**Abstract**

Human proteins are vulnerable towards disease-associated single amino acid replacements affecting protein stability and function. Interestingly, a few studies have shown that consensus amino acids from mammals or vertebrates can enhance protein stability when incorporated into human proteins. Here, we investigate yet unexplored relationships between the high vulnerability of human proteins towards disease-associated inactivation and recent evolutionary site-specific divergence of stabilizing amino acids. Using phylogenetic, structural and experimental analyses, we show that divergence from the consensus amino acids at several sites during mammalian evolution has caused local protein destabilization in two human proteins linked to disease: cancer-associated NQO1 and alanine:glyoxylate aminotransferase, mutated in primary hyperoxaluria type I. We demonstrate that a single consensus mutation (H80R) acts as a disease suppressor on the most common cancer-associated polymorphism in NQO1 (P187S). The H80R mutation reactivates P187S by enhancing FAD binding affinity through local and dynamic stabilization of its binding site. Furthermore, we show how a second suppressor mutation (E247Q) cooperates with H80R in protecting the P187S polymorphism towards inactivation through long-range allosteric communication within the structural ensemble of the protein. Our results support that recent divergence of consensus amino acids may have occurred with neutral effects on many functional and regulatory traits of wild-type human proteins. However, divergence at certain sites may have increased the propensity of some human proteins towards inactivation due to disease-associated mutations and polymorphisms. Consensus mutations also emerge as a potential strategy to identify structural hot-spots in proteins as targets for pharmacological rescue in loss-of-function genetic diseases.

## Introduction

Through evolution, mutations causing single amino acid replacements may occur and fixate causing beneficial functional and stability changes (adaptive mutations), while others may not show any apparent change on protein functionality (neutral mutations) or affect secondary (promiscuous) functions, while largely deleterious mutations are more rarely fixed (1, 2). Random mutations are often destabilizing, particularly when they affect the protein core (3), and may reduce protein stability below a certain threshold impairing functionality and organism fitness, which in principle often prevents their fixation (2). Fixation of destabilizing mutations can be tolerated if other stabilizing mutations occur before or afterwards (2, 4). In this context, stability-activity trade-offs can be biologically buffered by different mechanisms, such as control of protein expression and modulation of protein misfolding by molecular chaperones (2, 5). Importantly, mutations often show pleiotropic effects, manifesting different effects on primary and secondary functions as well as on protein stability (2, 4). Mutations can also contribute to the evolution of protein function and the acquisition of regulatory mechanisms involving protein allostery through modulation of the dynamics of protein conformational ensembles (1, 6-9).

The ability of proteins to fold into a native and stable structure intracellularly is often challenged by mutations, thus leading to disease (10, 11). During evolution, mammals have gathered a vast network of ~1300 different proteins involved in protein biogenesis, folding, trafficking, degradation and maintenance of the proteome named the *protein homeostasis network* (10, 11). Mutations may critically affect the ability of proteins to fold and remain stable, causing loss of enzyme function and metabolic defects commonly due to accelerated proteasomal degradation (12). Global

1  
2  
3 destabilization of the protein structure due to single amino acid replacements may play  
4  
5 an important role in this loss-of-function mechanism (13-15), although recent studies  
6  
7 support the idea that local stability and dynamics of protein structures may drive their  
8  
9 directional degradation via the proteasome (15-19). Accordingly, small molecules  
10  
11 aimed at locally or globally stabilizing protein structure constitute a promising new  
12  
13 battery of pharmacological tools to treat these diseases (12, 20-22). Mistargeting is  
14  
15 another consequence of some mutations (23, 24), and the compartmentalization of  
16  
17 metabolic pathways along evolution (25, 26) seems directly related to such mutations.  
18  
19

20  
21 Proteins are often stabilized upon replacement of a rare amino acid at a given  
22  
23 position by the most common one (i.e. the *consensus amino acid*) found in an alignment  
24  
25 of homologous sequences (27-32). These *back-to-consensus* or *consensus mutations*  
26  
27 increase protein stability primarily by local optimization of the interactions in the  
28  
29 environment of the mutated site, and in some cases, by decreasing local flexibility (28,  
30  
31 33, 34). It has been argued that consensus mutations are reversions to the ancestral  
32  
33 amino acid, and thus, their stabilizing effect reflects to some extent the thermophilic  
34  
35 nature of ancestral proteins (35-37), although the universality of this relationship is  
36  
37 unclear (38). Consensus mutations can act as global intragenic suppressors by providing  
38  
39 a stability boost towards destabilizing mutations (39). Since mammalian and vertebrate  
40  
41 consensus amino acids can be strongly stabilizing when incorporated to human proteins  
42  
43 (28, 32), it is intriguing that during the evolutionary history of mammals divergence  
44  
45 from consensus amino acids may have yielded some human proteins more prone to  
46  
47 loss-of-function and disease-causing mutations.  
48  
49  
50  
51

52  
53 To investigate the evolutionary divergence of consensus amino acids as potential  
54  
55 intragenic suppressors of human disease, we have chosen to study the most common  
56  
57 cancer-associated polymorphism (rs1800566/c.C609T/p.P187S) in NAD(P)H:quinone  
58  
59  
60

