Microstructure and shear strength evolution of a lime-treated clay for use in road construction

The results of a comprehensive experimental programme are presented with the aim of assessing the long-term microstructural modifications as well as evaluating the effects of microstructural rearrangement on the stress-strain behaviour of a lime-treated high-plasticity clay used for road embankments. The stress-strain behaviour at different lime content and curing time was investigated by means of direct shear tests and, simultaneously, microstructural analyses were carried out combining Scanning Electron Microscope observations and Mercury Intrusion Porosimetry tests. The collected results show that the stress-strain behavior of lime-treated clay is strongly dilatant and characterized by a high peak of strength, which increases with time and lime content. Furthermore, a hyperbolic function may be used with the aim to predict the increase in strength at the end of the stabilization process. Microstructural analysis shows that the treatment induces a redistribution of the porosity between macro- and micropores as well as a significant increase of matric suction, measured by means of the filter paper technique. This is also associated to a low reduction of water content and, in clay treated with 2% of lime, to aggregates shrinkage. This peculiar behaviour is affected by lime content and curing time since it results from the formation of the pozzolanic compounds, which mainly develops on the surface of clay aggregates. So, the formation of pozzolanic compounds induces both a bonding between hardened clay aggregates and an increase of their interlocking degree, which is considered as a further contribution to the increase of the shear strength.

Keywords: lime-treated soils; soil stabilization; clays; microstructural characterization; laboratory tests; shear strength

Introduction

Stabilization is a technique commonly used to improve the mechanical behaviour of soils (Bell, 1996; Boardman et al, 2001) and solid waste materials (e.g. biosolids) (Suthagaran et al., 2009; Disfani et al., 2015), that otherwise would not be suitable for earthworks. Several of stabilizers (geogrid, geofiber, lime, cement and many others) can be used as soil additives to improve its engineering properties. The effects of the chemical stabilizers depend on their chemical reactions with the soil elements in presence of water. In the last years, by-products or waste materials from industrial plants were also considered for stabilization in road subgrades or base application. Fly Ash (FA), cement kiln dust (CKD), lime kiln dust (LKD), blast furnace slag and others additives were successfully studied (Al-Rawas et al., 2002; Kang et al., 2015; Puppala, 2016; Mosa et al., 2017). However, experimental research in geotechnical laboratories and in the field has considerably increased the use of lime-based treatments, due to technical, economic and environmental advantages in road construction (Liu et al., 2012; Jawad et al., 2014; Celauro et al., 2015).

Previous studies have dealt with the time-dependent increasing strength of treated soils and nowadays the physic-chemical processes (cation exchange, pozzolanic reactions, etc.) induced by treatment between chemical stabilizers and soils, clay in particular, are well known (Abdi and Wild, 1993; Locat et al., 1990; Metelková et al., 2012; Pomakhina et al., 2012; Zhao et al., 2016; Ho et al., 2017; Choobbasti and Kutanaei, 2017). Moreover, some other studies have focused on the effect on the microstructure of the lime-treated clays (Cuisinier et al., 2011; Russo et al., 2007; Stoltz et al., 2012), also in the long time period (Choquette et al., 1987; Lemaire et al., 2013), as well as on the correlation between microstructural modifications and the improved geotechnical behaviour, e.g. increase of unconfined compression strength, reduction of compressibility and permeability (Al-Mukhtar

1
2
3 et al., 2012; Consoli et al., 2012; Di Sante et al., 2014; Wang et al., 2015; Vitale et al., 2017).
4
5 Furthermore, in-depth analyses were carried out in order to investigate the durability and the
6
7 microstructural modifications of lime-treated clay when exposed to severe environmental
8
9 conditions, as water infiltration (Chakraborty and Nair, 2018) or repeated wetting and drying
10
11 cycles (Tang et al., 2011; Stoltz et al., 2014; Deneele et al., 2016; Rosone et al., 2016b;
12
13 Rosone et al., 2017).
14

15
16 Very few studies (Mavroulidou et al., 2012; Zhang et al., 2014; Rosone et al., 2018a)
17
18 have focused so far on the effects of lime treatment on the drained shear strength behaviour.
19
20 In this connection, a comprehensive analysis of the mechanical behaviour of a complex
21
22 material, such as a lime-treated clay, should necessarily take into account the dependence on
23
24 both the microstructural features and their evolution during curing time.
25

