*Cryptococcus neoformans* is an opportunistic fungal pathogen and a leading cause of fungal-infection-related fatalities, especially in immunocompromised hosts. Several virulence factors are known to play a major role in the pathogenesis of cryptococcal infections, including the enzyme phospholipase B1 (Plb1). Compared to other well-studied *Cryptococcus neoformans* virulence factors such as the polysaccharide capsule and melanin production, very little is known about the contribution of Plb1 to cryptococcal virulence. Phospholipase B1 is a phospholipid-modifying enzyme that has been implicated in multiple stages of cryptococcal pathogenesis, including initiation and persistence of pulmonary infection and dissemination to the central nervous system, but the underlying reason for these phenotypes remains unknown. Here we demonstrate that a  $\Delta plb1$  knockout strain of *C. neoformans* has a profound defect in intracellular growth within host macrophages. This defect is due to a combination of a 50% decrease in proliferation and a 2-fold increase in cryptococcal killing within the phagosome. In addition, we show for the first time that the  $\Delta plb1$  strain undergoes a morphological change during *in vitro* and *in vivo* intracellular infection, resulting in a subpopulation of very large titan cells, which may arise as a result of the attenuated mutant's inability to cope within the macrophage.

*Cryptococcus neoformans* is a pathogenic fungus that can cause severe and often fatal meningoencephalitis, especially in immunocompromised hosts. In recent years, *C. neoformans* has become a major emerging pathogen, due largely to the global HIV pandemic. In sub-Saharan Africa, for example, *C. neoformans* likely accounts for up to 44% of fatal HIV-related secondary infections (1). During infection, *C. neoformans* is known to interact closely with host macrophages (2) following inhalation of infectious spores from the environment into the lungs (3). Many virulence factors expressed by *C. neoformans* allow the fungus to evade phagocytosis by macrophages or to improve survival once phagocytosed (4).

One such virulence factor is phospholipase B1 (Plb1), a phospholipid-modifying enzyme with multiple enzymatic activities (5). In cryptococcal cells, a significant proportion of Plb1 enzymatic activity is cell wall associated, although secretion of Plb1 from *Cryptococcus* is known to occur *in vitro* (6). Plb1 is secreted following cleavage of a glycosylphosphatidylinositol (GPI) anchor motif, which anchors the enzyme to the cell wall (7, 8), and export of Plb1 to the cell wall is facilitated by Sec14-1, which is part of *C. neoformans*'s protein export system (9). Plb1 has optimal activity under acidic conditions, at around pH 4.0 to 5.0 (conditions similar to that of the phagosome), and is active at 37°C (10).

In line with this putative role in pathogenesis, deletion of *PLB1* strongly attenuates virulence in *C. neoformans* (9, 11–13). Mice infected with a *PLB1* deletion *C. neoformans* strain ( $\Delta plb1$ ) show reduced fungal burden in the lungs (9). In addition, during murine infection Plb1 appears to be required for cryptococcal dissemination from the lungs into the bloodstream (12) and additionally may be involved in the translocation of cryptococcal cells across the blood-brain barrier into the brain (14).

The reason why the  $\Delta plb1$  strain is attenuated during infection has not yet been fully elucidated. In this study, we sought to explore the role of Plb1 during macrophage infection. We report that Plb1 is critical for both proliferation and survival within the macrophage. In addition, we show that the  $\Delta plb1$  strain responds to macrophage infection by significantly increasing both capsular diameter and overall cell size within the phagosome and in the murine lung. This morphology is reminiscent of previously reported titan cells (15–17) and suggests that control of cryptococcal cell size by Plb1 may play a vital role in the outcome of host macrophage infection.

## MATERIALS AND METHODS

**Ethics statement.** A total of 14 mice were handled in strict accordance with good animal practice, as defined by the relevant national and/or local

animal welfare bodies. All animal work was approved by the University of Minnesota Institutional Animal Care and Use Committee (IACUC) under protocol no. 1308A30852.

**Strains, media, and cell lines.** The strains used in this work are listed in Table 1. Strains were stored long-term in MicroBank vials at  $-80^{\circ}\text{C}$ . Strains were rescued onto yeast extract-peptone-dextrose (YPD) agar (YPD, 50 g/liter [Sigma-Aldrich]; 2% agar [Melford]) for 48 h at  $25^{\circ}\text{C}$  and then stored until needed at  $4^{\circ}\text{C}$ . Before experimentation, liquid cultures were grown from these stock plates in 2 ml YPD growth medium (50 g/liter) for 24 h at  $25^{\circ}\text{C}$  under constant rotation.

The J774 murine macrophage cell line was used for all *in vitro* infection assays. Cells were passaged in Dulbecco's modified Eagle medium (DMEM) culture media with serum (DMEM, low glucose, from Sigma-Aldrich; 10% fetal bovine serum [FBS] from Invitrogen; 1% 10,000 units penicillin–10 mg streptomycin from Sigma-Aldrich; 1% 200 mM L-glutamine from Sigma-Aldrich). Assays were performed with J774 cells between passages 4 and 15. Assays were performed in serum-free DMEM (DMEM [high glucose], 1% penicillin-streptomycin, 1% L-glutamine) unless otherwise stated.

