1. Introduction

The need to balance environmental sustainability, security of supply and energy equity, the *energy trilemma* (WEC, 2013), are strong drivers for the adoption of high volumes of intermittent and highly distributed electricity sources, thus necessitating a shift to a smarter grid as part of the transition to a low-carbon economy (Ofgem, 2014). A number of technologies affecting the demand- and supply-side of electricity are likely to be significant in this transition: Distributed energy resources (DER) place energy generation closer to demand and necessitate a two-way flow of electricity to maintain local reliability of supply. (Hledik et al., 2016). Large-scale intermittent sources such as windfarms require systemic flexibility for balancing purposes. Demand-side response (DSR) has been adopted since the 1970s to influence conventional demand patterns but could be scaled up substantially to allow a future shift to matching demand-to-supply rather than the traditional paradigm of demand-to-supply. Smart meters will monitor the electricity consumption and generation across the grid with a much greater granularity of data than has historically been possible – or feasible (Union of the Electricity Industry, 2013; van den Oosterkamp et al., 2014) and offer the potential to facilitate many network services. Heat pumps are expected to be a major tool in decarbonising heat, essentially via energy savings (Ofgem and DECC, 2014) but their use may increase electrical demand and demand volatility. Storage solutions may increasingly provide enhanced grid utilisation flexibility and improved reliability of supply (Pérez-Arriaga and Bharatkumar, 2014). Finally, any significant expansion in electric vehicles (EVs) will increase electricity demand and may provide mobile storage solutions (Pérez-Arriaga et

1 al., 2013). This study terms these technologies as *low-carbon electricity*
2
3 *generation and demand* (LEGD), unless stated otherwise.
4
5

6 The integration of LEGD into the network will affect network stakeholders (Teh
7 et al., 2011) and has already led to calls for the conventional paradigm of the
8 European electricity sector to be rearranged (Union of the Electricity Industry,
9 2013; van den Oosterkamp et al., 2014). Infrastructure investments are required
10 to balance increasing shares of intermittent electricity generation and to deal
11 with changing demand patterns. This will necessitate the installation of smart
12 information systems, the modernisation of technical standards and reshaping of
13 business models (Picciariello et al., 2015). Recent research calls for the revision
14 of the distribution network pricing mechanism to fund these investments and the
15 associated operation and maintenance (O&M) costs. While some of the studies
16 focus on DER only (Pollitt and Anaya, 2016), others consider only DSR (Wilks,
17 2011) or look at the system-wide impacts of LEGD (Picciariello et al., 2015).
18 However, to date the options for alternative distribution network pricing
19 mechanism that can be operationalised along the electricity supply chain and
20 consideration of what opportunities and challenges emerge as a result have not
21 been analysed. This work aims to address this gap by taking a whole-system
22 approach which considers policy and consumers across network stakeholders.

46
47

48 There is an ongoing debate over the financing of electricity distribution systems
49 in the future due to an increased number of distributed generators and
50 prosumers and the potential withdrawal of the latter from the need for network
51 services. This paper contributes to this debate through analysis of empirical
52 data collected by the researchers. It argues that a new approach is required for
53
54
55
56
57
58
59
60
61

1 a sustainable financing of distribution networks in the future. It identifies new
2
3 approaches and draws conclusions as to what alternative pricing mechanisms
4
5 could look like and what they should reflect. Argument and conclusions are
6
7 rooted in empirical data collected from key stakeholders from the UK and
8
9 Germany by conducting semi-structured interviews. More specifically, following
10
11 a review of the current pricing mechanism, this research aims (i) to develop an
12
13 innovative pricing mechanism that can address the challenges from LEGD and
14
15 (ii) to identify barriers and opportunities for the implementation of an innovative
16
17 mechanism along the electricity supply chain.
18
19
20
21
22

23 The study is structured as follows: Section 2 presents the electricity system
24
25 landscape, its tariff design principles, and broad characteristics of the current
26
27 pricing mechanism in the European Union. Section 3 demonstrates the
28
29 shortcomings of this mechanism. Section 4 describes the research methodology
30
31 while section 5 presents the results. Sections 6 and 7 are devoted to discussion
32
33 and conclusion, respectively.

42 **2. Current network pricing and the role of distribution network** 43 44 **stakeholders** 45 46

47 Distribution networks are natural monopolies because of their physical
48
49 characteristics and high investment costs for the construction of the required
50
51 infrastructure. Networks follow the economic principle: the more end users one
52
53 has, the merrier the benefit from the economics of scale (Vivek and Parsons,
54
55 2010). In the European Union (EU), distribution networks are usually owned by
56
57
58
59
60
61
62
63
64
65

1 Distribution System Operators (DSOs) (Anaya and Pollitt, 2015; Union of the
2 Electricity Industry, 2013). While the United Kingdom (UK) currently has
3
4
5
6 Distribution Network Operators (DNOs), some initiatives are underway by
7
8 individual DNOs and their trade association² for transition to a DSO model.
9

10
11 Across Europe, distribution networks used to be integrated at the national level
12
13 in a centralised electricity system consisting of large power plants from which
14
15 the electricity was transmitted on high voltage levels via transmission networks
16
17 to local distribution networks (Pérez-Arriaga et al., 2013). From the local level,
18
19 the electricity was supplied to the customer. It was common that companies
20
21 along the electricity supply chain were vertically integrated, had no competitors
22
23 and could set the electricity price (Jamasp and Pollitt, 2005).
24
25
26
27
28

29 Following national and pan-national efforts to privatise electricity the EU started
30
31 to reform the energy sector (EP, 2009) as a competitive energy and retail
32
33 market with regulated distribution and transmission networks. Four key actions
34
35 were taken to liberalise the energy sector (Jamasp and Pollitt, 2005):
36
37
38
39

40 (1) Unbundling of generation, transmission, distribution, and retail as well as a
41
42 horizontal division of production and supply.
43
44

45 (2) Establishment of competition in the wholesale market and in trading hubs.
46
47
48

49
50
51 ² Western Power Distribution is running a consultation at time of writing:
52 ([https://www.westernpower.co.uk/About-us/Our-Business/Our-](https://www.westernpower.co.uk/About-us/Our-Business/Our-network/Strategic-network-investment/DSO-Strategy.aspx)
53 [network/Strategic-network-investment/DSO-Strategy.aspx](https://www.westernpower.co.uk/About-us/Our-Business/Our-network/Strategic-network-investment/DSO-Strategy.aspx)) while another DNO,
54 UK Power Networks, has ended its consultation in September, 2017
55 (<http://futuresmart.ukpowernetworks.co.uk/>). Sectoral trade association, the
56 Energy Networks Association, has published a plan to enable this transition
57 (http://www.energynetworks.org/assets/files/electricity/futures/Open_Networks/T
58 [SO-DSO%20Project%20Framework%20v6.pdf](http://www.energynetworks.org/assets/files/electricity/futures/Open_Networks/T)).
59
60
61
62

1 (3) Authorisation of an independent regulator and third-party access to network
2
3 infrastructure.
4

