27 Abstract

Sprouting is a natural process that enhances the nutritional and sensory profile of 28 29 cereal-based foods. The present work addressed the possibility of using refined flour 30 from sprouted wheat (SWF) to improve the bread-making performance of some flours 31 in place of conventional improvers - i.e. enzymatic improver (EI) and malt (M). Either 32 0.5% EI or M was added to the control flour (CTRL), as conventionally used in bakeries, whereas SWF was used up to 2%. Unlikely EI and M, 1.5% SWF showed a 33 gluten aggregation strength similar to that of the CTRL, suggesting no worsening of the 34 35 protein network characteristics. As for the leavening properties, dough development 36 increased, thanks to the enrichment with 1.5% SWF. In addition, presence of SWF 37 improved the amount of gas production during leavening- resulting in bread with high 38 specific volume - and the crumb softness during storage. Addition of SWF may 39 represent a valid alternative to enzymatic improvers or malt for improving the 40 technological performance of wheat flours.

41 1.Introduction

42 During germination (or sprouting), high levels of hydrolytic enzymes - such as amylases and proteases – are accumulated in the cereal seed, so that the insoluble 43 44 endosperm starch and protein reserves are hydrolyzed into soluble forms that can be 45 transported to the embryo to meet the needs of the growing plant. Significant correlations between xylanase activity levels and sprouting-related parameters, such as 46 47 α-amylase activity, and viscous properties of flour-water suspensions, have been 48 reported (Dornez et al., 2008). 49 Under ideal growth conditions, ripe grains contain only small amount of enzymes 50 and the resulted flour can be used to produce a wide range of cereal-based products. On 51 the other hand, under non ideal conditions - e.g. when the grains are exposed to 52 prolonged wet or foggy conditions – amylases, proteases, and xylanases may be 53 retained or synthesized prior to harvest and as a consequence, the flour is unsuitable for 54 baked products (Prasada and Hemalata, 2014). 55 Indeed, pre-harvest sprouted wheat is usually associated with dough weakening and 56 stickiness, and with worsening of dough handling (Paulsen and Auld, 2004). Moreover, 57 bread from extensively sprouted wheat show very poor characteristics, with a sticky 58 and gummy crumb (McCleary and Sturgeon, 2002). Finally, the crumb color of the 59 breads is darker and the grain and texture inferior compared to bread baked from non-60 germinated wheat (Finney et al., 1980). 61 On the other hand, since the nutritional (Hubner and Arendt, 2013; Singh et al., 62 2015) and sensory (Heiniö et al., 2001) benefits of germination have been extensively 63 documented, using of sprouted grains in food formulations is continuing to gain traction in the marketplace and represents a re-emerging trend in healthy foods. 64

65 Recent studies reported that the use of flour from whole wheat germinated in 66 controlled conditions improved loaf volume and crumb texture (Bellaio et al., 2014; Richter, Christiansen, & Guo, 2014). These positive effects were ascribed to the natural 67 68 enzymes expressed during the germination process that might decrease or completely 69 replace the quantity of commercial enzymes added to bread formulation. Nonetheless, 70 the use of sprouted wheat as alternative to conventional flour improvers (e.g. enzymes, 71 malt) has not been thoroughly investigated up to now. 72 Using enzymes as flours improvers is a frequent practice for flour standardization 73 and also as baking aids. Enzymes – such as amylases, proteases and xylanases - are 74 usually added to modify dough rheology, gas retention and crumb softness in bread-75 making (Goesaert et al., 2006). Those enzymes can be added individually or in 76 complex mixtures, which may act in a synergistic way in the production of baked 77 goods. 78 The present work addressed the possibility of using refined flour from 79 controlled-sprouted wheat, as source of enzymes, to improve the bread-making performance of flours. The effects of the enrichment with low level (0.5-2%) of 80 sprouted wheat on dough rheology and bread-making performance were assessed and 81 82 compared to those of the improvers (e.g. malt and enzymatic improver) conventionally

84

85

2. Materials and Methods

used in bread making.

