**CONFLICT OF INTERESTS:** All authors declare they have no competing interests

**ROLE OF FUNDING SOURCE:** The present study was funded by CIBERESP as part of the aid for short internships granted to Jorge Arias-de la Torre.

**ACKNOWLEDGEMENTS:** We acknowledge Kayla Smith and Olga Martinez for their support in performing the study, and CIBER Epidemiology and Public Health (CIBERESP) for its funding

**ETHICAL APPROVAL:** The present project was developed in the framework of the Catalan Arthroplasty Register (RACat). Due to the nature of the data used to address the objectives and the belonging of the RACat to the Catalan Health System as a public health registry, it is not necessary an ethical approval. To guaranty the confidentiality of the patients according to the Spanish en European current regulation on data protection, the data are anonymised and continuously supervised by the steering committee of the RACat. This committee is composed by experts both from the orthopaedic surgery services of the different hospitals involved in data collection, as from the Catalan Health Service (CatSalut), the Catalan Society of Orthopaedic Surgery and Traumatology (SCCOT), and the Agency for Health Quality and Assessment of Catalonia (AQuAS).

24 **KEYWORDS:** Total Knee Arthroplasty; Unicompartmental Knee Arthroplasty; Risk of  
25 revision; Mortality; Register studies.

26

## 27 **INTRODUCTION**

28 Decisions on type of implant choice for knee arthroplasty should consider the evidence for  
29 all available implant-specific outcomes. Current literature suggests that Unicompartmental  
30 Knee Arthroplasty (UKA) may be associated with a higher rate of revision than Total Knee  
31 Arthroplasty (TKA), but with similar mortality rates [1–7]. In some studies, these results  
32 have been attributed, among other factors, to an imbalance in the characteristics of the  
33 population operated on, as well as to the hospital where the surgery was performed.

34 It is well-established that the decision regarding type of surgery should depend on an  
35 extensive evaluation of a patient's characteristics, since populations undergoing TKA,  
36 versus those having UKA, are generally not comparable. Patients undergoing UKA usually  
37 have fewer comorbidities and are less demanding, in surgical terms, than those having TKA  
38 [2,8,9]. These differences in patient characteristics make it challenging to compare surgical  
39 outcomes like mortality and the risk of prosthesis revision between TKA and UKA and  
40 could lead to biased results and incorrect conclusions since the baseline characteristics of  
41 patients undergoing these procedures are dissimilar. To solve this problem, propensity-  
42 score matching methods have moved a step forward in comparing populations in  
43 observational studies [10,11], which could lead to obtaining comparable patient populations  
44 of TKA and UKA, at least in terms of their baseline characteristics, thus allowing more  
45 precise comparisons to be made.

46 Another group of variables with a possible relationship to the risk of revision is hospital  
47 characteristics. Taking these characteristics into account, some register-based studies have

48 suggested that the volume of arthroplasties performed in a hospital by year is particularly  
49 relevant due to its influence on surgical outcomes [12–16]. This volume could have an  
50 influence on the outcomes, depending on the type of surgery the study focused on, and  
51 might be especially pertinent in UKA [13,15]. As previously found, hospitals performing a  
52 higher volume of UKA by year might have better results in terms of revision, and similar  
53 results in terms of mortality compared with those shown in lower volume hospitals.  
54 Slightly less of a difference in TKA over UKA has also been shown between higher and  
55 lower volume hospitals in risk of revision, with higher rates of revision among lower  
56 volume hospitals [12,16]. The volume-related differences in mortality in TKA are unclear,  
57 and might be influenced by differences in the populations operated on in lower and higher  
58 volume hospitals.

59 Therefore, in this framework and after obtaining comparable TKA and UKA populations,  
60 the aims of the present study are: 1) to evaluate and compare the risk of revision and  
61 mortality of matched TKA and UKA cohorts; and 2) to assess if the hospital volume is  
62 related to differences in revision and mortality between TKA and UKA.

## 63 **MATERIAL AND METHODS**

### 64 **Data and study population**

65 For the present study, data from the Catalan Arthroplasty Register (RACat) and the  
66 Minimum Basic Dataset at Hospital Discharge (MBDS-HD) were used. The RACat is a  
67 population-based arthroplasty registry that has collected information about hip and knee  
68 arthroplasty procedures performed in the Catalan region since 2005. The registry includes  
69 51 out of 56 public hospitals performing knee arthroplasty surgery in Catalonia, with a  
70 completeness of about 90% for primary arthroplasties and about 70% for revision  
71 procedures. The MBDS-HD is a mandatory population-based registry that compiles

72 information about procedures and morbidities for the entire population attended to in  
73 Catalan Hospitals. Its dataset includes information about different aspects of the  
74 hospitalization process, such as diagnosis and other factors related to patients and surgery  
75 like comorbidity, hospital discharge data and hospital admission data.

