Ehlers-Danlos Syndrome: A Multidisciplinary Approach

Generalized hypermobility has been known since ancient times, and a clinical description of Ehlers-Danlos syndrome (EDS) is said to have first been recorded by Hippocrates in 400 BC. Hypermobility syndromes occur frequently, but the wide spectrum of possible symptoms, coupled with a relative lack of awareness and recognition, are the reason that they are frequently not recognized, or remain undiagnosed.

This book is an international, multidisciplinary guide to hypermobility syndromes, and EDS in particular. It aims to create better awareness of hypermobility syndromes among health professionals, including medical specialists, and to be a guide to the management of such syndromes for patients and practitioners. It is intended for use in daily clinical practice rather than as a reference book for research or the latest developments, and has been written to be understandable for any healthcare worker or educated patient without compromise to the scientific content. The book is organized as follows: chapters on classifications and genetics are followed by chapters on individual types, organ (system) manifestations and complications, and finally ethics and therapeutic strategies, with an appendix on surgery and the precautions which should attend it. A special effort has been made to take account of the perspective of the patient; two of the editors have EDS.

The book will be of interest to patients with hypermobility syndromes and their families, as well as to all those healthcare practitioners who may encounter such syndromes in the course of their work.

Preface

We are a team of Dutch authors and editors, two of whom are Ehlers-Danlos syndrome (EDS) patients. In 2005, along with several co-authors and with financial support from the Dutch EDS support group "VED", we published a book entitled: "Ehlers-Danlos syndroom. Een multidisciplinaire benadering" (Ehlers-Danlos syndrome. A multidisciplinary approach). The aim of this multidisciplinary, practical book was to create more awareness for and increase the knowledge of hypermobility syndromes, especially EDS and benign joint hypermobility syndrome, among health professionals, including medical specialists, and to be a guide for patients. Hypermobility syndromes often are characterised by extra-articular signs and symptoms that often go unrecognised or are only recognized at a late stage. The ultimate goal was to improve care for patients with hypermobility syndromes, and this proved to be a great success.

Realising that this book indeed filled a gap in the health care system, some years ago the idea arose to publish an international multidisciplinary book on hypermobility syndromes with the help of international authors, with the same aims as those for the Dutch book. This has proven not to be a simple endeavour, but we think we eventually have succeeded. We hope it will meet our aims, described above, and your hopes and expectations. To make this book easily accessible to patients and health care workers, we decided to publish it as a freely available e-book. Financial support was given by many organisations (see the acknowledgements on the next page), for which we are very grateful.

Table of contents

Chapter 1. History and introduction

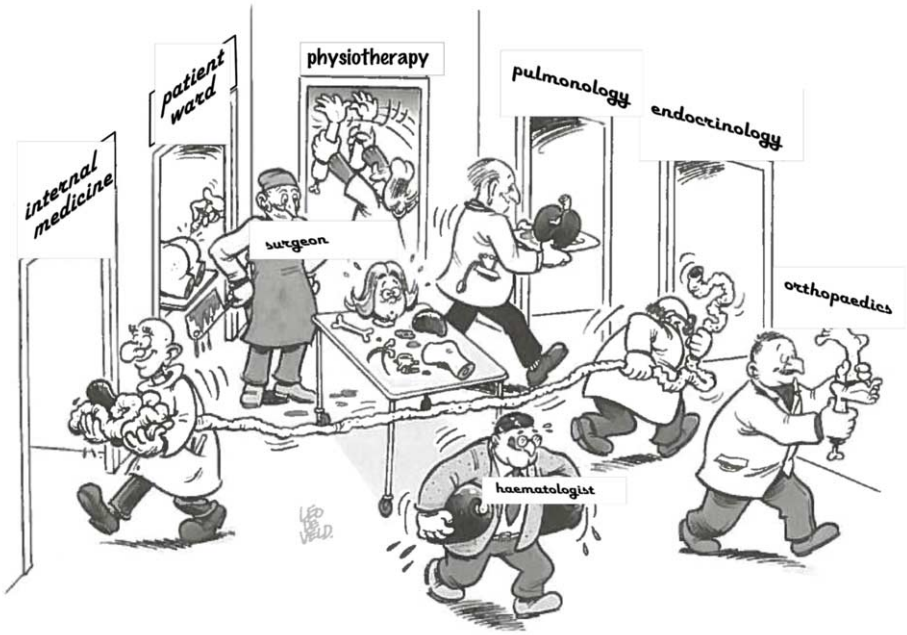
Generalised hypermobility has been known since ancient history; for instance Peruvian ceramic figures of 1200–200 B.C. visualize hypermobile individuals. The clinical picture of Ehlers-Danlos syndrome (EDS) is said to be first described by Hippocrates in 400 B.C. The Dutch surgeon Job Janszoon van Meek'ren in 1657 and the Russian dermatologist Tschernogobow in 1892 described the clinical picture of EDS, but EDS was named after the Danish dermatologist Edvard Lauritz Ehlers (1863–1937), who recognized the condition as a distinct entity in 1901 and after Henri-Alexandre Danlos, a French physician (1844–1912), who suggested in 1908 that skin extensibility and fragility are cardinal features of EDS.[1] Since about the first half of last century, several case reports of EDS and other hypermobility syndromes were published. In the earliest publications, several signs and symptoms have been described as associated with EDS, which later proved to be not to be related with EDS, such as mental retardation, bleeding disorders and anatomical cardiac anomalies.

In the second half of last century, also classifications were formulated,[2,3] based on patterns of inheritance and clinical features. With the development of genetic techniques and more systematic research, new genetic defects and subsequently several new types of EDS and other hypermobility syndromes have been recognised and very likely more will be distinguished in the future, necessitating continued updating of existing classification systems. This will probably take place during international congresses, such as that in New York City May 2016. Laboratory testing for most of the hypermobility syndromes has become possible. However, there is no curative treatment for these syndromes, though in vascular EDS celiprolol and in Marfan syndrome losartan have been proven to diminish the risk of vascular complications, likely due to mechanisms beyond that of lowering blood pressure.[4,5]

In contrast with these developments and the relatively frequent occurrence of hypermobility syndromes is the relative lack of awareness and recognition of these syndromes in daily clinical practice with underdiagnosis as result. This could be due to the wide spectrum of possible signs and symptoms. Although - as said - therapeutic options are meagre, recognition and diagnosis of a hypermobility syndrome in a patient are beneficial, ending an often year-long quest for the cause of signs and symptoms and guiding management. When the quest ends, finding a way of coping for patient and because of the genetic nature of these syndromes also for his/her family can start. For hypermobility syndromes with the risk of life-threatening complications, recognition and diagnosis might even be life-saving.

The aim of this book is creating more awareness for hypermobility syndromes, especially EDS, among health professionals, including medical specialists, and being a guide for patients, in order to improve the care for patients with hypermobility syndromes. This book is not meant as a reference book for basic research or the newest developments; it is meant for usage in daily clinical practice, with a practical, clinical scope, as much as possible in a reading level of text, health care worker or educated patient can understand, without compromise to the scientific content. Bearing our purpose in mind, we believe this book should be widely available, which we have attempted to achieve by publishing it as an E-book.

Patients with hypermobility syndromes, having a wide spectrum of signs, symptoms, manifestations and complications, often get to deal with a wide array of medical specialists and other health care providers, who each have a special interest in and knowledge about a specific organ or physical system. The description of these symptoms by only one person with one specialism is bound to be a bit one-dimensional (see figure).



A generalist with extensive knowledge of virtually all organ systems possibly affected or influenced by hypermobility syndromes does not exist. Next best for an individual patient would be a clinician acting as case manager. We would welcome development of multidisciplinary outpatient clinics for patients with hypermobility syndromes.
Both a case manager and a multidisciplinary outpatient clinic should take the whole spectrum of possible manifestations into account. This is the reason we chose for our book the scope and vision from different specialisms on the subject, trying to describe the whole spectrum of manifestations, as much as possible at the persons level, rather than at the organ level. The drawback of this choice is some heterogeneity in the medical level and length of chapters, and some overlap between chapters, which we accepted. The outline of the book is as follows: first there are chapters on classifications and genetics, then chapters on individual types, organ (system) manifestations and complications, and at the end ethics and therapeutic strategies, with an appendix on (precautions at) surgery. With the efforts of two of our editors, who suffer from EDS, we tried to incorporate also the patient's perspective.

In May 2016 in New York an international symposium of the Ehlers-Danlos Society took place, with propositions of changes regarding classification and nosology.[6] We incorporated these changes into this book. Given the fast developments in research, particularly in genetic testing through the widespread introduction of next generation sequencing, it might be that criteria sets, classifications and genetic tests, will be further updated in the near future. However, we feel that for the purpose of the book this is not a major obstacle, and can update the text, given this is an e-publication. So, if our book leads to earlier recognition of patients with hypermobility syndromes and better management, and functions as a practical guide for patients and their families and friends in daily practice, we feel we have met our aim. We hope you will enjoy reading it.

1. Introduction

Ehlers-Danlos syndrome (EDS) comprises a clinically and genetically heterogeneous group of heritable connective tissue disorders (HCTD), mainly characterized by a variable degree of generalized joint hypermobility, skin hyperextensibility, easy bruising and skin fragility. When in 1956 the first edition of McKusick's book entitled "Heritable disorders of connective tissue" was published, less than 100 papers had been devoted to EDS, mainly case reports.[1] At about the same time it became clear that EDS basically was an autosomal dominant, clinically and probably also genetically heterogeneous disorder. In his classical monograph on EDS, published in 1970, Beighton described 5 EDS types: I = gravis (severe), II = mitis (mild), III = hypermobility, IV = ecchymotic, and V = X-linked.[2] The Berlin classification listed 11 EDS types.[3] Revision became necessary because of new biochemical, molecular and clinical data, leading to the Villefranche nosology of 1997, in which 6 EDS types were recognized.[4] New clinical and molecular data required another revision, which was initiated during the Ehlers-Danlos Society International Symposium in New York, May 2016, the results of which have been published in the March 2017 issue of the American Journal of Medical Genetics Part C, Seminars in Medical Genetics. The most striking changes were:

- incorporating EDS types which were published since the Villefranche nosology, leading to a total number of 13 types.[5]
- deciding - not unexpectedly though - that EDS hypermobility type and benign joint hypermobility syndrome (BJHS; also called joint hypermobility syndrome or hypermobility syndrome) are in fact part of one and the same clinical spectrum ranging from apparently symptomatic generalized joint hypermobility to the most disabled individuals fitting the new diagnostic criteria. These new criteria are more strict than the Villefranche criteria and the Brighton criteria for BJHS in order to define a homogeneous phenotype for management and scientific purposes. Its name is hypermobile EDS.

It always has been, and still is, a challenge to classify individual patients in one of the existing EDS types. Often this is not possible. This is, among other things, due to:

- the clinical overlap between many of these EDS types
- absence of a pathogenic variant in any of the known EDS associated genes in an important proportion of EDS patients.
- the presence of associated features which do not fit into one of the existing types.
- the absence of a laboratory test for hypermobile EDS.

EDS is not a rare disorder; the prevalence is estimated to be about 1:5000. The hypermobile type - by far the most common - and the classical type comprise more than 90% of all cases.[6]

2. Classification and nosology

The New York classification is based on clinical, biochemical and molecular data.[5] Table 2-1 shows the New York nosology alongside the previous nosologies with inheritance patterns, genetic bases and proteins, while in table 2-2 EDS types are grouped according to underlying genetic and pathogenetic mechanisms; OMIM numbers (see glossary) are added.

In clinical practice, the clinical manifestations guide the choice for further investigations. The major clinical manifestations of EDS need some clarification, however.

Skin hyperextensibility should be tested at specific sites, e.g. the volar side of the non-dominant forearm or the dorsum of the hand by pulling up the skin until resistance is felt. In contrast to cutis laxa, a group of clinically and genetically heterogeneous disorders characterised by redundant, sagging and inelastic skin, with or without joint hypermobility, in EDS the skin snaps back after release.[7] The upper limit of normal for the forearm and dorsum of the hand is about 1 ½ cm.[8] In young children it is difficult to assess hyperextensibility due

to the abundance of subcutaneous fat. Skin hyperextensibility can also be assessed at the dorsal aspect of the elbow in 90^0 flection, where the upper limit of normal is 3 cm.
Joint hypermobility is scored using the Beighton mobility scale (table 2-3). In the New York nosology, a score of 5/9 or more defines generalized hypermobility in both sexes, though it is known that joint mobility depends, apart from age, family and ethnic background, also on gender. Since laxity decreases with age, patients with a Beighton score <5/9 may be considered positive based on their historical observations (five-point questionnaire = 5PQ; see footnote with table 2-4). For the diagnosis of hypermobile EDS different age and sex specific cut-off points were proposed (see table 2-4). In children under the age of about 5 years, the Beighton scale is less useful. Not infrequently, the Bulbena mobility score is also used (table 2-4), in which a score of 5/10 or more defines generalized hypermobility in females and 4/10 or more in males. It is more easily applicable in children. Generalised hypermobility is not rare: 5-10% of – mainly female – secondary school age Caucasian children is hypermobile.[8,9]
Easy bruising is seen as spontaneous ecchymoses, frequently recurring in the same bodily regions, of which long-term signs are often visible as brownish discoloration (haemosiderin), in particular on knees and shins. If it is the predominant presenting sign, child abuse and bleeding disorders need to be considered first.
Tissue fragility is manifested in the skin as easy bruising and impaired wound healing with dystrophic scars, which are usually found over pressure points like forehead, chin, elbow, knee and shin and which may have a wide and papyraceous appearance. Internal organs like arteries, lungs, intestines, liver, spleen and uterus may also show fragility, predominantly in the vascular type.
Some features are regularly observed, but are not criteria of generalised hypermobility syndromes. One example is the ineffectiveness of local anaesthetics in hypermobile EDS.[10]
In table 2-5 the major and minor diagnostic criteria are shown, minimal criteria for diagnosis and how to verify the diagnosis.
A major diagnostic criterion predominantly has high diagnostic specificity, which means that it is present in the vast majority of the affected individuals and/or it is characteristic for the disorder and allows differentiation from other EDS types and/or other HCTD. A minor criterion is a sign of lesser diagnostic specificity, but its presence supports the diagnosis. However, in the absence of major criteria, minor criteria are not sufficient for a given diagnosis. Because of the vast genetic heterogeneity and phenotypic variability of the EDS types and the clinical overlap between many of these, the definite diagnosis relies for all types, except the hypermobile type, on molecular confirmation.
In older publications features like facial dysmorphisms and mental retardation/intellectual disability were attributed to EDS, whereas nowadays these features are not any longer considered characteristics of EDS, except for facial dysmorphisms in vascular, dermatosparaxis, spondylodysplastic and musculocontractural EDS and intellectual disability in spondylodysplastic EDS (see table 2-5). Explanation for this could be that other syndromes associated with these features were erroneously diagnosed as EDS because of overlapping features with EDS. Another explanation is that these other features are not rare and consequently are found associated with EDS in a low percentage of cases.

The *classical EDS* has all the skin and joint characteristics of EDS, though in variable range of severity. Minimal diagnostic criteria are the presence of skin hyperextensibility and atrophic scars, plus either generalized joint hypermobility and/or 3 minor criteria (see table 2-5).[11] A recent paper reviews 62 molecularly confirmed cases from Italy.[12] It is inherited in an autosomal dominant fashion (see glossary), implying that each child (be it a boy or a girl) of an affected parent (be it father or mother) has a chance of 50% (= ½) of also having the classical type of which the expression (see glossary) cannot be predicted. However, sporadic

cases (i.e. without an affected parent) do occur due to a spontaneous mutation. Genetically, it is heterogeneous since in over 90% of patients, who fulfil all major criteria, a defect can be found in (products of) one of the two genes that are up to now known to be involved, *COL5A1* and *COL5A2*. An EDS type resembling the classical type but clinically characterized by a propensity to arterial rupture and molecularly by a specific mutation in *COL1A1* (c.934C>T; p.Arg312Cys) is regarded as a variant type of classical EDS.[13,14] Once the causative mutation has been found in a proband (see glossary), mutation analysis in relatives of the proband is possible. The major differential diagnosis of the classical type, at least in a sporadic case, is the classical-like EDS. Also, in mild cases of the classical type (partial expression), differentiation from the hypermobile type might be difficult, if not impossible.

Classical-like EDS resembles the classical type, however with normal wound healing and scar formation.[14,15] Minimal diagnostic criteria are the presence of all 3 major criteria, i.e. skin hyperextensibility, generalized joint hypermobility and easy bruisability and a family history compatible with autosomal recessive inheritance. It is characterised by generalized hypermobility, with a remarkable laxity of finger joints. In contrast with the classical type, its inheritance is autosomal recessive, so most cases are sporadic and some occur in sibships. It is due to tenascin-X deficiency. In serum, tenascin-X is completely absent and mutation analysis (*TNX-B*) is performed in blood.

The *cardiac-valvular EDS* is rare.[14,16] Apart from typical EDS features, it is associated with severe aortic and/or mitral valve insufficiency, necessitating valve replacement at relatively young age. Minimal diagnostic criteria are the presence of severe progressive cardiac-valvular problems, family history compatible with AR inheritance **plus** either one other major criterion and/or at least 2 minor (see table 2-4). The inheritance is autosomal recessive. It is due to homozygous or compound heterozygous *COL1A2* null mutations (see glossary).

The *vascular EDS* is the most severe form of EDS.[17] Minimal diagnostic criteria are the presence of of a family history of vascular EDS, arterial rupture/dissection <40 years, unexplained sigmoid colon rupture or spontaneous pneumothorax in the presence of other features consistent with vascular EDS. These and a combination of minor criteria warrant verifying diagnostic tests, i.e. DNA analysis (see table 2-5). Diagnosis in children is difficult, particularly in the absence of a family history. The vascular type is inherited in an autosomal dominant fashion. Arterial rupture is the most common cause of sudden death and has its peak incidence in the 3rd or 4th decade. Acute abdominal and flank pain is a common presentation of an arterial or intestinal rupture and needs urgent investigation and treatment. Recently, Frank et al. showed that the type of *COL3A1* mutation is associated with the phenotype and severity: patients with glycine substitutions and splice-site and in-frame insertions–deletions have a more severe phenotype, including digestive events, compared to e.g. mutations leading to non-glycine missense variants or haplo-insufficiency, due to a null allele. The latter may delay onset of complications by almost 2 decades.[17,18]
For women with the vascular type, pregnancy and delivery pose specific risks, which warrant pre-conceptional counselling with an experienced obstetrician and clinical geneticist.[19]
There is considerable clinical overlap between the vascular type and Loeys-Dietz syndrome type 1 and 2 (OMIM 609192 and 610168 respectively; see chapters 5 and 6 for details and 3 more types), which are due to *TGFBR1* (type 1) and *TGFBR2* (type 2) mutations.[20] Also other aortic aneurysm syndromes, such as Marfan syndrome, Thoracic Aortic Aneurysm and Dissection (TAAD), annulo-aortic ectasia should be included in the differential diagnosis.[21]
As said above, when extensive bruising is the initial presentation and the only sign/symptom, bleeding disorders and child abuse have to be considered.

The *hypermobile EDS*, incorporating BJHS, is dominated by generalized joint hypermobility and its possible sequelae, in particular chronic pain, which can be severe and invalidating, and possibly early osteoarthritis.[22] As said, the new diagnostic criteria are more strict than those of the Villefranche criteria and the Brighton criteria (see table 2-5 and chapter 5). The clinical diagnosis of hypermobile EDS needs the simultaneous presence of 3 criteria: criterion 1 = generalized joint hypermobility, criterion 2 = 2 or more of the features A, B and C (A = systemic manifestations of a more generalized connective tissue disorder; B = positive family history; C = musculoskeletal complications) and criterion 3 = absence of unusual skin fragility and exclusion of alternative diagnosis (for details see table 2-5 and chapter 5). Recently, also cardiovascular dysautonomia (mainly postural tachycardia syndrome = POTS), functional gastro-intestinal manifestations, sleep disturbance, fatigue, depression and anxiety disorders have been attributed to hypermobile EDS, but these are at the moment not sufficiently sensitive nor specific. Basically, there is no confirmative laboratory test for the hypermobility type, meaning that it is a pure clinical diagnosis. Recently, Syx et al. reported linkage to chromosome 8p22-8p21.1 in a 3 generation Belgian family with EDS hypermobility type, whereby whole exome sequencing revealed a possibly involved gene.[23] Up to recently, BJHS was considered a separate entity with its own diagnostic criteria.[24] It was already argued earlier that the hypermobility type and BJHS are in fact one and the same disorder with variable expression. Arguments put forward for this were among others the fact that haplo-insufficiency of *TNX-B*, assessed as about half of the normal activity of tenascin-X in blood, and/or heterozygosity for a pathogenic *TNX-B* mutation, is found both in cases with EDS hypermobility type and cases in whom BJHS is the more likely diagnosis.[25] Also, a changing phenotype from one diagnosis into the other in one individual and in some pedigrees the occurrence of both diagnoses argued for this statement.[26]
Castori et al. proposed a frame for the classification of joint hypermobility and related syndromes, which is worth reading.[27]

The *arthrochalasia EDS* is also rare, but diagnosable at birth.[14] Minimal criteria suggestive for arthrochalasia EDS are congenital bilateral hip dislocation plus either skin hyperextensibility or severe generalized joint hypermobility with multiple dislocations/subluxations and at least 2 other minor criteria It is inherited in an autosomal dominant fashion. It is due to specific mutations in *COL1A1*or *COL1A2*. Larsen syndrome, which also features congenital luxations, should be in the differential diagnosis.

The *dermatosparaxis EDS* derives its name from a similar phenotype and biochemical defect in cattle, sheep, and other animals.[14] It is the EDS type which has the closest resemblance to cutis laxa. However, in cutis laxa there is neither fragility nor bruising. Its mode of inheritance is autosomal recessive. It is one of the rarest of all types and since only very few cases have been described, possibly this type is characterised by other - as yet unrecognised - features. Recently, Van Damme et al. expanded the phenotype and suggested new diagnostic criteria.[28] The New York nosology requires for its diagnosis extreme skin fragility with congenital or postnatal skin tears AND characteristic craniofacial features **plus** either 1 other major and/or 3 minor criteria (for details see table 2-5). It is due to mutations in *ADAMTS2*. The mode of inheritance is autosomal recessive (see glossary), whereby both parents of a patient are healthy carriers and the recurrence risk for siblings is 25% (= ¼).

The *kyphoscoliotic EDS* is a rare but severe form of EDS, manifesting itself often at or shortly after birth.[14,29] The presence of congenital muscle hypotonia AND congenital or early onset kyphoscoliosis **plus** either generalized joint hypermobility and/or 3 minor criteria (either

general or *PLOD1* and *FKBP14* gene-specific) warrants laboratory testing. Kyphoscoliotic EDS is genetically heterogeneous and can be caused by mutations in *PLOD1* and *FKBP14*. Laboratory tests should start with measurement of the urinary lysyl and hydroxy-lysyl pyridinoline ratio. An increased ratio has a very high degree of sensitivity and specificity for *PLOD1* mutations, but not for *FKBP14* mutations. For molecular tests: see table 2-5. The mode of inheritance is autosomal recessive (see glossary), whereby both parents of a patient are healthy carriers and the recurrence risk for siblings is 25% (= ¼). Because of severe hypotonia, patients very often undergo a full scale neuromuscular work-up, including a muscle biopsy before the diagnosis is established. The differential diagnosis comprises all other causes of severe hypotonia, including neonatal Marfan syndrome.

The even rarer *brittle cornea syndrome* (formerly EDS VIB) resembles the kyphoscoliotic type, but is generally milder.[14,30] Minimal diagnostic criteria are thin cornea with or without rupture **plus** either at least one other major criterion and/or 3 minor criteria (see table 2-5). It shows a normal urinary lysyl and hydroxy-lysyl pyridinoline ratio, and is characterised by mutations in the genes *ZNF469* or *PRDM5.*

Spondylodysplastic EDS is genetically heterogeneous and is due to bi-allelic mutations in either *B4GALT7* (former name progeroid type 1[31]), *B3GALT6* (former name progeroid type 2[32]) or *SLC39A13* (former name spondylocheirodysplastic type[33]).[14] There is considerable overlap with kyphoscoliotic EDS. Minimal diagnostic criteria are short stature AND muscle hypotonia **plus** characteristic radiographic abnormalities and at least 3 other minor criteria (general or gene-specific; see table 2-5).
The urinary lysysl and hydroxylysyl pyridinoline ratio is moderately increased (to approximately 1 compared to normal values of ~ 0.2) with HLPC for *SLC39A13* mutations.

The *musculocontractural EDS* (formerly EDS VIB) is due to bi-allelic mutations in either *CHST14* gene (type 1) or more rarely *DSE* gene (type 2) and has also considerable clinical overlap with the kyphoscoliotic type.[14,34] Minimal diagnostic criteria are at birth or in early childhood congenital multiple contractures AND characteristic craniofacial features, while in adolescence and adulthood these are congenital multiple contractures AND characteristic cutaneous features.

Myopathic EDS is caused by heterozygous or bi-allelic mutations in *COL12A1*.[14,35] Minimal diagnostic criteria are congenital muscle hypotonia and/or muscle atrophy that improves with age plus either one other major criterion and/or three minor criteria. The phenotype highly overlaps with collagen VI type related myopathies, i.e. Bethlem myopathy and Ullrich Congenital Muscular Dystrophy.

The *periodontal EDS* has some overlap with the classical type, but has progressive and aggressive periodontitis as a distinguishing feature.[14] Minimal diagnostic criteria are severe, intractable periodontitis of early onset (childhood or adolescence) OR lack of attached gingiva plus at least 2 other major criteria and one minor criterion. Recently, it was found that gain-of-function mutations in the *C1R* gene or the *C1S* gene, encoding serine proteinases, cause periodontal EDS.[36]

The former EDS type V (X-linked) has been described in only 2 families and is not any longer accepted as belonging to EDS spectrum, the same holds true for the former fibronectin deficient type X, familial articular hypermobility EDS XI and Filamin A related EDS with heterotopia. The former type IX is an X-linked cutis laxa disorder and is renamed occipital

horn syndrome; it is due to mutations in the gene *ATP7A*, the same gene as is mutated in Menkes syndrome (disorder of copper metabolism)

For further reading, the excellent review by Byers and Murray is highly recommended, together with the more recent paper by Malfait et al.[14,37] In fact, the whole March 2017 issue of the American Journal of Medical Genetics Part C, Seminars in Medical Genetics provides a very good update not only about EDS nosology and diagnostic criteria, but also about management aspects of the various types of EDS.

Joint hypermobility is a symptom of large variety of syndromes.
A search in the London Medical Databases (suite.face2gene.com/lmd-library-london-medical-database-dysmorphology/) with "joint laxity or multiple joint dislocations" as key words gives more than 290 hits. Among these, one finds - not surprisingly - other heritable connective tissue disorders like cutis laxa, osteogenesis imperfecta, Stickler syndrome (see chapter 5), Loeys-Dietz syndrome and Marfan syndrome, but also skeletal dysplasias, inborn errors of metabolism, neuromuscular disorders, chromosomal abnormalities and syndromes like Larsen syndrome, Fragile X syndrome and Langer-Giedion syndrome.

3. How to achieve the diagnosis Ehlers-Danlos syndrome, including correct typing?
Like always in clinical practice, the results of history taking, including a family history, and physical examination are the basis for planning additional investigations and finally reaching a diagnosis. As mentioned above, additional investigations are often biochemical as a first screen, followed by targeted DNA analysis. However, with the introduction of new DNA technologies, like next generation sequencing, rapid search for the disease causing mutation by molecular analysis of (all) known EDS genes ("the EDS panel") at once has become possible. This is already standard routine diagnostic practice in some laboratories and will become routine in all in the near future (see chapter 3). Copy number variation analysis for large deletions and duplications has also a place in the molecular analysis in cases where NGS did not reveal a mutation in AD types and only one mutation in AR types.
As history taking and physical examination in relation to EDS are very important, they will be discussed below.

Good history taking starts with identifying the exact symptoms and complaints, which compelled the patient to see a physician: when and how did they start and evolve, how were they treated (what were the results, what was advised/prescribed and by whom?). Specific questions should elucidate the presence or absence of:

- Hypermobility and/or (sub)luxations. If (sub)luxation occurred: which joint(s) was/were involved, how often did it occur, was it spontaneous (also the first time) and painful? Was it seen/treated by doctors? If necessary also the Five-Point Questionnaire (5PQ; see footnote in table 2-5). Contractures? Congenital hip dislocation? (see chapters 5, 8, 22 and 24).[38,39]
- Painful joints.[40] If so: which ones, when, under which circumstances, exercise related, warm and swollen, if so, for how long? Use of analgesics? Sprains? What are the major limitations in daily life? (see chapters 20, 21, 22 and 24)
- Temporomandibular joint problems (see chapter 14).[41]
- Problems with bursae/tendons.
- (Spontaneous) fractures.
- Skin fragility and abnormal wound healing with wide atrophic scars (see chapter 9).
- Surgery, e.g. for inguinal hernia. If so: complications?
- Easy bruising and/or abnormal menstrual bleeding (see chapter 11).

- Abnormal exercise tolerance and/or fatigue.[42] Sports performed? Type of work: blue or white collar?
- Pneumothorax?
- Cardiac problems? Cardiovascular autonomic dysfunction?[43] (see chapter 12)?
- Genito-urinary tract problems, e.g. uterine prolapse, voiding dysfunction (see chapter 16).
- Gastro-intestinal tract problems, e.g. constipation, diverticula, rectal prolapse (see chapter 10).[44]
- For female patients with children: pregnancy and delivery problems (see chapter 17).[19]
- Rupture of internal organs (arteries, lungs, intestines, spleen, uterus).
- Psychiatric problems, like anxiety, depression, ADHD?[45]
- Neurological problems?[46,47] Headache? Migraine? (see chapter 13)
- Eye problems, e.g. refractive errors, abnormal vision (see chapter 15).
- Hearing?
- Growth?
- Motor and cognitive development?
- Miscellaneous: Gingivitis? Varicose veins? Abnormal effect of local anaesthesia?

The family history includes drawing a three generation pedigree with specific enquiry regarding hypermobility, easy bruising, abnormal scarring, arterial dissections and organ ruptures.

The physical examination is focused on signs relevant for connective tissue disorders:
- Build and biometry: height, weight, span and others when indicated. Marfanoid?
- Facial features: among others, Gorlin sign (ability to touch the tip of the nose with the tip of tongue)? High palate? Absence of subcutaneous fat? Prominent eyes? Thin, “pinched” nose? Normal earlobes? Epicanthic folds? Low-set ears? Midfacial hypoplasia? Micrognathia? Down-slanting palpebral fissures? Gingival recession?
- Teeth: dental crowding? Discoloured? Dysplastic? Periodontitis?
- Thorax: deformity?
- Back: (kypho)scoliosis?
- Extremities: Beighton score,; Bulbena score; arachnodactyly (wrist and thumb sign)? Brachydactyly? Clinodactyly? Contractures? Flat feet? Joints? Muscle strength? Edema? Hallux valgus?
- Skin: extensibility? Texture? Thickness and venous pattern? Striae distensae? Varicose veins? Piezogenic papules? Molluscoid pseudotumors? Spheroids? Scars? Herniae?
- Eyes: Blue sclerae? Microcornea? Strabismus? Clouded cornea? Glaucoma? Scleral/ocular fragility? Keratoconus?
- Neurological examination: muscle weakness? Reduction in vibration sense? Reduction of tendon reflexes?

Then a differential diagnosis will be established, on which basis additional investigations, such as biochemical and/or DNA analysis in blood and/or cultured fibroblasts, derived from a skin biopsy, are planned, if clinically relevant and available for the suspected type. Morphological examination of a skin biopsy is of limited value, except in some types, particularly in dermatosparaxis EDS. On indication, the patient will be referred to an ophthalmologist, cardiologist, orthopaedic surgeon, neurologist and/or others.
DNA analyses are available as diagnostic services in most of the developed countries. As already indicated, there is no DNA test available for hypermobile EDS. If there is any reason to believe the phenotype could be the classical-like, tenascin-X deficient type, then there is an indication to perform tenascin-X analysis in serum. If there is suspicion of vascular EDS, the

threshold to do DNA analysis should be very low, because of the consequences of that diagnosis in terms of management and genetic counselling. For some of the other EDS types the same holds true, because of their rareness, overlapping features with other EDS types and/or different modes of inheritance. In fact, for definite diagnosis molecular confirmation is needed for all types, except the hypermobile type.

4. Genetic counselling (see also chapter 19)
Since all the disorders which have been discussed have a genetic background, genetic counselling is an indispensable part of the management of patients and their families. During genetic counselling, information will be given about the mode of inheritance, recurrence risk, variability and penetrance of the disorder, the possibilities of prenatal diagnosis and diagnosis in relatives at risk and management. Prenatal diagnosis and diagnosis in relatives at risk is only possible if the causative DNA defect is known. A social worker should be available to assist whenever a need is perceived or requested. When there is a patient/parent support group, patients/parents should be informed. In case of a proband (see glossary) of non-EDS parents, it is essential to differentiate between an autosomal dominant (e.g. classical type) and an autosomal recessive type (e.g. classical-like, tenascin-deficient type): in the classical type the recurrence risk for a next child of these non-EDS parents is low (less than 1%) and for a child of the affected patient high (50%), while in the tenascin-deficient type the recurrence risk for a next child is high (25%) and for a child of the affected patient generally low (1% or less).

5. Areas of uncertainties/research agenda
- An international consensus on methods for measuring joint hypermobility and on more accurate tools for classifying patients with hypermobile EDS is needed.
- Controlled studies are necessary to establish the role of tenascin-X in hypermobile EDS.
- Controlled studies are needed to establish whether hypermobile EDS is a multisystem disorder, including among others cardiovascular dysautonomia (mainly postural tachycardia syndrome = POTS), functional gastro-intestinal manifestations, sleep disturbance, fatigue, depression and anxiety disorders. If that is the case, diagnostic criteria need to be adjusted.
- Research into the hypothesis: joint mobility is the end result of the contribution of many genes with each (probably) having a small effect, and exogeneous factors (multifactorial). The degree of joint mobility in a population shows a continuous distribution, comparable to body length and IQ. At the one extreme there is severe stiffness, and at the other severe hypermobility. At the extremes it is likely to find - rare - monogenic forms, but in between the extremes chances are high to find the more common forms of multifactorial origin. This could be the reason, that so far little has come out of genetic studies in EDS hypermobility type.
- Is classical-like, tenascin deficient EDS more frequent than thought up till now?
- Education of the general public and health care providers is needed to increase awareness of EDS with early diagnosis and proper management as a consequence. Particularly, it is important to understand that hypermobile EDS and benign joint hypermobility syndrome are one and the same disorder.
- International registries need to be established, particularly for the more rare types, in order to increase knowledge regarding the natural history, the phenotype and management.
- Provide evidence that management of EDS patients needs to be provided in multidisciplinary teams in expertise centres.