26
27 In order to investigate the effect of microstructural rearrangement and the cementation
28
29 bonding related on the increase of shear strength induced by lime treatment, this paper
30
31 presents the results of a wide test programme based on an analysis carried out by means of
32
33 different techniques applied on high-plasticity clay samples treated in a laboratory with
34
35 different lime contents. The tested materials come from excavation works of an artificial
36
37 tunnel for a road infrastructure in Sicily (Italy) and have been preliminary tested, according to
38
39 EN 13286-47 (2004) and 14227-11 (2006), to evaluate the lime affinity for stabilization in
40
41 road embankments construction. After this evaluation, the mechanical properties have been
42
43 thoroughly studied by means of direct shear tests carried out on samples saturated by water
44
45 submersion during the consolidation stage. Simultaneously, a microstructural analysis was
46
47 performed in order to assess the physico-chemical modifications and the cementitious
48
49 reactions with time; for this latter purpose the curing period was extended to one year from
50
51 treatment. Matric suction measurements were also carried out via filter paper method, in order
52
53
54
55
56
57
58
59
60

1
2
3 to clarify some macroscopic experimental evidences of the microstructural modifications
4
5 induced by the lime treatment during the curing time.

6
7 Thus, in this paper, the main aim was to combine the test results at different scales in
8
9 order to relate the comprehensive assessment of both micro- and macro- modifications with
10
11 the stress-strain behaviour of a lime-treated high-plasticity clay. This approach may provide a
12
13 significant microstructural perspective of the features induced by lime treatment and how
14
15 these peculiarities influence the macroscopic behaviour.
16
17

18 19 20 21 **Materials and experimental methods**

22
23 The tested materials come from excavation works of an artificial tunnel for a road
24
25 infrastructure in Sicily (Airò Farulla et al., 2014). The main geotechnical characteristics and
26
27 chemical properties of representative samples of the excavation sites are summarized in Table
28
29 1.

30
31
32 [Table 1 near here]

33
34 An *XRD* diffractometric analysis carried out on the raw material showed the presence
35
36 of smectite, illite and kaolin and non-clay minerals such as quartz, calcite, feldspar and
37
38 dolomite. The main characteristics of the quicklime used for the treatment are reported in
39
40 Table 2.

41
42 [Table 2 near here]

43
44 The initial consumption of lime (*ICL*), as obtained from laboratory tests (Hilt and
45
46 Davidson, 1960; Eades and Grim, 1966), was fixed at 1.5%. Preliminary studies were carried
47
48 out with the aim to define the mix design of the lime-clay mixtures, by means of the
49
50 evaluation of compaction properties and mechanical performances, in relation to the use for
51
52 road embankments (Celauro et al., 2012; EN 13286-47, 2004; 14227-11, 2006). Three lime
53
54 contents were selected (2%, 3% and 4%) in order to be representative of those typically
55
56
57

1
2
3 adopted for subgrade and layers of the upper and lower parts of embankments. The results of
4
5 the mix design tests for the different considered lime contents are summarized in Table 3, in
6
7 terms of optimum water content, w_{opt} , and maximum dry unit weight, $\gamma_{d,opt}$, for Standard
8
9 Proctor compaction effort, Immediate Bearing Index, *IBI*, California Bearing Ratio after 4
10
11 days of soaking, *CBR(4i)* Index, linear - $\Delta H/H_0$ (ΔH is the variation in height and H_0 is the
12
13 initial height of sample) - and accelerated volumetric swelling, G_v .

14
15
16 [Table 3 near here]

17
18 As reported in Table 3, the designed mixtures may be used for the different parts of
19
20 the embankment since the mechanical performances are higher than the minimum
21
22 requirements ($CBR(4i) > IBI$; $IBI > 10.5$ for the upper part and $IBI > 8.0$ for the lower part of
23
24 embankment) but they should not be used in layers immediately below the pavement due to
25
26 their result in terms of volumetric swelling, G_v , higher than 5%.

