Abstract

Wavelet families arise by scaling and translations of a prototype function, called the *mother wavelet*. The construction of wavelet bases for cardinal spline spaces is generally carried out within the multi-resolution analysis scheme. Thus, the usual way of increasing the dimension of the multi-resolution subspaces is by augmenting the scaling factor. We show here that, when working on a compact interval, the identical effect can be achieved without changing the wavelet scale but reducing the translation parameter. By such a procedure we generate a redundant frame, called a *dictionary*, spanning the same spaces as a wavelet basis but with wavelets of broader support. We characterise the correlation of the dictionary elements by measuring their 'coherence' and produce examples illustrating the relevance of highly coherent dictionaries to problems of sparse signal representation.

1   Introduction

Canonical Coherent States have played an important role in quantum physics from the early days to the present time [1–9]. Mathematically they have been studied within the structure of frames [6, 10, 11]. Their equivalent in the context of signal processing were first introduced by Gabor and nowadays frequently appear in some contexts under the name of Gabor frames or Weyl-Heisenberg frames [12, 13]. On the other hand, the particular class of coherent states arising from the affine group on the real line, called wavelets [6, 11–15], have also been broadly applied in physics [16–19], as well as in signal processing. The applications of wavelets notably increased when fast techniques, arising from the multi-resolution analysis scheme, became available. Ever since wavelet analysis has been a popular tool among practitioners.

For the most part multi-resolution analysis has been applied for generating orthogonal, semi-orthogonal and biorthogonal wavelet bases. Some redundant frames have been constructed within this framework as well. However, we should recall that countable sets of frame wavelets were first constructed by discretisation of the translation and scaling parameters of affine coherent states. According to the mathematical measure of coherence introduced in [20] an orthogonal basis has coherence zero and a non-orthogonal basis, although not redundant by definition, has coherence greater than zero. It is the purpose of the present effort to show that,

in some finite dimensional spaces, by *properly increasing the coherence one can generate spaces of higher dimension.*

The success in constructing a number of linearly independent wavelets with good mathematical properties, such as regularity or localisation, is very much appreciated by researchers in different fields (including the authors of this contribution) as a major achievement in the design of wavelets. Nevertheless, in this communication we would like to illustrate, by recourse to a very interesting example, a remarkable property of a class of highly coherent redundant wavelet systems. We will construct such systems for finite dimensional *cardinal splines spaces*, which are well characterised from a mathematical viewpoint [21] and will be shown to be useful for the problem of sparse signal representation by non-linear approximation.

The problem of non-linear approximation concerns the representation of a given function (signal) through the selection of waveforms, frequently called *atoms*, which are taken from a redundant set, called a *dictionary* [22]. This problem has been the subject of quite recent theoretical work with regard to quasi incoherent dictionaries [20, 23].

The term *spline wavelets* comprises a number of wavelet systems ranging from Haar piecewise constant wavelets to wavelet functions of much higher regularity. In our framework all such systems admit an equivalent construction and a particular one is obtained by setting the order of the corresponding B-spline scaling function. We will restrict wavelet systems to an interval and construct spline wavelet dictionaries on the basis of the following result: Let us focus on a cardinal spline space on a compact interval with distance 2^{-j}, $j > 0$ between two adjacent knots. We prove that such a space can be spanned by translating a wavelet taken from a multi-resolution subspace corresponding to a fixed scale, say scale 2^i, $0 < i < j$, as long as the distance between two consecutive functions is reduced to be 2^{i-j}. This interesting feature provides the foundations for the construction of a large variety of possible dictionaries for the identical space. In particular, multi-resolution-like dictionaries can be constructed by spline wavelets whose support at the finest scale is larger than that corresponding to the finest scale in a multi-resolution analysis of the identical space. This property provides a clear explanation of the 'power of coherence'. Our results for finite dimensional cardinal spline spaces on a compact interval assert that the benefit of increasing coherence, by decreasing the translation parameter of the functions, is not only a consequence of incorporating redundancy but also of the fact that by such a procedure one may *increase the dimension of the space.* This phenomenon emerges clearly from our construction.

As will be illustrated by numerical simulations, transforming a spline wavelet basis into highly coherent dictionaries has a significant impact on signal representation by non-linear techniques. It will be shown that some of these dictionaries may yield a significant gain in the sparseness of a representation with respect to the results produced by means of the corresponding basis. This is enhanced by the comparison with other techniques such as Best Basis Selection using Wavelet Packets.