5
6 (4) Support of privatisation of state-owned companies.
7

8
9 Economics dictates that a distribution network remains a natural monopoly
10 (Lavrijssen et al., 2016; Union of the Electricity Industry, 2013) while the
11 decisions about the network's structure and services affect every network
12 customer. Sakhrani and Parsons (2010) argue that distribution networks should
13 be considered as a shared resource and a public good since the costs for users
14 must be shared to maintain their benefits to all. A big part of network costs is
15 socialised (Pérez-Arriaga and Bharatkumar, 2014), effectively recovered
16 through elements of network tariffs that each customer has to pay (Anaya and
17 Pollitt, 2015; Union of the Electricity Industry, 2013).
18
19
20
21
22
23
24
25
26
27
28
29
30
31

32 Based on the experiences before the liberalisation process and because of the
33 network's characteristic as a natural monopoly, the costs distribution
34 businesses can pass to consumers are regulated (Union of the Electricity
35 Industry, 2013), based on the allowed CAPEX and OPEX of the DNO/DSO.
36
37 Regulatory authorities consider these costs (Table 1) in the revenue estimation
38 when setting the allowed revenue for DNOs/DSOs.
39
40

56
57
58
59
60
61
62
63
64
65

1 Rodríguez Ortega et al. (2008) identified three main drivers of network costs:
2
3

- 4 • a basic network as soon as a user exists,
5
6
- 7 • one user can affect the structure of the distribution network at all voltage
8 levels by injecting power in times of excess supply or by consuming
9 power at times of excess demand,
10
11
- 12 • network losses.
13
14
15
16
17

18 **2.1. Tariff level and the role of regulators in tariff design**

19
20
21

22 National Regulatory Authorities (NRAs) regulate the operations of Transmission
23 System Operators (TSOs), DSOs/DNOs, and system owners (EP, 2009). NRAs
24 set the allowed revenues for the period in question and have the authority to
25 approve pricing methods and allowed returns on investment where good
26 management is deemed to have been applied (EP, 2009). The calculation for
27 the allowed revenue is based on the requirements of each DSO/DNO to cover
28 the network costs listed in Table 1 (Union of the Electricity Industry, 2013). The
29 responsible NRA also determines the level of the interest rate and handles the
30 depreciation process, known as ratemaking. Thus it is important that the
31 revenue counterbalances the costs and generates a rate of return on capital
32 investment (Union of the Electricity Industry, 2013). NRAs should set this with
33 the perspective that effective network management is required to achieve the
34 rate of return.
35
36
37
38
39
40
41
42
43
44
45
46
47
48
49
50
51
52
53

54 Moreover, the framework for tariff design of NRAs across Europe is guided by
55 the following competing principles (Reneses and Rodríguez Ortega, 2014):
56
57
58
59
60
61
62
63
64
65

1 (1) Revenue adequacy: The tariff should provide a full cost recovery for the
2
3 DNO/DSO and should also enable reasonable/necessary future investments.
4
5

6 (2) Cost representation of induced cost: The tariff should represent the cost
7
8 contribution of each customer.
9

10 (3) Economic efficiency: The tariff should pass-through price signals.
11

12 (4) Cost allocation and transparency: The methodology used to determine the
13
14 price should be transparent. The tariff should protect customers from price
15
16 discrimination.
17
18
19
20
21

22 (5) Predictability: Based on the tariff, future costs should be projectable.
23
24

25 (6) Tariff additivity and intelligibility: The tariff structure should be coherent and
26
27 traceable instead of complex.
28
29
30

31
32 The different aims of these objectives lead to a number of trade-offs: An
33
34 adequate cost representation (1) could lead to price discrimination (4).
35
36 Economic efficiency (3) negatively impacts tariff additivity and intelligibility (6)
37
38 because in a regulated business, the market price is estimated based on long-
39
40 term costs, different to a competitive market where the marginal costs are equal
41
42 to the price. Hence, the approximation causes complexity (Reneses and
43
44 Rodríguez Ortega, 2014).
45
46
47
48

49
50 Despite general consensus about the regulatory objectives among the NRAs,
51
52 their positions can be distinguished in the scope of freedom they allow to
53
54 DSOs/DNOs. Two general approaches exist in the EU (Union of the Electricity
55
56 Industry, 2013): The first sees the NRA provide a threshold for allowed revenue
57
58
59
60
61

1 and frames the methodology for the tariff design. The DSOs/DNOs can decide
2
3 how they want to collect their revenue among connection charges and network
4
5 tariffs. The second approach requires NRA approval for network tariffs and the
6
7 NRA also sets the connection charge as well as the design of the tariffs. Hence,
8
9 the position of NRAs is stronger in countries following the second approach.
10
11

12
13 However, most European regulators adopted an outcome oriented incentive
14
15 regulation to assure good performance of the distribution network companies
16
17 (Union of the Electricity Industry, 2016, 2013). This means that the regulator
18
19 sets an allowed revenue and, for some services, it sets a benchmark and
20
21 leaves its realisation up to the DNO/DSO. Thus DSOs/DNOs can be rewarded
22
23 or disciplined for their services and are incentivised to improve their quality
24
25 (Union of the Electricity Industry, 2016, 2013).
26
27
28
29
30

31 32 33 34 35 **2.2. Current cost recovery of DNOs and DSOs across Europe**

36
37 The costs stated for the calculation of the allowed revenue are recovered
38
39 through the distribution use of the system charge (DUoS-charge) and the
40
41 connection charge (ENA, 2014; Picciariello et al., 2015). In most European
42
43 countries, network costs for distribution and transmission are indicated on the
44
45 electricity bill and collected by the electricity supplier who remits the share of the
46
47 network charges back to the TSO and DNO/DSO (Union of the Electricity
48
49 Industry, 2016, 2013).
50
51
52
53
54
55
56
57
58

59 **2.2.1. Distribution use of system charge**

60
61
62
63
64
65

1 The DUoS-charge is paid recurrently. It is set with the intention to cover the
2 capital and O&M costs as well as necessary network upgrades, and ideally to
3 do so only where network management can be demonstrated to be effective.
4
5 The basic components and their use are presented in Table 2.
6
7
8
9

10
11
12
13
14 [insert Table]
15
16

17 **Table 2: DUoS components**

18
19
20
21
22

23 The fixed charge represents a significantly smaller share of the DUoS-charge
24 than the volumetric charge (Faruqui et al., 2016).
25
26
27
28
29
30

31 **2.2.2. Connection charges**

32
33
34

35 The connection charge is needed to cover the costs for the connection to the
36 grid and can be considered as a one-off fee for all generators connecting to the
37 distribution network (ENA, 2014; Picciariello et al., 2015). It is necessary to note
38 that the connection charge is linked to the DUoS-charge because its structure
39 and grade defines the extent to which the costs will be socialised. The
40 connection charge structure can be organised in three types (EC, 2017;
41 Picciariello et al., 2015):
42
43
44
45
46
47
48
49
50

51
52 **Shallow:** The generator pays only the direct costs occurring from connection
53 that is typically costs of connection to the nearest point on the grid.
54
55
56
57
58
59
60
61
62
63
64
65

1 **Shallowish:** In addition to the direct costs that occur from the connection, the
2
3 generator pays also for the corresponding use of the network upgrade.
4
5

6 **Deep:** The generator pays the complete costs associated with the connection to
7
8 the grid, including at higher voltage levels.
9
10

