17 Running title: Fin whale density and distribution estimation.

18 **Abstract**

19 Passive acoustic monitoring of marine mammals is common, and it is now possible to
20 estimate absolute animal density from acoustic recordings. The most appropriate density
21 estimation method depends on how much detail about animals' locations can be derived from
22 the recordings. Here, a method for estimating cetacean density using acoustic data is
23 presented, where only horizontal bearings to calling animals are estimable. This method also
24 requires knowledge of call signal-to-noise ratios (SNR), as well as auxiliary information
25 about call source levels, sound propagation, and call production rates. Results are presented
26 from simulations, and from a pilot study using recordings of fin whale (*Balaenoptera*
27 *physalus*) calls from Comprehensive Nuclear-Test-Ban Treaty Organization (CTBTO)
28 hydrophones at Wake Island in the Pacific Ocean. Simulations replicating different animal
29 distributions showed median biases in estimated call density of less than 2%. The estimated
30 average call density during the pilot study period (December 2007 - February 2008) was 0.02
31 calls.hr⁻¹.km² (coefficient of variation, CV: 15%). Using a tentative call production rate,
32 estimated average animal density was 0.54 animals/1000 km² (CV: 52%). Calling animals
33 showed a varied spatial distribution around the northern hydrophone array, with most
34 detections occurring at bearings between 90 and 180 degrees.

35

36 **I. INTRODUCTION**

37 Using acoustic data to estimate animal density has been demonstrated for both terrestrial and
38 marine species (e.g., Buckland, 2006; Marques *et al.*, 2013, Stevenson *et al.*, 2015). A suite
39 of density estimation methods exist that can be applied to different types of acoustic survey
40 data. The most appropriate density estimation method depends on how much detail about
41 animals' locations can be derived from the recordings, which is often determined by the
42 number and configuration of deployed instruments. At best, three-dimensional locations of
43 calling animals can be estimated from acoustic data; conversely some recordings can yield
44 little to no information about animals' locations.

45 Distance sampling (Buckland *et al.*, 2001) and spatially explicit capture-recapture (SECR;
46 e.g., Borchers, 2012) are methods that estimate the probability of detecting animals (a key
47 parameter of any animal density estimation method) using spatial data collected during the
48 survey. Specifically, distance sampling can be used when the horizontal range between an
49 instrument and a calling animal can be estimated (e.g., Marques *et al.*, 2011), which, for
50 marine animals, typically requires animal depth to be estimable (or assumed). SECR requires
51 that the same acoustic event is matched across multiple recorders, creating "capture histories"
52 of acoustic events. Indirect information about the location of calling animals can be inferred
53 from these capture histories by assessing which recorders (with known locations) detected the
54 acoustic events. Although SECR does not need measured ranges, SECR analyses can be
55 supplemented with data relating to animals' locations such as direction, received sound level
56 and time of arrival (Borchers *et al.*, 2015). Given their data requirements, both distance
57 sampling and SECR require arrays of recorders to estimate detection probability (though
58 horizontal ranges to calling animals can, in some particular scenarios, be estimated from
59 single instruments, e.g., Harris *et al.*, 2013; Marques *et al.*, 2011; Tiemann *et al.*, 2004).

60 Conversely, when no spatial information can be estimated from recorded data (e.g., in most
61 scenarios where single instruments are deployed), detection probability can be estimated
62 using some form of auxiliary data. Marques *et al.* (2013) consider two types of auxiliary
63 information: (1) a sample of measured animal locations in relation to a recorder either from
64 animal-borne tags (e.g., Marques *et al.*, 2009) or combined visual and acoustic trials using
65 focal animals (e.g., Kyhn *et al.*, 2012); (2) acoustic modeling using elements of the passive
66 sonar equation (Urick, 1983) including information about the target species' call source level,
67 transmission loss, ambient noise levels, and the efficiency of the detection and classification
68 process. This latter information can be combined to estimate the probability of detection
69 using a simulation-based framework (e.g., Küsel *et al.*, 2011). Monte Carlo simulations have
70 been implemented for a range of cetacean species (Küsel *et al.*, 2011; Harris, 2012; Helble *et*
71 *al.*, 2013; Frasier *et al.*, 2016) but rely on accurate simulation inputs. One such input is the
72 distribution of simulated animals; however, there are often no *a priori* data about what this
73 distribution should be. This is a key limitation of the Monte Carlo simulation approach.

74 Here, a new method is presented for estimating cetacean density using acoustic data, for cases
75 where horizontal bearings to calling animals are estimable. This approach is suitable for
76 scenarios where neither distance sampling nor SECR can be implemented, due to lack of
77 recorders (note that SECR survey design is an ongoing area of research but, to date, the
78 minimum number of recorders used for acoustic capture histories has been three, Kidney *et*
79 *al.*, 2016). The new method is related to the Monte Carlo simulation methodology as it uses
80 the passive sonar equation; measured call signal-to-noise ratios (SNR) are required, as well as
81 auxiliary information about call source levels, sound propagation, and call production rates.
82 However, the additional bearing data give some empirical information about animal
83 distribution, conferring an advantage over the standard Monte Carlo simulation. Another

84 advantage of this method is that it produces a spatial map of estimated abundance (or
85 density), allowing inferences about spatial habitat preferences of acoustically active animals.

86 The paper is structured as follows. Section II presents a background to density estimation
87 using acoustic data, and a description of the new method. Details about the motivating case
88 study – fin whales recorded in the Pacific Ocean by Comprehensive Nuclear-Test-Ban Treaty
89 Organization (CTBTO) hydrophones – are given in Section III (including details of all the
90 required auxiliary analyses). Simulations are presented, which investigate method
91 performance under different known spatial animal distributions (Section IV). The method is
92 then applied to three months of recordings from Wake Island between December 2007 and
93 February 2008 (Section V). This analysis forms a pilot study prior to applying the method to
94 long-term CTBTO datasets from Wake Island and Diego Garcia in the Indian Ocean. Finally,
95 Section VI presents a discussion of the approach, including its limitations, benefits, and
96 potential implementations.

97 **II. DENSITY ESTIMATION USING ACOUSTIC DATA**

98 A general estimator of animal density using acoustic cues (e.g., animal calls) from static
99 instruments was presented by Marques *et al.* (2009) (Eqn. 1):

$$100 \quad \hat{D} = \frac{n_c(1-\hat{c})}{K\pi w^2 \hat{P}_a T \hat{r}} \quad (\text{Eqn. 1})$$

101 where \hat{D} = call density, n_c = number of detected signals, \hat{c} = false positive proportion, K =
102 number of monitoring points, w = maximum detection range, \hat{P}_a = average probability of
103 detection of an animal within radius w of the sensor, T = total monitoring time and \hat{r} = cue
104 production rate . This equation can be decomposed into three components:

105
$$\hat{D} = \frac{n_c(1-\hat{c})}{\hat{P}_a} \times \frac{1}{K\pi w^2} \times \frac{1}{T\hat{r}} \quad (\text{Eqn. 2})$$

106 where $\hat{N}_c = n_c(1 - \hat{c})/\hat{P}_a$ is the estimated abundance of cues, $K\pi w^2$ is the area monitored,
 107 so that dividing the abundance of cues by the area monitored gives a density of cues, and
 108 $1/T\hat{r}$ converts the density of cues to the density of animals.

109 The average probability of detection, \hat{P}_a , can be estimated in several ways, as shown by the
 110 variety of available density estimation methods (Marques et al. 2013). Each method has
 111 various assumptions that must be met to produce an unbiased detection probability and hence
 112 density. One key assumption in distance sampling is that the distribution of animals'
 113 distances from samplers (i.e., transect lines in a line transect survey, or monitoring points in a
 114 point transect survey) is known. This is achieved by random placement of multiple samplers
 115 within the study area so that, on average, animals are distributed uniformly in horizontal
 116 space. For a survey using many fixed monitoring points with circular detection areas, this
 117 assumed average distribution of animal distances is specifically a triangular distribution due
 118 to the linear increase in area with increasing incremental horizontal distance from each
 119 sample point (Buckland *et al.*, 2001). However, when single acoustic stations are used, it
 120 may not be reasonable to assume animal distances from that single station follow a triangular
 121 distribution, and standard distance sampling should not be used to estimate \hat{P}_a (even if ranges
 122 to animals can be estimated). Therefore, an alternative approach to estimating detection
 123 probability is required. In the method developed here, cue abundance is estimated using a
 124 Horvitz-Thompson-like estimator (after terminology used by Borchers & Burnham, 2004).
 125 These estimators are based on seminal work by Horvitz & Thompson (1952), who showed
 126 that when sampling at random from a population where each individual, i , has probability P_i
 127 of being sampled, then an unbiased estimator of population size is given by the sum over
 128 detected individuals of $1/P_i$. One can think of each detection “representing”, on average,

129 $1/P_i$ objects in the population. In animal density estimation methods, individual detection
130 probabilities for every detection can be estimated (rather than estimating an average detection
131 probability as shown in Eqn. 1) and combined to give $\hat{N}_c = \sum_{i=1}^{n_c} 1/\hat{P}_i$. However, the
132 detection probabilities, P_i , are estimated, not known (hence “Horvitz-Thompson-like”).
133 Horvitz-Thompson-like estimators are not unbiased; the bias is typically small unless
134 estimated probabilities are highly uncertain or close to zero (Borchers *et al.*, 2002). The key
135 advantage of this approach in the current case is that the individual detection probabilities can
136 be estimated without requiring any assumption about the distribution of animals with respect
137 to the samplers.