86 2.1 Materials

Flours from unsprouted wheat (USWF) and sprouted wheat (SWF) were kindly provided by Molino Quaglia (Molino Qualia S.p.A., Vighizzolo d'Este, Italy), as the commercial wheat flour (CTRL; W =260 *10⁻⁴ J; P/L = 2.08) used for blending studies.

90 Malt (M; Matlo 5, Bona s.r.l., Monza, Italy) and the enzymatic improver (EI, 91 PowerBake950, Danisco, Copenhagen, Denmark) were added to CTRL at 0.5% level, which represents conventional amount used in bread-making (De Leyn, 2006). SWF 92 93 was used at 0.5, 1, 1.5, and 2%. 94 95 2.2 Sprouting process Commercial wheat kernels were sprouted in an industrial sprouting plant (Bühler AG, 96 97 Uzwil, Switzerland). Wheat (10 tons) was soaked in water (kernels:water ratio of 1:2) 98 for 12-24h at 20°C, germinated for 72-90h at 20 °C, dried at 50 °C for 32 h. 99 Unsprouted and sprouted wheat were milled in the same industrial plant (Bühler AG, 100 Uzwil, Switzerland), and the related flours – USWF and SWF, respectively - were 101 obtained. 102 2.3 Chemical composition 103 104 Moisture, starch, protein, lipid and ash contents were assessed by AACC standard 105 methods (44-15.02, 76-13.01, 46-12.01, 30-10.01, and 08-01.01, respectively; AACC 2001). Sugars were determined by HPLC by Anion Exchange Chromatography with 106 107 Pulsed Amperometric Detection (HPAEC-PAD) (Zygmunt et al. 1982). Total, soluble and insoluble dietary fiber content was quantified by enzymatic-gravimetric procedure 108 109 (AOAC Method 991.43). 110 2.4 Enzymatic activities 111 112 Proteolytic activity was determined in triplicate in the conditions proposed by Arnon (1970) and using azocasein (Sigma Chemical Co., St Louis, MO, USA) as the 113

substrate. Alpha-amylase activity was determined in triplicate according to AACC

115	standard method n. 303, by using the Megazyme Amylase Assay Procedure
116	(Megazyme International Ireland Ltd., Wicklow, Ireland). Xylanase activity was
117	determined in triplicate using the Azo-wheat arabinoxylan kit (K-AZOWAX 09/04)
118	provided by Megazyme (Megazyme International Ireland Ltd., Wicklow, Ireland).
119	
120	2.5 Rheological properties
121	2.5.1 Pasting properties
122	Pasting properties were measured in duplicate using a Micro-Visco-Amylograph device
123	(MVAG, Brabender GmbH & Co. KG, Duisburg, Germany). An aliquot of sample (12
124	g) was dispersed in 100 mL of distilled water and stirred at 250 rpm. The following
125	temperature profile was applied: heating from 30 °C to 95 °C at a rate of 3 °C/min,
126	holding at 95 °C for 20 min, cooling from 95 °C to 30 °C at a cooling rate of 3 °C/min,
127	and holding at 30 °C for 1 min.
128	
129	2.5.2 Gluten aggregation properties
130	Gluten aggregation properties were measured at least in triplicate using the GlutoPeak
131	device (Brabender GmbH & Co. KG, Duisburg, Germany), as reported by Marti et al.
132	(2015a).
133	
134	2.5.3 Leavening properties
135	Leavening properties of doughs were assessed in duplicate with a
136	Rheofermentometer® device (Chopin, Tripette & Renaud, Villeneuve La Garenne
137	Cedex, France). Dough samples were prepared in an automatic spiral mixer (Bomann,
138	Clatronic s.r.l., Piadena, Italy) with 1.5% NaCl and 1.5% bakers' yeast. Mixing time
139	(1.6-1.8 min) and amount of water (54.5-55%) were those determined by the

140 Farinograph test, according to the ICC Standard Method 115/1 (ICC 1992). The rheofermentographic test was performed on 315 g portion of the dough and carried out at 30 °C for 3 h. 142

