Improving the Accuracy of Cosmic-Ray Neutron Probe Estimate of Soil Water Content Using Multiple Detectors and Remote Sensing Estimates of Vegetation

by

Xiaochen Dong

A THESIS

Presented to the Faculty of The Graduate College at the University of Nebraska In Partial Fulfillment of Requirements For the Degree of Master of Science Major: Natural Resource Sciences Under the Supervision of Professor Trenton E. Franz Lincoln, Nebraska

December 2017

Improving the accuracy of Cosmic-Ray Neutron Probe estimate of soil water content using multiple detectors and remote sensing estimates of vegetation

Xiaochen Dong, M.S.

University of Nebraska, 2017

Advisor: Trenton E. Franz

The recently developed Cosmic-ray Neutron Probe (CRNP) for estimating soil water content (SWC) fills a critical measurement gap between point scale methods and large scale measurements collected from remote sensing. CRNP works by measuring the change in low-energy neutron intensity over time. However, the accuracy of CRNP to measure SWC is well known to be affected by other hydrogen sources (e.g. soil organic content, atmospheric water vapor, vegetation and surface water). This study focuses on the influence of rapidly growing vegetation in agricultural fields on the accuracy of the CRNP method.

Here we use data from three long-term CRNP study sites in central Nebraska (Paulman Farms, est. 2015), eastern Nebraska (US-Ne3, est. 2011), and central Iowa (IVS, est. 2010) that span a natural precipitation gradient of increasing precipitation from west to east. All three fields grow maize and soybean depending on rotation. At each CRNP site both hourly moderated and bare neutron counts are recorded. Previous research has shown that the bare to moderated ratio may be a good indicator of changing vegetation conditions and useful as a correction to estimating SWC. In addition, I use the MODIS remote sensing dataset to calculate a widely used index to monitor vegetation, Green Wide Dynamic Range Vegetation Index (GrWDRVI or WDRVI). Finally, observed vegetation data from US-Ne3 was collected biweekly from 2003-2016 and used as a benchmark for the CRNP and remote sensing analyses.

My results indicate that biomass data determined from remote sensing (GrWDRVI) closely follows in-situ sampling of biomass (R^2 =0.677 for Maize and R^2 =0.567 for Soybean). The driest site (Paulman Farms) showed the best relationship between bare to moderated (B/M) ratios and GrWDRVI with an R^2 = 0.9188, while the wettest site (IVS) showed the worst relationship with R^2 = 0.09. I found that local correction factors using B/M ratio and moderated counts removing the influence of vegetation changes can be derived, thus removing bias in the CRNP SWC observations. The improved algorithm for estimating SWC from CRNP will be beneficial for long-term monitoring as well as validating remote sensing SWC products. More experiments with direct biomass observations and needed to fully understand the relationship between GrWDRVI, bare and moderated neutron counts, and in-situ biomass.

Acknowledgements

I would like to thank my advisor Dr. Trenton Franz for his help and support during past two years. Without his help and guidance, I couldn't have completed this thesis. His knowledge and passion made me a better graduate and developed my interests in natural science. With his support, I was able to prepare poster and oral presentations in research conference and develop research skills. His suggestion and advice encouraged me to be a better researcher in my future career.

I would like to thank my committee member: Dr. Derek Heeren, Dr. Elizabeth (Betty) Walter-Shea, Dr. Brian Wardlow. They provided me their valuable advice and suggestion which contributed to my success of my research and completion of my Master thesis. I would give my special thanks to Dr. Heeren. I worked with Dr. Heeren sometime during past two years and he provided me sources and advice for my future career.

Thanks to William Avery and Foad Foolad, they taught me how to use remote sensing data and helped me with data generation. They provided me their research data and valuable results. I would like to thank my friend, Dong Xu. He is pursuing PhD in Computer Science and he helped me with the computer programming. I really appreciate their help and friendship.

Chapter 1: Introduction

Hydrologic cycle plays a key role in water resources management. It will be beneficial to model and forecast hydrologic cycle in next decades (Vorosmarty, 2015). The rise of remote sensing, proximal sensing, citizen science, and opportunistic sensing have greatly increased our ability to observe the hydrologic balance (McCabe 2017). However, a critical gap remains in resolving the different spatial and temporal observation scales with scales at which decisions are made. For example, it is well known that estimating soil water content (SWC) at the appropriate spatial and temporal scale to make a management decision or compare with hydrological model output can be challenging (Vereecken 2008). There are many methods to measure SWC at point scale or large scale. However, these methods have well documented disadvantages. With respect to point measurements, we are not able to estimate SWC in surrounding areas due to spatially heterogeneous distribution of SWC over a range of length scales (Western, 1999). We can use satellite passive and active microwave sensor (i.e. SMOS and SMAP, Jackson, 1997, Kerr, 2010) to measure near-surface SWC over hundreds to thousands of square kilometers. But other influencing factors, such as vegetation cover, cloud cover, snow cover and surface roughness will affect the accuracy of satellite measurement (Njoku, 2003). Lastly the high initial cost of satellite data is of concern (Zreda, 2008, McCabe 2017 HESS).

