Just Accepted

“Just Accepted” manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides “Just Accepted” as a service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. “Just Accepted” manuscripts appear in full in PDF format accompanied by an HTML abstract. “Just Accepted” manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are citable by the Digital Object Identifier (DOI®). “Just Accepted” is an optional service offered to authors. Therefore, the “Just Accepted” Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the “Just Accepted” Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these “Just Accepted” manuscripts.

Abstract

Quantum dot sensitized solar cells (QDSSCs) are a promising photovoltaic technology due to their low cost and simplicity of fabrication. Most QDSSCs have an n-type configuration with electron injection from QDs into TiO₂, which generally leads to unbalanced charge transport (slower hole transfer rate) limiting their efficiency and stability. We have previously demonstrated that p-type (inverted) QD sensitized cells have the potential to solve this problem.

1
2
3 Here we show for the first time that electrodeposited CuSCN nanowires can be used as a p-type
4 nanostructured electrode for p-QDSSCs. We demonstrate their efficient sensitization by heavy
5 metal free $\text{CuInS}_x\text{Se}_{2-x}$ quantum dots. Photophysical studies show efficient and fast hole injection
6 from the excited QDs into the CuSCN nanowires. The transfer rate is strongly time dependent
7 but the average rate of $2.5 \times 10^9 \text{ s}^{-1}$ is much faster than in previously studied sensitized systems
8 based on NiO. Moreover, we have developed an original experiment allowing us to calculate
9 independently the rates of charge injection and QD regeneration by the electrolyte and thus to
10 determine which of these processes occurs first. The average QD regeneration rate ($1.33 \times 10^9 \text{ s}^{-1}$)
11 is in the same range as the hole injection rate, resulting in an overall balanced charge
12 separation process. To reduce recombination in the sensitized systems and improve their
13 stability, the CuSCN nanowires were coated with thin conformal layers of Al_2O_3 using atomic
14 layer deposition (ALD) and fully characterized by XPS and EDX. We demonstrate that the
15 alumina layer protects the surface of CuSCN nanowires, reduces charge recombination and
16 increases the overall charge transfer rate up to 1.5 times depending on the thickness of the
17 deposited Al_2O_3 layer.

42 **Introduction**

43
44 An increasing number of energy-related applications rely on nanostructured wide band gap
45 semiconductors. Due to their optical transparency and capacity to transport charges they find use
46 in photovoltaics, photocatalysis, light-emitting devices, energy storage and other fields. The vast
47 majority of semiconductors used are of n-type, such as TiO_2 and ZnO , which are responsible for
48 the electron transport in various devices.¹⁻³ Transparent nanostructured p-type semiconductors

56
57
58
59
60

1
2
3 are much less studied primarily because of the scarcity of inorganic materials suitable for
4
5 electronic applications compared to the n-type materials.⁴ The main problems of p-type materials
6
7 for sensitized photoelectrochemical devices are related to their low transparency and/or low
8
9 conductivity.⁵ A classic example is widely used nickel oxide, which can be made transparent, but
10
11 with low conductivity. Its conductivity can be improved by doping by increasing the
12
13 concentration of Ni(III) species, which in turn leads to the loss of transparency. In addition,
14
15 many preparation methods suffer from a lack of control over the NiO stoichiometry, affecting the
16
17 reproducibility. All factors together critically limit to date the performance of this material in
18
19 optoelectronic devices.
20
21
22

23
24 Copper (I) thiocyanate, CuSCN, represents a promising alternative to NiO as an inorganic p-
25
26 type material.⁶ This molecular inorganic semiconductor has high transparency combined with
27
28 decent hole-transporting properties: the hole mobility and the conductivity of the bulk material
29
30 are $0.01\text{-}0.1\text{ cm}^2\text{ V}^{-1}\text{ s}^{-1}$ and $0.1\text{-}1\text{ S/cm}$, respectively. Additionally, the stoichiometry of CuSCN
31
32 can be better controlled than for many types of oxides, it can be relatively simply chemically
33
34 modified^{7,8} and its thermal stability is excellent.^{9,10} Finally, CuSCN is inexpensive and easily
35
36 adaptable for large area applications. Recently, thin films of CuSCN have been successfully used
37
38 as hole-transporting layers in organic solar cells to replace traditionally used PEDOT:PSS
39
40 material leading to improved performance in terms of power conversion efficiency and
41
42 stability.¹¹⁻¹⁴ With the recent boom of hybrid perovskite photovoltaics, solution-deposited
43
44 CuSCN has found several applications as hole-transporting and/or electron blocking layer. In
45
46 these perovskite cells CuSCN replaced either spiro-OMeTAD in the case of n-i-p cells^{9,15-19} or
47
48 PEDOT:PSS in p-i-n ones,²⁰ outperforming the organic films even though some concerns about
49
50 the stability of the cells at the interface level have been raised.¹⁰ CuSCN was earlier used in dye-