1  
2  
3 oxidoreductase 1 (NQO1) that causes a Pro187 to Ser187 amino acid replacement (40).  
4  
5 This system is particularly suitable due to the multifunctional nature of this enzyme  
6  
7 (allowing us to investigate specific effects on different individual functions) as well as  
8  
9 the well-characterized mechanisms by which the polymorphism affects protein function  
10  
11 and stability *in vivo* (18, 41-45). NQO1 is a homodimeric FAD-dependent enzyme  
12  
13 involved in the activation of some anti-cancer pro-drugs (41, 46), which also interacts  
14  
15 with and stabilizes transcription factors associated with cancer and cell-cycle regulation,  
16  
17 such as p53, p73 $\alpha$  and HIF-1 $\alpha$  (47, 48). While wild-type (WT) NQO1 is kinetically  
18  
19 stable at physiological temperature *in vitro* (with a denaturation half-life of 9 h), the  
20  
21 P187S polymorphism accelerates denaturation by a factor of 60 (43). More importantly,  
22  
23 the P187S polymorphism largely abolishes NQO1 activity *in vivo* by affecting FAD  
24  
25 binding and promotes its proteasomal degradation, through dynamic destabilization of  
26  
27 two distant sites: the FAD binding site in the N-terminal domain (NTD, residues 1-224)  
28  
29 and the small C-terminal domain (CTD, residues 225-274), respectively (18, 42, 44,  
30  
31 49). As a consequence, binding of FAD to WT NQO1 protects it towards degradation *in*  
32  
33 *vivo* while binding of the inhibitor dicoumarol is required to stabilize P187S, supporting  
34  
35 a different directionality in their proteasomal degradation (i.e. initiated at the NTD vs.  
36  
37 the CTD, respectively) and their specific blockage by ligands affecting protein local  
38  
39 dynamics upon binding (18, 44, 45, 49).

## 46 **Results**

### 47 48 49 **Stabilizing consensus amino acids have been replaced during recent divergent** 50 **evolution of two disease-associated human proteins** 51 52

53  
54  
55 To identify consensus mutations for NQO1, we have used an alignment of  
56  
57 mammalian sequences, including those with high (over 80%) identity to that of human  
58  
59  
60

1  
2  
3 NQO1 from eighteen different orders overall (SI text) and a large representation of  
4 those from primates (15.3%), rodents (19.2%), artiodactyla (15.3%), carnivora (11.5%)  
5 and chiroptera (9.6%). Among these consensus mutations, H80R causes the most  
6 remarkable stabilizing effect either in WT or P187S NQO1 (Figure 1A,B and Table S1),  
7 consequently increasing their kinetic stability (i.e. slowing down irreversible  
8 inactivation, Table S2). Importantly, H80R causes a local dynamic stabilization of the  
9 N-terminal domain (NTD) of WT NQO1, increasing by 2-fold its resistance towards  
10 partial proteolysis by thermolysin (Figure 1C and D), which occurs between Ser72 and  
11 Val73 (18). The H80R mutation has no effect on the sensitivity of P187S towards  
12 proteolysis (Figure 1C and D), showing that the local stabilization of H80R on the NTD  
13 does not propagate to the cleavage site of P187S found at its CTD (18). To provide  
14 structural insight for the stabilizing effect of H80R, we have solved the structure of  
15 H80R in the presence of FAD and dicoumarol (a competitive inhibitor of NADH; (41))  
16 (Figure 1E, F and Table S3). The presence of the H80R mutation does not affect the  
17 overall fold of NQO1, with a RMSD of 0.42 Å (H80R, vs. WT, PDB ID: 2F1O, using  
18 PDBeFold (50)), showing two molecules of FAD and dicoumarol per dimer, and a third  
19 molecule of the inhibitor is found at the dimer interface (Figure 1E). Interestingly,  
20 Arg80 undergoes a transition to a less solvent exposed environment than that of His80  
21 (14 % vs. 30 %), and establishes a salt bridge with Glu78 (at 2.85 Å) and other  
22 electrostatic interactions mainly involving Lys59, and a water molecule (W88)  
23 hydrogen-bonded to Glu71 (not present in the WT enzyme; Figure 1F). Therefore, this  
24 cluster of electrostatic interactions mostly involving Glu71, Glu78 and Arg80 (hereafter  
25 named the “EER” cluster) appears to be critical for the local stabilization exerted by  
26 H80R. Importantly, the EER cluster seems to stabilize the adjacent loop 57-66, which is

6

7 Arg80 is found in most of the closely related mammalian sequences, suggesting  
8 that its stabilizing effect has disappeared recently in an evolutionary time scale.  
9 Specifically, this implies that the stabilizing effect of the consensus state at this position  
10 (i.e. Arg80) was present in mammalian ancestors of NQO1 and recently diverged to the  
11 non-consensus state found in the human enzyme (Figure 2). Consequently, Arg80 is  
12 present in rat NQO1, and its available X-ray crystal structure allows direct comparison  
13 of the structural consequences of the His-to-Arg transition in these orthologues with  
14 high (85%) sequence identity. Structural superposition of human WT and H80R  
15 enzymes with rat NQO1 show that the local structural switch triggered by Arg80 in the  
16 human enzyme is found in the murine enzyme (Figure 2A-B). In addition, the EER  
17 cluster is also structurally conserved in the murine protein, and Arg80 causes a similar  
18 local stabilization of the structure to that found in human H80R. The electrostatic local  
19 stabilization due to the EER cluster amounts to  $-1.8$  and  $-2.3$  kcal·mol<sup>-1</sup> for human  
20 H80R and rat NQO1 compared to the human WT enzyme (Figure 2C). Overall, Arg80  
21 develops more stabilizing electrostatic interactions with its environment in rat than in  
22 human NQO1 (Figure 2C-D), mostly due to the presence of a non-conserved Glu59 in  
23 the rat enzyme which is a Lys in human NQO1 and most of the mammalian sequences.  
24 Nevertheless, a comparison of pairwise electrostatic interactions within the EER cluster  
25 (including Lys/Glu59), clearly shows that the local stabilizing role of the EER cluster  
26 found in human NQO1-H80R is present in the rat enzyme (Figure 2D). This EER  
27 cluster contains the largely stabilizing Arg80 in most of mammalian sequences of  
28 different orders, including different primate families, but sharply shifts to His80 in the  
29 hominidae family (Figure 2E-F), indicating that the Arg-to-His mutation has been

3 recently fixed along primate evolution. Ancestral sequence reconstruction indicates that  
4 the Arg-to-His transition likely occurred after divergence of Cercopithecoidea and  
5 Hominoidea superfamilies from a common ancestor about 30 Myr ago (Figure 2G).  
6  
7  
8