138 Other key assumptions that apply to this new method are that (1) all data measurements and
139 derived parameters are accurate and (2) detections are independent of one another. It is
140 highly improbable that recorded whale calls are produced independently of each other, given
141 that one animal may produce many calls. However, violation of the independence
142 assumption should not produce severe bias, though variance estimation can be affected
143 (Marques *et al.*, 2013). Another assumption of any density estimation method is that
144 parameters used in the estimator are accurate for the time and place of the main survey. A
145 frequent limitation of auxiliary data used in density estimation analyses is that the additional
146 experiments (e.g., to estimate cue production rate) may have been conducted in a limited part
147 of the study area (or in a different location) and/or at a different time as the main survey,
148 which may lead to bias in the estimated parameters. Therefore, as many auxiliary analyses
149 should be undertaken using data from the main survey region and time period as possible.

150 **A. Method overview**

151 It is assumed that acoustic data have been recorded at known locations for a known time and
152 then processed using an automated detection and classification algorithm.

153 Estimation proceeds in the following stages, described in more detail in the next subsection.

154 1. Characterize the automatic detection process to estimate the probability of detecting a
155 call as a function of SNR ($P(SNR)$). The resulting fitted “detection characterization
156 curve” is used to estimate the detection probability for each detected signal.

157 2. Determine the monitored area: for each of a set of discrete bearings, use the assumed
158 call source level (SL) and the measured noise level (NL) distributions with a
159 transmission loss (TL) model to determine a set of ranges at which calls are almost
160 certain to be masked (i.e., the resulting SNR is so low that probability of detection is
161 very low) and exclude these areas from further analysis.

162 3. Estimate the distribution of possible ranges for each detection. Use the measured
163 received level (RL) and bearing of each detection, together with the assumed SL
164 distribution and TL model to estimate the probability density function (pdf) of ranges
165 for that detection. A probabilistic approach is required because (a) source level for
166 each detection is not assumed known, but is assumed to come from a probability
167 distribution; (b) even if source level were assumed known, the TL does not increase
168 monotonically with range and hence a detected signal with a given RL can correspond
169 to more than one range.

170 4. Estimate the range-specific distribution of number of signals corresponding to each
171 detection, i.e., scale each detection by its associated detection probability to account
172 for undetected signals. Using the Horvitz-Thompson-like estimator, each detection, i ,
173 on average corresponds to $1/P(SNR_i)$ signals within the area monitored.

- 174 5. Estimate spatial density of signals by summing over the estimated number of signals
175 at each bearing and range to yield an empirical spatially-explicit abundance of signals.
176 Then smooth this using a Generalized Estimation Equation (GEE) spatial model.
- 177 6. Estimate animal density: use additional multipliers i.e., false positive proportion, time
178 spent monitoring (excluding periods of high ambient noise that cause masking) and
179 cue rate (Eqn. 1). Also potentially restrict inference to areas where detection
180 probability is higher and hence inference more reliable.

181 **B. Further details**

182 *Stage 1: Characterize the automatic detector.* Detector characterization is performed using a
183 sample of manually-detected calls. To ensure the sample is representative, a systematic
184 random subset of recordings (i.e., short sections equally spaced in time – see Section III for
185 an example) should be analysed manually. SNR is measured for a sample of manually-
186 detected calls, as well as noting whether or not each call was detected by the automatic
187 detector. Logistic regression with automated detection/non-detection as the response and
188 SNR as the explanatory variable is used to model the probability of detecting a call as a
189 function of SNR. A Generalized Additive Model (GAM, Wood, 2006) is used to allow a
190 smooth, nonlinear relationship between probability of detection and SNR. The fitted detector
191 characterization curve is then used to predict probability of detection, $P(SNR)$, for each
192 detection (over the entire monitoring period), $\hat{P}_i = \hat{P}(SNR_i)$.

193 If bearings cannot be estimated for all detections, one of two approaches can be taken: the
194 detector characterization curve can be estimated where a successful detection is defined as
195 either (1) any detected fin whale call (regardless of whether it had an associated bearing or
196 not), or (2) detected fin whale calls that had an associated bearing measurement. The choice
197 of detector characterization approach will affect the value used for n_c in the estimator (Eqn.

198 1). Under the first definition, n_c will be the number of detections (with or without measured
199 bearings); under the second definition, n_c will be the number of detections with measured
200 bearings only. In both cases, an assumption is made that the measured bearings represent the
201 spatial distribution of all detected signals, including those for which bearings could not be
202 estimated.

203 *Stage 2. Determine area monitored.* This stage is analogous to identifying the maximum
204 detection range, w , in Eqn. 1, although a set of bearing-specific ranges are derived, allowing
205 TL to vary in different directions, and be non-monotonic with increasing range. Hence the
206 area monitored does not have to be circular or continuous.

207 SL is assumed to follow a normal distribution; so it is theoretically possible to detect calls
208 from implausibly large (or even infinite) ranges in Stage 3. Therefore, a pragmatic cut-off is
209 used that ensures detections from outside the area monitored will be very rare. The assumed
210 SL and NL distributions are evaluated at the 90th and 10th percentiles, respectively, to
211 represent a loud call in low noise. These values are used in the passive sonar equation along
212 with TL to calculate the SNR of the hypothetical call at various range and bearing steps
213 around the hydrophone ($SL - TL - NL = SNR$). The detection probability of the call at all
214 locations is evaluated from the detector characterization curve. Locations where the call has
215 a detection probability of equal to or less than 0.1 are considered to be acoustically masked.
216 The lowest TL associated with a masked location is used as a TL threshold to define
217 acoustically masked areas, which are then excluded from the remainder of the analysis.

218 *Stage 3. Estimate distribution of possible ranges for each detection.* Given a detection with
219 measured RL and bearing θ , the SL of the detection if the source was at range r can be
220 derived from the (simplified) passive sonar equation as

$$221 \quad SL(r, \theta) = RL + TL(r, \theta) \quad (\text{Eqn. 3})$$

222 where $TL(r, \theta)$ is range- and bearing-specific transmission loss. An SL distribution is
 223 required, which is assumed to follow a normal distribution with mean μ and standard
 224 deviation σ . In this analysis, SL could be estimated from a subsample of localized calls at
 225 short ranges. Then, the pdf of range is

$$226 \quad f(r|RL, \theta) = \frac{r}{v} \frac{1}{\sqrt{2\pi\sigma^2}} e^{-\frac{(SL(r,\theta)-\mu)^2}{2\sigma^2}} \quad (\text{Eqn. 4})$$

227 where v is a normalizing constant to ensure f is a proper pdf:

$$228 \quad v = \int_{r=0}^W \frac{r}{\sqrt{2\pi\sigma^2}} e^{-\frac{(SL(r,\theta)-\mu)^2}{2\sigma^2}} dr \quad (\text{Eqn. 5})$$

229 The need for an r in the denominator of Eqn. 4 is explained by viewing the analysis as
 230 analogous to distance sampling with measurement error on the distances. In this case, the
 231 geometry of a circular detection area means that random measurement error (in this case,
 232 uncertainty in location) will result in underestimation of detections' true locations (discussed
 233 in Buckland *et al.*, 2015), leading to biased density estimates at closer ranges.