27
28 After this preliminary mechanical characterization, in-depth mechanical and
29
30 microstructural analysis were carried out investigating a wider range of lime content with the
31
32 aim to better understand the peculiar modifications induced by the treatment, as well as to
33
34 widen its range of application, independently from a technical evaluation. However, lime
35
36 contents higher than 6% were not considered due to economic sustainability criteria. So, as-
37
38 compacted specimens were prepared in laboratory by moistening the selected air-dried
39
40 material passing through a no. 4 ASTM sieve (mesh opening 4.76 mm), by treating with lime
41
42 at different lime contents (0, 2, 4 and 6% by dry weight of soil) and statically compacting at
43
44 the target water content, set equal to the optimum condition under Proctor Standard
45
46 compaction effort (Table 3). The mixtures were left for 1 hour in an airtight container before
47
48 compaction for allowing the development of immediate reactions between the quicklime and
49
50 the soil particles. After compaction, the samples were coated with a transparent plastic film
51
52 and cured in a climatic chamber with temperature and relative humidity control ($T = 20^\circ\text{C}$,
53
54
55
56
57
58
59
60

1
2
3 $RH \geq 90\%$). For the purpose of microstructural analysis, the grain-size distribution curve had
4 to be reduced (maximum apparent particle size equal to 2 mm) (Rosone et al., 2016a) and a
5 small cylindrical mould with a diameter of about 9 mm and a height of 9.3 mm was used.
6
7

8
9 Suction measurements were carried out by means of Whatman n. 42 filter papers
10 placed in contact with the base of the specimens, in accordance with ASTM D5298 (ASTM,
11 2016). The soil samples were wrapped in multiple layers of a transparent plastic film and
12 stored in an insulated box for the whole curing period. Matric suction was estimated by means
13 of the water content of the filter papers, according to the calibration formula by Chandler and
14 Gutierrez (1986).
15
16
17
18
19
20
21

22 Direct shear tests were carried out on specimens saturated in the shear box at vertical
23 effective stress $\sigma_v' = 100$ kPa and sheared with a horizontal displacement rate equal to 0.002
24 mm/min. For the samples used in the direct shear tests, the curing time did not include the
25 duration of consolidation (24 h) as well as the duration of the shearing stage (48-60 hours).
26
27
28
29
30

31 Curing times, t , were chosen in accordance with previous experimental evidence
32 (Croft, 1968; Estéoule and Perret, 1979; Boardman et al., 2001) indicating that the
33 stabilization process evolves with time quite quickly at the initial stage and then at a reduced
34 velocity with increasing curing time. Thus, at the beginning, the testing time was set equal to
35 0, 7, and 14 days and progressively increased to 1, 2, and 6 months. The curing time was later
36 extended up to one year in order to assess the microstructural variation at the end of the
37 cementitious reaction process.
38
39
40
41
42
43
44
45

46 Microstructural analyses were carried out combining Mercury Intrusion Porosimetry
47 (MIP) tests and Scanning Electronic Microscope (SEM) observations. MIP tests were
48 performed using a porosimeter with a maximum intrusion pressure of 200 MPa
49 (corresponding entrance pore diameter of approximately 0.007 μm). The advancing non-
50 wetting contact angle between mercury and the clay minerals was assumed to be 140°
51
52
53
54
55
56
57
58
59
60

(Romero and Simms, 2008). *SEM* and *MIP* analyses were performed on freeze-dried samples (Delage and Pellerin, 1984). *SEM* observations were performed on gold-palladium coated samples for improving conductivity. This essential treatment represents a limit for adopted experimental technique because every analysis must be carried out on different samples. Anyway, very important morphological information and microstructural changes in the soils can be deduced from comparison of microphotograph (Mandaglio et al., 2016; Rosone et al., 2018c). Analyses were conducted on untreated samples as well as on samples treated with 2, 4 and 6% of lime immediately after treatment (curing time $t = 0$), after 1 month and after 1 year.

Results analysis

Shear strength behaviour

Fig.1 depicts the shear stress-horizontal displacement (τ - δ_h) curves of the direct shear tests carried out at vertical effective stress $\sigma_v' = 100$ kPa. The figure shows that as an effect of short-term reactions in the treated clay, irrespective of the lime content, the peak shear strength τ_p instantaneously increases to a value ($\tau_p = 139\div 151$ kPa) equal to about twice the shear strength of the untreated material ($\tau_p = 73$ kPa). The curves for the vertical displacement, δ_v , versus the horizontal displacement, δ_h , are also shown in Fig. 1; positive values of vertical displacement represent dilation of the specimen. As seen in the figures, the behaviour, after treatment, becomes strongly dilatant and characterized by high peaks of strength, which increase in intensity with the curing time and the lime content. However, the horizontal displacement at failure always increases during the overall curing time within the range $\delta_h = 0.3\div 1.5$ mm. As expected, the maximum rate of dilation corresponded to the peak