6. Summary

EDS comprises a group of heritable connective tissue disorders which has as cardinal features varying degrees of skin hyperextensibility, joint hypermobility, easy bruising and skin fragility. The 2017 New York nosology distinguishes 13 types of EDS, which all, except hypermobile EDS, have a known molecular basis. Hypermobile EDS is recognized as a common and often disabling disorder, incorporating benign joint hypermobility syndrome. EDS needs to be differentiated from other connective tissue disorders, in particular Marfan syndrome, Loeys-Dietz syndrome and cutis laxa. The frequent types of EDS can be diagnosed after careful history taking and clinical examination, but for definite diagnosis molecular confirmation is needed in all types. Management for EDS patients preferably is provided by multidisciplinary teams in expertise centres. After diagnosing EDS genetic counselling is an essential part of the management of patients and their family.

Table 2-1 Classification of Ehlers-Danlos syndrome (adapted from[5])

Berlin classification (1988) 11 types	**Villefranche classification (1997) 6 types**	**International classification (2017) 13 types**	**IP**	**Genetic basis**	**Protein**
Type I (gravis) and type II (mitis)	Classical type	Classical EDS cEDS	AD	Major: *COL5A1, COL5A1* Rare*: *COL1A1* c.934C>T, p.(Arg312)	Type V collagen Type I collagen
		Classical-like EDS clEDS	AR	*TNXB*	Tenascin XB
		Cardiac-valvular EDS cvEDS	AR	*COL1A2* (biallelic mutations that lead to *COL1A2* NMD and absence of pro a2(I) collagen chains)	Type I collagen
Type IVA,B,C,D	Vascular type	Vascular EDS vEDS	AD	Major: *COL3A1* Rare: *COL1A1* c.934C>T, p.(Arg312Cys) c.1720C>T, p.(Arg574Cys) c.3227C>T, p.(Arg1093Cys)	Type III collagen Type I collagen
Type III	Hypermobility type	Hypermobile EDS hEDS	AD	Unknown	Unknown
Type VIIA and B	Arthrochalasia type	Arthrochalasia EDS aEDS	AD	*COL1A1, COL1A2*	Type I collagen
Type VIIC	Dermatosparaxis type	Dermatosparaxis EDS cEDS	AR	*ADAMTS2*	ADAMTS-2
Type VIA	Kyphoscoliotic type	Kyphoscoliotic EDS kEDS	AR	*PLOD1* *FKBP14*	LH1 FKBP22

(continued on next page)

Type VIB		Brittle cornea syndrome BCS	AR	*ZNF469* *PRDM5*	ZNF469 PRDM5
		Spondylodysplastic EDS spEDS	AR	*B4GALT7* *B3GALT6* *SLC39A13*	b4GalT7 b3GalT6 ZIP13
Type VIB		Musculocontractural EDS mcEDS	AR	*CHST14* *DSE*	D4ST1 DSE
		Myopathic EDS mEDS	AD/ AR	*COL12A1*	Type XII collagen
EDS VIII		Periodontal EDS pEDS	AD	*C1R* *C1S*	C1r C1s
EDS V[#]			XL	Unknown	
EDS IX = cutis laxa syndrome			XL	*ATP7A*	Cu-transporting alpha polypeptide
EDS X[#] Fibronectin abnormality			AR	Unknown	
EDS XI[#] familial joint instability			AD	Unknown	

IP: inheritance pattern
NMD: nonsense mediated decay
* EDS classical type with (propensity to) arterial rupture.[13]
[#] No longer accepted as separate entities

Table 2-2 EDS grouping according to underlying genetic and pathogenetic mechanisms (adapted from[5])

Berlin or earlier name	**Villefranche name**	**New York name**	**OMIM**	**Gene**
GROUP A: Disorders of collagen primary structure and collagen processing				
EDS I EDS II	Classical type	Classical EDS (cEDS)	130000	*COL5A1* *COL5A2*
EDS IV	Vascular type	Vascular EDS (vEDS)	130010	*COL3A1*
EDS VIIA EDS VIIB	Arthrochalasia type	Arthrochalasia EDS (aEDS)	130060 130080	*Type I collagen*
EDS VIIC	Dermatosparaxis type	Dermatosparaxis EDS (dEDS)	225410	*ADAMTS2*
Cardiac-valvular EDS	-----	Cardiac-valvular EDS (cvEDS)	225320	*Type 1 collagen*
GROUP B: Disorders of collagen folding and collagen cross-linking				
Ocular-scoliotic EDS EDS VI/VIA	Kyphoscoliotic type	Kyphoscoliotic EDS (kEDS-*PLOD1*)	225400	*PLOD1*
----	----	Kyphoscoliotic EDS (kEDS-*FKBP14*)	614557	*FKBP14*
GROUP C: Disorders of structure and function of myomatrix, the interface between muscle and ExtraCellular Matrix				
----	----	Classical-like EDS (clEDS)	606408	*TNXB*
----	----	Myopathic EDS (mEDS)	616471	*COL12A1*
GROUP D: Disorders of glycosaminoglycan biosynthesis				
EDS progeroid type 1	----	Spondylodysplastic EDS (spEDS-*B4GALT7*)	130070	*B4GALT7*
EDS progeroid type 2	----	Spondylodysplastic EDS (spEDS-*B3GALT6*)	615349	*B3GALT6*
Adducted thumb-clubfoot syndrome Musculocontractural type EDS Kosho type D4ST1 deficient EDS	----	Musculocontractural EDS (mcEDS-*CHST14*)	601776	*CHST14*
----	----	Musculocontractural EDS (mcEDS-*DSE*)	615539	*DSE*

Table 2-3 Beighton mobility scoring scale*

Joint	Negative	Unilateral	Bilateral
Passive dorsiflexion of the 5th finger > 90°	0	1	2
Passive flexion of thumbs to the forearm	0	1	2
Hyperextension of the elbows > 10°	0	1	2
Hyperextension of the knees > 10°	0	1	2
Forward flexion of the trunk with knees fully extended and palms resting on the floor	0	1	
Total score (maximum=9):			

* a score of 5/9 or more defines generalized joint hypermobility for both sexes (for hypermobile EDS, age and sex related cut-off points are used; see table 2-5)

Table 2-4 Bulbena mobility scoring scale*

Joint	**Negative**	**Positive**
Passive exorotation of shoulder > 85º	0	1
Hyperextension of the elbow > 10º	0	1
Passive flexion of thumb to the forearm < 21 mm	0	1
Passive dorsiflexion of the 5th finger > 90º	0	1
Passive abduction of both hips > 85º	0	1
Heel touches nates on passive flexion of knee while lying on the abdomen	0	1
On passive movement of patella laterally it crosses the line between the anterior superior iliac spine and the medial malleolus	0	1
Passive dorsiflexion of ankle joint > 20º	0	1
Passive dorsiflexion of first metatarsophalangeal joint > 90º	0	1
Visible ecchymoses (on minimal trauma)	0	1
Total score (maximum=10):		

* a score of 5/10 or more defines generalized hypermobility in females and 4/10 or more in males.

Table 2-5 Diagnostic criteria, minimal criteria and verification of Ehlers-Danlos syndromes (data extracted from[5])

Types of EDS	Major diagnostic criteria	Minor diagnostic criteria	Suggestive minimal criteria for diagnosis	Verification of clinical diagnosis
Classical EDS	Skin hyperextensibility and atrophic scars Generalized joint hypermobility	Easy bruising Smooth, velvety skin Skin fragility (or traumatic splitting) Molluscoid pseudotumors Subcutaneous spheroids Hernia (or history thereof) Epicanthic folds Complications of joint hypermobility e.g. sprains, (sub)luxations, pain, pes planus First degree relative fulfilling clinical criteria	Skin hyperextensibility and atrophic scars, **plus** either generalized joint hypermobility and/or 3 minor criteria	Molecular screening of a targeted EDS gene panel, including at least *COL5A1*, *COL5A2*, *COL1A1* and *COL1A2*. When not available transmission electron microscopy (TEM) of skin biopsy (collagen flowers) might be supportive
Classical-like EDS	Skin hyperextensibility with velvety skin texture and absence of atrophic scarring Generalized joint hypermobility with or without recurrent dislocations Easy bruisable skin/spontaneous ecchymoses	Foot deformities: broad/plump forefoot, brachydactyly, pes planus, hallux valgus, piezogenic papules Edema of legs Mild proximal and distal muscle weakness Axonal polyneuropathy Atrophy of hand and foot muscles Acrogeric hands, mallet finger(s), clinodactyly, brachydactyly Vaginal/uterus/rectal prolapse	All 3 major criteria and a family history compatible with autosomal recessive inheritance	Molecular analysis of *TNXB* gene. If necessary CNV analysis for deletions. Complete absence of TNX in serum.
Cardiac-valvular EDS	Severe progressive cardiac-valvular problems Skin hyperextensibility, atrophic scars, thin skin, easy bruising Generalized or small joints hypermobility	Inguinal hernia Pectus deformity (mostly excavatum) Joint dislocations Foot deformities: pes (plano)valgus, hallux valgus	Severe progressive cardiac-valvular problems AND family history compatible with AR inheritance **plus** either one other major criterion and/or at least 2 minor	Molecular screening by Sanger sequencing of *COL1A2* or targeted resequencing of a EDS gene panel. If necessary CNV analysis for deletions and duplications. Total absence of (pro)α2(I) with SDS PAGE
Vascular EDS (continued on next page)	Family history of vEDS with molecular confirmation Arterial rupture at young age	Bruising without trauma and/or in unusual sites (cheeks, back) Thin, translucent skin with increased venous	A family history of vEDS, rupture/dissection <40 years, unexplained sigmoid colon rupture	Molecular screening by Sanger sequencing of *COL3A1* or targeted

	Spontaneous sigmoid colon perforation 3rd Trimester uterine rupture Carotid-cavernous sinus fistula (Last 3: in the absence of other explanations)	visibility Characteristic facial appearance Spontaneous pneumothorax Acrogeria Talipes equinovarus Congenital hip dislocation Hypermobility of small joints Tendon and muscle rupture Keratoconus Gingival recession and fragility Early onset varicose veins (<30 years and nulliparous if female)	or spontaneous pneumothorax in the presence of other features consistent with vEDS, a combination of other minor criteria should all lead to verifying diagnostic tests.	resequencing of a EDS gene panel, including *COL3A1* and *COL1A1*. If necessary CNV analysis for deletions and duplications.
Hypermobile EDS (continued on next page)	Generalized joint hypermobility (GHJ) assessed by Beighton score ≥ 6 for prepubertal children and adolescents ≥ 5 for pubertal men and women up to the age of 50 ≥ 4 for those > 50 years of age If the Beighton score is 1 point below the age- and sex-specific cut-off AND the 5-point questionnaire (5PQ)* is positive then a diagnosis of GJH can be made	***A:*** *systemic manifestations of a more generalized connective tissue disorder:* 1. unusually soft or velvety skin 2. mild skin hyperextensibility 3. unexplained striae distensae 4. bilateral piezogenic papules (heel) 5. recurrent or multiple abdominal hernias 6. atrophic scarring at 2 or more sites without truly papyraceous and/or hemosideric scars 7. pelvic floor, rectal and/or uterine prolapse in children, men or nulliparous women without obesity or other explanation 8. dental crowding and high/narrow palate 9. arachnodactyly (bilateral positive wrist or thumb sign) 10. arm span-to-height ≥ 1.05 11. mitral valve prolapse (echocardiographic criterion) 12. aortic root dilatation with Z-score > +2 ***B:*** *one or more first degree relatives independently meeting the criteria for hEDS* ***C:*** *musculoskeletal complications:*	1. Generalized joint hypermobility AND 2. Two or more among features A-C (A+B, A+C, B+C, A+B+C) must be present A: total of 5 must be present B: must be present C: 1 or more must be present AND 3. absence of unusual skin fragility AND exclusion of other heritable and acquired connective tissue disorders, including autoimmune rheumatologic disorders# AND exclusion of alternative diagnoses e.g. neuromuscular disorders, other Heritable Connective Tissue Disorders, and skeletal dysplasias	Not possible; hEDS is a clinical diagnosis. Sleep disturbance, fatigue, postural orthostatic tachycardia, functional gastro-intestinal disorders, dysautonomia, anxiety and depression are not part of the diagnostic criteria, but its presence may prompt consideration of hEDS in the differential diagnosis.

		1. pain in 2 or more limbs, recurring daily for at least 3 months 2. chronic widespread pain for ≥ 3 months 3. recurrent joint dislocations or frank joint instability in the absence of trauma (a or b) a. 3 or more dislocations in the same joint or 2 or more dislocations in 2 different joints occurring at different times b. medical confirmation of joint instability at 2 or more sites		
Arthrochalasia EDS	Congenital bilateral hip dislocation Severe generalized joint hypermobility with multiple dislocations/ subluxations Skin hyperextensibility	Muscle hypotonia Kyphoscoliosis Mild osteopenia (X-ray) Tissue fragility, including atrophic scars Easy bruisable skin	Congenital bilateral hip dislocation **plus** either skin hyperextensibility or severe generalized joint hypermobility with multiple dislocations/ subluxations and at least 2 other minor criteria	Molecular screening by Sanger sequencing of *COL1A1/A2* or targeted resequencing of a EDS gene panel, including *COL1A1/A2*. If necessary CNV analysis for deletions and duplications. Supportive might be SDS PAGE analysis of cultured skin fibroblasts and TEM of skin biopsies
Dermatosparaxis EDS (continued on next page)	Extreme skin fragility with congenital or postnatal skin tears Characteristic craniofacial features Redundant, almost lax skin, Increased palmar wrinkling Severe bruisability Umbilical hernia Postnatal growth retardation Short limbs, hands and feet Perinatal complications due to connective tissue fragility	Soft and doughy skin texture Skin hyperextensibility Atrophic scars Generalized joint hypermobility Complications of visceral fragility (bladder/diaphragmatic rupture, rectal prolapse) Delayed motor development Osteopenia Hirsutism Tooth abnormalities Refractive errors (myopia, astigmatism) Strabismus	Extreme skin fragility with congenital or postnatal skin tears AND characteristic craniofacial features **plus** either 1 other major and/or 3 minor criteria	Molecular screening by Sanger sequencing of *ADAMTS2* or targeted resequencing of a EDS gene panel, including *ADAMTS2*. If necessary CNV analysis for deletions and duplications. Supportive might be SDS PAGE analysis of cultured skin fibroblasts and TEM of skin biopsies

Kyphoscoliotic EDS	Congenital muscle hypotonia Congenital or early onset kyphoscoliosis Generalized joint hypermobility with multiple dislocations/ subluxations	Skin hyperextensibility Easy bruisable skin Rupture/aneurysm of a medium-sized artery Osteopenia/osteoporosis Blue sclerae Hernia (umbilical or inguinal) Pectus deformity Marfanoid habitus Talipes equinovarus Refractive errors (myopia, hypermetropia) ***PLOD1* specific minor criteria** Skin fragility (e.g. atrophic scarring, friable skin) Scleral/ocular fragility/rupture Microcornea Facial dysmorphology (e.g. low-set ears, epicanthal folds, down-slanting fissures, synophrys, high palate) ***FKBP14* specific minor criteria** Congenital sensorineural, conductive or mixed hearing impairment Follicular hyperkeratosis Muscle atrophy Bladder diverticula	Congenital muscle hypotonia AND congenital or early onset kyphoscoliosis **plus** either generalized joint hypermobility and/or 3 minor criteria (general or gene-specific)	Increased Dpyr/pyr (= LP/HP) ratio in urine by HPLC is highly sensitive for *PLOD1* kEDS. Molecular analysis: MLPA of *PLOD1* (duplication); if negative MLPA, targeted resequencing of a EDS gene panel, including *PLOD1* and *FKBP14*, but also *ZNF469, PRDM5, B4GALT7, B3GALT6, SLC39A13, CHST14* and *DSE*, because of overlapping phenotypes. If necessary CNV analysis for deletions and duplications. Supportive might be TEM of skin biopsies
Brittle Cornea syndrome (continued on next page)	Thin cornea with or without rupture Early onset progressive keratoconus Early onset progressive keratoglobus Blue sclerae	Enucleation or corneal scarring Progressive loss of corneal stroma depth High myopia Retinal detachment Progressive high frequency often mixed deafness Hypercompliant tympanic membranes Developmental hip dysplasia Mild hypotonia in infancy Scoliosis Arachnodactyly	Thin cornea with or without rupture **plus** either at least one other major criterion and/or 3 minor criteria	Molecular screening by targeted resequencing of a EDS gene panel, including *ZNF469* and *PRDM5*, but also *PLOD1*, *FKBP14*, *B4GALT7, B3GALT6, SLC39A13, CHST14* and *DSE*, because of overlapping phenotypes. If necessary CNV analysis for deletions and

		Hypermobility of distal joints Pes planus, hallux valgus Mild finger contractures (esp. 5th)		duplications.
Spondylodysplastic EDS (continued on next page)	Progressive short stature Muscle hypotonia (ranging severe congenital to mild later-onset) Bowing of limbs	Skin hyperextensibility, soft doughy, thin translucent skin Pes planus Delayed motor development Osteopenia Delayed cognitive development ***B4GALT7* specific minor criteria** Radioulnar synostosis Bilateral elbow contractures or limited elbow movement Generalized joint hypermobility Single transverse palmar crease Characteristic facial features Characteristic radiographic findings Severe hypermetropia Clouded cornea ***B3GALT6* specific minor criteria** Kyphoscoliosis Joint hypermobility, generalized or restricted to distal joints Joint contractures (esp. hands) Peculiar fingers (e.g. slender, tapered, spatulate, broad distal phalanges) Talipes equinovarus Characteristic facial features Tooth discoloration, dysplastic teeth Characteristic radiographic findings Osteoporosis (spontaneous fractures) Ascending aortic aneurysm Lung hypoplasia, restrictive lung disease ***SLC39A13* specific minor criteria** Protuberant eyes with bluish sclerae	Short stature AND muscle hypotonia **plus** characteristic radiographic abnormalities and at least 3 other minor criteria (general or gene-specific)	Molecular screening by targeted resequencing of a EDS gene panel, including *B4GALT7, B3GALT6* and *SLC39A13* but also *PLOD1*, *FKBP14*, *ZNF469*, *PRDM5*, *CHST14* and *DSE*, because of overlapping phenotypes. If necessary CNV analysis for deletions and duplications. GAG deficiency with *B4GALT7* and *B3GALT6* mutations in cultured fibroblasts. Moderately increased LP/HP ratio (to approximately 1 compared to normal values of ~ 0.2) with HLPC for *SLC39A13* mutations.

		Hands with finely wrinkled palms Atrophy of thenar muscles, tapering fingers Hypermobility of distal joints Characteristic radiographic findings		
Musculocontractural EDS	Congenital multiple contractures (adduction-flexion and/or clubfoot) Characteristic craniofacial features Characteristic cutaneous features (hyperextensibility, bruising, fragility, atrophic scars, increased palmar wrinkling)	Recurrent/chronic dislocations Pectus deformities (flat, excavatum) (Kypho)scoliosis Tapering, slender, cylindrical fingers Progressive talipes deformities (valgus, planus, cavum) Large subcutaneous hematomas Chronic constipation Colonic diverticula Pneumo(hemo)thorax Nephro/cystolithiasis Hydronephrosis Cryptorchidism Strabismus Refractive errors (myopia, astigmatism) Glaucoma/elevated intraocular pressure	<u>At birth or in early childhood</u> Congenital multiple contractures AND characteristic craniofacial features <u>In adolescence and adulthood</u> Congenital multiple contractures AND characteristic cutaneous features	Molecular screening by targeted resequencing of a EDS gene panel, including *CHST14* and *DSE* but also *PLOD1*, *FKBP14*, *ZNF469*, *PRDM5*, *B4GALT7, B3GALT6* and *SLC39A13* , because of overlapping phenotypes. If necessary CNV analysis for deletions and duplications.
Myopathic EDS	Congenital muscle hypotonia and/or muscle atrophy that improves with age Proximal joint contractures (knee, hip, elbow) Hypermobility of distal joints	Soft, doughy skin Atrophic scarring Delayed motor developmental Myopathy on muscle biopsy	Congenital muscle hypotonia and/or muscle atrophy that improves with age **plus** either one other major criterion and/or three minor criteria	Molecular screening by targeted resequencing of a EDS gene panel, including *COL12A1,* and *COL6A1/A2/A3*, because of overlapping phenotypes (Bethlem and Ullrich) . If necessary CNV analysis for deletions and duplications.
Periodontal EDS (continued on next page)	Severe, intractable periodontitis of early onset (childhood or adolescence) Lack of attached gingiva Pretibial plaques	Easy bruising Joint hypermobility, mostly distal Skin hyperextensibility and fragility, wide or atrophic scarring Increased rate of infection	Severe, intractable periodontitis of early onset (childhood or adolescence) OR lack of attached gingiva **plus** at least 2 other major criteria	Identification of known or compatible gain-of-function mutations by sequence analysis of *C1R* and *C1S*

	First degree relative who meets clinical criteria	Hernias Marfanoid facial features Acrogeria Prominent vasculature	and one minor criterion	

* The Five-Point Questionnaire (5PQ).
1. Can you now (or could you ever) place your hands flat on the floor without bending your knees?
2. Can you now (or could you ever) bend your thumb to touch your forearm? C
3. As a child, did you amuse your friends by contorting your body into strange shapes or could you do the splits?
4. As a child or teenager, did your shoulder or kneecap dislocate on more than one occasion?
5. Do you consider yourself "double-jointed"?

A "yes" answer to two or more questions (= positive 5PQ) suggests joint hypermobility with 80–85% sensitivity and 80–90% specificity.

Adapted from Hakim AJ, Grahame R. Int J Clin Pract 57:163-166, 2003.

In patients with an acquired connective tissue disorder (e.g. lupus, rheumatoid arthritis, etc.) additional diagnosis of hEDS requires meeting both features A and B of criterion 2. Feature C of criterion 2 (chronic pain and/or instability) cannot counted towards a diagnosis of hEDS in this situation.

Glossary

Autosomal dominant

Mode of inheritance whereby the disorder often occurs in multiple generations and both sexes are equally affected, because the affected gene is located on an autosome (= chromosomes 1 – 22; non-sex chromosomes). Generally, in autosomal dominant disorders one allele of a gene pair is mutated and the other allele is normal (heterozygosity). Since a child inherits one allele of a gene pair, the chance for an affected individual of transmitting the mutated allele and having an affected child is 50% (= ½).

Autosomal recessive

Mode of inheritance whereby the disorder occurs most often in a single nuclear family and both sexes are equally affected. In autosomal recessive disorders, both alleles of a gene pair are mutated (homozygosity/compound heterozygosity). Both parents of an affected child are healthy carriers (heterozygosity). Their chance of having another affected child is 25% (= ¼), because there is a fifty-fifty chance that one of the 2 alleles that is transmitted via the parents is the mutated one, and both mutated alleles have to be transmitted to cause disease (½ times ½ = ¼). For an affected individual the chance of having an affected child is usually low (= 1/100 or less), unless the sexual partner is at least carrier of the same abnormal gene. The chance this being the case, is higher when the partner is a relative (consanguinity)

Bi-allelic

Both alleles (members of a gene pair) of the involved gene are mutated, as occurs in autosomal recessive inheritance.

Compound heterozygous/heterozygosity

For an autosomal recessive disorder to occur both alleles (members of a gene pair) of the involved gene have to be mutated. Compound heterozygosity exists when these 2 mutations (changes) of the involved gene are not exactly the same.

Expression

The degree in which an individual is clinically affected by a genetic disease or disorder. Often expression is variable, i.e. ranges from mild or partial features to the full scale clinical picture.

Haemosiderin

A protein of red blood cells which presents as brownish iron-containing pigment.

Haplo-insufficiency

Generally speaking, genes produce proteins. Haplo-insufficiency relates to the activity of a protein and it means that its activity is reduced to - on average - 50%.

Heterozygous/heterozygosity

This is the state where only one of the 2 alleles of a gene pair is mutated, which is the case in patients suffering from an autosomal dominant disorder and in healthy parents (carriers) of a child with an autosomal recessive disorder.

Homozygous/homozygosity

This is the state where the 2 alleles of a gene have exactly the same mutation, which means disease for the individual in both autosomal dominant and recessive disorders.

Multifactorial disorder

Disorder which is caused by the contribution of - mostly - many genes, each having a small effect, and exogenous = non-genetic factors.

Null mutation

Any mutant allele where the normal gene product is not made or is completely non-functional.

OMIM numbers

OMIM = Online Mendelian Inheritance in Man = catalogue of heritable traits which have got numbers (www.ncbi.nlm.nih.gov/omim).

Penetrance

This denotes the percentage of mutation carriers who do have clinical features of the given disorder, i.e. who do have the given genetic disorder.

Proband

The first patient in the family in whom a particular disorder has been diagnosed

X-linked

Mode of inheritance whereby the disorder often occurs in multiple generations and only males are affected. Mothers of affected males are carriers, unless a spontaneous mutation has occurred. Though the majority of carriers are healthy, some do have features of the involved X-linked disorder. For a carrier mother, the chance of having an(other) affected son is 50% (= ½). An affected male will have healthy children though all his daughters will be carriers, since the causative mutation is on his X chromosome.

1. Introduction

The Ehlers-Danlos syndrome (EDS) comprises a group of inherited disorders, many of which involve a genetic defect in collagen and connective-tissue synthesis and structure.
The condition is extremely heterogeneous, both at the clinical and the molecular level. The diagnosis of all EDS types is based primarily on clinical evaluation and family history. Laboratory testing is available for a number of types, but is rather complex. This complexity results from the underlying genetic heterogeneity. In order to understand the link between EDS and genes that cause these disorders, an introduction to the basic principles of genetics will be given. An overview of the diagnostic testing possibilities that are currently available will be provided.

2. From genes to proteins

Most living organisms consist of cells that originate from one fertilized egg cell through cell division. The nucleus of each cell contains a substance called deoxyribonucleic acid (DNA). DNA is wrapped together to form structures called chromosomes. Most cells in the human body have 23 pairs of chromosomes, making a total of 46. One of these 23 pairs contains the sex chromosomes, XX in females and XY in males. Individual sperm and egg cells, however, have just 23 unpaired chromosomes. Each individual receives half of the chromosomes from the mother's egg and the other half from the father's sperm cell. A male child receives an X chromosome from his mother and a Y chromosome from his father whereas females get an X chromosome from each parent. At each cell division, the two chromosomes are duplicated and one copy of each chromosome separates into the daughter-cells during a process called “mitosis”. In this way, at the end of the cell division, each of the daughter cells has exactly the same 23 pair of chromosomes as the mother cell. During egg and sperm formation, DNA duplication is followed by two consecutive cell divisions, at the end of which each egg or sperm contains only one copy of the 23 chromosomes. This process is called “meiosis”.

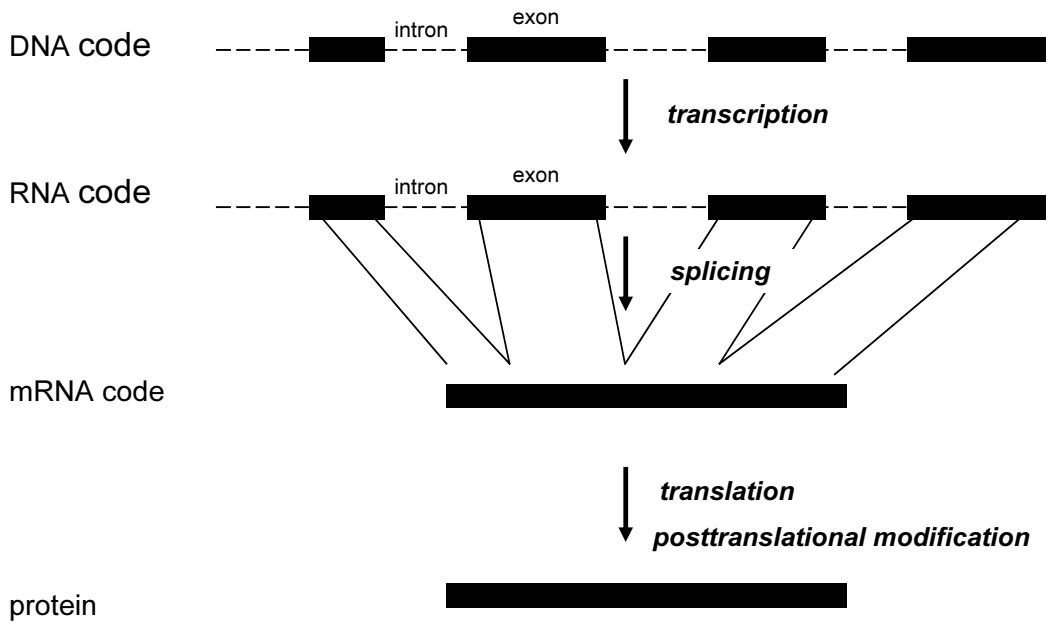
DNA consists of a string made of sequences of four building blocks, called bases (adenine, thymine, cytosine, and guanine: A, T, C, and G for short) that are strung in patterns on extremely thin, coiled strands in the cell nucleus. Each nucleated cell in the human body contains about 2 meters of DNA thread or a total of about 4.8 billion kilometres of DNA, if all the DNA strands were stretched out straight. Two complimentary strings of DNA form the famous “double helix”.

Genes are sections or segments of DNA that are present on the chromosomes. Genes are transmitted from parents to offspring and are considered to be the basic unit of inheritance. Through the transmission of genes physical traits, such as eye colour, are inherited in families. Because each parent gives a child one chromosome of each pair, in general a child has two copies of every gene (except for most of the genes on the X and Y chromosomes in males because males have only one of each). Some characteristics come from a single gene, whereas others come from gene combinations. Because every person has 20,000 to 25,000 different genes, accounting for less than 2% of the total DNA, there is an almost endless number of possible combinations.

Genes hold the instructions for making protein products, e.g. pigment that gives eyes their colour. The sequence of the bases within a gene forms the code that determines which protein is produced. Within a gene, these coding sequences, called exons, are interrupted by non-coding DNA-sequences, called introns. Also in between genes, non-coding stretches of DNA are present. These sometimes have a regulatory function.

The information contained in the DNA dictates the composition of the proteins. This involves two processes, called transcription and translation, see figure 3-1.

Figure 3-1 From DNA to protein: schematic overview of transcription and translation



courtesy of proto-col.com

Briefly, when a gene is active, the DNA-code in the nucleus is first transcribed to a single-stranded messenger ribonucleic acid (mRNA) that is very similar to DNA. The mRNA then migrates form the cell nucleus into the cell cytoplasm to be translated into protein. During this process, the non-coding introns are removed by nuclear enzymes (splicing). Via a few more steps, this mRNA is subsequently translated into protein. A protein is composed of amino acids. The body contains 20 different amino acids and the amino acid sequences that make up a protein must somehow be designated by the DNA after transcription into mRNA. Individual amino acids are encoded by units of three mRNA bases, termed codons. There are start and stop codons to designate the beginning and the end of a gene. Each gene also contains a code that determines in which cell-type the gene is active. This code, called the promoter, is involved in the regulation and the production of the mRNA and the protein. Finally, before a newly synthesized protein can begin its existence as a functional protein, it often undergoes further processing, termed posttranslational modification. These modifications can take a variety of forms such as, for example, combination with other polypeptides to form a larger protein, addition of carbohydrate side chains to the polypeptides etc. An example of a clinically important protein that undergoes considerable posttranslational modification is type I collagen.

3. Genes and hereditary disorders

Cells sometimes contain errors in the information in their genes. These errors are called gene mutations, and can spontaneously occur during the process of DNA replication or due to exposure to certain chemicals or radiation. Fortunately, cells usually recognize these mutations and repair them. If not, however, these mutations may cause disorders or illnesses.

As cells duplicate, they pass the genetic information to new cells. If a pathogenic, clinically relevant gene mutation exists in the DNA of an egg or a sperm cell, this will result in a hereditary disease, and children may inherit the mutated gene from their parents. The errors (mutations) that cause hereditary diseases are usually very small, often confined to the change of only one base in a gene. This then is called a point mutation.
The human DNA code contains approximately 3 billion bases and 20-25,000 genes. Each gene encodes one or more proteins. Although the DNA-code has been almost completely unravelled, the functions of most of the genes (i.e. the function of the protein they encode) and the genetic cause of many hereditary diseases remain to be elucidated.

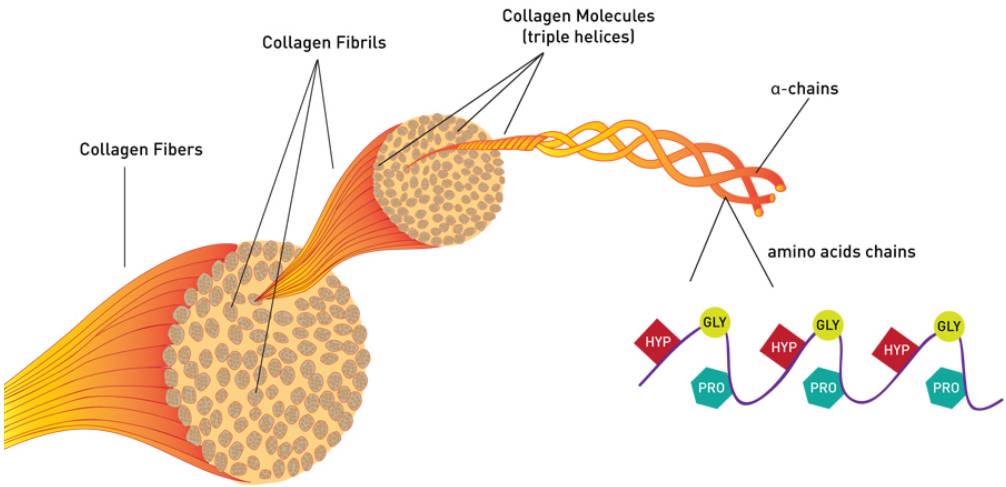
4. Heritability
A hereditary disorder can be **dominant** or **recessive** and **autosomal or X-linked** (see glossary chapter 2). For a person to have an autosomal dominant disease or disorder, a mutation in only one copy of a gene suffices. However, a person with an autosomal recessive disease or disorder has a mutation on both copies of the gene.
If a person has a dominant mutation in a gene implicated in a disease, he or she will usually have the disease. Moreover, each of that person's children will have a 1 in 2 (50%) chance of inheriting the gene and getting the disease. Sometimes a dominant disease occurs in a child of healthy parents; this is caused by a new mutation, which can then be transmitted to the children of that diseased child.
People who have a mutation in only one copy of a gene implicated in a recessive disease, are called carriers, and they usually do not have the disease because they still have a normal gene of that pair that can do the job. When two carriers of the same disease have a child together, however, the child has a 1 in 4 (25%) chance of getting the mutated gene from both parents, which results in the child having the disease. This is the basis of the higher prevalence of recessive diseases in children of blood-related or consanguineous (i.e. belonging to the same family), clinically healthy parents, who have more gene abnormalities in common, compared to not blood-related parents.
A peculiar situation arises if a disease gene is located on chromosome X (X-linked disorder), because this chromosome is present in one copy in males and two copies in females. In this case, a single mutation will suffice for a male person to get the disorder. Moreover, the mutated gene has always been transmitted to an affected male from his carrier mother, unless the affected male has a new mutation. An affected male will transmit the mutated gene to all his daughters. Females have two copies of chromosome X, of which only one is active in each cell of the organism. Depending on the proportion of cells with an active, mutated gene and the dominant or recessive nature of the disorder, females with a mutation in one copy of a X-linked gene will be clinically unaffected or have (a milder presentation of) the disorder.