The paper is organised as follows: Section 2 introduces some background on spline multi-

resolution analysis on a compact interval relevant for our purpose. Section 3 establishes the fact that, rather than increasing the wavelet scale to provide a representation of a cardinal spline space of higher dimension, the representation can be achieved by appropriate reduction of the distance between two consecutive wavelets. This result is used for constructing a multi-resolution-like redundant dictionary that, through the numerical examples of Section 4, is shown to be useful for sparse signal representation. The conclusions are drawn in Section 5.

2 Cardinal spline multi-resolution analysis on a compact interval

Let us recall that multi-resolution analysis restricted to the interval $[c, d]$, involves a sequence of nested spaces $V_0 \subset V_1 \subset \cdots$ satisfying that $\bigcup_{j \in \mathbb{Z}^+} V_j$ is dense in $L^2[c, d]$. The complementary wavelet subspaces W_j are constructed in order to fulfil

$$V_{j+1} = V_j \oplus W_j, \ j \in \mathbb{Z}^+ \tag{1}$$

so that

$$L^2[c, d] = V_0 \oplus W_0 \oplus W_1 \oplus \cdots = V_0 \oplus \bigoplus_{j \in \mathbb{Z}^+} W_j. \tag{2}$$

Without loss of generality we will assume throughout the paper that $c, d \in \mathbb{Z}$. Let us consider now that $V_j, j \geq 0$ are cardinal spline spaces of order m with simple knots at the equidistant partition of the interval $[c, d]$, having distance 2^{-j} between two adjacent knots. This implies that each V_j consists of piece-wise polynomials of order m having $m - 2$ continuous derivatives [21]. A basis for V_j arises from the restriction of the functions

$$\phi_{j,k}(x) := 2^{j/2} \phi(2^j x - k), \ k \in \mathbb{Z} \tag{3}$$

to the interval $[c, d]$. The corresponding scaling function $\phi(x) \equiv \phi_{0,0}(x)$ is the cardinal B-spline of order m associated with the uniform simple knot sequence $0, 1, \ldots, m$. Such a function is given as

$$\phi(x) = \frac{1}{m!} \sum_{i=0}^{m} (-1)^i \binom{m}{i} (x - i)_+^{m-1}, \tag{4}$$

where $(x - i)_+^{m-1}$ is equal to $(x - i)^{m-1}$ if $x - i > 0$ and 0 otherwise.

It should be stressed that different ways of constructing the boundary functions give rise to different bases for V_j. The restriction of the scaling functions to the interval $[c, d]$ provides one such basis, which is easy to construct. Indeed, considering that the support of $\phi_{j,k}(x)$ is $\operatorname{supp} \phi_{j,k} = \left[\frac{k}{2^j}, \frac{k+m}{2^j}\right]$, one has:

$$V_j = \operatorname{span}\{\phi_{j,k} : k \in (2^j c - m, 2^j d) \cap \mathbb{Z}\}. \tag{5}$$

Without loss of generality, we assume that at least one scaling function from V_0 and one wavelet from W_0 are completely contained in $[c, d]$. This is equivalent to assuming that $d - c \geq$

$\max\{m, w\}$ where w is the length of $\operatorname{supp}\psi$. A basis for W_j can then be constructed by restricting the functions

$$\psi_{j,k}(x) := 2^{j/2}\psi(2^j x - k), \ k \in \mathbb{Z} \tag{6}$$

to the interval $[c, d]$ and eliminating some redundancy introduced by the cutting process. One can start by considering all the functions $\psi_{j,k}(x)$ having non-trivial intersection with the interval (c, d), which restricts the values of the index k to $k \in (2^j c - w, 2^j d) \cap \mathbb{Z}$. Since the cardinality of such a set is $(d - c)2^j - 1 + w$, but $\dim W_j = \dim V_{j+1} - \dim V_j = (d - c)2^j$, in order to have a basis it is necessary to eliminate $w - 1$ boundary functions. A natural choice is to eliminate the first $\lceil z \rceil$ left boundary functions and the last $\lfloor z \rfloor$ right boundary functions where $z = (w - 1)/2$ and $\lceil \cdot \rceil$, $\lfloor \cdot \rfloor$ indicate the upper and lower integer part, respectively. A basis for W_j constructed by the cut-off process is thereby given as:

$$W_j = \operatorname{span}\left\{\psi_{j,k} : k \in \left(2^j c - \lfloor z \rfloor, 2^j d - \lfloor z \rfloor\right) \cap \mathbb{Z}\right\}. \tag{7}$$