**Intracellular proliferation assay.** The intracellular proliferation assay was performed as previously described (18). Briefly, 24 h before infection,  $1 \times 10^5$  J774 macrophages were seeded onto 24-well plastic plates (Greiner Bio One Cell Star) in 1 ml culture medium with serum and incubated for 24 h at  $37^{\circ}\text{C}$  and 5%  $\text{CO}_2$ . Before infection, J774 cells were activated with 150 ng/ml phorbol 12-myristate 13-acetate in dimethyl sulfoxide (DMSO; Sigma) in 1 ml serum-free culture medium for 45 min. This medium was then replaced with serum-free medium alone. Simultaneously, overnight *C. neoformans* cultures grown at  $25^{\circ}\text{C}$  in YPD were washed three times in sterile  $1 \times$  phosphate-buffered saline (PBS), quantified, and adjusted to  $1 \times 10^7$  cells per ml in PBS before opsonization for 1 h with 10  $\mu\text{g}/\text{ml}$  anticapsular 18B7 antibody (a kind gift from Arturo Casadevall, Albert Einstein College of Medicine, New York, NY, USA). The activated J774 cells were then infected with 100  $\mu\text{l}$  opsonized *C. neoformans* to give a multiplicity of infection (MOI) of 10 (e.g.,  $1 \times 10^5$  J774 cells for  $1 \times 10^6$  *C. neoformans* cells) in unsupplemented serum-free DMEM and incubated for 2 h at  $37^{\circ}\text{C}$ , 5%  $\text{CO}_2$ . After 2 h (time point 0), infected wells were washed at least 3 times with warm  $1 \times$  PBS until all nonphagocytosed *C. neoformans* cells were removed from the wells.

For calculation of the intracellular proliferation rate, the number of internal cryptococci was determined at time points 0, 18, and 24 (time points 0, 0 + 18 h, and 0 + 24 h, respectively). At each time point, each well to be counted was washed three times with  $1 \times$  PBS to remove any extracellular yeast. The macrophages in the well were then lysed in distilled water for 30 min. *C. neoformans* cells in the lysate were quantified at each time point with a cell-counting chamber, and the intracellular proliferation rate (IPR) was calculated by dividing the count at which the intracellular burden peaked by the count at time point 0. Viability testing of the recovered cells was achieved by diluting the lysate to give a concentration of 200 yeast cells per 100  $\mu\text{l}$  and then plating onto YPD agar at  $25^{\circ}\text{C}$  for 48 h prior to counting CFU.

**Phagocytosis assay.** Twenty-four hours before assaying, J774 macrophages were seeded onto 13-mm glass coverslips (nitric acid treated) inside 2-cm<sup>2</sup> 24-well plates at a concentration of  $1 \times 10^5$  cells per ml in 1 ml

DMEM culture medium with serum and incubated at  $37^{\circ}\text{C}$  and 5%  $\text{CO}_2$ . Activation and infection of the macrophages with opsonized *C. neoformans* cells followed the same protocol as described above for the intracellular proliferation assay. After 2 h of incubation, the cells were washed 3 times with  $1 \times$  PBS to remove unphagocytosed cells and then fixed for 10 min with 250  $\mu\text{l}$  4% paraformaldehyde in PBS at  $37^{\circ}\text{C}$ . Following fixation, coverslips were washed with  $1 \times$  PBS and sterile deionized water and mounted on glass slides using Mowiol mountant (100 mM Tris-HCl [pH 8.5], 9% Mowiol, 25% glycerol). Mounted coverslips were analyzed on a Nikon Ti-S inverted microscope fitted with a Plan apochromatic (APO) 60  $\times$  1.40 differential interference contrast (DIC) oil immersion objective.

**Cell size assay.** J774 cells were plated into 24-well plates, activated, and infected with opsonized *C. neoformans* strains as described above for the IPR assay. Two hours postinfection, each well was washed at least 3 times with warm  $1 \times$  PBS until all nonphagocytosed *C. neoformans* cells were removed from the wells, and 1 ml serum-free DMEM was then added to each well.

The 24-well plate was placed into an environmentally controlled stage (Okolabs) set to  $30^{\circ}\text{C}$ , 5%  $\text{CO}_2$ . The cells were imaged using a Nikon TE2000 microscope fitted with a Digital Sight DS-Qi1MC camera and a Plan APO Ph1 20 $\times$  dry objective. Images were recorded every 4 min for 20 h. Image acquisition and analysis was performed using the Nikon NIS Elements software package (Nikon).

Cell size was measured using the ellipse area tool, measuring from the center of each *Cryptococcus* cell to the edge, to obtain the diameter of each cell.