11
12 Hence, *deep charging* often impedes the enforcement of new generation utilities
13 such as DER (Picciariello et al., 2015) since it raises upfront capital costs. It can
14 be noted that different systems can apply for determining connection costs for
15 generators connecting to the transmission as opposed to the distribution
16 network, meaning the typically smaller-scale generation can be disadvantaged
17 compared to large-scale traditional generators (Mitchell, 2000).
18
19
20
21
22
23
24
25
26
27
28
29
30

31 **3. Reasons for an innovative network pricing**

32
33

34 The integration of intermittent generation from DER challenges the grid capacity
35 due to varying load factors necessitating more dispatch and balancing (Pollitt
36 and Anaya, 2016). There is an increasing need for DNO/DSOs to take a more
37 active approach to network management at the local level than has historically
38 been the case. Today, DNOs/DSOs must accept electricity from DER and
39 function as dispatchers on a local level. In a centralised system this function is
40 solely provided by the TSO (Anaya and Pollitt, 2015; Union of the Electricity
41 Industry, 2013).
42
43
44
45
46
47
48
49
50
51
52
53

54 Other issues arise from the transition of conventional customers to prosumers
55 who generate electricity with PV on their rooftop and change their demand
56
57
58
59
60
61
62
63
64
65

1 patterns, for example by driving EVs or by installing heat pumps (Pérez-Arriaga
2 and Bharatkumar, 2014). This self-sufficient electricity consumption reduces the
3 need for grid utilisation and affects other customers because of cross-
4 subsidisation and the “utility death spiral” (Pérez-Arriaga and Bharatkumar,
5 2014; Pollitt, 2016). These issues are presented in detail below.
6
7
8
9
10
11
12
13
14
15
16

17 **3.1. Grid capacity**

18
19
20 Reliability as the essential service of an electrical grid can be expressed by the
21 TSO as a reserve margin - the excess of available generation over total peak
22 load. An adequacy forecast by ENTSO-E shows reserve margins for the year
23 2020 of 2% for the UK and 6% for Germany (ENTSO-E, 2017).
24
25
26
27
28
29

30 Concerning terms of availability of generation, conventional electricity
31 generators have stable load factors of around 90% (see Table 3). In contrast,
32 the average load factors of onshore/offshore wind generation and PVs are
33 significantly lower and more variable (see Table 3).
34
35
36
37
38
39
40
41
42
43

44 [insert Table]

45
46
47 **Table 3: Average load factors of different technologies in the UK**
48
49
50
51
52

53 To identify the challenges to the grid caused by renewables, this research
54 analysed the electricity sector in Germany in 2014. Germany was chosen
55 because 35% of the German public electricity supply was generated from
56
57
58
59
60
61
62
63
64
65

1 renewable electricity sources (Burger, 2016). Table 4 presents data for net
2 installed capacity and maximum load of solar and wind in Germany for 2015.
3
4
5
6 Whereas the average load factor of wind turbines was 23.61 %, it increased by
7
8 more than three times to 79.2 % at its peak. Even greater differences had been
9
10 calculated for solar power where the load factor at peak production was almost
11
12 seven times higher than the average load factor. When the combined
13
14 generation of windmills and solar peaked in 2015, the load factor was more than
15
16 three times higher than the average one.
17
18
19
20
21
22

23 [insert Table]
24
25

26
27 **Table 4: Net installed capacity and maximum load of solar and wind in Germany**
28 **in 2015**
29
30

31
32 The combined electrical output from renewables such as wind and solar is
33
34 intermittent and can be difficult to predict compared to the relatively steady load
35
36 profile of conventional electricity generation. It is possible for DER to generate
37
38 such that it outdoes local network capacity, though in some locations this may
39
40 be addressed by preventing new capacity connecting to the network, though
41
42 there may be limits on the scope for DNO/DSOs to enforce such restrictions.
43
44 Where the DNO/DSO does not or cannot take action to limit DER capacity prior
45
46 to installation then there are limited options for the network operator. As an
47
48 immediate response, they can limit generation by requiring the generator to
49
50 temporarily cease production. They may continue with this approach or may
51
52 also reinforce grid capacity. Continuing constraint on generation will have
53
54 economic implications for the generator and these maybe passable to the DNO.
55
56
57
58
59
60
61
62
63
64
65

1 Even where this is not the case then the generator may have a case against the
2
3 DNO where it has been advised it can connect and has invested on this basis.
4
5 In terms of long-term ability of the network to deal with excess generation,
6
7 electricity markets with an energy mix and flexible generation have an
8
9 advantage (Pollitt and Anaya, 2016). Scenarios for future development of
10
11 electrical supply and demand, and its management, consider the additional
12
13 flexibility that might come from the supply side (Balta-Ozkan et al., 2014).
14
15
16
17

18 Hence, the required grid capacity for distribution networks in decentralised
19
20 systems also depends on the peak demand and on the peak generation of
21
22 DER. This leads to a higher grid utilisation and to the following consequences:
23
24
25

26 **Voltage control:** If the peak generation exceeds the regional demand, the
27
28 reverse power flows cause issues in controlling the voltage (Pollitt and Anaya,
29
30 2016).
31
32
33

34 **Frequency variation:** The rapidity of ramping of DER leads to variation in
35
36 network frequency. To minimise the frequency issue, the probability increases
37
38 that customers will get disconnected (Pollitt and Anaya, 2016). Furthermore, the
39
40 frequency issue has a negative impact on the transmission grid that has “low
41
42 inertia dynamics” (Elsayed, Mohamed and Mohammed, 2015, p.412).
43
44
45
46

47 The variation of the load factors of DER requires an upgrade of the grid which
48
49 increases capital costs (Pérez-Arriaga and Bharatkumar, 2014). Higher voltage
50
51 control and more variation in the frequency demand more balancing and will
52
53 therefore increase the O&M costs (Union of the Electricity Industry, 2013).
54
55
56
57 Furthermore, it will influence the TSO, that is responsible for system stability
58
59
60
61

1 (Elsayed et al., 2015). In Germany, the TSOs are already obligated to
2
3 commercialise energy from DER at the spot market (EEG, 2017).
4
5
6
7
8

9 **3.2. Utility death spiral**

10
11
12 As demonstrated in section 2.2.1, a big part of the network tariff is the
13 volumetric charge that is calculated according to the amount of consumed
14 energy. Depending on the type, a low-carbon technology can influence the
15 demand (EVs, heat pumps) or supply (DER) on the distribution network. Self-
16 sufficient customers cause a reduction in energy sales as soon as they begin to
17 generate their own power, thus reducing the income linked to the volumetric
18 charge (Pérez-Arriaga and Bharatkumar, 2014). Consequently, the revenues of
19 DSOs/DNOs decrease while the fixed costs for the network remain the same
20 and capacity utilisation may increase. Enhanced energy efficiency and DSR
21 may cause similar effects. Covering these costs with reduced volumetric
22 charging implies a cost increase for remaining users, thus causing a further
23 incentive for consumers to consider developing their own energy self-
24 sufficiency. Potentially this might impact network income and lead to the cycle
25 that has been called the “utility death spiral” (Pérez-Arriaga and Bharatkumar,
26 2014). The volumetric charge is therefore not appropriate to capture the full
27 impact of LEGD customer behaviour and ensure continued network viability. To
28 maintain network provision in a world with increasing LEGD will require
29 increases in the volumetric charge, substantive decreases in network costs or
30 some other income solution.