2
3 sensitized solar cells (DSSCs) as a hole-transporting material in solid state cells in combination
4 with sensitized TiO₂ or ZnO mesoporous electrodes,^{7,21–23} and lately in nanostructured form as a
5 p-type semiconductor scaffold in traditional liquid-junction cells.^{24,25} While considerable
6 progress has been achieved using CuSCN deposited on top of n-type semiconductors, its
7 application as a hole acceptor from the adsorbed dye has met only limited success for several
8 reasons: (i) the absence of an appropriate electrolyte system, as the iodide/triiodide redox couple
9 is known to dissolve thiocyanates, while cobalt based electrolytes are less suitable because of
10 faster recombination processes; (ii) the absence of appropriate dyes having suitable energy levels
11 and capable of efficient and fast hole injection into CuSCN.²⁵ Another concern is the dye
12 chemisorption: because of the soft Lewis acid character of the copper thiocyanate surface,
13 traditional anchors, such as carboxylic and phosphonic acids developed for hard Lewis acidic
14 TiO₂ electrodes, are not efficient. Therefore, alternative anchors for the dyes need to be
15 developed for CuSCN.²⁴ Recently, using first-principles DFT and molecular dynamics
16 calculations, a series of molecular anchors have been tested for the adsorption on CuSCN
17 showing that most of the molecules have only moderate binding strength.²⁶

Quantum dot sensitized solar cells (QDSSCs) appear as a promising photovoltaic technology
because of the low production cost of quantum dots, their high absorption coefficients, and easily
adjustable energy levels.²⁷ Moreover, the progress in the performance of QDSSCs is very fast
with a current record power conversion efficiency of 12%, which is almost on par with their
conventional dye-sensitized counterparts having a much longer history.²⁸ One of the factors still
blocking further progress in this field is unbalanced charge transfer because of the slower hole
regeneration compared to the fast electron injection into TiO₂ or similar materials.^{29,30} With the
goal of balancing both charge transfer processes and inspired by well-studied p-type DSSCs,³¹

1
2
3 inverted (or p-type) QDSSCs have been developed. They are based on the principle that faster
4 hole injection into a p-type material combined with slower electron regeneration by the redox
5 electrolyte can lead to similar transfer rates for both types of carriers. An additional advantage
6 over organic dyes, especially when using ternary chalcopyrite nanocrystals,^{32,33} comes from their
7 naturally long-lived excited states allowing for more efficient charge injection and smaller
8 recombination rates. Typically, NiO nanoparticles are used as mesoporous scaffold for the
9 deposition of PbS, CdSe or chalcopyrite-type QDs.³⁴⁻³⁷ The best cells, reaching 1.5% efficiency
10 and reported by our group,³⁸ are based on eco-friendly $\text{CuInS}_x\text{Se}_{2-x}$ QDs. In this previous work
11 we showed that the hole injection from QDs into NiO occurs on a similar timescale as electron
12 injection into TiO_2 in n-type systems, confirming the general feasibility of sensitization of p-type
13 materials by QDs. At the same time, because of the above-mentioned limitations of NiO, it is
14 important to develop alternative nanostructured materials for p-QDSSCs. To date only a handful
15 of working systems of this kind exists.^{39,40} To the best of our knowledge, copper thiocyanate has
16 never been used in QDSSCs, although a recent article demonstrated an efficient hole transfer
17 from a thin layer of electrodeposited PbS to nanostructured CuSCN.⁴¹

38 In this work, we investigate electrodeposited CuSCN nanowires (NWs) as p-type
39 semiconductors for sensitization with heavy metal-free $\text{CuInS}_x\text{Se}_{2-x}$ QDs for applications in p-
40 QDSSCs. One important advantage of CuSCN NWs over thin films is their much higher hole
41 concentration; an increase by a factor of 8 has been reported.⁴² Previously, we have optimized
42 the deposition of CuSCN NWs on various substrates,^{43,44} investigated their structural properties⁴⁵
43 and successfully integrated them into organic photovoltaic devices.¹¹ Here, we present strategies
44 for the efficient assembly of QDs on the surface of NWs and study the light harvesting properties
45 of the sensitized electrodes. Time-resolved photoluminescence studies are used to estimate the