234 In practice, range is discretized into a fixed set of range intervals, with midpoints $\{R\}$. TL is
 235 calculated at these ranges, and it is assumed that the TL values apply to each corresponding
 236 interval. Then, the probability a detection comes from interval k is

$$237 \quad \Pr(k|RL, \theta) = \frac{f(R_k|RL, \theta)}{\sum_{R_j \in R} f(R_j|RL, \theta)} \quad (\text{Eqn. 6})$$

238 *Stage 4. Estimate range-specific distribution of number of signals corresponding to each*
 239 *detection.* SNR for each detected signal is calculated from the RL and NL measurements
 240 associated with each signal (SNR = RL – NL). Detection probabilities of each detected
 241 signal are estimated using the detector characterization curve and the range-specific
 242 distribution for each detection is divided by the estimated detection probability. Using the

243 Horvitz-Thompson-like approach, the estimated number of signals in the population
244 “represented” by a signal detected with a given SNR is $1/P(SNR)$. Hence, the range-
245 specific distribution of number of signals corresponding to a particular detection is given by

$$246 \quad N_c(k|RL, NL, \theta) = \frac{\Pr(k|RL, \theta)}{P(SNR)} \quad (\text{Eqn. 7})$$

247 *Stage 5. Estimate spatial density of signals.* At each bearing and range interval, the estimated
248 number of signals are summed. This yields a spatial abundance surface, but one that is not
249 necessarily smooth because of random variation in detections. Given a long monitoring
250 period, the true distribution of calls around the sensor likely is smooth, so precision can be
251 gained by smoothing the raw estimates using a GEE model (Hardin & Hilbe, 2012), which
252 accounts for spatial autocorrelation. The response variable is the estimated signal abundance,
253 assuming an overdispersed quasipoisson error distribution and using a log link function.
254 Explanatory variables are the location of the centre of the bearing and range interval in (x,y)
255 space (2-dimensional Cartesian coordinates). To account for the fact that intervals at larger
256 ranges represent a larger area, the area of each interval is included as an offset in the model.
257 To account for spatial autocorrelation, spatial blocks of 100 km x 100 km are created through
258 the study area and an independent working correlation structure implemented; model
259 residuals can therefore be correlated within blocks but are assumed to be independent
260 between spatial blocks. The spatial GEE is fitted using CReSS (Complex Region and Spatial
261 Smoother, Scott-Hayward *et al*, 2014) and SALSA (Spatially Adaptive Local Smoothing
262 Algorithm, Walker *et al.*, 2011) methods, allowing a flexible surface with spatially-varying
263 smoothness to be modeled. Model fit is assessed using concordance correlation and marginal
264 R squared values (in both cases, values close to 1 indicates good fit). A predicted density
265 surface is created by predicting abundance on a regular (x,y) grid, and dividing by the area of
266 each grid cell.

267 *Stage 6. Estimate animal density.* The predicted density surface of signals is converted to a
268 predicted animal density surface by multiplying by $(1 - \hat{c})/T\hat{r}$, where c is the false positive
269 proportion, T is monitoring time, and r the cue production rate. False positive proportion is
270 estimated from the manually-validated sample of data. Monitoring time should be known as
271 part of the survey protocol. Furthermore, the NL measurements of the detections can be
272 compared to ambient NL measured throughout the dataset to determine a NL threshold,
273 above which total acoustic masking is likely to occur. Time periods of data where ambient
274 NL exceeds the maximum NL associated with a detection are omitted from the monitoring
275 time, T . Cue production rate must come from auxiliary information and is often not known,
276 in which case density of calls can be estimated but not density of animals.

277 Average density can be computed by taking the average across the prediction surface. To
278 increase robustness, grid cells far from the sensor, where detection probability is low, may be
279 excluded from this averaging. A Horvitz-Thompson-like estimator is known to produce
280 positively biased estimates, particularly when some of the \hat{P}_i values are small (Borchers *et al.*
281 2002) as is the case for more distant calls. To mitigate this, a simulation study can be used to
282 determine at what range bias may be minimised and this can be used to truncate the range
283 over which average density is inferred.

284 **C. Variance estimation**

285 The delta method (Seber, 1982) is used to combine the coefficients of variation (CVs) for
286 each random variable used in the density estimator to estimate the overall CV for the
287 resulting density estimate. Note that the encounter rate also contributes to the overall
288 variance of a density estimate, and is denoted by $CV(n_c)$ in Eqn. 8. All other density
289 estimator inputs such as K , T and w are known constants and therefore do not have an
290 associated variance.

291 $CV(\hat{D})^2 = CV(n_c)^2 + CV(\hat{c})^2 + CV(\hat{P}_a)^2 + CV(\hat{f})^2$ (Eqn. 8)

292 where: \hat{P}_a = overall mean probability of detection, defined as

293 $n_c / (\sum_{i=1}^n 1/\hat{P}_i)$ (Eqn. 9)

294 In surveys with multiple samplers (i.e., monitored line or points), between-sampler variance
295 in encounter rate is usually estimated. With only one monitoring point as in this study, there
296 is no spatial variance in encounter rate and, instead, variance in encounters is linked only to
297 the detection process. Following guidance in Buckland *et al.*, (2001), the encounters are
298 assumed to follow an overdispersed Poisson distribution. Therefore, encounter variance can
299 be estimated using the Poisson expression for variance (multiplied by a factor of 2 to
300 acknowledge assumed aggregation in the encounters) (Eqn. 10), which can then be used to
301 calculate the CV:

302 $var(n_c) = 2n_c$ (Eqn. 10)

303 The false positive proportion and call production rate have weighted means (see Section III
304 for details) so variance is estimated using Cochran's approximation (Cochran, 1997,
305 recommended by Gatz and Smith, 1995). Detection probability variance is estimated using
306 parametric bootstrapping of the SL and NL distributions, the coefficients of both the logistic
307 regression and GEE spatial models, then taking the empirical variance of the resulting
308 bootstrapped signal densities. As these signal densities are uncorrected for false positives,
309 the only parameter used in their estimation is \hat{P}_i , and so the signal density CV will be
310 equivalent to $CV(\hat{P}_a)$.

311 **III. CASE STUDY - FIN WHALES IN THE PACIFIC OCEAN**

312 The pilot study focused on fin whale calls recorded in the Pacific Ocean. Fin whales, the
313 second largest cetacean, occur globally and are currently listed as "Endangered" in the IUCN

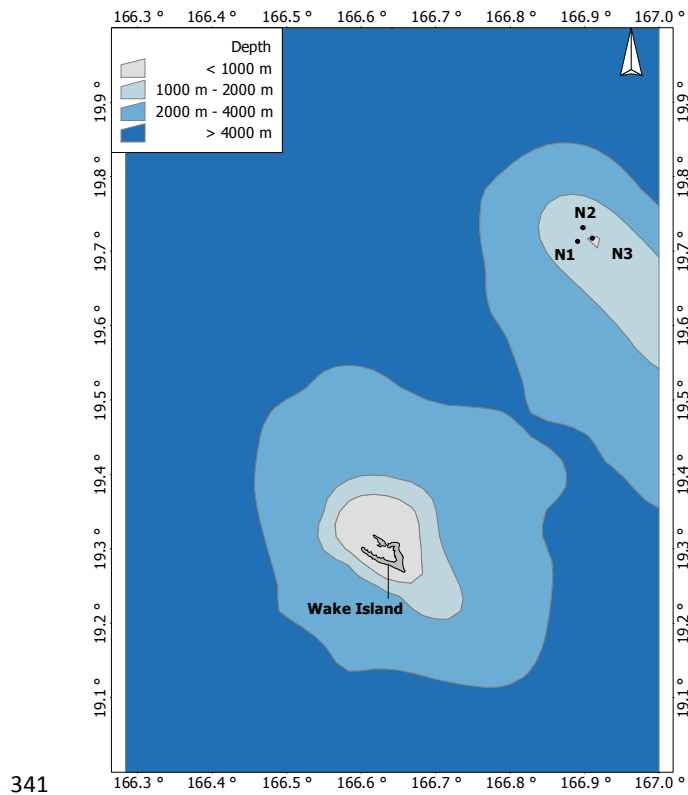

314 Red List (Reilly *et al.*, 2013). Fin whales produce a low-frequency pulsed call, the “20-Hz”
315 call (Watkins *et al.*, 1987), which has been widely utilized to investigate fin whales’
316 distribution and density through passive acoustic monitoring (e.g., Širović *et al.*, 2015). In
317 particular, a study of fin whales near Oahu, Hawaii, was an early example of using passive
318 acoustic data to estimate density (McDonald & Fox, 1999). Multipath arrivals and the
319 passive sonar equation were both used to estimate ranges to calling animals. However,
320 neither detection probability nor non-calling animals were explicitly accounted for, so the
321 resulting estimates were interpreted as a minimum number of animals (McDonald & Fox,
322 1999).

323 Data from the CTBTO IMS station at Wake Island (station identifier: H11) in the Equatorial
324 Pacific Ocean were used (1) as a basis for simulation studies to test the efficacy of the
325 method and (2) to demonstrate a pilot analysis using fin whale 20 Hz calls. Data from peak
326 seasonal detections from Dec. 1, 2007 to Feb. 29, 2008 were used, and details of data
327 processing and auxiliary analyses are given throughout the rest of this section.