143

144

141

2.6 Bread-making

Either wheat flour or blends were mixed with compressed yeast and salt, each 145 146 comprising 1.5g/100g of the total mixture, and previously dissolved in water. The 147 amount of water added to each formulation varied according to the farinographic water 148 absorption index, previously determined. For each formulation, the ingredients were 149 mixed in an automatic spiral mixer (Bomann, Clatronic s.r.l., Italy), for 8 min. 150 Immediately after mixing, the dough was left to rest for 10 min at room temperature. 151 After that, the dough was divided into portions of 250 g, molded into cylinder shapes, 152 put in baking pans (8×15×5 cm) and left to rest for 60 min in a proofing chamber at 30 153 °C and 70% RH. Samples were baked in an oven (Self Cooking Center®, Rational 154 International AG) for 4 min at 120 °C with vapor injection for 7 s. Then, the oven temperature was increased to 230°C for 11 min. Two hours after removing loaves from 155 156 the oven, they were packaged in perforated orientated polypropylene film and stored at 157 controlled conditions (20 °C, 60% RH) for three days. For each sample, two baking 158 experimental tests were performed and three loaves were obtained from each baking 159 test.

160

161

2.7 Bread properties

162 A reflectance color meter (CR 210, Minolta Co., Osaka, Japan) was used to measure the lightness and saturation of the color intensity of bread crumb and crust. Each 163 measurement was replicated five times and the average value was used.

165 The apparent volume (n=6) was determined by the rapeseed displacement 166 method, two hours after baking. The weight of the bread (n=6) was recorded and the specific volume was determined through the volume/mass ratio and expressed in mL/g. 167 168 Three central slices (15 mm thickness) were selected from each bread and used for crumb moisture, water activity, porosity and texture analysis. 169 170 Moisture content of the crumb was measured in triplicate by drying the sample at 130 °C until the weight will not change of 1 mg for 60 s, by an infrared balance (MA 171 172 210.R, Radwag Wagi Elektroniczne, Poland). The crumb core water activity (aw) was 173 measured in triplicate by an electronic hygrometer (Aqua Lab, CX-2 – Decagon 174 Devices, Pullman, WA). 175 Crumb porosity was evaluated by image analysis. The images were acquired at 176 a resolution of 600 dpi (dots for inch) using a flatbed scanner (Epson Perfection 3170 Photo, Seiko Epson Corp., Japan). The images were converted to 8 bit grey scale and 177 178 subjected to spatial calibration before the analysis. The images were calibrated, 179 standardized and optimized applying appropriate filters to evaluate the morphological characterization of the bubbles area (mm²) and porosity (%) using an Image-Pro Plus 180 6.0 (Media Cybernetics Inc., USA) software. The bubbles, moreover, have been 181 182 classified into four different size classes according to their surface: class 1: bubbles area between 0.01 and 0.99 mm²; class 2: bubbles area between 1.00 and 4.99 mm²; 183 class 3: bubbles area between 5.00 and 49.99 mm²; class 4: bubbles area greater than 184 50.00 mm². The number of pores and the area occupied by each class (expressed as 185 186 percentage of the total number of pores and total pore-area, respectively) were also evaluated. 187 Crumb texture characteristics were assessed using a testing machine (Z005, 188 Zwick Roell, Ulm, Germany), equipped with a 100 N load cell as described by Marti et 189

190 al. (2014). A 30 mm diameter cylindrical aluminum probe and a test speed of 2 mm/s 191 were used. Crumb hardness was measured (n = 6) after 0 (two hours after baking), 1, 2 and 3 storage days and expressed as the load (N) at 30% strain. 192

193

194 2.8 Statistics

Analysis of variance (ANOVA) was performed utilizing Statgraphics XV version 195 15.1.02 (StatPoint Inc., Warrenton, VA, USA). Different dough samples were 196 197 considered as factors for ANOVA. When a factor effect was found significant 198 $(p \le 0.05)$, significant differences among the respective means were determined using 199 Fisher's Least Significant Difference (LSD) test.

