Abstract

The *P-T* phase stability field, the thermo-elastic behavior and the *P*-induced compression mechanisms at the atomic scale of pargasite crystals from the "phlogopite peridotite unit" of the Finero mafic-ultamafic complex (Ivrea-Verbano Formation, Italy) have been investigated by a series of in-situ experiments: *a*) at high pressure (up to 20.1 GPa), by single-crystal synchrotron X-ray diffraction with a diamond anvil cell, *b*) at high temperature (up to 823 K), by powder synchrotron X-ray diffraction using a hot air blower device, and *c*) at simultaneous H*P*-H*T* conditions, by single-crystal synchrotron X-ray diffraction with a resistive-heated diamond anvil cell (P_{max} = 16.5 GPa, T_{max} = 1200 K). No phase transition has been observed within the *P-T* range investigated. At ambient *T*, the refined compressional parameters, calculated by fitting a second-order Birch-Murnaghan Equation of State (BM-EoS), are: V_0 = 915.2(8) $Å^3$ and $K_{P0,T0}$ = 95(2) GPa ($β_{P0,T0}$ = 0.0121(2) GPa^{-1}) for the unit cell volume; a_0= 9.909(4) Å and $K(a)_{P0,T0}$ = 76(2) GPa for the *a*-axis; b_0 = 18.066(7) Å and $K(b)_{P0,T0}$ = 111(2) GPa for the *b*-axis; c_0 = 5.299(5) Å and $K(c)_{P0,T0}$ = 122(12) GPa for the *c*-axis [$K(c)_{P0,T0}$ ~ $K(b)_{P0,T0}$ > $K(a)_{P0,T0}$]. The high-pressure structure refinements (at ambient *T*) show a moderate contraction of the TO_4 double chain and a decrease of its bending in response to the hydrostatic compression, along with a pronounced compressibility of the A- and M(4)-polyhedra [$K_{P0,T0}$(A) = 38(2) GPa, $K_{P0,T0}$(M4) = 79(5) GPa] if compared to the M(1)-, M(2)-, M(3)-octahedra [$K_{P0,T0}$(M1,2,3) ≤ 120 GPa] and to the rigid tetrahedra [$K_{P0,T0}$(T1,T2) ~ 300 GPa]. The thermal behavior, at ambient pressure up to 823 K, was modelled with Berman's formalism, which gives: V_0 = 909.1(2) $Å^3$, $α_0$ = 2.7(2)·10^{-5} K^{-1} and $α_1$= 1.4(6)·10^{-9} K^{-2} [with $α_0(a)$ = 0.47(6)·10^{-5} K^{-1}, $α_0(b)$ = 1.07(4)·10^{-5} K^{-1}, and $α_0(c)$ = 0.97(7)·10^{-5} K^{-1}]. The petrological implications of the experimental findings of this study are discussed.

Keywords: pargasite, amphibole, high pressure, high temperature, phase stability, synchrotron X-ray diffraction

Introduction

Amphiboles are an important supergroup of rock-forming minerals, with an unusually high chemical variability and the ability to crystallize under almost all conditions relevant to the petrogenesis of crustal or upper mantle rocks, as well as subducting slabs (*e.g*., Robinson et al. 1982, Green and Wallace 1988, Hawthorne 1981). This chemical diversity originates from their structure, which is able to accommodate almost all the elements of the periodic table (Hawthorne and Oberti 2007). In particular, the occurrence of hydroxyl groups into the structure has proved to be a significant agent in the water cycle within the upper mantle (*e.g*., Gill 1981). Amphiboles crystallise from basaltic magmas at mid ocean ridges and are eventually dragged into the upper mantle at subduction zones. During subduction, many hydrous minerals become unstable and water is released, migrating into the overlying and much hotter mantle wedge, causing melting and arc volcanism as *e.g*. described for the case of talc (Bose and Ganguly 1989). In order to better understand the water cycle in the upper and potentially lower mantle, it is essential to determine the stability of all hydrous minerals subducted into the mantle. Because amphiboles are volumetrically the most abundant hydrous minerals in the lithospheric mantle, they play an important role in a number of metasomatic and metamorphic processes (*e.g.,* Wallace and Green 1991; Ionov and Hofmann 1995; Vannucci et al. 1995; Niida and Green 1999; Foley et al. 2002; Ionov et al. 2002). Thus, a series of studies have been devoted to the *P-T* stability of amphiboles in subducting slabs, and to clarifying their role in transporting hydrogen (*e.g*., Poli and Schmidt 1995; Schmidt and Poli 1998; Stern 2002; Forneris and Holloway 2003; Fumagalli and Poli 2005). Owing to their importance, a number of in-situ high-pressure (H*P*) and high-temperature (H*T*) studies have been performed in order to describe the *P-T* stability fields, the thermo-elastic behavior and the *P*- or *T*-induced deformation mechanisms of amphiboles at the atomic scale. Comodi et al. (1991) reported the compressibility of tremolite, pargasite and glaucophane on the basis of in-situ single-crystal X-ray diffraction experiments with a diamond anvil cell (DAC) up to about 4 GPa. The