1
2
3 strength. Furthermore, the ultimate strength was not fully reached since in some tests the
4
5 dilation was still ongoing even at a horizontal displacement as large as 6 mm.
6

7 Fig. 2a shows the evolution with the curing time of the peak shear strength of clay
8
9 treated with different lime contents. The material treated with 2% of lime after 14÷28 days
10
11 reached an almost steady resistance ($\tau_p = 199$ kPa), probably because all the available lime
12
13 was already consumed and pozzolanic reactions stopped; for lime content equal to 4%, the
14
15 time required to complete the stabilization process increased to at least 60 days. Conversely,
16
17 when the clay is treated with 6% of lime, an increase in strength, significantly more evident in
18
19 the first 60 days, is observed for the whole curing time (180 days). Then the maximum
20
21 drained shear strength ($\tau_p = 253$ kPa) was measured on the clay treated with 6% of lime after
22
23 180 curing days.
24
25

26
27 The experimental data were interpolated with very good accuracy by means of a
28
29 hyperbolic function (Gens, 1993; Airò Farulla & Rosone, 2014) modified for predicting the
30
31 increase in strength with time, as follows:
32
33

$$\tau_p = \tau_{p,0} + \frac{t}{\frac{1}{r} + \frac{t}{\Delta\tau_{p,lt}}} \quad (1)$$

34
35
36
37
38
39
40 where t is the curing time in days, while $\tau_{p,0}$, r and $\Delta\tau_{p,lt}$ are material parameters. In particular,
41
42 $\tau_{p,0}$ is the peak shear strength at $t = 0$, r represents the initial tangent at $t = 0$ (the initial time
43
44 evolution of strength) and $\Delta\tau_{p,lt}$ is the long-term increase in strength. The coefficient of
45
46 determination, R^2 , for the different lime contents, varied in the range between 0.928 and
47
48 0.994. In Fig. 3 the parameters of the increasing strength equation are reported as a function
49
50 of the lime content. It is quite evident that, in the range considered, the immediate and long-
51
52 term increase in strength, ($\tau_{p,0}$ and $\Delta\tau_{p,lt}$) directly depends on the lime content while the time
53
54 evolution (r), i.e. the rate of strength increase, is essentially independent of lime content.
55
56
57

1
2
3 In Fig. 2b shows that the dilatancy angle at failure ($v'_f = \Delta\delta_v / \Delta\delta_h$) of the clay treated
4 with 4% and 6% of lime, also increases as a hyperbolic function of time. The maximum value
5 of the dilatancy angle was approximately 30° , similar to very dense silica sands (Valore et al.,
6 2017; Ziccarelli et al.; 2017) or quartz locked sands (Celauro et al., 2014). The clay treated
7 with 2% of lime initially shows similar behaviour to the one of the samples treated with
8 greater amounts of lime; after 14 days, the dilatancy angle, from a maximum of about 16° ,
9 decreases and, for curing times higher than 60 days, reaches a steady value equal to 12° .
10 Therefore, the experimental results show that dilatancy provides a strong component of shear
11 strength in lime-treated soils.

17
18
19
20
21

22 With the aim of depicting failure envelopes of drained strength, experimental data of
23 direct shear tests carried out at vertical effective stress $\sigma'_v = 100 \div 300$ kPa on treated samples
24 after 28 day of curing and untreated clay are reported in Fig. 4. Comparison between the
25 envelopes highlights the effectiveness of lime treatment in a wider range of effective stress,
26 since the envelope of untreated clay is characterized by $c' = 38$ kPa and $\phi' = 20^\circ$. The
27 obtained peak shear strength parameters are similar to those of other natural high plasticity
28 clays (Cotecchia et al., 2007; Airò Farulla et al., 2015; Rosone et al., 2018b)
29
30
31
32
33
34
35
36
37

38 The shear strength envelopes of treated clay lie in a tight range far from untreated
39 clay, considering that the peak shear strength angle is quite constant ($\phi' = 38 \div 40^\circ$) and the
40 intercept cohesion varies with the lime content ($c' = 75 \div 132$ kPa). However, very low
41 increase of strength is obtained after 28 days passing from 4% ($c' = 121$ kPa) to 6% of lime
42 even if, especially for the higher lime content, the long-term shear strength will further
43 increase up to 6 months of curing time (Fig. 2a).

