatures.

#### 3.4.1 Sol-gel mechanism

The mixing of citric acid, C<sub>3</sub>H<sub>4</sub>OH (COOH)<sub>3</sub>, with deionised water results in partial dissociation of H<sup>+</sup> ions from the chelating ligands (COOH) and protonation of the water, equation 1. The solvation of the metal cations, introduced as metal nitrates is described by equation 2 (Brinker and Scherer 1990).

The second step involved adding the solvated precursor solution into the citrate solution to achieve the substitution reaction given in equation 3. A coordinative complex structure was formed between the metal cations and citrate anions (Blosi et al. 2009).

During drying, the precursor sol partially hydrolysed to form a cross-linked polymer chain between the chelating ligands and the metal ions, i.e. it formed a gel that was, in turn, dried to form a porous fluffy mass, which was ground further and then calcined. Equation 4 and 5 show the reactions being followed during calcination:

During calcination at 1000°C, the transformation of the  $(COO^-)_3 Y^{3+} - Al^{3+} (COO^-)_3$  network to metal oxygen bonding (M-O-M) took place and complete crystallisation was achieved, as supported by the thermal analysis and XRD data. A thermally induced anionic redox reaction (reduction and oxidation) took place between the  $(COO^-)_3$  and the  $NO_2^-$ , with the citrate acting as a reductant and the nitrate as an oxidant (Li et al. 2008).

### 3.4.2 Co-precipitation mechanism

The co-precipitation process for YAG requires an accurate control over the pH. This is because of the difference in saturation solubility of the yttrium hydroxide and amphoteric aluminium hydroxide (which can react as both an acid and a base). These are stable at different pH range, i.e. pH 7 - 9 for  $Y(OH)_3$  and pH 5 - 9 for  $Al(OH)_3$  (Pourbaix 1974). If the pH is not maintained between the above specified ranges, then the hydroxides redissolve into  $M^{3+}$  ions,  $M = Y$  or  $Al$ , resulting in a heterogeneous precipitation. Besides the pH control, the particle size of the precipitate was controlled by the concentration of the precipitating species and the nucleation and growth of the precipitates (Townshend and Jackwerth 1989).

In this process, the stoichiometric amounts of yttrium and aluminium nitrate were mixed to obtain an aqueous solution of the metal ions and  $HNO_3$ , equation 2. Equation 6 explains the co-precipitation reaction between the solvated precursor solution and the  $NH_4OH_{(aq)}$  solution. The presence of nitrate ions in the precursor solution makes it even more critical to sustain the pH for precipitation. Therefore, the concentrated precipitant solution was added concurrently to maintain the pH. In the present work, the concentration ratio of the precursor solution was kept at <1, a narrow pH window ( $\pm 0.05$ ) was maintained and a precipitation rate of about 4 ml/min was used to control the nucleation and growth of the homogenous precipitates. In addition, a nucleophilic substitution reaction between the precursor solution and the  $NH_4OH$  occurred yielding an aqueous ammonium nitrate ( $NH_4NO_3$ ) and  $H_2O$ .

Equation 7 describes the possible reaction mechanism during calcination. The metal hydroxides are oxidized to form an amorphous Y-O-Al (M-O-M bonding) network and the atomic diffusion between them transformed to a crystalline YAG phase at 925°C. The overall reaction is accompanied by the thermal decomposition of the volatiles and crystallisation kinetics of the CP-nYAG precursor as obtained from thermal analysis, FT-IR and XRD.

### 3.5 TEM morphology

Figure 5 shows the TEM images of the SG-nYAG and CP-nYAG powders. It is evident that for both powders the primary particle size is in the range between 20-30 nm and a significant degree of agglomeration occurs for the SG-nYAG powder, figures 5a and 5b. This could be due to the complex networking of metal ions in the gel matrix, which the organics were burned off from the network, and led to a severe agglomeration of the primary particles.