3 Spline wavelet dictionaries

In a previous publication we have shown that a cardinal spline space on a compact interval can be spanned by dictionaries consisting of functions of broader support than the corresponding B-spline basis [24]. In the present notation this entails that for an integer $\ell \geq 1$ the set of B-splines of order m

$$\mathcal{V}_{j,\ell} = \{\phi_{j,k_\ell} : k_\ell \in (2^j c - m, 2^j d) \cap \mathbb{Z}/2^\ell\} \tag{8}$$

satisfies

$$\operatorname{span}\{\mathcal{V}_{j,\ell}\} = V_{j+\ell}. \tag{9}$$

Note that the support of a function in (8) completely contained in $[c, d]$ is 2^ℓ-times the support of a corresponding basis function from $V_{j+\ell}$, and we have introduced a new translation parameter k_ℓ which is no longer an integer but $k_\ell \in \mathbb{Z}/2^\ell$.

We call the set $\mathcal{V}_{j,\ell}$ a *B-spline dictionary* and wish to consider now the possibility of creating cardinal spline dictionaries of wavelets. To this end we construct the set $\mathcal{W}_{j,\ell}$, $\ell \geq 1$ as follows: The wavelets are translated using the translation parameter, k_ℓ, defined above. All the functions $\psi_{j,k_\ell}(x), k_\ell \in \mathbb{Z}/2^\ell$ whose supports have non-trivial intersection with the interval (c, d) are considered. Thus

$$\mathcal{W}_{j,\ell} := \{\psi_{j,k_\ell} : k_\ell \in (2^j c - w, 2^j d) \cap \mathbb{Z}/2^\ell\}. \tag{10}$$

Our proposal for constructing cardinal spline wavelet dictionaries stems from the fact that $\operatorname{span}\{\mathcal{W}_{j,\ell}\} = V_{j+\ell}$. This result is established in the next theorem. The proof is achieved by using an equivalent technique to that for the proof of Theorem 1 in [24] and is given in Appendix A.

Theorem 1. *Let* $\mathcal{W}_{j,\ell}$ *be given as in* (10) *for a given integer* $\ell \geq 1$. *Then the following relation holds:*

$$\operatorname{span}\{\mathcal{W}_{j,\ell}\} = V_{j+\ell}. \tag{11}$$

Remark 1. *The above theorem gives us a tool for designing different wavelet dictionaries for cardinal spline spaces. Notice that simply by setting different values of the index ℓ in (10) we obtain dictionaries of wavelets of different support spanning the identical cardinal spline space $V_{j+\ell}$.*

As described below the result of Theorem 1 allows us to create multi-resolution-like dictionaries for the space being considered.

We denote by $\mathcal{V}_{j,0}$ the B-spline basis (5) for V_j and by $\mathcal{W}_{j,0}$ the spline wavelet basis (7) for W_j. The classical wavelet decomposition $V_j = V_0 \oplus W_0 \oplus \cdots \oplus W_{j-1}$ in terms of bases can then be expressed in our "dictionary notation" as $V_j = \mathrm{span}\{\mathcal{D}_{j,0}\}$ where:

$$\mathcal{D}_{j,0} = \mathcal{V}_{0,0} \cup \mathcal{W}_{0,0} \cup \mathcal{W}_{1,0} \cup \cdots \cup \mathcal{W}_{j-1,0}. \tag{12}$$

Considering $\ell \geq 1$ we construct multi-resolution-like dictionaries spanning V_j as

$$\mathcal{D}_{j,\ell} = \mathcal{V}_{0,\ell} \cup \mathcal{W}_{0,\ell} \cup \mathcal{W}_{1,\ell} \cup \cdots \cup \mathcal{W}_{j-\ell,\ell}. \tag{13}$$

Remark 2. *It follows from (12) and (13) that the minimum support of an inner wavelet in $\mathcal{D}_{j,\ell}$ is $2^{\ell-1}$-times the minimum support of an inner wavelet in $\mathcal{D}_{j,0}$.*

The top left graph of Fig. 1 shows two consecutive scaling functions (dark line) and two consecutive wavelets at the coarsest scale (light line) in a linear spline basis (order $m = 2$). The right graph shows the equivalent functions in a dictionary constructed by considering $\ell = 2$. The bottom graphs depict an equivalent example but involving cubic splines, which correspond to order $m = 4$. Let us remark that, since in both examples the dictionaries arise by setting $\ell = 2$, for representing the same space as the corresponding basis we should consider a coarser scale, i.e, if the finest scale in the basis corresponds to a scaling factor 2^j in the dictionary the finest scale corresponds to a scaling factor 2^{j-1}.