76 To develop the proposed objectives, all individuals recorded in the Catalan Arthroplasty  
77 Register (RACat) between 1/1/2005 and 31/12/2016, with a primary diagnosis of  
78 osteoarthritis, undergoing cemented UKA (n=1,210) or cemented TKA (n=38,032  
79 posterior-cruciate retaining, posterior-cruciate sacrificed and posterior stabilised) were  
80 included in the study population. Patients with a diagnosis for the primary procedure other  
81 than Osteoarthritis (OA), those with other types of knee arthroplasty, and those whose  
82 prosthesis had a cementless, hybrid or inverse hybrid fixation were excluded. After  
83 matching, a total of 2,374 patients, 1,187 patients for each type of intervention, remained in  
84 the study to perform the comparative analyses between UKA and TKA outcomes in the  
85 whole population.

#### 86 **Study variables**

87 Two main outcomes were considered: mortality and risk of revision for any reason. A  
88 revision arthroplasty was defined as any procedure involving removal, exchange or addition  
89 of any implant part. Additionally, for competing risks models, the death of the patient was  
90 considered as a competing risk, i.e. an event that changes the likelihood that the main event  
91 occurs.

92 The main exposure variable considered was the type of arthroplasty (TKA and UKA).

93 The volume of procedures, defined as a dichotomous variable (higher and lower), was  
94 considered as the absolute frequency of a specific type of arthroplasty performed in each  
95 hospital for each year of the study period prior to matching. The cut-off point for lower

96 volume was fixed at 10 procedures for UKA and 100 procedures for TKA, based on the  
97 lower volume groups for UKA and TKA observed in previous literature [13,15,16], and the  
98 population distribution within the volume groups. The same hospital could contribute to a  
99 different volume group depending on the year and number of procedures performed.

100 The following confounders were taken into account for propensity score matching: sex  
101 (male and female), age (in years, defined as a continuous variable), number of  
102 comorbidities from the Elixhauser index, year of intervention (categorized: 2005-2006,  
103 2007-2008, 2009-2010, 2011-2012 and 2013-2016), type of hospital (high technology,  
104 reference, regional and other type or not specified), type of admission (Emergency,  
105 scheduled and other types) and healthcare region (Barcelona, Girona, Catalunya Central,  
106 Camp de Tarragona, Lleida, Terres de l'Ebre, Alt Pirineu i Aran and other healthcare  
107 region or not specified).

#### 108 **Data analysis**

109 Descriptive analyses of the population's characteristics were done. A matching method  
110 based on propensity score was used to obtain comparable populations from the main  
111 exposure. The score was calculated considering arthroplasty type (UKA or TKA) as the  
112 exposure variable, and including the following confounders: sex, age, number of  
113 comorbidities (Elixhauser), year of the primary intervention (continuous), type of hospital,  
114 type of admission and healthcare region. Matching between UKA and TKA was 1:1  
115 without replacement, and included 2,374 matched prostheses overall (1,187 of each type).  
116 Differences in UKA and TKA populations at the bivariable level were assessed before and  
117 after matching using Chi-square tests and Mann-Whitney U tests for age, due to its non-  
118 normal distribution. Mortality and risk of revision rates at 30 days, 90 days and 1, 3 and 5  
119 years were obtained using the Kaplan-Meier method, and Cox regression models were

120 fitted to assess differences in mortality between TKA and UKA. Incidence of revision was  
121 calculated taking the competing risk of death into account. The risk of revision was  
122 estimated by summing up to  $t$   $S(t-1) * h'(t)$ , where  $S(t-1)$  is the Kaplan-Meier estimate of  
123 the overall survival function and  $h'(t)$  is the cause-specific hazard at the time  $t$ . In addition,  
124 to evaluate differences in the risk of revision, Competing Risks models considering death as  
125 the competing event were implemented. From these models, hazard ratios (HR) for  
126 mortality, sub-hazard ratios (SHR) for revision and their 95% Confidence Interval (95%CI)  
127 were obtained. To account for the possible effect of infection as the cause of revision, all  
128 competing risks models were adjusted for the cause of revision. Additionally, to assess the  
129 influence of hospital volume on the risk of revision, all analyses were stratified by volume  
130 group. The stratified matched samples included 1,472 patients in the higher volume group  
131 (736 UKA and TKA) and 632 in the lower volume group (316 UKA and TKA). Statistical  
132 significance of the study variables was evaluated using a Likelihood Ratio test for Cox  
133 models and a Wald test for Competing Risks models. The significance level was fixed at  
134  $\alpha=0.05$  and all analyses were carried out using the statistical software Stata v.14 [17].