328 **A. Wake Island CTBTO IMS station**

329 The Wake Island station is composed of two 3-element triangular arrays with 2.5 km spacing
330 between elements, with three hydrophones located to the north of the island (Fig. 1) and three
331 to the south. These cabled hydrophones are suspended in the deep sound channel. The three-
332 month pilot study used data from the northern array (hydrophone depths were 731 m, 732 m,
333 and 729 m). The average water depth at the array was 1068 m (estimated from Amante &
334 Eakins, 2009). Sound levels were recorded continuously at a 250 Hz sampling rate and 24 bit
335 A/D resolution. The hydrophones were calibrated individually prior to initial deployment in
336 January 2002 and re-calibrated while at sea in 2011. All hydrophones had a flat (within 3
337 dB) frequency response from 8-100 Hz. Information from individual hydrophone response

338 curves was applied to the data to obtain absolute values over the full frequency spectrum (5-
339 115 Hz). Data less than 5 Hz and from 115-125 Hz were not used due to the steep frequency
340 response roll-off at these frequencies.

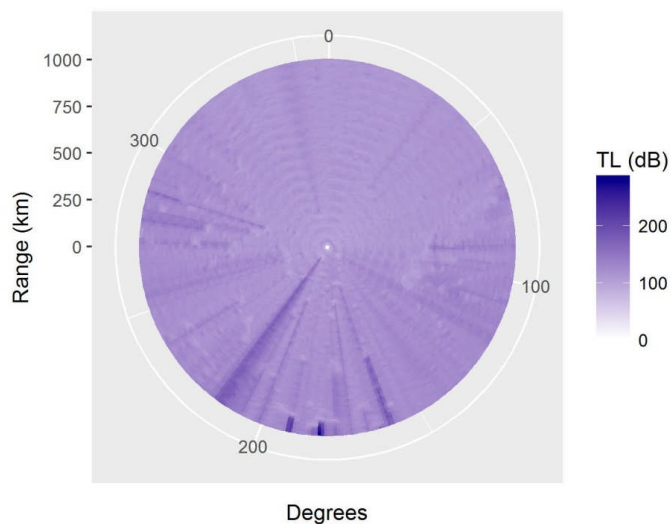

342 Figure 1. Map showing the location of Wake Island (coordinates: 19.30, 166.63) and the
343 northern hydrophone array. Water depth contours (1000 m, 2000m and 4000 m) are also
344 depicted.

345 **B. Transmission loss of a fin whale call**

346 The transmission loss due to range-dependent propagation between a vocalizing whale using
347 a 20 Hz call and one of the northern hydrophone receivers (labelled N1) at 731 m depth was
348 modelled along 360 bearings at 1° resolution using the OASIS Peregrine parabolic equation
349 model out to 1000 km from N1 (Heaney & Campbell, 2016) (Fig. 2). The transmission loss

350 was modelled at 1 km range steps over the three-month study using seasonal sound speed
351 profiles obtained from The World Ocean Atlas
352 (<https://www.nodc.noaa.gov/OC5/indprod.html>). It was assumed that the source was at a
353 depth of 15 m, in keeping with results about fin whale calling behavior (Stimpert *et al.*,
354 2015). The bathymetry was taken from the global bathymetry database ETOPO1 (Amante &
355 Eakins, 2009). Surface loss was negligible due to the low frequency of signals. Sea floor
356 parameters of soft sand sediment were used representing a global average of deep ocean
357 sediment. Details of the geoacoustics parameters in the specific Wake Island region are not
358 known but should not affect propagation in this environment due to direct path/sound channel
359 propagation.

360

361

362 Figure 2. Transmission loss of a 20 Hz signal propagating from Wake Island N1 at a depth of
363 15 m. The model was run for every bearing between 0 and 359 degrees at 1 km range steps.
364 In this plot, 0 degrees indicates north.

365

366 **C. Ambient noise levels**

367 Mean spectral levels within the 10-30 Hz band were calculated for each minute of the three-
368 month dataset, resulting in spectral levels with units of dB re 1 $\mu\text{Pa}^2/\text{Hz}$. Ambient noise
369 levels were calculated in the targeted 10-30 Hz band to directly overlap with the frequency
370 range of the fin whale 20-Hz pulse. Mean spectral levels were calculated using a Hann
371 windowed 15,000 point Discrete Fourier Transform with no overlap to produce sequential 1-
372 min power spectrum estimates. Note that these measurements included fin whale calls,
373 where present; it was important that the noise levels reflected all noise sources that each fin
374 whale call could be exposed to, which included calls by conspecifics.

375 **D. Source level estimation**

376 A sample of fin whale calls were localized using the northern array so that a source level
377 distribution could be estimated. Source level (SL) estimates of detected fin whale
378 vocalizations were computed using the passive sonar equation (Eqn. 11) that incorporated
379 environmental noise levels present at the time of the call within the received level (RL) of the
380 vocalization.

381 $SL = RL + TL - DI + DT - PG$ (Eqn. 11)

382 As the low-frequency calls are omnidirectional, the directivity index (DI) was set to zero.
383 Processing gain (PG) and detection threshold (DT) are accounted for in the calibration of the
384 recording system. Received levels were calculated for individual vocalizations recorded at
385 N1 using a custom MATLAB (Mathworks, 2016) code. Spectrograms were calculated using
386 a 512-point FFT and 93.75% overlap. Calls were then manually detected, with a human
387 analyst selecting the upper and lower frequency and time bounds of an individual call. The
388 rms (root-mean- square) RL of the call was then calculated from the selected spectral data.

389 The TL of a signal of a given frequency is dependent on the range, bearing, and depth of the
390 vocalizing animal. The time difference of arrival (TDOA) between each hydrophone pair was
391 found by cross-correlation of received signals and was supplemented with manual inspection
392 due to dispersed waveforms. 2D hyperbolic localization was then used to find the range and
393 bearing of the vocalizing animal. Location information was then input into the site-specific,
394 seasonal transmission loss models to back calculate the SL of each identified vocalization.
395 The depths of the sources were unknown but assumed to be at a depth of 15 m following
396 results from Stimpert *et al.* (2015). For comparison, source levels of the same sample of calls
397 were also calculated using simple spherical spreading instead of the more complex Peregrine
398 transmission loss model.

399 **E. Automated fin whale call detection**

400 Fin whale calls were detected from the N1 hydrophone using the automatic detection feature
401 of Ishmael, an open-access bioacoustic analysis software package (Mellinger, 2002). The
402 spectrogram correlation method was utilized for the full three-month dataset, cross-
403 correlating the spectrogram of the dataset with a synthetic call kernel. The kernel is a
404 template that indicates the time and frequency endpoints of the desired call. To prepare the
405 dataset for autodetection, time-waveform data were first passed through a 10-30 Hz bandpass
406 filter. Spectral data were then calculated using a 512-point FFT with a 93% overlap, and a 22-
407 14 Hz one-second downsweep call kernel was applied.

408 Results from the automatic detector were compared with the manually detected calls from a
409 subset of data. The three-month dataset was divided into six-hour sections, and a systematic
410 random sample of these sections was taken. Every 11th six-hour section was selected under
411 the sampling scheme, resulting in 32 six-hour sections. All calls within the 32 selected
412 sections were manually detected, and a receiver-operator curve was generated for the

413 automatic detector that compared the false positive proportion (the number of false positives
414 divided by the total number of automatic detections) with the proportion of missed calls (the
415 number of missed calls divided by the total number of manually detected calls, i.e., false
416 negative proportion) for a range of detection thresholds. The ROC curve indicated that the
417 optimal detection threshold had a 10% false positive proportion and a false negative
418 proportion of 59%. The mean false positive proportion was weighted by the number of
419 detections checked in each six-hour section.

420 **F. Bearing measurements**

421 Bearings were calculated using the TDOA of received signals. Using the known distances
422 between receivers and the seasonal sound speed, an estimated bearing was calculated for each
423 pair of hydrophones (Eqn. 12).

$$424 \quad \varphi = \arcsin(\tau * c/d) \quad \text{(Eqn. 12)}$$

425 where τ represents the TDOA of a signal between a hydrophone pair, d is the distance
426 between a hydrophone pair, and c is the speed of sound.