Of course, considering the result of Theorem 1 one could construct many different dictionaries for the identical space. Each such dictionary constitutes a frame for a cardinal spline space of order m with distance 2^{-j} between knots. As will be illustrated in the next section, particular dictionaries constructed as in (13) may yield a significant gain, as far as sparseness is concerned, in problems of signal representation.

For the examples given in Section 4 we construct specific dictionaries on the interval $[0, 8]$ as follows: We consider cubic splines and use the semi-orthogonal wavelets (Chui-Wang4 family) introduced in [25] to construct the basis for each $\mathcal{W}_{i,0}$, $i = 1, \ldots, j - 1$ by the simple cut off process described in Section 2. In order to construct the dictionary we take a prototype function from each subspace $\mathcal{W}_{i,0}$, $i = 1, \ldots, j - 2$ (and also from $\mathcal{V}_{0,0}$) and translate such a function to a distance 2^{-2}. Notice that we do not use functions from $\mathcal{W}_{j-1,0}$. This is because by reducing the distance between functions to 2^{-2} we need one less scale than the wavelet basis to represent the same space.
Figure 1: The top left graph shows two consecutive scaling functions (dark line) and two consecutive wavelets at the coarsest scale (light line) in a linear spline wavelet basis (order $m = 2$). The right graph shows the equivalent functions in a dictionary constructed by considering $\ell = 2$. The bottom graphs have the same description as the top ones, but involving cubic spline wavelets (order $m = 4$).

In order to characterise the coherence of the dictionaries at hand we use the *cumulative coherence* function, $\mu(p)$, introduced in [20]. Given a dictionary $\{\alpha_\omega\}_{\omega \in \Omega}$, where Ω is the set of indices labelling the dictionary atoms, $\mu(p)$ measures how much a collection of p atoms resembles a fixed one. It is defined by

$$\mu(p) = \max_{|\Lambda| = p} \max_{\omega \notin \Lambda} \sum_{\lambda \in \Lambda} |\langle \alpha_\omega, \alpha_\lambda \rangle|, \tag{14}$$

where $|\Lambda|$ indicates the cardinality of the set Λ.

The cumulative coherence for the basis $\mathcal{D}_{6,0}$ and the dictionary $\mathcal{D}_{6,2}$, which will be used in the next section, is plotted in Fig. 2. It is clear from this figure that the coherence of the dictionary $\mathcal{D}_{6,2}$ is much more larger than the coherence of the basis $\mathcal{D}_{6,0}$.

Remark 3. *An increment in coherence also implies that the construction of the dual frame for the dictionary may become an ill posed problem. However, when the aim is to use dictionaries*
Figure 2: Cumulative coherence function $\mu(p)$, $p = 1, \ldots, 200$ as defined in (14). The lower line corresponds to the basis $\mathcal{D}_{6,0}$ of cubic spline wavelets for V_6. The other line corresponds to the dictionary $\mathcal{D}_{6,2}$ for the same space.

for sparse signal representation one is not interested in the dual frame for the whole space. On the contrary, in order to produce orthogonal projections onto the approximation subspace, the duals for the particular subspace need to be determined. For the representation to be useful for compression purposes the dimension of the approximation subspace should be considerable smaller that the dimension of the dictionary space. Thus, the construction of the duals in the corresponding subspace is well posed. Recursive techniques for adapting dual functions are discussed in [26–28].

4   Application to sparse signal representation

In this section we use the multi-resolution-like dictionary characterised in the previous section, corresponding to considering $\ell = 2$. The central aim is to compare the sparseness of the signal representation achieved by using the basis $\mathcal{D}_{j,0}$ and the dictionary $\mathcal{D}_{j,2}$. Moreover, the results produced by a number of other techniques will be presented for further comparison. The two signals to be represented are the chirp and the seismic signal of Fig. 3.