4

compressibility of grunerite was investigated by Zhang et al. (1992) up to 5 GPa (single-crystal X-ray diffraction experiment with a DAC). Yang et al. (1998) reported the compressional behavior and the P-induced $C2/m$-$P2_1/m$ phase transition (at about 1.2 GPa) in cummingtonite, by in-situ X-ray and infra-red experiments with a DAC. Later, Boffa Ballaran et al. (2000) investigated the HP transformation behavior of the cummingtonite-grunerite solid solution (single-crystal X-ray diffraction experiments with a DAC). Comodi et al. (2010) reported the compressional behavior of two kaersutites up to 8 GPa, highlighting the role of the oxo-component on the elastic behavior of amphiboles (single-crystal X-ray diffraction experiments using a DAC). Jenkins et al. (2010) reported the compressibility of glaucophane based on an in-situ X-ray powder diffraction experiment compressed within DAC up to 10 GPa. Zanazzi et al. (2010) investigated the high-pressure behavior of a crystal of protomangano-ferro-antophyllite up to 9 GPa with a DAC. Welch et al. (2011a) described the elastic behavior of a Mg-rich antophyllite and its deformation mechanisms at the atomic scale up to 7 GPa, by in-situ single-crystal X-ray diffraction with a DAC. The compressional behavior of gedrite up to 7 GPa was later reported by Nestola et al. (2012) (single-crystal X-ray diffraction experiments with a DAC). More recently, Thompson et al. (2016) investigated the relation between the frequency of O-H bonds stretching modes and the hydrogen bond symmetrization induced by pressure. The elastic parameters obtained by the aforementioned experiments are listed in Table 1. However, as pointed out in Welch et al. (2007), there is a need to extend the compressibility measurement to P higher than 10 GPa, in order to improve the accuracy of the refined isothermal bulk modulus values and their P-derivatives.

A series of in-situ experiments have been performed on the low and high thermal behavior of amphiboles, on the basis of several experimental techniques (e.g., Sueno et al. 1978; Cameron et al. 1983; Cámara et al. 2003, 2007; Iezzi et al. 2005a; Jenkins and Corona 2006), reviewed by Welch et al. (2007). Some more recent studies are, e.g., those of Tribaudino et al. (2008), Welch et al. (2008) and Iezzi et al. (2011) on richterite, Welch et al. (2011b) on anthophyllite and Zema et al. (2012) on gedrite.

148   Neutron diffraction experiments at low- and room-T aimed to describe the atomic site

149   ordering and the H-bonding scheme in amphiboles have also been performed (*e.g.*, Welch and

150   Knight 1999; Iezzi et al. 2005b; Gatta et al. 2017).

151   To the best of our knowledge, no simultaneous in-situ P-T studies have been conducted on

152   amphiboles. This lack of knowledge prevents a detailed description of the behavior of amphiboles

153   that are stable at HP-HT conditions and consequently it is still difficult to assess their petrological

154   implications.

155   As pointed out by Niida and Green (1999), pargasite is recognized as a ubiquitous hydrous

156   phase in the Earth's upper mantle. In this light, we have selected crystals of pargasite from the

157   peridotite of the "phlogopite peridotite unit" of the Finero mafic-ultamafic complex (Ivrea-Verbano

158   Formation, Italy) (Cawthorn 1975; Rivalenti et al. 1975, 1984; Coltorti and Siena 1984; Siena and

159   Coltorti 1989), in order to describe: *a*) the HP elastic behavior of this amphibole (at $P > 4$ GPa) and

160   its main compression mechanisms at the atomic scale, *b*) its HT behavior, along with its potential

161   de-hydroxilation phenomenon, and *c*) its phase stability field at simultaneous HP-HT conditions.