When the results obtained in the present work are compared to the literature, the particle size observed by (Chen et al. 2007, Wang et al. 2000), both using co-precipitation, was in a similar region, 30-60 nm, but their powders displayed a higher degree of agglomeration. One reason for our CP-nYAG particles being a little finer, figures 5c and 5d, might be due to the lower calcination temperature used, whilst the reduced degree of agglomeration might be attributed to three possible effects, (i) controlling the pH with a minimal tolerance, (ii) suitable thermal conditions for precipitation and (iii) dehydrating the hydroxyl ions by the *n*-butanol treatment.

Controlling the pH is considered to be the most important factor during co-precipitation reactions. In this case, the precipitating conditions for Y<sup>3+</sup> and Al<sup>3+</sup> ions are different for nitrate precursors; Y<sup>3+</sup> ions precipitates at pH 8.1 whilst Al<sup>3+</sup> precipitates at pH 3.5 (Apte et al. 1992). To avoid the heterogeneity of the co-precipitation, aqueous solutions of Y<sup>3+</sup> and Al<sup>3+</sup> ions were mixed and added drop-wise to the precipitant solution, which was maintained at pH 8.20±0.05 by adding concentrated NH<sub>4</sub>OH concurrently. It was observed that when the pH of the precipitant solution increased or decreased by just 0.10, both the homogeneity and the morphology of the precipitates changed, Figure 6.

From Figure 6a, it is clear that whilst the precipitates are approximately spherical, there was a significant variation of their size, which is due to the difference in precipitating conditions of  $Y^{3+}$  and  $Al^{3+}$  ions. When the pH was maintained at  $8.20 \pm 0.05$ , Figure 6b, the hydroxides of the mixed metal cations displayed a stable nanostructure and the precipitates were found to be discrete and to have a uniform size distribution. In contrast, bulk precipitation morphology is displayed in Figure 6c. When the pH was increased to  $8.30 \pm 0.05$ , the precipitation reaction surpasses the saturation limit and resulted in agglomeration of the precipitates. This could be due to the excess  $OH^-$  ions provided by the  $NH_4OH$  solution, which dissolves  $Al(OH)_3$  (acts as a Lewis acid) into  $AlO_2^-$  ions (Pourbaix 1974) and resulted in heterogeneous precipitation. At the best pH conditions ( $8.20 \pm 0.05$ ) a closer look at the nanostructure of the precipitates reveals the formation of a clear core-shell structure, figure 7, during the co-precipitation process. Similar results were reported by Wang (2000) at pH values of 8 which retard the agglomeration.

The effect of processing temperature is shown in the figure 8. From the results, it is evident that the thermal conditions such as  $10 \pm 1^\circ C$  and  $20 \pm 1^\circ C$  (figure 8a and 8c) resulted in bulk precipitation, which could result in composition inhomogeneity and particle agglomeration. The precipitates processed between these conditions,  $13 \pm 3^\circ C$  (figure 8b), offered a homogenous precipitation. The TEM result suggests that a suitable processing temperature is also appears to be required for obtaining homogenous precipitates.

During the *n*-butanol treatment, the surface hydroxyl groups are replaced by the butoxyl groups and thus form an azeotropic layer (Qiu et al. 1995), which acts as a potential barrier between the particles. Due to the low surface tension of *n*-butanol compared to water, the binding force among the particles decreased whilst drying and so hard agglomeration caused by the capillary forces was avoided. Consequently, depletion of the excess  $OH^-$  ions in the precipitates controlled the agglomeration during drying and resulted in soft agglomerates of the dried precipitates.

#### **4 Conclusions**

Nanocrystalline YAG powders have been synthesised *via* sol gel and co-precipitation using nitrate precursors. The thermal and phase evolution for the formation of nYAG were investigated using DTA/DSC, FT-IR and XRD techniques. It has been observed that  $925^\circ C/2h$  and  $1000^\circ C/1h$  are the optimum temperatures to calcine nYAG by the co-precipitation and sol-gel methods respectively. From the TEM morphologies, the CP-nYAG route yielded particle sizes of 25-30 nm with less agglomeration when compared to the sol-gel synthesis. The

proposed co-precipitation mechanism suggests that an extremely narrow pH range ( $8.2\pm 0.05$ ), processing temperature ( $13\pm 3^\circ\text{C}$ ) and the effective dehydration of n-butanol appears to be required for production of a homogeneous nYAG powder.