428 Left-right ambiguity of each bearing estimate could be resolved by comparing with the other
429 two estimates. The median bearing was then selected. An acceptable bearing is one where
430 the three bearings resulting from the three pair combinations all produced bearings within 10
431 degrees of each other. TDOA between each pair of hydrophones (N1 and N2, N2 and N3, N3
432 and N1) were found through three different methods, as described in order of application
433 below. If the cross-correlation method failed to produce an acceptable bearing, manual
434 estimation was performed. When manual estimation using the start point of each call failed
435 to produce an acceptable bearing, a band energy analysis was performed. The first step of all
436 methods was to pass the signals through a 10-30 Hz band pass filter. Bearings were rounded
437 to the nearest integer, to correspond with the resolution of the TL model.

438 **(1) Cross-correlation**

439 Once the data were filtered, a simple cross-correlation was performed in MATLAB to
440 determine time delays. Characteristics of the environment cause dispersion in the waveforms
441 traveling from distant ranges. As a result, a simple cross-correlation was not a viable option
442 for many of the distant calls.

443 **(2) Manual Estimation**

444 TDOA was found by manually selecting the start of each call from the time waveform.
445 Manual inspection eliminates the discrepancies that arise from the modal dispersion. Manual
446 selection also provided reliable results for calls with a low (< 6 dB) signal-to-noise ratio
447 (SNR), which is not always possible with automated methods. Manual detections were
448 feasible for a limited pilot study, but this method would not be appropriate for large datasets.

449 **(3) Band Energy Analysis**

450 Filtered data from N1 were analyzed in 3 Hz bands with 1 Hz overlap, starting at 10 Hz,
451 finding the peak in each band. The first band with a peak of at least 5 dB SNR was then
452 selected. The time index of the first peak in this frequency band for each sensor was then
453 noted and time delays were calculated from the identified time index.

454 **G. Detector characterization**

455 All calls were manually detected in the subsampled six-hour sections. The rms RL of each
456 call was measured, and the SNR of the call was calculated using a noise level measured from
457 the second of data preceding the call (in the same frequency bandwidth as the measured call
458 rms RL). Whether or not the call was detected by the automatic detector was also noted. The
459 detector characterization curve was modeled using the statistical analysis software, R version

460 3.3.1 (R Core Team, 2016). A GAM (Wood 2006) with a binary response and logit link
461 function was fitted to the data.

462 **H. Call production rate**

463 No call production rate data were available for fin whales occurring near Wake Island, but
464 call production rate data from the Southern California Bight in the North Pacific Ocean have
465 been published (Stimpert *et al.*, 2015). The fin whale data from southern California were
466 collected in summer months, and so it is possible that this cue rate is biased for the fin whales
467 calling near Wake Island in the winter months. Cue rates from Stimpert et al. (2015) were
468 applied here as a proof of concept only, and resulting animal density estimates must be
469 treated cautiously.

470 **IV. SIMULATION STUDIES**

471 **A. Simulation overview and input data**

472 The primary aim of the simulation studies was to investigate whether the method returned
473 unbiased (1) detection probability estimates and (2) distribution maps under a range of
474 scenarios. To that end, call density only was estimated in the simulations (i.e., a false
475 positive proportion and call production rate were not considered).

476 Ambient noise and source level information, as well as the detector characterization curve,
477 were measured directly from the Wake Island dataset. The source level distribution (assumed
478 to be normally distributed) had a mean of 177.7 dB re 1 $\mu\text{Pa}^2/\text{Hz}$ @ 1m (standard deviation:
479 3.30, $n = 79$) using the Peregrine transmission loss model and 177.6 dB re 1 $\mu\text{Pa}^2/\text{Hz}$ @ 1m
480 (standard deviation: 3.03) using spherical spreading to predict propagation loss. Further,
481 estimated source level decreased significantly as a function of range when using the
482 Peregrine model (linear regression coefficient = -2.20, p-value < 0.001, $n = 76$ due to the

483 removal of three outlying data points using Cook's distance measures). Estimated source
484 levels assuming spherical spreading also decreased slightly with range, though not
485 significantly (linear regression coefficient = -0.62, p-value = 0.27, n = 76) (Fig. 3). Given
486 that the means and standard deviations of the two source level distributions were almost
487 identical, the source level estimates using the more complex, bathymetry-dependent
488 Peregrine model were used for all simulations and analyses (though see Section VI for a
489 discussion of the regression results). The mean of the noise level distribution (also assumed
490 to be normally distributed) measured in association with manually detected calls was 92.5 dB
491 re 1 $\mu\text{Pa}^2/\text{Hz}$ (standard deviation: 2.74, n = 1484). The detector characterization curve was
492 estimated using 1484 manually detected calls, which were found in 20 out of 32 manually
493 checked six-hour sections (12 sections contained no calls). The mean SNR of automatically
494 detected calls was 13.98 (standard deviation: 7.09, n = 612) and the mean SNR of calls missed
495 by the automatic detector was 4.45 (standard deviation: 1.59, n = 872). The fitted GAM
496 predicted that the majority of calls with an SNR greater than 10 dB were certain to be
497 detected (Fig. 4).

498

499 Figure 3. Source levels estimated from 79 calls using transmission loss derived from (left)
 500 the Peregrine model and (right) assuming spherical spreading. Both plots show a fitted linear
 501 regression model (black line), with associated 95% confidence intervals shaded in gray.

502

503

504 Figure 4. Detector characterization curve (with 95% confidence interval) predicting detection
 505 probability as a function of SNR for known fin whale calls (n = 1484).

506

507 Simulation TL data were based on TL data from Wake Island but were modified due to
 508 extreme TL encountered in the real Wake Island data (see Section V). Wake Island TL data
 509 were extracted at a depth of 15 m to reflect realistic fin whale calling behavior. TL ranged
 510 between 71.70 dB and 286.46 dB. For the simulation studies, the minimum TL value (71.70
 511 dB) was subtracted from all TL values resulting in simulated TL values that ranged between
 512 0 and 214.76 dB.

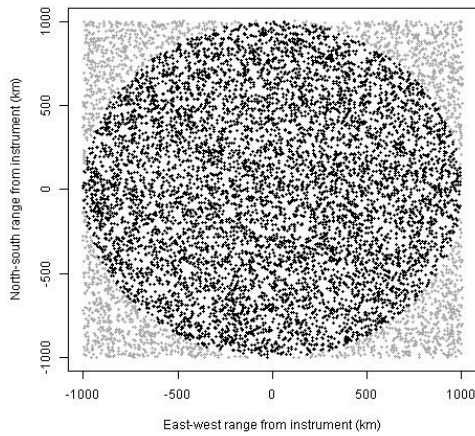

513 Three call spatial distributions were tested via simulation, designed to reflect differing calling
 514 animal distributions (Figure 5): calls were distributed (1) uniformly throughout the study
 515 area, (2) limited to the north-east, and (3) limited to the south of the hydrophone. The
 516 simulation was set up as follows:

517 (1) Calls were simulated through the study area; call distribution were changed by drawing x-
518 and y-coordinates from either a uniform or scaled beta distribution, depending on the desired
519 spatial call pattern (Fig. 5).

520 (2) Each simulated call was assigned an SNR based on the passive sonar equation; each call
521 was assigned a source level (SL) and noise level (NL) by drawing values from Normal
522 distributions with mean and standard deviations as measured from the Wake Island dataset,
523 which were then combined with the bearing- and range-specific TL value for that call, taken
524 from the modified TL data.

525 (3) Each call's detection probability was evaluated from the detector characterization curve
526 and a Bernoulli trial was used to determine whether a given simulated call was detected or
527 not.

528 (4)The TL value above which no calls are detected was determined using the approach
529 described in Section II.

530

531

532 Figure 5. Examples of distributions of simulated signals (clockwise from top left: uniform,
 533 northeastern and southern distributions). The black dots denote signals within the 1000 km
 534 maximum detection radius. Gray dots show signals outside the maximum detection range.

535 All simulations were run 500 times in R. The maximum detection range of the recording
 536 system was specified as 1000 km in all cases. In both simulations and analyses, the
 537 maximum detection range is set as an upper limit for a given instrument but may be reduced
 538 when the monitored area is defined (Step 2, Section II.A). Call density or abundance (density
 539 could then be used to calculate abundance or *vice versa*) was also specified. Secondly,

540 following the simulated detection process, the simulated RL, NL, and bearing values for each
541 simulated detected call were used as inputs for analysis instead of using measurements from
542 real recordings. In each of the three simulation scenarios, the initial abundance was altered
543 so that the number of detected calls was similar across all scenarios. The estimated call
544 density was compared to the known true value by calculating the median percentage bias
545 (with associated 2.5% and 97.5% percentiles). Additionally, because the true number of
546 simulated calls was known at increasing range steps from the array, the percentage bias as a
547 function of range from the array could also be assessed by comparing the true number of
548 simulated calls and the predicted number of calls within each range step. The maximum
549 range at which the percentage bias of call density was minimised was calculated for every
550 iteration (in some cases, the same minimal bias was calculated at multiple ranges, so the
551 largest range was selected). The distribution of these ranges could then be assessed after all
552 iterations were run to see whether there was an optimal prediction range, beyond which
553 percentage bias was likely to become larger, decreasing the robustness of the final predicted
554 density. This feature of the simulation algorithm may be useful for analysts to decide
555 whether to restrict the area of inference following an analysis to potentially reduce bias in the
556 reported density estimate. However, it is important to note that the simulation relies on an
557 assumed distribution of animal calls, which is likely to be different from the true, and
558 unknown, animal distribution, so a reduction in bias in analysis results is not guaranteed.