162
163
164   **Structure of pargasite**
165
166   Pargasite is a Ca-amphibole associated to medium- or high-pressure/high-temperature

167   conditions. On the basis of the general amphibole formula $A_{0-1}B_2C_5T_8O_{22}W_2$ (Hawthorne and

168   Oberti   2007),   the   ideal   chemical   formula   of   pargasite   can   be   written   as:

169   ^{A}Na^{B}Ca$_2$^{C}(Mg$_4$Al)^T(Si$_6$Al$_2$)O$_{22}$^{W}(OH)$_2$. Its structure, described in the space group $C2/m$, is

170   characterized by double chains of TO$_4$ tetrahedra running parallel to [001] (Fig. 1). In each chain,

171   there are two distinct TO$_4$ tetrahedra (with two crystallographically independent T(1) and T(2)

172   sites). The TO$_4$ tetrahedra are connected in such a way that an alternation of pseudo-hexagonal

173   rings, delimitated by six TO$_4$ units, occurs (Fig. 1). On the basis of single-crystal X-ray diffraction

174   experiments, Papike at al. (1969) observed the preference of Al for the T(1) site. This finding was

175 later confirmed by Welch and Knight (1999) on the basis of a neutron diffraction experiment on a

176 synthetic pargasite. Hawthorne and Oberti (2007) showed that the $<T\text{-O}>$ distance varies linearly

177 with the Al content, when the Al fraction is higher than 0.50 atoms per formula unit (*apfu*);

178 furthermore, Hawthorne and Oberti (2007) proposed an equation in which the fraction of Al is

179 correlated to the average $<T\text{-O}>$ bond length. The topological configuration of the double silicate

180 chains of the octahedral sites (with three crystallographically independent positions M(1), M(2) and

181 M(3), *i.e.*, the C sites of the general amphibole formula), of the 8-fold site M(4) (*i.e.*, the B site) and

182 of the A site are shown in Figs. 1 and 2. The M(1), M(2) and M(3) sites are occupied mainly by Mg

183 and, in lower fractions, by other cations including: Fe^{2+}, Mn^{2+}, Fe^{3+}, Al, and Ti^{4+}. The M(4) site is

184 occupied by Ca, Na, Mg, and Fe^{2+}. The A sites can be vacant or occupied by Na^+ (and K^+).

185

186 **Experimental methods**

187 Several crystals of pargasite from the same rock sample of the "phlogopite peridotite unit",

188 Finero mafic-ultramafic complex (Ivrea-Verbano Formation, Italy), were selected on the basis of

189 optical and X-ray diffraction quality. Preliminary single-crystal X-ray diffraction experiments,

190 aimed to select the best crystals, were performed using a KUMA-KM4 four-circle diffractometer

191 (equipped with point-detector and Mo$K\alpha$ radiation) at the Earth Science Department - University of

192 Milano (ESD-MI). The chemical composition of the pargasite crystals was determined by electron-

193 microprobe analysis in wavelength dispersive mode (EPMA-WDS), using a Jeol JXA-8200

194 microprobe at the ESD-MI. The system was operated with an accelerating voltage of 15 kV, a beam

195 current of 5 nA, a counting time of 30 s on the peaks and 10 s on the backgrounds and a beam

196 diameter of 10 μm. Minerals (graftonite for Fe and Mn; grossular for Si, Al and Ca; K-feldspar for

197 K; forsterite for Mg; rutile for Ti; omphacite for Na; and hornblende for F) were used as standards.

198 The raw data were corrected for matrix effects using the φρZ method as implemented in the JEOL

199 suite of programs. Crystals were found chemically homogeneous. The average anhydrous chemical

200 formula (40 points analysis), calculated on the basis of 23 oxygen atoms is:

7

201      $Na_{0.60}K_{0.15}Ca_{1.80}Mn_{0.01}Cr_{0.24}Fe_{0.39}Mg_{4.10}Ti_{0.05}Al_{1.62}Si_{6.71}O_{23}$; the structural formula is

202      $^A(Na_{0.52}K_{0.15})^B(Mg_{0.11}Mn_{0.01}Ca_{1.80}Na_{0.08})^C(Al_{0.33}Ti_{0.05}Cr_{0.24}Fe_{0.39}Mg_{3.99})^T(Al_{1.29}Si_{6.71})O_{22}{}^W(OH)_2$,

203   assuming H_2O content by stoichiometry (crystals are F-free).

204   The H*P*-and the H*P*-H*T* synchrotron X-ray single-crystal diffraction experiments were

205   conducted at the Extreme Conditions Beamline P02.2 at PETRA-III/DESY, Hamburg, Germany,

206   using fragments of one of the crystals previously checked by single-crystal X-ray diffraction and

207   EPMA-WDS at the ESD-MI. Data collections were performed with an incident beam of 42.7 keV

208   in energy (λ = 0.2904 Å), and a focusing spot of ~8.5 (H) μm x 1.8 (V) μm originated from a

209   compound refractive lenses system, consisting of 110 Be lenses with a radius of 50 μm (400 μm

210   beam acceptance) and a focal length of 1221 mm. A single crystal of pargasite (~20x30x40μm^3)

211   was selected for the H*P* experiment (at room *T*). The crystal was loaded in a symmetric DAC

212   equipped with Boehler-Almax design diamonds/seats with a 70° opening and 300 μm culets size. A

213   250 μm thick rhenium gasket was pre-indented to 50 μm and then drilled with 200 μm hole, in

214   which the crystal of pargasite, along with some ruby spheres for pressure determination (Mao et al.