Certain disorders are not caused by mutations in a single gene, but can be triggered by combinations of several variant genes, which interact with each other and often with the environment. These are called “complex or multifactorial disorders”. In case of “complex inheritance”, transmission of a “variant” in a gene can increase or decrease the susceptibility to develop a disease.

5. Connective tissue, genes and EDS
EDS is a group of related conditions that share a common decrease in the tensile strength and integrity of the skin, joints and other organs with connective tissues. This is mainly caused by various abnormalities in the structure of collagen, an important component of the connective tissues.

Collagens are the most abundant proteins in humans and the animal kingdom. They are multimeric and are characterized by the presence of triple-helical domains (so called collageneous domains, see figure 3-2).

Figure 3-2 The multimeric and triple-helical domains of collagen.



(www.proto-col.com)

To date, 43 collagen genes have been described, the products of which combine to form at least 28 different collagen molecules. Besides collagen, connective tissues also contain elastic fibres, proteoglycans, and a variety of other different glycoproteins. Elastic fibres are composed of two distinguishable components: an amorphous component, “elastin”, which contributes to the elasticity of the fibre, and a surrounding sheet of microfibrils. An example of a microfibrillar protein is fibrillin, which is abnormal in patients with Marfan syndrome. Elastin and other structural proteins are woven onto the microfibrillar array to provide the basic meshwork for the connective tissue matrix. Abnormalities of elastin have been associated with other connective tissue disorders, such as cutis laxa. Proteoglycans are core proteins that are bound to one or more sugar chains (glycans). Essentially, proteoglycans are the glue of the connective tissue protein that seal and cement the underlying connective tissue matrix. Recently, abnormal proteoglycan metabolism has been shown to underlie a few types of EDS. Other glycoproteins of the extracellular matrix include fibronectin, fibulins, laminins and tenascins. Tenascin-X has also been implicated in some EDS types (classical-like and hypermobile EDS).

EDS is classified into different types, based on the clinical characteristics, the mode of inheritance and the underlying molecular and genetic defect . At first, mutations have been identified in the genes encoding collagens type I, type III and type V, as well as in genes encoding proteins that are involved in posttranslational modifications processes of these collagens, such lysyl hydroxylases (*PLOD1*) and procollagen I-N-proteinase (*ADAMTS2*). The Villefranche classification (1997) of EDS into 6 clinical types was based on this knowledge.[1] Later, also mutations were identified in non-collagenous proteins, showing that EDS can also be caused by defects in proteins other than collagen. In the last decade, several forms of EDS have been recognised which fall outside the Villefranche classification; this led to the 2017 International Classification of EDS (see table 2-1 of chapter 2).[2] For most of these EDS types, one or more underlying genetic defects have been identified. For some of them,

the causal molecular defect remains to be discovered. Thus, many different proteins may be involved in the pathogenesis of EDS and others still remain to be discovered. Moreover, even if the abnormal gene is known, the condition is in almost every family with EDS caused by a unique mutation in that gene.

Due to the variability in clinical presentation and the overlap in clinical features among different EDS types, the search for the causal mutation in a EDS patient can be a cumbersome and time-consuming task. Till a few years ago, a combination of biochemical and molecular assays represented the gold-standard- first-step in the diagnostics of EDS. In this "traditional" diagnostic approach, biochemical findings are used to confirm or guide molecular analysis of the specific collagen gene involved. However, with the introduction of new DNA technologies (e.g. Next Generation Sequencing, NGS), rapid search for the disease causing mutation by molecular analysis of (all) known EDS genes at once has become possible. This technology has been recently introduced in several diagnostic laboratories and will become standard routine diagnostic practice in the future.

6. Guidance for diagnostic biochemical and molecular testing

Clinical diagnosis is the primary means of identifying all EDS types. In many cases, a comprehensive clinical evaluation can be sufficient to establish a correct clinical diagnosis. However, in a growing subset of EDS types, molecular and, to a lesser extent, biochemical and/or ultrastructural analyses can be used in order to confirm the diagnosis.

Traditionally, the first step in the laboratory diagnosis of many EDS types was the biochemical analysis of collagen type I, III and V, performed on cultured fibroblasts obtained from a skin biopsy. This step could guide molecular diagnostics for several EDS types, pinpointing the causative gene, therefore simplifying the search for the underlying genetic defect. This approach could help confirming the diagnosis in patients with vascular EDS, in a subset of patients with classical EDS, and in patients with arthrochalasia, dermatosparaxis and kyphoscoliotic EDS.
However, biochemical analysis of collagen cannot identify defects in non-collageneous related types of EDS. For all these EDS types, molecular analysis of the causative gene is necessary to confirm the diagnosis.

With the introduction of new DNA technologies (NGS), the molecular approach is becoming the first tool to confirm a clinical diagnosis of EDS. These new technologies allow testing of all known genes involved in EDS at once, allowing rapid achievement of a molecular diagnosis in important subsets of EDS patients.
However, not all genes involved in EDS have been discovered as yet. In particular, this is not (yet) the case for hypermobile EDS. Haplo-insufficiency of tenascin-X (encoded by *TNXB*) has been associated with hypermobile EDS in a small subset of affected individuals. In most individuals with this type of EDS, the underlying genetic defect is unknown and unmapped. Also, hypermobile EDS is not associated with biochemical defects of collagen proteins. Therefore, the diagnosis of hypermobile EDS is based entirely on clinical evaluation and family history.

The most recent classification of Ehlers-Danlos syndrome types, the inheritance patterns, genetic causes and defective proteins, is given in table 2-1 of chapter 2.[2]
Table 3-1 summarizes the most important differential diagnoses of EDS, their distinguishing features, underlying protein and gene defects and their diagnostic work-up.

6.1 Ultrastructural and biochemical analyses in EDS

6.1.1 Ultrastructural examination of the skin

Ultrastructural examination of the skin, performed by electron microscopy, usually reveals abnormalities of collagen fibrils in EDS. These include irregular, disrupted collagen fibrils (”collagen flowers”) and variability of the diameters of the collagen fibrils. However, these abnormalities are found in several EDS variants and are usually insufficient to discriminate between EDS types.

Only in dermatosparaxis EDS, a pathognomonic ultrastructural aspect of the collagen fibril architecture is observed. Collagen fibrils in this type lose their normal cross-sectional circular aspect and have an irregular, branched, “hieroglyphic” appearance instead.[3]

6.1.2 Skin biopsy for fibroblast culture and biochemical analysis

Traditionally, the first step in the laboratory diagnosis of EDS, when possible and indicated, consisted of a skin biopsy to obtain a fibroblast culture (a culture of the cells that synthesize all elements of the connective tissue, including collagen). Biochemical protein-based analysis of the collagens type I, III and V, by means of gel electrophoresis, can detect abnormalities of these collagen proteins, regardless of the underlying cause.

In case of vascular EDS, biochemical analysis of type III collagen is highly sensitive and probably identifies more than 95% of individuals with structural alterations in the proteins synthesized. It allows to detect quantitative abnormalities (reduced amounts of type III collagen) or qualitative abnormalities (abnormal type III collagen with altered electrophoretic mobility) of type III collagen.

Biochemical analysis of the fibrillar collagens is also helpful in the diagnosis of the arthrochalasia, kyphoscoliotic and dermatosparaxis EDS. For the majority of patients with classical EDS, biochemical analysis of type V collagen, which is abnormal in this EDS type, is an ineffective method for routine diagnostic evaluation.[4] The strands of type V collagen are synthesized by fibroblasts at a low rate, causing poorly reproducible quantification and evaluation of alterations in electrophoretic mobility of this collagen.

In hypermobile EDS biochemical analysis of the fibrillar collagens shows no abnormalities and is therefore not indicated.[5]

6.1.3 Other available biochemical assays

For kyphoscoliotic EDS , a highly specific and highly sensitive urinary assay is available for clinical testing.[6]

A serum-based screening assay has been successfully used to detect tenascin-X-deficiency in classical-like EDS.[7]

6.2 Molecular genetic testing

6.2.1 Classical EDS and related phenotypes

In approximately 90% of the patients with classical EDS, mutations in one of the genes encoding type V collagen (*COL5A1* and *COL5A2)* are detected.[4] The most common types of defects that are observed in type V collagen lead to the production of about half of the amount of type V collagen (quantitative defect) and are caused by a mutation in the *COL5A1* gene.[4,8,9] Only a minority of identified defects results in the production of a structurally abnormal type V collagen (qualitative defect).

More recently, mutations in a non-collagenous protein, tenascin-X, have been shown to cause a condition with great similarities to classical EDS and is known as classical-like EDS. A

complete lack of tenascin-X in the serum was observed in some patients with a classical EDS-like phenotype, with hyperextensible skin, hypermobile joints and easy bruising, but without atrophic scarring.[7,10] In contrast to classical EDS, this condition shows recessive inheritance and is caused by mutations in both copies of the *TNXB* gene. These mutations, including a deletion which abolishes a large part of the *TNXB* gene, prevent production of tenascin-X.[10] The *TNXB* gene is located in a very complex genomic region on chromosome 6. This complexity has hindered molecular diagnostic of this gene in large groups of patients. However, several diagnostic centres are currently offering DNA testing of *TNXB*.

In a small subsets of patients with clinical symptoms (partially) resembling the classical EDS, biochemical defects of collagen type I and/or mutations in the *COL1A1* and *COL1A2* genes have been identified.
Complete deficiency of the pro-alpha2(I) collagen chains, due to mutations preventing protein production in both paternal and maternal *COL1A2* genes, has been associated with a rare autosomal recessive form of EDS, named cardiac-valvular EDS.[11,12]
Furthermore, mutations in the *COL1A1* gene specifically causing the substitution of an arginine residue by a cysteine residue in the triple collagen helix, have been described in a rare classical EDS variant, with a propensity for arterial rupture.[13,14]

In the remaining patients with classical EDS, no molecular defect is found in any of these genes, suggesting that also other genes are involved in this phenotype.

6.2.2 Hypermobile EDS

To date, the genetic basis of hypermobile EDS remains largely unknown. The diagnosis is based entirely on clinical evaluation and family history.
Carriership of mutations in tenascin-X have been identified in a small subset (~5%) of patients with hypermobile EDS.[15] As previously reported in this chapter, a serum-based screening assay to detect tenascin-X-deficiency / haplo-insufficiency is available and several centres are offering DNA testing of *TNXB*.

6.2.3 Vascular EDS

The diagnosis of vascular EDS is based on clinical findings and confirmed by identification of a causative mutation in *COL3A1*, the only gene in which mutations are known to cause this type of EDS. Traditionally, molecular analysis of *COL3A1* was performed if an abnormal migration pattern of type III collagen was identified by biochemical analysis. With progress of DNA technology, molecular analysis of the *COL3A1* gene can be considered a rapid and highly sensitive first-line diagnostic tool in all cases in whom clinical findings support a diagnosis of vascular EDS. This is especially important in clinical life-threatening situations, when confirmation of a clinical diagnosis of vascular EDS can have immediate consequences for the treatment of the patient. With the introduction in diagnostics of the NGS technology, which allows testing of all genes of a panel of genes at once, molecular analysis of the *COL3A1* gene is also becoming part of the routine diagnostic test in patients presenting with vascular symptoms as arterial aneurysms and dissections. As a matter of fact, a few patients with *COL3A1* mutations have been described, whose clinical manifestations in contrast to characteristic vascular EDS phenotype seemed to be limited almost entirely to vascular events. In these patients, *COL3A1* “null” mutations, having no collagen protein production as a result, were found.[16]

6.2.4 EDS types due to defective processing of collagen type I

The arthrochalasia EDS is a rare autosomal dominant condition caused by a deletion of a well-defined part of one of the genes that code for type I collagen (*COL1A1* and *COL1A2*). This deletion inhibits the normal cleavage of the aminoterminal non-helical part of type I procollagen. Consequently, type I procollagen, which is a precursor of type I collagen, will not be processed correctly. This results in specific abnormalities in the electrophoretic mobility of type I procollagen, which can be detected on biochemical analysis.[17,18] Molecular analysis of the *COL1A1/A2* genes, targeted to the region containing the cleavage site of the aminoterminal non-helical part of type I procollagen, is available.

Deficient activity of the protein responsible for cleavage of the N-terminal propeptide in type I, II and III collagen, due to mutations in the *ADAMTS2* gene, causes a rare autosomal recessive condition, dermatosparaxis EDS.[19,20] Molecular analysis of *ADAMTS2* is available. Moreover, pathognomonic abnormalities of dermal collagen fibril architecture can be detected by ultrastructural skin examination, while biochemical collagen protein analysis shows a characteristic aberrant migration pattern.

6.2.5 Kyphoscoliotic EDS and related phenotypes

The kyphoscoliotic EDS is an autosomal recessive disorder caused by deficient activity of the lysyl-hydroxylase 1 protein, due to mutations in the *PLOD1* gene.[21,22] This protein is involved in the formation of intermolecular cross-links, which provide tensile strength and stability to the collagen fibrils. Historically, kyphoscoliotic EDS is the first type of EDS for which the molecular defect has been elucidated. For kyphoscoliotic EDS, a highly specific and highly sensitive urinary assay is also available for clinical testing i.e. measurement of the urinary hydroxy-lysyl and lysyl pyridinoline ratio. Moreover, the activity of the lysyl hydroxylase-1 activity can be measured in cultured fibroblasts.

Mutations in the *FKBP14* gene, encoding a chaperone protein, thought to be involved in protein folding, have been identified in patients with kyphoscoliotic EDS, characterized by kyphoscoliosis, myopathy, and hearing impairment.[23,24]

Recently, search of the underlying genetic defect in consanguineous families with a variety of rare phenotypes which show overlapping features with the kyphoscoliotic EDS, led to the identification of new EDS related genes and biological pathways.

One of these conditions, spondylodysplastic EDS, was shown to be caused by mutations in the *SLC39A13* gene. This gene encodes a protein involved in the trafficking of zinc, an element which is necessary for normal lysyl hydroxylase-1 activity. A slightly abnormal hydroxy-lysyl and lysyl pyridinoline ratio due to defective lysyl hydroxylase-1 activity can be detected in the urine of patients.[25] Defects of proteoglycan metabolism also underlie spondylodysplastic EDS.[26] This rare recessive condition has recently been associated with mutations in the *B4GALT7*[27,28] and in the *B3GALT6* gene.[29,30] These genes are involved in the correct biosynthesis of the glycosaminoglycan ('sugar') side chains of proteoglycans.

Another of these rare disorders, Brittle Cornea Syndrome, has been associated with mutations in two different genes which probably are involved in the same biological pathway: *ZNF469*, which encode a protein of unknown function belonging to the Zinc-finger protein family[31] and *PRMD5*, which code for a protein involved in the regulation of expression of extracellular matrix components.[32]

In the last years, defects of proteoglycan metabolism have been shown to be responsible for some of these rare EDS conditions. One of these is musculocontractural EDS , which can be caused by mutations in the *CHST14*[33,34] or the *DSE* gene.[35]

6.2.6 Other EDS types

Recently, recessive and dominant *COL12A1* mutations have been identified in affected individuals from two families with a novel overlapping syndrome, which combines generalised joint hypermobility with myopathy, myopathic EDS.[36] *COL12A1*, coding for collagen XII, has been shown to be expressed in collagen I containing tissues and to interact with other extracellular matrix components, such as tenascin-X.

Heterozygous missense or in-frame insertion/deletion gain-of-function variants in *C1R* and *C1S* cause periodontal EDS, which is characterised by early onset, aggressive periodontitis and skin and joint features. *C1R* and *C1S* encode subunits C1r and C1s of the first component of the classical complement pathway. The exact mechanism of periodontal EDS remains to be clarified.[37,38]

7. Research topics

While a growing number of the EDS types has been characterized at the molecular level, the genetic basis of some of the most frequent forms, such as the hypermobility type and a subset of the classical type have not or not fully been elucidated. Recently, it has been shown that other, non-collagenous molecules may be causally involved in the pathogenesis of EDS.

There are several features which make the search for the genetic causes of hypermobile EDS a challenging task. First of all the clinical variability and second, the possible contribution of other, genetic and non-genetic, factors in the phenotypic expression of the disorder (e.g. hormones may explain the apparently different phenotypic expression between females and males); and at last, the disorder is likely to be genetically heterogeneous.

Elucidation of the genetic bases of these hypermobility syndromes will give better insight into the natural history and the biochemical and molecular pathogenesis of these disorders. This will improve early recognition and diagnosis of these conditions, lead to a more logical classification and possibly will allow development of more effective preventive and management strategies.

8. Summary

EDS is a clinically and genetically heterogeneous group of connective tissue diseases, mainly characterised by a decrease in the tensile strength and integrity of the skin, joints and other connective tissues.

Abnormalities in the structure of collagen have long been recognised as being involved in the aetiology of this condition. However, in the past years, a growing number of different types has been identified, the underlying molecular defect of some of which involves other, non collageneous, connective tissue molecules.

The diagnosis of EDS was traditionally based on a combination of clinical, biochemical and ultrastructural examinations which guided molecular analyses of involved genes. With the introduction of new DNA technologies (e.g. NGS), rapid search for the disease causing mutation by molecular analysis of (all) known EDS genes at once has become possible. This technology has been recently introduced in several diagnostic laboratories and will become standard routine diagnostic practice in the near future.

However, in many cases of EDS the underlying molecular defect still is unknown, and the clinician as well as the patient must rely on the clinical diagnosis. This holds particularly true for hypermobile EDS.

The ongoing elucidation of the biochemical and molecular basis of EDS together with increasing clinical experience, will add value to diagnosis, genetic counselling and management of these heritable disorders. Future research will further increase the understanding of the molecular mechanisms involved and possibly open perspectives for gene therapy.

Table 3-1 Conditions to be considered in the differential diagnosis of EDS.

Condition	**Discriminating signs**	Protein	**Gene**	**Laboratory Testing**
Osteogenesis imperfecta	History of multiple fractures Short stature Blue sclerae	Type I collagen	*COL1A1* *COL1A2*	DNA sequencing and quantitative analysis of *COL1A1/COL1A2*
Marfan syndrome	Marfanoid habitus Ectopia lentis Aortic dilatation/aneurysm	Fibrillin 1	*FBN1*	DNA sequencing and quantitative analysis of *FBN1*
Loeys-Dietz syndrome	Aortic root and/or arterial dilatation/dissection Arterial tortuosity Hypertelorism Bifid uvula Cleft palate	TGFβ receptor 1 TGFβ receptor 2 SMAD3 *TGFβ2* *TGFβ3*	*TGFβR1* *TGFβR2* *SMAD3* *TGFB2* *TGFB3*	DNA sequencing analysis of *TGFβR1, TGFβR2, SMAD3, TGFB2, TGFB3*
Stickler syndrome	Sensorineural hearing loss Vitreoretinal abnormalities Cleft palate	Type II collagen Type XI collagen Type IX collagen	*COL2A1* *COL11A1, COL11A2* *COL9A1, COL9A2, COL9A3*	DNA sequencing analysis of *COL2A1, COL11A1, COL11A2, COL9A1, COL9A2, COL9A3*
Cutis laxa syndromes	Cutis laxa: redundant skin, hangs in loose folds, returns slowly to former position Normal wound healing Absence of skin fragility	Elastin Fibulin 4 Fibulin 5 A2V- ATPase Pyrroline-5-carboxylate reductase	*ELN* *FBLN4* *FBLN5* *ATP6V0A2* *PYCR1*	DNA sequencing analysis of *ELN, FBLN4, FBLN5, ATP6V0A2, PYCR1*
Larsen syndrome and related disorders	Craniofacial dysmorphism Short stature	Filamin B Beta-1,3-glucuronyltransferase 3 Chondroitin 6-sulfotransferase	*FLNB* *B3GAT3* *CHST3*	DNA sequencing analysis of *FLNB, B3GAT3, CHST3*
Occipital horn syndrome	Presence of "occipital horns" (parasagittal bone exostoses arising from the occipital bone) Bladder diverticulae Inguinal herniae Vascular tortuosity	Cu++* transporting, α polypeptide (*Cu++ = copper)	*ATP7A*	DNA sequencing analysis of *ATP7A*

1. Introduction

The most common type Ehlers-Danlos syndrome (EDS), after hypermobile EDS (formerly EDS hypermobility type or type III) is classical EDS, a combination of what used to be EDS type I (gravis) and EDS type II (mitis),

The estimated overall incidence of EDS is 1:5000 births, of which the classical and hypermobility types account for approximately 90%.[1] A recent questionnaire on EDS sent to members of the Dutch EDS Patient Federation showed a similar occurrence of EDS patients with classical and hypermobile types.

Classical EDS is inherited as a autosomal dominant trait. Typically for an autosomal dominant trait, it affects males and females equally often and there is interfamilial clinical variability. Skin and joint symptoms and signs are often the most common presenting features so that early skin fragility is especially typical in toddlers or preschool children.[2] Causative mutations in two collagen type V fibrillar genes *COL5A1* and *COL5A2* have been identified. As a consequence, the faulty type V collagen molecules cause failure in the regulation of fibrillogenesis, resulting in misassembly of type I and III collagen fibrils.

By electron microscopy, this disturbed collagen fibrillogenesis can be observed in a skin biopsy as abnormal rosetting (cauliflower fibrils). This finding is, however, not specific for one of the EDS types.

The combination of clinical, molecular and ultrastructural diagnostic strategies (as discussed in chapters 2 and 3), leads to earlier diagnosis with consequent improvements of clinical management and accurate genetic counselling.

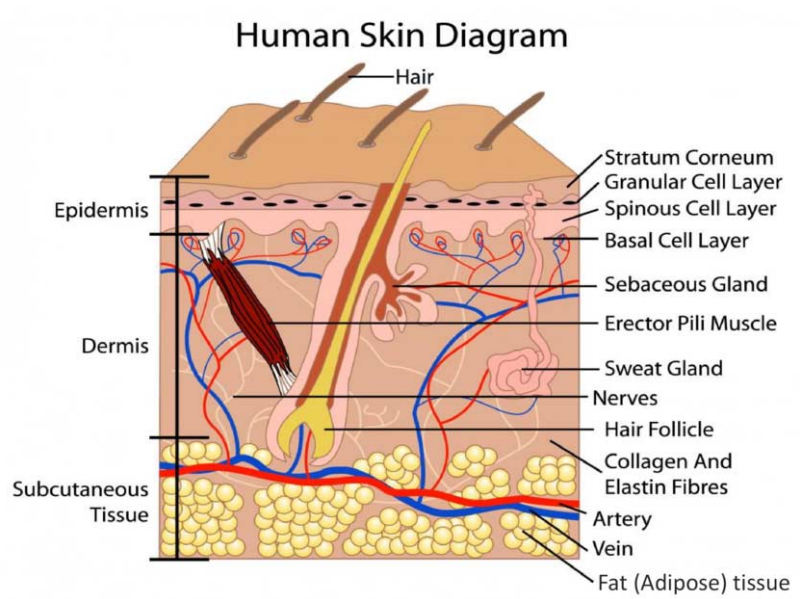
As the skin plays an important role in the diagnosis, this chapter will particularly focus on the skin and the symptoms it causes in classical EDS.

2. The skin

2.1 The healthy skin

The human skin has several distinct layers, see figure 4-1.

Figure 4-1



(www.health-advisors.org)

- the **epidermis**, containing the keratinocytes, pigment cells and cells involved in the immunological defence of the body such as the Langerhans cells,
- the **dermis** which contains, apart from blood vessels, lymphatic vessels and nerves, the connective tissue, and
- the **hypodermis or subcutis**, which contains fat-containing adipocytes in addition to blood and lymphatic vessels, loosely arranged elastic fibres and fibrous bands of connective tissue. The latter anchors the dermis to the hypodermis and the skin to the deep fascia.

For normal skin mechanics, dermal connective tissue is of major importance. It contains elastic fibres, collagen fibres and ground substance, an amorphous substance that fills the spaces between the various fibres and bundles. The ground substance contains various glycoproteins such as tenascin and various sugar containing proteoglycans, such as hyaluronic acid and chondroitin sulphate. Fibrillar collagen fibres are arranged in a wave-like pattern. Flattening of these fibres allows normal skin to extend, even though the constituent collagen fibres themselves, are relatively inextensible. Extreme extension may damage the skin, which is subsequently visible as stretch marks.[3,4]

Dermal elastic fibres are much sparser and are generally entwined among the collagen bundles. Unlike collagen, these fibres are rubber-like and extensible. After stretching they return to their original shape.

Translating this to the mechanical properties of normal skin: the collagen is responsible for the strength and stiffness of the skin, consequently limiting skin extension if the collagen is normal. Similarly, when extended, return to its normal shape is mediated by elastic fibres. In the presence of abnormal collagen, the skin becomes abnormally extensible whilst the normal elastic fibres will still have the mechanical properties to make the skin return to its normal shape after extension. When elastic fibres are abnormal, as in Cutis Laxa, the skin will not return to its normal shape after extension: instead it will be hanging in lax folds. Second, since in Cutis Laxa collagens are normal, the skin is not hyperextensible. Furthermore, joint hypermobility is the exception rather than the rule.

2.2 The skin in classical EDS

In short, in classical EDS the skin collagen fibrillogenesis is visibly abnormal. This subsequently leads to hyperextensibility of the skin. Both the specific cutaneous and other generalised clinical features of classical EDS are caused by the faulty collagen and are described below.

2.2.1 Hyperextensibility

The skin in classical EDS is hyperextensible and seems to be hyperelastic. In the clinical setting standard tests to determine this may be used. Beighton suggested an arbitrary score for skin extensibility.[5] He scored cutaneous stretching of the ventral left forearm on a numeric rating scale of 0 to 5 in a range of 4 to 8 centimetres. Only in significantly abnormal hyperextensibility a score higher than zero will be given. Skin extensibility is easily estimated by testing at several sites of the skin such as the elbows, knees, neck or face, or the presternal thoracic skin**.**

These tests are easy to apply and to interpret in adults, but are less discriminating in children (see also chapter 18) since their skin is by nature more extensible than that of adults; moreover, the amount of subcutaneous fat is higher in the very young children making tests more difficult to perform adequately. To objectively measure the skin extensibility in children, the properties of volar forearm skin of 13 children (3-10 years of age) with classical EDS were recently studied using a cutometer equipped with a suction head (rheologic evaluation), to assess dermal and hypodermal mechanics.[6] Data of patients with classical EDS were compared both to those of patients with hypermobile EDS and to those of age-matched

healthy controls. Skin of patients with classical EDS showed both abnormal hyperextensibility as well as hyperelasticity when compared to the two other groups. Because the dermis is thin in EDS and histology shows rarefaction of connective tissue septae in the hypodermis, it was hypothesized by the authors that the "slipping mobility" of the dermis onto the hypodermis was the main factor yielding these data, whereas the contribution of the dermal component was present, but of less importance.

2.2.2 Reduced skin thickness

While skin dermal thickness is *diminished by 50-66%* in all patients with vascular EDS, in classical EDS, there is a *less impressive* reduction in skin thickness. In the latter almost 50% of patients is affected, though to a lesser degree. Skin thickness in classical EDS and healthy controls was compared on the chest and the lower leg, with a 20MHz ultrasound probe. Overall, in 21 patients with classical EDS dermal thickness was significantly lower compared to that in controls.[7]

2.2.3 Skin fragility (figure 4-2)

The skin of classical EDS is abnormally fragile, with gaping wounds following very minor traumas, which produce the characteristic fish-mouth or tissue paper scars. Beighton suggested the use of an arbitrary analogue score of 1-5 based upon the extent of scarring, using five bony sites e.g. left elbow and forearm, right elbow and forearm, left knee, right knee and forehead as reference points. Other typical scarring sites are the chin and shins, which are not included in the scoring calculations. Because of tissue fragility patients often suffer from repetitive hernia, such as inguinal, umbilical, hiatal, or incisional hernia.

Figure 4-2 Skin fragility: cigarette paper aspect

2.2.4 Easy bruisability

Classical EDS patients bruise very easily and sometimes extensively, often after trivial injuries. In general, bleeding and clotting tests are normal, and no consistent haematological abnormalities are found. Beighton suggested an analogue scoring system, ranging from 0, for no bruising, to 5, for gross changes. In the absence of clotting or bleeding abnormalities, explanations for the bruising include faulty platelet binding to the abnormal underlying collagen fibres, or fragility of connective tissue round small venous and arterial capillaries.

2.2.5 Varicosities
Due to the disturbed type I and III fibril packing, venous walls have a collagen defect. This, together with weakened perivenous connective tissue and faulty venous valve formation, predisposes to venous varicosities (an abnormal condition of a vein, characterized by swelling and tortuosity).

2.2.6 Molluscoid pseudotumors (figure 4-3)
Fleshy spongy lumps of 2 to 3 cm in diameter over pressure points, form so-called molluscoid pseudotumors. These are usually concentrated at sites such as the Achilles tendons, knees and elbows. These sites are easiest identified when the patient is standing. Molluscoid pseudotumors probably are benign reactive fibrous hypertrophy, in response to recurrent microtrauma and repair.

Figure 4-3 Molluscoid pseudotumors

(www.regionalderm.com, courtesy of RegionalDerm.com)

2.2.7 Spheroids
Small, mobile, easily palpable, subcutaneous papules are common over the forearms and shins. When calcified they may be detected by X-ray examination. The origin of these spheroids is not clear: some think they represent subcutaneous fat globules that have lost their blood supply, becoming fibrosed and calcified.

2.2.8 Soft skin
Contact with the skin of patients with classical EDS reveals the interesting clinical sign of soft and velvety peach-like skin. Moreover, when shaking hands one directly notices the very hypermobile hand joints. The skin softness is presumably related to the misaggregated and abnormally packed collagen fibres, characteristic for classical EDS.

2.2.9 Striae distensae
The occurrence of these linear atrophic depressions of the skin (cutaneous striae) is influenced by many factors including hormones (particularly glucocorticoids), mechanical stress, and genetic predisposition. Light microscopy shows epidermal atrophy, with some loss of the rete ridges and sharply demarcated dense packing of thin, eosinophilic collagen bundles in a parallel array, horizontal to the skin surface. Elastic fibres appear to be diminished in a stretch mark as well.[4]

Striae are most common in areas of rapid growth, such as breasts and belly in pregnant females, lumbar spine in adolescents or upper legs and arms in active sportsmen and sportswomen. Caused by easy tearing of collagenous connective tissue, in particular collagen, striae are not restricted to classical EDS, but also occur in hypermobile EDS, vascular EDS and Marfan syndrome.

2.2.10 Piezogenic papules (figure 4-4)
Piezogenic papules are small, sometimes painful, reversible herniations of underlying adipose tissue globules through the fascia into the dermis, such as on medial and lateral aspects of the feet on standing.

Figure 4-4 Piezogenic papules on lateral side of the foot

(www.pediatricsconsultant)

3. Joint hypermobility
Joint hypermobility is common in classical EDS, just as it is in most other types, and will be dealt with specifically in chapter 5. Just as mentioned earlier for scarring and bruising assessments, a similar analogue scoring system exists for joint hypermobility.

4. Other features
Classical EDS is generally not characterized by vascular complications, though arterial rupture does occur.[7] However, recently, a subtype of classical EDS has been identified which is clinically also characterized by a propensity to arterial rupture and molecularly - as it seems - by a specific mutation in *COL1A1* (c.934C>T; p.R134C).[8,9,10] For other features, like gastro-intestinal, neurological, urological and gynaecological/obstetric: see the respective chapters 10, 13, 16 and 17.

5. Objective criteria for diagnosing classical EDS
When the adapted scoring system of Beighton is used, the sum of the skin hyperextensibility score, the scarring and bruising score adds up with the hypermobility score (see table 2-3 of chapter 2). If this total score is ≥ 7, further diagnostic procedures should start to confirm or reject the diagnosis of classical EDS.[1] However, most clinicians will require the presence of the three major Villefranche criteria, i.e. skin hyperextensibility, dystrophic scarring and joint hypermobility, in order to establish the diagnosis classical EDS. In 2017 a new international classification of EDS has been published with new diagnostic criteria for the different EDS types, including classical EDS and with management related aspects of the different types.[11,12] Minimal diagnostic criteria for classical EDS are the presence of skin hyperextensibility and atrophic scars, plus either generalized joint hypermobility and/or 3 minor criteria (see also chapter 2, table 2-5)

6. The laboratory diagnosis of classical EDS

6.1 Histopathology of the skin.

Skin biopsies of classical EDS may show minor increases of collagen/elastin ratios. Sometimes dermal collagen is more intensely stained and shows an irregular pattern.[11] However, diagnostically, it is of no use.

6.2 Electron microscopy of the skin

Ultrastructural examination of dermal collagen in classical EDS typically shows variable diameters of collagen bundles and irregular contours in cross-section, some showing flower-like appearances.[13] These changes are best visualised at a print magnification of 50-70,000. They are caused by longitudinal mispacking and unravelling of type I and III collagen fibres, which is the result of the faulty type V collagen. Haplo-insufficiency or other mutations of collagen type V have this effect. Cauliflower fibrils are a consistent feature of classical EDS, but are not specific for it, as they may be seen in other inherited defects of connective tissue as well, such as pseudoxanthoma elasticum (PXE), osteogenesis imperfecta, and scleredema adultorum of Buschke.[13] Therefore, it is of very limited diagnostic use.