61
62
63
64
65

3.3. Cross-subsidisation

Even though the uptake of low-carbon technologies is growing and is supported by EU and Member State policies and incentives, high entry costs and a lack of access to other resources can deter customers from using them (Picciariello et al., 2015). A network tariff that mainly consists of a volumetric charge does not reflect the costs of balancing the system, so that customers who cannot afford LEGD will have higher energy bills in comparison to prosumers. Thus, consumers with less potential to take up LEGD cross-subsidise the investments in LEGD by prosumers in addition to any subsidy specific to encouraging LEGD (Picciariello et al., 2015; Sajn, 2016). Many LEGD adopters may still need grid supplied electricity at some points in time. These consumers need the network to be there when they need it. This argument obviates the potential for charges based on infrastructure availability.

4. Methodology

The challenges identified in section 3 demonstrate that current network pricing is inefficient. To find out what required adjustments and new approaches need to look like and which barriers exist for their implementation, interviews with 21 experts were conducted.

The experts' views were collected in semi-structured interviews. This interview design was selected as suitable because it allows adjustment of interviews to the dialogue and its design gives the opportunity to ask follow-up questions as

1 necessary (Robson and McCartan, 2016). When selecting the interviewees, the
2
3 main focus was to gain insights of stakeholders along the electricity distribution
4
5 supply chain (see Table 5).
6

7
8 [insert Table]
9

10
11 **Table 5: Expert mix of the conducted interviews**
12

13
14
15
16
17 Each of the twenty-one interviews lasted around 30 minutes, was conducted by
18
19 phone in English or German, and followed the telephone interview
20
21 recommendations by Robson and McCartan (2016). The interviews consisted of
22
23 eleven questions, divided into two categories. The first five questions dealt with
24
25 developments in the electricity sector and emerging cost drivers from the
26
27 employment of LEGD in the grid. The remaining six questions dealt with
28
29 necessary requirements for innovative network pricing approaches, their
30
31 opportunities, and constraints.
32
33
34
35
36

37
38 If agreed by the interviewees, the interviews were recorded to facilitate their
39
40 analysis. Before conducting the interviews, all interviewees were informed that
41
42 the main interest of the research is to discuss the whole electricity market of the
43
44 EU. Therefore, even though the vast majority of the interviewees were based in
45
46 the UK, their answers were in most cases applicable to all EU-member states.
47
48
49

50
51 To identify relevant information, the interviews were analysed thematically. The
52
53 encoding process followed the principles set out by Boyatzis (1998). That is,
54
55 labelling the thematic codes, defining them, finding criteria as to how they can
56
57 be recognised, setting criteria for when to exclude them, and drafting examples
58
59
60
61

1 for them. As result of this process, seven themes were defined which are
2
3 presented in section 5.
4
5

6
7 If it was applicable, direct quotes of the experts were added in the text, marked
8
9 with the letter *E* followed by an Arabic numeral which had been randomly
10
11 assigned to the interviewees to protect the interviewees' anonymity.
12
13
14
15

16 17 18 **5. Results** 19

20
21 The following themes had been defined through the encoding process: **(1)**
22
23 **Technology and policy drivers of network pricing** captures challenges from
24
25 LEGD in the electricity sector that make a new pricing approach necessary. **(2)**
26
27 **Conditions for an innovative pricing approach** describes necessary
28
29 requirements to make an innovative pricing approach feasible. **(3) New**
30
31 **customer role** concerns emerging customer segments. **(4) Cost drivers from**
32
33 **LEGD** deals with costs that should be reflected in the price. **(5) Cost recovery**
34
35 **and allocation** analyses necessary elements of an innovative pricing approach
36
37 to recuperate the costs fairly. **(6) New business models** sum up implications
38
39 for the functions of DNOs/DSOs due to LEGD and how they can benefit from
40
41 these developments. **(7) Flexibility** can emerge from demand or supply side or
42
43 both and can vary depending on the available technology and services within
44
45 the system and network constraints at the time.
46
47
48
49
50
51
52
53
54
55

56 57 **5.1. Technology and policy drivers of network pricing** 58 59 60 61 62 63 64 65

1 The interviewed experts agree that the main developments in the electricity
2 sector can be distinguished into technical developments and policies. The
3 experts confirm that the intermittency and unpredictability of the load factors of
4 wind and solar energy as well as anticipating where and when they will
5 generate electricity are challenging. The potential increase in demand and
6 demand volatility linked to LEGD is likely to require more system balancing to
7 maintain system reliability (Perez-Arriaga and Battle, 2012; Tarroja et al., 2012).
8 Efficient and affordable storage solutions are potentially disruptive technologies
9 because they will provide greater independence from seasonality, though they
10 may further contribute to the utility death spiral since they may enable additional
11 on-site auto-consumption. One expert explains that *“storage solutions are
12 challenged by a large supply of electricity, respectively its low wholesale price,
13 and the high investment costs of storage solutions which make them financially
14 inefficient for domestic customers”* (E20). The influence of EVs is mainly
15 described as a mobile storage solution. Its use to stabilize the distribution
16 network during peak hours is seen as a good opportunity *“but not as a feasible
17 one until batteries are capable to deal with an increasing number of charge
18 cycle”* (E21). The experts state that low-carbon policies by the EU and national
19 governments are enablers for these developments. On the other hand, they
20 generally agreed that *“current network pricing is obsolete and the regulation
21 cannot catch up with the technological happenings in the sector”* (E7). One
22 expert sees risks in policies that explicitly facilitate specific technologies
23 because they might prevent investments in other technologies and their
24 implementation. The expert points out that in Germany Power-to-Gas would be

1 able to shift energy from the distribution network to the gas distribution network
2
3 but that “*policies do not focus on Power-to-Gas*” (E20). For the future, all
4
5 experts expect a reduction in incentives for solar because costs will soon reach
6
7 grid parity. This is already apparent in a number of Member States where tariffs
8
9 have been reduced to match real world price reductions (Sahu, 2015).
10
11
12
13
14
15
16

17 **5.2. Conditions for an innovative pricing approach**

18
19
20 The experts highlight that “*smart grids, smart metering, and better information*
21
22 *systems are a necessary condition*” (E13) for network stakeholders to display
23
24 the electricity consumption of customers, to analyse consumption patterns, to
25
26 send correct price signals, and for efficient system balancing. These are seen
27
28 as essential for the development of new pricing algorithms because they
29
30 facilitate the indication of the real-time use of the system (RTUoS) by
31
32 customers. The experts are concerned about the customers’ negative
33
34 perception of smart meters regarding their privacy protection, which gels with
35
36 concerns expressed by UK experts (Balta-Ozkan et al., 2014). The probability
37
38 that smart meters will reduce consumption is seen as relatively small, but they
39
40 are considered as enablers for RTUoS. It should be noted that there are a
41
42 significant number of other barriers to enabling RTUoS. Installed smart meters
43
44 have to be sufficiently advanced (many are not, including many of the current
45
46 generation being rolled out across the UK). Data collection and analysis has to
47
48 be able to deal with the volume of data rapidly. Regulation has to allow for data
49
50 to get to the appropriate market actors (for example, the UK does not currently
51
52
53
54
55
56
57
58
59
60
61
62
63
64
65

1 allow DNOs to access consumer data, even if smart meters were capable).
2
3 Service providers have to be able to find a way to monetise the market. There
4
5 may be other barriers.
6