201 3. **Results and Discussion**

Chemical composition and enzymatic activities before and after sprouting 203 Wheat kernels were germinated in an industrial plant by modulating temperature and 204 humidity conditions, in order to promote a controlled sprouting (Figure S1). The sprouting process did not affect the ash, protein, lipids, and fiber contents (Table S1). 206 On the other hand, after sprouting, the starch content decreased and, consequently, the amount of total sugars increased, with particular regards to maltose, sucrose and 208 glucose (Table S1). These variations are due to the high enzymatic activities after sprouting. Indeed, SWF had much more enzymatic activities (amylases, proteases and xylanases) than USWF (Table 1). The enzymatic data confirm the synthesis and accumulation of enzymes during the germination phase. This phenomenon is necessary 212 to assure the hydrolysis of proteins, polysaccharides and lipids to allow the growth of the embryo (Nelson et al., 2013). Table 1 also showed the enzymatic activities of a 213 214 commercial malt (M) and an enzymatic improver (EI) that are conventionally used in

bread-making to improve the baking performance and shelf-life of the product. In the following sections, the effects of small amounts of SWF (0.5-2%) on dough rheology and bread quality will be compared with those promoted by conventional flour improvers at similar dosage (De Leyn, 2006).

219

215

216

217

218

3.2 Pasting properties

220 221 The MVAG indices of commercial wheat flour alone (CTRL) or after addition of malt 222 (0.5% M), enzymatic improver (0.5% EI), or sprouted wheat flour (0.5, 1, 1.5, 2% 223 SWF) are reported in Table 2. The progressive addition of SWF (from 0.5 to 2%) 224 resulted in a significantly ($p \le 0.05$) decrease in viscosity during heating and cooling 225 phase as a consequence of the high amylase activity in germinated wheat (Table 1). 226 The effect of amylase activity on paste viscosity has been already documented (Dobraszczyk and Dendy, 2001). 227 228 Although a decrease in peak viscosity has been measured in presence of SWF, 229 the starch in the mixture has still the ability to form a gel at temperature lower than 230 95°C. This result is of great interest in view of incorporating SWF in food formulation, 231 without dramatically compromising the starch behavior during baking. In presence of 232 SWF, peak temperature significantly (p \leq 0.05) decreased, indicating the starch 233 granules reached maximum viscosity earlier compared to CTRL. 234 During the cooling step the gelatinized starch is reorganized, giving the structure of 235 a gel. The setback value - which reflects the retrogradation tendency of amylose in a starch paste - decreased with increasing percentage of SWF (Table 2), suggesting a 236 237 decrease in starch retrogradation compared to the CTRL. The outer branches of the amylopectin are hydrolyzed by the alpha-amylase and thus made unavailable for 238 forming large amylopectin crystals. These small crystallites do not form a three-239

240 dimensional network capable of promoting an important increase in viscosity during 241 cooling (Dobraszczyk and Dendy 2001). This trend could be of great interest, since low 242 setback values indicate low rate of starch retrogradation and syneresis. This aspect 243 would contribute to the maintenance of a soft crumb during bread storage. 244 The addition of 0.5% EI (having xylanase as the main activity, Table 1) lead to 245 no significant changes in the pasting properties of the CTRL, despite previous studies 246 showed that xylanase cleaves the arabinoxylans into oligomers resulting in the decrease 247 in peak viscosity (Hemalatha et al., 2010). Differences in xylanase activity among 248 commercial improvers might account for the differences in results. 249 As expected the addition of malt – even if at low level (0.5%) - causes a 250 considerable decrease in pasting temperature, maximum viscosity, and peak 251 temperature (Table 2), in agreement with the studies of Rao, Manohar, & 252 Muralikrishna (2007). Due to the high amount of α -amylase, this mixture did not show 253 the typical pasting profile of wheat flour; in particular, there is no real viscosity peak 254 and the curve is flat throughout the analysis period. 255 256 3.3 **Gluten Aggregation Properties** 257 The GlutoPeak indices of the commercial wheat flour (CTRL) or added to malt (0.5% 258 M), to the enzymatic improver (0.5% EI), or to the sprouted wheat flour (0.5, 1, 1.5, 259 2% SWF) are shown in Table 2. 260 GlutoPeak is a new device proposed for gluten quality evaluation, by measuring protein aggregation capability (Marti et al., 2015a). Bread flours with poor 261 262 technological quality (e.g. resulting in a low bread volume) are usually characterized by a rapid build-up in consistency and a sharply defined peak followed by a rapid 263

