ABSTRACT

A term male fetus suddenly and unexpectedly died in utero at the 40th week of gestation. The mother had a regular and unremarkable pregnancy except for an anticardiolipin antibodies positivity. The histological examination of the cardiac conduction system showed islands of conduction tissue in the central fibrous body, known as persistent fetal dispersion. The brainstem examination revealed a severe bilateral hypoplasia of the arcuate nucleus. This morphological finding has been described in more than 35% of our stillborn as well as sudden infant death syndrome (SIDS) cases, independently from the presence of anticardiolipin antibodies. Some authors have given emphasis to the possible lethal association of maternal autoantibodies and QT prolongation. Our findings emphasize the need of an accurate postmortem examination including the study of brainstem and cardiac conduction system in every case of unexpected late intrauterine death, following the same standardized autopsy protocol adopted in SIDS cases.

KEYWORDS: Stillbirth, sudden unexplained intrauterine death, anticardiolipin antibodies

Stillbirth is defined as late intrauterine death before the complete expulsion of the fetus from the mother.¹ A high frequency of hypoplasia of the arcuate nucleus occurs in fetuses who have died sine causa in a similar manner to that observed in sudden infant death syndrome (SIDS).²

Herein we report a case of a term fetus dying suddenly and unexpectedly, delivered by cesarean

section to a 35-year-old mother presenting with elevated anticardiolipin antibodies.

For several years we have been interested in the histological study of bulbar cardiorespiratory centers in victims of SIDS and sudden intrauterine unexplained death (SIUD).^{2,3} The importance and frequency of sudden death in late fetuses and infants prompted us to analyze in more detail the brainstem

changes in these infants. Preliminary findings have been reported in abstract form.⁴

CASE REPORT

A term male fetus suddenly and unexpectedly died in utero at the 40th week of gestation. He was delivered by cesarean section. The mother, a 35-year-old woman, gravida 2, para 1 + 1, had an unremarkable pregnancy except for a mild positivity for anticardiolipin antibodies. Antenatal screening was negative for lupus anticoagulant. During the pregnancy she had been treated with low-dose aspirin.

There was no significant family history relevant to the case. An antenatal electrocardiogram (ECG) recording of the fetus was reported to be normal.

Postmortem examination was requested with clinically suspected atrioventricular block caused by anticardiolipin antibodies.

MATERIALS AND METHODS

A complete autopsy was performed, according to the autopsy protocol usually followed at our institute in cases of sudden infant death, particularly including the assessment of the cardiac conduction system and the central and peripheral autonomic nervous systems.^{2,3,5,6} Multiple samples of all organs were fixed in 10% buffered formalin, processed, and embedded in paraffin. Five-micrometer sections were stained with hematoxylin and eosin. The heart was examined for pathologic changes in the atria, septum, ventricles, pericardium, endocardium, and coronary arteries. Sections of the myocardium were stained with hematoxylin and eosin and Heidenhain's trichrome (azan). Histological observations were focused on the cardiac conduction system, which was removed in two blocks: the first included the sinoatrial node and the

crista terminalis; the second contained the atrioventricular node, His bundle, bifurcation, and bundle branches.

Transverse serial 5- μ m sections were made through the entire pons and medulla oblongata, and were stained with hematoxylin and eosin, Bielschowsky, and Klüver-Barrera stains. The pertinent nuclei were outlined, namely the parabrachial/Kölliker-Fuse complex in the pons, the arcuate nucleus, the hypoglossus nucleus, the dorsal vagus motor nucleus, the tract solitarius nucleus, the ambiguous nucleus, the trigeminal tractus and nucleus, and the ventrolateral reticular formation in the medulla oblongata. Plates in the atlas of Olszewski and Baxter were used for reference.⁷ A morphometric analysis of the brainstem was performed with an Image-Pro Plus Image analyzer (Media Cybernetics, Silver Spring, MD). The volume of the arcuate nucleus was measured by 3-dimensional reconstruction.

The lung examination to determine the stage of development was evaluated on the basis of a macroscopic criterion, namely the correlation between lungs weight and body weight and according to microscopic criteria; that is, the presence of cartilaginous bronchi up to the distal peripheral level and the radial alveolar count.⁸

PATHOLOGIC FINDINGS

At autopsy, the fetus was described as a well-developed, well-nourished white infant, with body length of 35 cm and body weight of 3180 g. The external and internal examinations were entirely normal for gestational age and sex.

The sinoatrial node, atrioventricular node, His bundle, and bundle branches were found to be normal histologically. Close to the atrioventricular node, islands of conduction tissue in the central fibrous body, known as fetal dispersion of the atrioventricular node,^{5,9} were observed (Fig. 1).

The histological examination of the brainstem revealed a bilateral hypoplasia of the arcuate

nucleus (Fig. 2) and hypoplasia of the reticular formation. No pulmonary hypoplasia was observed.

DISCUSSION

Anticardiolipin antibodies in pregnancy are associated with recurrent fetal death. Several treatments have been proposed: low-dose aspirin, corticosteroids, heparin, and intravenous immunoglobulin.¹⁰

Pre- or perinatal death from heart block as a result of severe autoimmune lesions of the atrioventricular junction has been reported.^{11,12} In this case, the atrioventricular node and the entire cardiac conduction system appeared to be well developed. Our findings rule out the clinically suspected atrioventricular block caused by the anticardiolipin antibodies. The islands of conducting tissue detected in the central fibrous body (Fig. 1) represent the pattern of fetal dispersion and are considered to be a physiological process during fetal life.

The histological examination of the brainstem on serial sections revealed a severe bilateral hypoplasia of the arcuate nucleus (Fig. 2), which is an important chemoreceptor center for the control of breathing activity, located on the medullary ventral surface. This morphological finding has been described in more than 35% of our stillborn as well as SIDS cases.^{2,3,13}

The hypodevelopment of the arcuate nucleus, which is often associated with respiratory reticular formation hypoplasia and pulmonary hypoplasia in stillborn fetuses,¹³ is analogous in SIUD and SIDS cases,^{2,3} independent of the presence of anticardiolipin antibodies.

Recently, some authors^{11,12} have emphasized the possible lethal association of maternal autoantibodies and QT prolongation, but they did not perform a postmortem examination of the brainstem, which is considered to be of great importance by the present authors. Furthermore, in this case, the antenatal ECG did not show a prolongation of the QT interval.

Our findings emphasize the need of an accurate postmortem examination including the study of the brainstem and cardiac conduction system on serial sections in every case of SIUD, following a standardized autopsy protocol similar to the one adopted in SIDS cases.

ACKNOWLEDGMENTS

The authors wish to express their gratitude to Mrs. Graziella Alfonsi for skillful technical cooperation. Appreciation is extended to Mrs. Delfina Tosi for her advice and assistance with the photographic prints. This work was supported by the Lombardy Region project 49210–243.00: Program of Research and Intervention for the Reduction of the Risk of Sudden Infant Death and Unexpected Fetal Death.
