Abstract: *Purpose:* Several studies analyzed muscle activity after pre-fatigue due to co-contraction, but the effects of antagonist contraction on agonist muscle performance are still incompletely known.

The purpose is to determine if a previous workout of an antagonist muscle can affect muscular fatigue appearance during the subsequent agonist muscle performance.

Methods: Surface EMG was used to estimate biceps brachii muscle fatigue during isometric contraction executed after previous contractions of the antagonist muscle. Eight expert male body-builders performed five series of isometric contractions (30 s) alternatively according to the agonist and antagonist protocols.

Results: Within each repetition, for both biceps brachii muscles and experimental protocols, data showed a progressive fatigue, but no continuous quantitative decreasing trend of the median frequency of the spectrum along the five repetitions. Contraction time explained 1-91% (r^2 values) of the reduction of mean activation frequency along the 30 s (agonistic protocol); 0.7-92% for antagonistic protocol. The decrement in median frequency was only partially time-related. A repeated measures Anova found significant differences between subjects ($p < 0.0001$), protocols (antagonistic greater than agonistic, $p = 0.03$), while between sides ($p = 0.93$) and repetitions ($p = 0.50$), and for all interactions no significant differences were found.

Conclusion: The present results did not confirm that the antagonistic pre-fatiguing can delay the fatigue appearance during agonistic performance (isometric tasks). Accordingly, the antagonistic protocol does not seem to be functional in improving the upper arm performance from a fatigue point of view, at least in trained subjects.

Keywords: Agonistic-antagonistic, biceps brachii, electromyography, fatigue, isometric contraction, training.

INTRODUCTION

Fatigue is commonly defined as an exercise-induced decline in performance [1]; it is task dependent and produces impairments either in the activation signal or muscle contractility [2-4]. During an isometric constant and prolonged force effort, even in absence of mechanical manifestations, strong modifications in the intra and extra-cellular environment occur [5], the increase in intramuscular pressure determines occlusion of blood flow [3], the electric properties of the muscular fiber membrane change [6], and myoelectric manifestations of muscle fatigue become evident [2, 7].

During sustained contractions, the amount and rate of change of selected myoelectric signal variables are used to estimate muscular fatigue. Indeed, amplitude and spectral estimators obtained from surface electromyography (sEMG)

can provide an important assessment of neuromuscular strategies and muscle performance [2, 4, 7-12].

In particular, the recorded signal consists of a weighted summation of the spatial and temporal activity of many Motor Units Action Potentials that propagate along the fibers. Aiming to evaluate muscular fatigue, it is well known how myoelectric manifestations change according to fatigue type, and are proportional to the percentage of maximum voluntary isometric contraction [10].

The relation between the Motor Units Conduction Velocity (MUCV) and the Power Spectrum Density (PSD) is used to study muscle fatigue: a reduction of the MUCV in the time domain corresponds to a scaling of the PSD towards lower values in the frequency domain, due to a decrease of muscle fiber conduction velocity, action potential duration, and motor unit synchronization [8]. The global effect on the sEMG signal is an increase in amplitude and a decrease in mean power frequency [10].

Muscular fatigue affects the athlete training, requiring time to restore muscle conditions, and prolonging the number of sessions and the total time necessary to achieve the desired goals. In parallel with the study of fatigue,

therefore, other efforts are focused on new methods to reduce training time without decreasing the efficacy of the session [13]. According to this goal, one of the most applied methods, known as ‘super-set’, consists of immediate contraction of ‘back to back’ muscles [13, 14] with no recovery time between the two contractions.

Although this kind of training is considered useful for sport actions where both muscles/ muscular groups are active, the effects of pre-fatiguing antagonistic muscles on the activity of reciprocal agonistic muscles are not fully known yet [13, 14]. Differences about tested muscles, load and type of contraction make the results difficult to compare [13-16]. To date, most of EMG fatigue studies are relative to limb ballistic movement and are focused on concentric/eccentric muscle contraction.

Thus, in the current study, two fatiguing protocols for biceps brachii muscle training (classical and super-set methods) [17, 18] were examined to verify muscular fatigue during time. In particular, we wanted to find the best training method to hinder the fatigue effects. sEMG was used to estimate muscular fatigue parameters [2, 7, 11, 12, 19, 20] to verify which protocol was more efficacious to delay the appearance of fatigue [13], and consequently to hold higher level of strength during time.