215   1986), were located. Neon was used as a hydrostatic pressure-transmitting medium (Angel et al.

216   2007; Klotz et al. 2009). Pressure was increased with an automated pressure-driven membrane

217   system and measured with the online ruby/alignment system. Diffraction data were successfully

218   collected up to ~20.1 GPa; at higher pressure the crystal was irredeemably damaged by bridging

219   between the two diamonds.

220   A modified 4 pin DAC, equipped with a graphite resistive heater (modified version of the

221   cell used by Shen et al. 2007) and with Boehler-Almax type diamonds/seats with a 64° opening and

222   300 μm culets size, was used for the H*P*-H*T* experiments. A 250 μm thick rhenium gasket was pre-

223   indented to 50 μm and then drilled with a 200 μm diameter hole, in which the crystal of pargasite,

224   together with some ruby chips and a gold fragment (~20 μm thick) as pressure standards, were

225   loaded. Silicone-oil was used as a *P*-transmitting medium. Placing the resistive heated DAC in a

226   vacuum vessel allowed the collection of single crystal data during two T-ramps performed at

227   pressures of ~7.5 and ~16.5 GPa, respectively . The unit-cell parameters of gold were determined

228   by the least-squares refinement of the (111), (200), and (220) diffraction lines. The temperature in

229   the pressure chamber was controlled using a Pt:Pt–Rh thermocouple, and the actual pressure at

230   each point was determined according to the P-T-V equation of state of gold of Fei et al. (2007).

231   For both the single-crystal HP and HP-HT experiments, diffraction patterns were acquired

232   on a PerkinElmer XRD 1621 flat panel detector, using an in house script for collecting step-scan

233   diffraction images. Sample to detector distance was calibrated using a CeO_2 standard (NIST 674a).

234   The diffraction images were then converted to conform to the "Esperanto" format of the program

235   CrysAlis (Agilent Technologies 2011; Rothkirch et al. 2013). At all the pressure points, the adopted

236   data collection strategy consisted of a pure ω-scan (-30°≤ ω ≤ +30°), with a step size of 1° and an

237   exposure time of 1 s/frame; then Bragg peaks were indexed. Intensities of the diffraction peaks were

238   integrated and corrected for Lorentz-polarization effects, using the CrysAlis package (Agilent

239   Technologies 2011). Scaling and correction for absorption (due to the DAC components) was

240   applied by the semi-empirical *ABSPACK* routine implemented in CrysAlis. The refined unit-cell

241   parameters of the HP and HP-HT experiments are listed in Table 2 and Table 3, respectively. No

242   evidence of phase transitions was observed within the *P*- and *P-T*-ranges investigated; all the

243   diffraction patterns were successfully indexed in the *C*2/*m* space group.

244   In-situ HT powder diffraction data of pargasite were collected at the MCX beamline at

245   ELETTRA (Trieste, Italy), using the high-resolution diffractometer available at the station (Rebuffi

246   et al. 2014). The sample was loaded in a quartz capillary. High temperature was generated with a

247   hot air blower device, and temperature was monitored with a thermocouple and calibrated against

248   thermal expansion and phase transition of quartz. Monochromatic radiation (λ = 0.8202 Å) was

249   used. Diffraction data were collected up to 823 K. The diffraction patterns were treated by Le Bail

250   full-profile fit (Le Bail et al. 1988), using the GSAS package (Larson and Von Dreele 1994), aimed

251   to obtain the unit-cell parameters only. All diffraction patterns were fitted using the pseudo-Voigt

252 profile function of Thompson et al. (1987); the background curves were modelled with a Chebyshev

253 polynomial. The refined unit-cell parameters are listed in Table 4; the evolution of the unit cell

254 parameters with T is shown in Fig. 3.