3 hole transfer rate between photoexcited $\text{CuInS}_x\text{Se}_{2-x}$ QDs and CuSCN NWs. In addition, for the
4 first time the electron regeneration rate of the reduced QDs in the presence of a redox electrolyte
5 has been calculated and the photophysical description of the complete system has been achieved.
6
7 CuSCN NWs are sensitive to the pH of the medium and turned out to be incompatible with the
8 polysulfide electrolyte commonly used in QDSSCs. An alternative electrolyte is proposed as
9 well as a passivation strategy aiming at both NW protection against degradation and the
10 suppression of charge recombination processes at the interface with the electrolyte. In the case of
11 standard QDSSCs, passivation is typically achieved by coating thin layers of wide band gap ZnS
12 or CdS onto the sensitized electrodes using successive ionic layer adsorption and reaction
13 (SILAR). However, this method is not compatible with some materials.⁴⁶⁻⁴⁸ Alternatively,
14 atomic layer deposition (ALD) can be used to deposit highly conformal layers of metal oxides
15 (e.g. Al_2O_3 , HfO, TiO_2 , ZnO) with tightly controllable thickness and composition.⁴⁹ This method
16 has been previously used to coat TiO_2 and ZnO electrodes and indeed resulted in reduced
17 recombination losses and improved QDSSC performance.⁵⁰⁻⁵² Here we present the deposition
18 and X-ray photoelectron spectroscopy (XPS) analyses of thin Al_2O_3 layers on CuSCN NWs and
19 study the influence of this passivation layer on the efficiency of the hole transfer.

3 **Atomic layer deposition.** ALD of Al₂O₃ thin films were carried out using trimethylaluminum
4 (TMA) and H₂O as precursors in a Fiji200 reactor (Cambridge Nanotech). The deoxidized
5 samples were placed in the deposition chamber under 100 °C, 10⁻² Torr, argon purge gas and an
6 automated recipe alternating 4 steps (0.06 s TMA, 30 s purge, 0.06 s H₂O and 30 s purge) was
7 performed until the desired amount of cycles was attained. The deposition rate was estimated to
8 be roughly around 0.9 Å/cycle, thus 1 and 3 nm thick layers were obtained using respectively 11
9 and 33 ALD cycles.

10
11 **Characterisation.** Air Photoemission Spectroscopy (APS) measurements were performed
12 using a KP Technology APS03 Kelvin Probe setup. The sample was grounded and a gold tip was
13 held ~100 microns above the sample. The sample was illuminated with monochromatic UV light
14 in the energy range 4 – 6.5 eV and the resultant photoelectrons were collected by the tip, which
15 was held at a constant +10V potential. The cube root of the number of photoelectrons was plotted
16 against the energy of the incident photons, and the HOMO energy was calculated by
17 extrapolating the straight line part of the graph to zero. The work function of the sample was
18 measured before and after the APS measurement, using the APS03 setup in Kelvin Probe
19 configuration, in order to ensure that the sample was not degraded by the high energy UV light.
20 X-ray Photoelectron Spectroscopy (XPS) analyses were carried out with a Versa Probe II
21 spectrometer (ULVAC-PHI) equipped with a monochromated Al K α source ($h\nu = 1486.6$ eV).
22 The core level peaks were recorded with constant pass energy of 23.3 eV. The XPS spectra were
23 fitted with CasaXPS 2.3 software using Shirley background and a combination of Gaussian
24 (70%) and Lorentzian (30%) distributions. Binding energies are referenced with respect to the
25 adventitious carbon (C 1s BE = 284.6 eV). Scanning electron microscopy (SEM) images were
26 acquired with a ZEISS Ultra 55+ Electron Microscope equipped with EDX detector.

2
3 **Solar cells fabrication.** QD sensitized solar cells were prepared using various electrolytes:
4 polysulfide (1.0 M Na₂S, 1.0 M S, 0.1 M NaOH in water), cobalt (0.1 M [Co²⁺(dtb-bpy)₃](PF₆)₂,
5 0.1 M [Co³⁺(dtb-bpy)₃](PF₆)₃ where dtb-bpy is 4,4'-diterbutyl-2,2'-bipyridine, and 0.1 M LiClO₄
6 in propylene carbonate)³⁵, ferrocyanide/ferricyanide (0.01 M K₃Fe(CN)₆, 0.2 M K₄Fe(CN)₆ in
7 water).⁵⁴ As a counter electrode for polysulfide electrolytes, brass plates was activated in 1.0 M
8 HCl solution at 85°C for 30 min followed by rinsing with water. For cobalt and ferrocyanide
9 electrolytes, platinum counter-electrodes (Solaronix SA, Switzerland) were used. Sensitized
10 CuSCN NWs grown on glass/ITO substrates were assembled with counter-electrodes using
11 parafilm spacers and the electrolyte was injected in the cavity. The device active area was 0.6 x
12 0.6 cm (that is 0.36 cm²). The solar cells were measured using a Keithley 2400 unit and 1000
13 Wm⁻² air-mass 1.5G simulated solar light generated by a Newport class AAA solar simulator. A
14 calibrated monocrystalline silicon solar cell (P/N 91150V from Oriel) was used as a reference.