559 **B. Simulation results**

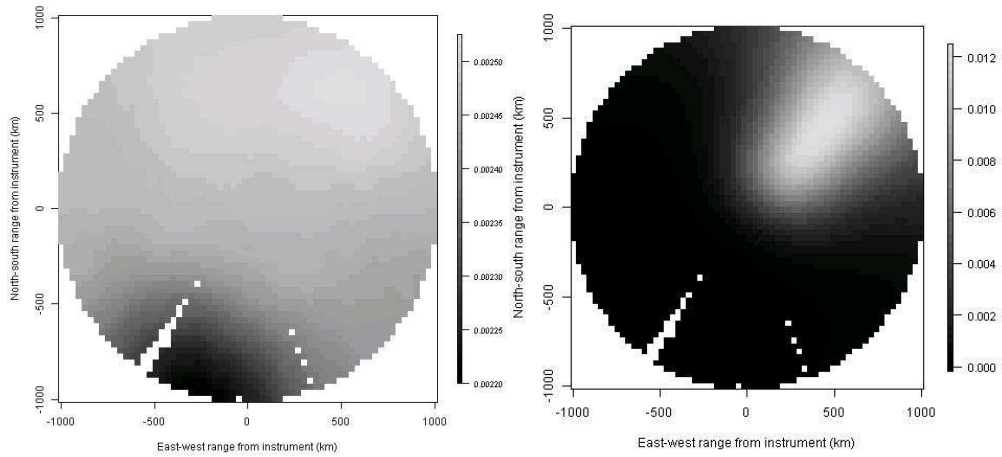

560 The simulations performed well – results from all scenarios had median percentage biases
561 less than 2% (Table 1). Percentage bias did not exceed 5% in any of the simulations. In
562 some scenarios, assessing the bias as a function of range showed that bias in call density
563 estimates could be substantially reduced when call density was inferred over a reduced range.
564 Bias was negligible for the uniform and southern distributions at median ranges of 678 km,

565 and 360 km, respectively, suggesting that these ranges were the optimal prediction ranges for
566 these scenarios. The NE distribution results were not improved by reducing the range of
567 prediction. Spatial model fit across scenarios varied, with uniform distribution models
568 displaying the poorest fit and the NE distribution producing spatial models with the best fit
569 (median marginal R squared values: 0.51, 0.79 and 0.92; median concordance correlation
570 values: 0.68, 0.88 and 0.96, for uniform, southern and NE distributions, respectively.).
571 However, all spatial models produced density maps that replicated the initial distributions
572 (Fig. 6).

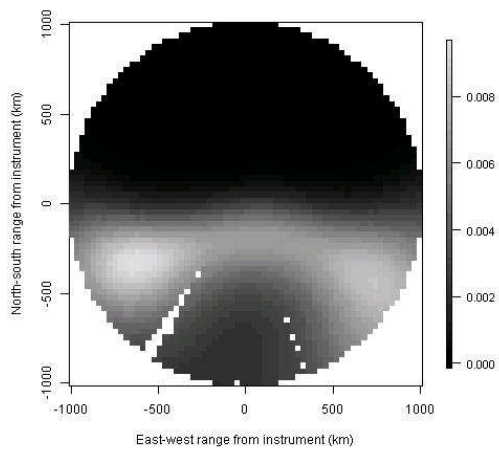

573 Table 1: Simulation results from three scenarios with different call distributions. Simulations
 574 were run 500 times and all results report the median value, and the 2.5 and 97.5 percentiles in
 575 parentheses.

Scenario→	Uniform distribution	Southern distribution	NE distribution
Number of detections	7243 (7147, 7354)	7597 (7484, 7714)	7408 (7389, 7427)
Percentage bias	-1.52 (-3.13, 1.12)	-1.88 (-3.96, 0.97)	0.01 (-0.45, 0.86)
Minimised % bias	-1.93e-4 (-0.98, 0.32)	-0.02 (-0.67, 0.70)	-0.01 (-0.38, 0.32)
Range at which bias minimised (km)	678 (50, 993)	360 (235, 1000)	1000 (45, 1000)

576

577

578

579 Figure 6. Distribution maps of signal density (signals/km²) predicted by a Generalized
 580 Estimating Equation . Initial simulated distributions were, clockwise from top left, uniform,
 581 northeastern and southern distributions. The depicted maps are the median estimated surface
 582 from 500 simulations.

583

584 **V. PILOT STUDY**

585 **A. Pilot study overview and input data**

586 The pilot study analysis estimated fin whale density based on the detected calls (and
587 associated SNR and bearing measurements) from three months of data. A simulation was
588 also run to investigate the level of potential bias in the analysis results, and whether inferring
589 density over a smaller area may reduce any bias (as discussed in Sections II.B and IV.A).
590 Calls were uniformly distributed through the simulated study area and the steps of the
591 simulation set-up were the same as those described in Section IV.A, except for the TL data
592 used.

593 A key difference between the simulations described in Section IV.A and the pilot study
594 analysis and simulation was that unmodified TL data were used in the pilot study, reflecting
595 the true environmental conditions at Wake Island (Fig 7).

596

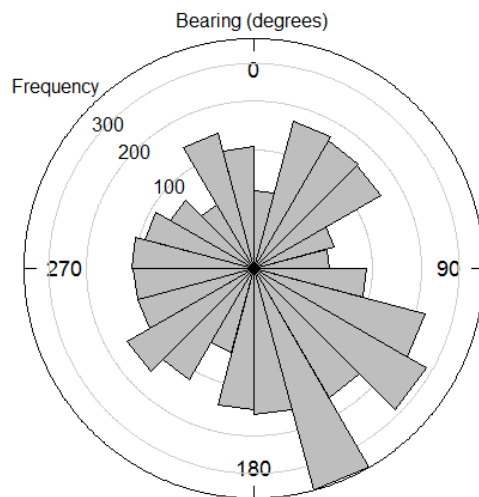

597

598 Figure 7. Transmission loss of a 20 Hz signal propagating from Wake Island N1 at a depth of
599 15 m, averaged across 360°. The main plot shows mean TL values up to the maximum range

600 without any unmeasurable infinite TL estimates (1231 km). The inset plot shows the same
601 data plotted up to 200 km; this inset shows the decrease in TL at ~ 50 km.

602 Inputs for the analysis were the following: number of detections, n , was 6552. The
603 automatic detector detected 6658 signals but the SNR of 106 signals fell below the lower
604 SNR limit of detected calls in the detector characterisation analysis (2.24 dB) and so were
605 removed to prevent model extrapolation when estimating detection probability using the
606 detector characterization curve. Of the remaining detections, 3086 (47%) had measurable
607 bearings, which ranged between 1.69 and 359.40 degrees (Fig. 8). While detections occurred
608 at all bearings around N1, the quadrant with the greatest number of detections occurred
609 between 90 and 180 degrees.

610

611 Figure 8. Histogram of measured bearings (in degrees) from the three-month pilot study
612 dataset ($n = 3086$). In this plot, 0 degrees indicates north.

613 The highest NL associated with a detection was 123.89 dB re $1 \mu\text{Pa}^2/\text{Hz}$. Of the 91 days of
614 continuous monitoring, 27 mins had an average NL of 124 dB re $1 \mu\text{Pa}^2/\text{Hz}$ or above.
615 Therefore, it is possible that high noise levels in these minutes could have prevented any

616 detections taking place, so these periods were considered “off effort” and were excluded from
617 the time spent monitoring, T .

618 The false positive proportion, \hat{c} , was 0.097 (standard error: 0.05). The maximum detection
619 radius, where detection probability was assumed to be negligible, was set to 1000 km and a
620 total of 2183.55 hours were analysed (excluding 27 mins of recordings where ambient noise
621 was assumed to be too high to successfully run the automatic detector).