Microstructural modifications

The *SEM* micrograph of the as-compacted untreated clay (Fig. 5) shows an evident massive close packing structure; aggregates of clay plates are assembled in a dispersed arrangement and are largely in mutual contact. Boundary aggregations often cannot be distinguished and only a few μm -sized voids are visible.

The *SEM* microphotograph shown in Fig. 6a highlights the fact that immediately after treatment the microstructure of clay with 2% of lime is characterized by aggregates smaller than those of the untreated clay. Furthermore, aggregates are characterized by edge-to-face and edge-to-edge flocculated texture. Macropores in the order of 30-50 μm are clearly visible although the aggregates are rather compact considering that micropores are indistinguishable inside them. The effect of treatment is more evident at higher lime content, i.e. for samples treated with 4% (Fig. 6b) and 6% (Fig. 6c). In both cases, a more open structure is clearly visible and several nodules of hydrated lime which have not reacted yet are discernible. In particular, the image of the as-compacted samples of clay treated with 6% of lime content brings out a structure completely obliterated by the lime, which has segmented the aggregates and flocculated smaller single particles (Fig. 6c). The flocculated nature of the structure is more evident with treated clay particle clusters interspersed by large openings. Due to the short-term processes (exothermic hydration process, cation exchange), the aggregated structure is transformed into small lump arrangements. Moreover, the more fragmented structure undoubtedly will facilitate the attack gel cementing on the aggregate edges.

After 1 month of curing (Figs. 6d, e and f), it is clearly evident that the flocculation process has progressed further. At the same time, some pozzolanic compounds are already visible. The microstructure of the clay treated with 2% of lime (Fig. 6d) is characterized by some pozzolanic compounds which develop, together with flocculated smaller single particles, several bridges between clay aggregates of higher dimensions. *SEM* microphotographs of clay treated with 4% (Fig. 6e) and 6% (Fig. 6f) show that clay

1
2
3 aggregates, still visible in the images taken immediately after the treatment (Figs. 6b and c),
4
5 have been divided into much more segmented elements while lime particles which have not
6
7 reacted are still recognizable due to their negligible self-cementing properties (Solanki and
8
9 Zaman, 2012). However, after 1 month, in the clay treated with 6% of lime (Fig. 6f),
10
11 pozzolanic compounds formation is already quite visible and persistent.

12
13 A *SEM* microphotograph of the sample treated with 2% and cured for 1 year (Fig. 6g)
14
15 shows a compact structure characterized by very dense aggregates due to the closing of
16
17 smaller pores on their surface. This process could be related to the cementing of the
18
19 pozzolanic reaction products, which evidently appears to be limited to the surface of some
20
21 aggregates. Conversely, the samples with 4% and 6% of lime after 1 year (Figs. 6h and 6i)
22
23 show similar rather stable structures from both the chemical and morphological points of
24
25 view, very differently from the original one (i.e. $t = 0$, Fig. 2b and 2c). In addition, they are
26
27 almost entirely covered by white cementation compounds due to the completion of the
28
29 pozzolanic reactions.
30
31

32
33 *SEM* microphotographs at low magnification (100x) of samples treated with 2% and
34
35 6% of lime 1 year after treatment (Figs. 7a and b) highlight some peculiar characteristics of
36
37 enhanced microstructures. Macropores in the order of 15-20 μm and long fissure-like pores
38
39 having width of 3-10 μm between aggregate contacts are clearly visible in the clay treated
40
41 with 2% of lime. On the other hand, the microstructure of clay treated with 6% of lime is
42
43 characterized by aggregates with well-defined physical boundaries and intensely interlocked
44
45 with one another similarly to what happens in calcareous, quartz and pumice sands subjected
46
47 to very high stresses (e.g. Valore and Ziccarelli, 2009; Ziccarelli, 2016). This microstructural
48
49 configuration can contribute to increasing the shear strength.
50
51

52
53 The results of MIP tests are shown in Figs. 8, 9 and 10 in terms of intruded void ratio
54
55 $e_i = V_{int} / V_s$ (where V_{int} is the cumulative volume intruded by mercury and V_s is the volume of
56
57