MATERIALS AND METHODOLOGY

Subjects

Eight expert male body-builders (age, 24 ± 3.5 years; weight, 80.5 ± 8.3 kg, Table 1) volunteered for the study after a detailed explanation of the procedures and possible risks involved. They were selected because they are people able to manage load and usually have an equilibrated level of force (agonistic and antagonistic muscles) in all paired muscles (right vs left). All body builders could interrupt the protocol at any time. Approval was obtained from the local ethics committee; all procedures were not invasive and not potentially harmful.

All subjects were right handed [21] and free from neurological and neuromuscular disorders. They were tested during training regime.

Instrumentation

sEMG was made using an 8 channels electromyograph and disposable surface electrodes (Freely, De Götzen srl; Legnano, Italy). To detect the sEMG (differential mode) in accord to the SENIAM Protocol [22] disposable, pre-gelled, silver/silver chloride bipolar surface (21 ± 1 mm center-to-center; diameter 10 mm) electrodes (FLAB, Vicchio, Florence, Italy) were placed (Fig. 1) over the longitudinal axis of the biceps brachii muscle [23] parallel to the estimated direction of muscle fibers [24]. A disposable reference electrode was applied to the forehead [25]. Before electrode placement, the skin was cleaned with ethanol. No EMG signal was collected from the triceps brachii muscle because the experimental set up (preacher curl bench, see below and Fig. 1) makes impossible the placement of electrodes on the muscular bellies.

The analog sEMG signal was amplified and digitized (gain 150, peak-to-peak input range 28 mV, that is ± 14 mV, 12 b resolution, 2230 Hz A/D sampling frequency, theoretical resolution 16 μ V) using a differential amplifier with a high common mode rejection ratio (CMRR = 105 dB in the range 0-60 Hz, input impedance 10 G Ω), and filtered (analogue filtering: lowpass filter with a cut off 580 Hz; digital filtering: range 30-400 Hz; band-stop for common 50 Hz interference with a notch filter [26], approximate range 47-53 Hz).

The signals were recorded for further analysis. Very low frequency (<10Hz) artifacts were limited by the use of the reference electrode (forehead).

To perform the endurance training exercises, a preacher curl bench with 60° incline plane, a flat bench, a barbell (length 200 cm, diameter 2.8 cm, weight 10 Kg) and some iron plates of different weight (1-10 Kg) were used.

Experimental Procedure

The one repetition maximum (1RM) in eccentric-concentric modality was determined for each subject on “preacher curl” (biceps brachii exercise) and on “close grip bench press” (triceps brachii exercise). The two exercises require the use of a barbell and a preacher curl bench (Fig. 1)

because this set avoids or reduces the intervention of shoulder and trunk muscles. On both exercises the grip width on the barbell was close to shoulder width and the setting. An expert trainer controlled the correct position of the subjects during the performance of all exercises.

Three days after the 1RM test [3, 27], each subject executed the experimental protocol which had been previously randomly assigned to him (4 subjects at the *agonist protocol group*, 4 subjects at the *antagonist protocol group*). In the *agonist protocol* the subjects were asked to perform isometric contractions of the biceps brachii muscles, while in the *antagonist protocol* (super set method) the biceps brachii contractions were preceded by contractions of the antagonist muscle (triceps brachii).

After a general warm-up composed of a low intensity aerobic activity, the subjects had a specific warm-up (eccentric-concentric contractions) which depended on their specific experimental protocol (Tables 2 and 3). Subsequently, each subject performed five series of prolonged isometric contractions (simple task used to avoid putative compensation between muscles) [23] while sEMG was recorded from their biceps brachii muscles [28, 29].

Loads and isometric contraction times are reported in Tables 4 and 5. The *agonist protocol* subjects executed an isometric contraction of biceps brachii in the preacher curl exercise, holding up a barbell (loaded according to personal 1RM) with an elbow angle of 90°. The recovery after each contraction was 270 s.