***In vivo* titan cell and phagocytosis assay.** *Cryptococcus neoformans* cells were grown in YPD broth overnight. Cells were pelleted and resuspended in sterile phosphate-buffered saline at a concentration of  $1 \times 10^7$  cells/ml based on hemocytometer count. Groups of 6- to 8-week-old female A/J mice (Jackson Laboratory, Bar Harbor, ME) were anesthetized by intraperitoneal pentobarbital injection. Four to five mice per treatment were infected intranasally with  $5 \times 10^5$  cells in 50  $\mu\text{l}$  PBS. At 3 days postinfection, mice were sacrificed by  $\text{CO}_2$  inhalation. Lungs were lavaged with 1.5 ml sterile PBS three times using a 18.5-gauge needle placed in the trachea. Cells in the lavage fluid were pelleted and fixed in 3.7% formaldehyde at room temperature for 30 min. Cells were washed once with PBS, and >500 cells per animal were analyzed for size by microscopy (AxioImager, Carl Zeiss, Inc.). Cell body sizes were measured, and cells were classified as small cells (<15  $\mu\text{m}$  in cell body diameter) or titan cells (>15  $\mu\text{m}$  in cell body diameter).

**Titan cell flow cytometry.** H99 was cultured in YPD broth overnight. Cells were pelleted, washed three times in PBS, and fixed in 3% paraformaldehyde at room temperature for 10 min. Bronchoalveolar lavage (BAL) samples were washed once in 0.05% sodium dodecyl sulfate (SDS) to lyse mammalian cells and then washed three times in sterile water. Cells were pelleted and fixed in 3% paraformaldehyde at room temperature for 10 min. Following fixation, samples were washed with PBS, stained with 0.5  $\mu\text{g}/\text{ml}$  Hoechst (Sigma, St. Louis, MO) at room temperature for 10 min, washed again with PBS, and then resuspended in PBS. Approximately 10,000 cells were examined for cell size by forward scatter (FSC) and for DNA content by Hoechst staining using an LSR II flow cytometer with FACSDiva software (BD Biosciences, San Jose, CA). Graphs were generated using Flowjo software (Tree Star, Inc., Ashland, OR). The *t* test was used to analyze the differences in titan cell formation and phagocytosis, and *P* values of <0.05 were considered significant.

**Cell stress.** Overnight *C. neoformans* cultures in 2 ml YPD were grown at  $25^{\circ}\text{C}$ . Cultures were diluted 1:1,000 into 500  $\mu\text{l}$  buffered YPD (pH 7.0, 15 mM HEPES) in plastic-bottomed 48-well plates (Greiner) with various concentrations of SDS (0, 0.01, 0.05, 0.1, 0.25, and 0.5 mM), of  $\text{H}_2\text{O}_2$  (0, 0.125, 0.25, 0.5, 1, 3, 6, and 14 mM), or of NaCl (0, 125, 250, 500, 1,000 mM). The plate was then sealed with a breathable membrane, and growth curve assays were performed for 24 h at  $30^{\circ}\text{C}$  in a Fluostar Omega plate reader using a custom script that took 600-nm absorbance readings from

**FIG 1** (A) Percentages of macrophages within a population that show *C. neoformans* infection following 2-h incubation with opsonized cryptococci at an MOI of 1:10 ( $n = 4$ ). A minimum of 500 macrophages were counted for each condition. (Unpaired *t* test was performed, no significance.) (B) Total burden of infection within a fixed population of J774 cells ( $1 \times 10^5$ ) following 2-h incubation with opsonized cryptococci at an MOI of 1:10 ( $n = 9$ ). \*\*\*, H99 versus  $\Delta plb1$  strain,  $P = 0.0003$ ; \*\*,  $\Delta plb1$  versus  $\Delta plb1::PLB1$  strains,  $P = 0.0038$  (unpaired *t* test).

the bottom of the plate every 30 min. Between reads, the plate was shaken at 200 rpm with a linear shaking pattern.

**Statistics.** Unless otherwise stated, all statistics were performed using Prism Graphpad software. For cell size measurement comparison between time points, a Mann-Whitney U test was performed (e.g., StrainX 0 h versus StrainX 18 h). Unless stated otherwise, a *P* value below 0.05 was taken as significant. Unless otherwise stated, all figures have error bars representing standard errors. Significance is shown on figures by asterisks as follows: \*,  $P \leq 0.05$ ; \*\*,  $P \leq 0.01$ ; \*\*\*,  $P \leq 0.001$ ; and \*\*\*\*,  $P \leq 0.0001$ .