Currently, most land surface models (LSM) aiming at characterizing the fluxes of water, energy, and nutrients, have relied on either sparse point scale SWC monitoring networks (Crow et al. 2012) or remote sensing products with large pixel sizes (~36 km) and shallow penetration depths (e.g., ~ 2-5 cm for SMOS/SMAP; Kerr et al., 2010 and SMAP Entekhabi et al., 2010). There is a critical scale gap between these methods requiring innovative monitoring strategies (Robinson et al., 2008). Moreover, as LSMs continue to move towards highly refined spatial resolutions of 1 km or less (Wood et al., 2011), the need for accurate and spatially exhaustive SWC datasets continues to grow (Beven and Cloke, 2012).

The recently-developed cosmic-ray method for measuring area-average soil moisture at the hectometer horizontal scale is being implemented in the COsmic-ray Soil Moisture Observing System and other complimentary networks around the globe (COSMOS, Zreda 2012, Andreasen 2017). The stationary cosmic-ray neutron probe measures the neutrons that are generated by cosmic rays within air and soil and other materials. The measured neutrons have been, moderated by mainly hydrogen atoms located primarily in soil water, and emitted to the atmosphere where they mix instantaneously at a scale of hundreds of meters; thus the density of neutrons is inversely correlated with SWC (Andreasen, 2016). Cosmic-ray Neutron Probe (CRNP) for estimating SWC fills a critical measurement gap between point scale methods and large scale measurements collected from remote sensing.

Atmospheric water vapor, surface liquid and solid water, vegetation liquid and solid water, soil water vapor and liquid and solid water, lattice water, plant tissue carbohydrates, and organic soil horizons are hydrogen pools existing at and near the land surface (Franz, 2012). When applying CRNP in complex ecosystems, uncertainty caused by other hydrogen sources should be accounted to improve the SWC measurement accuracy (Bogena, 2013). Based on previous research, hydrogen in biomass and organic matter in soil is usually small compared to the hydrogen in soil pore space and lattice water contained in the mineral grains. However, other researchers pointed out that

neutron counts have been shown to be affected by fast growing vegetation, like maize or soybeans, and may require a correction factor for unbiased soil moisture measurements in time (Baatz, 2015).

In light of these challenges described above the main motivations for my thesis are the following:

1) Satellite estimates of SWC have large spatial footprints, are infrequent due to gaps in overpass times, and are constrained to near surface estimates.

2) Point scale soil water content observations are difficult to scale up to the landscape level where they are more relevant for decision making or model validation.

3) The CRNP contains both moderated and bare detectors that may be useful for detecting crop biomass and soil water content simultaneously at intermediate scales. To date minimal work has been explored using the bare and moderated detector (see Desilets 2010, Tian 2016, and Andreasen 2016, 2017 for preliminary work).

The overarching goal of this study is to explore the utility and accuracy of currently available remote sensing and vegetation datasets for use in the CRNP calibration function. To be more specific, my objectives are to explore the potential use of remote sensing products (i.e. MODIS) to determine what are the required cropping systems biomass information for integration in the standard CRNP calibration process, and investigate a strategy to simultaneously estimate crop biomass and soil water content using the CRNP moderated and bare detectors. The remainder of this thesis is organized as follows. Chapter 2 is summary of field experiments and remote sensing data at three existing study sites across the Midwest. This study specifically looked at MODIS satellite data and bare and moderated tubes for up to a 6-year period. Using the remote sensing data, neutron observations, and in-situ biomass data I explored statistical relationships to predict crop biomass information from neutron counts alone. Chapter 3 presents a summary of research and recommendations for future work.