15
16
17 **Photophysical studies.** Varian Cary 300 UV-Vis spectrophotometer was used to measure the
18 absorption spectra of samples and Edinburgh Photonics Instrument FLS980 was used to measure
19 the photoluminescence decays. For lifetime measurements, the samples were excited with a 470
20 nm PicoQuant picosecond pulsed laser and PL was measured at 770 nm using time correlated
21 single photon counting (TCSPC). The instrument has a time resolution of ~200 ps.

22 23 24 25 26 27 28 29 30 31 **Results and Discussion**

32
33 **Deposition of QDs onto CuSCN nanowires.** CuSCN NWs with 1 μm length and 100 nm
34 diameter have been fabricated by electrodeposition from aqueous solutions to yield uniform
35 layers on ITO-coated glass substrates (Figure 1). It is worth noting that it is generally challenging

to obtain an image of CuSCN nanowires by electron microscopy as the probing beam rapidly modifies the morphology of the NW arrays rendering the aspect ratio of nanowires progressively lower and ultimately resulting in tapered structures. Deposition of a thin layer of a conducting material such as carbon or Pt is thus necessary to get high quality images.

Figure 1. Scanning electron microscope (SEM) image of CuSCN nanowires array coated with Pt (left). Hypothetical energy level alignment (right).

While the electronic properties, such as energy level positions, charge mobility and conductivity of spin- or dip-coated films of commercial CuSCN are relatively well studied,⁵⁵ little is known about the nanowire form of this material having completely different crystallinity and morphology. The band gap value of 3.6 eV, having an indirect contribution in the case of the NWs, is close to that of bulk CuSCN.^{11,45} The absolute position of the valence band (VB) has been determined by ambient pressure photoemission spectroscopy (APS), by investigating a plot of cube root of the photoelectron yield as a function of photon energy for a CuSCN layer on ITO electrodes. The intercept and fit of the curve allowed calculating the position of the VB at -5.16 ± 0.10 eV, while the work function (WF) is situated at roughly the same value: -5.17 ± 0.01 eV (see Fig. S1). For comparison, the VB and the WF of flat electrodeposited CuSCN films were

1
2
3 measured under the same conditions at -4.81 eV and -4.85 eV, respectively. In a recent work the
4
5 WF of spin-coated commercial CuSCN films was determined as -5.35 ± 0.11 eV.⁵⁶
6

7
8 Alloyed $\text{CuInS}_x\text{Se}_{2-x}$ QDs have been used as photosensitizers in this work. Taking into account
9
10 the levels of their VB and conduction bands recently determined by differential pulse
11
12 voltammetry,³⁸ one can establish the scheme of the energy level alignment of the
13
14 CuSCN/ $\text{CuInS}_x\text{Se}_{2-x}$ QDs junction (Figure 1). The proposed alignment is beneficial for hole
15
16 injection from the VB of the excited QDs into the VB of CuSCN with an energy difference of
17
18 0.27 eV acting as an efficient driving force. Moreover, the deep-lying VB of the CuSCN NWs
19
20 gives the possibility of attaining high open-circuit voltages (V_{OC}) in solar cells. In p-type
21
22 QDSSCs the V_{OC} is defined by the difference of the VB of the p-type semiconductor and the
23
24 redox potential of the electrolyte. At the same time, the wide band gap of CuSCN is essential for
25
26 limiting its direct light absorption and avoiding QD quenching.
27
28
29

30
31 By using molecular linkers higher QD loading on the nanostructured electrodes can be
32
33 achieved because of the increased deposition density due to specific binding. One of the most
34
35 efficient linkers developed for TiO_2 sensitized by various QDs are mercaptocarboxylic acids,
36
37 such as 3-mercaptopropionic acid (MPA). According to the Pearson acid base concept, the
38
39 carboxylate group, having hard acid character, will preferably bind to Ti^{+4} sites, while the soft
40
41 thiol group will selectively bind to the soft base cations of the QDs. Although working well for
42
43 TiO_2 , this concept has previously proved incompatible with ZnO nanowires⁵⁷ and less efficient
44
45 for NiO.³⁸ In the present case, the functionalization of CuSCN nanowires with MPA to improve
46
47 the QD loading turned out to be counterproductive because of the gradual dissolution of the NWs
48
49 in the acidic medium. Interestingly, the dissolution proceeds through flower-like structures of
50
51 high surface area and the diffraction peaks corresponding to vertically oriented CuSCN NWs
52
53
54
55
56
57
58
59
60

(JCPDS 04-017-0744) are strongly diminished giving rise to others, probably related to the copper sulfides, as observed by the XRD (Figure 2).