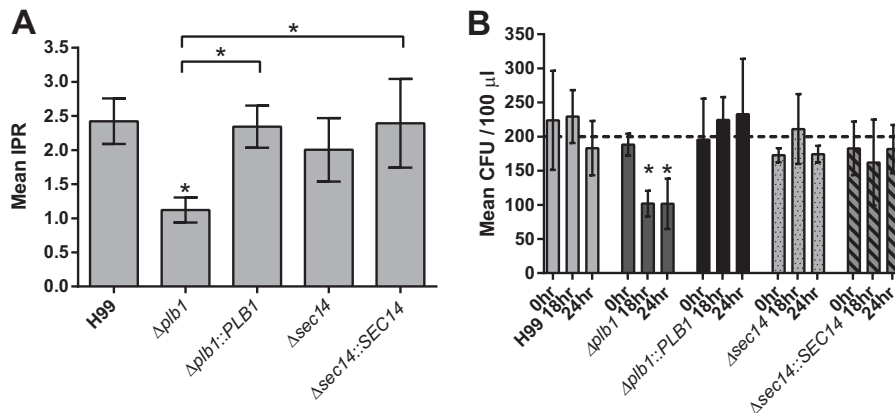

**RESULTS**

**Plb1 deficiency leads to increased uptake of *C. neoformans* cells by J774 macrophages.** We first assessed to what extent the *PLB1* knockout strain,  $\Delta plb1$  strain, was phagocytosed by macrophages in comparison to the wild-type parent strain H99 and a genetically reconstituted strain,  $\Delta plb1::PLB1$  strain. We found that, following 2 h of infection, the percentage of J774 murine macrophages with at least one internalized *C. neoformans* cell did not differ significantly between wild-type strain H99,  $\Delta plb1$  strain, and  $\Delta plb1::PLB1$  reconstituted strain (Fig. 1A). Quantification of the fungal burden per macrophage, however, revealed a 2-fold increase in the

number of  $\Delta plb1$  cells phagocytosed per host cell (Fig. 1B,  $P = 0.0003$ ). This suggests that Plb1 activity contributes significantly to the well-known antiphagocytic phenotype of cryptococci.

**Plb1 is required for intracellular proliferation of *C. neoformans* within J774 macrophages.** *PLB1* knockout leads to a reduced fungal lung burden during murine infection; in addition, it abrogates dissemination to the brain (9, 14) and has previously been shown to reduce budding of *C. neoformans* within macrophages (11). To investigate this phenotype further, we performed an intracellular proliferation rate assay. We observed an intracellular proliferation defect for the  $\Delta plb1$  strain versus the wild-type strain (IPR = 1.12 versus 2.42 for H99;  $P = 0.023$ ), a defect that was fully restored in the  $\Delta plb1::PLB1$  reconstituted strain (Fig. 2A). Interestingly, no intracellular proliferation defect was observed when we tested the  $\Delta sec14$  strain (Fig. 2A). Since Sec14-1 is required for efficient secretion of Plb1 (9), it appears that intracellular, but not secreted, Plb1 is important for proliferation within host cells.

Due to the increased efficiency of  $\Delta plb1$  cell uptake observed, we wondered whether the reduced proliferation we see for  $\Delta plb1$

**FIG 2** (A) Mean intracellular proliferation rate for each *C. neoformans* strain within murine J774 macrophages ( $n = 3$ ). \*, H99 versus  $\Delta plb1$  strain,  $P = 0.023$ ; \*,  $\Delta plb1$  versus  $\Delta plb1::PLB1$  strains,  $P = 0.033$ ; \*,  $\Delta plb1$  versus  $\Delta sec14::SEC14$  strains,  $P = 0.0263$  (one-way analysis of variance [ANOVA] plus Tukey posttest). (B) Viability of *C. neoformans* cells recovered from J774 macrophages following the IPR assay. Cells recovered following macrophage lysis were counted and diluted, giving an expected plated inoculum of 200 cells ( $n = 4$ ). \*,  $\Delta plb1$  strain 0 h versus  $\Delta plb1$  strain 18 h,  $P = 0.0422$ ; \*,  $\Delta plb1$  strain 0 h versus  $\Delta plb1$  strain 24 h,  $P = 0.0415$  (two-way ANOVA plus Tukey posttest comparing time points for each strain).

cells simply reflects initial overcrowding within the host macrophage. To test this, we reduced the uptake of  $\Delta plb1$  cells by omitting the opsonization step before infection. Infecting with unopsonized *Cryptococcus* reduced uptake for all three strains (see Fig. S1Ci in the supplemental material: unopsonized *Cryptococcus* can still be phagocytosed by macrophage but at a lower rate [19, 20]) but did not alter the growth defect observed (see Fig. S1Cii in the supplemental material). To test a different method of opsonization, we also tried opsonizing with pooled serum instead of antibody. At the concentration used (5% pooled human serum), we did not see significant differences in uptake, compared to antibody opsonization (see Fig. S1Bi in the supplemental material), and the proliferation defect remained (see Fig. S1Bii in the supplemental material). Taken together, these data suggest that Plb1 plays a direct role in regulating intracellular proliferation in cryptococci regardless of the fungal intracellular burden.

**Plb1 contributes to *C. neoformans* cell survival during infection.** The low intracellular proliferation defect observed for  $\Delta plb1$  could be due to slower *Cryptococcus* proliferation and/or increased intracellular killing by the macrophage. To address the second possibility, we plated *C. neoformans* cells recovered from macrophages at 18 and 24 h postinfection on YPD agar to enumerate CFU. No significant difference in CFU among any of the five strains was seen at time point 0 (2 h postinfection); however, at time point 18 (20 h postinfection), the viability of  $\Delta plb1$  strain but not that of the  $\Delta sec14-1$  strain had dropped significantly ( $P = 0.04$ ) (Fig. 2B) compared to that of H99. Taken together, these data suggest that both growth and survival of the  $\Delta plb1$  strain are impaired within the phagosome during macrophage infection.