The piece of seismic signal was taken from the WaveLab802 Toolbox [29] (it is acknowledged there that such a signal is distributed throughout the seismic industry as a test dataset). Both signals have a good approximation, coinciding with the graphs of Fig. 3, in V_6, the space of cardinal cubic splines with the distance 2^{-6} between two adjacent knots. In order to represent this space we will use: The basis $\mathcal{D}_{6,0}$ and the dictionary $\mathcal{D}_{6,2}$. In both cases we apply the same strategy for selecting the atoms $\{\alpha_{l_n}\}_{n=1}^{N}$ to approximate the given signal by the *atomic decomposition*

$$f^N = \sum_{n=1}^{N} c_n^N \alpha_{l_n}, \tag{15}$$

where the superscript indicates that the coefficients c_n^N yield the orthogonal projection of the
Figure 3: Chirp signal $f = \cos(2\pi x^2)$ (left). Seismic signal (right).

given signal onto the subspace spanned by the selected atoms $\{\alpha_{l_n}\}_{n=1}^{N}$.

Our strategy evolves by stepwise minimum residual error selection and is carried out in three stages:

i) The atoms are selected one by one according to the adaptive pursuit method [30] in order to reach a predetermined precision in the representation of the signal.

ii) The previous approximation is improved by means of a "swapping procedure" which operates as follows: at each step an atom of the atomic decomposition is replaced by a dictionary atom, provided that the operation improves the residual error [31].

iii) A backward pursuit method [32] is applied to disregard some coefficients in order to produce an approximation up to the error of i).

MATLAB codes for constructing the proposed dictionaries and implementing the selection strategy are available at [33].

For further comparison we have represented the signals using Fast Wavelet Transform (FWT) with the biorthogonal (cubic spline) family Bior4.4 and the Daubechies orthogonal family Daub10. With these two families we also considered a number of different criteria for Best Basis Selection (BBS) from the corresponding Wavelet Packets (WP) [34]. These techniques were applied by using the Wavekit tool [35] and iteratively tuning the threshold in order to produce a signal approximation of the same quality (with respect of the L^2 error norm) by all the approaches. The results are presented in Table 1. The first column labels the wavelet families. The second one specifies the approach and the third and fourth column the number of atoms needed by those approaches to represent the corresponding signal up to the same precision.

Table 1: Comparison of the sparseness achieved by selecting atoms from the basis $\mathcal{D}_{6,0}$, the dictionary $\mathcal{D}_{6,2}$, FWT and BBS from WP using different criteria and wavelet families.

Family	Approach	N (chirp)	N (seismic)
Chui-Wang4	Basis $\mathcal{D}_{6,0}$	254	210
	Dictionary $\mathcal{D}_{6,2}$	**166**	**125**
Bior4.4	FWT	423	223
	BBS Shannon entropy	315	217
	BBS L^1 norm	301	206
	BBS $L^{0.5}$ norm	289	206
Daub10	FWT	401	222
	BBS Shannon entropy	279	201
	BBS L^1 norm	271	195
	BBS $L^{0.5}$ norm	271	194

As can be seen in Table 1, to obtain the desired approximation of the chirp of Fig. 3 using the basis $\mathcal{D}_{6,0}$ we need 254 atoms. Sparseness is improved to 166 atoms by using the proposed redundant dictionary $\mathcal{D}_{6,2}$ involving functions of the same nature. On the contrary, the number of atoms that are needed to represent the chirp signal by all the other approaches is larger. The same feature is exhibited in the representation of the seismic signal. However, there is an interesting phenomenon that can be observed: In the previous case the FWT (for both the Bior4.4 and Daub10 families) was shown to produce a much poorer sparseness property than the basis $\mathcal{D}_{6,0}$. In this case the results yielded by the three wavelet bases are comparable. This is due to the fact that the nature of the chirp near the left boundary is very different from that near the right one. Hence, the periodic boundary conditions in the implementation of FWT have a very negative effect in relation to the spareness of the representation. We believe this is the reason why the cut-off approach performs much better in representing the chirp. However, in the case of the seismic signal for which the two ends of the signal are not so different and of small magnitude, the approximations obtained by all the wavelet bases are comparable. The representation of this signal by selecting atoms from the proposed dictionary is again significantly superior to all the other techniques.

5 Conclusions

The construction of wavelet dictionaries for cardinal spline spaces on a compact interval was discussed. It was first proved that if 2^{-j} is the distance between consecutive knots in a cardinal spline space on a compact interval, such a space can be spanned by translating wavelets at scale 2^i a distance 2^{i-j}. This result can be used for building a large variety of wavelet dictionaries for the identical space. In particular, multi-resolution-like highly coherent dictionaries of wavelets of different supports were constructed. An interesting feature of the proposed construction is that it allows us to span a spline space of given dimension by using wider wavelets than

those necessary in multi-resolution analysis. As illustrated by the numerical examples, this feature is relevant to sparse signal representation by non-linear techniques. The simulations presented here clearly show that the proposed multiresolution-like dictionaries, which are easily constructed by simple translations of prototype functions at different scales, may yield a very significant gain in the sparseness of a signal representation by step-wise selection techniques. This outcome could be somewhat 'expected', since by decreasing the translation step one also generates more choice so as to chose the suitable functions for representing a given signal. However, what is definitely a very interesting and somewhat surprising result is that, when working on a compact interval, by decreasing the translation step of a wavelet family one can generate higher dimensional spaces. In our mind this is a mathematical characterisation of the 'power of coherence'.