breakdown, while high bread quality flours have a much slower build-up in dough 265 consistency and require more time to reach peak consistency (Marti et al., 2015a,b). 266 Adding M or EI at the 0.5% no significant differences in the maximum consistency 267 value were observed. A similar result was obtained when 0.5% SWF was added; 268 whereas, increasing SWF levels (1-2%) determined a significant (p \leq 0.05) increase in 269 maximum torque (Table 2). 270 As regards the time at which the maximum aggregation occurred, a significant (p \leq 271 0.05) decrease in value has been measured when M, EI, and SWF have been added to 272 flour. The faster aggregation was measured for SWF at levels $\geq 1.5\%$. The decrease in 273 time can be related to gluten dilution, since the same phenomenon was observed adding 274 1% of starch (data not shown). Nevertheless, the action of proteases, which are 275 synthetized during germination, could be responsible for changing the aggregation 276 properties. In general, the shorter the time until the formation of gluten, the lower the 277 quality of the network (Melnyk et al., 2012). However, on the basis on previous work 278 (Marti et al., 2015a,b) the mixtures with germinated wheat flour show a gluten 279 aggregation kinetic similar to that of a flour with good bread-making quality. Indeed, it 280 seems that wheat sprouting under controlled conditions determined protein hydrolysis 281 without compromising their ability of aggregating and forming gluten network. 282 More recently the area under the peak – which takes into account both maximum 283 torque and maximum peak time - has been found the most suitable parameter for 284 predicting conventional parameters related to dough strength and extensibility (Marti et 285 al., 2015b). The energy value decreased when either M or EI were added to the CTRL. 286 Interestingly, when SWF was present at 1 or 1.5%, samples showed a similar energy value as the CTRL (Table 2), suggesting that the enrichment of 1.5% SWF did not 287 288 compromise the gluten aggregation properties of the flour.

3.4 Leavening properties

The Rheofermentometer allows evaluating the proofing behaviour of doughs by measuring dough development and gas release during the fermentation process. The main indices obtained from the curves during dough development and gas production are summarized in Table 2. Adding 0.5% EI to control flour did not affect either the dough height or the gas production and retention. Both samples showed a slight dip in height after 1 h and 30 min of proofing (data not shown). When 0.5% M was added to the flour, dough developed without showing any decrease in height within the first 2 hours of proofing. Moreover, the use of malt increased the dough final height from 57 to 70 mm (Table 1), likely due to the more intense yeast activity in presence of free sugars formed from the starch hydrolysis from α -amylase. The positive effect of α -amylase on dough leavening properties have been already demonstrated (Penella, Collar, & Haros, 2008). The height reached by dough during fermentation is related to loaf specific volume; therefore, maximum height is an important parameter when evaluating baking performance.

Adding SWF led to increase the development of the dough (Table 2). The maximum dough height was reached in the mixture with \geq 1.0% SWF. Even the time when this maximum height is reached, which is in closed relation to the yeast activity (Huang et al., 2008), is similar for all samples. However, the mixture with 1.5 % and 2.0% SWF showed a better response than the other percentages.

Rheofermentometer analysis yields insight into CO₂ production, retention and dough height throughout the dough fermentation process and therefore gives a good indication of yeast fermentation performance. Either the improvers conventionally used in bread-making or SWF affect the porosity time (corresponding to the loss of CO₂

from the dough; Table 2). On the contrary all of them, but EI, positively affected the total volume of CO_2 produced and retained into the dough. Previous studies have also shown that gas formation of doughs prepared with fungal α -amylase during fermentation generally increased significantly (Penella et al., 2008).