Figure 2. SEM (left) and powder XRD diffractograms (right) showing the influence of 3-mercaptopropionic acid (MPA) treatment (1 M in water) on the morphology of CuSCN nanowires. * - ITO substrate peaks.

As a consequence of the high sensitivity of CuSCN towards the tested bifunctional linkers, a specific binding route to deposit QDs on the NWs has been abandoned in favor of direct adsorption, which has been shown to be efficient in a range of systems.^{38,47,58} Figure 3 shows the absorption spectra of the QD sensitized CuSCN NWs as a function of the deposition time. Because of its wide band gap CuSCN is not expected to absorb light above 350 nm. Therefore the absorption of the uncoated nanowires observed at larger wavelengths is explained by light scattering due to the high diffusivity of the array. The absorption of the NWs in the visible range greatly increases upon QD deposition. Assuming that the absorption values are proportional to

the QD loading onto the nanowires, we can deduce that the loading gradually increases with time.

Figure 3. Absorption spectra of CuSCN NWs sensitized with $\text{CuInS}_x\text{Se}_{2-x}$ QDs at different sensitization times.

Hole and electron transfer studies of the assemblies. In order to estimate the hole and electron transfer efficiency, time-resolved photophysical studies have been carried out taking the photoluminescence (PL) peak of QDs at around 770 nm as the indicator. First, the PL decay of a thin film of QDs was measured in the absence of electron or hole accepting materials on a glass substrate. Then, with the goal to determine the hole transfer rate, the same experiment was repeated for QDs deposited on CuSCN NWs. However, to get a complete picture of the charge separation in systems used for the photovoltaic conversion, also electron transfer studies have to be conducted. It is of prime importance to understand which of both processes takes place first to identify the rate-limiting one to be able to optimize the system. Their rates should be compared

1
2
3 in conditions close to those occurring in real solar cells to be able to elucidate and optimize the
4 full mechanism of charge separation. Only a handful of studies have been focused so far on this
5 problem.^{29,59,60} We have designed an experiment allowing the estimation of the electron
6 extraction in the absence of a hole quencher: a simple cell was constructed with a QD film on
7 glass in contact with a redox electrolyte, mimicking the configuration in a QDSSC. Upon photo-
8 excitation the charges are extracted by the electrolyte allowing the determination of the rate of
9 the other electrode half-reaction. Finally, the combined rate constant of hole and electron transfer
10 of the complete system was determined by QD lifetime measurements on sensitized CuSCN
11 electrodes in the presence of the electrolyte.

24 Inspired by the state of the art of QDSSCs we initially intended to use the widely applied
25 polysulfide electrolyte as a redox shuttle. However, it turned out that it was not compatible with
26 the CuSCN nanowires. The elevated basicity (pH=11-12) coupled with the presence of active S²⁻
27 species in the polysulfide electrolyte led to the rapid corrosion of the nanowires (see Fig. S6)
28 rendering further studies impossible. Consequently, we have selected an alternative organic
29 electrolyte based on the Co^{II}/Co^{III} redox couple ((tris(4,4'-ditert-butyl-2,2'-bipyridine)
30 cobalt(III/II)).^{35,61} This system is more inert and gives also the possibility to access higher V_{OC}
31 values in solar cells compared to polysulfides.⁶² The use of cobalt electrolyte significantly
32 increased the stability of the nanowires.

44 The QD PL decays of the different systems are shown in Figure 4a. As expected, the QDs
45 decay is faster in the presence of a quencher (CuSCN, electrolyte or combination of both) than
46 on glass due to charge transfer processes competing with radiative recombination. The PL
47 quenching rate is determined by taking the natural logarithm of the ratio of the PL decay of the
48 QDs on CuSCN to their decay on glass (see Fig. S5 and Eq. 1). This method has proven to be
49
50