6.3 Collagen protein and DNA analysis

Collagen type V, which was first purified from placenta,[14] is a typical fibrillar collagen, in which a central perfect uninterrupted triple helix, of general formula (Gly-X-Y)333, has both specific N- and C-terminal extensions.[15] These fibrillar triple helices co-assemble in a so-called quarter staggered format. Compound fibrils of for example types I, III and V collagen are formed in skin, whilst in the vitreous there are heterogeneous associations of collagens types II, Valpha2 and XIalpha1. Unlike collagens types I, II and III, which have small N-terminal extensions, those of type V collagen, coded by the *COL5A1* and *COL5A2* genes, are much larger. Collagen type V proteins form four different types of alpha chains, alpha1(V), alpha2(V), alpha3(V) and alpha4(V), of which the most common is, especially in the skin, a heterotrimer consisting of two alpha1(V) chains and one alpha2(V) chain. Whilst types I, III and V fibrils co-assemble, the N- terminus of type V collagen has a special role in regulating fibril growth, length and lateral associations. This has been convincingly demonstrated by Birk and colleagues, both in vivo and in vitro, in tissues such as skin, ligaments and cornea, in mice made haplo-insufficient for the equivalent mouse Col5a1 gene.[16] Such animals had signs very similar to classical EDS in humans, with decreased tensile strength of normal or wounded skin and vasculature. The decreased dosage of collagen type V allowed the formation of both relatively normal and highly abnormal type I collagen fibrils. The latter was caused by faulty nucleation, lateral aggregation and longitudinal growth, resulting in the formation of abnormal rosettes, triggered by the unrestrained growth of type I collagen fibrils. This is caused by the absence of the restraining type V protein.[17] Eyelids and corneal tissues[18], in which type V collagen forms 10-20% of corneal collagens, were studied in the Col5a1 mouse and compared to similar studies of defined human *COL5A1* or *COL5A2* mutants. In brief, affected patients had thin, steep and transparent corneas, with lax eyelids, blue sclerae, scleral fragility, microcornea, keratoconus, keratoglobus, ectopia lentis and retinal detachment. The mouse model showed significantly enlarged and distorted corneal collagen fibrils, however, less severely disrupted than dermal fibrils.

The recognition that collagen type V mutations caused classical EDS lagged more than 20 years behind similar discoveries of the role of collagen III in vascular EDS. Retrospectively, this was due to the rarity of collagen V protein abnormalities. Nevertheless in 1994[19] a shortened alpha1(V) chain in a classical EDS (mitis) variant was discovered, which showed impressively disorganised collagen fibrils in dermis and various ligamentous tissues, as well

as corneal flattening.[18] Later it became apparent that this was caused by a 54bp deletion leading to heterozygous skipping of exon 65 of the *COL5A1* gene.[20] Other mutations quickly followed, including a translocation, which interrupted the *COL5A1* gene.[21] Gene linkage confirmed that the *COL5A1* gene is involved autosomal dominant classical EDS.[22,23] At least one of the mutations of *COL5A2*, causing both , the gravis and mitis variants of classical EDS,[24,25] showed deficiency of collagen alpha2 chains, in vitro. Later, haplo-insufficiency of *COL5A1* gene dosage, caused by a variety of mechanisms,[26, 27] proved to be the most common cause of EDS classical type. Furthermore, this caused a misdirection of collagen fibrillogenesis. Very occasionally, and rather puzzlingly[28], homozygosity for a helical glycine mutation can also cause a mild form of classical EDS. A 2005 study of 48 patients with classical EDS, showed abnormal collagen protein profiles in only 2/48 (4.4%), whilst ten times as many (43%) were haplo-insufficient. In these 48 patients, 22 mutations of either *COL5A1* or *COL5A2* were detected, including 17 stop codons and 5 structural mutations of the types mentioned above. As three of the patients with a positive null allele test carried no detectable *COL5A1* mutation, only 52% of classical EDS patients have detectable *COL5A1* or *COL5A2* defects.[29] Ritelli et al. also found in 50% of their 40 cases a mutation in *COL5A1* (18) or *COL5A2* (2).[30] However, Symoens et al. detected in over 90% of patients, who fulfil all three major Villefranche criteria for classical EDS (n = 102), a defect in (products of) either *COL5A1* (80) or *COL5A2* (13).[31] It remains to be seen whether other elements in fibrillogenesis, such as *COL5A3*, decorin, tenascin X, thrombospondin or unidentified extracellular matrix constituents contribute to the molecular pathology of classical EDS.
The recently identified subtype of classical EDS which is clinically characterized by a propensity to arterial rupture, is caused - as mentioned earlier - by a specific mutation in *COL1A1* (c.934C>T; p.R134C).[8,9,10]

7. Differential diagnosis

Here we address only those inherited defects of connective tissue, in which cutaneous symptoms and signs predominate (see[32]).

7.1 Tenascin-X (TNX) deficient EDS

TNX deficient EDS is an autosomal recessive variant of classical EDS, named classical-like EDS (see chapter 2).[11] Clinically it shows elastic, velvety skin, hypermobile joints and easy bruising, without abnormal wound healing or atrophic scars. In 3 of the 8 patients described, multiple subluxations were part of the clinical picture and in 2 cases joint pain was mentioned. Moreover, the patients were also reported to have a range of additional clinical problems not frequently associated with EDS, including spina bifida occulta, mitral-valve prolapse, stroke, gastrointestinal bleeding and premature arteriosclerosis. It is not clear whether these findings are related to the TNX deficiency. Skin biopsy shows both abnormal elastic fibres and reduced collagen deposition. TNX may contribute to matrix stability by interacting with other matrix components, such as proteoglycans. This might also regulate collagen fibrillogenesis.[33] TNX is undetectable in serum in affected homozygotes, whilst it is 50% of normal control levels in heterozygotes carriers of whom some had signs and symptoms of hypermobile EDS.

7.2 Other similar EDS types

Classical EDS must be distinguished from other EDS types, especially hypermobile EDS, with which there may be clinical overlap. Particularly in mild cases of classical EDS, hypermobile EDS can be difficult to distinguish.

7.3 The Occipital Horn syndrome

The Occipital Horn syndrome is a very rare disorder of copper metabolism which, in the old Berlin classification of 1988, was included as a curious form of EDS, but it is no longer part of the EDS classification. It is an X-linked recessive syndrome. Clinical features include soft, mildly extensible, loose and redundant skin with easy bruisability, but without fragility. Other clinical signs include a persistent anterior fontanel, frequent loose stools, obstructive uropathy and mild mental retardation. Increased joint hypermobility may occur, except for the knee and elbow joints which show only limited extension. Radiologically, occipital horns, wedge shaped calcifications at the attachment sites of the trapezius and sternocleidomastoid muscles, are characteristic. It is caused by a mutation in the Cu(2+)-transporting ATPase, alpha polypeptide. The concentrations of copper and ceruloplasmin in serum are low and probably impair collagen cross-linking.

7.4 Cutis Laxa

Cutis Laxa (CL) refers to the redundant inelastic quality of the skin, which, in contrast to EDS- types, is not (hyper)elastic. Original descriptions of EDS often did not readily distinguish between the easily stretched skin of EDS and the ill-fitting, overstretched integument of true CL. Autosomal dominant and autosomal recessive as well as X-linked subtypes of primary CL, frequently seen with accompanying lung and aortic pathology, are caused by abnormalities of elastin or elastic microfibrils. Secondary CL complicates conditions such as PXE and EDS.

7.5 Child abuse

Child abuse is certainly included in the differential diagnosis of classical EDS. Not surprisingly, the predisposition to bruising and cutaneous damage sometimes raises this possibility. Similarly, EDS is included in the differential diagnosis of child abuse. Of course, it must be realised that EDS and child abuse are not necessarily mutually exclusive diagnoses.
In distinguishing the one from the other, familiarity with the various clinical criteria included in the most recent classification is essential, as is a thorough family history, clinical examination and, where indicated, laboratory tests, such as electron microscopy, protein electrophoresis, metabolic analysis and DNA analysis. Similarly, there are very well established clinical criteria which deal with bruise distribution and morphology, and other accompanying clinical signs, likely to indicate child abuse.[34]
For example, in child abuse, bruising mostly occurs over relatively protected sites of the skin (trunk, buttocks, genital area), while in traumas and in classical EDS and other types, the knees, the anterior tibial area and bony prominences are mostly affected.[35]

8. Protection and preventative measures

Here we focus mainly upon measures which protect the skin or promote cutaneous wound healing. For measures concerning other problems associated with classical EDS, one is referred to other chapters, like 10, 13, 16 and 17. Unfortunately, in the absence of specific therapy for classical EDS or any other type, only simple preventive measures to protect the skin are applicable. All are anecdotal, common sense measures, rather than evidence based upon appropriate clinical trials.

8.1 Protection

Particularly in younger children, protective bandages or pads applied at sites of repetitive trauma such as the forehead, elbows, knees and shins, can minimise wounds and lacerations. Older children might prefer protection by more fashionable sports devices, such as those used for knees, elbows and shins in skiing, skating or football rather than protection by medical

bandages. Head protection for certain contact sports or cycling is also desirable, whilst for games such as tennis and squash eye protection with fragmentation resistant goggles is desirable.
At home the corners of tables and other furniture can be protected and the tables or other barriers should not be put in the centre of the room, in order to prevent trauma.
Contact sports are to be discouraged.
In case more specific advice is needed, one may consider rheologic evaluations of the skin (see 2.2.1), since these tests may detect patients with very vulnerable skin more reliably; it also may be used to predict the difficulty in suturing.[3]

8.2 Bleeding prevention
In case of bruising, a pressure bandage can be used, or elevation of the affected limb will help to prevent further cutaneous bleeding. In case of tooth extractions, surgery and a history of heavy bleeds, further bleeding and clotting tests are indicated and, if abnormal, measures can be taken, see chapter 11.

8.3 Sun protection
Skin thinning and increased fragility, together with reduced subcutaneous fat formation, is part of normal ageing. Although this occurs also in sun protected areas, it is especially evident in sun-exposed areas. Sunlight damages the epidermis, leading to a higher risk of skin tumours, but also damages the dermis. In the latter, it causes loss of elasticity in elastic fibres (elastosis). Also sunlight causes collagen-fibres to decrease and degenerate. This effect is magnified in classical and other EDS types, in which the underlying collagen is already abnormal. Sun protection is therefore particularly important in EDS patients.

8.4 Smoking
Smoking is also associated with elastosis (see 7.3) among both sexes,[36] so it is wise to refrain from smoking in case of EDS.

8.5 Medication
Suggestions made in the literature that the use of 1-2 grams of ascorbic acid (vitamin C) a day may promote collagen synthesis, thereby assisting collagen repair and wound healing or even reduce vascular fragility, should be regarded as unproven.
Generally avoiding aspirin (acetylsalicylic acid) or non-steroidals such as ibuprofen, all of which enhance bleeding and bruising due to their negative effect on platelet function, is sensible. Similarly, skin atrophy as adverse effect of chronic inhaled or systemic glucocorticoid treatment is more outspoken in EDS than in otherwise normal individuals.

9. Surgical advice
All surgical procedures have additional risks in classical EDS, since the skin is fragile: it heals slowly and sutures are more damaging and less stable than in normal skin. Specific advice on how to treat wounds is given in the addendum on surgery. Bearing these facts in mind, major elective surgery can be surprisingly uncomplicated. This contrasts with vascular EDS, in which the repair of hollow organs and vascular anastomoses can be very problematic. Procedures such as dermabrasion or skin filling are probably contraindicated and laser treatment carries the risk of hypertrophic scarring. See also the addendum.

10. Areas of uncertainty

10.1 Absence of inferior labial or lingual frenulum

As the labial and lingual frenula consist mainly of ligament-like connective tissue structures, the morphology of these structures has been examined in EDS.[37] Opinions vary as to whether the fraenum of the lower lip and the sublingual frenulum are missing in classical EDS. [37,38,39] Further studies are required to resolve these disparities.

Previously, a positive Gorlin sign was regarded as common in EDS. The sign is positive when the tip of the nose can be touched by the tip of the tongue.[40] Presently, its exact frequency in classical EDS is unclear and further studies are needed.

10.2 Knowledge of the aetiology

As described earlier in section 6, mutations of *COL5A1* or *COL5A2* explain 50 to over 90% of classical EDS. It remains to be seen which other matrix genes and proteins are involved in the remainder of the patients.

10.3 Treatment possibilities

So far, no double blinded, placebo controlled trials have been done to test the efficacy of substances such as ascorbic acid, glucosamine, Coenzyme Q10, pycnogenol and may be others.[41] Because the expected effect will most probably be not too big, multicentre trials of adequate numbers of EDS patients would be necessary to prove therapeutic efficacy.

A version of this chapter has been published: Jacobs JWG, da Silva JAP. Hypermobility syndromes from the clinician's perspective: an overview. Acta Reumatol Port 2014; 39: 124-36.

1. Introduction

Joint hypermobility is defined as an increased range of movement in one or more joints. When many joints are hypermobile in an individual, we speak of ***generalised joint hypermobility***, a relatively common condition. There are several classification criteria and scores sets for this physical trait - scores of Beighton and Bulbena are presented in chapter 2;[1,2] classification criteria are discussed in other paragraphs.[3] While the Beighton score is limited to the assessment of the range of motion of a pre-determined set of joints/groups of joints, the Bulbena score also scores ecchymosis. For this reason, the Beighton score is now considered the most appropriate tool for assessing generalised joint hypermobility in adults and children, though with different cut-offs.[4] The adjective "generalised" implies that joint hypermobility is present at multiple sites, but distribution and extent of joint hypermobility are quite variable and influenced by constitutional and acquired factors. A scoring system ideally accounting for all variables has not yet been developed and scoring with available tools is influenced by the practitioner's experience.

Individuals with (generalised) joint hypermobility may be asymptomatic. Often, however, joint hypermobility is accompanied by musculoskeletal symptoms such as pain in joints, ligaments, entheses (attachment sites of tendons or ligaments to the bone) and muscles - this may be referred to as ***symptomatic joint hypermobility***. In addition, (generalised) joint hypermobility can be associated with a wider spectrum of symptoms and signs reflecting involvement of other tissues, organs, and organ systems, attributable to the pleiotropic nature of underlying defects. In such cases the term "***joint hypermobility syndromes***" seems appropriate. The term "syndrome" refers to group of signs and symptoms recurring in association and defining a cluster of clinical relevance, known or thought to be causally (etiologically) related. Joint hypermobility syndromes are conditions with a strong genetic basis, in which (generalised) joint hypermobility is the shared congenital trait.

Although many individuals with (generalised) joint hypermobility do not stand out clinically, and do not meet criteria of a specific syndrome, others meet criteria of a specific defined syndrome, potentially associated with chronic disabilities or life-threatening complications. This makes it important not to overlook these diagnoses.

The aim of this chapter is to provide the rheumatologist and other health professionals an overview of the broad spectrum of symptomatic joint hypermobility and joint hypermobility syndromes they may be confronted with, as guidance in daily practice. Clinical aspects, with emphasis on musculoskeletal problems, are described and clues for diagnosis and management are provided.

2. Epidemiological aspects

Generalised joint hypermobility may actually be a variant of normal joint mobility, along the upper tail of the Gaussian curve describing the range of motion of normal joints in the population, just as individuals can be short or tall. In general, the range of motion of most joints and thus the chance of observing generalised joint hypermobility decreases with increasing age. Generalised joint hypermobility is more common in females than males and occurs more often in some racial groups, e.g. Asians when compared to Caucasians.[5] Many healthy young individuals, especially females performing ballet or gymnastics, would probably meet the criteria of generalised joint hypermobility according to the Beighton set, if they were screened. In some sports, generalised joint hypermobility may be an advantage, but it may also be a liability due to the increased risk of injuries.[6,7] Reassuringly, a study among professional dancers concluded that generalised joint hypermobility was not associated with a higher risk of injuries when assessed prospectively.[8] However, this observation does not rule out an increased risk of injury associated with generalised joint hypermobility in the (less trained) general population. In fact, those more prone to injuries may have fallen short of a

desired professional sports career.

People presenting for medical care with symptomatic joint hypermobility are most probably a subgroup of those with generalised joint hypermobility in the population. Furthermore, not all cases of this subgroup will meet criteria of available scoring systems for generalised joint hypermobility. An even smaller number will meet criteria for a specific joint hypermobility syndrome, such as Ehlers-Danlos syndrome (EDS), a group of syndromes with as key features multi-site joint hypermobility, abnormal skin texture and a variable range of dysfunctions or fragility of vessels and internal organs. A description of all EDS types is beyond the scope of this chapter.

Exact prevalence estimates for EDS are difficult to make for two main reasons. First, there is the problem of recognition: not all individuals with joint hypermobility have relevant symptoms and reach medical attention. If generalised joint hypermobility is borderline and skin manifestations are mild, they might stay unrecognized. As a consequence, estimates on the prevalence of EDS types depend on whether they are based on clinical reports of the syndromes or on screening studies in populations and, in this case, on methodological properties of screening methods. In the latter case, the prevalence estimates will be probably more accurate and higher. A study in a general dermatology population revealed that common variants (phenotypes, see chapter 2) of EDS might be present in up to 9% of this population.[9]

Second, there is the problem of older and current classifications: significant overlap exists between the signs, symptoms and classification criteria of hypermobile EDS and those of the benign joint hypermobility syndrome (BJHS),[10] both of which may show familial aggregation. In the past, the presence of generalised joint hypermobility and its secondary musculoskeletal manifestations was thought sufficient for defining a "genetic syndrome"; e.g. BJHS may be diagnosed, if a Beighton score ≥4 and joint pain at multiple sites (i.e. the two major Brighton criteria) are present. But, familial clustering of generalised joint hypermobility (either symptomatic or not) is not always the marker of a hereditary syndrome affecting multiple soft connective tissues. This was in 2016 the rationale to mend the double, overlapping terminologies and keep a single syndromic entity (i.e. hypermobile EDS), which would define only patients with a likely multisystem disorder. Alternative names (not including the term "syndrome") should be preferably used for patients showing symptomatic generalised joint hypermobility, but not meeting the criteria for hypermobile EDS or any other partially overlapping hereditary soft connective tissue disorder. Recently, the term "hypermobility spectrum disorders" has been proposed as an exclusion diagnosis for those individuals who show some range of joint hypermobility and related musculoskeletal complaints, but who do not meet the criteria for presently defined joint hypermobility syndromes, including hypermobile EDS.[11]

The prevalence of what was classed as generalised joint hypermobility was estimated to range from 10–30% in adults, varying from 10-15% in male youngsters between 11–17 years and up to 20–40% in girls of this age group,[12] which seem high percentages. The prevalence of EDS is probably higher than the current estimate of 1: 5,000,[13] although the most recent and stricter criteria for hypermobile EDS will impact such an assumption.

3. General symptoms, signs and complications of generalised joint hypermobility and joint hypermobility syndromes

Patients with symptomatic generalised joint hypermobility may share many clinical characteristics, typically including chronic musculoskeletal pain, fatigue, signs of autonomic dysfunction, functional gastro-intestinal manifestations and joint (sub)luxation. Pain and fatigue are the dominant symptoms. In the following section, we discuss the most prevalent symptoms and signs the clinician and health professional are confronted with, and their associations. Among these general symptoms, the non-musculoskeletal functional ones (e.g.

fatigue, cardiovascular dysautonomia, gastrointestinal motility issues) are now termed as "joint hypermobility-related co-morbidities".[11] Joint hypermobility-related co-morbidities may be common in individuals with non-syndromic, symptomatic joint hypermobility (i.e. hypermobility spectrum disorders) as well as in the various joint hypermobility syndromes. Hence, joint hypermobility-related co-morbidities are not specific enough for etiological or nosologic discrimination, although their assessment is crucial for prognostication and management.

3.1 Pain

There is an increased prevalence of arthralgia (joint pain), chronic generalised myalgia and fibromyalgia (chronic generalised pain in muscles and joints) in children and adults with generalised joint hypermobility.[5,10,14-20] In adults, joint hypermobility is also associated with back pain.[18,21] Perhaps surprisingly, the basis of the association of joint hypermobility and pain is not established. The most consensual view is that pain is due to repetitive strain, sprain and microtraumas of muscles and ligaments by the abnormal range-of-motion permitted by hypermobile joints, aggravated by diminished joint proprioception, position sense,[22-24] and decreased passive muscle tension.[25] Pain is also related with anxiety and depression, both of which seem to be more prevalent in EDS, especially hypermobile EDS, as well as in the former BJHS.[26-28] It is commonly believed that chronic pain elicits depressive feelings and that depression has an amplifying effect on chronic pain and fatigue, leading to a vicious circle. These latter symptoms could lead to reduced physical activity and thus physical deconditioning (reduced physical condition), increasing the propensity to injury, chronic pain and fatigue and initiating a downward negative spiral.
Furthermore, there seems to be a primary involvement of muscle in hypermobile EDS: muscle weakness has been found in the absence of reduced muscles mass, which would have been present if muscle weakness was the results of reduced physical activity only.[29] A hypothetic model of pain, including fatigue and physical deconditioning is depicted in figure 5-1.

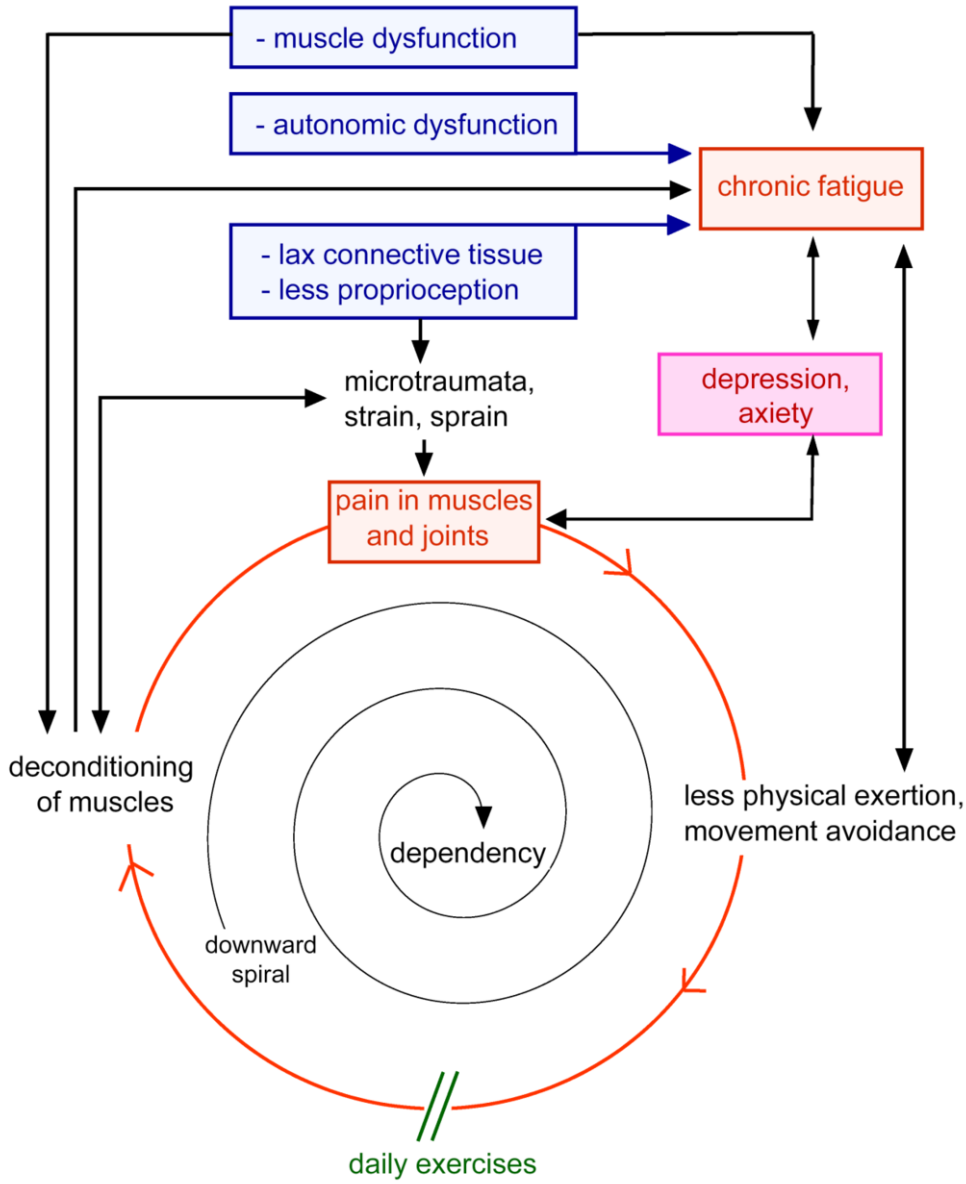
3.1.1 Insufficient effect of local analgesics

An insufficient effect of local analgesics either by intradermal injection or as topical cream application has been reported in patients with hypermobile EDS. A similar ineffectiveness has been observed in patients with generalised joint hypermobility.[30] This was thought to be due to the lax connective tissues in the skin allowing too much dispersal of the analgesic.[31,32] However, the dispersal of a radioisotope labelled solution following deep dermal injection did not differ between EDS patients and healthy controls in a small study.[33] So, the reason for the insufficient effect of local analgesics is not yet known.

3.2 Fatigue

Generalised joint hypermobility syndromes, particularly hypermobile EDS, are associated with increased fatigue.[34-36] A hypothesis is that fatigue is a symptom of autonomic dysfunction or dysautonomia, described below.[35,36] Others suggest that the ligamentous laxity demands increased vigilance, muscle tension and coordination to maintain adequate joint position and body balance,[24,37,38] thus leading to fatigue. In addition, these patients often show muscle weakness,[29] reduced exercise tolerance, physical deconditioning and pulmonary symptoms (see below),[39] commonly attributed to reduced exercise because of chronic pain (figure 5-1). Finally, fatigue could be associated with depression and other psychological problems associated with generalised joint hypermobility.[36,40] Most probably, fatigue is caused by a constellation of these factors, of which the individual impact will vary between patients.

Figure 5-1 Vicious circle in generalised hypermobility of chronic pain and fatigue



Via several mechanisms, pain and chronic fatigue may ensue, leading to less physical exercise. This leads to physical deconditioning, associated with chronic pain and fatigue, and a vicious circle. The way to break this vicious circle and often downward spiral is to prevent or treat (further) physical deconditioning by daily physical training (exercises). Not all features have to be clearly present in all patients.

Fatigue and generalised pain are paramount among the symptoms that establish a clinical similarity and diagnostic confusion between joint hypermobility syndromes and fibromyalgia[14-17,41]. Some authors even argue whether fibromyalgia is merely a description of the symptoms of EDS or a separate disease entity in these patients.[14-17]

3.3 Autonomic dysfunction

Autonomic dysfunction comprises disturbances in a variety of functions dependent on the autonomic nervous system, leading for instance to orthostatic hypotension or tachycardia, leading to (pre)syncope and palpitations. Such symptoms have been reported in higher than expected frequency in patients with BJHS and EDS.[35,36] Lower urinary tract dysfunction associated with generalised joint hypermobility might also be related to autonomic dysfunction, alongside laxity of the connective tissue of the pelvic floor and the sphincter.[42,43] Gastro-intestinal disturbances, such as gastro-oesophageal reflux, constipation and irritable bowel syndrome or malabsorption, are more common in BJHS and EDS, and might share a similar pathophysiology.[44] The prevalence of both urinary and faecal incontinence has been described as significantly higher in women with joint hypermobility syndromes than in women without these conditions.[42,43,45-48]

3.4 Joint (sub)luxation

Joint luxation or subluxation are not specific features of generalised joint hypermobility and generalised joint hypermobility syndromes. Probably (sub)luxation reflects the severity of the joint laxity and impaired local muscle strength and coordination. If (sub)luxation occurs frequently in a specific joint, this often becomes less painful and sometimes (sub)luxation can be demonstrated by the patient on request.

3.5 Decreased bone mass and increased risk of fractures

In EDS and Marfan syndrome, a higher prevalence of low bone mineral density, osteopenia or osteoporosis are reported in most studies,[49-53] but not all.[54] In a study with 23 patients with hypermobile EDS and 23 matched controls, EDS subjects had a significantly lower bone mineral density at the femoral neck, but this difference disappeared after adjustment for body height, weight and physical activity levels.[55] Thus, reduced exercise or immobility induced by generalised joint hypermobility may be important in determining osteopenia, probably in association with the inherited structural deficit. Furthermore, an increased incidence of falls (and thus increased risk of fractures) has been reported in hypermobile EDS,[38] due to impaired balance and muscle weakness. This might be at least partially preventable by appropriate exercise programs. Early-onset osteoporosis and increased risk of fractures are features of rare EDS types with marked bone involvement, such as the EDS/osteogenesis imperfecta overlap.

3.6 Osteoarthritis

A relationship between joint hypermobility syndromes and osteoarthritis would be expected especially as long-term complication in patients with frequent (sub)luxations. However, the literature data are equivocal: while some papers describe a relation between joint hypermobility and osteoarthritis[56,57], others even indicate an inverse relation.[54,58,59]

3.7 Life-threatening manifestations and complications

Some specific joint hypermobility syndromes, e.g. vascular EDS, Marfan syndrome and Loeys-Dietz syndromes may have life-threatening manifestations, such as aneurysms and arterial ruptures. Next to vascular complications, life-threatening ruptures of the bowel and of the pregnant uterus are also manifestations of vascular EDS.[60,61] Fortunately, these manifestations or complications do not happen in the more frequently occurring joint hypermobility syndromes.

4. Classification into a specific joint hypermobility syndrome

For some of the joint hypermobility syndromes, the diagnosis can be made early based on

evident signs and symptoms, although because of profound muscle hypotonia, patients initially are suspected of having a muscle disorder. However, more frequently, the clinician will be faced with previously undiagnosed generalised joint hypermobility in a patient presenting with symptoms; in such cases, it most often concerns hypermobile EDS.[62] More rarely, such patients may present with another syndrome, such as classical EDS, Marfan syndrome or vascular EDS (yet without clear vascular complications).
So, the first and most important step in eliciting such diagnosis is awareness of the broad spectrum of joint hypermobility syndromes.
Would classification of such cases into a specific syndrome be clinically important? And, if so, how could we best do that?

4.1 Why classify generalised joint hypermobility?

It is important to identify and classify generalised joint hypermobility, not only to optimise management, but also because some syndromes are associated with life-threatening risks outside the musculoskeletal system, as described above. Although these diseases cannot be cured and complications cannot be totally prevented, awareness and appropriate measures will diminish the risks of such events. For patients with these severe disorders, family planning and management are also indicated.

4.2 How to go about classification?

Clinical diagnosis was in the past, for most of the syndromes, based on clinical recognition of reported symptoms and signs at physical exam, but nowadays the diagnosis of most syndromes is supported by molecular testing, which is especially important for syndromes with life-threatening risks, like vascular EDS, Marfan syndrome and Loeys-Dietz syndromes. Hence, a formal diagnosis of a recognized syndrome with joint hypermobility should be always supported by a positive molecular testing and/or strict adherence to available diagnostic criteria. The hypermobile EDS, presumably the most common clinical variant of EDS, still remains without any confirmatory molecular testing. In order to support clinicians in the assessment of this condition, the most recent classification of EDS includes a detailed description of the procedural diagnostics and stricter diagnostic criteria for the hypermobile EDS (see chapter 2),[3] compared to the former classification of EDS hypermobility type.
For nomenclature, it is recommended that specific joint hypermobility syndromes are only diagnosed or referred to if published classification criteria are satisfied. Patients who do not satisfy such classification criteria should be described simply as having *generalised joint hypermobility, no specific syndrome* or *hypermobility spectrum disorders*, according to the most recent EDS classification. Clinicians should refrain from using supposed synonyms for specific syndromes, composed of various combinations of terms ‘benign’, ‘familial’, ‘generalised’, ‘articular’, ‘joint’, ‘hypermobility’ and ‘syndrome’, leading to abbreviations like AHS, BFHS, BHS, BJHS, BJFHS, FAH, FGAH, FHS, JHS and HS. Such terms do not correspond to distinctive features and their use adds to confusion. Given the overlap of former EDS hypermobility type and BJHS, many clinicians considered these two disorders one and the same, sometimes referred to with the acronym (B)JHS/ EDSht. This approach has been demonstrated realistic in familial cases with a convincing Mendelian pattern of inheritance, although doubts still remain for sporadic/simplex cases.

5. Specific hypermobility syndromes presenting to the clinician

It can be challenging to classify a patient with generalised joint hypermobility. Note that specific joint hypermobility syndromes differ most in the non-musculoskeletal symptoms and signs. In fact, if such non-musculoskeletal symptoms and signs are absent or scarce, clinical classification is difficult given that the skeletal manifestations are very similar. In the face of

such uncertainty, it is important to remind what the key objective is: to make sure that syndromes with a high risk of life threatening, especially vascular, complications are not overlooked.
Pattern recognition and evaluation of discriminating features (table 5-1) help making the right diagnosis. Important clues come from the patient's history. For example, uncomplicated bowel and vascular surgery and uncomplicated vaginal delivery are arguments against vascular EDS, even if they do not exclude this diagnosis completely.[63,64] Specific discriminating signs or symptoms include the specific physique (phenotype) and lens dislocations in Marfan syndrome and the appearance of the skin,[65,66] for instance in EDS. A family history of people dying relatively young of cardio-vascular complications, especially vascular ruptures, are clues for vascular EDS, the related Loeys-Dietz syndromes and Marfan syndrome.

5.1 Joint hypermobility syndromes with potentially life-threatening complications
Recognizing these conditions early in their course is important, as they lead to chronic disabilities with loss of many working days, force patients to multiple consultations and a myriad of ineffective therapies, and decrease quality of life. This is especially true for joint hypermobility syndromes with potentially life-threatening complications. These include vascular EDS, Loeys-Dietz syndrome,[67,68] and Marfan syndrome.

Vascular EDS is associated with a severe prognosis: patients often die prematurely from rupture of arteries and/or hollow organs, such as intestines and uterus during pregnancy.[69] The typical phenotype consists of thin and translucent skin, showing underling veins, giving especially the hands an aged appearance ('acrogeria', see figure 5-2) and nonspecific dysmorphic features of the face. However, typical features may be absent.

Figure 5-2 Acrogeria in a 32-year old woman with vascular EDS: the hand looks much older than the patient really is

The family history may reveal cases of ruptures of arteries and/or hollow organs, but the presenting patient could also be the only one in the family with vascular EDS, due to a novel *point-mutation* in the COL3A1 gene. So, making a clinical diagnosis is not always easy; luckily there are genetic tests for this EDS type.
Measures to prevent complications are possible, including life-style measures: avoiding sports with risk of trauma and with elevations of blood pressure, stop smoking, meticulous monitoring and control of blood pressure to low-normal values. In a study of 5-years duration, therapy with the beta-blocker celiprolol prevented major complications in patients with vascular EDS, compared to EDS patients randomly assigned no drug therapy.[70,71]

The phenotype of *Loeys-Dietz syndromes* partially overlaps that of vascular EDS (vascular ruptures and extensive easy bruising) and of Marfan syndrome (aortic aneurysm/dissection, dolichostenomelia and arachnodactyly). The syndrome is caused by *TGFBR1, TGFBR2, TGFB2, TGFB3* and *SMAD3* mutations. *TGFBR1 or TGFBR2* mutations are in the genes encoding for transforming growth factor β receptor type 1 or type 2, respectively. Transforming growth factor β is a cytokine that exerts diverse roles in cell proliferation and differentiation, apoptosis (programmed cell death), and extracellular matrix formation.[72] Patients with *TGFBR1* or *TGFBR2* tend to have aortic dissections at smaller aortic-root diameters compared to patients with Marfan syndrome, but compared to patients with vascular EDS , outcomes after aortic surgery are better.[68,73] Patients with a mutation in the *SMAD3* gene, next to vascular complications, have osteoarthritis at a relatively young age.[74] Patients with mutations in *TGFB2* and *TGFB3* are at the moment phenotypically not distinguishable from those with mutations in *TGFBR1* and *TGFBR2*.