9  
10 To test whether similar events to the recent Arg-to-His transition at position 80  
11 in mammalian NQO1 may have occurred in other consensus amino acids as well as for  
12 other proteins, we have performed consensus analyses using essentially the same set of  
13 mammalian species for NQO1 with human alanine:glyoxylate aminotransferase 1  
14 (hAGT). hAGT is associated, due to inherited mutations and the polymorphism P11L,  
15 with the life-threatening disease *primary hyperoxaluria type I* (OMIM #259900), in which  
16 genetic variations cause loss-of-function of hAGT activity notably due to protein  
17 mitochondrial mistargeting and peroxisomal aggregation (23, 24). We have recently  
18 performed a detailed characterization of the effect of consensus mutations in hAGT,  
19 including quantitative stability and structural analyses for single- and multiple-  
20 consensus mutants (28). As shown in Figure 3A, consensus analyses reveal a similar set  
21 of stabilizing mutations to that previously found using somewhat different groups of  
22 mammalian and eukaryotic sequences and experimentally validated for hAGT (28).  
23 Interestingly, murine orthologues of human NQO1 and hAGT (for which there are X-  
24 ray structures) display a large fraction of these consensus amino acids (Figure 3B).

43 Detailed sequence, phylogenetic and structural analyses support the proposal  
44 that the fixation of a non-consensus (potentially disease-predisposing) amino acid in  
45 human NQO1 (i.e. His80) is not an unusual or isolated event (Figure 3, S1 and S2).  
46 Consensus amino acids are found in mammalian sequences with very high identity to  
47 the human orthologue, and divergence at these sites and consequent loss of stability  
48 seem to have occurred particularly along primate evolution (Figure 3B and C). Indeed,  
49 ancestral sequence reconstruction analyses support that about 70-80% of the  
50

2  
3 mammalian consensus amino acids analysed in NQO1 and AGT have been  
4 progressively replaced through the last 40 Myr (Figure 3D).  
5  
6

7 Our interpretation on the loss of stability due to divergence from consensus  
8 amino acids implies that their stabilizing effects on human NQO1 (this work) and  
9 hAGT (28) are conserved between highly similar orthologue proteins, a plausible  
10 assumption considering that site specific amino acid preferences are often highly  
11 conserved along evolution (39, 51). The available crystal structures for human and  
12 murine enzymes containing consensus amino acids at these sites provide further  
13 structural and energetic support for the interspecies conservation of the local  
14 stabilization exerted by consensus amino acids. Human and murine WT proteins, as  
15 well as human enzymes containing a single (NQO1-H80R) or multiple (hAGT-  
16 RHEAM) consensus mutations share the overall fold (Figure S1A and S2A). In human  
17 NQO1, all six consensus mutations are individually stabilizing (Figure 1A), and only  
18 the adjacent A27V and A28E mutations are spatially close (Figure S1B), while the five  
19 consensus mutations on human AGT are individually stabilizing and their effects are  
20 additive (28), with four of them forming a intersubunit cluster of stabilizing interactions  
21 (Figure S2B). With a few exceptions, the consensus mutations do not cause large  
22 changes in the solvent accessibility (Figure S1C and S2C), and a significant fraction of  
23 them show an electrostatic origin for their stabilizing effects (Figure S1D and S2D). In  
24 rat NQO1, the consensus amino acids Arg80 and Glu28 combined cause a  $\approx 3$  kcal·mol<sup>-1</sup>  
25 stabilization compared to His80 and Ala28 in the human enzyme, due to local  
26 optimization of electrostatic interactions (Figure S1D,E and Figure 2). In mouse AGT,  
27 the consensus amino acids Arg23 and Glu52 create an electrostatic cluster of favourable  
28 interactions similar to that found in hAGT-RHEAM and including Arg175 and Arg333.  
29 This cluster amounts to 3-4 kcal·mol<sup>-1</sup> of electrostatic stabilization, besides some small

10 **The consensus mutation H80R rescues P187S NQO1 activity intracellularly**  
11 **through local stabilization of the FAD binding site without affecting the interaction**  
12 **with p73 $\alpha$ .**  
13  
14

15  
16 To test whether mammalian consensus amino acids can act as suppressors of  
17 disease phenotype, we have further investigated the mutation H80R in the presence of  
18 the cancer-associated P187S NQO1 polymorphism. Notably, the local stabilization  
19 exerted by H80R at the NTD affects the environment of the FAD binding site (Figure  
20 4A), whose destabilization by P187S in the apo-state (particularly at the loop 57-66)  
21 causes enzyme inactivation by reducing the affinity for FAD (18). Accordingly, H80R  
22 increases the content in FAD of P187S as purified (Figure 4B), causing a concomitant  
23 large increase in specific activity (Figure 4C) without perturbing other kinetic properties  
24 (e.g. the apparent affinities for NADH and DCPIP as substrate; Table S4 and Figure  
25 S3). Results from thermal denaturation experiments with an excess of FAD ruled out  
26 that the stabilizing effect of H80R on P187S is due to the presence of higher FAD levels  
27 in the proteins as purified (Figure S4). Local stabilization of the FAD binding site of  
28 P187S by H80R also translates into a 10-fold higher binding affinity for FAD, with  
29 little consequence on the WT enzyme, as shown by fluorescence titrations (Figure 4D  
30 and S5). Molecular dynamics (MD) simulations recapitulate the structural switch caused  
31 by H80R (Figure S6) further showing that this switch dynamically stabilizes the loop  
32 57-66, particularly in the apo-state of P187S (Figure 4E,F).