54
55
56
57
58
59
60

well suited for emitters, which do not show monoexponential decay, which is the case for ternary metal chalcogenide NCs.⁵⁷ While this procedure would give a flat line in the absence of quenching (no charge transfer) and a line of a constant slope in the case of constant transfer rate, our curves show non-linear behavior. This suggests a strongly time-dependent charge transfer similar to that observed for QDs on NiO, TiO₂ or ZnO.^{38,57} The time-dependent rate constants were calculated through differentiation of the natural logarithm of the PL ratio using equation 1:

$$k_{CT}(t) = -\frac{d}{dt} \left(\log_e \left(\frac{PL \text{ of QDs with quencher}}{PL \text{ of QDs on glass}} \right) \right) \quad (1)$$

Figure 4: (a) PL decay profiles of CuInS_xSe_{2-x} QDs in the absence and presence of electrolyte. The black curve is the PL decay of QDs on glass, the blue curve is the decay of QDs deposited on CuSCN, the green curve is the decay of QDs on glass in the presence of electrolyte and the orange curve is the decay of QDs in the presence of electrolyte and CuSCN. Inset: Scheme of deactivation pathways in various systems. (b) Rate constants of charge transfer determined through differentiation of the natural logarithm of the PL decay ratios.

1
2
3 The charge transfer rates (Figure 4b) were determined by fitting the natural logarithm of the
4 PL decay ratios with three exponentials before differentiation. The obtained curves clearly show
5 that the charge transfer rates are strongly time dependent. It can be seen from Figure 4b that in
6 the first nanosecond, the transfer from QDs deposited on CuSCN is faster than that from QDs on
7 glass in the presence of electrolyte, which is in turn faster than QDs the presence of electrolyte
8 and CuSCN. For comparison, we determine the average charge transfer rate by integrating the
9 rates over the times for the PL to fall to 1/e of its initial value using equation 2:

$$\langle k_{CT} \rangle = \frac{1}{\tau_{1/e}} \int_0^{\tau_{1/e}} k_{CT}(t) dt \quad (2)$$

19
20
21
22
23 The resulting values (Table 1) show that the hole transfer from QDs to CuSCN is almost twice
24 as fast as the charge extraction of the excited QDs by the redox electrolyte, occurring on a
25 timescale of 0.4 ns and 0.75 ns, respectively. We assume that the PL decay rate constant
26 corresponds to the hole transfer (k_{HT}) in the case of the CuSCN/QD system and to the charge
27 extraction (k_{ET}) in the case of QDs in the presence of the redox electrolyte. However, at this QD-
28 electrolyte interface we cannot fully exclude that quenching also occurs *via* hole extraction from
29 the reduced form of the redox mediator (cf. energy level alignment in Fig. 1). For the complete
30 systems with both electron and hole quenchers, the determined constant has arbitrary character
31 and reflects the averaged influence of both interfaces on the QD PL decay. Noteworthy, the
32 obtained average hole transfer rate value ($2.5 \times 10^9 \text{ s}^{-1}$) is almost 50 times higher than in
33 previously studied NiO based systems, confirming the benefits of using CuSCN nanowires as
34 hole acceptor.³⁸ Furthermore, k_{ET} is 10 times higher than the electron injection into n-type
35 materials in QD assemblies.

k_{CT} (10^9 s ⁻¹)	2.50	1.33	0.66

An important criterion for the efficient functioning of the sensitized solar cells is balanced charge transfer. One of the reasons is that the QDs remain charged between the event of charge (electron or hole) injection occurring first and the consequent opposite charge injection (or regeneration) to regain neutrality. If the injection/regeneration rate of one type of charge carriers is much faster than that of the opposite one, charges will accumulate in the QDs.⁶⁰ This can lead to increased recombination or to lower stability, as charged QDs are more reactive. In the case of n-type QDSSCs hole regeneration can be 2-3 orders of magnitude slower than initial electron injection, which may lead to undesired photocorrosion.²⁹ In the studied CuSCN/QD/electrolyte system the hole and electron extraction rates are comparable, resulting in balanced charge transfer, which is beneficial for the overall performance and stability of the system. The lower charge transfer rate in the complete systems with electrolyte compared to the QDs on nanowires alone may indicate some modification of the CuSCN surface in the presence of the cobalt electrolyte leading to a lower electronic coupling with the QDs.