Marfan syndrome is an autosomal dominant hereditary connective tissue disorder with a prevalence of about 1:5000; about 25% of the cases is caused by a new mutation.[72,75] The 1996 Ghent criteria for diagnosis of Marfan syndrome[76] have been updated in 2010,[77] and include involvement of the skeletal system (generalised hypermobility and marfanoid habitus), of the ocular system (lens dislocation), the cardiovascular system (increase aortic diameter or dissection), results of genetic testing and the skin.[78] However, among individual patients, considerable heterogeneity of phenotype, signs and symptoms is present.[72]
Genetic testing of Marfan is directed at finding a causative mutation in the *FBN1* gene, encoding the structural protein fibrillin-1. Less than 10% of patients fulfilling the revised Ghent criteria for Marfan syndrome have no mutation in this gene. The angiotensin II receptor blocker losartan seems to inhibit progressive aortic root dilation in patients with Marfan syndrome.[75,79]

5.2 Stickler syndrome

Stickler syndrome (hereditary progressive arthro-ophthalmopathy) is another likely under-recognized hereditary connective tissue disorder which may show generalised joint hypermobility. It shares a leptosomic/dolichostenomelic habitus with Marfan syndrome and joint pain/arthralgia with EDS. However, skin laxity and severe vascular complications are not features of this syndrome (table 5-2).[80,81] It is usually distinguished by the typical facial features, cleft palate, severe and early-onset myopia, and deafness. Although typical cases may be recognized at a young age, the diagnosis often is delayed due to the variability of the phenotype.[82] Different variants of Stickler syndrome exist, distinguishable by the presence/absence of key clinical features and/or inheritance pattern.[83] Genetic testing of the *COL2A1*, *COL11A1*, *COL11A2*, *COL9A1*, *COL9A2, COL9A3* and *LOXL3* genes can confirm the clinical diagnosis.

6. Principles of management of musculoskeletal problems in patients with symptomatic joint hypermobility and joint hypermobility syndromes

Although there are no randomized controlled studies regarding the effects of existing treatments for musculoskeletal problems in patients with symptomatic hypermobility, this does not mean that certain therapeutic strategies could not be helpful.[84] They are mentioned only briefly below.

6.1 Education is the first step after the diagnosis. It should tackle the feelings of frustration with misunderstanding of the complaints by the medical profession and social entourage, often during many years;[85] and the frustration about the absence of clear physical signs and laboratory abnormalities. It also comprises life-style advices (e.g. on rest, sleep hygiene, activities, prevention of trauma and of overweight), directions on self-help, redirecting false cognitions and other cognitive-behavioural strategies, coping, improving patient self-esteem and self-efficacy, genetic counselling.

6.2 Physical therapy and daily exercises at home should be performed: toning exercises for stabilization of joints, exercises improving proprioception, exercises diminishing physical deconditioning (figure 5-1) and improving posture. Heavy resistance training seems feasible and effective in classical EDS patients, improving tendon and skeletal muscle properties.[86] In patients with osteoarthritis of the hip or knee (without a joint hypermobility syndrome) exercise therapy has demonstrated efficacy in reducing pain and disability;[87] in hypermobile children also a beneficial effect of physiotherapy on pain was found.[88] It seems prudent to advice exercises to improve muscle strength and proprioception of joints, although in patients with joint hypermobility syndromes there is lack of data.[89] The prospective study showing no relationship between joint hypermobility and injury in dancers,[8] who often have a trained body, could also be an argument for exercises. There seems to be no contra-indication against prudent stretching exercises, but prolonged joint hyperextension, e.g. standing with hyperextended knees, should be avoided.
Modalities like heat or cold application, electrical stimulation to alleviate pain, acupuncture, acupressure, biofeedback, yoga and conscious relaxation are not evidence-based, but might have a beneficial effect on pain in some patients.
It seems prudent to advise weight-bearing exercises for the long bones and spine and an adequate intake of calcium and vitamin D in patients with symptomatic joint hypermobility, to prevent fractures.

6.3 Adaptations and assistive devices (braces, grasps, waterbed, mattress, wheelchair, electric scooter), adapted shoes, adaptations to living and working environment could all have a place in the management strategy. Care should be put in avoiding that adaptations and assistive devices lead to less physical exercises or activities, as this could potentially be harmful by increasing physical deconditioning and ensuing complaints. However, adaptations and assistive devices may lead to increased activities and there can be medical and social reasons to prescribe them.

6.4 Drugs, such as medications for pain, disturbed sleep, depression and fatigue could have a place in the management of selected patients with symptomatic hypermobility. However, in chronic diseases, these drugs usually only have a mild, often temporarily symptomatic effect. Apart from treating hypertension, which is always necessary, in Marfan syndrome losartan has a place and celiprolol in vascular EDS,[71] to diminish the risk of vascular complications.

6.5 Surgical procedures on joints should be avoided, if possible. For example, in patients with joint hypermobility and repetitive luxation of the shoulder, surgery often is ineffective, according to clinical experience.

7. Areas of uncertainty

The exact incidence of most of the joint hypermobility syndromes is not known. Possibly specific (types of) joint hypermobility syndromes are genetically based on different genetic defects; most new types of EDS have been recognized on the basis of genetic defects over the past years. Although specific drugs have been shown beneficial in Marfan syndrome and vascular EDS, it has not been investigated whether (other) antihypertensive medications would have a similar effect. Although scarce literature data indicate a beneficial effect of physiotherapy and exercises, the real long-term effect is not known, nor the effects, pros and cons of specific physiotherapeutic modalities.

8. Summary

Symptomatic joint hypermobility is a frequent occurring condition among patients referred to the rheumatologist or seen by other health care professionals. In a subset of patients, a further classifying diagnosis of a specific syndrome can (and should) be made, based on pattern recognition and knowledge of the spectrum of hypermobility syndromes. Diagnostic clues are the patient's and family history and signs at physical examination, including skin abnormalities. It is especially important to recognize hypermobility syndromes with potentially life threatening complications. Genetic testing is available for many syndromes and is now indicated to confirm/exclude the diagnosis in most circumstances. Referral to a specialized centre for diagnosis and long-term management is recommended.

The therapy is for the major part of conditions featuring joint hypermobility only symptomatic; key features of management are education and physical exercises; joint surgery is to be avoided.

Table 5-1 Classification of generalised joint hypermobility syndromes*

Classification	Possibly distinguishing feature(s)
Generalised joint hypermobility, no specific syndrome	None, associated/secondary musculoskeletal manifestations only
Ehlers-Danlos syndromes *	Abnormal skin texture, fragility and/or dysfunctions of internal organs and vessels, additional features by EDS type
Osteogenesis imperfecta	Liability to fractures, intensely blue sclera, bone deformities, dentinogenesis imperfecta, deafness
Loeys-Dietz syndromes	Vascular tortuosity and dissections, progressive aortic dilatation, facial dysmorphism, dolichostenomelia, arachnodactyly
Stickler syndrome	Early-onset myopia, vitreous degeneration, deafness, facial dysmorphism, cleft palate, spondyloepiphyseal dysplasia
Marfan syndrome	Progressive aortic dilatation, lens dislocation, dolichostenomelia, arachnodactyly

* not comprehensive; see related chapters

Table 5-2 Involved organ systems with their manifestations in Stickler syndrome* [81]

- Orofacial abnormalities:
  - cleft palate (open cleft, submucous cleft, or bifid uvula), highly arched palate
  - characteristic face (malar / midfacial hypoplasia, broad and/ or flat nasal bridge, micro / retrognathia)

- Ocular abnormalities: vitreous and retinal degeneration (lattice degeneration, retinal hole, detachment or tear), high myopia

- Auditory abnormalities:
  - high frequency (4–8 kHz) sensorineural hearing loss: at age<20: ≥ 20 dB, at age 20–40: ≥ 30 dB and at age >40: ≥ 40 dB
  - hypermobile tympanic membranes

- Skeletal abnormalities and symptoms:
  - generalised joint hypermobility
  - chronic musculoskeletal pain
  - femoral head disorders (slipped epiphysis or Legg–Perthes-like disease)
  - radiographically demonstrated osteoarthritis before age 40
  - scoliosis, spondylolisthesis, or Scheuermann-like kyphotic deformity
  - mild spondyloepiphyseal dysplasia
  - pectus excavatum or carinatum

* This list is by no means exhaustive; there is variable intra- and interfamilial heterogeneity in the involvement of these organ systems

1. Introduction and historical perspective

Although first described as a form of Cutis Laxa in 1892 by Tschernogobov, Ehlers-Danlos syndrome (EDS) vascular type was later recognized as autosomal dominantly inherited by Weiner in 1924 and finally categorized as a specific disorder of connective tissue by McKusick in 1956. A single patient with a vascular EDS phenotype was also clearly described by Sack (1936); the disorder was more formally defined by Barabas, as a separate type in 1967.[1] He recognized that the combination of extensive easy bruising and bleeding was associated with potentially lethal arterial fragility. Barabas and then Beighton (1968), almost simultaneously, proposed three or four distinctive types,[2] followed by McKusick's 1972 proposal of 5 types including the rare X-linked form first recognized by Beighton.[3] Later this was followed by the Berlin (1988), the Villefranche nosologies (1997), and then the 2017 International classification.[4,5,6] Similarly, the nosology of vascular EDS has varied, including terms such as EDS IV, EDS vascular type, acrogeria and ecchymotic EDS. As regards the role of defective connective tissue, by 1955, Jansen suggested that a genetic defect of the collagen "wickerwork" of the connective tissue would explain the mutant phenotypes.[7] In 1975, Pope et al. described type III collagen deficiency in the aorta and skin of three patients, including a teenage boy with "acrogeric EDS type IV", who had died of a dissecting subclavian aneurysm and ruptured aorta.[8] The family and biochemical data strongly suggested that the defect was a homozygous deficiency of procollagen type III.[9] Later, Byers et al. (1981) confirmed that, although procollagen type III secretion was indeed diminished, there also was intracellular accumulation, due to altered post-translational modification.[10] Furthermore, in common with *COL1A1* and *COL1A2* defects, this phenomenon became explicable by the dominant-negative effect of single mutations upon triple-helical assembly.[11] The first *COL3A1* mutations were published in 1989 by Superti-Furga et al.[12] A very recent review on vascular EDS was published by Byers et al.[13]

2. Epidemiology

The prevalence of vascular EDS has been estimated at 1/50.000 to 1/150.000.[14] Actually, the true rate is unknown and estimates based on ascertained cases might be serious underestimates of the prevalence in the population. Vascular EDS has been estimated to account for 5-10% of the six Villefranche classified EDS types.[15]

3. Clinical presentation

Vascular EDS (old designation EDS vascular type or type IV) is a member of the so-called inherited defects of connective tissue diseases family, which include disorders such as Marfan Syndrome, osteogenesis imperfecta, cutis laxa, pseudoxanthoma elasticum and EDS. Unlike other forms of EDS, the skin hyperextensibility and joint hypermobility in vascular EDS are variable, often being mild or even absent. In 1997, a medical advisory group sponsored by the Ehlers-Danlos Foundation (USA) and the Ehlers-Danlos support group (UK) defined at Villefranche a modified set of diagnostic criteria which refined the previous Berlin classification, and more clearly distinguished the various EDS types.[4] In this Villefranche nosology, the clinical categorization of vascular EDS is based on four major criteria: (1) a characteristic facial aspect (Madonna facies, see below) (2) thin and translucent skin with visible subcutaneous veins, (3) easy bruising with haematomas and ecchymoses and finally (4) arterial, intestinal and uterine ruptures. The combination of any of the two major diagnostic criteria is highly specific for vascular EDS. Further biochemical and genetic testing is recommended to confirm the diagnosis. The presence of one or more minor criteria supports the clinical diagnosis of vascular EDS vascular type but is not sufficient to establish the diagnosis. Minor criteria include a positive family history of sudden death from vascular or intestinal rupture in a close relative, acrogeria (aged aspect of the hands and/or feet),

hypermobility of small joints, tendon and muscle rupture, club foot (talipes equinovarus), early onset varicose veins and spontaneous pneumothorax or haemothorax. In the 2017 International classification the minimal criteria for diagnosis are a family history of vascular EDS, arterial rupture or dissection <40 years, unexplained sigmoid colon rupture or spontaneous pneumothorax in the presence of other features consistent with vascular EDS should each lead to verifying diagnostic tests as does a combination of other minor criteria (for details see chapter 2, table 2-5).[6]

3.1 Facial appearance

Characteristic acrogeric facial appearance of vascular EDS patients is present only in about 30% of patients.[16] Acrogeria defines features such as an emaciated facies with prominent cheek bones and sunken, hollow cheeks. The eyes may be sunken, (perhaps due to a lack of orbital fat), or more commonly, bulging often with darkly coloured orbits, and capillary telangiectasia of the eyelids.[17] The nose is pinched, delicate and thin, as are the lips, particularly the upper lip. Sometimes tightness of the skin over the face may lead to a more youthful appearance, similar to a face-lift and this is known as Madonna facies. The ears are firm and tight, frequently with small ear lobes. There is sometimes accompanying diffuse alopecia and such patients have been categorized as having metageria.[18]

3.2 Cutaneous changes

Unlike in other types of EDS, affected individuals often have inelastic, thin, translucent skin.[19] The skin is smooth and soft (and sometimes referred to as “velvety”). The capillaries and subcutaneous veins under the skin are easily visible, especially over the chest, shoulders, thighs and calves, or less often, the abdomen. The dorsal skin of the hands and feet is often very thin with atrophic fine wrinkling: acrogeria.[15] Bazex and Dupre noted that forward flexion of the trunk easily reveals subcutaneous veins on the lower back, although it might also be seen in other EDS types.[20] Fragility of the skin, especially of knees and shins, is less severe than in classical EDS. Poor quality wound healing and pretibial deposition of orange blue haemosiderin occurs in vascular EDS, as well as in classical and periodontal EDS. Scar formation can be abnormal, leading to atrophic, widened scars, referred to as cigarette paper scarring. Keloid formation and elastosis perforans serpiginosa are suggestive of vascular EDS, but not specific for it. Typically, elastosis perforans serpiginosa presents with well marginated circular lesions with central atrophy, typically distributed over the neck and upper and lower extremities. Biopsy with staining of elastic fibres distinguishes this from granuloma annulare, perforating collagenosis and fungal infections.

3.3 Easy bruising

Excessive bruising is a common sign and is often the first presenting complaint, but is not specific for vascular EDS, as it is also common in classical and arthrochalasia EDS.[21] Gum fragility following normal dental hygiene is common, but also complicates the hypermobile and periodontal (formerly type VIII) EDS , whilst profuse bleeding after tooth extraction can also occur. Bleeding and clotting studies are usually normal, as in other EDS types, whilst the Rumpel-Leede or Hess test may be positive, suggesting capillary fragility (see Chapter 11).[22]

3.4 Vascular fragility

Vascular fragility in vascular EDS is manifested both in the arterial and the venous vascular bed.

Arterial complications include arterial dissection and rupture, aneurysm formation, carotid-cavernous and other arterio-venous fistulae. Arterial dissection or rupture is the most common cause of death in vascular EDS, but the vascular pathology varies widely among individuals.

In many patients ruptures occur at locations that appear normal by angiography.[23] In a literature review, Berqvist et al. reported arterial rupture without underlying aneurysm in 33% of patients with a serious haemorrhagic complication.[23] Aneurysmal dilatation may occur at any site, with ensuing risk for dissection and arterio-venous fistulae, especially of the carotid cavernous sinuses. The visceral branches of the aorta, especially the renal, mesenteric, iliac and femoral arteries are particularly affected.[24] In series by Pepin et al. about half of the arterial complications in vascular EDS involved the thoracic and abdominal arteries and the rest was equally divided between the head, neck and limbs.[25] The distribution in the Mayo clinic series showed a higher proportion of complications in the thoraco-abdominal region.[26] There may also be widespread multifocal segmental arterial abnormalities.[16] Histological changes include thinning of the medial layer of the arteries, collagen depletion and elastic fragmentation and hypertrophy.

Intracranial haemorrhages occur in 4% of cases and although uncommon, vascular EDS is a cause of stroke in young adults.[27] In a series on neurological complications inpatients with vascular EDS, the mean age of onset of intracranial aneurysmal rupture, spontaneous carotid-cavernous sinus fistula and cervical artery aneurysm was 28 years.[28] Carotid-cavernous aneurysms commonly present with acute unilateral exophthalmos and cranial nerve palsies, manifested by tinnitus, thrill, headaches or pulsating exophthalmos with Horner syndrome.[28,29]

Although acute myocardial infarction is a rare complication, a number of case reports has been published.[30,31,32] Specific pathology includes coronary artery dissection, saccular, fusiform or other coronary aneurysms, or pericardial tamponade from ventricular rupture.[33] In one case this was accompanied by coincidental dextrocardia.[34] In our own series of vascular EDS, some of which is unpublished, there were three cases of vascular EDS with myocardial infarction, two of which were caused by coronary artery dissection. One of these had previously presented with a carotid-cavernous sinus aneurysm[35], another is described in Soonaawale et al.[36], whilst a third, a 28 year old female declined further investigation, because of insurance pressures.

Early onset varicose veins have been documented in up to 1 out of five patients in the Mayo clinic cohort[26] and venous aneurysms have also been reported.

3.5 Intestinal rupture

Since intestinal walls are rich in collagen type III, intestinal fragility is also an important risk in vascular EDS patients. Most perforations occur in the sigmoid colon but the small intestine can also occasionally be affected.[15] Spontaneous ruptures of the spleen and the liver have also been described.[37] Exceptionally, oesophageal rupture during vomiting (Boerhaave syndrome) has been observed.[38] There is a high risk (50%) of multiple colonic perforations and leakage from the anastomosis in case of simple segmental resection with immediate re-establishment of continuity.[39]

3.6 Uterine ruptures

Uterine rupture in the last trimester of pregnancy, during labour or soon after delivery is a well-known complication of vascular EDS. Maternal mortality has historically been estimated as high as 12%.[25] Pregnancy is also associated an increased risk of vascular ruptures either at delivery or post-delivery, although many women with vascular EDS have uncomplicated pregnancies.[40] Recent observations in a large study by Murray et al. reported slightly lower percentages of pregnancy-related deaths in 5.3% of pregnancies and found no difference in survival between parous and nulliparous women, suggesting that age is the main risk factor and not pregnancy itself.[41] The most common pregnancy-related complications in this study were third-/fourth-degree lacerations (20%), arterial dissection/rupture (9.2%), uterine rupture

(2.6%), and surgical complications (2.6%). Preterm delivery (occurring in up to 19% of cases), occurs more frequently when the foetus is affected, owing to increased fragility of the membranes.[42]

3.7 Other findings and complications

Although earlier reports have suggested an association with mitral valve prolapse and aortic root dilatation, more recent studies could not confirm these finding.[40,43,44] Mitral valve prolapse reports are limited to case reports. There are other published examples of mitral valve pathology in vascular EDS such as that confirmed at post-mortem examination, including that following papillary muscle rupture by Seve et al. and the case report of Watanabe et al.[45,46] Mitral valve prolapse should therefore be regarded as an nonspecific but possible complication of vascular EDS. Whether the nature of aortic root dilatation is progressive is also a matter of debate.

Pneumothorax and haemorrhagic cavitary lesions of the pulmonary parenchyma have occurred in vascular EDS.[47] Recurrent haemoptysis was also reported.[46]

Low birth weight, club foot and congenital hip dislocation can be early presentations of vascular EDS. In childhood, nonspecific complications such inguinal hernia or joint hyperlaxity with dislocations may be present, just as they do in other EDS types and other inherited defects of connective tissue.

4. Natural history

Out of a large survey of patients with vascular EDS, 220 patients with biochemically proven vascular EDS and 199 of their affected relatives have been described.[25] Among the 220 index patients, 154 had at least one complication. Overall complications were rare in childhood but 25% of patients had a first complication by the age of 20 years and more than 80% had suffered from at least one complication by the age of 40 years. The average age at the time of a first complication was 23.5 years. The median survival was 48 year meaning that 50% of patients had died before that age. There were no differences between men and women. Survival ranged from 6 to 73 year, showing extensive individual variability. Arterial and organ rupture are associated with a higher mortality rate than intestinal rupture (estimated only 2%), which was more often amenable to surgical treatment. Also, the nature of the first complication does not seem to predict the nature of the next complication.

This large series essentially reported on the natural evolution. A more recent smaller scale study on 31 patients treated for vascular events showed slightly better survival rates with 68% of patients surviving at the age of 50 years.[26]

As both of these reported surveys were retrospective, caution in the interpretation is warranted. Prospective large scale studies are essential for the correct interpretation of survival rates.

5. Biochemical and molecular diagnosis

5.1 Biochemical diagnosis

The gold-standard for confirmation of a clinical diagnosis of vascular EDS, still is the biochemical testing of cultured dermal fibroblasts. Collagen proteins synthesized by these cells are labelled with radioactive-labelled proline and separated by SDS-PAGE (sodium dodecyl-sulphate polyacrylamide gel electrophoresis) (see chapter 3). This technique quantitatively measures both the proportion of secreted type III collagen, secreted into the medium, or retained intracellularly, together with its electrophoretic migration. Vascular EDS fibroblasts have abnormal type III procollagen production, intracellular retention, reduced secretion and/or altered mobility. Biochemical testing identifies an estimated 95% of vascular

EDS mutants. Only patients with more rare and subtle quantitative decreases of collagen type III may be missed by this technique.[25,48]

5.2 Molecular genetics

Having preselected those affected by vascular EDS by protein screening, direct sequencing either of cDNA or gDNA *COL3A1* sequences should follow. The latter approach, although generally efficient, can miss whole exon, multiple exon or whole gene deletions. To detect these, a *COL3A1* null allele test and/or MLPA testing can be performed. MLPA testing will allow to detect intragenic duplications and deletions. More recently, next generation sequencing is evolving as the new sequencing methodology. In this approach *COL3A1* might be part of a larger set of genes involved in aortic/arterial aneurysm and dissection or vascular fragility (see chapter 3).

6. Genetics

6.1 *COL3A1* gene

Type III collagen is coded by a unique fibrillar collagen gene, *COL3A1*, located on chromosome 2q24.3-q31 (www.le.ac.uk/ge/collagen/nomenclature.html). In keeping with other fibrillar collagens, there are N and C terminal propeptides, coded respectively by 5 exons for the N propeptide and 4 exons for the C propeptide and in between an uninterrupted perfect triple helix coding for Gly XY triplets, in which X or Y are frequently lysine (4%) or proline (10*%). COL3A1* has close analogies with the various other fibrillar collagens, especially the *COL1A1* and *COL1A2* genes of type I collagen. Like *COL1A1* it has 52 exons, but unlike *COL1A1* and *COL1A2*, exons 4 and 5 combine in a single exon (4/5).

6.2 Types of mutations

Mutations of the triple helix are generally caused by missense point mutations converting glycine to some other larger amino acid. Such errors distort the dimensions of the triple helix, such that helical winding and therefore incorporation of mutant alpha chains into mature triple helices, is impaired. This leads to diminished collagen secretion and assembly, such that tissues which contain the mutant molecules become seriously weakened. Similar effects arise from exon skips in which shortened triple helices are similarly disruptive. In the case of stop codon mutations or large deletions, dosage effects are exerted, by virtual haplo-insufficiency. Unlike the *COL1A1* and *COL1A2* genes in which exon 6 mutations which disrupt the N terminal protease cleavage site, so disrupting collagen fibrillogenesis, no such mutations have been detected in EDS vascular type. By analogy however, this may be explicable by phenotypical variability, such that a syndrome other than EDS vascular type occurs. Alternatively this may be genetically lethal. Similar to *COL1A1* and *COL1A2* genes in which homozygous mutations causing autosomal recessive osteogenesis imperfecta or valvular/arterial fragility[49], a recent report also suggests the existence of rare cases of compound heterozygous *COL3A1* mutations with more severe clinical presentations.[50] It is not unconceivable that *COL3A1* homozygotes are mostly genetic lethals, as they often are in mice explaining the paucity of this observation.[51]
An extensive list of *COL3A1* mutations and polymorphisms can be found at www.le.ac.uk/ge/collagen/col3a1.html.

6.3 Genotype/phenotype correlation

Two recent studies have suggested that individuals with glycine substituting missense mutations and splice site or in frame insertions-deletions have a more severe and earlier onset than *COL3A1* null mutations, non-glycine mutations or mutations in the N- or C-terminal part

of *COL3A1*.[52,53] The latter groups also have less digestive complications.[53] Within the glycine substituting group, substitutions for serine and arginine seem to have a better outcome than those for valine and aspartic acid.[52] Others have suggested that the acrogeroid appearance is more common in patients with mutations that affect the carboxy-terminal of the type III collagen triple helix.[54]

In one family with clinical findings compatible with hypermobile EDS, a *COL3A1* mutation was identified but it is likely that this family was a mild presentation of vascular EDS.[55] In many other families with hypermobile EDS, no type III collagen abnormalities were detected on collagen biochemistry. *COL3A1* mutations are occasionally encountered in patients presenting with thoracic aortic dissections.[56]

Despite the fact that vascular EDS is known for a long time and the identification of the underlying genetic defect dates from the early 1990's, there has been limited progress in understanding the disease mechanism beyond that of connective tissue weakness due to structural defects or reduced amounts of type III procollagen. Based on the recent established role of the altered TGFβ-signalling in Marfan syndrome and related thoracic aortic aneurysm disorders, the role of this mechanism was studied by Morissette et al. They observed that mutations in *COL3A1* do not seem to alter the TGFβ-signalling pathway in dermal fibroblasts of vascular EDS patients.[57] Data regarding TGFβ-signalling in arterial tissue are unfortunately not yet available.

6.4 Mosaicism

Somatic and germline mosaicism, although rare, may occur in vascular EDS.[58]

7. Differential diagnosis

7.1 Classical EDS (MIM 130000, ORPHA 287 – *COL5A1, COL5A2, COL1A1*)

This type of EDS can be differentiated from vascular EDS by the presence of skin hyperelasticity, more pronounced abnormal scarring and significant large-joint hypermobility (with dislocations) without accompanying arterial, bowel and organ rupture. In addition, both types are usually distinguishable by light microscopy and electron microscopy (EM). In vascular EDS light microscopy shows striking depletion of collagen dermal thickness with elastin hypertrophy. At the EM level the cauliflower rosettes of classical EDS are easily distinguished from the irregularity of collagen fibril diameters which characterize vascular EDS.[59]

7.2 Kyphoscoliotic EDS (MIM 225400, ORPHA 1900 – *PLOD1*, *FKBP14*)

This autosomal recessive form of EDS can be distinguished from vascular EDS by the presence of congenital kyphoscoliosis, severe neonatal hypotonia and ocular problems (scleral fragility, globe rupture, microcornea). These patients can present with vascular ruptures, but show no distinguishable histological features.

7.3 Periodontal EDS (MIM 130080, ORPHA 75392 – *C1R*, *C1S*)

Patients with this type of EDS share the easy bruising with EDS vascular type patients, but differ in some respects. Very obvious cases can be distinguished by the presence of early onset severe periodontal disease leading to early teeth loss and the typical appearance of chronically inflamed pretibial plaques. In families with more subtle periodontal fragility, formal testing is necessary to distinguish them. It should also be noted that mild premature periodontal recession and pretibial haemosiderosis can also complicate some families with classical EDS.

7.4 Loeys-Dietz syndrome (MIM 609192, 610380, 610168, 608967 - ORPHA 60030 – *TGFBR1/2*, *SMAD3*, *TGFB2/3*)

In its most typical presentation Loeys-Dietz syndrome (LDS) presents with the triad of hypertelorism, cleft palate/bifid uvula and arterial aneurysm with tortuosity. Other systemic findings include craniosynostosis, joint hypermobility, bicuspid aortic valve, blue sclerae. At the other end of the clinical spectrum patients with vascular EDS like presentation (but normal collagen type III biochemistry) have been recognized and identified with mutations in the *TGFBR1/2* genes (transforming growth factor beta receptor 1 or 2 genes). These patients also present with widespread vascular involvement (aneurysms throughout the arterial tree) and thin, velvety skin. In contrast to vascular EDS, vascular complications are mostly preceded by aneurysm formation and hence regular imaging of the vascular tree is a crucial screening tool. Although the arterial dissections in LDS tend to occur at an earlier age compared to those in vascular EDS they are amenable for surgery and therefore mandate early and extensive arterial imaging.[60] The presence of bifid uvula or hypertelorism may allow to suspect *TGFBR1/2* mutations in patients with a vascular-like EDS presentation. More recently, three other genes (*SMAD3, TGFB2, TGFB3*) have been identified in patients with phenotypes that show many similarities to LDS.[61,62,63]

7.5 Marfan syndrome (MIM 154700, ORPHA 558 – *FBN1*)

Cardinal clinical manifestations in Marfan syndrome are ectopia lentis and aortic root dilatation. Other important features include long bone overgrowth (dolichostenomelia, pectus deformities and arachnodactyly). The diagnosis of Marfan syndrome is based on the identification of typical clinical manifestations as defined in the revised Ghent nosology.[64] Arterial dissection in Marfan syndrome is confined to the aorta and is nearly always preceded by aortic dilatation. Most dissections (>85%) are type A dissections. The risk of aortic rupture or dissection is not only influenced by the degree of aortic dilation.[65] Silverman et al. demonstrated that a family history of severe cardiovascular complications in MFS is associated with increased aortic diameter and decreased survival.[66]

Unlike in patients with vascular EDS, surgical outcome in Marfan syndrome patients is excellent in an elective setting and prophylactic aortic root replacement is generally recommended at diameters exceeding 50 mm.[67,68] Marfan syndrome also has hypermobility and pneumothorax in common with vascular EDS.

7.6 Arterial tortuosity syndrome (MIM 208050, ORPHA 3342 – *SLC2A10*)

This autosomal recessive disorder is characterized by generalized tortuosity of arteries, but can also present with other connective tissue findings such as cutis laxa, joint hypermobility or skin hyperextensibility. Arterial stenoses may occur in the systemic as well as in the pulmonic vascular bed and mild aortic root dilatation has occasionally been reported. So far, no vascular ruptures have been reported in patients with this syndrome.[69,70]

7.7 Pseudoxanthoma elasticum (MIM 264800, ORPHA 758 – *ABCC6*)

Isolated gastrointestinal bleeding, with haematemis and melaena are relatively rare but typical features of pseudoxanthoma elasticum (PXE). In PXE, haematemesis and melaena are due to a variety of causes, including microaneurysms, arterio-venous malformations, ulceration and increased susceptibility to bleeding induced by the use of non-steroidal anti-inflammatory drugs. Other key features of PXE include angioid streaks and related retinal abnormalities, elastic cutaneous flexural infiltrates of the neck, axillae and flexural skin with either peau d'orange or macular, ivory-yellow cutaneous deposits. In common with vascular EDS, PXE is also associated with elastosis perforans serpiginosa and premature coronary artery disease.

Skin biopsy with collagen and elastic fibre staining will unambiguously discriminate vascular EDS from PXE, as will collagen protein analysis, if necessary.[71]

7.8 Other inherited disorders with vascular fragility

Other conditions that can present with aortic and arterial aneurysms are autosomal dominant polycystic kidney disease (ADPKD), familial thoracic aortic aneurysm disease (FTAAD, ORPHA 91387), a heterogeneous group of diseases with predominant aortic aneurysm/dissection as the presenting symptom and fibromuscular dysplasia (FMD). ADPKD can be easily diagnosed by ultrasound of the kidneys which reveals the presence of multiple cysts. FTAAD usually presents with no or minor systemic involvement. Several genes causing FTAAD have been identified: *ACTA2, MYH11, MYLK, MAT2A, MFAP5*.[72] In addition, mutations in nearly all genes that may underlie LDS (*TGFBR1/2, SMAD3, TGFB2/3*) and the gene causing Marfan syndrome (*FBN1*) have been identified in patients presenting FTAAD.[73,74,75]

Importantly, aortic aneurysms in FTAAD can also occur distally from the sinuses of Valsalva warranting imaging of the entire aorta. Clinical presentation is extremely variable with regards to the age of onset and degree of progression of the dilation.

FMD is a non-atherosclerotic, non-inflammatory vascular disease that can affect almost every artery, but most frequently affects the renal and internal carotid arteries. Most commonly medial hyperplasia leads to a classic “strings of beads” stenotic arterial appearance. Macro-aneurysms and dissections are complications.

8. Management and treatment

8.1 Preventive measures

Given the known tissue and especially vascular fragility it is sensible to limit exposure to vigorous contact sports and isometric exercise, such as weight lifting, the carrying of unusually heavy loads, or sudden changes of acceleration because of risk of bruising and increases in blood pressure, respectively. Thus whilst jogging is acceptable, sprinting is contraindicated and similar considerations apply to tennis as contrasted with squash rackets. Similarly, because of the adverse effects of vascular overload, regular monitoring of blood pressure and meticulous control to normal values is sensible in both young and older adults. Because of significant risks of arterial pathology and fragility, any sudden onset of unusual pain needs prompt and meticulous investigation, by both clinical examination and appropriate non-invasive imaging.

Anti-platelets and anticoagulants should be used only after careful consideration of the risks and benefits. This also applies to the use of NSAID’s. A Medical Alert Bracelet or the carrying of a note with essential medical information which briefly notifies attending physicians of potential vascular EDS complications. When at home affected patients should identify a specific medical attendant, such as a general practitioner, paediatrician, adult physician or clinical geneticist, who can co-ordinate information for emergency treatment, if required. Some general guidelines for anaesthesia and surgery have been suggested.[76] These include cross-matching of adequate amounts of blood for transfusion, avoid intramuscular premedication, establish adequate peripheral venous access and the avoidance of arterial lines and central venous lines whenever possible.

8.2 Vascular management

In general, the management of a vascular dissection or rupture should be conservative, whenever possible. If surgery is unavoidable, minimal and very gentle vessel manipulation is essential and anastomoses should be strengthened with Teflon pledgets (non-absorbable

fabrics that act as bolsters when placed on a suture) and carried out without tension.[26] Surgery is more likely to be successful if the surgeon is well-informed about the condition. The types of technical difficulties in vascular emergencies have been well illustrated by Ascione et al., who clearly describe the problems associated with venous ligature and arterial repairs.[77] Endovascular repair has also been successful in this context.[76] Ideally and wherever practicable the management and imaging of such complex and potentially lethal problems should be centralized in designated specialist vascular centres. The outcome of surgical management in such highly specialized centres is better than the average natural evolution, but remains associated with high morbidity as demonstrated by complication in 46% in a series of 31 patients from the Mayo clinic and in 33% in 9 patients from the Johns Hopkins hospital.[26,79] In a recent systematic review by Bergqvist, including 231 patients, arterial aneurysms (often multiple) were reported in 40% of cases, arterial ruptures without preceding aneurysms in 1/3 of the patients and carotid-cavernous fistulae in 18%.[23] Mortality of open surgery and endovascular procedures was 30% and 24% respectively and the overall mortality was 39%. As with all retrospective analyses, and especially in the case of rare disorders, selection bias cannot be excluded.