54 The local stabilization exerted by H80R on the NTD should increase the FAD  
55 binding affinity of P187S, and consequently its activity inside cells, without affecting  
56  
57  
58  
59  
60

1  
2  
3 degradation rates or protein levels (which are largely influenced by the dynamic CTD;  
4  
5 (18)). We have thus investigated the effects of H80R on the intracellular activity,  
6  
7 protein levels and degradation rates of WT and P187S by combining experiments in  
8  
9 stably transfected Caco-2 cells (showing low endogenous levels of NQO1 protein due to  
10  
11 being homozygous for P187S; (18)) with pulse-chase experiments in a rabbit  
12  
13 reticulocyte cell-free system (Figure 4G-K). Western-blot analysis of transfected Caco-  
14  
15 2 cells reveal a 3-fold increase in protein levels of P187S in the presence of the  
16  
17 suppressor H80R mutation, while this effect is weak in WT NQO1 (1.4-fold increase;  
18  
19 Figure 4G and H). The levels of endogenous NQO1 P187S in Caco-2 cells (lower  
20  
21 immunodetected bands in Figure 4G) are somewhat higher when cells are transfected  
22  
23 with NQO1 variants containing the H80R mutation, suggesting that the presence of this  
24  
25 mutation favors hetero-oligomerization between exogenous (i.e. transfected) and  
26  
27 endogenous P187S NQO1. Since degradation of NQO1 proteins upon expression in  
28  
29 rabbit reticulocyte extracts is mediated by the proteasome (52), we have used this  
30  
31 system to determine whether H80R affects proteasomal degradation rates. The obtained  
32  
33 results show that H80R has little effect on the degradation rates of WT and P187S  
34  
35 (Figure 4I), suggesting that the effect of H80R on intracellular protein levels of P187S  
36  
37 reflects an improved intracellular folding efficiency. Functional rescue of P187S by  
38  
39 H80R is further supported by measurements of NQO1 activity in transfected cell  
40  
41 extracts using DCPIP as substrate (Figure 4J) and corroborated by the increased  
42  
43 capacity of intact transfected cells to activate the drug 17-AAG (17-*N*-allylamino-17-  
44  
45 demethoxygeldanamycin) into its cytotoxic form (53) (Figure 4K and S7). Importantly,  
46  
47 NQO1 activity measurements (Figures 4J and K) correlate well with the levels of  
48  
49 transfected NQO1 proteins (Figure 4G and I), supporting that hetero-oligomerization of  
50

1  
2  
3 transfected proteins with endogenous P187S plays a minor role in the functional rescue  
4  
5 exerted by H80R on P187S.  
6

7         So far, we have shown that the consensus H80R mutation is capable of  
8  
9 reactivating P187S NQO1 to a significant extent *in vitro* and in cells likely due to  
10  
11 enhanced FAD binding affinity and folding efficiency. To determine whether this  
12  
13 consensus mutation might affect further functions, such as their ability to interact with  
14  
15 transcription factors (e.g. p73 $\alpha$ □□□we have used□NMR spectroscopy to investigate  
16  
17 binding of NQO1 variants with the C-terminal domain of p73 $\alpha$ □(SAMP73 $\alpha$ □□(49).  
18  
19 Even though small quantitative differences are observed between NQO1 variants, these  
20  
21 analyses support that the core of the residues involved in NQO1:SAMP73 $\alpha$  interaction  
22  
23 is not greatly affected by the H80R mutation (Figure S8 and Table S5).  
24  
25  
26  
27  
28  
29

### 30 **E247Q cooperates with H80R to rescue NQO1 P187S through long-range epistatic** 31 **interactions** 32 33

34         During the evolution of proteins, the effects of a single mutation often depend on  
35  
36 the presence of additional mutations (a type of *epistatic interactions*; (2, 4)). In the  
37  
38 context of this work, divergence from consensus amino acids at different sites in a short  
39  
40 evolutionary time period (see Figure 3), may have cooperated to enhance the sensitivity  
41  
42 of human NQO1 and AGT towards disease-associated inactivation through this type of  
43  
44 interactions. This cooperation is further expected from the additive effects of consensus  
45  
46 mutations on protein stability (28, 30, 54). To test this hypothesis, we have  
47  
48 characterized the effects of the consensus NQO1 mutation E247Q, in the absence or  
49  
50 presence of H80R (Figure 5). These two sites are not spatially close (at ~40 Å) and the  
51  
52 Glu247 is also far from the FAD binding site (at ~25 Å; Figure 5A). We found that  
53  
54 E247Q locally stabilizes the CTD of P187S, decreasing by 2-fold the sensitivity to  
55  
56  
57  
58  
59  
60

1  
2  
3 partial proteolysis, and its effects propagate to the distal NTD enhancing the local  
4 stabilization exerted by H80R in the WT enzyme (Figure 5B). This long-range  
5 communication of the stabilizing effect of E247Q concomitantly increases the FAD  
6 content and specific activity of P187S, boosting the effects of H80R (Figure 5C-D).  
7 FAD titrations confirmed stronger binding of FAD to P187S in the presence of E247Q,  
8 particularly in combination with H80R (Figure 5E and S5), while very tight FAD  
9 binding was found for all variants of WT NQO1 (Figure 5F and S5). As described  
10 earlier in this work for H80R, the presence of E247Q did not largely affect the core of  
11 residues in SAMp73 $\alpha$  involved in the formation of its complex with NQO1 (Figure S8  
12 and Table S5).  
13  
14  
15  
16  
17  
18  
19  
20  
21  
22  
23  
24

25 These results demonstrate that the additive stabilizing effects of consensus  
26 mutations can propagate to distal functional sites, in line with our recent findings on the  
27 long-range communication existing between the Pro187 site, the FAD binding site and  
28 the CTD, in particular when the CTD is withdrawn (49). Surprisingly, the epistatic  
29 effects described here for H80R and E247Q mutations support directionality in their  
30 propagation (in agreement with some ensemble descriptions of allosteric mutational  
31 effects; see (55)): the H80R mutation locally stabilizes the NTD, with no apparent  
32 effects on the stability or dynamics of the CTD (Figure 1C-D), while the E247Q  
33 mutation stabilizes the CTD and the distal NTD, and importantly, enhances the local  
34 stabilization exerted by H80R on the NTD (Figure 5B).