1
2
3 solid), and of Pore Size Density, ($PSD = \delta e_i / \delta(\log d)$), as a function of the intruded equivalent
4 diameter, d (Washburn, 1921; Romero and Simms, 2008). The evolution of the characteristics
5 of the samples in terms of initial void ratio, e_0 , intruded void ratio, e_i , and non-intruded void
6 ratio, $e_0 - e_i$, are plotted in Fig 11. In this regard, the volume of pores with dimension smaller
7 than the resolution of the *MIP* apparatus (i.e. the inter-layer porosity and the smallest
8 micropores) was considered as negligible since this porosity is significant mainly for high
9 activity clays (Delage et al., 2006; Seiphoori et al., 2014). This hypothesis seems to be
10 confirmed by the evidence that the ending tangent of the intrusion curves is substantially
11 horizontal. Hence the difference ($e_0 - e_i$) between the measured and overall intruded void ratio
12 is primarily the consequence of the non-detected largest pores filled by mercury before the
13 start of the test (Koliji et al., 2010).

23
24
25

26 Fig. 8 shows the results of tests carried out on an air-dried intact clay fragment ($w =$
27 4.5%) as well as on an untreated clay sample statically compacted at optimum conditions
28 (w_{opt} , $\gamma_{d,opt}$) (see Table 3). The intact clay is characterized by a single-mode pore size
29 distribution (Fig. 8b) with a micropore range having a modal value equal to 0.26 μm . The
30 untreated compacted clay presents a double porosity distribution. The smallest pores are those
31 inside the aggregates, while the macropores are those between the aggregates. Excluding pore
32 diameters smaller than 0.07 μm , (very likely still to be filled with water for the sample air-
33 dried at its hygroscopic water content, $w_h \approx 4\%$), the microporosity is strongly influenced by
34 the increase in water content and it is characterized by a very marked peak corresponding to d
35 = 0.5 μm . Assuming the diameter $D_{m-M} = 2.5 \mu\text{m}$ as a limit between the micropores and
36 macropores, the intruded void ratio in the field of macropores, defined as macroporosity void
37 ratio, e_M , is less than 12 % of the total intruded void ratio and shows a uniform size
38 distribution between 3 and 100 μm .

Effect of the lime content

The effects of the lime content (2 and 6%) is evident in Fig. 8. Tests on clay treated with 4% of lime are not reported in the paper due the similarity of their microstructure to that of the samples treated with 6% lime. The treated clays always keep the typical double porosity distribution. The macropore modal value is substantially coincident, equal to about 30 μm , while the macroporosity intruded void ratio e_M increases with the lime content (Fig. 11). Conversely, both the micropore modal value and the micropores intruded void ratio, e_m , decrease with increasing lime content (Fig. 8). The intruded void ratio of the treated specimens increases with the lime content due to the increase macropores intruded void ratio while, as shown, the intruded volume in the micropore field decreases. This result is consistent with the gradual reduction in the dry unit weight due to the increase in the lime content (see Table 3). It was convenient to differentiate the value of the diameter D_{m-M} .

Indeed, *SEM* microscopy observations at $t = 0$ highlighted fragmentation of clay aggregates and consequent dissolution induced by Ca^{2+} cation exchange. This process produces a reduction of the diffuse double layer and flocculation of clay particles due to the reduction in the repelling force (Bhattacharja et al., 2003). Then, the D_{m-M} value was set equal to 1.5 μm for samples treated with 2% of lime and equal to 0.5 μm for samples treated with 6%.

Effect of the curing time

In order to highlight the effect of the curing time, Figs. 9 and 10 present the results of the *MIP* tests carried out on clay treated with 2% and 6% of lime, for curing times of 0 days, 7 days, one month and one year. So far, the *PSD*, irrespective of lime content and curing time, maintains a markedly bimodal arrangement. Moreover, at a constant curing time, the intruded void ratio increases with the lime content. This result, as seen in Fig. 8, is due to ion exchange and flocculation, which lead to an increased inter-aggregate pore volume (macropores).