255

256

257 **Structure refinement protocol**

258 All the structure refinements, based on the intensity data of the HP experiment (at room-T),

259 were performed using the software JANA2006 (Petříček et al. 2014), starting from the structure

260 model of Hawthorne et al. (1996), in the space group $C2/m$. Reflections with an interplanar distance

261 $d \leq 0.8$ Å were excluded. In order to reduce the number of variables to refine, the sites were

262 modelled as follows: T(1) and T(2) sites were modelled as fully occupied by Si; the M(1) site

263 populated by Mg only; the M(2) was modelled with a mixed (Mg + Cr) X-ray scattering curve; the

264 M(3) site populated by Mg only; the M(4) site populated by (Ca + Na); the partially occupied A site

265 (located at 0, 0.48, 0) was modelled with a mixed (K + Na) scattering curve. In all the refinements,

266 some restraints were applied: the T(1) and T(2) sites were refined with the same isotropic

267 displacement parameter (U_{iso}), and the same strategy was applied for all the oxygen sites (O1, O2,

268 O3, O4, O5, O6, O7); the M(1), M(2) and M(3) sites were modelled with a fixed U_{iso} equal to 0.006

269 $Å^2$.

270 The principal statistical parameters of the structure refinements are listed in Table 5

271 (deposited). Atomic coordinates and site occupancies of selected structure refinements are given in

272 Table 6 (deposited). The relevant bond distances related to the M(4) and A sites are reported in

273 Table 7. Other relevant structural parameters are listed in Table 8.

274

275 **Results**

276 - **Compressional behavior**
277

278   The *P*-induced evolution of the unit-cell parameters of pargasite up to 20.1 GPa is shown in Fig.

279 4. The experimental *P-V* data have been best fitted using the (isothermal) Birch-Murnaghan

280 Equation of State (BM-EoS), which is based on the assumption that the strain energy of a solid

281 undergoing compression can be expressed as a Taylor series in the finite Eulerian strain. The

282 equation has the following form:

283    $P = 3/2\ K_{P0,T0}[(V_0/V)^{7/3} - (V_0/V)^{5/3}]\{1 - 3/4(4 - 3/2\ K'_{P0,T0})[(V_0/V)^{2/3} - 1]\} + \ldots$

284 where $K_{P0,T0}$ is the bulk modulus at ambient conditions ($K_{P0,T0} = -V_0(\partial P/\partial V)_{P0,T0} = 1/\beta_{P0,T0}$, where

285 $\beta_{P0,T0}$ is the volume compressibility coefficient at ambient conditions) and $K'_{P0,T0}$ is its *P*-derivative.

286 Truncated to the second order (in energy), $K'_{P0,T0}$ is fixed to 4. The least squares fit was performed

287 using the EoSFit 7.0 software (Angel et al. 2000, 2014), with data weighted by the uncertainties in

288 *P* and *V* (Table 9). An apparent change in the volume compressional behavior of pargasite can be

289 observed between 6.53 and 7.20 GPa (Fig. 4). In this light, two different Birch-Murnaghan

290 equations of state, truncated to the second order, have been fitted to the experimental data within the

291 *P*-ranges 0.0001-6.53 GPa and 7.20-20.14 GPa, respectively. The refined elastic parameters are: V_0

292 $= 915.2(8)$ Å^3 and $K_{P0,T0} = 95(2)$ GPa for the low-*P* range; $V_0 = 907(1)$ Å^3 and $K_{P0,T0} = 111(2)$ GPa

293 for the high-*P* range (Table 9).

294   The axial compressibilities were calculated within the range 0.0001-6.53 GPa, using the

295 "linearized" second-order BM-EoS (Angel 2000), and the least squares fits were performed

296 accounting for uncertainties in *P* and length (Table 9). The relatively high *e.s.d.* on the elastic

297 parameter of the *c* axis is probably due to the orientation of the crystal in the pressure chamber.

298 Pargasite shows a significant anisotropic compressibility with $K(c)_{P0,T0} \sim K(b)_{P0,T0} > K(a)_{P0,T0}$ (Table

299 9). The change of the volume compressional behavior is coupled with the change of the high-*P*

300 behavior of the monoclinic β angle above 7 GPa, which increases its value with *P* reaching a

301 saturation at *P* > 12 GPa (Fig. 4).

302

303

304

305   -   **Thermal expansion**

306

307   The unit-cell volume variation as a function of T exhibits a continuous trend up to 823 K, as

308   shown in Fig. 3. Within the T-range investigated, the volume thermal expansion coefficient α_T

309   increases approximately linearly with temperature. T-V fits to different thermal equations were

310   performed. The best fit was obtained with the (isobaric) equation reported by Berman (1988):

$$V_T = V_0[1 + \alpha_0(T-T_0) + 1/2\ \alpha_1(T-T_0)^2],$$

312   where the parameter α_0 is the thermal expansion coefficient at T_0 (and P_0). Given the small changes

313   in volume with temperature, the thermal expansion coefficient at high-T can be expressed as: $\alpha_T \approx$

314     $[\alpha_0 + \alpha_1(T-T_0)]$. The refined parameters for the unit-cell volume are: $\alpha_0 = 2.7(2) \cdot 10^{-5}$ K^{-1} and $\alpha_1 =$

315     $1.4(6) \cdot 10^{-9}$ K^{-2}. The thermal expansion of pargasite is anisotropic with $\alpha_0(b) \sim \alpha_0(c) > \alpha_0(a)$ (Table

316   10). No evidence for a phase transition was observed within the T-range investigated.