## 49 Discussion

50 We have provided evidence supporting that consensus amino acids among  
51 mammalian sequences have diverged over the last 50 Myr, decreasing the local stability  
52 of some human proteins and potentially predisposing them towards disease-associated,  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 destabilizing and inactivating single amino acid changes. Due to the conservation of the  
4  
5 stabilizing effect of consensus amino acids, at least in protein orthologues with highly  
6  
7 similar sequences, their additive effects on stability, and the existence of long-range  
8  
9 epistatic interactions between some consensus amino acids, it is intriguing to propose  
10  
11 that some extant mammalian proteins (such as those from rodents) might be more  
12  
13 robust towards disease-associated and destabilizing single amino acid replacements.  
14  
15 Importantly, we demonstrate the potential of consensus amino acids to protect towards  
16  
17 disease-associated single amino acid changes. This case also exemplifies well how  
18  
19 deeply evolution can affect the protein conformational landscape through single  
20  
21 mutations altering protein functionality *in vivo*, and particularly, the key role of long-  
22  
23 range propagation of structural and dynamic effects to different functional sites. An  
24  
25 interesting application of consensus mutations as disease suppressors could be the  
26  
27 identification of druggable spots in proteins, i.e. to mimic the suppressor effect of the  
28  
29 mutation using small pharmacological ligands.  
30  
31  
32  
33

34 From the perspective of natural selection, it is difficult to conceive how  
35  
36 destabilizing mutations diverging from consensus amino acids are fixed along  
37  
38 evolution, unless the mutated sites are under low selective pressure. In this case,  
39  
40 mutations diverging from the consensus amino acid would be eventually fixed if they  
41  
42 have little or no effect on protein function *in vivo* (or ultimately, in the reproductive  
43  
44 capacity of the species), therefore constituting networks of neutral mutations (or *neutral*  
45  
46 *networks*; (2)). Indeed, this *neutral network* scenario explains well the experimentally  
47  
48 observed effects on human NQO1 and AGT proteins (this work and (28)). In the case of  
49  
50 NQO1, a paradigm of multi-functional stress protein, mutation of the consensus Arg80  
51  
52 (to His) and Gln247 (to Glu) have little or no effect in many different molecular traits,  
53  
54 such as its specific activity, FAD content, intracellular stability and folding efficiency,  
55  
56  
57  
58  
59  
60

1  
2  
3 or interaction with p73 $\alpha$ . For human AGT, the simultaneous absence of up to five  
4  
5 consensus amino acids only slightly affects its specific activity and has no impact on the  
6  
7 intracellular folding, stability and peroxisomal import upon interaction with the  
8  
9 peroxisomal receptor Pex5p (28). It can also be argued that the divergence of some  
10  
11 consensus amino acids in these human proteins has been driven by natural selection, for  
12  
13 instance by fine-tuning of some intracellular functions, unfortunately not yet identified  
14  
15 by the functional analyses performed so far.  
16  
17

18  
19 Our results with NQO1 have also important implications for understanding the  
20  
21 stability and dynamics of the human flavo-proteome. A recent comprehensive  
22  
23 proteomic analysis has shown that the stability of human flavo-proteins is strongly  
24  
25 dependent on the bioavailability of the flavin cofactor, and NQO1 has emerged as a  
26  
27 particularly sensitive case (45). Our results further highlight the importance of the apo-  
28  
29 state ensemble, in particular its structure, stability and dynamics (18, 42-45, 49, 56), in  
30  
31 determining the cofactor binding affinity of human flavo-proteins, and consequently,  
32  
33 their function and stability *in vivo*. This can be of particular relevance to understand the  
34  
35 large number of metabolic diseases associated with flavo-proteins (linked to about 60%  
36  
37 of all human flavo-proteins, based on a recent and exhaustive analysis (57)), and the  
38  
39 significant fraction of them associated with riboflavin supplementation (57, 58).  
40

42  
43  
44

## 45 **Materials and methods**

46  
47 **Consensus and phylogenetic analyses.** The sequences of mammalian NQO1 and AGT  
48  
49 enzymes were retrieved using BlastP and the human sequences as queries. This set of  
50  
51 sequences (see SI) was used to identify consensus amino acids as those displaying the  
52  
53 highest frequencies in the alignment. Therefore, the consensus ratio was defined as the  
54  
55 number of sequences containing the most common amino acid in the alignment divided  
56  
57  
58  
59  
60

1  
2  
3 by the number of sequences containing the amino acid found in the human protein at the  
4  
5 same site. In NQO1, the six consensus mutations displaying consensus ratios higher or  
6  
7 equal to 5 were selected for further characterization.  
8

9  
10 Phylogenetic trees based on the sequences of the NQO1 and AGT proteins were  
11  
12 made according to the UPGMA method with the phangorn package (59) from the gnu-R  
13  
14 statistical software. Analysis of time divergence was performed according to (60, 61).  
15

16 **Materials.** Antibiotics, HEPES, cacodylate, KOH, DCPIP, FAD, NADH and  
17  
18 thermolysin from *Bacillus thermoproteolyticus rokko* were purchased from Sigma  
19  
20 Aldrich (Madrid, Spain). Chromatographic columns for protein purification were from  
21  
22 GE Healthcare (Barcelona, Spain). Concentration devices (cut offs of 3-30 kDa) were  
23  
24 from Millipore (Madrid, Spain) or Sartorius (Madrid, Spain). Other chemicals were  
25  
26 purchased from standard suppliers.  
27  
28

29 **Mutagenesis, expression and purification of NQO1 variants in *E. coli*.** Site-directed  
30  
31 mutagenesis was performed using the QuickChange lightening kit (Agilent  
32  
33 Technologies, Madrid, Spain) by standard protocols and confirmed by sequencing.  
34  
35 Expression in and purification from *E. coli* BL21 (DE3) was performed as described  
36  
37 (43).  
38  
39

40 ***In vitro* characterization of NQO1 proteins.** NQO1 activity was measured by  
41  
42 following the reduction of DCPIP as described (49). FAD content in purified NQO1  
43  
44 samples was estimated from UV-visible absorption spectra. Briefly, NQO1 proteins in  
45  
46 K-HEPES 50 mM pH 7.4 were prepared  $\sim 0.6 \text{ mg}\cdot\text{mL}^{-1}$  and the absorption spectra  
47  
48 registered in a HP 8453 spectrophotometer (Agilent) at 25°C. The corresponding  
49  
50 spectra were converted into molar extinction units using a corrected extinction  
51  
52 coefficient at 280 nm for each purified NQO1:  $\epsilon_{280} = 47900 \cdot (1 + \frac{22000}{11300} \cdot A_{450})$ , that  
53  
54 considers the contribution from apo-NQO1 ( $\epsilon_{280} = 47900 \text{ M}^{-1}\cdot\text{cm}^{-1}$ , derived from the  
55  
56  
57  
58  
59  
60