Chapter 2: Incorporation of Multiple Detectors and Remote Sensing Estimates of Vegetation for Estimating Field Scale Soil Water Content

2.1. A Summary of the Cosmic-ray Neutron Probe (CRNP) Method

Instead of measuring soil moisture directly, CRNP monitors soil water content by measuring low energy neutron intensity (Zreda et al. 2008, 2012). Incoming higher level energy particles from out space will first interact with earth's atmospheric nuclei (Zreda et al., 2012 and Kohli et al., 2015, Andreasen 2017). After this process, fast neutrons are created. Then fast neutrons will continue to interact with nuclei in atmosphere and soil which resulting in more energy loss. Epithermal neutrons are the products of fast neutrons collision with nuclei (epithermal neutrons are measured by moderated neutron intensity, showing in Fig 2.1). The removal rate of epithermal neutrons are mainly controlled by hydrogen atoms in atmosphere and soil. (Zreda et al. 2012). Soil water content (SWC) is one of the largest sources of hydrogen present in terrestrial systems (McJannet et al. 2014). Thus, the changes in soil water content would cause the changes of epithermal neutron intensity. However, the shape of the calibration function is modified by local soil and vegetation parameters (Zreda et al. 2012) reflecting the variation of background hydrogen levels across landscapes.

Figure 2.1: Ground level (1.5 m above the ground surface) energy spectra of cosmic-ray neutrons at volumetric soil moisture (SM) of 0.05 and 0.45 at an agricultural field site in western Denmark (bare ground conditions). The spectra are modeled using a modified model setup of Andreasen et al. (2016). The neutron transport model MCNP6 was used with the galactic cosmic-ray source option. Note the moderated detector primarily records epithermal neutrons while the bare detector records thermal neutrons. Figure was first published as Figure 2 in Andreasen et al. 2017.

The neutron detector of CRNP can measure up to ~300 m in radius with vertical penetration depths of 12 to 76 cm depending on soil water content (Zreda et al. 2008). Other researchers has proved that the footprint of CRNP is affected by atmospheric water vapor, elevation, surface heterogeneity, vegetation and soil water content (Desilets and Zreda, 2013, Kohli et al., 2015). With the large measurement footprint area up to tens of hectares, CRNP is an ideal new technology to monitor average field soil water content throughout the world. Over 200 fixed CRNP station are located in the United States of America, Australia, Germany, South Africa, China, and the United Kingdom currently

(see Andreasen 2017 for recent review, Fig. 2.2).

Figure 2.2: Current global distribution of cosmic-ray neutron stations (blue points), the cutoff rigidity of 2010 (in GeV, red lines; numbers in front of parentheses) and the attenuation length (in g/cm2, red lines; numbers in parentheses). Figure was first published as Figure 1 in Andreasen et al. 2017.

Additionally, roving version of CRNP or mobile CRNP has been applied to measure hourly soil water content. The temporal resolution is about 1 minute which can provide a reliable measurement over hundreds of square kilometers in a single day (Avery, 2016, see Fig. 2.3 and 2.4). Moreover, using fixed and mobile CRNP measurement, we can further obtain an accurate, real-time and multiscale soil water content monitoring network (Franz et al. 2015). With the increase of detector footprint, the traditional in-situ sampling is not practical in CRNP calibration functions. Avery, 2016 pointed out that global dataset (i.e. remote sensing dataset, global soil map et al.) can be used to correct CRNP calibration procedure. In this study, the capacity and reliability of remote sensing dataset was tested and in-situ biomass was used to explore the relationship between bare and moderated neutron intensity vs vegetation.

Figure 2.3: Cosmic-ray neutron probe at US-Ne3 site in Mead eastern Nebraska. The CRNP contains both bare and moderated detectors.

Figure 2.4: Mobile Cosmic-ray Neutron Probe Rover with moderated detectors only.

2.2. Methods

2.2.1 CRNP Calibration Function

A calibration function has been developed in order to convert moderated neutron counts to near surface SWC. The following set of equations (eqs 2.1-2.4) have been developed by Desilets et al. 2010, Zreda et al. 2012, and Franz et al. 2015 to account for various forms of hydrogen present in the CRNP footprint:

$$\left(q_p + q_{LW} + q_{SOC_{eq}}\right) = \frac{0.0808}{\frac{N}{N_0} - 0.372} - 0.115$$
(2.1)

Where θ_p is pore water content (g/g), θ_p (cm³/cm³) = $\theta_p * \frac{\rho_b}{\rho_w}$, θ_{LW} is lattice water content (g/g), $\theta_{SOC_{eq}}$ is soil organic carbon water content (g/g), ρ_{bd} is dry soil bulk density (g/cm³), ρ_w is the density of water = 1 (g/cm³), N is the corrected moderated neutron counts per hour (cph), and N_0 is an instrument specific calibrated parameter that represents the count rate over dry silica soils (cph). The three coefficients were determined by Desilets et al. 2010 from a semi-analytical solution of a neutron diffusion equation. Furthermore:

$$\theta_{SOC_{eq}} = \left(TC - \frac{12}{44}CO_2\right) 0.494 \tag{2.2}$$

Where *TC* is the soil total carbon (g/g), *CO*₂ is the soil *CO*₂ (g/g), 12/44 is the stoichiometric ratio of carbon to *CO*₂, and 0.494 is the stoichiometric ratio of H₂O to organic carbon (assuming organic carbon is cellulose $C_6H_{10}O_5$).