For the subjects of the *antagonist group*, the isometric contraction in preacher curl exercise were preceded (with a 2 minute interval) by isometric contractions (30 s) of triceps

brachii in the close grip bench press with an elbow angle of 140°. The angular elbow positions were checked by an expert technician within a range of 2-3° [1]. In the antagonist protocol, the recovery between preacher curl and close grip bench press was arranged to have the same timing between subsequent biceps brachii contractions as in the agonist protocol. Strong verbal encouragement was given to the subjects during the task.

In both protocols, sEMG potentials were detected during the preacher curl isometric contraction (30 s) according to the endurance time found by Dimitrova *et al.* (2009) [30] using 80% of 1RM.

After a week, period in which the body-builders did not perform any upper limb training, the groups were shifted and the tests were repeated at the same time of the first day to avoid the effect of circadian rhythms [3].

Room was kept stable at 24°C [6] to avoid reductions in force production and changes in sEMG characteristics [31].

Data Analysis

The EMA software (De Götzen srl; Legnano, Italy) was used to analyze the frequency spectrum. In particular, Fast Fourier Transform (FFT) was assessed in 1-s epochs along the signal [2] and the median frequency of the spectrum was calculated. For each right and left biceps brachii muscle acquisition in every repetition (from 1 to 5) and for both protocols (agonistic and antagonistic), 30 median frequencies (Hz) were thus obtained in each repetition. To assess the time-related variations in the median frequency associated to the effects of fatigue on muscular contraction [19], separately for

each muscle and repetition, all median frequencies were interpolated by linear regression analysis [8] and then slope coefficient (m) was calculated. Thus, 160 regression lines were obtained: 2 m slope coefficient (right and left side) for each subject x repetition.

A repeated measures ANOVA was used to determine differences between subjects, experimental protocol, side and repetition. The level of significance was set at 5%.

RESULTS

Within each repetition, for both biceps brachii muscles and experimental protocols, data showed a progressive muscular fatigue (90% of the m values were negative, Tables 6 and 7).

Comparing the first repetition with the fifth one during the performance of the antagonistic protocol, all body builders, except M5, M6 and M7, showed an increasing muscular fatigue in both arms (larger absolute values of m coefficient). In contrast, M5 and M6 did not show fatigue manifestations (the absolute value of m in the fifth repetition was smaller than the first one), while M7 showed an EMG effect of fatigue only in his right arm.

The same comparison within the agonistic protocol did not show a regular decreasing trend; only M2 and M4 showed EMG indicators of fatigue in both sides.

M8	-0.42	-0.93	-0.71	-0.90	-0.39	-1.01	-0.67	-0.92	-0.12	-1.08	0.33 (0.25)	0.86 (0.03)

The average m values did not show a continuous quantitative decreasing trend along the five repetitions (Fig. 2). The difference between close repetitions about the same side (1-2, 2-3, 3-4, 4-5, absolute m values) was not negative in all cases (similar trend within side). This manifestation was more frequent in the antagonistic protocol than in the agonistic one.

Contraction time explained from 1 to 91% (r² values, mean values reported in Tables 6 and 7) of the reduction of the median power frequency along the 30 s (agonistic protocol) and from 0.7 to 92% for antagonistic protocol. The large variability in r² value indicated that the decrement in median frequency was only partially time-related.

A repeated measures Anova (Table 8) found significant differences between subjects (p<0.0001), protocols (antagonistic greater than agonistic, p=0.03), while between sides (p=0.93), repetitions (p=0.50) and for all interactions no significant differences were found.

DISCUSSION

sEMG can help trainers and athletes to better their training session and global performance. In the current study, we tried to define the fatiguing appearance due to two different kinds of exercise sequences for the elbow muscles. In the first protocol, all body builders performed isometric contraction of biceps brachii muscles (agonistic) while in the second one the same contraction followed a previous isometric contraction of triceps brachii muscles (antagonistic or super-set).

The EMGs were detected during isometric contraction because it is the best way to record the signal with minimal crosstalk and without electrode movements [7]; the frequency spectrum analysis could explain the fatigue appearance with or without a previous antagonistic contraction.

The median frequency collected in 1-s epochs along the 30-s signal was significantly different between the two protocols while no differences were found between sides [3]. The lack of side-related differences is in accord with Williams *et al.* (2002) who monitored a sustained maximum isometric fatiguing task of the elbow flexors, and did not find significant differences in the frequency spectrum between dominant and non-dominant arm.