1  
2  
3 primary sequence; (43)) and the FAD bound assuming that spectroscopic features of the  
4  
5 cofactor do not largely depart from those in the free form ( $\epsilon_{280}= 22000$  and  $\epsilon_{450}= 11300$   
6  
7  $M^{-1}\cdot cm^{-1}$ ; (43)). This procedure yields estimates for the FAD content in purified  
8  
9 samples by using a reference value of  $\epsilon_{450}= 11300 M^{-1}\cdot cm^{-1}$  for 100% saturation.

11 Thermal denaturation of NQO1 proteins was determined in K-HEPES 50 mM  
12  
13 pH 7.4 at a protein concentration of 2  $\mu M$  in the presence of the fluorescent probe  
14  
15 SYPRO Orange (Life Technologies, Madrid, Spain). Thermal scans were registered in a  
16  
17 IQ5 Real-time PCR detection system (Biorad, Madrid, Spain) by monitoring  
18  
19 fluorescence upon excitation at 460 nm and emission at 510 nm at a scan rate of  
20  
21  $0.5^{\circ}C\cdot min^{-1}$ . The melting temperature was determined from the maximum of the first  
22  
23 derivative ( $T_{der}$ ) or as the half-denaturation temperature upon normalization of the  
24  
25 unfolding curves ( $T_{0.5}$ ) as described (21). Additionally, thermal stability of NQO1  
26  
27 proteins in the absence or presence of FAD (2  $\mu M$  NQO1 monomer and 10  $\mu M$  FAD)  
28  
29 was determined by following intrinsic fluorescence (exc. 280 nm, em. 340 nm; slits 5  
30  
31 nm) in K-HEPES 50 mM pH 7.4. Thermal scans were registered using 0.3 cm path-  
32  
33 length quartz cuvettes in a Cary-Eclipse spectrofluorimeter (Agilent Technologies),  
34  
35 using  $2^{\circ}C\cdot min^{-1}$  scan rate and  $T_m$  values determined as described above ( $T_{0.5}$  procedure).  
36  
37 Data are reported as mean $\pm$ s.d. from three independent scans. Inactivation kinetics was  
38  
39 determined by incubation of protein samples (40  $\mu M$ ) for different times at  $42^{\circ}C$ ,  
40  
41 chilling on ice and measurement of residual activity as described (49).  
42  
43  
44  
45  
46

47  
48 Proteolysis kinetics by thermolysin were performed as recently described (18).  
49  
50 Protease concentration was 100-200 nM (WT variants) or 0.5-1 nM (P187S variants).  
51  
52 For each variant, two independent experiments were performed and data of intact  
53  
54 NQO1 protein vs. time decays were used to determine first-order rate constants from  
55  
56 exponential fits. These constants were divided by the thermolysin concentration used to  
57  
58  
59  
60

yield second-order proteolysis rate constants ( $k_{\text{prot}}$ ). For sake of comparison, ratios of  $k_{\text{prot}}$  value for WT and the corresponding variant are provided, which indicate a stabilizing effect when these are larger than one and a destabilizing effect when lower than one.

Fluorescence titrations were performed at 25°C using 1 cm path-length cuvettes in a Cary Eclipse spectrofluorimeter (Agilent Technologies) and a final volume of 2 mL. FAD was prepared in K-HEPES 50 mM pH 7.4 (at a final concentration 0-5  $\mu\text{M}$ ) in 1.9 mL and incubated for 5 min in the cuvette while the fluorescence of these blanks (exc. 295 nm; em.: 340 nm; slits 5 nm) was registered. Then, 100  $\mu\text{L}$  of apo-NQO1 (4  $\mu\text{M}$  in monomer) was added, manually mixed, and fluorescence was measured for 10 min to ensure proper equilibration. The fluorescence intensity of the last 60 s was averaged and the signal of the blank without protein was subtracted. Control experiments in the absence of FAD showed that apo-NQO1 did not significantly denature under these experimental conditions. For each protein variant, at least two different protein preparations and FAD stock solutions were used.  $K_d$  values were determined from fittings to 1:1 binding model using the following expression:

$$F = F_{\text{apo}} + (F_{\text{holo}} - F_{\text{apo}}) \cdot \left( \frac{[E] + [FAD] + K_d - \sqrt{([E] + [FAD] + K_d)^2 - 4 \cdot [E] \cdot [FAD]}}{2 \cdot [E]} \right)$$

where  $F$  is the fluorescence intensity of the sample at a given total FAD concentration ( $[FAD]$ ),  $F_{\text{holo}}$  and  $F_{\text{apo}}$  are the intensities of the holo- and apo-proteins and  $[E]$  is the total concentration of NQO1 (0.2  $\mu\text{M}$  in monomer). In all cases, fittings using this model provided a good description of the experimental data within the experimental uncertainty (Figure S5).