**Plb1 deficiency does not significantly affect cryptococcal stress responses.** We hypothesized that low IPR in the macrophage may be a result of stressful conditions during macrophage infection—possibly because the  $\Delta plb1$  strain is unable to control or resist cellular stresses within the macrophage. However, exposing the  $\Delta plb1$  strain to a variety of stresses showed no significant difference from the wild type other than the previously reported susceptibility to SDS (9) (Fig. 3A and B).

**PLB1 knockout leads to changes in cryptococcal cell body morphology.** During the course of this work, we noticed that some  $\Delta plb1$  cells showed a marked increase in cell body diameter within infected macrophages, a morphology that was not observed for H99 or the  $\Delta plb1::PLB1$  strain (Fig. 4E and F). Quantification of this phenomenon (Fig. 4) showed that the diameter of both the cell body and the capsule of  $\Delta plb1$  cells increased significantly during an 18-h macrophage infection (Fig. 4A to E). Interestingly, we observed a significant decrease in cell diameter for H99 and  $\Delta plb1::PLB1$  cells over the same incubation period (see Table S1 in the supplemental material), which is probably due to active cell budding occurring within the macrophage, leading to a drop in mean diameter for the overall population. Extending the period of live cell imaging to 48 h, we found that the enlarged  $\Delta plb1$  cells did not noticeably increase in size after 18 h postinfection.

Changes in *Cryptococcus* cell size during *in vivo* infection have been previously documented, ultimately resulting in the production of very large titan cells (15–17, 21). To our knowledge, though, this is the first published observation of a similar (albeit less dramatic) process occurring within a macrophage (rather than extracellularly) and the first time that *PLB1* has been implicated in this pathway. Previous studies have reported that the size