622 Call production rate was determined from Stimpert *et al.* (2015). Deployment duration and
623 number of calls recorded were reported for 18 digital acoustic recording tag (DTAGs,
624 Johnson & Tyack, 2003) records. Ten animals were tagged with a version of the DTAG (v3)
625 that enables calls from the tagged animal to be identified from other calls made by non-
626 tagged conspecifics. It is crucial when estimating call production rate that only calls from the
627 focal animal are included in the analysis, so the other 8 animals tagged with v2 DTAGs were
628 omitted from the analysis. The v3 DTAGs were deployed between 1.60 and 6.30 hours. Six
629 tags did not record any calls, while the number of calls produced by the remaining four
630 tagged whales ranged between 23 and 942. The weighted mean call production rate was
631 45.08 calls.hr⁻¹ (standard error: 22.31).

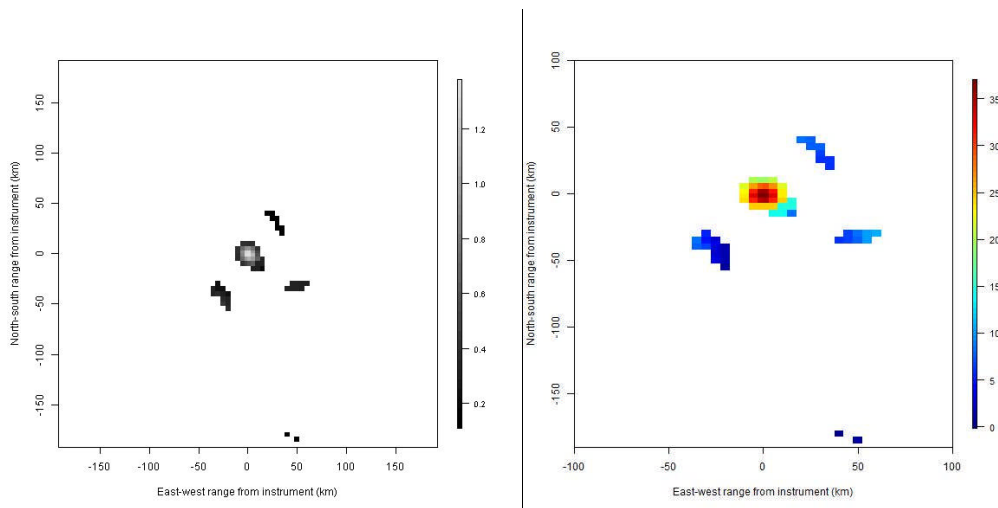

632

633 **B. Pilot study results**

634 The pilot study simulation was run 500 times assuming a uniform distribution with an initial
635 starting abundance of 5e+6 calls, and a maximum detection range of 1000 km. The median
636 number of observations was 238, and the resulting median percentage bias in estimated
637 density was -56.37%, but decreased to -10.76% if density was only estimated up to a range
638 step of 10 km. The median estimated density surface showed that the area within which the

639 calls were predicted to originate was very restricted, compared to the detection area initially
640 considered (~12 million km²) and is fragmented (Fig. 9a).

641 The pilot study analysis estimated initial average call density over the three month period
642 from Dec 2007 – Feb 2008 to be 0.014 calls.hr⁻¹.km² (CV: 0.15). Applying the call
643 production rate from the Southern Californian Bight resulted in an average fin whale density
644 of 0.32 animals.1000 km². The CV for the density estimate was 0.52. The overall monitored
645 area for both the pilot study simulation and analysis (once spatial acoustic masking was taken
646 into consideration) was 973 km² (Fig. 9b). Based on the results of the simulation, the pilot
647 analysis results were re-analyzed with a range step restriction of 10 km. There was no way to
648 determine which of the detections without bearings would have been detected within 10 km,
649 so it was assumed that the relative abundances of the two detection types (which could be
650 calculated from the initial analysis across the whole survey region) was not altered by making
651 inference over a smaller area. Therefore, an additional multiplier, *b*, was used to scale the
652 estimated density based on detections with bearings (*b* = 1.22). The resulting call density
653 estimate was 0.02 calls.hr⁻¹.km² (CV: 0.15), which resulted in a density of 0.54 animals.1000
654 km² (95% confidence interval: 0.21 - 1.40 animals/1000 km²). The CV associated with the
655 density estimate was 0.52.

656

657 Figure 9. Distribution maps of signal density (signals/km²) predicted by a Generalized
 658 Estimating Equation based on the pilot study data inputs. Fig 9a (left) the median estimated
 659 surface from 500 simulations. Fig 9b (right) the map from the analysis of fin whale calls
 660 from the three-month pilot study (signals/km²).

661

662 VI. DISCUSSION

663 There are already several existing methods that can be used to estimate animal density from
 664 acoustic data. However, the large variety of acoustic hardware and instrument configurations
 665 continue to present new surveying challenges and require current density approaches to be
 666 adapted. The CTBTO dataset presents such a case; there are 6 hydroacoustic stations similar
 667 to Wake Island situated in the Pacific, Atlantic, and Indian Oceans (CTBTO, 2016), which
 668 have provided a wealth of baleen whale recordings (e.g., Stafford *et al.*, 2011, Samaran *et al.*,
 669 2013; Le Bras *et al.*, 2016). Each site is configured in a similar way to Wake Island, with
 670 two triads of cabled hydrophones, one located to the north and one to the south of a land-
 671 based station that collects data round the clock. However, to date, it has not been possible to
 672 utilize CTBTO data fully for cetacean density estimation. Distance sampling is not a suitable

673 method for CTBTO data: only two monitoring points would be formed by the two triads at
674 each site, which is too few for distance sampling (due to the animal distribution assumption
675 discussed in Section I). In addition, the array spacing within triads only enables call
676 localization using traditional time difference of arrival methods at close ranges, meaning that
677 detections from greater distances would have to be omitted from an analysis. Given that the
678 large detection ranges due to the deep sound channel moorings are an advantageous feature of
679 CTBTO hydrophones, distance sampling would not be an optimal analysis method in cases
680 where the majority of signals were originating from distant locations and could not be
681 localized (recently, however, Le Bras *et al.* (2015) presented an alternative location
682 methodology using bearing and amplitude information in a Bayesian framework to estimate
683 calling animals' locations from CTBTO data, which may extend the localization capabilities
684 of these arrays). The array design at each site is also not configured well for an SECR
685 analysis. Although six hydrophones are available per site, acoustic masking is expected
686 between the northern and southern arrays, creating an acoustic barrier (Pulli & Upton, 2001).
687 Furthermore, the close spacing of the hydrophones in each triad would likely lead to many
688 detections being recorded by all three instruments. SECR depends on a variety of capture
689 histories to infer the location of calling animals; in this case, the array design may provide
690 limited information (i.e., scenarios where all instruments are ensounded on each occasion
691 yields little spatial information about the calling animals).

692 Therefore, data from the CTBTO arrays required a density estimation approach that used
693 auxiliary data. Although Monte Carlo simulations have been used to estimate call density of
694 blue whales in the Indian Ocean using CTBTO data (Harris, 2012), the method presented
695 here used the additional distributional information available in the measured bearings. The
696 more empirical data about animals' locations that can be collected during the acoustic survey,
697 the fewer methodological assumptions are required during the analysis. Although this

698 method was developed specifically for CTBTO data, there are other instrument systems that
699 record similar information. For example, DIFAR (directional frequency analysis and
700 recording) sonobuoys record bearings and have been used to detect blue whales at distances
701 over 100 nautical miles (e.g., Miller *et al.*, 2015).

702 The simulations demonstrated that the method performed well under the three different
703 simulated animal distributions (though with less extreme propagation conditions as modelled
704 at Wake Island). In two of the three cases, bias was further reduced when density was
705 predicted over a smaller area than the detection radius originally set for the simulation. For
706 example, in the median surface plot of the uniform distribution scenario, an area on the
707 periphery of the detection radius has some negative bias (as shown by the darker region to the
708 south of the array in Fig. 6a) and the simulation results recommended that density only be
709 predicted out to 678 km. The same issue was also encountered during the pilot study.
710 Running a simulation specifically for the pilot study suggested that the initial estimates were
711 likely to be negatively biased and inference was restricted to a smaller area. In this case,
712 restricting the area nearly doubled the point estimate (from 0.32 to 0.54 animals.1000 km²).
713 In summary, the simulation code provides a tool for users to explore optimal detection ranges
714 for their given target species, survey location, and automated detection software. A natural
715 extension to the work would be to incorporate more complex animal distributions into the
716 simulation algorithm.