The interaction of NQO1 and SAMp73 $\alpha$  was investigated by NMR spectroscopy. NMR data were acquired at 20 °C on a Bruker Avance DRX-500 spectrometer equipped with a triple-resonance probe and z-gradients. Samples

1  
2  
3 containing NQO1 proteins (at ~300  $\mu\text{M}$ , in monomer units) and  $^{15}\text{N}$ -labelled SAMp73 $\alpha$   
4 (~120  $\mu\text{M}$ ) were prepared in 50 mM phosphate buffer pH 6.9. The 2D  $^1\text{H}$ - $^{15}\text{N}$  HSQC  
5 (heteronuclear single-quantum coherence) experiments (62) were acquired in the phase  
6 sensitive mode. Experiments were acquired and analyzed as described (49).  
7  
8

9  
10  
11 **Crystallography.** Crystallization trials were carried out via the hanging-drop vapour  
12 diffusion method using previously reported conditions (63) at pH 7-9 and crystal  
13 improvement was achieved by the capillary counter diffusion technique (64) set-up  
14 using the Domino Granada Crystallization Boxes<sup>®</sup> (Triana Science & Technology,  
15 Granada, Spain). Good quality diffracting crystals were obtained using 30% of PEG  
16 3350, 200 mM sodium acetate, 100 mM sodium tricine pH 9.0, 1% DMSO and 10 mM  
17 dicoumarol, as precipitant agent. NQO1 H80R (70  $\text{mg}\cdot\text{ml}^{-1}$ ) mixed with agarose (0.05%  
18 w/v) was used to fill capillaries of 0.2 mm inner diameter. Crystals were equilibrated for  
19 24 hours with the mother liquid supplemented with 15% (v/v) glycerol before being  
20 extracted from the capillaries and flash-cooled in liquid nitrogen. Data were collected at  
21 ID-29 beam-line of the European Synchrotron Radiation Facility (ESRF, Grenoble,  
22 France) from flashed cooled crystals. Data were indexed and integrated using XDS (65)  
23 and scaled with SCALA from the CCP4 suite (66). The structure was determined by  
24 molecular replacement using the structure of WT NQO1 (PDB: 1D4A) without waters,  
25 as search model. The molecular replacement solution was found using Phaser (67)  
26 locating the two monomers in the asymmetric unit. Structure refinement was done with  
27 phenix.refine (68) with cycles of manual building steps and ligand identification  
28 performed with Coot (69). Titration-Libration-Screw (TLS) was included in the last  
29 steps of refinement. Model quality was checked using MolProbity (70) implemented  
30 within the Phenix suite (68). Coordinates and structure factors have been deposited at  
31 the PDB with accession code 5FUQ. Figures were prepared with PyMOL (71). Details

of data collection and processing, refinement statistics and quality indicators of the final model are summarized in Table S3.

**Electrostatic calculations.** Calculation of the energy of charge–charge interactions ( $E_{q-q}$ ) was performed using the solvent-accessibility-corrected Tanford–Kirkwood model (72). The input for these calculations were the atomic coordinates of: human NQO1 WT (2F1O) and H80R (2FUQ), rat NQO1 (1QRD), human AGT WT (1H0C) and RHEAM (4CBS), and mouse AGT (3KGX). We used an in-house software (kindly provided by Prof. Jose Manuel Sanchez-Ruiz, Department of Physical Chemistry, University of Granada) at pH 7.4 and 0.025 M (for NQO1) or 0.2 M (for AGT) ionic strength. The output of these analyses provide the energy of charge–charge interactions of a given ionizable residue with all or individual ionizable residues in the protein dimer, and are expressed per ionizable residue.

**MD simulations.** MD simulations were performed as recently described for WT and P187S NQO1 (18). The structures containing the mutation H80R were prepared using MOE (73) based on a crystal structure of the NQO1 complex with FAD (PDB: 1D4A) (63). The side-chain of Arg80 was modelled using two distinct conformations, solvent-exposed and partially buried. Nevertheless, after an extensive equilibration protocol (74) and a 100 ns sampling simulation, we observed a consistent orientation for Arg80 in the buried state after few ns. Analyses of MD trajectories were performed as recently described (18).

**NQO1 expression in Caco-2 cells.** Caco-2 cells were grown and maintained in Dulbecco's Modified Eagle Medium (Lonza, Barcelona, Spain) supplemented with 10% heat inactivated fetal bovine serum (HyClone, GE Healthcare, Barcelona, Spain), 100 U·mL<sup>-1</sup> penicillin and 100 µg·mL<sup>-1</sup> Streptomycin (Sigma Aldrich, Madrid, Spain) and cultured at 37°C in a humidified incubator with 5% CO<sub>2</sub>. Cells were transfected using

1  
2  
3 Lipofectamine LTX with Plus Reagent (Thermo Fisher Scientific, Madrid, Spain)  
4 according to manufacturer's protocol and pCINeo plasmids containing the cDNA of  
5 NQO1 enzymes and selected using  $400 \mu\text{g}\cdot\text{mL}^{-1}$  of G418 (Sigma Aldrich) for a month.  
6  
7

8  
9 For immunoblotting, cells were scrapped and lysed in RIPA buffer (50 mM Tris-  
10 HCl, 150 mM NaCl, 0.1% Triton X-100, 0.1% sodium dodecyl sulphate, 1 mM sodium  
11 orthovanadate, 1 mM NaF pH 8) with protease inhibitors (COMPLETE, from Roche,  
12 Spain). After centrifugation at 20000 g for 30 min, soluble extracts were collected and  
13 the amount of total protein determined by the BCA method (Pierce). Samples were  
14 denatured with Laemmli's buffer under reducing conditions, resolved using 12% SDS-  
15 PAGE and transferred to polyvinylidene difluoride membranes (GE Healthcare) using  
16 standard procedures. Immunoblotting was carried out using primary monoclonal  
17 antibodies anti-NQO1 and anti- $\beta$ -actin (Santa Cruz Biotechnology) from mouse at  
18 1:500 and 1:10000 dilutions, respectively. As a secondary antibody, we used chicken  
19 anti-mouse IgG-HRP (Santa Cruz Biotechnology) at 1:2000 dilution. Protein bands  
20 were visualized using luminol-based enhanced chemiluminescence and images were  
21 acquired with ChemiDoc MP imaging system and analyzed using Image Lab 5.0  
22 software (both from BioRad Laboratories).

40 For NQO1 activity measurements, cells were collected in 50 mM K-HEPES pH  
41 7.4 with protease inhibitors (COMPLETE, Roche) and lysed by freezing-thawing  
42 cycles. Soluble extracts were obtained upon centrifugation at 18000 g for 15 min at  $4^{\circ}\text{C}$   
43 and total protein content was determined by the BCA method (Pierce) and immediately  
44 used for measurements. Activity measurements were carried out as described (18, 49)  
45 using DCPIP ( $75 \mu\text{M}$ ) as electron acceptor and 0.5 mM NADH. Upon blank  
46 subtraction, the activity was normalized by the amount of total protein used in each  
47 measurement (50-130  $\mu\text{g}$ ).