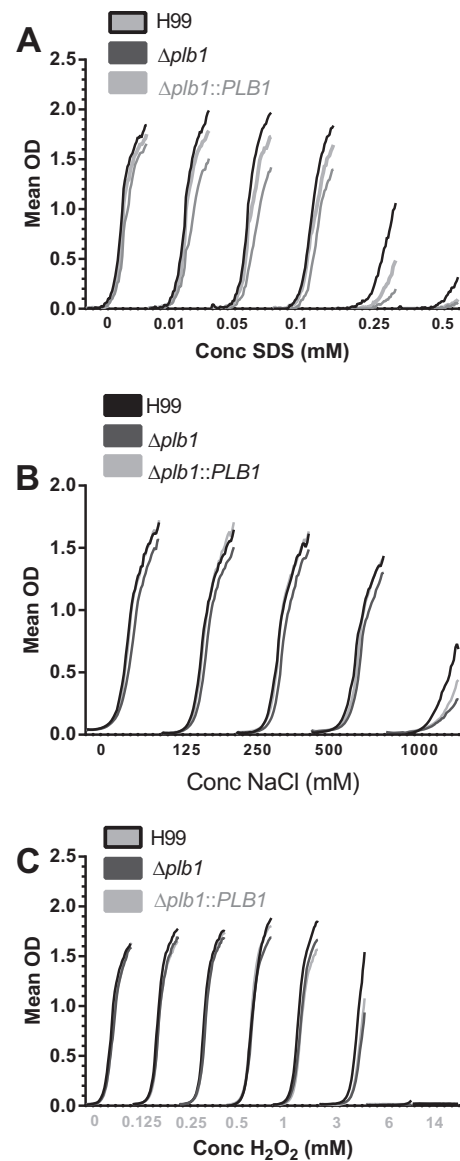

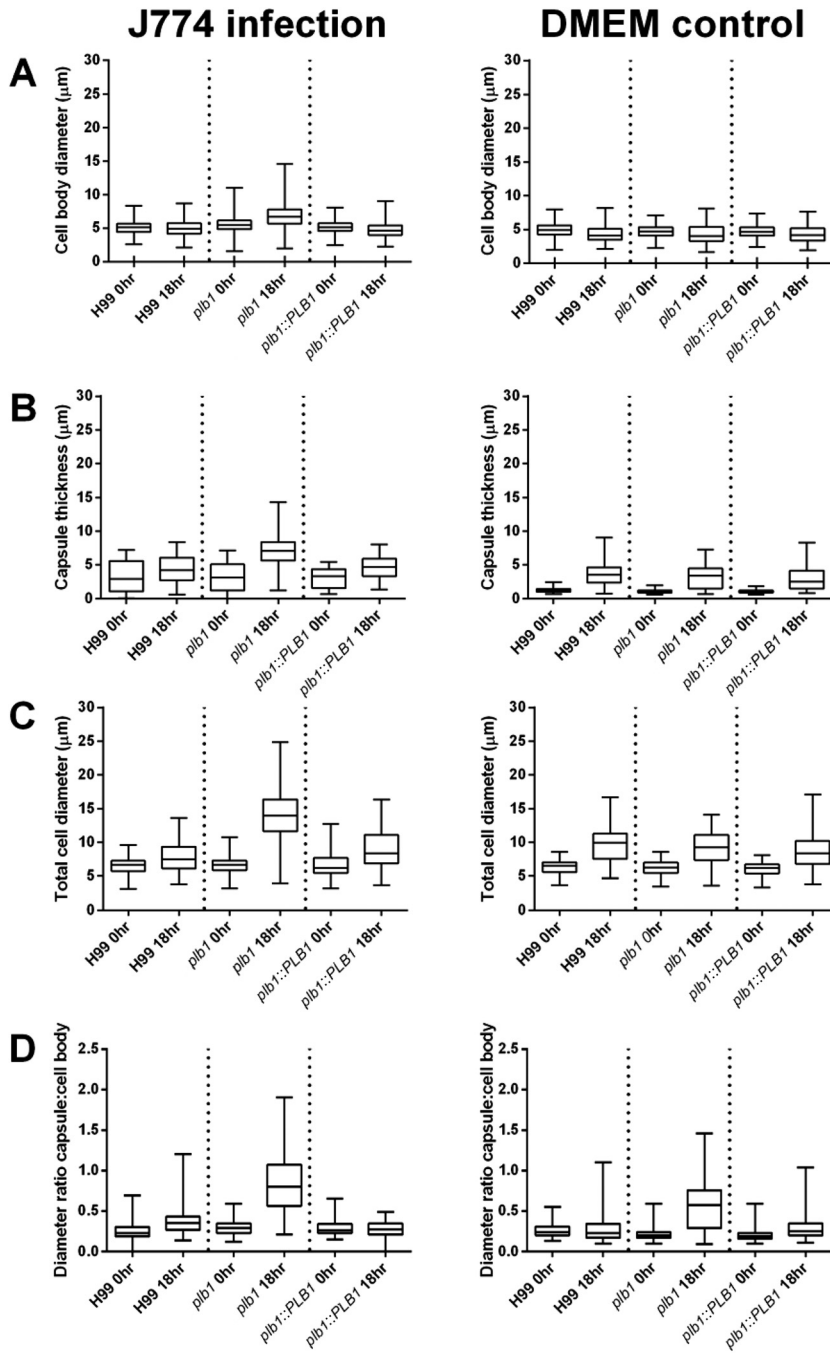

FIG 3 Overlaid growth curves with increasing concentrations of stress factors that partly mimic stresses in the phagosome. (A) SDS (membrane instability); (B) NaCl (osmotic shock); (C)  $H_2O_2$  (reactive oxygen).

increase observed in titan cells is accompanied by increased nuclear content due to polyploidy (15, 16). In agreement with this, flow cytometric analysis of  $\Delta plb1$  cells following macrophage infection demonstrated a positive correlation between cell size and DNA quantity (Fig. 5A), indicating increased nuclear content within these cells.

**$\Delta plb1$  cells have a higher rate of titan cell formation than do wild-type cells during *in vivo* murine infection.** Our *in vitro* observation of  $\Delta plb1$  cell enlargement was reminiscent of the titan cell morphology observed during *in vivo* murine pulmonary infection (15, 16, 21). To test whether this phenotype was recapitulated *in vivo*, we conducted pulmonary infections in mice and then quantified cryptococcal size following bronchoalveolar lavage (BAL) at 3 days postinfection. As with our *in vitro* data, *in vivo* infection with  $\Delta plb1$  cells produced about 2.5 times more titan

**FIG 5** (A) Flow cytometric analysis of *C. neoformans* samples pre- and postinfection with J774 macrophages (18 h). Samples were stained with Hoechst to quantify DNA content; FSC-A (forward scatter area) indicates the relative cell size across the samples. Cells were gated based on size and nuclear content with cells in Q3 consistent with small cells in  $G_1$ , cells in Q4 indicative of small cells in  $G_2$ , and cells in Q2 indicative of polyploidy titan cells with both large size and increased DNA content. (B) Mean percentage of total events (10,000 collected) across 3 repeats occurring in the Q2 gate. A one-tailed *t* test was performed for H99 and  $\Delta plb1$  strains as well as  $\Delta plb1$  and  $\Delta plb1::PLB1$  strains to determine if the increase in events within the Q2 gate observed was significant: \*, H99-infected versus  $\Delta plb1$  strain-infected cells,  $P = 0.034$ ; \*,  $\Delta plb1$  strain-infected versus  $\Delta plb1::PLB1$  strain-infected cells,  $P = 0.015$ ; \*\*,  $\Delta plb1$  strain-uninfected versus  $\Delta plb1::PLB1$  strain-uninfected cells,  $P = 0.001$ .

cells (cryptococci with a cell body diameter greater than 15  $\mu\text{m}$ ) than H99 or  $\Delta plb1::PLB1$  cells (Fig. 6Ai). Flow cytometry of lavaged, Hoechst-stained  $\Delta plb1$  titan cells indicated that these cells are polyploid, in agreement with previously published characterization of titan cells (15, 16) as well as our own *in vitro* observation of  $\Delta plb1$  cells (Fig. 5A). Taken together, these findings suggest that the morphological changes that we observed in our  $\Delta plb1$  cells are consistent with an increase in the production of titan cells by this strain both *in vitro* and *in vivo*.