317

318   -   *P-T- phase stability*

319   During the two P-T ramps, no evidence of phase transition (*e.g.,* no reflections violating the

320     $C2/m$ extinction conditions, which would be indicative of a transformation to $P2_1/m$, as observed

321   *e.g.* in cummingtonite, Yang et al. 1988) or de-hydroxilation was observed. It is worth to note that

322   every data collection was performed after at least 20 minutes of equilibration at any given P-T

323   condition. However, since the pargasite structure could be metastable at the highest P-T here

324   investigated, the sample was kept for 40 minutes at $T > 1161(2)$ K before the last data collection.

325   Even in this case, no reflections violating the $C2/m$ symmetry were detected, suggesting that the

326   pargasite structure is stable within the entire P-T range investigated. The temperature was then

327   progressively decreased down to ambient-T and, after 150 minutes, a data collection at ambient

328   temperature and 9.4(3) GPa was performed: the structure refinement showed that any P-T effect on

329   the structure of pargasite was fully reversible after T release.

330

331

332   -   **Pressure-induced structural evolution**

333   The most significant changes of the $(Si,Al)O_4$ double chains, in response to the applied pressure,

334   can be described in terms of the O-O-O inter-tetrahedral angle variation (Fig. 1). As pressure

335   increases, the kinking of the TO_4 tetrahedra causes a decrease of O6-O5-O7 and O6-O7-O6 (Fig. 5).

336   These two angles are related respectively to O5-O6-O7 and O5-O7-O5 by an inverse geometrical

337   relation (*i.e.*, if the first decreases, the second increases) (Table 11). These *P*-induced mechanisms

338   affect the diameters of the pseudo-hexagonal rings confined by the double silicate chains. The

339   diameters O7-O7 and O6-O6 decrease by about 3% and 6.5%, respectively, from *P*3 (1.99 GPa) to

340   *P*19 (20.14 GPa). On the contrary, the distance O5-O5 remains practically constant within 2σ (Fig.

341   6). The kinking of the tetrahedral units of the chains leads to the closure of the O6-O5-O6 angle.

342   This is the main effect that leads to the contraction of the TO_4 double chain (Fig. 2). One of the

343   further structural effects in response to hydrostatic compression is the reduction of the tetrahedral

344   double-chain bowing, towards a flat configuration at high pressure. Such a behavior can be

345   described, for example, on the basis of the difference between the atomic *x* coordinates of the O4

346   and O7 oxygen atoms (*i.e.*, Δx(O4-O7) $\cdot$ *a* (Å)), as shown in Fig. 7 and Table 12: the bowing

347   decreases with *P*, and approaches a flat configuration (with Δx(O4-O7) $\cdot$ *a* = 0) at about 15-16 GPa.

348   At the same pressures, we observe the saturation effect on the *P*-induced evolution of other

349   structural parameters, *e.g.*, O6-O5-O7, O5-O6-O7, O5-O7-O5, O6-O7-O6 and the *β* angle behavior

350   (Fig. 4).

351   The volumes of the TO_4 polyhedra, reported in Table 13, do not show substantial variations

352   within the *P*-range investigated, suggesting that the TO_4 tetrahedra behave, at a first approximation,

353   as rigid units (with bulk moduli of about 300 GPa, Table 14). The distorted polyhedra coordinated

354   by the A site is the softest one, with a bulk modulus, calculated with a second-order BM-EoS, of

355   38(2) GPa, followed by M(4) (bulk modulus 79(5) GPa). The M(1)-, M(2)- and M(3)-octahedra are

13

356   stiffer than A- and M(4)polyhedra, with bulk moduli respectively of 120(11), 107(14) and 108(18)

357   GPa (Table 14).

358

359   **Discussion**

360   This is the first study in which the compressional behavior of paragasite is described at

361   pressures up to ~ 20 GPa, its thermal behavior up to 823 K, and its thermo-elastic behavior under

362   the combined effect of P and T by in-situ experiments.