Franz et al. (2015) corrected for variations between instruments and for changes in Biomass Water Equivalent (*BWE*) by scaling fixed probe observations against the rover:

$$N_{0,F}\left(BWE\right) = N_{0,F}\left(0\right) \overset{\text{a}}{\underset{\text{e}}{\xi}} \frac{m_R}{N_{0,R}\left(0\right)} BWE + 1 \overset{0}{\underset{\text{i}}{\vdots}}$$
(2.3)

Where $N_{0,F}(0)$ is the fixed probe estimate of N_0 with no standing biomass, $N_{0,R}(0)$ is the rover estimate of N_0 with no standing biomass, and m_R is the slope of the relationship between N_0 and *BWE* from the rover surveys and calibration datasets. The *BWE* was found from the calibration sampling as:

$$BWE = SWB - SDB + SDB * f_{WE}$$
(2.4)

Where *SWB* is the standing wet biomass per unit area (kg/m² ~ mm of water/m²) and *SDB* is the standing dry biomass per unit area (kg/m² ~ mm of water/m²) found by oven drying samples at 70°C for 5 days. Note f_{WE} is = 0.494 like in Eq. [2.2] above. Franz et al. (2015) found the CRNP rover had a statistically significant linear relationship yielding the coefficients of $N_{0,R}(0) = 518.34$ cpm and $m_R = -4.9506$ with an R² = 0.515 and p value = 0.03. Here, I explore if there is a direct relationship between moderated neutron counts, bare neutron counts and BWE as a potential means of correcting for the influence from site specific vegetation.

2.2.2 Study sites

To achieve my objectives, data were used from three long-term CRNP study sites in central Nebraska (Paulman Farms, est. 2015), eastern Nebraska (US-Ne3, est. 2011), and central Iowa (IVS, est. 2010) that span a natural increasing precipitation gradient from west to east (Figure 2.5).

The eastern Nebraska site US-Ne3 is part of University of Nebraska Eastern Nebraska Research and Extension Center near Mead. The site is under a maize-soybean rotation and is not irrigated. This site continues to collect CRNP neutron data since 2011 that is part of Cosmic-ray Soil Moisture Observing System (COSMOS). The soil types of this site are mainly silt loam and silty clay loam (Web Soil Survey, 2016, http: //websoilsurvey.nrcs.usda.gov). Planting density, cultivars, and herbicide and pesticide applications and other crop managements has been applied in this site since 2001. According to data collected from High Plains Regional Climate Center (HPRCC) station Mead 6S, Average growing season precipitation for the recent 18 year period is about 22inch with a maximum precipitation during this period is about 30-inch (2008) and the minimum precipitation is about 12-inch (2012). (Data from 2000-2016, High Plains Regional Climate Center, https://hprcc.unl.edu/). The approximate footprint of the CRNP measurement is up to 300m at all sites.

The central Iowa site, IVS, is located near Ames, Iowa. It consists of a square kilometer of gently rolling Des Moines Lobe soils in central Iowa. The site is under a maize-soybean rotation and is not irrigated. The crop is normally planted in late April to early May and is harvested in late September or early October. During the balance of the year the site is essentially bare with a small amount of crop residue. Nearly every aspect of the terrestrial hydrologic cycle is regularly observed, including soil moisture (at a variety of depths), depth to water table, net radiation, sensible and latent heat flux, and precipitation, all at multiple locations within the site (COSMOS, 2016, http://cosmos.hwr.arizona.edu/Probes/StationDat/016/index.php). According to HPRCC precipitation data collected from station AMES MUNICIPAL AP, the recent 18 year growing season average precipitation is 25.64 mm with the maximum precipitation during May-Oct is about 43-inch (2010) and the minimum precipitation is about 16-inch (2012) (Data from 2000-2016, High Plains Regional Climate Center, https://hprcc.unl.edu/).

The third site is at Paulman Farms, which is a 53 ha quarter section under variable rate center pivot irrigation near Sutherland, NE. The site is historically a maize-soybean rotation but was in maize production during 2015-2016. Significant topo-edaphic gradients make it an ideal crop field for variable rate irrigation. The field has a wide gradient in field capacity and wilting point values depending on soil classification (Soil Survey Staff, 2016). According to HPRCC precipitation data collected from station

HERSHEY 5 SSE, the maximum precipitation during growing season is about 21-inch in 2011 and the minimum precipitation is about 3-inch in 2012.