***In vivo*  $\Delta plb1$  titan cell formation is not associated with phagocytosed cells.** In addition to quantifying overall titan cell formation in BAL samples, we also counted the *Cryptococcus* cells within host phagocytes following BAL and measured the cell body diameter of each *Cryptococcus* cell within each lavaged host cell.

We found that there were significantly fewer lavaged host cells containing *Cryptococcus* for  $\Delta plb1$  strain-infected mice than for mice infected with H99 or  $\Delta plb1::PLB1$  strain (Fig. 6Aii, H99 versus  $\Delta plb1$ ,  $P = 0.0001$ ;  $\Delta plb1$  versus  $\Delta plb1::PLB1$ ,  $P = 0.0018$ ).

**FIG 4** (A to D) *C. neoformans* cells were measured after either 18 h inside J774 macrophages or 18 h in serum-free DMEM. The top and bottom of each box mark the 75th and 25th percentiles, respectively, the bisecting line in the box marks the median, and the two whiskers mark the maximum and minimum of the range. Mann-Whitney U tests were performed for each time point pair. Full statistical results are given in Tables S1 and S2 in the supplemental material. (B) Capsule thickness was calculated by subtracting cell body diameter from total diameter including capsule. (D) The ratio of cell body to capsule was calculated by dividing cell body diameter by capsule thickness. (E) Still bright-field images from live-cell microscopy following the same macrophage over 18 h for H99,  $\Delta plb1$ , and  $\Delta plb1::PLB1$  strains. Black arrows indicate the location of single *C. neoformans* cells within the macrophage. (F) Still bright-field images from live-cell microscopy following viable  $\Delta plb1$  strain-infected macrophages. Images were taken at 40 h postinfection; bar, 10  $\mu\text{m}$ .

**FIG 6** *In vivo* titan cell assay on *Cryptococcus* cells lavaged from mouse lungs 3 days postinfection. (Ai) A minimum of 500 cells per animal were analyzed to quantify cell body diameter, *Cryptococcus* cells >15  $\mu m$  in diameter were considered titan cells (\*\*\*, H99 versus  $\Delta plb1$  strain,  $P = 0.0001$ ; \*\*\*,  $\Delta plb1$  versus  $\Delta plb1::PLB1$  strains,  $P = 0.0018$  [two-tailed unpaired  $t$  test]). (Aii) Host cells lavaged from the lungs were examined for phagocytosed *Cryptococcus* cells (\*\*\*, H99 versus  $\Delta plb1$  strain,  $P = 0.0001$ ; \*\*\*,  $\Delta plb1$  versus  $\Delta plb1::PLB1$  strains,  $P = 0.0001$  [two-tailed unpaired  $t$  test]). (Aiii) The cell body diameter of phagocytosed *Cryptococcus* cells within lavaged host macrophages was quantified, and data for phagocytosed cells >10  $\mu m$  are given. (B) Bronchoalveolar lavage samples with *Cryptococcus* from H99 and  $\Delta plb1$  strains were stained with Hoechst and analyzed for size and nuclear content. Cells were gated based on size and nuclear content with cells in Q3 consistent with small cells in G<sub>1</sub>, Q4 indicative of small cells in G<sub>2</sub>, and Q2 indicative of polyploidy titan cells with both large size and increased DNA content. (C) Bright-field images of lavaged cells from H99,  $\Delta plb1$ , or  $\Delta plb1::PLB1$  strain-infected lungs. Bar, 15  $\mu m$ .

Very few of these internalized *Cryptococcus* cells were above 10  $\mu m$  in diameter, and those that were above 10  $\mu m$  could be found in similar numbers for H99,  $\Delta plb1$ , and  $\Delta plb1::PLB1$  cells (Fig. 6Aiii). No cells greater than 15  $\mu m$  were found inside phagocytes

in either the control or the  $\Delta plb1$  strain infections (data not shown). This leads us to conclude that *in vivo*  $\Delta plb1$  titan cell formation potentially occurs initially within host cells (as we observe *in vitro*) but these large cryptococci are released from host

cells either by host cell lysis *in vivo* or due to the physical process of lysis prior to the time point examined.

## DISCUSSION

During cryptococcal pathogenesis, *C. neoformans* interacts with professional phagocytes in the alveolar space (2), in the bloodstream, and in other tissues following dissemination. The outcome of this interaction appears to be vital for disease progression, as the macrophage provides a protective niche for replication (18) and a potential “Trojan horse” for dissemination to the central nervous system (22, 23). Together with previous studies, our findings strongly suggest that expression of Plb1 is critical in regulating cryptococcus-macrophage interactions.

First, we show that *PLB1* deletion leads to enhanced uptake by phagocytes *in vitro* (Fig. 1B). Since Plb1 is a GPI-linked, cell wall-associated protein (7), it is likely that loss of this enzyme affects the cryptococcal cell surface and, presumably, this change facilitates more-efficient binding of phagocyte receptors. Examination of different opsonization methods (see Fig. S1 in the supplemental material) suggests that increased uptake is due to a combination of antibody, complement, and nonopsonic ligands. Cryptococcal cell wall instability following *PLB1* deletion has been published previously (8), and thus this instability could lead to increased ligand exposure on the *Cryptococcus* cell surface. In light of these observations, a detailed chemical analysis of the cell surface composition in this strain would be of considerable future interest.