1
2
3 Conversely, both the volume and the diameters of the micropores decrease, due to the
4 presence of lime compounds on the surface of the aggregates. Nevertheless, the intruded void
5 ratio of micropores is always higher than that of macropores (Fig. 11). The gradual reduction
6 with time of the intruded volume is associated with formation of stable bonding compounds at
7 the particle contact edges due to the long-term effects induced by lime (Russo and Modoni,
8 2013). Hence, mercury penetration in the micropores is further reduced by tightening of
9 contacts between aggregates. This process, indeed, is significant when clay is treated at a lime
10 content higher than the amount of lime consumed by short-term reactions (Eades and Grim,
11 1966; Hilt and Davidson, 1960). At the same time, the clay aggregates shrink, probably due to
12 pore water consumption as a consequence of pozzolanic reactions in the inter-aggregate
13 micropores. This contraction ends up in a reduction of the micropore intruded void ratio and,
14 consequently, in a slight increase in the macropores intruded void ratio, due to the increase in
15 the frequency of pores having equivalent diameters between 3 and 15 μm . Overall, the
16 microstructure becomes denser and more stable. The process is strongly marked in clay
17 treated with 2% of lime because aggregates still retain a clayey nature and, therefore they are
18 more subject to volumetric contraction upon drying. Large expanded macropores at the
19 contact between aggregates, as shown in Fig. 7a, 1 year after treatment, may be the
20 consequence of such volumetric shrinkage. At the same time, the reduction in the macropore
21 modal value is caused by partial pore occlusion through the cementing effect of the
22 compounds. A measure of the constricted porosity, defined as the porosity referring to pores
23 that are only accessible through smaller ones (Delage and Pellerin, 1984), is provided by the
24 value of the intruded void ratio at the end of the mercury pressure reduction phase. The
25 difference between the intruded void ratio at the end of the pressure increase and at the end of
26 the pressure decrease, $e_{int}-e_{dec}$, gives the interconnected void ratio. As reported in Figure 11,
27 the interconnected void ratio decreases with the curing time. The intruded void ratio curves of

1
2
3 the clay treated with 6% of lime (Figs. 10) show that the reduction of porosity is evident in
4
5 the field of pores with a diameter between 0.04 to 0.4 μm while a slight pore volume increase
6
7 is observed in the range of diameter between 0.4 and 20 μm only. Hence the inter-aggregate
8
9 porosity (macropores) becomes partially occluded, and partially interconnected too, due to the
10
11 ink-bottle effect (Russo and Modoni, 2013).
12

13 14 15 16 17 *Effect of the pozzolanic reactions*

18
19 Indeed, the distribution and frequency of the micropores is also affected by the progress of
20
21 pozzolanic reactions. The diameter corresponding to the peak of micropores is strongly
22
23 dependent on both the lime content and the curing time. At constant curing time, it decreases
24
25 with an increase in lime content and, at constant lime content, it decreases with an increase in
26
27 the curing time. Figure 10 shows that the micropores intruded void ratio of the clay treated
28
29 with 6% decreases with time since the larger diameters of the intra-aggregate pores, higher
30
31 than the modal value, decrease in frequency. Thus, the modal value decreases and the
32
33 micropore distribution slightly shifts to the left side of the diagram (Fig. 10b). In clay treated
34
35 with 2% of lime content, this phenomenon is substantially limited to the first month of curing
36
37 since the micropore distribution after 1 year is considerably shifted towards smaller
38
39 diameters, as discussed before, due to the effect of volumetric shrinkage on clay aggregates.
40
41 In this regard, matric suction, s , and water content measurements, w , carried out for curing
42
43 times equal to 7 and 14 days, and 1, 2, 3 and 6 months, reported in Fig. 12, prove that the
44
45 treated samples were subjected to processes that significantly increased the matric suction and
46
47 slightly reduced the water content with time. The consumption of water is more evident in the
48
49 first part of the curing period, due to development of pozzolanic reactions, while a higher
50
51 increase in matric suction, at almost constant water content, is observed later. However, the
52
53 lime treatment-induced drying process is deeply affected by the different lime contents, as
54
55
56
57
58
59
60

1
2
3 well as the curing time. The higher suction variations during the overall curing period
4
5 considered were observed in clay treated with 2% of lime. Under the assumption that soil
6
7 pores can be considered as a bundle of cylindrical tubes of various diameter subjected to
8
9 capillarity mechanism, it is possible to link the matric suction to the equivalent pore diameter,
10
11 d , by means of Laplace's equation ($s = 4 T_s \cos \theta / d$). Considering the initial measured
12
13 suction (at $t = 7$ days) and the final measured suction (at $t = 6$ months) in Laplace's equation
14
15 and assuming a surface tension of water T_s of 0.074 N/m (at 20°C) and a zero contact angle θ ,
16
17 it can be considered that pores having diameters in the range of about 0.7 μm and 0.1 μm ,
18
19 which were initially subjected to capillary forces, dried during the whole curing time. Fig. 9b
20
21 shows that in the curing time between 1 month and 1 year, the microstructure of 2% lime
22
23 treated clay is markedly affected in the above range of diameters. Considering that the water
24
25 is a fundamental element for the formation of cementing pozzolanic products, this process
26
27 should be taken into account when long-term microstructure variations are analysed.