Figure 2.5: Location of three CRNP study sites in Central Nebraska (Paulman Farms, 41.058323,-101.102742 est. 2015), eastern Nebraska (US-Ne3, 41.179859,-96.441235, est. 2011), and central Iowa (IVS, 41.9832,-93.6837, est. 2010)

2.2.3 CRNP and MODIS data generation

All three fields grow maize and soybean depending on rotation. I evaluated growing season data (May to Oct) from 2011-2015 at the US-NE3 and IVS study sites. Since the Paulman Farms site was equipped with a CRNP in 2015, I only evaluated data from the 2015 and 2016 growing seasons. At each CRNP site both hourly moderated and bare neutron counts are recorded. Bare and moderated neutron counts data for the growing season (May-Oct) were obtained from Cosmic-ray Soil Moisture Observing System (COSMOS) publically available website (http://cosmos.hwr.arizona.edu/Probes/probemap.php).

Previous research has shown that the thermal to fast, or bare to moderated ratio (B/M) may be a good indicator of changing vegetation conditions and useful as a correction to estimating SWC (Tian, 2016). To document vegetation changes, MODIS data were used. Here I use the MODIS remote sensing dataset to calculate Green Wide Dynamic Range Vegetation Index (GrWDRVI or WDRVI). Compared with other vegetation indeices, GrWDRVI has more significant relationship with in-situ biomass. (Nguy-Robertson, 2015). Using the Python Integrated Development Environment built into ArcGIS a series of steps were taken to estimate GrWDRVI. (1) MODIS reflectance dataset was converted into green and near-infrared electromagnetic spectrum range (see Avery 2016). (2) Next, Any pixels that were skewed by incidental cloud cover were removed. (3) Using the following equation, green and near-infrared electromagnetic spectrum range were converted into the Green Wide Dynamic Range Vegetation Index (GrWDRVI):

$$GrWDRVI=(0.1*NIR-Green) / (0.1*NIR+Green)$$
(2.5)

Where NIR is near-infrared light that has a wavelength between 841 and 876 nm and green light has a wavelength between 545 and 565 nm (Gitelson, 2004).

2.2.4 Time-lapse Video

As mentioned in Chapter 1, fast growing vegetation has potential impact on the accuracy of CRNP. As an additional visual aid for understanding and interpreting the neutron observations, I used a time-lapse video to capture the diurnal growing process and dynamics (most in green-up stage) of maize at the US-Ne3 site during rapid green up. During June 2017, a camera (5Ds, Canon) located close to CRNP detector was used to take a series of time-lapse images. The time interval varied from 10s to 3min depending on the weather and growth status. I obtained more than 2000 raw images for evaluation. Each image was inspected for quality assurance and quality control by first checking the availability of each image and resizing image quality. Using Photoshop and Lightroom software, I created a series of time-lapse video with 24fps and 29fps, which can show the growing condition within one day and within one month.

2.2.5 HPRCC Precipitation Data

Daily and monthly precipitation data from High Plains Regional Climate Center (HPRCC) from 2000 - 2017 near the US-Ne3, IVS and Paulman farm sites were obtained to investigate the influences of precipitation on the results.

| US-Ne3 Monthly and total season precipitation (.in) | | | | | | | | |
|---|------|------|------|----------|------|------|--------|--|
| Year | May | Jun | Jul | Aug | Sep | Oct | Season | |

Table 2.3: 18-year precipitation data near Paulman farm research site.

2.2.6 Standing Biomass

Among the three study sites, US-Ne3 site is our most familiar and well sampled study site. In-situ biomass data from previous researchers is made available through the Carbon Sequestration Program and Ameriflux programs. Here I used two separate biomass data. One is collected by Nguy-Robertson A, 2013 (from 2003-2013) and further generated and published by Avery, 2016. This dataset was used as a benchmark for the neutron and remote sensing analyses to investigate if any linear relationships existed between GrWDRVI and moderated neutron counts and bare to moderated (B/M) ratio during each growing season for each site.

The other observed vegetation data from US-Ne3 was collected biweekly from 2003-2016 by Prof. T. Arkebaur of the University of Nebraska-Lincoln. Data from 2011 to 2016 was used to investigate the relationship between in-situ biomass and bare and moderated neutron counts.