Intracranial and carotid-cavernous aneurysms are very acute medical emergencies, which may often be managed successfully by interventional neuroradiology, with coil embolization. Generally, apart from these particular intracranial aneurysms, conservative vascular imaging by MRI is preferable to the more invasive angiography because of the intrinsic arterial fragility of vascular EDS.

Once the acute event has stabilized, more extended non-invasive vascular imaging (echo doppler, angio-MRI, CT-angioscan) may be indicated for detection of arterial aneurysms or dissections in the remainder of the arterial tree. Invasive vascular procedures, requiring catheterization should be avoided because of the risk of vascular ruptures. Arterial thrombosis after dissection may require conservative and carefully controlled anti-coagulation.[15] Recombinant Factor VIIa fraction proved useful in controlling persistent intra-abdominal haematoma formation in one case.[80]

The pros and cons of serial vascular imaging are so far unclear, but are probably at least potentially beneficial. One should balance the risk of causing anxiety against the potential benefits of detecting previously unknown aneurysms or progressive dilatations that are potentially treatable and potentially life-saving.[23,26] So far, the reduction of mortality or morbidity by serial imaging capable of predicting potential early signs of arterial wall weakness has not been systematically explored in vascular EDS .

Boutouyrie et al. demonstrated that abnormally low intima-media thickness, potentially increases the risk of dissection and rupture, by generating higher mechanical mural stress.[81] This led to the hypothesis that treatment by celiprolol, a cardioselective β1 blocker with β2 agonist vasodilatory properties could decrease the continuous and pulsatile mechanical stress on collagen fibres within the arterial wall. A multicentre randomized open label controlled trial with celiprolol in 53 patients was ended prematurely due to treatment benefit with a 36% reduction in vascular events in the treated group as compared to the untreated group.[82] It needs to be acknowledged though that the occurrence rate of vascular events remained high at 20% in the treated patient group.

8.3 Intestinal management

Colonic perforations are a very serious complication, with a high mortality are common in vascular EDS families. Because of the high risk of leakage and new perforations at the site of anastomosis, a de-functioning colostomy, with or without partial colectomy, is a very safe emergency procedure. The re-establishment of secondary continuity also has significant risks

of re-perforation and leakage, but is sometimes successful.[39,83] Alternatively, total colectomy with closure of the rectal stump or ileo-rectal anastomosis have both been suggested.[84]

8.4 Pregnancy and embryo selection

Because of the multiple risks (uterine and arterial), it is prudent to follow pregnant vascular EDS women in a high-risk obstetrical program (see Chapter 17). Although no randomized trial data are available, prudent clinical management includes early pre-delivery hospital admission, followed by elective caesarean section in a tertiary centre, with access to vascular surgical assistance and a department experienced in vascular coiling. Routine caesarean section is generally surgically uncomplicated. It is also prudent to have adequate supplies of fresh frozen plasma available and occasionally the administration of desmopressin is a useful option.[85]

Given the 50% chance of transmitting vascular EDS to future children, some families opt either for adoption or to remain childless. However, modern techniques of embryo selection should certainly be considered by the spouses of affected vascular EDS men. Such manoeuvres are potentially much more hazardous for affected females, as laparoscopic ovum collection itself may be risky, the well-known pregnancy complications, notwithstanding. Similar considerations also apply to the technically simpler techniques of foetal blood sampling, testing for vascular EDS, followed by selective termination of the pregnancy, if the test is positive for vascular EDS (see chapter 17).

9. Areas of uncertainty regarding medication

9.1 Beta-blockers or angiotensin receptor blockers

A trial comparing the effect of beta-blockers or angiotensin receptor blockers is currently testing the benefit of the use of these agents to prevent complications of the disease (primary prevention).

9.2 Desmopressin

A recent retrospective study of 26 EDS children suggested that desmopressin which is known to stimulate the release of endothelial von Willebrand factor and of aminocaproic acid to counteract fibrinolysis can normalize bleeding times, when abnormal.[86] This had been suggested earlier but needs specific confirmation in vascular EDS.[87]

9.3 Vitamin C

Although vitamin C has been suggested as a possible therapeutic agent, helping to decrease bruising, no firm proof for its effect has been provided.

10. Summary

In addition to marked tissue fragility, patients with vascular EDS most often present with a thin, translucent skin, easy bruising and a family history of premature death whereas the characteristic facial appearance with low amounts of subcutaneous fat is less prevalent. Neonates may present with clubfoot and/or congenital dislocation of the hips. In childhood, inguinal hernia, pneumothorax, and recurrent joint dislocation or subluxation can occur. Typically, vascular involvement affects the middle-sized, predominantly thoracic or abdominal arteries, but aortic complications have been reported. In a substantial subset of patients, arterial ruptures or dissections are not preceded by progressive dilatation. This, together with the need to stay as conservative as possible in case of vascular signs and symptoms (see above), questions the use of standard screening for vascular abnormalities.

The vascular complications of vascular EDS are difficult to manage and cause premature death, with a median age of death being 48 years in a retrospective series and slightly better in a cohort of treated patients. The role for beta-blockade or prophylactic repair of un-ruptured aneurysms is unclear. Moreover, surgery is frequently complicated by severe bleeding and problems related tissue fragility. Although arterial ruptures are considered the landmark of this type of EDS, about one quarter of all major complications include spleen, uterus but most often bowel rupture. Colostomy is the preferred treatment in case of bowel rupture. The diagnosis of vascular EDS is based on clinical findings and confirmed by abnormal type III collagen biosynthesis as evidenced by qualitative and quantitative electrophoretic evaluation of the type III collagen production by skin fibroblasts. Subsequently, a mutation in COL3A1 may be identified that is autosomal dominantly inherited. In individuals with a clinical suspicion of vascular EDS and normal collagen biochemistry, the diagnosis of LDS should be considered and molecular analysis of the TGFβ-pathway related genes should be performed.

1. Introduction

This chapter describes three types of Ehlers-Danlos syndrome (EDS): kyphoscoliotic EDS (formerly EDS type VI), arthrochalasia EDS (formerly EDS types VIIA and B), and dermatosparaxis EDS (formerly EDS type VIIC). Each of these types manifests characteristics of EDS with affected skin and joints. Kyphoscoliosis is a combination of kyphosis and scoliosis in which the spine respectively makes an exaggerated curve backward and sideward; arthrochalasia means abnormal relaxation or floppiness of joints; and dermatosparaxis stands for sagging of skin and very fragile skin. Clinically, the appearance or phenotype of the kyphoscoliotic type is severe muscle hypotonia (floppiness) at birth, fragile, easily bruisable skin and generalized joint laxity, accompanied by kyphoscoliosis. Patients with arthrochalasia EDS have severe generalized joint hypermobility with relatively unaffected skin, whereas patients with dermatosparaxis EDS do not have lax joints but are characterized by extremely fragile skin which tears easily.

The aim of this chapter is to describe these three types of EDS in terms of their clinical and biochemical characteristics, their prevalence and demographics, and their genetic defects and pathomechanisms. The diagnostic tests for these types will be described, together with a differential diagnosis. Finally, the management and treatment of each type will be addressed.

2. Kyphoscoliotic EDS

The kyphoscoliotic EDS (OMIM 225400 and 614557) is caused 1. by the deficiency of the collagen-modifying enzyme procollagen-lysine, 2-oxoglutarate 5-dioxygenase 1 (PLOD1 or LH1 [lysyl hydroxylase 1], OMIM 153454), due to homozygosity or compound heterozygosity for mutant *PLOD1* allele(s) and 2. by the deficiency of FKBP22 (OMIM 614505), due to homozygosity or compound heterozygosity for mutant *FKBP14* allele(s). It is clinically characterized as follows[1,2]:

Major diagnostic criteria

- Congenital muscle hypotonia
- Congenital or early onset kyphoscoliosis
- Generalized joint hypermobility with multiple dislocations/subluxations

Minor diagnostic criteria

- Skin hyperextensibility
- Easy bruisable skin
- Rupture/aneurysm of a medium-sized artery
- Osteopenia/osteoporosis
- Blue sclerae
- Hernia (umbilical or inguinal)
- Pectus deformity
- Marfanoid habitus
- Talipes equinovarus
- Refractive errors (myopia, hypermetropia)

***PLOD1* specific minor criteria**

- Skin fragility (e.g. atrophic scarring, friable skin)
- Scleral/ocular fragility/rupture
- Microcornea
- Facial dysmorphology (e.g. low-set ears, epicanthal folds, down-slanting fissures, synophrys, high palate)

***FKBP14* specific minor criteria**

- Congenital sensorineural, conductive or mixed hearing impairment
- Follicular hyperkeratosis
- Muscle atrophy
- Bladder diverticula

Minimal criteria for diagnosis are congenital muscle hypotonia and congenital or early onset kyphoscoliosis plus either generalized joint hypermobility and/or 3 minor criteria (general or gene-specific). When these minimal criteria are met, verifying laboratory testing is warranted. In the majority of cases, the condition is caused by the LH1 enzyme deficiency. This enzyme deficiency - and not FKBP14 deficiency - leads to an abnormal pattern of urinary pyridinoline cross-links and thus to an increased ratio of lysyl-pyridinoline (LP) to hydroxylysyl-pyridinolines (HP).[2,3]

2.1 Background

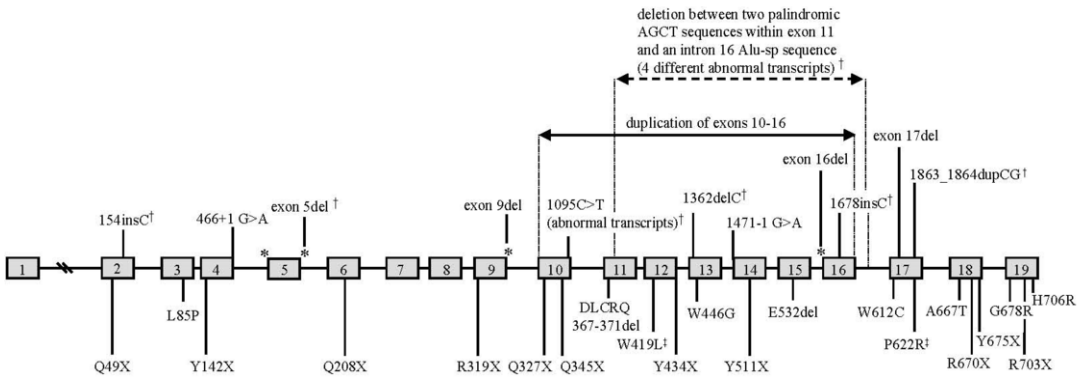
EDS comprises a group of inherited disorders of connective tissue that is clinically, biochemically and genetically heterogeneous.[1,3] The kyphoscoliotic EDS caused by LH1 enzyme deficiency was the first type of EDS to be characterized at the biochemical level. In a 1972 study, a family was described with two sisters with the now-known clinical characteristics of kyphoscoliotic EDS.[4] Their parents and an older sister were unaffected. Amino-acid analysis of skin collagen showed a marked decrease of 5-hydroxylysine to approximately 5% of control and an assay of lysyl hydroxylase activity showed it to be decreased to 10% of control. As these amino-acid and enzyme levels were normal in the clinically unaffected family members, an autosomal recessively inherited disorder was suspected. Several years later following cloning of the gene coding for lysyl hydroxylase,[5-7] now described as *PLOD1*, it was shown that this type of EDS was caused by mutations in one of the three *LH* genes, *PLOD1*, coding for LH1, that normally hydroxylates specific Lys residues in the –Y- position of the –Gly-X-Y- tripeptide repeat in the collagen triple helix.[3,8] Lysyl hydroxylase plays an important role as a post-translational modifying enzyme in collagen biosynthesis exemplified by the fact that the hydroxylated side chains can both serve as attachment sites for galactose or glucosylgalactose and can also participate in cross-link formation with hydroxylysine and lysine side chains in collagen telopeptide (non-helical) sequences.

Over the past twenty years, it has become clear that many individuals with a clinical diagnosis of kyphoscoliotic EDS but a normal ratio of urinary total LP to HP do exist. In 2012, linkage analysis in one family identified bi-allelic nonsense variants in *FKBP14* in 2 affected individuals, and in an additional 4 individuals confirmed *FKBP14* mutations as the cause of an autosomal-recessive variant of Ehlers-Danlos syndrome (EDS) characterized by severe muscle hypotonia at birth, progressive scoliosis, myopathy, hearing impairment, and normal pyridinoline excretion in urine.[9] Due to the major clinical overlap of this phenotype with kEDS-*PLOD1*, both conditions are now grouped within the kyphoscoliotic EDS in the 2017 EDS classification.[1]

2.2 Clinical findings

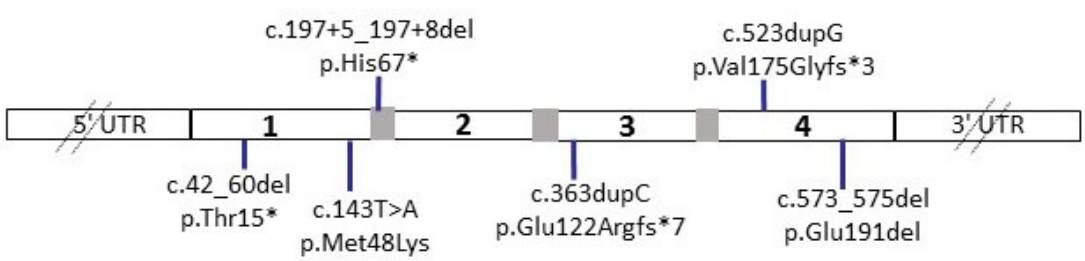
A range of clinical severity is observed in individuals with the kyphoscoliotic EDS.[3,9,10,11] No relationship has been reported between the location/type of mutation in either the *PLOD1* or the *FKBP14* genes and the severity of the clinical phenotype. Figures 7-1 and 7-2 below show all the mutations identified in the *PLOD1* and *FKBP14* genes, respectively and their locations in the gene.

Figure 7-1 Structure of the *PLOD1* gene coding for LH1 and mutations leading to kyphoscoliotic EDS



*The shaded boxes represent the 19 exons in the PLOD1 gene joined by the single lines representing the introns (not drawn to scale). Below the line, the effects of point mutations, insertions, and deletions on the amino acid sequence are shown; ‡ represents mutations that produce downstream premature termination codons. Above the line, the effects of other mutations in the DNA are shown; † represents mutations that produce downstream premature termination codons and * represents splice site mutations that result in exon skipping. The common duplication of exons 10-16 is represented by (↔). The large deletion which produces abnormal transcripts is represented by (←−→). (Adapted with permission from[32])*

Figure 7-2 Structure of the *FKBP14* gene coding for FKBP22 and mutations leading to kyphoscoliotic EDS



The boxes 1-4 represent the 4 exons and the rather large 5' and 3' UTR regions encoded by exon 1 and exon 4, respectively. The introns are represented by shaded boxes and are not drawn to scale. The six mutations published to date are shown with both cDNA and protein nomenclature.[9,20, 21]

2.2.1 Clinical findings in kEDS-*PLOD1*

A total of 94 reported and unreported patients with kEDS-*PLOD1* are known to the authors, in which the clinical findings have been biochemically confirmed. The newborns with available neonatal history are generally described as floppy, with a weak cry, difficulty in

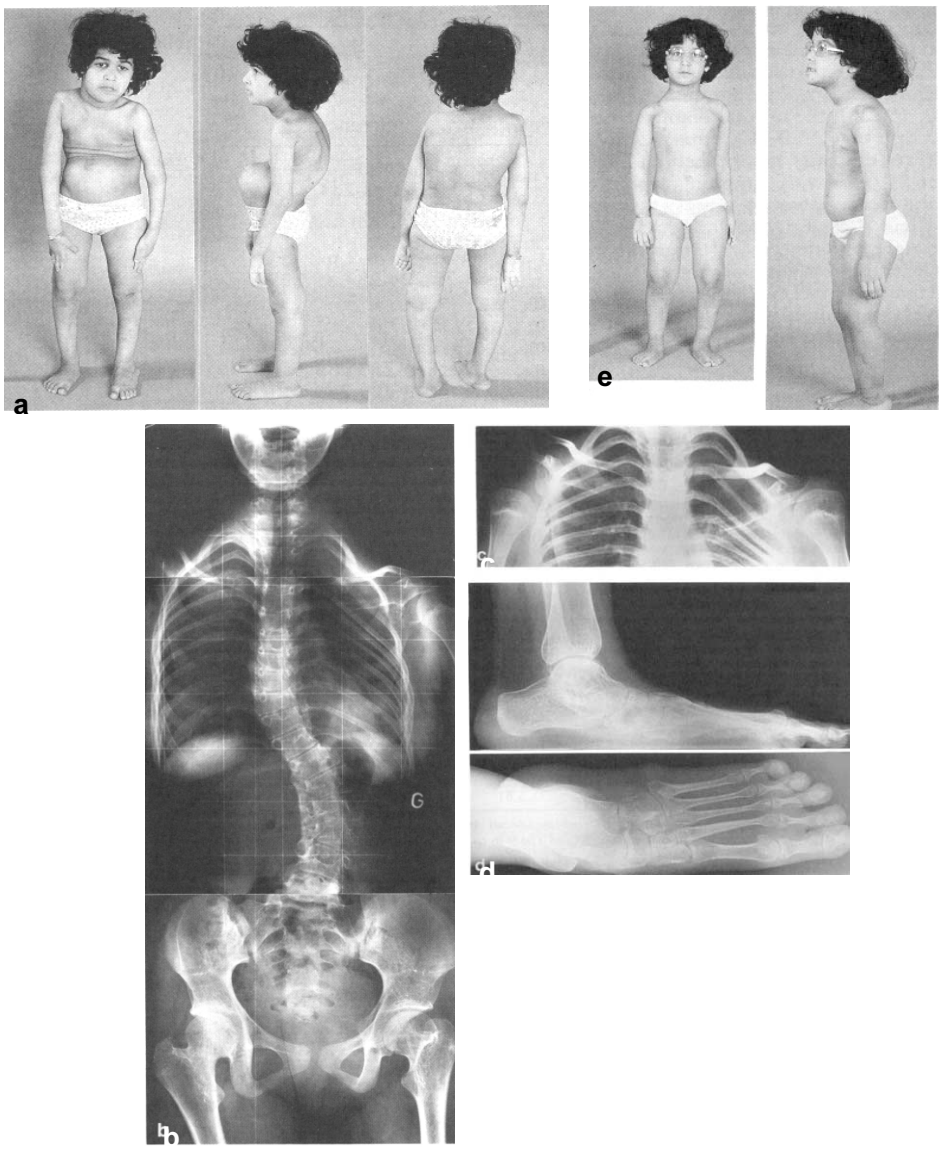
sucking, and delayed motor development. Sometimes poor foetal movements were reported by the mothers. In infants, the observed muscle hypotonia accompanied by muscle weakness contributes to the phenotype of the floppy infant syndrome. As this has the characteristics of a neuromuscular disorder, extensive neuromuscular work-ups are often initially carried out to give normal results. It is only at this late stage that a diagnosis of kyphoscoliotic EDS is considered.[12,13] Intellect is unaffected. All individuals with kyphoscoliotic EDS have hyperelastic and easily stretched skin, with an estimated 60% of individuals subject to abnormal scarring, characterized by thinness and widening. Bruising occurs easily in all patients and, in about 50% of cases, bruising is severe.

Kyphoscoliosis is generally present at birth and is progressive and severe in most cases examined, Figure 7-3. As the vertebral bodies are structurally normal, the scoliosis is attributed to muscular hypotonia together with laxity of ligaments and is often resistant to external bracing. As reported in 3 cases, adults with severe kyphoscoliosis are at risk for complications from restrictive lung disease, recurrent pneumonia, cardiac insufficiency and early death. A Marfanoid habitus is often striking. Osteoporosis occurs in all individuals but without tendency to fracture. Recurrent joint dislocations are a common serious problem. Ocular fragility, which was observed in the original reports of individuals with LH1 deficiency is found in a minority of individuals.[4] It can lead to retinal detachment and bleeding and rupture of the globe, rather than of the cornea as in the brittle cornea syndrome after minor trauma.[14] High myopia (near sightedness) is common. Most patients have microcornea. The sclerae often have a bluish hue.

Vascular rupture is the major life-threatening complication in this disorder. One patient died at 51 years with symptoms typical of dissecting aneurysm of the aorta and her brother had a cerebral accident in the distribution of the right middle cerebral artery at age 19,[15] and a third patient died of arterial rupture at age 14.[16] Mitral valve prolapse is common. Maternal and perinatal mortality in pregnancy has been reported in a case of kyphoscoliosis. Autopsy of the mother showed a spontaneous rupture of the right iliac artery;[17] on the other side, two affected cousins with the homozygous *PLOD1* mutation (c.2198C>T; p.Arg703X) had a total of seven pregnancies resulting in three miscarriages and four healthy children, three of whom were born vaginally at term and the fourth was born at 24 weeks; there were no maternal complications . Steinmann, Rosser and Giunta, unpublished

Life span is markedly shortened because of arterial rupture and cardiopulmonary insufficiency due to severe kyphoscoliosis.
Interfamilial variability of kEDS-*PLOD1* is quite considerable, and intrafamilial variability has been observed in al least 8 pairs of siblings (one pair of siblings ‘a’ and ‘e’ are shown in Figure 7-3). [8,10,own observation] This suggests the influence of other factors such as environmental and genetic factors other than, or in addition to, mutations in the *PLOD1* gene in determining the clinical phenotype.

Figure 7-3 Kyphoscoliotic EDS caused by *PLOD1* mutations



Patients a and e are the third and fifth children of healthy parents from Qatar who are first cousins. This family was the first in which the disorder was characterized at the molecular level.[8]
(a) The 5½ years old girl presents with severe kyphoscoliosis, dislocation of the right shoulder, flat feet in valgus position, microcornea.
(b) X rays of the spine 4 years after Harrington rodding and 3 years after removal of the rod because of its displacement due to premature loading (11 years).
(c) X ray of the shoulder showing dislocation of the right humerus (11 years).
(d) X ray of the foot showing marked osteoporosis and flat feet (11 years). Because of joint instability, arthrodesis of the lower ankle joint was required 2 years later.
(e) The younger affected sibling who has a much milder phenotype, at age 5 years, is shown for comparison, and thereby demonstrating marked intrafamilial variability. (a and e, and b, c, and d are reprinted with permission from[82] *and*[3]*, respectively).*

2.2.2 Clinical findings in kEDS-*FKBP14*

Individuals with kEDS-*FKBP14* present with a clinical phenotype almost indistinguishable from kEDS-*PLOD1* but with a normal ratio of total urinary LP and HP (Figure 7-4 shows 6 patients with kEDS-*FKBP14*). There are currently 30 patients diagnosed with this disorder on a molecular level which are known to the authors (26 of them have been published).[18,19,20,21]

All affected individuals are reported to have muscle hypotonia at birth and delayed gross motor development, progressive scoliosis either congenital or of later onset, joint hypermobility, hyperelastic skin, myopathy and hearing impairment.[21] Because of severe early onset muscle hypotonia and delayed motor development, affected children usually undergo extensive neuromuscular workup in the neonatal period. However, symptoms of congenital hypotonia and weakness may improve with age during childhood. Unassisted walking has been shown to be delayed ranging from 2 to 7 years.[21] Reduced motor function and fatigue in adulthood was only reported in 2 adult patients [9,19] and might represent an age-dependent feature in the natural course of the disorder.
In 7 patients prominent congenital contractures of fingers, wrist, elbows or knees have been described and amelioration was documented in half of the affected.[21]
A cleft of the soft palate was observed in two patients[9], a bifid uvula in one patient[20]. and a cleft palate, defined as bifid uvula with submucous cleft palate or wide cleft palate was found in five patients.[21]

Vascular complications, for instance a dissection of the celiac artery at age 41 years[19], a hypogastric artery pseudoaneurysm rupture at age 6 years[20] , an internal carotid artery dissection at age 50 years[21] and tortuosity of the arterial tree have been described. Moreover, in a baby at one month of age echocardiogram showed a pseudo bicuspid valve, small muscular ventricular septum defect (VSD), and dilatation of the ascending aorta, but normal cardiac function. A later echocardiogram at 10 months in addition showed a small atrial septum defect (ASD) and aortic dilatation with a Z score of +3.75 just beyond the tubular junction.[21]

Occasional features underlying systemic connective tissue involvement have been described such as subdural hygroma (potentially due to subdural bleeding or spontaneous intracranial hypotension), bluish sclerae, bladder diverticula, inguinal or umbilical herniae, and premature rupture of membranes.[21]

Figure 7-4 Kyphoscoliotic EDS caused by *FKBP14* mutations: clinical findings

The clinical phenotype of six patients with kEDS-FKBP14. (a) 8 year-old patient with the p.Met48Lys mutation after surgical correction of the progressive severe scoliosis; joint hypermobility, congenital talipes and pes planus; (b) 4 year-old boy with severe kyphoscoliosis (onset at 6 months of age) and postural talipes; (c) Micrognathia at age 1 year, skin hyperextensibility valgus position of the foot and hallux varus; (d) Pes planovalgus and rocker bottom feet; small joint hypermobility; (e) 8 year-old girl presenting with pectus excavatum; (f) Girl aged 9 years with contracture of the elbows, kyphoscoliosis, pes planovalgus and follicular hyperkeratosis.

2.3 Prevalence and demographics

The kyphoscoliotic EDS is rare; the exact prevalence is unknown. A disease incidence of approximately 1:100,000 live births is a reasonable estimate. Prevalence does not vary by gender, race or ethnicity. The carrier frequency is estimated to be 1:150.

2.4 Genetic defect

2.4.1 The normal *PLOD1* gene product

Lysyl hydroxylase 1 (LH1; EC 1.14.11.4; procollagen-lysine, 2-oxoglutarate 5-dioxygenase; PLOD1; OMIM 153454) exists as a dimer of identical subunits of molecular weight approximately 80-85 kDa, depending on the state of glycosylation.[22] Each unit is comprised of 709 amino acids with a signal sequence of 18 residues. The C-terminal region is very well conserved among species; residues 570-709 of the processed polypeptide are 94% identical between chicken and human LH1 and the region between residues 621 and 697 is even more highly conserved (99%) and is thought to contain the active site of the enzyme. In the human polypeptide, two histidine residues (H638 and H690) and one aspartate (D640) that bind to Fe^{2+}, together with an arginine (R700) that binds to α-ketoglutarate, have been shown to be critical residues in the active site of the LH isoforms.[23,24] Human LH1 has four potential attachment sites for asparagine-linked oligosaccharide units.[23] Unlike prolyl 4-hydroxylase (P 4-H), LH1 does not have endoplasmic reticulum (ER)-specific retention motifs in the primary structure, but a single 40 amino acid C-terminal peptide segment has been identified in LH1 that mediates both membrane association and localization of LH in the ER.[25]

2.4.2 Enzyme and cofactors

The ascorbate-dependent enzyme LH requires Fe^{2+}, α-ketoglutarate, and O_2 as cofactors and catalyses the formation of hydroxylysines in collagen chains and other proteins with collagen-like amino-acid sequences.[26,27] The hydroxylysine groups of collagen have at least two important functions: their hydroxy groups are essential for the stability of the intermolecular collagen cross-links that provide tensile strength to most soft tissues and bone, and they serve as attachment sites for galactose or glucosylgalactose. This enzymatic glycosylation event is catalysed by another member of the LH family, the multifunctional enzyme LH3.[28]

2.4.3 Collagen cross-linking

The strength and type of collagen cross-links formed depend on telopeptide (non-helical) lysines and whether or not they are hydroxylated. The cross-links that are formed between lysyl and hydroxylysyl residues can be formed via two major related routes: the allysine route in which the cross-link is formed from telopeptide lysine, and the hydroxyallysine route in which the cross-link is formed from telopeptide hydroxylysine. The bifunctional cross-links formed via the hydroxyallysine route (in which the hydroxylysine-derived aldehyde reacts with a specific peptidyl lysyl or hydroxylysyl residue in the triple helical domain of a neighbouring collagen molecule) mature into either the trifunctional crosslinks, hydroxylysyl-pyridinoline (HP; formed from three hydroxylysyl residues) or lysyl-pyridinoline (LP; formed from two hydroxylysyl and one lysyl residue). The relative expression of these two types of cross-links therefore demonstrates the degree of lysyl hydroxylation which has occurred and provides the basis for a diagnostic test for lysyl hydroxylase deficiency in which a highly increased LP : HP ratio is indicative of kyphoscoliotic EDS.[29]

2.4.4 *PLOD1* gene

The 40kb *PLOD1* gene coding for human LH1 is located in the p36.2→p36.3 region of chromosome 1 and includes 19 exons and an unusually large first intron of 12.5kb.[6] The gene

has a 5' flanking region with characteristics shared by housekeeping genes.[30] The constitutive expression of the gene in different tissues suggests that LH1 has an essential function.[7] The presence of five and eight Alu-sequences located in introns 9 and 16, respectively, result in extensive homology thereby offering potential sites for recombination.[31]

2.4.5 Mutations in the gene coding for lysyl hydroxylase

The mutations in the *PLOD1* gene responsible for decreased enzyme activity that result in the clinical phenotype of kyphoscoliotic EDS are described in Figure 7-1. More than 30 different mutations in *PLOD1* have been associated with kyphoscoliotic EDS.[10,11,32-35] These mutations are located throughout the gene. The most common mutation, an 8.9-kb duplication of seven exons (exons 10 to 16), is caused by a homologous recombination event between identical 44-bp Alu sequences in introns 9 and 16.[36] The allele frequency of the duplication is 20% in probands with kyphoscoliotic EDS, from 94 families.[37] Two other common mutations in *PLOD1* occur in exon 9 (R319X) and exon 14 (Y511X) at allelic frequencies of 10% and 5%, respectively. Other mutations are as described in Figure 7-1.

2.4.6 *FKBP14* gene and FKBP22 protein function

The 16kb *FKBP14* gene coding for human FKBP22 maps to the minus strand of chromosome 7p14.3 and consists of 4 small exons and 3 rather large introns. It is conserved among chimpanzee, Rhesus monkey, dog, cow, mouse, rat, chicken, zebrafish, fruit fly, mosquito, and frog. FKBP22 belongs to the FK506-binding protein (FKBP) class of immunophilins, which have been implicated in catalysing cis-trans-isomerization of peptidyl-prolyl peptide bonds and are supposed to accelerate protein folding. It has been shown that FKBP22 catalyses the folding of type III collagen and interacts with type III collagen, type VI collagen, and type X collagen, but not with type I collagen, type II collagen, or type V collagen.[38] Remarkably, mutations in type III and type VI collagens are the genetic hallmark of the vascular type of EDS (vEDS) and of COL6-related dystrophies, respectively. Therefore, the clinical features of vascular abnormalities and myopathy documented in the affected individuals clearly correlates with the interaction of FKBP14 with type III and VI collagens.[21]

2.4.7 Mutations in the gene coding for FKBP22

The mutations in the *FKBP14* that result in the clinical phenotype of kyphoscoliotic EDS are described in Figure 7-2. Nucleotide numbering starts with +1, which corresponds to the first ATG translation initiation codon at position 294 of the reference sequence NM_017946.3, whereas amino acid residues are numbered from the first methionine residue of the reference sequence NP_060416.1

Since its first description in 2012[9] only six different mutations have been associated with the disorder.[21] These disease causing variants are located throughout the gene. The mutation c.362dupC p.(Glu122Argfs*7) which is found with a frequency of approximately 70% and it is thus considered to be a common disease variant, has been linked to the same haplotype in all individuals tested.[9,19]

2.5 Inheritance

The kyphoscoliotic EDS is inherited as an autosomal recessive trait. This is supported by the occurrence of affected siblings from unaffected parents and by the birth of affected children from consanguineous parents.

2.6 Diagnostic tests

The clinical diagnosis of kyphoscoliotic EDS is generally suspected very late and often only after a negative workup of neuromuscular disorders. For kEDS-*PLOD1*, the clinical diagnosis

is confirmed biochemically by measuring the ratio of collagen-derived pyridinoline cross-links in the urine. Whereas, for kEDS-*FKBP14* molecular genetic analysis by either Sanger sequencing of *FKBP14* or NGS sequencing of a gene panel including *FKBP14* is mandatory for confirming the clinical diagnosis.

1) Deficiency of the enzyme LH1 results in a significant decrease in hydroxylysine-based pyridinoline cross-links in collagens. Detection of an increased ratio of lysyl-pyridinoline (LP) to hydroxylysyl-pyridinoline (HP) cross-links in urine, quantitated by high-performance liquid chromatography (HPLC) is a non-invasive, highly sensitive and specific test for kEDS-*PLOD1*. The normal ratio of cross-links LP : HP is approximately 1 : 4 (~0.2), whereas in kyphoscoliotic EDS due to *PLOD1* mutations the ratio is approximately 6 : 1 (10-40 times increase, range 2-9).[3] Such testing is clinically available.[39] Obligate heterozygous parents have normal values.
2) Mutation analysis of the *PLOD1* gene may be carried out to identify the mutation(s) responsible for the enzyme deficiency.[2,10,32] As the most common mutation in the *PLOD1* gene is the large seven exon duplication caused by an Alu-Alu recombination in introns 9 and 16 in the *PLOD1* gene occurring at a frequency of approximately 30%,[2] the gene should be initially screened for this mutation. The duplication can be readily detected/confirmed in genomic DNA by MLPA of *PLOD1* or PCR using duplication-specific primers.[11,34] Detection of other mutations may involve sequence analysis of all exons and flanking intronic sequences.[13] Otherwise, mutation analysis can be carried out by targeted resequencing of a gene panel that includes *PLOD1,* a method that also allows the detection of the common duplication.
3) The determination of LH activity in patients' fibroblasts as well as the measurement of hydroxylysine content of dermis is now used for research purposes, only.[40,41]
It should be noted here that carriers of a *PLOD1* mutation can only be identified by mutation analysis and not by biochemical testing or enzyme assay.