363   The isothermal bulk modulus of pargasite obtained in this study (*i.e.*, $K_{P0,T0} = 95(2)$ GPa for

364    $P \leq 6.53$ GPa and $K_{P0,T0} = 111(2)$ GPa for $P \geq 7.20$ GPa) is among the highest found so far for

365   amphiboles, ranging between 50 and 100 GPa (Table 1; Comodi et al. 1991, 2010; Zhang et al.

366   1992; Yang et al. 1998; Boffa Ballaran et al. 2000; Welch et al. 2007, 2011a; Zanazzi et al. 2010;

367   Nestola et al. 2012). The axial bulk moduli show that the stiffest crystallographic directions of

368   pargasite are [010] and [001], whereas [100] is the softest one, as $K(c)_{P0,T0} \sim K(b)_{P0,T0} > K(a)_{P0,T0}$

369   (Table 9). This elastic anisotropy can be explained, at the atomic scale, on the basis of the structural

370   refinements of this study:

371   -   The tetrahedral double chains lie on the *bc* plane. The TO_4 tetrahedra behave, at a first

372   approximation, as uncompressible units (Table 14). The principal effect, in response to

373   the hydrostatic compression, is the kinking of the TO_4 units of the tetrahedral double-

374   chain, with the closure of the O6-O5-O6 angle and the consequent (moderate)

375   contraction of the chains along [001] (Fig. 5, Table 11). This mechanism is common

376   among inosilicates. In addition, the configuration of the double chain, with the six-

377   membered rings of tetrahedra (Fig. 1), hinders the contraction along [010], making the

378   compression along [010] similar to that along [001].

379   -   Along [100], the effects of pressure are mainly accommodated by the compression of the

380   M(1)-, M(2)-, and M(3)-octahedra, M(4)- and A-polyhedra, which are drastically softer

381   than the TO_4 units (Fig. 2, Table 14). Their bonding configuration and, in general, the

14

382   high compressibility of the M(4) and A-polyhedra govern the axial compressibility of

383   the pargasite structure along [100], making the compression along this direction

384   significantly higher than those along [010] and [001]. The compression and deformation

385   of the A- and M(4)-polyhedra are, in turn, responsible for the change of the bending of

386   the tetrahedral double chains, as can be deduced on the basis of the evolution of the

387   polyhedra bond distances with P (Table 7, Fig. 7).

388   The anisotropic compressional scheme of pargasite found in this study is consistent with that

389   previously reported by Comodi et al. (1991), based on data collected up to 4 GPa, and more in

390   general to the elastic anisotropy found in monoclinic amphiboles (*e.g.*, Comodi et al. 1991, 2010;

391   Zhang et al. 1992; Yang et al. 1998; Boffa Ballaran et al. 2000; Welch et al. 2007), irrespective of

392   their chemical composition. These findings suggest that the anisotropic compressional scheme of

393   amphiboles is dictated by the topology of the structure, though the different compositions govern

394   the magnitude of the volume and axial compressibilities.

395   The compressional anisotropy of pargasite is consistent with the thermal expansion scheme:

396   almost identical axial expansion behaviors are observed along [010] (*i.e.*, $\alpha_0(b) = 1.07(4)\cdot10^{-5}$ K^{-1})

397   and [001] (*i.e.,* $\alpha_0(c) = 0.97(7)\cdot10^{-5}$ K^{-1}), which are significantly higher than that along [100] (*i.e.*,

398    $\alpha_0(a) = 0.47(6)\cdot10^{-5}$ K^{-1}) (Table 10), with the following anisotropic scheme: $\alpha_0(b) \sim \alpha_0(c) > \alpha_0(a)$. In

399   this case, data reported in the literature show that $C2/m$ amphiboles experience a different

400   anisotropic thermal-elastic behavior in response to their composition or to the *T*-range investigated

401   (i.e., the thermal expansion anisotropic scheme can change within different *T*-ranges): $\alpha_0(a) \sim \alpha_0(b)$

402    $> \alpha_0(c)$ (e.g., K-fluor-richterite, Cameron et al. 1983); $\alpha_0(a) > \alpha_0(b) > \alpha_0(c)$ (e.g., tremolite, Sueno et

403   al. 1973; synthetic Na(LiMg)Mg$_5$Si$_8$O$_{22}$(OH)$_2$, Iezzi et al. 2005a; synthetic

404   Na(NaMg)Mg$_5$Si$_8$O$_{22}$(OH)$_2$, Cámara et al. 2003; synthetic Na(NaMg)Mg$_5$Si$_8$O$_{22}$F$_2$, Cámara et al.