The quantity of CO_2 lost by the dough when proofing is directly linked to the porous nature of the dough, which appears more or less prematurely and is closed linked with the quality of the protein network. The highest amount of retained gases is observed in presence of either malt or 2% SWF. According to literature, the α -amylase provoked a negative effect in the gas retention coefficient, associated with an increase in dough permeability. According to Penella et al. (2008), this phenomenon was induced by increased hydrolysis of starch chains.

3.5 Bread Properties

Based on the results obtained on dough rheological properties, we decided to compare the bread-making performance of CTRL, with that of 0.5% EI, 0.5% M, and 1.5% SWF. Crumb porosity is shown in Fig. 1, whereas bread characteristics are reported in Table 3. Adding 1.5% SWF significant increased the porosity area from 44.5% (CTRL) to 54.9%. This figure was similar to that of bread with 0.5% EI (53.9%) and higher than sample with 0.5% M (52.4%). Looking at the cells, despite the number of cells of each class was very similar among the samples (data not shown), differences in cell area were observed (Fig. 1). In particular, small cells (<5 mm²) area represented more than 70% of the total pore area in the CTRL bread and about 40% in 0.5% M, 0.5% EI and 1.5% SWF products. Crumb of bread with M, EI, and SWF was characterized by the presence of large cells (5-50 mm²) whose area accounted for the 60% of the total porosity.

The effect of SWF on crumb colour was similar to that of malt. Both of them significantly decreased the lightness and increased the redness compared to the control bread, with no effect on yellowness. Once again, this result could be related to the increased amount of amylases in the flour mixture of this two bread types.

As expected, adding malt or germinated wheat flour resulted in a decrease in luminosity, redder and more yellow crust compared to CTRL. These changes were likely caused by increase in Maillard reaction extent (Hefni and Witthöft, 2011) due to the hydrolytic action of amylases and proteases (Goesaert et al., 2006). On the contrary, the use of EI did not affect the bread crust colour, likely due to the low amylase content and thus to low levels of released glucose.

The highest specific volume was observed for the bread with SWF, whereas no significant differences were observed in presence of either 0.5% EI or 0.5% M (Table 3). Enzymes concentrations seem not to account for the observed differences in breadmaking performance. On the other hand, the nature of sample should be considered. Indeed, adding SWF contains also proteins that might contribute to gluten formation and thus maintain the structure during baking. Also Mäkinen and Arendt (2012) reported no significant increased bread volume with 0.5% malt. The effectiveness of xylanase present in EI (Table 1) in improving bread volume is contributing to result in the redistribution of water from the pentosane phase to the gluten phase. The increase in gluten volume fraction assures more extensibility to gluten and consequently a better oven-spring (Goesaert et al., 2006). However, it should be considered that the improver used in our study was not a pure enzyme but included various enzymatic activities, with xylanase as the highest activity.

The presence of either malt or SWF improved the textural properties of the bread by significantly decreasing the crumb firmness of fresh samples (2h after baking)

(Fig. 2). On the contrary, EI at 0.5% did not affect the crumb texture. During storage (up to 3 days), all the samples exhibited lower firmness than CTRL (Fig. 2). The best result in terms of increasing crumb softness and lowering the staling process was obtained in presence of M or SWF. Differences in bread textural properties cannot be related to bread crumb moisture nor to water activity, as no significant differences were observed among the samples (data not shown).