To validate the approach of CuSCN sensitization by $\text{CuInS}_x\text{Se}_{2-x}$ QDs we have constructed p-QDSSCs using these systems. The cells using polysulfide electrolyte and vulcanized brass as counter-electrode developed a J_{SC} of 0.59 ± 0.08 mA/cm² with a modest open-circuit voltage V_{OC} of 53 ± 8 mV. For comparison, CuInS_2 QDs without Se additive resulted in a V_{OC} of 159 ± 43 mV. One of the possible reasons of the poor solar cell performance is the aforementioned low stability

1
2
3 of the CuSCN NWs in alkaline solutions of polysulfide electrolyte. On the other hand, using the
4 cobalt-based electrolyte, which is expected to be less corrosive, similar performances were
5 obtained (J_{SC} : 0.54 mA/cm², V_{OC} : 40 mV). An important limiting factor here is the potential of
6 the redox couple in the Co^{II}/Co^{III} electrolyte: the maximum V_{OC} of p-QDSSCs is defined by the
7 difference between the electrolyte redox potential and the VB level of p-type semiconductor.
8 Because of losses due to the series resistance and recombination processes, even for the best
9 reported p-QDSSCs a voltage drop of about 50% (500 mV) has been reported.³⁸ While with the
10 polysulfide electrolyte this potential difference reaches 1.06 eV (the VB of CuSCN NWs is at -
11 5.16 eV vs. vacuum and the redox potential of polysulfide is -4.10 eV), it is limited to 0.27 eV
12 for the organic cobalt electrolyte because of its lower lying redox potential (-4.89 eV) (Fig. 1),
13 which may critically limit the theoretically attainable V_{OC} in such systems. These issues need to
14 be addressed in future work; despite these shortcomings, our results demonstrate the first
15 successful sensitization of CuSCN NWs by QDs.

33 **Al₂O₃ coating of CuSCN nanowires.** With the goal to protect the NWs against corrosion by
34 the electrolyte and to passivate their surface to reduce charge recombination, thin layers of Al₂O₃
35 of varying thickness were deposited by ALD on their surface. The ALD technique has the
36 advantage of depositing thin, very conformal coatings of precisely controlled thickness and
37 composition. As expected, the stability of the NWs in various electrolytes was improved after
38 such coating.

39
40
41
42
43
44
45
46
47 The elemental composition of the NWs coated by 1 nm of Al₂O₃ was studied by EDX (Table
48 2) revealing that the CuSCN material remains intact and close to the nominal stoichiometry with
49 a small contribution of aluminum in the overall composition.
50
51
52
53
54

Table 2. Chemical composition of CuSCN nanowires coated by 1 nm of Al₂O₃ determined by EDX.

	Cu	S	C	N	Al	O
Composition, %	27.5±4.6	19.8±2.0	28.2±2.0	19.9±0.1	0.7±0.2	3.3±0.5

The surface of the coated nanowires is the key interface for the electronic processes such as charge transfer and recombination. One of the essential methods allowing to probe the surface composition is X-ray photoelectron spectroscopy (XPS). In the survey spectrum of CuSCN / Al₂O₃ nanowires the peaks of all expected elements are observable (Figure 5). The aluminum 2p peaks at 74.4 eV are clearly visible, while the Cu 2p, S 2p and N 1s signals are undoubtedly attenuated upon deposition of Al₂O₃ layers of increased thickness (see Fig. S3) because the average probing depth of the surfaces of XPS beam is about 3 nm. This attenuation coupled with a slight shift of the peaks position confirms the conformal deposition of Al₂O₃ layer onto the CuSCN nanowires (see also Fig. S7).⁶³ The chemical structure of the NWs after the coating revealed by the XPS remains essentially intact with respect to the previously studied uncoated nanowires.⁴⁵ Elemental composition found by XPS is considerably different from that determined by the EDX analysis: the ratio [Cu]:[Al] is 1:1.44 and 1:5.59 for 1 and 3 nm coating, respectively, while the ratio measured by EDX is much lower, in the order of 1:0.03. This difference is explained by the surface sensitivity of XPS technique, while the EDX probes the full volume of the nanowires: a much higher contents of Al at the surface confirms that Al₂O₃ material is not incorporated into the CuSCN NWs during the deposition and occurs essentially as a surface layer.

Figure 5. XPS spectra of CuSCN NWs coated with Al_2O_3 : survey spectra (left), Cu 2p high resolution region (right).

The effect of the deposited Al_2O_3 layer on the charge transfer processes was studied by time-resolved PL spectroscopy. First, we investigated the PL decays of sensitized CuSCN films in the presence of 1 or 3 nm Al_2O_3 layers in air (Figure 6). For comparison, the PL decay in the absence of the Al_2O_3 layer was also plotted (black line). The hole transfer rates were determined using eqs. 1 and 2 and the obtained average values are given in Table 3. Upon the deposition of the passivation barrier the hole transfer becomes slower, dropping almost by a factor of 3 for an alumina coating of 3 nm, which can be explained in terms of the potential barrier introduced by this wide band gap material. Charge transfer from QDs to CuSCN through the Al_2O_3 layer is not favorable kinetically albeit remains possible *via* electron tunneling. With the increasing thickness of the insulator the tunneling expectedly becomes less efficient.