717 The pilot study analysis demonstrated how most of the required auxiliary data for this
718 approach can be generated using subsampled data from the main three-month survey. It is
719 crucial that all parameters in the density estimator have been estimated accurately for the time
720 and place of the main survey, otherwise resulting density estimates may be biased. Source
721 levels, noise levels, transmission loss, the proportion of false positives, and the detector

722 characterization curve were all estimated specifically for the Wake Island dataset. The source
723 level analysis suggested that, while the choice of transmission loss model made little
724 difference to the source level distribution parameters used in the simulations and analyses, the
725 negative relationship between estimated source level and range of the call from the
726 hydrophone when using the Peregrine transmission loss model warrants further investigation.
727 Parabolic equation models can have limitations at high incidence angles (i.e., small ranges in
728 this case) (Jensen *et al.*, 2000), which could result in the discrepancies seen between the two
729 sets of source level results. Further, a fixed source depth of 15 m was assumed for all TL
730 data used in both the simulations and analyses; an extension to this work would be to see
731 whether changes in source depth (or using a distribution of source depths) significantly
732 affects the Peregrine TL (and therefore SL) results. The one parameter that could not be
733 estimated from the collected data was call production rate. In the absence of any other
734 available data, call production rates from the Southern Californian Bight collected during
735 summer months were applied to the estimated call densities. It is highly probable that the call
736 production rates of fin whales around Wake Island and southern California are different; cue
737 production rates do show spatiotemporal variation (e.g., Warren *et al.*, 2017). Therefore, the
738 fin whale densities estimated around Wake Island should be considered a “ballpark” estimate
739 at best.

740 The pilot study also demonstrated the flexibility of density estimation methods. In this case,
741 bearings could not be measured for all detections, but all detections (except those with SNR
742 values below the lower SNR limit of the detector characterization curve) could still be
743 incorporated into the analysis. It should be noted, however, that the estimated distribution
744 map was based on those detections with measurable bearings only. In order to interpret the
745 resulting distribution map as the predicted spatial distribution of calling fin whales, an
746 assumption must be made that the measured bearings represent the spatial distribution of all

747 detections. In any method that makes assumptions, it is important to assess whether the
748 assumptions are reasonable, or whether they may have been violated. Therefore,
749 consideration should be given as to whether there are any oceanographic or bathymetric
750 features of the study area that may result in certain bearings being difficult, or impossible, to
751 measure (other than high TL values, which are accounted for by identifying areas of acoustic
752 masking at the start of the analysis). In these cases, the resulting map would not depict the
753 distribution of all calling animals.

754 The most striking result of the pilot analysis was the fact that the monitored area at Wake
755 Island for fin whale calls was much smaller than originally anticipated. Sirovic *et al.*, (2007)
756 estimated detection ranges of fin whale calls in the Antarctic Ocean up to 56 km, though their
757 instruments were not moored in the deep sound channel. Previous work investigating
758 detection range of blue whale calls at CTBTO sites in the Indian Ocean (Samaran *et al.*,
759 2010, Harris, 2012) predicted that blue whale calls could be detected hundreds of kilometres
760 away, facilitated by the deep sound channel. However, the pilot study results are supported
761 by previous work that predicted detectability of low frequency signals at Wake Island to be
762 lower than at Diego Garcia (Miksis-Olds *et al.*, 2015). The results of all simulations and pilot
763 analysis also demonstrated that the monitored area may be an irregular shape, or even
764 fragmented, as seen in the pilot study. The fragmentation of the monitored area in the pilot
765 study is most likely caused by fluctuations in TL with range; the TL decreases at
766 approximately 50 km (Fig. 8, inset), which corresponds to the fragmented regions.
767 Monitored areas with unusual shapes should not lead to biased density estimates, as long as
768 the results are not extrapolated to areas outside the defined monitored area.

769 The pilot study has demonstrated the importance of quantifying the size and shape of the
770 monitored area (by estimating detection probabilities of the target species) during acoustic
771 surveys. The same site may show temporal variation in detection probability as

772 oceanographic conditions change through the year. Geographic variability in detection
773 probability between sites, caused by local bathymetric and ocean conditions should also be
774 considered, even if the acoustic system is the same. Detection probability may also alter if
775 the behavior of the target species changes e.g., if animals increase call source levels in certain
776 behavioral contexts. Investigating such spatial and temporal variation in detection
777 probabilities at Wake Island and another CTBTO site, Diego Garcia in the Indian Ocean, will
778 comprise the next stage of this research. Another natural extension to this work would be to
779 analyse the southern site at Wake Island to investigate whether the same monitoring
780 conditions are present at a site ~ 200 km from the focal instrument in this initial study.

781 **ACKNOWLEDGMENTS**

782 DH and LT were funded by the Office of Naval Research (Award: N00014-14-1-0394).
783 JMO and JV were funded under Award: N00014-14-1-0397 also from the Office of Naval
784 Research. Kevin Heaney (OASIS, Inc.) generously contributed the TL modelling results for
785 which we extend sincere thanks. Thanks also to Lindesay Scott-Hayward for her help with
786 implementing CReSS and SALSA methods. The CTBTO data was accessed from the Air
787 Force Tactical Applications Center/US National Data Center. Thanks are extended to James
788 Neely (AFTAC), Richard Baumstark (AFTAC), Mark Prior (formerly CTBTO), and Andrew
789 Forbes (CTBTO) for their assistance in data transfer and transfer of knowledge of CTBTO
790 data. Thanks also to the CTBTO for making available the virtual Data Exploitation Center
791 (<https://www.ctbto.org/specials/vdec/>). Finally, please note that the views expressed in this
792 study are those of the authors and not necessarily represent the views of the CTBTO
793 Preparatory Commission.

923 Table 1: Simulation results from three scenarios with different call distributions. Simulations
 924 were run 500 times and all results report the median value, and the 2.5 and 97.5 percentiles in
 925 parentheses.

Scenario→	Uniform distribution	Southern distribution	NE distribution
Number of detections	7243 (7147, 7354)	7597 (7484, 7714)	7408 (7389, 7427)
Percentage bias	-1.52 (-3.13, 1.12)	-1.88 (-3.96, 0.97)	0.01 (-0.45, 0.86)
Minimised % bias	-1.93e-4 (-0.98, 0.32)	-0.02 (-0.67, 0.70)	-0.01 (-0.38, 0.32)
Range at which bias minimised (km)	678 (50, 993)	360 (235, 1000)	1000 (45, 1000)

926

927

928 **FIGURE LEGENDS**

929 Figure 1. Map showing the location of Wake Island (coordinates: 19.30, 166.63) and the
930 northern hydrophone array. Water depth contours (1000 m, 2000m and 4000 m) are also
931 depicted (color online).

932 Figure 2. Transmission loss of a 20 Hz signal propagating to Wake Island N1 at a depth of
933 15 m. The model was run for every bearing between 0 and 359 degrees at 1 km range steps.
934 In this plot, 0 degrees indicates north (color online).

935 Figure 3. Source levels estimated from 79 calls using transmission loss derived from (left)
936 the Peregrine model and (right) assuming spherical spreading. Both plots show a fitted linear
937 regression model (black line), with associated 95% confidence intervals shaded in gray.

938 Figure 4. Detector characterization curve (with 95% confidence interval) predicting detection
939 probability as a function of SNR for known fin whale calls ($n = 1484$).

940 Figure 5. Examples of distributions of simulated signals (clockwise from top left: uniform,
941 northeastern and southern distributions). The black dots denote signals within the 1000 km
942 maximum detection radius. Gray dots show signals outside the maximum detection range.

943 Figure 6. Distribution maps of signal density (signals/km²) predicted by a Generalized
944 Estimating Equation. Initial simulated distributions were, clockwise from top left, uniform,
945 northeastern and southern distributions. The depicted maps are the median estimated surface
946 from 500 simulations (color online).

947 Figure 7. Transmission loss of a 20 Hz signal propagating to Wake Island N1 at a depth of 15
948 m, averaged across 360°. The main plot shows mean TL values up to the maximum range
949 without any unmeasurable infinite TL estimates (1231 km). The inset plot shows the same
950 data plotted up to 200 km; this inset shows the decrease in TL at ~ 50 km.

951 Figure 8. Histogram of measured bearings (in degrees) from the three-month pilot study
952 dataset ($n = 3066$). In this plot, 0 degrees indicates north.

953 Figure 9. Distribution maps of signal density (signals/km²) predicted by a Generalized
954 Estimating Equation based on the pilot study data inputs. Fig 9a (left) the median estimated
955 surface from 500 simulations. Fig 9b (right) the map from the analysis of fin whale calls
956 from the three-month pilot study (signals/km²) (color online).