2.3. Results

2.3.1 Comparison of GrWDRVI and In-situ Biomass Data

Figure 2.6 shows the relationship between observed standing wet biomass and GrWDRVI at US-Ne3 site during growing seasons between 2003-2016. The data show a linear correlation coeffcient (R²) of 0.677 for maize and 0.5672 for soybean for all years. Avery et al. (2016) found that GrWDRVI from CSP3 and two other fields was dependent not only on vegetation type (maize vs. soybean), but also on irrigation vs. rainfed, and green-up vs. senescence periods of crop development. The influence of different crop development stage will be discussed in following sections.

On one hand this result underscores that remote sensing estimates of biomass are useful but also contain a large amount of variation. On the other hand, direct observations of biomass are limited given the large amount of effort and time such observations require. Therefore, a note of caution is warranted for comparison between remote sensing data, neutron data, and observed biomass.

2.3.2 Comparison of GrWDRVI, B/M Ratio and Moderated Neutron Intensity

Time series are presented for moderated neutron counts for each site between 2011 and

2016 (Fig. 2.7), the B/M ratio (Fig. 2.8), and the GrWDRVI (Fig. 2.9). Table 2.4

summarizes the linear and multivariate liner regression analysis for each site and each year. The western irrigated site (Paulman Farms) showed the best relationship ($R^2 = 0.9188$) while the eastern site (IVS site) showed one of the worst relationship (R^2 is always not significant). Also US-Ne3 2014 had the lowest R^2 value.

Figure 2.7: Time series of moderated neutron counts between 2011 and 2017 for three study sites. Note a second axis represents Paulman Farm moderated neutron intensity given the higher count rates.

Figure 2.8: Time series of daily B/M ratio between 2011 and 2016 for three study sites.

Figure 2.9: Time series of daily (MODIS overpass) GrWDRVI calculated values between 2011 and 2016 for three study sites.

Figure 2.10: Linear correlation between growing season in-situ biomass data and B/M and Moderated neutron intensity for US-Ne3 site from 2011 to 2016.

Results in Table 2.4 indicate that B/M ratio is a reasonable predictor of vegetation changes (i.e. GrWDRVI), however the results vary considerably between sites. The western site (Paulman Farms) showed the best relationship as more hydrogen is contained in the vegetation instead of the soil as compared to the eastern sites. This likely improves the signal to noise ratio of detecting vegetation with the method. There is a fair linear relationship between B/M and biomass. As expected the relationship between moderated neutron intensity and biomass is weak. Thus, a multivariate analysis using B/M and moderated neutron intensity differed little from that with B/M alone.

Also note that 2012, 2013 and 2014, the relationship was not very strong at US-Ne3 and IVS sites, which was probably caused by drought and limitations of GrWDRVI. In the following section I will discuss the potential reasons and how it affects the results.

Table 2.4: Multivariate linear regression of moderate, B/M and GrWDRVI of each study site for each year.

2.3.3 Comparison of in-situ biomass, B/M and Moderated neutron intensity

Based on a previous study conducted by Avery (2016), different crop development stages have significant influence on GrWDRVI estimating crop condition. Because during August and September, crop will dry out and leaves lose their chlorophyll and leaf structure beings to collapse. This process will result in increasing reflected green and reducing near-infrared radiation (Avery, 2016). Similarly, I compared the relationship between B/M and in-situ biomass in green-up vs senescence (Figure 2.11). From previous research by Tian (2016), I expected the comparison to have a positive relationship. Figure 2.11 indicates that in years 2012, 2013 and 2014 there is no significant relationship or even negative relationship between B/M and biomass in both green-up and senescence stage. In 2011and 2015 there is strong relationship for both green-up and senescence. No consistent linear relationship between B/M and fresh biomass is observed between years, crop stage, and vegetation type.

Using a multivariate linear analysis I found significant improvement by using both B/M and moderated neutron counts. Table 2.5 summarizes the univariate and multivariate results. I found that the R² increased for both the green-up and senescence crop stages. In addition the multivariate R² values made the largest gains in the drought years of 2012 and 2013. Smaller to minimal R² gains were seen in the multivariate analysis during the non-drought periods. This analysis shows that both B/M and moderated counts could be used to predict fresh biomass, especially under non-drought conditions. I suspect the Tian (2016) results using just B/M ratios vs. fresh biomass had non-limiting soil moisture conditions and did not experience the same level of water stress conditions as was experienced in 2012 and 2013 at US-Ne3 and IVS sites. Future work should explore this finding more explicitly.

Figure 2.11: Linear relationship between B/M and total fresh biomass from 2011 to 2016 in green-up and senescence.