The lack of significant differences among the five repetitions and the sides can be explained by both the selected task (30 sec of contraction may be insufficient to produce fatigue, or recovery time may be too long) or by the good level of training of the current group of body builders that use their right and left side muscles almost symmetrically. Different results may be obtained with less trained subjects, and it may be the topic of a future study. Indeed, Hendrix *et al.* (2009) [10] during isometric elbow flexor contraction found a significant correlation between force and fatigue threshold when the contraction was maintained for an extended period of time without exhaustion.

The two analyzed protocols produced different decrements (antagonistic greater than agonistic) of the median frequency during the muscular effort (isometric

contraction). These results disagree with previous data collected during isokinetic tasks of the quadriceps muscles [13]. Those authors found decrements in peak torque and peak power as compared with the non-fatigued state, but no significant differences in quadriceps EMG activity whether muscles were pre-fatigued or not, were detected.

Thus, we do not confirm that the antagonistic pre-fatiguing could increase agonistic force generation, at least during low speed actions [13], and during isometric tasks. Indeed, during slow movements (and overall in sustained isometric task) all muscles around the joints change the motor unit control strategies to stabilize the bones with progressive concentric and eccentric contractions [6].

Table 8. Repeated Measures ANOVA on the Slope (m) of Median EMG Frequencies During Time

Effect	Degrees of Freedom	F Value	P Value
Protocol	1, 152	4.77	0.03

Protocol x repetition	4, 152	1.28	0.27
Side x repetition	4, 152	0.15	0.96
Protocol x side x repetition	4, 152	0.26	0.90
Subject	7, 152	13.73	<0.0001

The present study was made with a reduced number of subjects (but in line with the numbers typical of this kind of investigations) [2, 5, 6, 19, 23, 30], and even if we tried to standardize their performance using the 1RM, as previously done in literature [8, 23], this was not sufficient to reduce inter-subject variability. Additionally, the current values of r^2 were very variable [10], and in several occasions the median frequency decrement was not time related, with r^2 values close to 0. The estimation of “m slopes” values is therefore to be taken with caution.

Decreasing in peak power in slow tasks ($60^\circ \text{ sec}^{-1}$) [13] and a fatiguing manifestation in median frequency during sustained back to back muscle isometric contractions suggest the use of super-set training only during ballistic limb movements [32]. Indeed, Baker & Newton (2005), using a computerized Plyometric Power System, found an acute effect on power output after antagonistic effort. The alternation of antagonistic and agonistic contractions could reduce the interfering effect of co-contraction, and increase the braking action of antagonists, thus favoring power output action during the performance of fast joint movements [14]. It has to be mentioned that the co-activation of agonist and antagonist muscles plays a key role in joint stability [11, 16], and that triceps contraction modulates elbow flexion during this position task (supporting inertial load while maintaining a constant joint angle) thus making the global contraction pattern very complex. Fatigue effects can be different in the agonist and antagonist muscles of a single joint when concentric contractions had been performed [16], but similar with eccentric [11] and isometric (no differences between side) contractions.

Moreover, body builder are able to generate a great level of force that could hide fatigue trend in back-to-back muscles because they are used to managing load in slow movements (at least not ballistic).

CONCLUSION

In conclusion, the ‘antagonist protocol’ is not apparently improving the force generation with respect to the fatigue effects, in particular during an isometric task and with trained people.

Further investigations are necessary to fully understand the complex neuromuscular strategy during fatiguing task, the differences between concentric and eccentric muscle contractions [9, 11], the role of restricted blood flow during high percentage of 1RM load task [10, 23, 30], the influence of antagonist muscle activation during agonist muscle isometric contraction, and the fatigue manifestations about antagonist muscle.

Moreover, the variability in spatial change activity, amplitude cancelation [10], variation in the number of active motor units (overall in low load contraction) suggest other investigations and new mathematical model analysis [6, 8]. A further improvements may be the application of long detecting electrodes to enhance the detection of the EMG signal [30], and the assessment of ‘normal-trained’ subjects group to evaluate the reliability of the protocol.