2.7 Prenatal testing

Prenatal diagnosis for pregnancies at risk is possible by analysis of DNA extracted from foetal cells obtained by amniocentesis usually performed at approximately 15-18 weeks' gestation or chorionic villus sampling (CVS) at approximately 10 to 12 weeks' gestation. Both disease-causing alleles must be identified before prenatal testing can be performed.[32,42]

2.8 Differential diagnosis

The kyphoscoliotic EDS has some overlapping clinical features with other types of EDS, particularly classical and vascular EDS. Abnormal wound healing and joint laxity are present in many EDS types. Although all types of EDS are characterized by a relatively high risk of scoliosis compared to the general population, scoliosis in kyphoscoliotic EDS is usually more severe and of earlier onset than that seen in other EDS types. Most congenital myopathies present with poor muscle tone and increased range of motion of small and large joints. Joint laxity can be difficult to distinguish from muscle hypotonia, particularly in infants and children. In kyphoscoliotic EDS, in which both hypotonia and joint laxity are present, the increased range of motion is often striking. Primary myopathies caused by mutations in collagen, such as the type VI (COL6) collagenopathy Ullrich congenital muscular dystrophy (UCMD; MIM 254090) may show substantial connective tissue involvement including kyphoscoliosis, joint hypermobility, joint contractures and abnormal scar formation, however velvety and hyperextensible skin is absent and motor function does not improve with age. Unlike spinal muscular atrophy, kyphoscoliotic EDS is characterized by normal tendon reflexes. Many syndromic and metabolic disorders include early-onset hypotonia. In these

disorders, however, the other manifestations of kyphoscoliotic EDS are generally absent, and additional features usually present. Kyphoscoliotic EDS needs also to be differentiated from myopathic EDS, a new entry in the 2017 International classification and due to heterozygous or biallelic *COL12A1* mutations, since it also features congenital muscle hypotonia (see also chapter 2, table 2-5).[1,2]

The Nevo syndrome, first reported in 1974, has been identified as an allelic condition to the kyphoscoliotic EDS and is clinically indistinguishable from it.[43]

Recently, rare autosomal recessive entities with distinct molecular and biochemical abnormalities such as Brittle cornea syndrome, musculocontractural EDS, and the spondylodysplastic EDS have been described which should be considered in the differential diagnosis of the kyphoscoliotic EDS.[2] These disorders have been classified among the types of EDS because of shared common characteristics, such as joint hypermobility, skin hyperextensibility, and tissue fragility. These disease entities except for spondylodysplastic EDS, due to *SLC39A13* mutations, are biochemically distinct from kyphoscoliotic EDS since the urinary pyridinoline ratios measured in the patients are within the normal range.

Brittle cornea syndrome (BCS; MIM 229200) is an autosomal recessive generalized connective tissue disorder caused by mutations in *ZNF469* and *PRDM5*.[44,45] It is characterized by extreme thinning and fragility of the cornea that may rupture in the absence of significant trauma leading to blindness. Keratoconus or keratoglobus, high myopia, blue sclerae, hyperelasticity of the skin without excessive fragility, and hypermobility of the small joints are additional features of BCS.

The musculocontractural EDS is due to mutations in *CHST14* (OMIM 601776) and *DSE* (OMIM 615539), respectively.[46] Neonates with mc-EDS present with distal arthrogryposis and muscular hypotonia. Musculocontractural EDS patients develop a Marfanoid habitus with narrow shoulders and spinal and pectus deformities, brachycephaly, a characteristic facial appearance, hyperextensible and bruisable skin, a tendency to atrophic scars, tapering fingers, instability of large joints, hyperalgesia to pressure, and recurrent subcutaneous haemorrhages are consistent clinical findings. Musculocontractural EDS patients show muscular hypoplasia and weakness.

The spondylodysplastic EDS (OMIM 612350)[47,48] is a very rare, recessive connective tissue disorder caused by mutations in *SLC39A13* (OMIM 608735) encoding the zinc transporter ZIP13. Clinically it resembles kyphoscoliotic EDS, with some distinct phenotypic manifestations including platyspondyly, osteopenia, short stature, widened metaphyses, tapered fingers, thenar muscle atrophy and a tendency to develop contractures of the small joints. An elevated ratio of urinary pyridinolines LP : HP (but to a lesser degree than in kyphoscoliotic EDS), and underhydroxylated collagens in culture despite normal *in vitro* activities of lysyl-and prolyl 4-hydroxylases, respectively, are characteristic biochemical findings.[47] Spondylodysplastic EDS can also be caused by mutations in 2 other genes, *B4GALT7* and *B3GALT6* (see also chapter 2, table 2-5), in which the LP : HP ratios are normal.[1,2]

Establishing a specific diagnosis of patients with features resembling the kyphoscoliotic EDS currently relies on the analysis of urinary pyridinoline cross-links, and upon exclusion of this form, on the accessibility of modern genomic technologies based on gene targeted exome-sequencing.

2.9 Management

2.9.1 Evaluations following initial diagnosis

To establish the extent of disease in an individual diagnosed with kyphoscoliotic EDS, the following evaluations are recommended:

*Musculoskeletal: To evaluate kyphoscoliosis, photographic and radiologic documentation of the spine are recommended in view of the often progressive character of the kyphoscoliosis. Physical therapy evaluation is needed to develop a plan for ongoing therapy.

*Cardiovascular: Measurement of aortic root size and assessment of heart valves by echocardiogram should be carried out at the time of diagnosis or by age five years. Awareness for possible serious vascular complications in different age groups in patients with kEDS-*FKBP14* should be raised, and vascular screening should start at pediatric age.

*Ophthalmologic: Formal ophthalmologic evaluation is needed at diagnosis for myopia, astigmatism, and potential for retinal detachment.

2.9.2 Treatment of manifestations

*Musculoskeletal: Referral to an orthopaedic surgeon for management of kyphoscoliosis is appropriate. Orthopaedic surgery is not absolutely contraindicated in individuals with kyphoscoliotic EDS and can be performed if necessary. Physical therapy is recommended for older children, adolescents, and adults to strengthen large muscle groups, particularly at the shoulder girdle, and to prevent recurrent shoulder dislocation. Swimming is recommended.

*Cardiovascular: Vigilant observation and control of blood pressure can reduce the risk of arterial rupture. Vascular surgery is fraught with danger. Although virtually no surgical literature exists on kyphoscoliotic EDS, a review on surgical complications of vascular EDS is relevant.[33] Individuals with aortic dilation may require treatment with beta blockers or losartan to prevent further expansion.

*Ophthalmologic: Myopia and/or astigmatism may be corrected by glasses or contact lenses. Laser treatment of the retina is indicated in case of imminent detachment.

2.9.3 Surveillance

The following routine examinations are recommended: 1. Ophthalmologic examination for management of myopia and early detection of glaucoma or retinal detachment. 2. Routine examination for inguinal hernia and surgical referral as necessary. 3. Vigilant observation of blood pressure. 4. Regular follow-up by an orthopaedic surgeon for management of kyphoscoliosis. 5. Echocardiogram at five-year intervals (or less, depending on the severity of findings), even if the initial echocardiogram is normal by ultrasound measurements.

2.9.4 Other

Ascorbate has been suggested as a treatment, but its effectiveness has not been biochemically proven.[2]

3. Arthrochalasia EDS

3.1 Diagnostic criteria

The arthrochalasia EDS is a rare inherited autosomal dominant trait caused by mutations leading to the entire or partial loss of exon 6 of *COL1A1* (formerly EDS type VIIA) and *COL1A2* (formerly EDS type VIIB) during pre-mRNA maturation, and thus affecting the processing of the amino terminal end of proα1(I) or proα2(I) chains of collagen I, respectively. It is characterized as follows:[1]

Major diagnostic criteria
- Congenital bilateral hip dislocation
- Severe generalized joint hypermobility with multiple dislocations/ subluxations
- Skin hyperextensibility

Minor diagnostic criteria
- Muscle hypotonia
- Kyphoscoliosis
- Mild osteopenia (X-ray)
- Tissue fragility, including atrophic scars
- Easy bruisable skin

Minimal criteria for diagnosis are congenital bilateral hip dislocation **plus** either skin hyperextensibility or severe generalized joint hypermobility with multiple dislocations/ subluxations and at least 2 other minor criteria. When these minimal criteria are met, verifying laboratory testing is warranted.[1,2]

3.2 Background

Hass and Hass suggested that there is a distinct entity of loose-jointedness, which they called arthrochalasis multiplex congenita (congenital flaccidity of the joints), which represents, to some extent, the antithesis of "arthrogryposis multiplex congenita" (a rare congenital disorder characterized by multiple joint contractures) and which may occur with or without skin changes.[49] This disorder was classified as EDS type VII.[50] In 1973, three patients with EDS type VII were reported who accumulated procollagen in their skin and tendons, and it was thought, therefore, that their disorder resembled dermatosparaxis in cattle.[51] Since it was felt that the accumulation of procollagen was most likely to be due to a defect in the conversion of procollagen to collagen, the activity of the converting proteinase was determined in the culture medium of fibroblasts from these patients and found apparently to be reduced to between 10 and 40% of normal.[51,52] However, when Steinmann and colleagues reinvestigated the youngest of the three reported patients[52] they found the activity of the procollagen N-proteinase to be normal in cell extracts, and the presence of mutant pNα2(I)-like chains in collagen extracted from skin or produced by fibroblasts.[53] The authors concluded that there was a structural abnormality in the portion of the proα2(I) chain that is normally cleaved by N-proteinase (and other proteinases). The authors speculated further, that for sterical reasons molecules containing pNα2(I) chains would interfere with fibrillogenesis and cross-linking, thus leading to abnormal collagen fibrils and increased solubility of collagen. After the description of a similar patient, in whom the condition was due to a mutant pNα1(I) rather than pNα2(I) chain, the classification of EDS VII was subdivided into types VIIA and VIIB, respectively, depending on whether the α1(I) or α2(I) chain was affected.[2,3,54]

3.3 Clinical findings

The hallmark of arthrochalasia EDS is the involvement of ligaments and joint capsules. The disorder is characterized by severe multiple joint hypermobility and recurrent subluxations and luxations of both small and large joints, and ligamentous tears. To date, there are at least 51 patients from 38 families published or known to the authors. All patients are ascertainable in the newborn period, although the correct diagnosis is still frequently only made years later. Congenital bilateral hip dislocation is the rule (Figure 7-5a and 7-6), and muscular hypotonia is prominent; both factors predispose to the high incidence of breech presentation and delayed gross motor development. Short stature, if present, is due to severe thoracolumbar scoliosis

and hip dislocation. In striking contrast to dermatosparaxis EDS, the skin is only moderately affected; it is usually thin, velvety, and moderately extensible, doughy and redundant over the limbs. An unusual criss-cross patterning of the skin on the hands and feet has been observed (Figure 7-5e and 7-5f)[55], and occasionally the skin is affected by poor healing of wounds with atrophic and haemosiderotic scars, especially in the adult. The face appears to be normal, however facial dysmorphic features with frontal bossing, hypertelorism, depressed nasal bridge, macrostomia and bluish sclerae have been described (Figure 7-5a and 7-5b).[55] Judging by six affected members from a three-generation family, intrafamilial variability is slight.
The occurrence of recurrent fractures, Wormian bones (also known as sutural bones or Inca bones: abnormal extra bone plates in the skull), and abnormally wide fontanels indicate that the arthrochalasia EDS phenotype includes bone changes and fragility similar to those reported in mild osteogenesis imperfecta (OI).[56] Wormian bones have been observed in several patients. X-rays of one of our patients[56] disclosed bone abnormalities such as exostoses, e.g. discrete occipital horns (parasagittal bone exostoses arising from the occipital bone), a thickened calvarium (skullcap), and Wormian bones.

Figure 7-5 Arthrochalasia EDS. Clinical photos before and after open reduction of the hip dislocation [55]

a, c, e, f: The patient at 12 months of age presents with bilateral hip dislocation with lateralisation and elevation of both femurs, and anterolateral subluxation of the knees. The skin is doughy and redundant mostly over the abdomen, the limbs, the fingers and the toes. A marked criss-cross patterning of the skin on the hands and feet, and contractures of the first,

second and fourth digits of both hands are present (e, f). Note the excess skin folds and the large umbilical hernia (c, circle).
b, d: The patient at 23 months of age, photographed 6 months after successful open reduction of bilateral hip dislocation. Postural thoracolumbar kyphosis due to hypotonia and ligament laxity is shown (d). From [55] with permission.

Figure 7-6 Arthrochalasia EDS, due to *COL1A1* mutation. Radiographs before and after open reduction of the hip dislocation [55]

a) Radiograph of the pelvis from the patient at 12 months of age shows bilateral luxation of the hips, and anterolateral subluxation of the knees due to severe ligamentous instability.
b) Radiograph of the pelvis from the patient at 23 months of age, 6 months after open reduction, shows successful correction of bilateral dislocation of the hips.
c) A radiograph of the right foot shows the disorganization of the metatarsal bones. Please note the striking osteopenia which is more marked than in arthrochalasia EDS due to COL1A2 mutation. From [55] with permission.

3.4 Defect and pathogenesis

The molecular defect in all cases elucidated to date is remarkably homogeneous: entire or partial loss of exon 6 during pre-mRNA processing causes lack of the N-telopeptide linking the N-propeptide to the major triple helical domain of the α1(I) and the α2(I) chain, respectively. Deletion of the N-telopeptides in the pro-α1(I) (24 amino acid residues) and the pro-α2(I) chain (18 amino acid residues[57]) results in loss of the small globular region of the

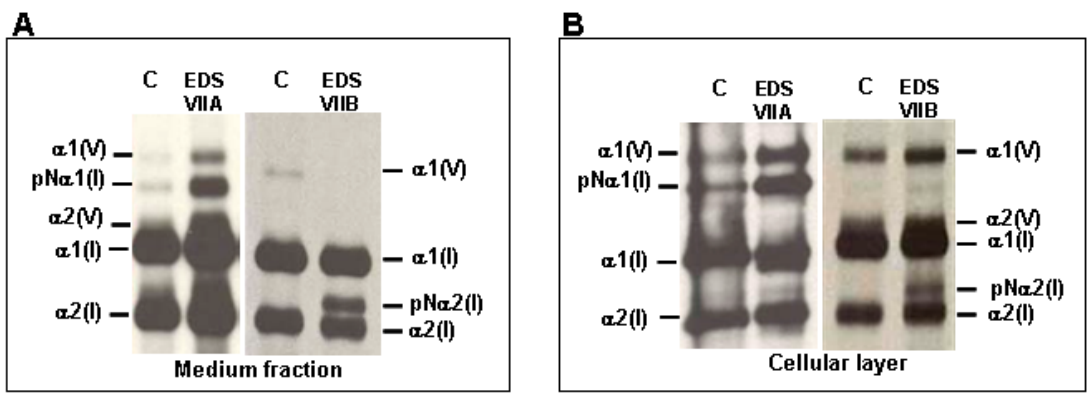
N-propeptide (present only in the pro-α1(I) chain), the N-proteinase cleavage site (Pro-Gln and Ala-Gln), the cross-linking lysine residue of the N-telopeptide, the cleavage site for proteinases (for example, pepsin and a-chymotrypsin) and the first triplet of the main helical Gly-X-Y domain. The loss of the N-proteinase cleavage site causes the retention of the N-propeptide in the mature α1(I) and α2(I) molecules, which are referred to as pNα1(I)- and pNα2(I)-like chains, respectively.

In two patients with arthrochalasia EDS, a G to C change at the splice acceptor site of intron 5 in *COL1A2* activates a cryptic splice site in exon 6, removing 5 amino acid residues including the N-proteinase cleavage site, but preserving the cross-linking lysine residue.[58, Giunta & Steinmann, unpublished] Both mother and son, and father and daughter, respectively, were affected with typical arthrochalasia EDS.

Analysis by SDS-polyacrylamide gel electrophoresis (SDS-PAGE) of pepsin-digested collagens produced by fibroblasts of affected patients reveals, in addition to normal α1(I) and the α2(I) chains, the presence of mutant pNα1(I)- or pNα2(I)-like chains, respectively. The pNα2(I)-like chains migrate between the α1(I) and the α2(I) chains of collagen I, whereas the pNα1(I)-like chains migrate as a faint band just above the normal α1(I) chains (Figure 7-7).

Studies by Wirtz et al.[59] showed that in arthrochalasia EDS (type VIIB), the α1(I) N-propeptide, although cleaved from the α1(I) chain by the N-proteinase or (less likely) by non-specific proteases, is retained by non-covalent association with the mutant pNα2(I) chain in native mutant collagen molecules, both in vivo and in vitro; the α1(I) N-propeptide was readily demonstrable by Western blotting of skin extracts, and rotary shadowing of pepsin-treated collagen produced in culture disclosed kinked molecules which were longer than their normal counterparts.[59] These data suggest that the retention of a partially cleaved, but essentially intact N-propeptide in mutant collagen may play a critical role in the pathogenesis of this disease.

Figure 7-7 SDS–PAGE gel electrophoresis of collagens produced by skin fibroblasts from patients with EDS VIIA (arthrochalasia EDS, due to *COL1A1* mutation) and EDS VIIB (arthrochalasia EDS, due to *COL1A2* mutation) and controls (C)



*Legend: Collagens extracted from the medium fraction (**A**) and the cell layer (**B**) are shown. The strong pNα1(I) band in the EDS VIIA patient is barely detectable in the control (C). Similarly, the pNα2(I) band is present in the EDS VIIB patient only. From [55] with permission.*

3.5 Morphology

The skin collagen fibrils have a smaller and more variable diameter than normal. They are irregular in outline, and also appear to be more loosely and randomly organized into fibrils resembling a loosely wound rope (Figure 7-8).[55,60] These changes are more pronounced in the patients affected with arthrochalasia EDS, due to mutation in *COL1A1* (Figure 7-8a and 7-8c) compared to those observed in arthrochalasia EDS, due to *COL1A2* mutation (Figure 7-8b and 7-8d), but less severe than those present in dermatosparaxis EDS (Figure 7-9).

3.6 Inheritance

Arthrochalasia EDS is inherited as an autosomal dominant trait, and some of the sporadic cases have been shown to be heterozygous for a new mutation. Gonadic mosaicism may occur. From published results, it appears that the relative incidence of arthrochalasia EDS, due to *COL1A2* mutation is higher compared to that of arthrochalasia EDS due to *COL1A1* mutation, although the risk of a spontaneous mutation affecting exon 6 is expected to be similar for both *COL1A1* and *COL1A2* genes.[2] This may have to do with the difficulty in detecting the latter type by routine standard biochemical techniques, as shown recently.[55]

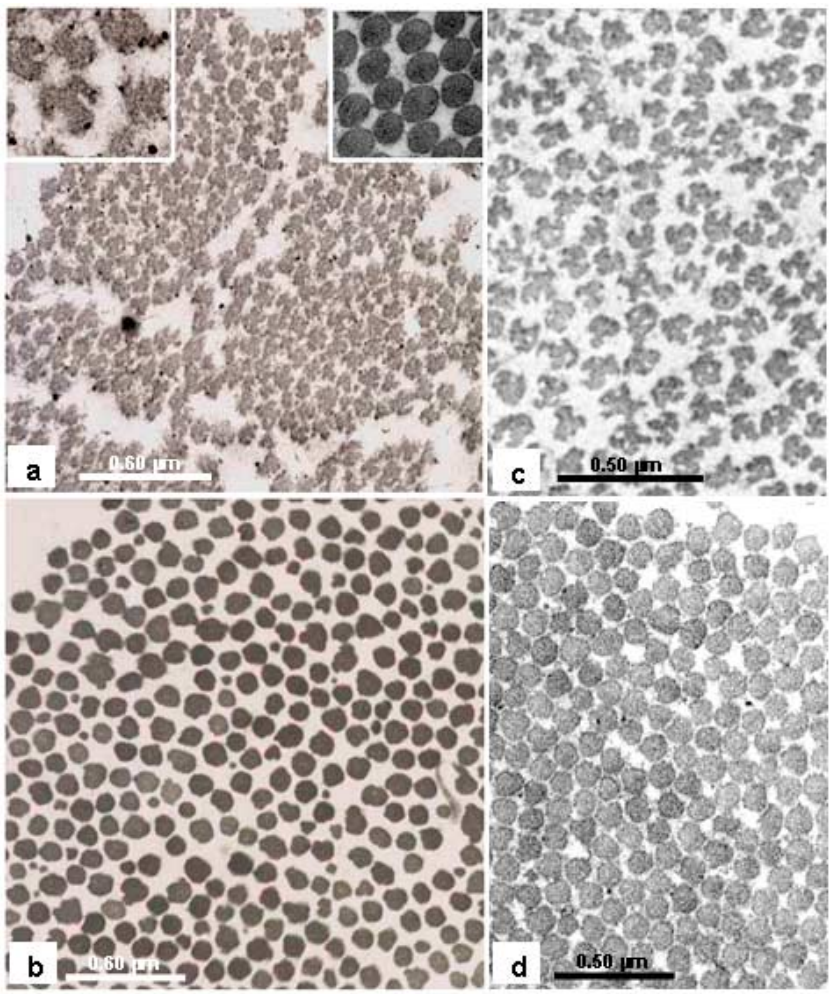
3.7 Genotype-phenotype correlation and locus heterogeneity

Interfamilial and intrafamilial phenotypic variability seems to be slight. In arthrochalasia EDS, due to *COL1A2* mutation, the heterotrimeric collagen I molecules consist of one population of normal collagen I and one population of abnormal collagen I containing the mutant α2(I) chain. In contrast, in arthrochalasia EDS, due to *COL1A1* mutation, three quarters of collagen I molecules would be expected to be abnormal because they contain one or two mutant α1(I) chains and, thus, the phenotype would be expected to be more severe than that due to *COL1A2* mutation.

The clinical documentations demonstrate the severity of *COL1A1* mutation type and clearly suggests that the *COL1A1* mutation type is more severe than the *COL1A2* mutation type, as expected by the different stoichiometry of the α(I)-chains.[55] This statement is supported by the more extensive ultrastructural changes of the collagen fibrils[55], as well as by the comparison of the five personally examined patients with the *COL1A2* mutation type. However, among the reported cases of the *COL1A1* mutation type, three involve substitutions for the last nucleotide of exon 6. This results in two alternative splice variants, one in which the exon 6 sequence from mRNA is completely deleted, and another in which normal splicing is permitted, and the protein product contains an isoleucine rather than a methionine at position 3 of the first Gly-X-Y triplet of the triple helix. The normally spliced product containing an amino acid substitution diminishes the dysfunctional effect of the three quarters of abnormal molecules; this results in a less severe clinical phenotype which is indistinguishable from that of the *COL1A2* mutation type. In contrast, complete skipping of exon 6 from mutant proα1(I) chains leads to three quarters of the collagen I molecules being abnormal and dysfunctional, thus explaining the more severe phenotype, which almost resembles dermatosparaxis EDS, in which none of the collagen I molecules are processed.[56]

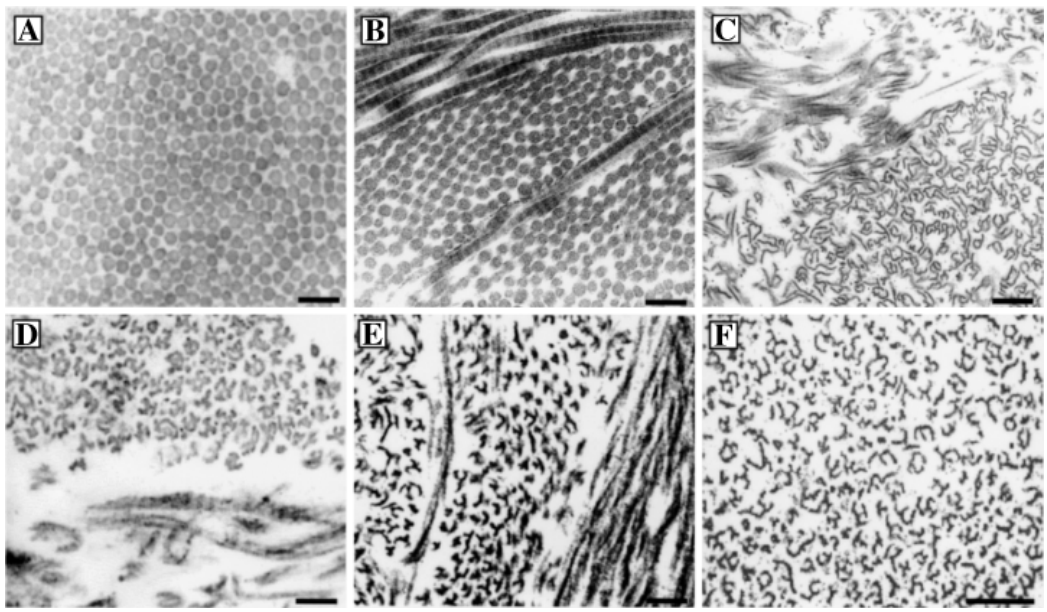
Locus heterogeneity (trait caused by mutations in genes at different chromosomal loci) is exemplified by several patients who are clinically similar to arthrochalasia EDS. However, they have smooth, hyperelastic skin but without skin fragility. Their fibroblasts produce normal collagens[53], the procollagen N-proteinase is active and the electron microscopic appearance of dermal collagen fibrils is normal. It remains uncertain whether patients such as these are examples of EDS types of unknown cause, or whether they represent the extreme end of severity of hypermobile EDS.

Figure 7-8 Ultrastructural appearance of collagen fibril cross sections in the dermis of two patients with arthrochalasia EDS: one due to *COL1A1* mutation (VIIA; a and c) and one due to *COL1A2* mutation (VIIB; b and d)



Legend: The skin collagen fibrils of the EDS VIIA patients (a[55]; c[83]) are more loosely and randomly organized, and have highly irregular contours (note the "angel-like" shape of the fibril in the left inset) and have more variable diameters than normal (right inset). Two patients with EDS VIIB (b[56]; d (figure 32[3]) have loosely organized fibrils with irregular contours and more variable diameters than controls; however the contours of the fibrils are far less abnormal than those of arthrochalasia EDS, due to COL1A1 mutation (VIIA) . Please note that the EM photographs are at different scales (the black bars correspond to 500 nm, while the white bars correspond to 600nm). From [55] with permission.

Figure 7-9 Structure of collagen fibrils: of normal human controls, of mouse models of dermatosparaxis EDS, of patients with dermatosparaxis EDS



Collagen fibrils from skin of human (A, D, E, F) and mouse (B, C) studied by transmission electron microscopy. In normal skin (A, B), collagen fibrils appear cylindrical in cross section and elongated with a typical banded pattern in longitudinal section. In the animal model for the disease (C, ADAMTS2 null mouse), and in dermatosparaxis EDS patients (D: P7; E, and F: P8), fibrils are hieroglyphic in cross section and disorganized in longitudinal section. The level of observed hieroglyphic pattern is influenced by the angle of the section and can vary slightly between different regions within a single skin biopsy (C-F). Scale: lengths of black bars in right lower corners = 0.3μm.

3.8 Diagnosis and differential diagnosis – EDS-OI overlapping syndrome

The diagnosis is first made on clinical grounds, supported by the abnormal collagen fibril morphology, as well as by protein data pertaining to collagen extracted from skin or produced by fibroblasts, and proven by the demonstration of complete or partial loss of exon 6 in cDNA and of the mutation in genomic DNA. The existence of individuals with a clinical picture of arthrochalasia EDS but normal collagen I structure, normal procollagen N-proteinase activity and normal electron microscopic findings in skin indicates further heterogeneity.

Congenital hip dislocation is also found in Larsen syndrome (OMIM 150250, 245600), and as an isolated disorder (OMIM 142700), and in an as yet less well defined disorder, i.e., dislocation of the hip, congenital, with hyperextensibility of fingers and facial dysmorphism (OMIM 601450).

Assuming paternity, the risk to healthy parents of having another affected child is small, and due to the possibility of parental germline mosaicism. The mother of the four patients reported[61] was the least severely affected individual within the family and may either represent a symptomatic mosaicism of the mutation in *COL1A2*, or may simply be the expression of intrafamilial variability (G. Wallis, personal communication 1991). The risk of

an affected person transmitting the disorder is 50%, and prenatal diagnosis is possible by either DNA or protein studies on a chorionic villus biopsy if the defect in the index case has been characterized.[62]
Glycine substitutions in the first 90 residues of the α1(I) helical region disrupt a stable N-anchor domain and prevent or delay N-propeptide removal. The pNα1(I) chain is incorporated into the matrix, decreases fibril size and causes a phenotype with characteristics of both OI and EDS.[63,64] Disruption of N-propeptide processing by defects in the helical part of the α2(I) chain also leads to this phenotype.[65-70] In particular, one patient[70] presented with generalized osteoporosis, platyspondyly, Wormian bones, blue sclerae, but no fractures, and carried a 19 bp deletion that caused skipping of exon 11 of *COL1A2*,[67] thus deleting one of the lysyl residues involved in intermolecular cross-link formation. The presence of the shortened proα2(I) chain in procollagen synthesized by the proband's fibroblasts both lowered the thermal stability of the molecules and prevented or delayed their processing by procollagen N-proteinase.[65] Thus, the deletion disturbed both the helical domain and the cleavage site of the molecule, thereby resulting in the mixed EDS-OI phenotype, which is not included in the 2017 International EDS classification.

3.9 Management

The orthopaedic outcome is often unsatisfactory as premature degenerative arthritis of the hips and other joints occurs.

The principal orthopaedic problem in arthrochalasia EDS patients is bilateral congenital dislocation of the hips. To gain an insight into the management of this problem, Giunta et al. reviewed the treatments and their outcomes in 16 patients from 12 families.[56] Stable reductions were infrequently achieved following closed reduction with orthoses or hip spicas. Anterolateral open reductions with capsular plication, even in infancy, were also inadequate as most of the patients continued to have subluxated or dislocated hips. The poor outcome of the latter procedure is likely to be due to early stretching of the capsulorrhaphy sutures. In contrast, in few patients the addition of an iliac osteotomy of the Pemberton or Salter type with or without femoral osteotomy achieved some good results.

From published results and the findings of Giunta et al., it appears that open reduction with capsulorrhaphy and iliac osteotomy, with the addition of femoral osteotomy in some cases, is required to achieve and maintain stable reduction.[9,47] These requirements are similar to those shown to be necessary to achieve and maintain stable reduction in other laxity conditions such as Down and Larsen syndromes. As with the latter conditions, careful planning of osteotomy is required to ensure that adequate acetabular coverage of the femoral head is achieved in the functional positions of the limb.[56]

Generalized joint hypermobility is worst in infancy when marked muscular hypotonia accompanies the severe ligamentous laxity. Motor development is consequently slow, and aids such as knee-ankle-foot and ankle-foot orthoses are often required to stabilize the lower limb joints for standing and walking. As muscle tone improves, the knee-ankle-foot orthoses may be reduced to ankle-foot orthoses. Surgical procedures to stabilize the knees and the patello-femoral joints have been used occasionally. Orthotic stabilization is likely to be more reliable. Ankle or subtalar fusions have been undertaken in a few cases but the arthrodesed joints need to be in an optimal position for this to be successful.[56]
Recurrent and/or persistent dislocations, as well as hypermobility of upper limb joints, are also frequently disabling. Operative procedures appear rarely to have been undertaken in the upper limbs and one would predict that capsulorrhaphy and osteotomy would not stabilize

these joints.[56] Arthrodesis may be useful in stabilizing some small joints, such as the metacarpophalangeal joints of the thumbs, although fusion rates cannot be predicted.

Postural thoracolumbar kyphosis due to hypotonia and ligamentous laxity is a feature of infants (Figure 7-5d). The spinal posture improves as the children gain in muscle power. However, structural scoliosis has been reported in eight cases. Spinal fusion was undertaken in two patients, although few details are available concerning curve patterns and surgery. Spondylolisthesis of L5-S1 was noted in one patient only.

The findings in 20 molecularly proven cases of arthrochalasia EDS reviewed show how difficult the management is and how important early diagnosis may be.[47] The homogeneous nature of the molecular defects allows laboratories with the appropriate expertise rapidly to establish the diagnosis, after which the clinical problems, in particular those relating to the dislocated hips, can be predicted. Adequate physical and occupational therapy and orthotic management can be given to assist with standing, walking and activities of daily living. Appropriate surgical treatment of the dislocated hips should also diminish the frequency of hip re-dislocation, recurrent dislocation, avascular necrosis and premature osteoarthritis. However, more experience correlating detailed orthopaedic management and long-term outcome is needed before sound recommendations can be made.[56]

4. Dermatosparaxis EDS

The dermatosparaxis EDS (OMIM 225410) is caused by deficiency of procollagen N-terminal proteinase as a result of homozygosity or compound heterozygosity of mutant alleles coding for the enzyme procollagen N-proteinase. This disorder is inherited as an autosomal recessive trait and is clinically characterized as follows:[1]

Major diagnostic criteria

- Extreme skin fragility with congenital or postnatal skin tears
- Characteristic craniofacial features
- Redundant, almost lax skin,
- Increased palmar wrinkling
- Severe bruisability
- Umbilical hernia
- Postnatal growth retardation
- Short limbs, hands and feet
- Perinatal complications due to connective tissue fragility

Minor diagnostic criteria

- Soft and doughy skin texture
- Skin hyperextensibility
- Atrophic scars
- Generalized joint hypermobility
- Complications of visceral fragility (bladder/diaphragmatic rupture, rectal prolapse)
- Delayed motor development
- Osteopenia
- Hirsutism
- Tooth abnormalities
- Refractive errors (myopia, astigmatism)
- Strabismus

Minimal criteria for diagnosis are extreme skin fragility with congenital or postnatal skin tears and characteristic craniofacial features **plus** either 1 other major and/or 3 minor criteria. When these minimal criteria are met, verifying laboratory testing is warranted.[1,2]

4.1 Background

Dermatosparaxis (torn skin) in cattle was the first defect in collagen metabolism to be elucidated, whereas it has only relatively recently been defined in man.[71,72] The hallmark of dermatosparaxis EDS is the excessive fragility of the skin with mild to absent involvement of tendons and ligaments; this distinguishes this disorder from arthrochalasia EDS in man, which is characterized by extreme joint laxity.

4.2 Clinical findings

Currently, only 15 patients from 14 unrelated families have been identified to date. Nine of the patients were born prematurely after rupture of the membranes, two of them by Caesarean section one because of breech presentation and the other at 33 weeks gestation because of foetal heart decelerations.[73]. Two additional patients were delivered at term by Caesarean section, one because of large size, another due to breech presentation. One patient died shortly after birth (39 weeks of gestation) due to severe hemorrhage and shock.[74] The premature boy born with a gestational age of 33 weeks presented at birth with excessive skin folds, multiple skull fractures and extensive subgaleal hemorrhage.[73] He died at 145 days from septic shock due to a secondary infection. Most patients display a severe phenotype that is clinically recognizable at birth and is characterized by premature rupture of the membranes, extreme fragility and laxity of the skin, soft and doughy skin texture, excessive and severe bruising with the formation of large subcutaneous hematomas, delayed closure of the fontanels, umbilical hernia, postnatal growth retardation and characteristic dysmorphic features. These include prominent and protuberant eyes with puffy, edematous eyelids and excessive periorbital skin, large fontanels and/or wide cranial sutures, a hypoplastic chin, and blue or gray sclerae. Nonrhizomelic shortening of the limbs and short, plump hands and feet with stubby fingers and toes have been reported in eleven patients. Joint hypermobility is common but often mild at birth and becomes more pronounced with age. A history of fractures has been reported in four patients, including (congenital) skull fractures in three, whereas osteopenia has been reported in only two patients. Delayed ossification of the cranial vault in three individuals, Wormian bones and delayed bone age in two patients, and persistence of woven bone in the ribs of one patient[74] have been described. Increased palmar wrinkling and atrophic scarring has been reported in half of the patients. In three patients described recently,[75] at birth and in infancy the typical facial features were absent and skin fragility was quite mild. However, their clinical presentation become more pronounced and similar to the reported phenotype during childhood.[75]

4.3 Genetic defect

The defect is due to an autosomal recessively inherited deficiency of procollagen N-proteinase due to loss-of-function bi-allelic mutations in the *ADAMTS2* gene. Only eight different *ADAMTS2* mutations have been reported to date.[75] The enzyme is mainly responsible for cleavage of the N-terminal propeptide of procollagen type I. This has been demonstrated by the direct measurement of enzyme activity. Indirect evidence is given by the extraction of pN-collagen from fibroblast cultures of skin from patients with dermatosparaxis EDS which could be cleaved by the addition of N-proteinase activity or normal cell extracts.[72,76] In addition, cultured fibroblasts from dermatosparaxis EDS patients failed to cleave the amino-terminal propeptides from the proα1(I) and proα2(I) chains of type I collagen.[78] These findings confirmed that the enzyme, not the substrate, was defective.