7
8
9 Increased data sharing and potentially steadily increasing data sharing is
10
11 considered as likely to become very important because of the interdependences
12
13 between the TSO and DSO/DNO regarding dispatch and balancing and the
14
15 information imbalance among grid stakeholders about the location of
16
17 decentralised generation assets. It is considered helpful to know if a customer
18
19 has one or more of: a storage solution, a heat pump or an EV, and whether they
20
21 participate in demand response. According to the experts, current legislative
22
23 frameworks do not consider the need for data sharing among different
24
25 stakeholders to enable an efficient managing of the system along the electricity
26
27 distribution supply chain. Data sharing will also have value for other
28
29 stakeholders including suppliers and other third parties, including potentially
30
31 disruptive market entrants. The scope of access seems likely to conflict with
32
33 degrees of political will to facilitate different levels of consumer privacy. One
34
35 expert expects that therefore *“the lack of data sharing will increase the*
36
37 *operating costs for the overall electricity system”* (E6). While there is a reported
38
39 expectation among experts in a UK study where there was an expectation that
40
41 data access would be relaxed over time this has not yet begun to happen
42
43 (Connor et al., 2014; Xenias et al., 2015).
44
45
46
47
48
49
50
51
52
53
54
55
56

57 **5.3. New customer role**

58
59
60
61
62
63
64
65

1 The interviewees agreed that new customer classifications will emerge based
2 on RTUoS profiles and dependent on different levels of LEGD uptake by
3 individual consumers. Hereby, it will be relevant whether a customer only
4 consumes power from the grid or also injects electricity into it. Currently, LEGD-
5 customers are seen as early adaptors, eleven experts pointed out that
6 increasing self-sufficiency is an expected future trend. These developments are
7 seen as complementary to conventional demand customers. The experts argue
8 that in the near future not every customer will participate in LEGD and that this
9 will have implications for relative costs for LEGD participants and non-
10 participants.
11
12
13
14
15
16
17
18
19
20
21
22
23
24
25

26 Most of the experts agree that vulnerable customers need to be protected from
27 increasing electricity bills. Moreover, vulnerable customers are disadvantaged
28 because they cannot afford or have limited scope for applying LEGD and
29 therefore do not qualify for LEGD-incentives and may also be less likely to be
30 able to shift power consumption within the context of RTUoS.
31
32
33
34
35
36
37
38

39 One expert envisioned: "*The future distribution grid customer is less interested*
40 *in the commodity power, instead his interest are the services provided from the*
41 *grid*" (E4). Additionally, it is expected that the role of customers will expand to
42 become *flexibility providers*. And therefore, the relationship between supplier,
43 DNO/DSO and customer will change (see section 5.5).
44
45
46
47
48
49
50
51
52
53
54

55 **5.4. Cost drivers from low-carbon generation and demand**

56
57
58
59
60
61
62
63
64
65

1 According to the experts, the cost driver for distribution networks in the near
2
3 future will be the capital expenditure to reinforce the grid because of the two-
4
5 way flow of electricity from DER and their varying load factors. Especially “in
6
7 *areas with a high electricity production from solar, DNOs/DSOs notice the need*
8
9 *to reinforce their distribution grids. In contrast, the electricity produced by wind*
10
11 *farms has a smaller impact on the distribution grid, because it is often injected*
12
13 *to the transmission grid” (E18). Improvement in local network infrastructure is*
14
15 likely to be required in many locations to update the substations, to upgrade grid
16
17 capacity, and to facilitate smart metering where this is DSO led. This may be by
18
19 reinforcement or increasingly by ‘smart’ methods as a permanent alternative or
20
21 to defer reinforcement expenditure. The interviewees expect maintenance costs
22
23 to remain constant but they predict that the operational costs, especially for
24
25 balancing, will increase. “*The need for balancing will require more human*
26
27 *capital” (E7), one participant stated. Disagreement among the experts exists*
28
29 about the time frame when the reinforcement costs will become due. Some
30
31 experts expect the grid extension to be completed within the next ten years,
32
33 others are more cautious and argue that the grid upgrade is also dependent on
34
35 other yet unknown developments. This is to be expected since the need will
36
37 vary for DNOs/DSOs in different countries and even within countries, dependent
38
39 on current infrastructure, rates of increase in LEGDs, network geography and
40
41 other variables such as consumer buy-in to a more active role. One expert
42
43 mentions that “*affordability and efficiency of storage will be a game changer for*
44
45 *the grid reinforcement” (E9).*
46
47
48
49
50
51
52
53
54
55
56
57
58
59
60
61
62
63
64
65

1 Overall the experts agree that the reinforcement of the grid and more active
2 balancing at the distribution network level is necessary to provide sufficient
3 capacity. However, the interviewees disagree as to the extent to which grids will
4 need to be reinforced. One group suggests reinforcing the grid only until it has
5 enough capacity to deal with the varying load factors. The other group states
6 that some reinforcement costs could be saved if the overall system coordination
7 was improved so that the dispatch and balancing were more efficient. This
8 essentially reflects the uncertainty emergent from the many variables, including
9 the possible role of smart network solutions as an alternative to grid
10 reinforcement.

11 Maintaining DNO income heavily rooted in the volumetric charge is considered
12 “*ineffective to capture the costs occurring from the integration of DER*” (E5)
13 because it does not take grid utilisation into account and is based purely on the
14 overall consumed energy. The experts indicate that the costs prosumers cause
15 to the network are currently mitigated by customers with high energy demand
16 and that in systems with a high share of DER, the current network pricing is
17 failing the second regulation principle *cost representation of induced cost* (see
18 2.1). The interviewees also agreed on the trade-off between a charge according
19 to the RTUoS profile and wide scale installation of LEGD. In this RTUoS
20 approach, all actions of the grid users at every point in time are monitored and
21 the customers will be charged according to their utilisation of the grid. Hence, at
22 peak times they are charged with a higher price. This charging methodology will
23 increase the costs for LEGD-customers and will reduce the incentives to install
24 LEGD. Experts disagree on how these costs should be recovered. They

1 particularly disagree on the level of socialisation of the costs and how
2
3 vulnerable customers should be protected.
4
5

6 Some experts favour an increase in general taxation to cover the shortfall in
7
8 funds to sustain the networks. There are a number of possible variations of how
9
10 this might apply and where the funds would be directed. While some experts
11
12 propose to use the revenue to redesign the conventional electricity sector to a
13
14 smarter, more actively managed system more suited to the added complexities
15
16 of managing growing low-carbon technology usage, others recommend using it
17
18 solely to mitigate costs to vulnerable customers. An intermediate solution would
19
20 be to direct the funds to two separate pots to address both sides of this, though
21
22 it should be noted that increases in costs due to distribution network upgrades
23
24 will not be the only factor impacting consumer vulnerability as regards energy
25
26 access. Under the first proposal to allocate these funds to the DSO/DNO for
27
28 network investments, independently from the consumed energy, such a tax
29
30 could address the trade-off between an RTUoS-charge and the encouragement
31
32 of customers to install LEGD because the DNO/DSO would benefit from this tax
33
34 and could charge less to their customers.
35
36
37
38
39
40
41
42
43