3 For 17-AAG activation assays, cells were dispensed in 96 well plates at a  
4 density of  $2 \cdot 10^4$  cells/well. After 24 h, cells were treated with 0-30  $\mu\text{M}$  17-AAG (Santa  
5 Cruz Biotechnology). After two days of incubation, 20  $\mu\text{L}$  of  $0.125 \text{ mg} \cdot \text{mL}^{-1}$  of Alamar  
6 Blue solution (Sigma-Aldrich) was added to each well and incubated for 12 hours prior  
7 to absorbance measurement at 600 nm. Maximal inhibition of cell viability was  
8 determined from non-linear regression analysis of dose-response experiments.

16 **NQO1 expression in a cell-free system.** Pulse-chase experiments were performed  
17 using a TnT rabbit reticulocyte cell-free system (Promega, Madrid, Spain) at 30 °C as  
18 described in (49).

## Legends to Figures

**Figure 1. Structural basis of the global and local stabilization of human NQO1 by the consensus H80R mutation *in vitro*.** A) Consensus mutations derived from mammalian NQO1 sequences stabilize NQO1; the consensus ratios and changes in denaturation temperature vs. WT ( $\Delta T_m$ ; from  $T_{0.5}$  values in Table S1) are shown; B) Thermal stabilization of WT and P187S by the H80R mutation; data are means from at least five experiments.  $T_m$  from  $T_{0.5}$  values are shown (Table S1); C and D) Normalized proteolysis rates (C) and degradation patterns (D) for NQO1 enzymes showing local stabilization of the NTD by H80R. Normalized proteolysis rates are calculated from ratios of  $k_{\text{prot}}$  (in  $\text{M}^{-1}\cdot\text{min}^{-1}$ ) for WT/variants, and thus, values higher/lower than one reflect quantitatively the stabilizing/destabilizing effect, respectively; E and F) Structural comparison of H80R (PDB 5FUQ) and WT (PDB 2F1O) shows the preservation of the NQO1 overall fold (E) and the local stabilization exerted in the environment of the mutated site (F; WT in grey and H80R in pink).

**Figure 2. Overall conservation of the stabilizing effect of Arg80 across species and its divergence along primate evolution.** A and B) Structural overlay of human NQO1 WT (hWT, blue, PDB 2F1O) and H80R (hH80R, cyan, PDB 2FUQ) and rat NQO1 (red, PDB 1QRD), showing the environment of the 80 residue and the loop 57-66 (A) and the EER cluster (B; values indicate solvent accessibilities); C) Total electrostatic interaction energies for individual residues of the EER cluster; D) Pairwise electrostatic interaction energies (in  $\text{kcal}\cdot\text{mol}^{-1}$ ) between residue 59 and the EER cluster (residues in yellow are those diverging from human NQO1; the green and red color scale indicates the stabilizing/destabilizing nature of the interaction for visual aid); E and F)

1  
2  
3 Conservation of the EER cluster among representative individual mammalian sequences  
4 (panel E) and a set of fifty-three mammalian sequences (see SI text) grouped by  
5 order/family as sequences diverge in identity (F, circles indicate mean values and  
6 crosses their corresponding ranges); G) Ancestral sequence reconstruction for the Arg-  
7 to-His transition at position 80.

13  
14  
15  
16 **Figure 3. Recent evolutionary divergence of stabilizing consensus amino acids in**  
17 **NQO1 and AGT.** A) Consensus analyses performed using a similar set of mammalian  
18 sequences for NQO1 and AGT; B and C) Divergence of the relevant set of consensus  
19 amino acids in highly similar mammalian sequences; in panel B, divergence is shown  
20 for individual sequences, in panel C as clustered in orders/families as the identity  
21 decreases (values are mean $\pm$ s.d.; fifty-three sequences were used overall, see SI text);  
22  
23  
24  
25  
26  
27  
28  
29  
30 D) Phylogenetic trees based on sequences of NQO1 (left) and AGT (right). Numbers at  
31 some branches show the bootstrap values of 100 replicates. Only values above 50 are  
32 indicated. The lower panels show the approximate times at which mutations have  
33 occurred according to ancestral sequence reconstruction.

2  
3 and F) Dynamic changes at residue level from MD simulations showing specific effects  
4 of H80R on the backbone dynamics of apo-P187S (highlighted by green circles). G and  
5 H) representative western-blot of Caco-2 cells stably transfected with pCINEO (mock,  
6 no insert), pCINEO-NQO1 WT, H80R, P187S, H80R/P187S (panel G). The position of  
7 transfected (exogenous) NQO1 in the blots is indicated. In panel H, densitometric  
8 analyses of exogenous NQO1 protein normalized using  $\beta$ -actin content (the signal of  
9 WT is set to 1 in each experimental series;  $n=3$ ;  $\text{mean}\pm\text{S.D.}$ ). Statistical differences are  
10 provided by an unpaired t-test; I) chase experiments after a pulse synthesis in rabbit  
11 reticulocyte extracts. Fits to a single exponential provide the half-lives for the  
12 corresponding NQO1 variants;  $\text{mean}\pm\text{S.D.}$  from three independent experiments; The  
13 inset displays a representative gel for a pulse of synthesis to show that proteins levels  
14 are comparable for all variants, although somewhat lower for P187S; J) NQO1 activity  
15 in Caco-2 cell extracts transfected with different NQO1 variants and using DCPIP as  
16 substrate; K) Capacity of different NQO1 variants to activate 17-AAG, determined as  
17 the maximal inhibition of cell viability and normalized using the value of Caco-2 cells  
18 transfected with pCINEO (mock)(see Figure S7). Data in J and K are best-fit  
19 values $\pm$ standard errors and statistical significance is provided by a t-test.