Following phagocytosis, we find that *C. neoformans* requires the expression of Plb1 to proliferate and survive normally within the macrophage (Fig. 2). This finding provides a mechanism to explain previous reports of reduced fungal burdens following infection with  $\Delta plb1$  cells (9). Interestingly, however, the  $\Delta sec14-1$  strain shows no such defect in intracellular proliferation. Since this strain shows strongly reduced Plb1 secretion (9), the most likely explanation is that the primary role of Plb1 in driving intracellular proliferation is in the metabolism of fungal phospholipids within the cryptococcal cell, rather than in acting directly upon host phospholipids. However, secreted Plb1 appears to have additional roles in virulence, since the  $\Delta sec14-1$  strain is attenuated in animal models (9). It is tempting to speculate that the documented involvement of *SEC14* in regulating vomocytosis (9) may be one such role.

A striking morphological observation arising from our macrophage infection model was that  $\Delta plb1$  cells showed a marked increase in both cell body diameter and capsule thickness during infection, with a maximum measured diameter (including capsule) of almost 25  $\mu\text{m}$  (Fig. 4C). That this size change was not seen in the wild-type or  $\Delta plb1::PLB1$  reconstituted strains suggests that this morphology results from the loss of Plb1. Previously reported titan cells grown *in vivo* range in diameter from 15 to 100  $\mu\text{m}$ , excluding the capsule (15, 16). Therefore, the size increase that we observed is smaller than that of previously reported titan cells but significantly larger than the normal cryptococcal size range. Interestingly, previous reports of titan cells induced *in vitro* also noted that the cells tended to be smaller than those generated *in vivo* (16). Flow cytometry analysis of  $\Delta plb1$  cells following macrophage infection (Fig. 5) indicates that the large cells show increased DNA content, consistent with the defining feature of titan cells (16). Thus, these cells may represent individual yeast cells that are “en route” to becoming Titan cells or have somehow been constrained by the macrophage, or it may

be that the *in vitro* conditions do not provide the necessary stimulus to produce the largest titan cells.

From our *in vitro* data, we conclude that the  $\Delta plb1$  strain forms large cells within macrophages, which are similar to the titan cell morphology seen *in vivo*. Titan cell formation has previously been induced *in vitro* using macrophage-conditioned media (16); however, titan cell formation induced inside an infected macrophage has to our knowledge not previously been reported. Although we have not identified the trigger for this morphology, it is evidently linked to Plb1 deficiency. The development of this morphology within the macrophage may be a response to increased stress experienced by the  $\Delta plb1$  strain, as indicated by the decreased viability of this strain within the phagosome. Although we did not detect any significant difference stress tolerance for  $\Delta plb1$  organisms *in vitro*, other than the previously published susceptibility to SDS (9), growth within the phagosome exposes cryptococci to a diverse repertoire of additional stresses, and it is likely that these complex conditions limit the growth of this mutant. One possible source of stress within the phagosome, which links our observed phenotypes, is the observation that in wild-type cryptococci, Plb1 concentrates at the neck of newly forming buds (24). This suggests that Plb1 may have a role in bud development, and thus it is conceivable that modification of membrane phospholipids by Plb1 during budding could be required for membrane curvature at the newly formed bud site or release of the daughter cell. The inability of the  $\Delta plb1$  strain to properly bud would explain the proliferation defect observed and could generate sufficient cellular stress to reduce cryptococcal viability and trigger the development of titan-like cells.

A strong link between our *in vitro* observations and previously published *in vivo* development of titan cells is supported by our finding that the  $\Delta plb1$  strain forms greater numbers of “classical” titan cells (i.e., cell body diameter above 15  $\mu\text{m}$  and high nuclear content indicative of polyploidy) *in vivo* than do the wild-type and reconstituted strains (Fig. 6Ai). These data suggest that Plb1 activity is involved in the repression of titan cell formation during infection. In addition, the fact that the  $\Delta sec14-1$  strain does not manifest similar cell size increases during *in vitro* infection (our unpublished data) indicates that intracellular rather than extracellular Plb1 activity regulates the titan cell morphology. Interestingly, titan cell development may be linked to phospholipid availability (25), suggesting a potential link to Plb1 activity. Titan cell formation *in vivo* has been reported to increase the pathogenicity of *C. neoformans* (16, 17); our conclusion that the  $\Delta plb1$  strain has increased titan cell formation therefore seems at odds with the *in vitro* data presented in Fig. 1 and 2 showing that the  $\Delta plb1$  strain is attenuated in macrophages. It is therefore possible that the large  $\Delta plb1$  cells may not exhibit all the features of titan cells (for instance, in conferring “cross-protection” on nontitan cells in the same host). Alternatively, it may be that full pathogenicity requires only a minor titan cell population and hence, the enhanced titan cell frequency seen in the  $\Delta plb1$  strain actually reduces overall virulence.

In summary, our data indicate that Plb1 plays a key role both in intracellular survival within host phagocytes and in driving cryptococcal cell size changes both *in vitro* and *in vivo*.