## 135 RESULTS

### 136 Comparison of patient characteristics

137 Table 1 shows the characteristics of the study population before and after matching.  
138 Statistically significant ( $p<0.001$ ) differences between the UKA and the TKA populations  
139 in all study variables were found, except in circumstances of hospital admission. After  
140 matching, none of these differences remained statistically significant. When taking patient  
141 characteristics into account by volume groups (Table 2), prior to matching, statistically  
142 significant differences in all study variables were found, except in the type of hospital  
143 admission and, in the lower volume group, in the year of the primary intervention and in

144 median follow-up. None of these differences remained significant in any group after  
145 matching. After matching, 18 hospitals' patients contributed to the higher volume group for  
146 TKA and 4 for UKA; and in the lower volume group the contribution was 42 for TKA and  
147 29 for UKA.

#### 148 **Risk of revision, mortality and the influence of hospital volume**

149 Table 3 shows that the risk of revision for TKA was 0.1% at 30 days, 0.3% at 90 days,  
150 0.4% at 1 year, 2.9% at 3 years and 4.2% at 5 years, while for UKA, no revision was  
151 performed at 30 days follow-up, and it was 0.1% at 90 days, 1.3% at 1 year, 5.5% at 3  
152 years, and 6.6% at 5 years. The mortality for TKA was <0.1% at 30 days, 0.1% at 90 days,  
153 0.5% at 1 year, 3.0% at 3 years and 4.1% at 5 years, while for UKA it was <0.1% at 30  
154 days, 0.2% at 90 days, 0.3% at 1 year, 2.3% at 3 years and 3.0% at 5 years, as shown in  
155 Figure 1. Additionally, Table 3 shows a significant adjusted revision risk of SHR of 1.98  
156 (95% CI: 1.25-3.17) for UKA compared to TKA (the reference category) in a Competing  
157 Risks model, and a non-significant adjusted HR of 0.74 (95% CI: 0.46-1.21) for mortality  
158 in a Cox model.

159 Table 4 shows the risk of revision (Figure 2) and mortality rates (Figure 3) for higher  
160 volume and lower volume hospitals. Higher volume hospitals performing TKA had a  
161 higher, but not statistically significant, risk of revision than UKA (SHR: 1.36; 95% CI:  
162 0.57-3.21), while in lower volume hospitals, UKA had a higher, statistically significant,  
163 risk of revision than TKA (SHR: 1.95; 95% CI: 1.11-3.44). Non-statistically significant  
164 differences were found in mortality between UKA and TKA, independent of hospital  
165 volume (HR higher volume: 0.83, 95% CI: 0.43-1.60; HR lower volume: 0.49, 95% CI:  
166 0.21-1.15), with lower rates among UKA than among TKA, particularly in the lower  
167 volume group.

168 **DISCUSSION**

169 Our study shows that UKA has a higher risk of revision when compared to TKA. However,  
170 when the annual volume of UKA and TKA procedures performed in a specific hospital is  
171 taken into account, this difference is not seen. While hospitals conducting a higher volume  
172 of UKA have reduced their revision rate to that commensurate with or even lower than  
173 TKA levels, hospitals conducting a lower volume of UKA have a clearly increased revision  
174 rate over hospitals conducting a low volume of TKA. Additionally, our study shows that  
175 these volume-related differences do not exist in terms of mortality since the rates in UKA  
176 are lower but not significant like in TKA.