The results of our study confirm the positive effects of amylase, proteases and xylanase on crumb firmness and bread staling (Caballero, Gómez, & Rosell, 2007). The antistaling effect of these enzymes have been widely reviewed (De Leynm, 2006; Goesaert et al., 2006). In particular, α -amylase has been proved to be useful for reducing amylopectin retrogradation and the firming rate of wheat bread crumb (Champenois et al., 1999). Through studies on model systems, Rojas, Rosell, & De Barber (2001) stated that maltodextrins were responsible for the antistaling effect promoted by addition of α -amylase to bread formulation. Jiménez and Martínez-Anaya (2001) proved that water-insoluble pentosans were positively correlated with crumb elasticity and hardness during storage. Xylanases would lead to cleavage of the backbone of arabinoxylans, with the consequent release of water and decrease in waterinsoluble pentosans (Rouau, El-Hayek, & Moreau, 1994). Both phenomena could explain the positive effects of xylanases in bread freshness. Similarly, the improvement of bread shelf-life through protease addition possibly would be tied with the increase of the water available for starch, in conjunction with a simultaneous diminution of starchprotein interactions as consequence of the hydrolysis of peptide bonds in the protein molecules. In addition to enzymatic activities, during germination the lipid hydrolysis promotes the production of mono- and diglycerides. This process slows the staling of bread, which corresponds to a longer shelf life of the product.

390 4. Conclusions

This study provides evidence that refined flour from sprouted wheat can be considered 391 392 as an ingredient for improving the technological performance of commercial flours. 393 Refined flour from industrial-scale germinated wheat shows increased enzymatic 394 activities without compromising the aggregation properties of gluten proteins. Wheat sprouting under controlled conditions increases sugar production with a concomitant 395 396 improvement of dough leavening properties. The bread-making performance evaluated 397 in terms of loaf volume and crumb softness, confirms that flour from sprouted wheat is 398 a promising and interesting ingredient for formulating baked products, avoiding the use 399 of enzymatic improvers or malt with a positive impact on consumers' acceptance and 400 facilitating the adoption of clean label.

504

505 **List of Tables** Table 1. Enzymatic activities of flour from unsprouted (USWF) and sprouted (SWF) 506 507 wheat, malt (M) and enzymatic improver (EI). 508 **Table 2.** Rheological properties of commercial wheat flour (CTRL), with either malt 509 510 (0.5% M), enzymatic improver (0.5% EI), or sprouted wheat flour (0.5, 1, 1.5, 2% 511 SWF). 512 Table 3. Specific volume, moisture, water activity, color and firmness of bread from 513 514 commercial wheat flour (CTRL), with either malt (0.5% M), enzymatic improver 515 (0.5% EI), or sprouted wheat flour (1.5% SWF). 516

517 **List of Figures** 518 Fig. 1. Pictures of the bread prepared from commercial wheat flour (CTRL), with either 519 malt (0.5% M), enzymatic improver (0.5% EI), or sprouted wheat flour (1.5% SWF) (a) 520 and crumb porosity by image analysis (b). Bars associated with different letters in the 521 same class of pores are significantly different (one-way ANOVA, LSD test, $p \le 0.05$). 522 523 Fig. 2. Crumb firmness of bread prepared from commercial wheat flour (CTRL), with 524 either malt (0.5% M), enzymatic improver (0.5% EI), or sprouted wheat flour (1.5% 525 SWF) during storage. Values associated with different letters are significantly different 526 (one-way ANOVA, LSD test, $p \le 0.05$). 527

Table 1. Enzymatic activities of flour from unsprouted (USWF) and sprouted (SWF)wheat, malt (M) and enzymatic improver (EI).

	USWF			SWF			M			EI		
α -amilase (ceralpha unit * g ⁻¹)	0.094	±	0.001 ^a	12.904	±	0.040 ^b	247.744	±	0.298 ^c	0.118	±	0.006 ^a
Xylanase (unit * g ⁻¹)	0.701	±	0.003 ^a	2.316	±	0.032 ^b	80.47	±	0.08 ^c	256.27	±	0.17 ^d
Protease (unit * g ⁻¹)	0.66	±	0.90 ^a	1.43	±	0.29 ^b	8.280	±	0.057 ^d	4.290	±	0.124 ^c
31												

Values associated with different letters in the same row are significantly different $(one-way\ ANOVA,\ LSD\ test,\ p\leq 0.05).$

EI, enzymatic improver; M, malt; SWF, flour from sprouted wheat; USWF, flour

from un-sprouted wheat