405   2007; glaucophane, Jenkins and Corona 2006); $\alpha_0(b) > \alpha_0(a) > \alpha_0(c)$ (e.g., Na-fluor-richterite,

406   Cameron et al. 1983; richterite at $T > 600$ K, Tribaudino et al. 2008; synthetic

407   K(NaCa)(Mg$_{2.5}$Ni$_{2.5}$)Si$_8$O$_{22}$(OH)$_2$, Welch et al. 2008); $\alpha_0(b) > \alpha_0(c) > \alpha_0(a)$ (e.g., richterite at $T <$

15

408   600 K, Tribaudino et al. 2008). In addition, we observed a T-induced increase of the monoclinic β

409   angle (e.g., this study), other amphiboles showed an opposite behaviour (e.g., tremolite, Sueno et al.

410   1973; cummingtonite, Reece et al. 2000, 2002; synthetic Na(NaMg)Mg$_5$Si$_8$O$_{22}$(OH)$_2$, Cámara et al.

411   2003; synthetic Na(NaMg)Mg$_5$Si$_8$O$_{22}$(OH)2 and Na(LiMg)Mg$_5$Si$_8$O$_{22}$(OH)$_2$, Iezzi et al. 2005a;

412   richterite, Tribaudino et al. 2008; glaucophane, Jenkins and Corona 2006; synthetic

413   K(NaCa)(Mg$_{2.5}$Ni$_{2.5}$)Si$_8$O$_{22}$(OH)$_2$, Welch et al. 2008). The lack of high-T structural refinements in

414   this study do not allow a description of the T-induced mechanisms at the atomic scale. No de-

415   hydroxilation was observed up to the maximum temperature achieved in our HT experiment (*i.e.*,

416   823 K). De-hydroxilation in amphibole was observed at $T > 1000$-1100 K, at ambient P (*e.g.*, Zema

417   et al. 2012 and reference therein).

418   Unfortunately, because of significant P-fluctuations during the measurements, leading to

419   large P uncertainties, it was not possible to fit the data of the two P-T ramps to a thermal EoS.

420   Attempts at correcting the P estimates using different levels of approximation (*i.e.*, using an average

421   P) do not lead to any conclusive improvements. The HP-HT data of this study do show

422   unambiguously, however, that pargasite is stable, in its $C2/m$ form, under the combined conditions

423   of high pressure and temperature up to at least ~16.5 GPa and ~1200 K, without any evidence for

424   de-hydroxylation within the P-T range investigated. As a matter of fact, the unit cell volume of the

425   sample employed in the highest P-T ramp and then measured after T-release at ambient-T and 9.4(3)

426   GPa (*i.e.*, 840(2) Å^3), is virtually identical to the volume of the sample used for the HP experiment

427   at the same P-condition (*i.e.,* 840.0(6) Å^3 at 9.74(5) GPa); in addition, the structural refinement

428   based on the intensity data collected at ambient-T and 9.4(3) GPa, after the P-T ramp, did not show

429   any evidence of de-hydroxylation. However, we cannot entirely exclude that, even in the P-T range

430   here investigated, but increasing the exposure time at the highest T, pargasite might experience

431   (partial) de-hydroxylation.

432   In Fig. 8, all the P-T data points collected on the pargasite crystal in this study are shown. In

433   addition, Fig. 8 also shows the P-T paths of the slab surface for arc segments in Tonga and central

Peru, determined by Syracuse et al. (2010) on the basis of high-resolution finite-element models. The stability field of pargasite observed in this study intersects the *P-T* paths estimated for subducting slabs when considering either a *hot subduction* (*e.g.,* central Peru subduction) or a *cold subduction* pathway (*e.g.,* Tonga subduction). The majority of phase equilibria studies involving pargasite have tested its stability within mafic or ultramafic assemblages and found it to be unstable above approximately 3 GPa and 1273 K. However, in these assemblages pargasite normally breaks down reacting with coexisting minerals, such as clinopyroxenes, whereas our experiments examined the stability of a pure pargasite crystal at H_2O-undersaturated conditions. As shown by Mandler and Grove (2016), significant variations in the stability of pargasite occur for assemblages containing differing proportions of H_2O and with varying Na/K ratio. To the best of our knowledge, the stability field of individual pargasite compositions has not been previously examined at the conditions employed here, but must extend to a wider *P-T* range than those obtained in previous studies on multiple mineral assemblages. Overall, this study shows that pargasite has some potential to carry H_2O (along with Na, K and Ca) into the transition zone and possibly beyond, within even *hot subduction* zones. This may have a significant influence on the H_2O cycle of the mantle. Further experiments at simultaneous higher pressure and temperatures, as well as with prototypical subduction plate compositions, are needed.