Acknowledgements

Appendix A: Proof of Theorem 1

Proof. The inclusion span$\{\mathcal{W}_{j,\ell}\} \subset V_{j+\ell}$ is obvious because for $\ell \geq 1$ all the spline wavelets in W_j are, by definition, in $V_{j+\ell}$. Since the distance between two adjacent knots in $V_{j+\ell}$ is $2^{-(j+\ell)}$, by moving the wavelets such a distance it is ensured that they remain in $V_{j+\ell}$. We can then build scaling-like equations for all the functions of the dictionary $\mathcal{W}_{j,\ell}$:

$$\psi_{j,k_\ell}(x) = \sum_{n=2^{j+\ell}c-m+1}^{2^\ell(k_\ell+w)-m} g_{k_\ell,n}\phi_{j+\ell,n}(x), \ k_\ell \in (2^j c - w, 2^j c) \cap \mathbb{Z}/2^\ell, \tag{16a}$$

$$\psi_{j,k_\ell}(x) = \sum_{n=2^\ell k_\ell}^{2^\ell(k_\ell+w)-m} g_{k_\ell,n}\phi_{j+\ell,n}(x), \ k_\ell \in [2^j c, 2^j d - w] \cap \mathbb{Z}/2^\ell, \tag{16b}$$

$$\psi_{j,k_\ell}(x) = \sum_{n=2^\ell k_\ell}^{2^{j+\ell}d-1} g_{k_\ell,n}\phi_{j+\ell,n}(x), \ k_\ell \in (2^j d - w, 2^j d) \cap \mathbb{Z}/2^\ell. \tag{16c}$$

The proof of the inclusion span$\{\mathcal{W}_{j,\ell}\} \supset V_{j+\ell}$ is achieved by showing that every function $\phi_{j+\ell,n}(x) \in V_{j+\ell}$ can be written as a linear combination of functions from $\mathcal{W}_{j,\ell}$. For every $n \in [2^{j+\ell}c, 2^{j+\ell}d) \cap \mathbb{Z}$ (corresponding to an inner or right boundary function $\phi_{j+\ell,n}(x)$) there is a unique index $p(n) = n/2^\ell$ such that $g_{p(n),n} \neq 0$ and $g_{p(n),i} = 0$ for every $i < n$. Hence, in the line of [24], by using (16b) or (16c) the function $\phi_{j+\ell,n}(x)$ is substituted by $\psi_{j,p(n)}(x)/g_{p(n),n}$ plus a linear combination of $\phi_{j+\ell,l}(x)$, $l > n$. This recursive process ends with the substitution $\phi_{j+\ell,n}(x) = \psi_{j,p(n)}(x)/g_{p(n),n}$ where $n = 2^{j+\ell}d - 1$.

As for every $n \in (2^{j+\ell}c - m, 2^{j+\ell}c) \cap \mathbb{Z}$ (corresponding to a left boundary function $\phi_{j+\ell,n}(x)$) there is also a unique index $p(n) = (n + m)/2^\ell - w$ such that $g_{p(n),n} \neq 0$, and $g_{p(n),i} = 0$

for every $i > n$. Thus using (16a) the function $\phi_{j+\ell,n}(x)$ is substituted by $\psi_{j,p(n)}(x)/g_{p(n),n}$ plus a linear combination of $\phi_{j+\ell,l}(x), l < n$. The recursive process ends with the substitution $\phi_{j+\ell,n}(x) = \psi_{j,p(n)}(x)/g_{p(n),n}$ where $n = 2^{j+\ell}c - m + 1$.

Consequently, by back-substitution, we have the decomposition of each function $\phi_{j+\ell,n}(x)$, $n \in (2^{j+\ell}c - m, 2^{j+\ell}d) \cap \mathbb{Z}$ in terms of $\psi_{j,k_\ell}(x)$, $k_\ell \in (2^j c - w, 2^j d) \cap \mathbb{Z}/2^\ell$. $\qquad\square$