Table 2.5: Multivariate linear regression of moderate, B/M and biomass of US-Ne3 site for each year.

2.3.4. Influence of Precipitation and Drought at US-Ne3

According to Table 2.1, precipitation of US-Ne3 site in 2012, 2013 and 2014 growing season are less than the 18-year average. So the influence of drought should be taken into account.

Among the three sites chosen for this study, US-Ne3 (Mead) is our most familiar and well instrumented site to do further analysis. This is done by comparing GrWDRVI, B/M, vegetation and precipitation. According to the precipitation data note in 2012, 2013 and 2014 US-Ne3 site experienced drought during the growing season. The seasonal precipitation in 2014 was similar to other years which did not experience drought. But in early grow-up stage (July), maize only received 0.55 in precipitation. The GrWDRVI and B/M still responded to biomass changes (Figure 2.12) but crop water stress may affect our ability to accurately use remote sensing tools to detect biomass changes.

Figure 2.12: Comparison of in-situ biomass, B/M and GrWDRVI in US-Ne3 site.

Figure 2.13 illustrates the relationship between B/M, Moderated neutron intensity and insitu biomass using data from average rainfall conditions (2011 and 2015-2016) at the US-Ne3 site. Without drought, I found a better relationship between B/M and Biomass (R²= 0.56 in green-up and 0.34 in senescence). Using B/M I found the ability to monitor crop growth is reasonable when there is sufficient water supply. At US-Ne3 site in 2012-2014 the linear correlation was decreased due to the lack of precipitation. During that period of time the maize and soybean experienced drought and water stress conditions. I found that GrWDRVI still showed a good relationship with in-situ biomass during those same conditions. Lastly, the seasonal precipitation in 2014 was similar to other years which did not experience drought. But in early grow-up stage (July), maize only received 0.55 in precipitation. Thus resulted in a poor relationship between GrWDRVI and B/M ratio. Again, Table 2.5 illustrates reasonable multivariate relationships between fresh biomass and B/M and moderated neutron counts.

Figure 2.13: Comparison of B/M, Moderated Neutron and In-situ Biomass data of year 2011 and 2015-2016 without influence of drought.

2.4 Discussion and Conclusions

In this section I discuss the advantages and disadvantages of the Cosmic-ray Neutron Probe for soil water content monitoring. The main disadvantage of the CRNP method is the dependence of changing vegetation on the SWC observations. Therefore, my objectives were to: 1) investigate strategies to incorporate remote sensing products (i.e. MODIS) to determine the required cropping systems biomass information for integration in the standard CRNP calibration process, and 2) investigate a strategy to simultaneously estimate crop biomass and soil water content using the CRNP moderated and bare detectors.

My work showed that there is unlikely a general linear relationship that exist for all sites between fresh biomass and GrWDRVI. Besides the well-known influencing factors, crop type, drought, or the timing of dry conditions may have impacts on the accuracy of GrWDRVI. Like previous work (Avery 2016) my results also showed that fresh biomass (SWB) is correlated to GrWDRVI. However the relationship is noisy with $R^2 = 0.6$ for maize and 0.55 for soybean for US-Ne3. There are some opportunities to use MODIS data but are limited by MODIS time collection (~8 day product) and pixel size (250 to 500 m). More importantly, note the relationship between GrWDRVI and SWB is dependent on crop type, irrigated vs. rainfed and green up vs. senescence. In this study, I used MODIS data to obtain GrWDRVI which is used as reference to estimate the crop growth condition. In that case, soil water content measured by CRNP could be corrected using GrWDRVI and equations presented in Chapter 2. The comparison of 2003-2016 of in-situ vegetation samples from maize and soybeans at US-Ne3 site in eastern Nebraska indicated that the GrWDRVI was able to predict biomass in agricultural fields. I believe GrWDRVI shows a reliable relationship with in-situ biomass data, especially if we partition GrWDRVI into green-up vs senescence and irrigated vs. rainfed (Avery, 2016). However, this method still has some limitations. The difference of time interval between in-situ measurement and satellite MODIS overpass may have potential effect on the accuracy of our measurement. Low resolution of MODIS image is another problem. GrWDRVI obtained from MODIS image data may not represent the true surface conditions. Only 2-4 pixels cover for whole research site, which made it hard to get accurate values due to edge effects. In addition, MODIS data are influenced by weather

where it is not available on cloudy days. This results in missing MODIS data during critical summer time growth periods.