44 However, imposition of a tax unlinked to consumption has significant potential to
45
46 be highly regressive because customers with a low use of the system, for
47
48 example due to their low and stable demand profile, would proportionally have
49
50 to pay more than customers with a high use of the system. There is some
51
52 potential to make this a partial solution, wherein it is applied alongside a
53
54 volumetric charge as two components to support DNO income and investment.
55
56
57
58
59
60
61
62
63
64
65

1 Applying public funding to the strengthening of networks also raises the issue of
2
3 ownership of the new additions to the network, and the poor fit this would have
4
5 with either adding to the capital base for a DNO or charging for elements of the
6
7 network which do not come from their own capital investment.
8
9

10
11 Another approach is to link additional reinforcement costs to the individual
12
13 demand of customers. This would avoid the problem of the additional capacity
14
15 being financed directly from the public purse. This approach would also have
16
17 implications for vulnerable customers since it will also add to overall costs.
18
19 Again, the problem of vulnerable consumers being less likely to be able to take
20
21 advantage of LEGD might mean a double impact to their overall billing. One
22
23 participant mentioned that *“no matter how we allocate the costs, there will*
24
25 *always be winners and losers. So, in the end, it stays a political question”* (E13).
26
27
28
29
30
31
32
33

34 **5.5. New business models**

35
36
37 Mutual understanding existed amongst the experts as to the need for change
38
39 from a passive to a more active network requiring more system management.
40
41 New control and information systems will help to facilitate this development and
42
43 the role of DSOs/DNOs will change. Concerning Great Britain, twelve experts
44
45 (British and German) agree that the DNOs must at least become DSOs as part
46
47 of a process of becoming increasingly active in terms of balancing and dispatch
48
49 and to allow future scope for more active system management, to take
50
51 advantage of larger volumes of data availability from energy consumers and to
52
53 allow the use of a greater range of tools in system balancing.
54
55
56
57
58
59
60
61
62
63
64
65

1 Further, all the experts agree that the volume of ancillary services which can be
2 provided by or through the DSOs/DNOs will increase and that the dispatch of
3 electricity flows will become a shared responsibility between the DSOs/DNOs
4 and the TSO. They highlighted the need for cooperation between supplier and
5 DSO/DNO to be intensified. Here, some experts mention contractual difficulties.
6 Most experts agree that it is important to pass on the price signal related to
7 network costs through the energy bill. They are also concerned that this may
8 lead to a more complex electricity bill. One expert pointed out that *“the price
9 signal in the electricity bill for the actual use of the distribution network is in the
10 hands of the supplier, who possibly has other interests”* (E13). There was a
11 mutual understanding among the interviewees as to responsibility for the
12 reliability of the infrastructure remaining with the DSOs/DNOs. The experts also
13 agree that demand-side response aggregators are emerging new actors in the
14 electricity market, enabling a more efficient use of the system capacity and with
15 the potential to expand to be more significant in the future. Their emergence
16 seems likely to require regulatory change in some territories concerning
17 licensing and regulatory oversight, but also to ensure access to markets and
18 that they are not held back by incumbents. Other service providers may also
19 emerge and will require similar transformation to enable them to access
20 markets.

21 The future functionality of the distribution network is seen as being a
22 conventional deliverer of electricity but also a backup provider and an acceptor
23 of electricity for prosumers as well as its historical and conventional taking only
24 from larger generators. DNOs/DSOs will adjust their business models

1 accordingly, responding to both the market and to amendments to regulation.
2
3 Comparable to the reinsurance business, it is expected that DNOs/DSOs in the
4
5 future will be paid for straightforward distribution as currently but also to provide
6
7 services that ensure reliable supply to customers when their own generation is
8
9 too low or their consumption is too high.
10
11
12
13
14
15
16

17 **5.6. Flexibility**

18
19
20 General agreement among the experts exists about the importance of
21
22 incorporating flexibility in to both the demand- and supply-side to enable more
23
24 effective generation dispatch. According to the interviewees, DSR and storage
25
26 become key providers of flexibility. They also make it clear that possible
27
28 customers should be incentivised by appropriate market arrangements, such as
29
30 *“incentive based contracts, that change consumer behaviour and therefore*
31
32 *optimise the grid utilisation”* (E6). Hence, providers of flexibility should have the
33
34 opportunity to compete and to get paid for their services. It should be noted that
35
36 investment in this increased flexibility will ideally reduce the need for investment
37
38 in infrastructure. While some interviewees argue that the business of the
39
40 aggregation service provider should be integrated in the business model of the
41
42 supplier, others want to strengthen the position of third party aggregators.
43
44 However, all the interviewees highlighted that regulators need to be involved in
45
46 encouraging customers to become flexibility providers as a necessity for
47
48 providing reliability of supply.

63
64
65

1 **6. Discussion**

2
3
4 Based on the literature and after analysing the interviews, it can be stated that
5
6 the current pricing mechanism no longer meets five of the six regulatory
7
8 principles (see Table 6, DUoS-charge). First of all, the DUoS charge neither
9
10 recovers the costs of LEGD nor does it pass-through the price signal. Its
11
12 volumetric component derived from the amount of consumed energy does not
13
14 adequately reflect the grid utilisation and leads to cross-subsidisation. This
15
16 impedes the predictability of price developments for network stakeholders.
17
18
19

20
21
22 In the following, innovative pricing approaches are discussed and their
23
24 compatibility with the regulatory principles assessed (see Table 6).
25
26

27 [insert Table]

28
29
30 **Table 6: Innovative pricing approaches vs. regulatory principals**

31
32
33
34
35
36
37 In the interviews, some experts suggested increasing the **fixed-cost element** of
38
39 the DUoS-charge to cover increasing O&M and reinforcement costs caused by
40
41 the integration of DER. Furthermore, an increased fixed-charge would not
42
43 resolve the issue of excess demand and supply because customers would not
44
45 save money if they shifted their demand to off-peak times or installed storage
46
47 solutions for an optimised use of the electricity system. Rodríguez Ortega et al.
48
49 (2008) identified excess demand and supply as one of the main cost drivers for
50
51 the network. Therefore, higher fixed-charges alone are not adequate approach
52
53
54
55
56
57
58
59
60
61
62
63
64
65

1 because they only meet three regulatory principles (see Table 6) and do not
2
3 resolve the capacity problem and excess demand.
4
5

6 Two strategies to improve the grid's capacity have been identified in the
7 interviews. The first intends to reinforce the grid until it has enough capacity to
8 deal with the variation of the DER-load factors, a strategy currently introduced in
9 Germany (Bundesregierung, 2016). The second strategy aims to provide
10 sufficient capacity with an effective system balancing of the grid and a light grid
11 upgrade, as has been envisioned for the UK (Veany, 2014).
12
13
14
15
16
17
18
19
20
21

22 To cope with excess demand, **peak pricing methods** might incentivise
23 customers to shift their demand to off-peak times. This might mean customers
24 would have to pay significantly more during peak periods for electricity they
25 either inject to or draw from the grid (Brown et al., 2015). These on- and off-
26 peak tariffs could result in significant increases which could be a problem for
27 vulnerable customers³. Additionally, this approach does not meet the principle
28 of cost representation and predictability.
29
30
31
32
33
34
35
36
37
38
39