32
33

34 Discussion

35
36 The high increasing shear resistance can undoubtedly be related to the formation of the
37
38 pozzolanic reaction products, which act as bonding and also increase the interlocking degree
39
40 between aggregates. In fact, primarily, the higher persistent areas with developed pozzolanic
41
42 products, shown in Fig. 3b, are responsible for the highest peak of strength. The development
43
44 of chemical reactions is progressive in time and shows, as discussed before, intensive
45
46 microstructural variation during the curing time. The rate of the chemical reaction, correlated
47
48 to the r parameter of equation (1), seems to be independent of the amount of lime. In fact, in
49
50 deep analysis of direct shear tests shows that in the first 14 days the increase of strength
51
52 proceeds with the same rate for different lime contents. Most of the increasing resistance is
53
54 obtained with the addition of 2% of lime, but if this limit is exceeded, the long-term
55
56
57
58
59
60

1
2
3 performance of the treated clay, identified after 180 days, is directly proportional to the
4 amount of lime, at least for the range explored. In fact, the time required to complete the
5 pozzolanic reaction for clay treated with 4 and 6% (60-180 days) is much higher than that for
6 lime treated with 2% (14-28 days). Hence, the time required to complete the process is a
7 direct function of the lime available in the mixture.
8
9
10
11
12

13 In addition to the failure of the cementing bonds, proportional in strength to the
14 amount of lime added, there is a further high contribution to the peak shear strength increase
15 due to the strong interlocking created between the aggregates. The high dilatant contribution,
16 linked to existing interlocking between aggregates, is time-dependent but it is also deeply
17 affected by the amount of added lime (Fig. 2b). The higher dilatant behaviour develops after 1
18 year, for lime content equal to 6%, when the physical boundaries of aggregates are quite
19 recognizable although widespread products of pozzolanic reactions have linked them (Figs 6i
20 and 7b). Conversely, the expansion of macropores, after 28-60 days, due to aggregate
21 shrinkage in clay treated with 2% of lime, may be responsible for the reduction of the dilatant
22 behaviour in the long-term performance. However, lime treatment can be considered as
23 effective in the behaviour after the peak (Fig. 1) since bonding effects disappear after failure
24 but the results of physical-chemical modifications persist despite the accumulation of shear
25 deformations (Rosone et al., 2018a).

45 **Conclusions**

46 In line with the main aim of this research, the experimental program carried out in this study
47 provided a significant insight on the microstructural features and on their link with the
48 macroscopic behavior of the lime treated clay. In fact, few studies so far have focused on the
49 coupling between micro and macro effects on both the structure and on the drained shear
50 strength of lime treated clay, which is deeply investigated in the present paper. The results
51
52

1
2
3 confirm that the shear strength of lime-treated clay is a function of lime content, since it
4 affects the extent of cementing bonds as well as the intensity of the dilatant behaviour. It is
5 possible to conclude that the lime treatment is a markedly time-dependent process that
6 induces not only macroscopic improvements in the mechanical response of the treated soil,
7 but also fundamental microstructural modifications. In particular, the microstructural analysis
8 shows that the treated clay keeps a typical double porosity distribution irrespective of the
9 microstructural variations, which are strongly dependent on the amount of lime and the curing
10 time.

11
12 Lime content higher than the quantity of lime consumed by the short-term reactions (ICL)
13 induces a redistribution of the porosity, with a reduction of the micropore volume and an
14 increase in the volume of macropores. In this connection, pozzolanic products are able to
15 partially fill the pores and reduce the microporosity. This process, linked to development of
16 pozzolanic reactions, is time-dependent and is already significant for curing times lower than
17 1-2 months.

18
19 As proved by MIP analysis, long-time pore size distribution, at least for low lime content
20 values, is also affected by volumetric shrinkage of aggregates, due to matric suction and water
21 content variations, and consequently induced variation in macropores. Thus, the development
22 of the improved mechanical behaviour due to lime addition is proved to be closely linked to
23 microstructural features such as the formation of pozzolanic reaction products (bonding) as
24 well as to the increase in the interlocking degree between aggregates. This evidence may be of
25 particular interest when predicting the long-term behaviour as well as the long term resistance
26 of the stabilized soils for design purposes in road construction.