177 Regarding the risk of revision, after discarding differences in baseline characteristics of the  
178 UKA and TKA populations and the stratification done, it is reasonable to attribute the  
179 differences found to the volume of the hospital where the arthroplasty was performed. In  
180 this sense, it should be emphasized that, after obtaining comparable populations, a higher  
181 risk of revision was found in UKA over TKA for the entire population and especially in the  
182 lower volume group, since the risk of revision in UKA was more than 2.5 times higher than  
183 in TKA. Moreover, in the higher volume group, a lower but statistically non-significant risk  
184 of revision was found for UKA compared to TKA. These results support, for the entire  
185 population, those obtained from one previous study in which the risk of revision in UKA  
186 was higher than in TKA [7], and are comparable to the evidence obtained by other studies  
187 that focused on UKA only [13,15,18]. These studies show that lower volume hospitals had  
188 worse results when compared to higher volume hospitals. Taking into account the  
189 mortality, no statistically significant differences between TKA and UKA were found in the  
190 population as a whole or when the analyses were stratified by volume group. Nevertheless,  
191 despite that the differences found were non-significant, we should highlight that the

192 mortality rates were lower for UKA than for TKA in all groups studied. These results show  
193 new evidence supporting the hypothesis pointed out by previous research about the  
194 similarity in results in terms of mortality between UKA and TKA [1,8,10]. Thus, to carry  
195 out studies with larger sample sizes, longer follow-up times and taking hospital volume into  
196 account, might be adequate to confirm the abovementioned hypothesis. Finally, though  
197 there are outcomes that were not considered in our research, previous studies have shown  
198 lower rates of complications and readmission and better results in terms of Patient Related  
199 Outcome Measures (PROMs) in UKA than TKA [1,8,9,19]. These studies have also shown  
200 that UKA could be a cost-effective option, additionally suggesting that these outcomes  
201 might be better in higher volume hospitals than in lower volume hospitals. Therefore, all  
202 proposed evidence suggests TKA might be a suitable decision for patients undergoing knee  
203 arthroplasty, both in higher and lower volume hospitals, while UKA is appropriate only in  
204 higher volume hospitals. Furthermore, due to the evidence-based consequences that  
205 implanting UKA in lower volume performing hospitals might have, from the results in our  
206 context, it might be pertinent to limit UKA procedures to hospitals that can guarantee that a  
207 higher volume of this type of procedure is performed.

208 There are some limitations in this study that need to be discussed. First, limitations related  
209 to the number of volume groups and the differences in the number of contributing hospitals.  
210 In our context, only four hospitals were included in the UKA higher volume hospital group  
211 when the cut-off point was fixed at 10 procedures per year. However, despite this  
212 limitation, we can assume that higher volume hospitals performing TKA and UKA are  
213 highly specialized in these types of procedures and therefore can be considered as  
214 suitable candidates for comparison. Besides, crossover between hospital volume groups  
215 was not taken into account. Nevertheless, as observed in hospitals participating in the

216 RACat [5], this change of volume group was, in most cases, an increasing or decreasing  
217 trend of hospital activity. In terms of the limitations related to the study variables, the  
218 indication for surgery was unknown and could be different between TKA and UKA.  
219 Furthermore, surgeon related variables, like differences in surgeons' expertise by volume  
220 group, were not taken into account. Despite this, given that reporting this data to the RACat  
221 has been mandatory since 2017, we expect to be able to take these aspects into account in  
222 the upcoming years. In addition, we should emphasize the limitation related to including all  
223 implant sub-types. Though some registers and studies show differences between sub-types,  
224 these differences are unclear [3–5,20,21]. Besides, including all models together could be  
225 advantageous when establishing conclusions at the population level. Finally, we want to  
226 stress that the completeness of the information, particularly in revision arthroplasties, is not  
227 perfect, but we expect an improvement in these rates in the upcoming years since hospital  
228 participation in the registry is now mandatory. Moreover, it might be advantageous to  
229 explore the influence of the volume of procedures by hospital with longer follow-up times,  
230 as well as with other outcomes like complications, readmissions or PROMs [1,19]. Future  
231 research considering long-term results, other outcomes and volume-dependent  
232 specialization might be useful in reducing the burden of morbidity and revision of knee  
233 arthroplasties and improving patient-specific decision-making.

## 234 **CONCLUSIONS**

235 After overcoming the possible bias related to differences in patients' characteristics, our  
236 results show that in Catalonia there are currently differences in the risk of revision between  
237 UKA and TKA, but not in mortality. The evidence presented in this article shows that the  
238 seemingly poorer results in terms of risk of revision of UKA when compared to TKA, are  
239 closely related to the volume of UKA procedures performed in a specific hospital.

240 Therefore, to improve results in terms of revisions, we suggest performing TKA in both  
241 higher and lower volume hospitals, while UKA should be done only in hospitals  
242 performing a higher annual volume of this type of procedure.