40 Another approach deals with the individual contribution of customers to grid
41 utilisation. Wood et al. (2014) propose a **capacity charge**. The charge would be
42 based on the maximum capacity required by each customer in a year
43 determined by their maximum demand. Hence, each customer would have to
44 pay for their contribution to the network costs. Under such an approach, some
45 customers will be better off while others worse off compared to business as
46
47
48
49
50
51
52
53
54

55
56 ³ In a demonstration project in London, it has been reported that total price of electricity might
57 increase by 16 times (Laguna, 2014). However, it should be noted that the duration and the
58 frequency (once a year for a few hours versus half an hour on a weekly basis) of such an
59 increase would determine the magnitude of the impacts for vulnerable customers.
60
61
62
63
64
65

1 usual. Collectively, it is highly likely that consumers will have to pay more
2
3 overall for transmission and distribution, reflecting the need for greater network
4
5 investment as part of the low-carbon transition (BMW, 2014). New and smarter
6
7 approaches to network management are expected to mitigate this overall
8
9 increase to some extent. Greater levels of prosumption means a different use of
10
11 the network which may mitigate some of the total costs, for example through
12
13 reduced losses. Thus, increased prosumption may reduce overall costs but the
14
15 general upward trend will need to be met by remaining non-LEGD customers.
16
17 These customers might not have LEGD because it is not a viable business case
18
19 for their electricity consumption or they simply cannot afford or install it. In
20
21 addition, these customers do not participate in LEGD incentive schemes.
22
23 Hence, a move away from volumetric charging opens up a debate regarding
24
25 equitability of outcomes, along with the political elements of what equitability
26
27 means in this context. A capacity charge approach might lead to a trade-off
28
29 between the desired low-carbon economy and cost allocation (Pollitt and
30
31 Anaya, 2016). Yet, this trade-off could be mitigated for customers with DSR
32
33 or/and storage who can be incentivised to become flexibility providers. Willing
34
35 customers would effectively create spare grid capacity for the DNOs/DSOs as
36
37 necessary (AF-Mercados et al., 2015). However, even though this approach
38
39 reflects the grid utilisation of each customer, it would not necessarily incentivise
40
41 customers to avoid peak times if those times were not priced at a higher rate.
42
43
44
45
46
47
48
49
50

51
52 Another approach to including the grid utilisation in network pricing is to charge
53
54 customers for all distribution **services** they require (Brown et al., 2015).
55
56
57
58 Thereby, the DNOs/DSOs might offer a catalogue of services around reliability,
59
60
61
62
63
64
65

1 electricity volume, balancing, capacity, and maintenance that customers can
2
3 access based on customised profiles derived from their LEGD and demand
4
5 patterns. Faruqui et al. (2012) suggest an approach along these lines, with
6
7 suppliers making provision for volume and price risk in electricity rates. They
8
9 effectively suggest suppliers recover their hedging costs through an insurance
10
11 fee paid by customers. Likewise, DNOs/DSOs could offer LEGD-customers
12
13 such an insurance service securing the reliability of supply to them when their
14
15 own generation is too low or their consumption is too high. Hereby,
16
17 DNOs/DSOs would be compensated for their services to provide back-up grid
18
19 capacity and electricity and LEGD-customers would hedge their risk of high
20
21 rates by paying a recurring fee. Nevertheless, this approach fails to meet the
22
23 principle of economic efficiency because it does not incentivise customers to
24
25 avoid excess demand and supply. Its potential complexity might also act as a
26
27 disincentive to small-scale LEGD uptake, which is politically and
28
29 environmentally undesirable.
30
31
32
33
34
35
36
37

38 A possible solution for a sustainable distribution price, as a fraction of the
39
40 overall energy bill, might emerge from the **combination of a service charge**
41
42 **with a peak price element, an increased fixed-charge, and a general tax.**
43
44 The first three elements would provide cost recovery. Depending on the LEGD-
45
46 profile, services would need to be booked that actually reflected the costs each
47
48 customer generates. The electricity price during on-peak times would be higher
49
50 than during off-peak times and customers, exceeding their booked capacity,
51
52 would have to pay a higher price for each additional unit. This threshold function
53
54 would make customer profiles more predictable, incentivise them to stay below
55
56
57
58
59
60
61
62
63
64
65

1 their contractual agreed limit, would shift demand to off-peak times, and would
2
3 lead to a fairer cost allocation. On the other hand, some LEGD-customers could
4
5 be rewarded by the DNOs/DSOs or suppliers to provide flexibility which would
6
7 reduce their overall electricity bill. Again, the added complexity might deter
8
9 consumers from taking up LEGD, which would be undesirable. To mitigate the
10
11 effects of the peak price element as well as the higher fixed-charge, vulnerable
12
13 customers could be financially supported by a general energy tax, as some
14
15 experts suggested. Addressing fuel poverty however might be seen by some
16
17 politicians as something that can be addressed separately through a more
18
19 directed policy that does not need to be specifically tagged to policy more
20
21 concerned with ensuring distribution networks remain financeable in a strongly
22
23 LEGD-enabled future (for example as with Great Britain's Energy Company
24
25 Obligation, (DECC, 2014)). However, a combination of a service charge with a
26
27 peak price element, an increased fixed-charge and a general tax would turn
28
29 today's simple electricity bill into a far more complex summary and customers
30
31 seem unlikely to have – or wish to develop – sufficient knowledge about the
32
33 services they require. All approaches demonstrate that cooperation between the
34
35 DNOs/DSOs and suppliers must be intensified to pass-through the price signals
36
37 indicating to customers a necessary shift in their demand patterns. If the price
38
39 signals cannot be passed along via electricity bills or more immediately via
40
41 smart meters and linked apps, customers will be unable to optimise their
42
43 consumption. Most of these approaches will require smart metering, to allow
44
45 data collection and analysis of customer use profiles and a market framework
46
47 which allows new services to come to market (Balta-Ozkan et al., 2014; Wood
48
49
50
51
52
53
54
55
56
57
58
59
60
61
62
63
64
65

1 et al., 2014). As stated by the experts, this also requires a legal framework to
2
3 allow the TSO, DNOs/DSOs and suppliers to be able to access and share data
4
5 in order to improve system balancing and dispatch. It further requires a data
6
7 collection and communication system capable of dealing with large data
8
9 volumes and also buy-in from consumers (McKenna et al., 2012). Since the
10
11 development in the sector requires a greater provision of ancillary services, the
12
13 business model of the DNO/DSO has to change to an active service provider,
14
15 and a regulatory framework which provides them with incentives for investment
16
17 in either active network management or more traditional forms dependent on
18
19 what is best for the network. The TSO will need to share its responsibility for
20
21 dispatch with the DNOs/DSOs.
22
23
24
25
26
27
28
29
30

31 **7. Conclusions and policy implications**

32
33
34 The transition to a smart grid in a low-carbon economy will change the function
35
36 of the grid to an acceptor, at least from the perspective of many consumers
37
38 turned prosumers or clients to ESCOs or aggregators, a backup provider of
39
40 electricity due to the intermittent generation and self-sufficient solutions of
41
42 LEGD, in particular to meet the demands of cities and large industrial users
43
44 (Balta-Ozkan et al., 2014). DNOs/DSOs will become active system managers to
45
46 satisfy the increased need for balancing and dispatch. Customers will need to
47
48 be incentivised to become providers of flexibility, moving demand to avoid peak
49
50 demand or to peak supply. The primacy of the volumetric charge in the current
51
52 pricing mechanism is obsolete. It neither reflects actual LEGD costs and the
53
54
55
56
57
58
59
60
61
62
63
64
65