With respect to the CRNP, I found at US-Ne3 that a multivariate linear relationship between fresh biomass and B/M and moderated counts was reasonable ($R^2>0.6$, Table 2.4) in most years. However, in dry years (2012 and 2013) this relationship behaved more poorly with $R^2 < 0.3$. Overall, my results indict that correcting in-situ biomass measurements using B/M and moderated counts is reasonable when locally calibrated with biomass data. Including moderated counts as well as B/M is an improvement over previous research that only considered B/M ratios to predict biomass changes (Tian 2016). Additional work is needed to further generalize these relationships and make the methodology more practical and transferrable between sites.

Based on previous research, CRNP can accurately measure average soil moisture in the field particularly when correcting for local biomass changes using remotely sensed vegetation indices (Coopersmith, 2014). Another study showed that B/M ratios can be used to estimate aboveground biomass and make further adjustment (Tian, 2016). In our study, I investigated the relationship between fresh biomass changes in crops with GrWDRVI and bare and moderated neutron counts. I found that the relationship between biomass changes and neutron counts was improved by including both moderated counts and B/M ratios in a multivariate linear regression. In addition, I also found evidence that rainfall and irrigation (non-limiting soil moisture conditions) affected the relationships between neutron counts and fresh biomass changes. When comparing remotely sensed GrWDRVI and B/M ratios from the three study sites from western Nebraska to central lowa, western study sites under irrigation showed a stronger linear relationship (R²= 0.92

vs $R^2 < 0.2$). This is likely due to the fact that CRNP is a hydrogen mass detector and more hydrogen is contained in the vegetation instead of the soil at the non-limiting soil moisture sites. I note that the western site is irrigated as opposed to rainfed for the other two sites. While the irrigation is additional pmoisture it is likely to be contained in the top 0.3 m of soil. The CRNP is more sensitive in the top soil and likely responding to the water and vegetation changes. Unfortunately given the lack of in-situ biomass data at all sites the robustness of this conclusion will need to be further evaluated in future work. Clearly the B/M and GrWDRVI both reflect changes in crop biomass albeit with their own local calibration issues. I suggest more research is needed before a biomass fix can be included in the CRNP SWC calibration equations. A clear first step is resolving a more robust statistical relationship between in-situ biomass data, B/M and moderated neutron count data across a diverse set of sites with varying crops, soil, and soil moisture conditions.

Chapter 3: Conclusions and Future Directions

In this thesis I investigated using remotely sensed or neutron observations to correct for biomass changes to improve the use of the Cosmic-ray neutron probe for soil water content observations. By combining both bare and moderated detectors with remote sensing MODIS data I found evidence that a local relationship may be derived to estimate vegetation biomass changes and thus improve the accuracy of this new technology. The comparison of remote sensing MODIS data and in-situ biomass from US-Ne3 (2003-2016), show a linear relationship between GrWDRVI and fresh biomass could be used to correct the CRNP observations via the calibration procedure. Other work has shown that there is unlikely a general relationship or set of coefficients that exist for all sites. It is known that influencing factors such as crop type, irrigation type and drought conditions impact the accuracy of the GrWDRVI to fresh biomass observations. Lastly, a remaining challenge of using MODIS/GrWDRVI biomass correction for CRNP are the 8-day repeat overpass time and large band sizes of 250 to 500m to fully capture hourly and daily vegetation changes.

With respect to the CRNP, I found the B/M ratio and moderated counts are good predictors to capture crop growth at US-Ne3 albeit with some dependency on crop growth stage and local rainfall. However, the in-situ biomass data was limited to a single site and only a few times during the growing season. Taking samples every 10-14 days is actually quite frequent, but more samples are needed to make more reliable linear regression. The data was collected by a different research group for another study thus limiting its full usefulness to this study. I would encourage future work to collect more in-situ biomass data and corresponding SWC datasets focused on better deriving local and potentially general relationships between biomass changes and neutron observations. This work is encouraging on the future use of bare and moderated neutron counts to estimate fresh biomass changes directly and improve the accuracy of the CRNP calibration function for estimating SWC. Given the wide range of 200+ CRNP sites globally, bare and moderated neutron counts offer an interesting dataset to investigate both SWC and vegetation changes simultaneously at large scales.

Moreover, the influence of vegetation changes on CRNP SWC monitoring is still unresolved in this study. In-situ SWC samples are needed to investigate the relationship between vegetation changes and accuracy of the CRNP observations. I would suggest a dedicated study with weekly biomass and SWC sampling at US-Ne3 to resolve this issue following Franz (2015). Additionally, a field campaign coordinating sampling efforts across the three long-term CRNP monitoring sites would be preferred. This will be a time and labor intensive effort but needed to fully understand the potential of using both moderated and bare neutron counts to monitor vegetation and SWC simultaneously.