Figure 6. Photophysical studies of CuSCN/QD systems as a function of Al_2O_3 thickness in air (left panel) and in the presence of electrolyte (right panel).

By adding the redox electrolyte to the system the effect of the deposited Al_2O_3 layer on the overall charge transfer (in actual solar cell conditions) has also been investigated. The results are shown in Figure 6 (right panel). The obtained average values of charge transfer (combination of both electron and hole transfer) are given in Table 3 and follow the trend observed previously for the uncoated nanowires: the charge transfer processes occur at similar rates on the CuSCN quencher and in the presence of the electrolyte. Interestingly, in the presence of the electrolyte the average charge transfer rates actually become faster with increasing Al_2O_3 layer thickness. This behavior confirms our interpretation of the lower transfer rate in the complete systems CuSCN/QD/electrolyte (Table 1). We assume that the cobalt electrolyte slightly modifies chemical and thus electronic properties of the CuSCN surface (e.g. by shifting its Fermi level)

1
2
3 leading to a less efficient charge injection from the QDs into CuSCN. Similar behavior has been
4
5 previously observed in the case of NiO sensitized with organic dyes in the presence of iodide
6
7 electrolyte.⁶⁴ However, when the surface of the NWs is coated with the alumina layers of
8
9 increasing thicknesses, the mentioned effects of the electrolyte on the CuSCN NWs are
10
11 becoming weaker and consequently the charge transfer becomes faster. In other words, despite
12
13 the relative slowing of the charge injection from the QDs into CuSCN, in the complete systems
14
15 with the electrolyte Al₂O₃ plays the role of a protecting barrier leading to an overall
16
17 improvement of the charge transfer process.

35 Solar cells using QD-sensitized nanowires with a 3 nm Al₂O₃ overlayer demonstrated modest
36
37 photovoltaic performance with a V_{OC} of 30±15 mV and a photocurrent density of 0.27±0.22
38
39 mA/cm², probably limited again by electrolyte incompatibility issues. An alternative
40
41 ferri/ferrocyanide electrolyte⁵⁴ was also tested, however, its deep lying redox potential (-5.0 eV)
42
43 and corrosivity towards the NWs render it unsuitable for such type of solar cells. These results
44
45 show that the high potential of CuSCN NWs for use as photoelectrodes in QD sensitized solar
46
47 cells currently remains unexploited because of the absence of suitable redox electrolytes. The
48
49 quest for appropriate redox couples to take full advantage of this promising material is

3 underway. Another viable strategy allowing to benefit from promising properties of CuSCN
4
5 NWs for sensitized solar cells is to use solid electrolytes as electron transport materials.⁶⁵
6
7

10 **Conclusions**

11
12 Heavy metal free $\text{CuInS}_x\text{Se}_{2-x}$ QDs have been successfully used to photosensitize CuSCN
13
14 NWs. The established energy diagram shows optimal alignment of the energy levels for efficient
15
16 hole injection from the QDs into CuSCN and regeneration with two electrolytes studied
17
18 (polysulfide and organic cobalt complex based redox systems) is also possible. Photophysical
19
20 studies confirm efficient hole injection with a strongly time-dependent rate. When averaged over
21
22 the first $1/e$ of decay, an average rate of $2.5 \times 10^9 \text{ s}^{-1}$ is obtained, which is faster than the hole
23
24 injection rate into NiO with the same QDs. For the first time we have also studied the
25
26 regeneration of the $\text{CuInS}_x\text{Se}_{2-x}$ QDs in presence of the electrolyte and absence of the CuSCN
27
28 NWs. The resulting average charge transfer rate of the electrolyte is $1.33 \times 10^9 \text{ s}^{-1}$ showing that
29
30 hole injection into CuSCN takes place at a faster rate than electron transfer to the redox
31
32 mediator. However, both rates are of the same order of magnitude, enabling overall balanced
33
34 charge separation. To reduce recombination processes in the sensitized systems, Al_2O_3 coating of
35
36 the CuSCN NWs has been realized using the ALD method. As expected, the presence of an
37
38 insulating barrier on the NW surface reduces the hole injection rate from QDs to CuSCN,
39
40 measured in the absence of electrolyte. To the contrary, in the presence of the electrolyte the
41
42 charge separation dynamics approaches the case of QD/electrolyte systems (without CuSCN)
43
44 with increasing alumina thickness. Concluding, our results demonstrate the appealing
45
46 fundamental features of QD-sensitized CuSCN NWs for use in photoelectrochemical devices. To