1 grid utilisation of each customer nor does it reward DNOs/DSOs for service
2
3 provision. Beyond that, as consumers start to leave the grid the volumetric
4
5 charge will become increasingly expensive for those that remain, increasing
6
7 electricity bills for non-prosumers and potentially contributing to energy
8
9 access/poverty issues, intensifying the potential for a utility death spiral and
10
11 forcing increased cross-subsidisation among customers.
12
13
14
15

16 Concerning an innovative pricing approach, this research identifies four
17
18 essentials for a successful implementation of a new mechanism: (i) Closer
19
20 collaboration between the TSO and DNO/DSO concerning local dispatch to
21
22 improve system efficiency (in the UK this will include the need for the transition
23
24 from DNO to DSO). (ii) Installation of sufficiently advanced smart meters to
25
26 collect data and provide information about the actual contribution to the grid
27
28 utilisation of each customer (iii) Intensified cooperation between supplier and
29
30 DNO/DSO to pass-through price signals on the electricity bill. This is likely to
31
32 require changes in regulation relating to the structure of the sector and the way
33
34 that the current relationships are defined. (iv) A legislative framework to
35
36 facilitate data sharing and data management and communication among
37
38 network stakeholders – essentially a relaxation of current privacy law as an
39
40 enabler for new approaches to network management, and potentially to reduce
41
42 costs to the consumer.
43
44
45
46
47
48
49
50

51 This suggests the focus for future network pricing should be on services and
52
53 functions provided by the grid rather than on the commodity *power* itself. An
54
55 innovative approach might also incentivise customers to avoid times of peak
56
57 demand (and eventually perhaps favour times of peak supply), should reflect
58
59
60
61
62
63
64
65

1 the grid utilisation of each participant. Protection of vulnerable customers will
2
3 remain important and may become more complex as an issue.
4
5

6 Concerning DNO/DSOs, future network pricing must be sufficient to secure the
7
8 funding of grid maintenance, reinforcement and extension, and must allow
9
10 appropriate incentives for investments under conditions where there is
11
12 increased risk. The regulation needs to reward good management of this
13
14 increased risk while disallowing rentier behaviour. Innovation in pricing is
15
16 essential to enabling all of these outcomes.
17
18
19
20
21

22 Building on these aspects while balancing the regulatory principals, this
23
24 research proposes a pricing mechanism consisting of a *service charge*
25
26 *combined with a peak price element, an increased fixed-charge, and a general*
27
28 *tax*. Since this would lead to a more complex electricity bill, more research is
29
30 needed on either simplifying it for the consumer or on introducing practices for
31
32 educating customers about more complex tariff options. Further research is
33
34 needed to explore whether consumers will respond to the potential for
35
36 accessing reduced rates as an incentive for this engagement. While
37
38 increasingly complex tariffs are seen by many as a possible by-product of the
39
40 switch to a smarter grid the switch to adopt them will require political support,
41
42 which may not be available. The UK political paradigm for example currently
43
44 favours simplification of tariffs (Richards and White, 2014).
45
46
47
48
49
50

51 The exact charging mechanism concerning LEGD-costs recovery or
52
53 socialisation is a political and regulatory question since the distribution network
54
55 is a shared resource and the trade-off associated with the regulatory principals
56
57
58
59
60
61
62
63
64
65

1 cannot be resolved. Any selection may favour different patterns of electrical
2 generation or consumption and may involve equitability and access issues
3 which need to be considered in the decision making process. Resolving this
4 question will determine the winners and losers from a revised pricing approach
5 to support a low-carbon electricity sector.

Table 1

Capital costs	Depreciation, interest rate, overhead lines, underground cables, information and communications technology, substations, metering systems, control centres and costs that occur from asset upgrades
O&M costs	System services, maintenance
Procurement costs	Distribution losses (linked to the level of the power price)
Services	Commercial costs, information technology systems, communication systems, concentrators
Overhead costs	Indirectly linked to O&M costs

Source: Adapted from Union of the Electricity (Union of the Electricity Industry, 2013).

Table 2

Element type	Determination	Use
Volumetric charge (€/kwh/period)	According to the consumed energy by the customer	Variable network costs
Fixed charge (€/period)	Independent from consumed power or energy	Costs for infrastructure supply Costs for shipping

Source: Derived from Picciariello et al. (2015) and AF-Mercados et al. (2015).

Table 3

Energy technology	Average lifetime load factor
Closed-cycle gas turbine	93 %
Nuclear	91 %
Coal ¹	90 %
Onshore Wind ²	28 %
Offshore Wind ³	39 % ³
Large scale solar PV	11 %

Source: (DECC (2013))

¹ Integrated Gasification Combined Cycle (IGCC) with Carbon Capture and Storage (CCS); first of a kind.

² Larger than 5 MW installed in the UK.

³ This load factor is for *Round 3 offshore windmills* only.

Table 4

Energy source	Net installed capacity ¹	Peak production ²	Load factor at peak production ³	Average load factor in 2015 ⁴
Solar	38.310 GW ⁵	27.3 GW ⁶	71.26 %	10.88 %
Windmills ⁷	44.947 GW ⁸	35.6 GW ⁹	79.20 %	23.61 %
Solar & Windmills	78.210 GW ¹⁰	43.4 GW ¹¹	55.49 %	17.48 %

¹ *Net installed capacity* is the maximum electricity that could have been generated by the selected *energy source* under the condition that the load factor of the selected *energy source* was 100%.

² *Peak production* is the highest electricity output of the selected *energy source* that was actually generated.

³ *Load factor at peak production* is the percentage of the *net installed capacity* that was reached by the actual electricity generation at time of the peak. Calculation: *peak production* divided by *net installed capacity*.

⁴ The *average load factors in 2015* are calculated based on data provided by Fraunhofer ISE (2016) and Burger (Burger, 2016). Calculation: Electricity production of the selected energy source divided by the product of the average net installed capacity of the selected energy source multiplied by 8760 hours.

⁵ *Net installed capacity of solar* in April 2015 (month of the peak). Data retrieved from Fraunhofer ISE (2016).

⁶ *Peak production of solar* in 2015 was on 21 April 2015 and is based on Burger (Burger, 2016).

⁷ The data of *windmills* combines onshore and offshore wind power generation.

⁸ *Net installed capacity of windmills* in December 2015 (month of peak production). Data retrieved from GWEC (GWEC, 2016).

⁹ *Peak production of windmills* in 2015 was on 21 December 2015 and is based on Burger (Burger, 2016).

¹⁰ *Net installed capacity of solar & windmills* in March 2015 (month of joint peak production) was calculated by adding the net installed capacity of solar (38.22 GW; retrieved from Fraunhofer ISE (2016)) and the sum of net installed capacity of onshore wind (38.39 GW) and offshore wind (1.6 GW) in March 2015. Because only yearly figures for the installed offshore capacity are available, the value 1.6 GW has been calculated by adding the installed capacity at the end of 2014 to three times the average monthly increase of the installed capacity in 2015.

¹¹ The joint peak production of *solar* and *windmills* at the same time was on 30 March 2015 at 14:00h and is based on data provided by Fraunhofer ISE (2016).