Procollagen N-proteinase (ADAMTS-2, a disintegrin and metalloproteinase with thrombospondin type I motifs, OMIM 604539) is a large, neutral zinc metalloproteinase which is expressed in all tissues rich in type I collagen. This enzyme, isolated by affinity chromatography on immobilized collagen XIV cleaves the amino-propeptides in the processing of pN-collagens I and II to collagens I and II, respectively.[77] The N-proteinase includes 1,205 amino acid residues with two sequences in the N-terminal domain that are substrates for furin-like enzymes. This suggests that the proenzyme is processed to its mature form as is generally observed for metalloproteinases.[77] This has been confirmed in more recent work showing that the activation of the ADAMTS-2 zymogen involves several cleavages and generates at least seven distinct processed forms with different levels of activity.[78] In addition, the C-terminal domain was shown to negatively regulate enzyme activity, whereas two thrombospondin repeats were enhancer regulators. Results from this study suggested that ADAMTS-2 may act as a multifunctional enzyme, acting via different cleavage specificities.

4.4 Diagnosis and differential diagnosis

The diagnosis is suspected on a clinical basis. As a consequence of the uncleaved pN-propeptides, their incorporation disturbs the normal collagen fibril formation and leads to a decrease in the normal tensile strength of tissues. Striking abnormalities of the collagen fibril architecture are observed in skin, with fibrils that have lost their normal cross-sectional circular appearance and have an irregular, branched, hieroglyphic appearance instead (Figure 7-9c-f). Longitudinally, the fibrils resemble ribbons twisting in both directions (Figure 7-9d and 7-9e).[76,79] Although distinctive, these abnormal collagen fibrils may be almost indistinguishable from those in certain patients with the arthrochalasia EDS.[75,80] Furthermore, the collagen fibril abnormalities can be mild and their degree of severity may differ upon region within the same skin biopsy. Biochemical confirmation is based on the electrophoretic analysis showing the accumulation of pNα1(I) and pNα2(I) chains of type I collagen extracted from dermis in the presence of protease inhibitors.[71] Determination of N-proteinase activity is performed on a research basis only. Direct mutational analysis of the *ADAMTS2* can be performed[79,81] otherwise, targeted resequencing of a gene panel that includes *ADAMTS2* is indicated.

5. Areas of uncertainty

- Comprehensive prevalence and natural history studies are needed for each type.
- Comprehensive genotype-phenotype studies for each type are needed.
- Due to their rarity, management of the types discussed in this chapter should be centralized in centres of excellence.
- For the same reasons international registers are needed for all types.
- What is the frequency of kyphoscoliotic EDS among cases of neonatal hypotonia and/or those suspected of having a myopathy?
- How should patients, who want to become pregnant, be counselled and how to manage pregnancies?
- Is there a place for Celiprolol in the management of kyphoscoliotic EDS?
- Next generation sequencing techniques using targeted EDS panels needs to be used in order to allow early diagnosis and management of these rare types.

Acknowledgements

The authors would like to thank Linda Walker of Duke University Medical Center for her help in compiling the chapter and the bibliography.

Chapter 8. Orthopaedic issues in Ehlers-Danlos syndrome

JR van Horn

J.R. van Horn, MD, PhD, orthopaedic surgeon, deceased,
Professor emeritus
Department of Orthopaedics
Groningen University Medical Centre
Groningen, The Netherlands

1. Introduction

Although most physicians and paramedics at some time have heard of Ehlers-Danlos syndrome (EDS) and can generally visualise patients with loose skin and joints that are prone to subluxations and dislocation, it is not always clear how such patients present and what is required to treat his or her complaints.[1,2,3] A much more critical view than that of the past has been adopted regarding the correct diagnosis of EDS and a formal diagnosis of EDS is therefore made less frequently. On further investigation several patients diagnosed with EDS in the past were found not to have this condition, but benign joint hypermobility syndrome (BJHS). Obviously this does not lessen the problem of painful joints prone to dislocation or of other related complaints such as fatigue.
Recently, the two conditions BJHS and EDS hypermobility type have been recognized as one and the same clinical spectrum ranging from apparently symptomatic generalized joint hypermobility to the most disabled individuals fitting the new diagnostic criteria. These new criteria are more strict than the Villefranche criteria and the Brighton criteria for BJHS in order to define a homogeneous phenotype for management and scientific purposes. Within the new EDS nosology, its name is hypermobile EDS (see chapters 2 and 5).

This chapter begins by describing a case with hypermobility and providing a summary of the history and classification of EDS. Some of the basic aspects of anatomy that are relevant to a better understanding of EDS are discussed. The complaints and symptoms that can accompany hypermobility will subsequently be reviewed, and, finally, consideration will be given to the various conservative and surgical treatment options available. Although these paragraphs discuss the joints of patients with classical and hypermobile EDS, generally the text applies as well to those patients who do not have EDS, but another hypermobility disorder.

Patients with a hypermobility syndrome can easily be missed in orthopaedic practice. This will be illustrated by describing a patient with EDS.

2. Case study

In 1985, a woman of approximately 25 years of age presented at an orthopaedic clinic. She had dislocated her right shoulder whilst sporting; it was an injury she had sustained several times before, each time with increasing ease. The shoulder dislocated when she raised her right arm above 60 degrees. A surgical intervention (capsular shift) was proposed with which the surgeon had obtained good results in the past. No complications occurred during the operation and the patient left the hospital in good health with her arm in a sling and the advice to see a physiotherapist for guided active exercises. While the shoulder had dislocated anteriorly (towards the front) before the operation, after some time, the humeral head was seen to descend caudally (downward). The shoulder became increasingly painful as the humeral head progressively dislocated caudally and, finally, again anteriorly. The patient could not move her arm now due to the pain. Even bending her elbow caused pain in her shoulder.

At that time, EDS was becoming better known. An EDS patient organisation had been established and although the Internet did not yet exist, this patient and her doctor had done their ‘homework’ and studied the available literature. Together, they came to the conclusion that EDS must be the condition involved, due to the hypermobility, also of other joints and the soft velvet-like skin. After some time, when the shoulder condition had become unbearable, the patient underwent a shoulder arthrodesis, an operation in which the joint between the arm and the shoulder blade is immobilised permanently (as example arthrodisis

in another patient is depicted in figure 8-1). After consolidation of the arthrodesis, the patient was completely pain-free and although her shoulder joint was immobile, due to powered motion she enjoyed increased movement of the arm as a whole, which she had not experienced for many years. This movement occurs between the shoulder blade and the thoracic cage. Powered motion is purposeful movement using muscle contraction (muscle power), in contrast to undirected movement, which occurs not by means of muscle power but by gravitational force.

Figure 8-1 Possible arm movement following shoulder arthrodesis

Left image: patient with right shoulder arthrodesis (the joint between the arm and shoulder blade has been permanently immobilised) with the arm at maximum abduction. The remaining stable and pain-free movement occurs between the shoulder blade and the thoracic cage: abduction of the arm causes the shoulder blade to tilt.
Right image: accompanying x-ray image: arm at maximum abduction.

Some years later, the patient presented again to her orthopaedic surgeon, explaining that her other shoulder now also dislocated regularly. The doctor subsequently explained that although it is possible to immobilise both shoulders and live well with two arthrodesed joints, the advantages of this would not outweigh the disadvantages. She was given a supportive orthosis, which allowed her to move the shoulder without dislocating it.
The lesson to be learned from this case is that an hidden, underlying condition may exist even if the cause of the dislocation (in this case a sports injury) appears to be obvious. This case also teaches us that whilst arthrodesis can indeed result in a limited range of movement in a part of the body, overall function can sometimes increase. Finally, it shows that similar problems do not always require the same solution.

3. History
In 1682, Van Meek'ren first described a patient with EDS, a Spaniard who could pull the skin of the right part of his chest up to his left ear and the skin from under his chin over his head. In 1891,Tschernogobow published the first clinical (i.e. the first medico-technical) description of fragility and hyperelasticity of the skin (see chapter 4), the inability of the skin to maintain sutures and the presence of molluscoid pseudotumours (wart-like bumps) around the knees and elbows. Furthermore, he described the hypermobility of joints and their enhanced susceptibility to dislocation. It was only in 1901 that Ehlers described the first clinical case of patients with loose joints and subcutaneous bleedings, while Danlos described patients with

subcutaneous pseudotumours in 1908. In later medical literature, the syndrome acquired the name it is known by today: Ehlers-Danlos syndrome.
EDS is a group of hereditary conditions affecting the connective tissue,. They share characteristics such as hyperelastic, thin and fragile skin, loose joints, and easy bruising.[3,4] A significant number of EDS patients cannot be classified in one single type. There is a wide variability of expression and a significant clinical heterogenicity.[3,5]
Due to the nature of the underlying pathology, in particular the inherited congenital defects of the collagen, EDS belong to the class of diseases for which there is, as yet, no cure. It is only possible to relieve the symptoms, but not to eradicate the underlying cause.

4. Classification

Until some years ago, EDS had been classified into nine types.[6] Increasing knowledge and availability of diagnostics tests led in 1997 to a classification system, which recognised only six types.[7] Recently, a new classification, recognizing 13 EDS types was published.[8] The classification shows that the key feature, hypermobility, is accompanied by others, which are characteristic for each type. Bearing this in mind is of importance in determining the type and prognosis of the disease, particularly with regard to the therapeutic options available and the quality of life experienced by the patient.
In order to diagnose hypermobility, a score can be used that was published by Beighton and Horan in 1969 and by Beighton et al. in 1973.[2,9] They gave the first systematic description of the anomalies of the musculoskeletal system in EDS and formulated the score, which comprises five tests (see chapters 2 and 5). The Beighton score only proves the existence of generalised hypermobility. However, the diagnosis of EDS remains exclusive to those patients with hypermobility that is accompanied by abnormalities of the skin. Diagnosis is mainly clinical, but laboratory tests on tissue samples increasingly play an important role, though not so in hypermobile EDS (see chapters 2 and 3).

5. Anatomy

In order to assess the effect that collagen defects have on the structure and function of the musculoskeletal system, it is important to understand some of the basic aspects of the components that form a joint. The short description covers those aspects that are relevant to understanding how EDS can affect joints and it is not intended as a comprehensive guide.
Bone in EDS is normal in shape and function[10] and is usually normal in strength. Osteoporosis (decalcification of bone) can occur, but this is rare, and fractures heal normally and can be treated according to protocol. Also the hyaline cartilage is normal in EDS. The bony and cartilaginous aspects of joints in EDS are therefore morphologically normal.
Some joints, such as the hip, have deep sockets; the hip socket, for example, surrounds over half of the femoral head. Simply as a result of its shape, an adult hip joint is extremely stable and is therefore unlikely to dislocate. However, the shoulder joint, with its often very shallow socket, makes the shoulder a naturally unstable joint. As a consequence, dislocations of the shoulder occur frequently, even in patients who do not have EDS.
Ball and socket joints are held together within a joint capsule, which is composed largely of densely packed collagen fibres forming a joint plate, and are sometimes further supported by bands (ligaments). The capsule is firmly attached to both ends of the connecting bones along the border of the cartilage, forming a fully encapsulated joint cavity. The inner surface of the capsule (the fibrous capsule) is lined with a mucous membrane (the synovial capsule), which produces synovial fluid. If the synovial capsule becomes irritated due, for example, to dislocation of the joint, other injuries or as a result of inflammation, extra synovial fluid is produced which leads to oedema (accumulation of fluid) . This occurs in what is known as ‘footballer’s knee’. Oedema is an unequivocal sign of damage to or inflammation of the joint.

The strength of the capsule is of great importance in maintaining joint stability, particularly in those joints that have shallow sockets, such as the shoulder, wrist, ankle, jaw and finger joints. These joints therefore lose their stability in EDS patients, because the capsule is weak and often 'stretched' as a result of multiple dislocations. Dislocations contribute towards increasing instability in joints. Each new dislocation becomes less painful, and more easy to reduce. When this affects the shoulder, it is referred to as 'habitual shoulder dislocation'. Once the capsule has become stretched due to repeated dislocations, normal joint function becomes more and more difficult, due to the joint's tendency to dislocate and the difficulty experienced in exerting pressure. Each dislocation causes damage, not only to the capsule, but also to the cartilage. Following damage, cartilage generally lacks the ability to recover. Damage caused by a dislocation is therefore additional to any damage sustained previously. The cartilage becomes severely worn and the joint gradually becomes arthritic, known as degenerative 'wear and tear'. The more often a joint dislocates, the sooner arthritis will occur and the more serious it will be, particularly when it affects weight-bearing joints such as the knees. Arthritis therefore, occurs more frequently in patients with EDS than in patients who do not have these conditions.[5]

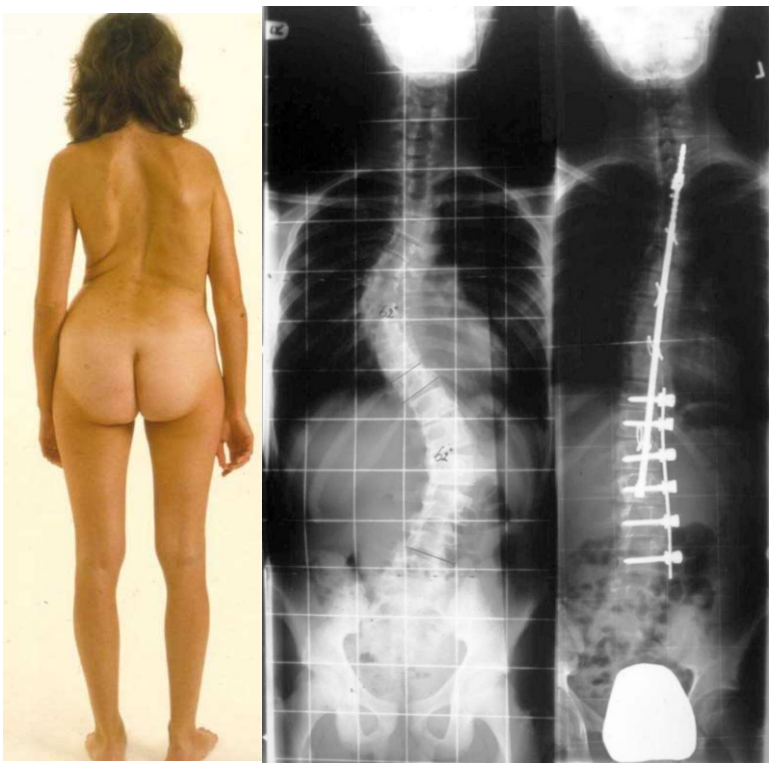
6. Signs and symptoms

EDS patients usually consult an orthopaedic surgeon due to pain or instability in one or several joints. Joint and back pain is very frequent and appears to increase with advancing age. On the other hand, instability and hypermobility appear to decrease with age as do dislocations, unless these are already habitual. Over half of EDS patients over the age of forty suffer from varying degrees of degenerative arthritis,[3,5] with joints that are severely hypermobile being particularly susceptible. There is a direct relationship therefore between the incidence of degenerative arthritis and the degree of hypermobility. Persistent joint oedema occurs in 20 percent of EDS patients. Dislocations of the shoulder, ankle, jaw and patella (knee cap) occur most frequently. Instability of the ankles (sprains) and of the knees in children is often accompanied by delayed motor development[3,5] as a result of poor limb control. Pectus excavatum (sunken or funnel chest) also occurs frequently [3,5], as do flat feet (pes planus). Scoliosis (lateral curvature of the spine) occurs in 50 percent of cases, particularly in adults (see figure 8-2).

A distinction can be made between scoliosis that can be corrected, for example, by a brace, resulting in a normal-shaped spine, and those in which this correction is not possible. In young children, scoliosis can sometimes be corrected easily but, if a brace is not applied over a long period, it will progress rapidly nevertheless. Later in life, this abnormal curvature of the spine tends to become increasingly rigid and thus more difficult to correct. Therefore, particularly in young patients, frequent follow-up visits are required in order to determine whether the scoliosis is progressing, and if the scoliosis has exceeded the critical angle of 30 degrees. Then the body becomes unstable and the vertebral column should be surgically stabilised (see figure 8-2). The risk of the original angle of the curve progressing quickly is less frequent in older patients, in whom the potential increase in secondary spinal curves presents a greater problem. Although in most patients treatment of scoliosis is not necessary, frequent follow-up examinations are advisable.[11,12]

Extreme mobility of the vertebral column can sometimes result in dislocation of vertebrae, which occurs in the small intervertebral joints behind the vertebral bodies. Excessive pressure to the spine as a result of a fall, for example, can cause a spinal cord lesion or even complete paraplegia.

Figure 8-2 Scoliosis in EDS and X-ray showing surgical treatment



Left image: a 35-year-old woman with a right-sided convex scoliosis as a result of EDS. Notice the trunk asymmetry demonstrated by the left and right-sided asymmetrical spaces between the arms and trunk.
Middle image: an X-ray of the vertebral column in an adult EDS patient with severe scoliosis, which was progressive despite conservative treatment, causing vertebral column instability and pain, and therefore necessitating surgical treatment.
Right image: an X-ray of the patient shown in the middle image, in whom the vertebral column had undergone major correction and fixation (= spondylodesis = arthrodesis of the spine) using bars and screws.

The ribs are attached to the spine and the sternum (breastbone) by small joints. The capsule of these joints can become increasingly slack, which can result in subluxations and dislocations. No effective therapy is available for these often very painful subluxations and dislocations, as mobility of these joints is required to facilitate breathing. Over time, the abnormal mobility can cause the breastbone to drop forwards and downwards, decreasing the distance between the first rib and the clavicle, thereby putting pressure on important structures such as the blood vessels and nerves that pass from the thorax to the arm. This can result in symptoms typical of 'thoracic outlet syndrome', which include pain radiating from the neck and the shoulder to the arm and hand.
Hypermobility of the hand and wrist are very frequent. Dislocation of the hip is rare in adults without dysplasia of the hip thanks to the unusual shape of the joint, as said before. Only as a result of force being exerted, such as in an accident, luxation takes place. In young children dislocation of the hip occurs but it is usually caused by factors such as the abnormal and

EDS-unrelated development of the hip (hip dysplasia). In combination with EDS-related collagen defects, the joint's tendency to dislocate increases. Bone fractures are not more frequent in EDS patients than in healthy persons and, if a fracture does occur, healing is usually normal.

Chronic pain is a frequent symptom of EDS and is usually localised in the shoulders, hands and knees.[13,14] Nocturnal cramps are also very frequent. These may be the result of poor blood circulation at night or excessive exertion during the day. In the nocturnal recuperation phase, when the muscles are not helping pump blood to the legs, circulation is inadequate and accumulated lactic acid can cause spastic contractions of the muscle fibres. Muscular weakness also is a common symptom as the muscles become deconditioned.[5] It is not clear whether this is a direct result of EDS or a result of decreased muscle use, due either to pain or weakening of the tendons and ligaments, whereby muscle tone diminishes (see chapter 13).

Fragility makes the skin highly prone to injury and bruising and adversely affects healing of wounds following trauma or surgery.

Fatigue has a crippling effect on many EDS patients[15], although the exact way in which this is related to EDS is still unclear. One possible explanation is, that chronic pain in the muscles and joints causes fatigue, as does the use and coordination of weakened muscles. Orthostatic problems such as venous insufficiency, particularly in the legs, may cause excessive fatigue.

7. Management

Not all patients with hypermobility have a hypermobility syndrome; hypermobility can also be localised, and likewise not all patients with generalised hypermobility have EDS. There are many different treatment options, depending particularly on the severity of the complaints and the stage of the disease. Many patients with hypermobile EDS have relatively few symptoms and do not require any treatment at all. These patients can often benefit from a well maintained exercise regimen at home, particularly in the early stages of the disease, provided the regimen has been explained adequately and patients have the option for counselling when necessary.

Orthopaedic treatment options are either non-surgical (conservative) or surgical, although conservative treatment remains the primary option of choice where possible.[3] If this proves inadequate, surgery may then be considered. The results of surgery are never entirely predictable; recurrence and complications can occur and the results of surgical intervention are usually irreversible.[12] The conservative and surgical treatment options available are discussed below.

7.1 Conservative treatment

It is always essential to fully inform patients, particularly those with non-curable, chronic conditions such as EDS. It is essential that patients learn to recognise and accept their own limitations and adopt a suitable lifestyle that includes a good balance between physical load and their capacity for load-bearing with regard to daily activities, occupation and sport. For the same reason overweight has to be avoided. It cannot be stressed enough that the limited reserve capacity of the musculoskeletal system is what determines the limitations experienced by EDS patients. It is important for patients with EDS to realise that their body has a limited capacity to withstand physical load. Physical loads which are too heavy, too protracted and too frequent can lead to the early onset of chronic fatigue and pain due to unstable joints and arthritis.

7.1.1 Physiotherapy – exercise therapy (see also chapter 22)

It is important to realise that active exercise therapy[16] should be carried out in carefully controlled way. Following physiotherapy, patients should not experience more pain than

beforehand. If this occurs, the therapy was too strenuous, exercises too heavy and weight training too intense. Physiotherapy should be used in moderation and the intensity increased only very gradually. If the pain or cramp increases nevertheless, the therapy should be adapted in intensity, force and duration. Particular care must be taken with weight training. The force exerted by muscles is transferred to the tendons, ligaments and joint capsules, which are highly prone to 'stretching'. It is not possible to strengthen these structures through exercise or weight training. Weight training can cause joints to become unstable and painful if they were not so already.
It is possible, however, to train muscle coordination and in some cases proprioception (the sense of how one's own limbs are oriented in space).[16] Proprioception coordinates muscle activity, or the subtle interplay between agonists and antagonists, allowing for smooth joint movements (see chapter 13). A well-trained muscular system can help to stabilise the function of unstable joints. It is more important for patients to be able to make smooth, well-coordinated movements than to be able to exert great force. Moreover, it is rarely necessary for the patient to exert great force in their daily activities, and many assistive devices are available to help patients to, quite literally, save their strength. However, this does not mean patients no longer have to exercise actively. On the contrary, home exercises must be carried out twice a day for at least thirty minutes to prevent further muscle deconditioning and loss of the muscles' capacity for coordination.
EDS patients who regularly experience pain, must be taught how to cope with the pain. They should be discouraged to become passive, becoming bedridden or chair/wheelchair bound without moving. The motto 'to move is to live' also applies for EDS patients. Almost all rehabilitation centres have a programme dedicated to dealing with pain. If necessary, particularly in cases of acute pain, temporary analgesia may be given to relieve the symptoms, although it is important that these are prescribed with caution, partly due to the risk of side-effects. EDS patients must continue to walk as much as possible as this (more than any other activity) helps to maintain good physical condition. Unlike in the past, it is nowadays accepted that fatigue, which is a common complaint in EDS patients, must not be treated with long-term rest. Acute fatigue may be treated with short periods of rest. Chronic fatigue must be treated using periods of rest alternated with controlled periods of movement and walking or exercise.

7.1.2 Mensendieck therapy and Cesar therapy

It can often help patients to determine a daily routine of movement tailored to their own capacity, and help them find a balance between physical load and the patient's physical capacity.

7.1.3 Occupational therapy (see also chapter 24)

It can be helpful in treating patients to cope with the limitations experienced in day-to-day activities and to help protect joints using, for example, assistive devices and instruments. Crutches may be required for patients with leg problems although care must be taken in ensuring that this does not cause new problems in the shoulders and wrists, which are highly prone to instability. A wheelchair may be useful in some cases, although it is important that, where possible, wheelchair use is alternated with walking, even when only for short distances. Patients with EDS may benefit in the early stages of the disease from intermittent wheelchair use for long distances and long-term physical load in order to use their physical capacity reserves as efficiently as possible. In later stages wheelchair use can be necessary more frequently. Unstable joints can be stabilised externally, using braces, which allow movement of the joints. Braces can also be made in such a way that they only allow limited joint movement, or only a slight range of movements. These braces are sometimes available over-

the-counter but can also be made to measure by an orthopaedic instrument technician. Spinal braces have only a very limited application for back complaints such as scoliosis. Scoliosis is progressive in some patients, often despite the use of a brace. Evidence has shown that many patients, adults in particular, discard the brace after a short time as they find it highly inconvenient. It is essential that the progression of the scoliosis is checked regularly (see above).

7.1.4 Orthopaedic shoes

Arch supports and orthopaedic shoes can be tailor-made (see chapter 24), often preventing or postponing the need for surgery. Surprisingly, patients often prefer to walk in shapeless sports shoes that no longer offer any support. This is acceptable in the short term, provided they do not result in further problems, but this type of footwear does not help to maintain correct shape and therefore function of the foot in the long term. Often, it is only later in life that patients realise how much pain can be caused by malformed feet, for which it is also more difficult to find proper shoes. Nowadays, orthopaedic footwear by using modern materials are much lighter and more elegant than they used to be.

7.2 Surgical treatment methods

Orthopaedic surgery, and joint replacement surgery in particular, can be successful and contribute to the patient's quality of life. Unfortunately, this does not always apply for patients with EDS. The specific collagen abnormalities in EDS patients can result in complications of the healing process in the various layers of the surgical wound. Joint surgery always involves wounds to the skin, the underlying fibrous tissue and tendons, muscles, ligaments and the joint capsule. Efficient healing of these layers requires normal collagen and scar tissue formation. Scar tissue is known to be naturally inferior to normal tissue in its ability to withstand wear and tear, as the collagen in scar tissue is different and often of poorer quality than in normal tissue. The collagen in EDS patients is abnormal in composition and patients therefore have an increased risk of experiencing problems with wound healing. Problems range from, sometimes very severe bleeding[17], particularly during and following surgery, the ‘bursting’ open of surgical scars that would normally have healed (wound dehiscence), wide and distorted scar formation, and defects in subcutaneous fibrous and adipose tissue, causing wound herniation. The scar itself can be as thin as cigarette paper (see figure in chapter 4) and therefore remain vulnerable to damage. Tendons, ligaments and capsules that have been cut during the operation and which already had the tendency to overstretch, might weaken and stretch due to their poor healing quality and the inferior scar tissue, even after healing well initially. The intended effect of tightening the capsule and ligaments is therefore often lost entirely within several months. Attempts to stabilise loose and unstable joints in EDS patients by ‘soft tissue operations’ are therefore generally ineffective. The joints usually become unstable again, and sometimes even more unstable, soon after the operation. Operations to strengthen capsules and ligaments using artificial or donor ligaments are usually also unsuccessful. Artificial ligaments have a limited lifespan, particularly in physically active patients, and often rupture within two years on average due to material fatigue.

Those who advocate the use of artificial ligaments maintain that these have usually become infiltrated with the patient’s own collagen already. Even if this is the case, the infiltrated fibres are composed mainly of inferior scar collagen which also contains EDS abnormalities and are therefore inherently weaker than normal tissue. This also applies for donor ligaments.

Replacing unstable, painful joints with artificial joints in EDS patients is usually unsuccessful and therefore not recommended. Artificial joints are made up of two parts, a ball and a socket, both of which have to be attached to bone. They are usually held in place by the patient’s own joint capsule. The capsule is opened surgically in order for the two joint sections to be

attached to the bone and must be repaired and closed up once the two components have been inserted. This again results in the formation of scar tissue containing EDS collagen in the inferior quality capsule. Moreover, there is a high risk that the artificial joint will not function adequately due to instability. The only type of operation with reasonable potential for success is arthrodesis, in which the unstable joint is fixed permanently by removing the cartilage and fusing the two bones with metal plates and screws (see figure 8-1 and 8-2). A plaster cast can subsequently provide temporary support for several weeks or months. When the two bones have fused firmly, the metal can then be removed surgically (methods vary for the different types of arthrodesis). Scoliosis can be treated relatively successfully in this way, although sometimes the metal components can become loose. Arthrodesis of the hand, wrist, ankle and foot can also be successful, providing good stability and pain relief.
Nevertheless, the indications for arthrodesis must be considered very carefully. It is important to realise that eliminating the movement in one joint results in extra load to both adjacent joints in the movement chain, increasing the risk of instability and pain. For this reason, it is also advisable to further discuss the balance between physical load and physical capacity following surgical stabilisation of a joint.

8. Conclusion

The main orthopaedic treatment options comprise conservative measures with moderate and well-balanced exercise therapy, the use of braces, and adaptive measures in a patient's daily routine and environment with the aim of achieving a balance between physical load and physical capacity. Surgical intervention, such as arthrodesis, can also be successful provided the indications are correct. On the other hand, reconstructive surgery, such as soft tissue procedures (tightening or shortening the ligaments and capsules, and inserting artificial and donor ligaments, and joint replacement surgery are not usually recommended. These interventions are likely to fail within a short time. The indication for conservative treatment becomes more urgent as the degree of instability and hypermobility becomes more severe. The use of a wheelchair, particularly for long distances, to preserve the patient's remaining mobility may be unavoidable in such cases.

Addendum by the editors

In the March 2017 issue of the American Journal of Medical Genetics Part C Seminars in Medical Genetics, all papers were devoted to EDS, covering a new EDS nosology,[8] new diagnostic criteria of the different types and also management related topics (see also chapter 2). One of these papers entitled "Orthopaedic management of the Ehlers-Danlos sydromes", is recommended for further reading.[18]

1. Introduction

For a plastic surgeon, the skin is the central issue of the Ehlers-Danlos syndrome (EDS); skin abnormalities often occur in EDS patients.[1] The skin often is thin (likened to cigarette paper), hyperextensible, vulnerable and prone to easy injury. The skin consists of two layers, the epidermis (upper layer) and dermis. In EDS the dermal collagen is abnormal, in particular collagen type 1, 3, and 5. A slight trauma, e.g. on the shin, elbow, or knee may result in a wound. Once sutured, the stitches tear easily and the scar may widen. With the application of plastic surgical techniques the risk of such problems can be reduced.[2,3,4] Of course, not all wounds of EDS patients have to be treated by a plastic surgeon; practitioners should be familiar with EDS and have mastered basis plastic surgical techniques. One of these techniques is the use of so called Lange's skin lines or lines of relaxed skin tension. When an incision is made in one of these skin lines, it is possible to close it with minimal tension which will result in better healing. For surgery, another problem is the diminished effect of local anaesthetics,[5,6] which cannot be explained by rapid dispersal of the solution because of the lax skin.[7]

Typical complaints of EDS patients visiting a plastic surgeon are poor and disfiguring scars after an operation or injury, and permanent skin pigmentation after haemorrhages. Additional problems are ligament injuries of the wrist and finger joints, as well as general cosmetic interventions like breast enlargement or reduction and facial improvements. Ruptures of scar tissue are also treated by general surgeons.

General guidelines and recommendations for operations on EDS patients will be discussed as well as surgery for specific EDS abnormalities, and general cosmetic procedures.

2. General measures and precautions concerning surgery of EDS patients

2.1 Surgery in general

Medically necessary surgery can and should take place as normal, but regarding "rejuvenations" and other cosmetic operations, the risks of poor and disfiguring scar formation and the likelihood of other complications should be weighed against the possible benefits. EDS patients are also at greater risk of haemorrhaging and bleeding.

2.2 Acute lacerations (injuries)

The patient with classical EDS, with "cigarette paper skin" is at risk of wide disfiguring scar tissue, often with brown pigment spots in or around the injured area. Lacerations of the skin should be closed in 2 layers, with minimal tension on the stitches. Usage of adhesive bandages should be dissuaded, as blisters will appear quickly while the skin is pulled to bring the edges of the wound together. After stitching the wound, local immobilisation by means of a plaster cast is recommended, as well as leaving the stitches in for a few extra days compared to the normal situation. This is necessary since the wound is less resistant to stretch compared to stitched wounds in normal individuals, and therefore there is a risk of wound dehiscence after removing the stitches too soon. Normally, stitches in the face are removed after 5-7 days and elsewhere in the body after 10-14 days, depending on the location. The use of skin glue in EDS patients has thus far not been shown to be of benefit.

2.3 Scars

Correcting a wide scar may be necessary if the wound has healed "per secundam" or by secondary intention, i.e. the wound has not been stitched, but has healed over time after the formation of granulation tissue. Also a wide scar as a result of stitching the skin under tension or without local immobilization can be corrected. Scar tissue running over the joints often becomes wide due to movement of the joint and is therefore unlikely to be improved

permanently by revision. Brown pigment spots in the skin are the result of iron disposition, due to bruising. It may not be possible to remove them.

3. Correction of abnormalities related to EDS

3.1 Molluscoid pseudotumours

These are benign swellings (tumours) that originate in pressure locations such as elbows or knees. They can be 2 to 3 cm in diameter and are probably the result of repeated haemorrhages with scarring, or herniations of subcutaneous fat tissue through the weak dermal fibrous tissue. Removal is possible, but should only be done in case of complaints, e.g. if it results in discomfort or injury of the skin when wearing shoes. Such a pseudotumour can be removed by dissecting the swelling with a surgical incision parallel to the direction of the collagen fibres.

3.2 Epicanthic eye folds

These are symmetric extra skin folds in the inner corners of the eye giving the impression of the nose being widened. In case of the classical type this is often diagnosed during childhood and frequently spontaneously disappears with age.

4. Joints and tendons

Painful wrist or finger joints of EDS patients are not necessarily the result of a trauma (injury). The ability to overstretch the joints when using the joints, which are 'designed' for a normal range-of-motion, may lead to abnormal strain, resulting in inflammation, swelling, cartilage damage and eventually osteoarthritis with joint degeneration.[8]

Joints may become even more unstable, eventually resulting in (sub)luxations. Instability of the wrist is not very common, however instability is common in finger joints, making e.g. typing and opening bottles difficult. In general, splint therapy would be indicated, but it should be mentioned that this is not always satisfactory and sometimes arthrodesis (fixation of the joint) is necessary. A disadvantage of arthrodesis is that as a result the adjoining joints have to compensate for the loss of function, and therefore more strain is put on the adjoining joints. Plastic surgery of tendons for stabilization of joints is not meaningful in EDS patients as the effect is short-lived, as we learned in the past, especially if it was unclear that we were dealing with EDS.

EDS patients may also develop luxation of tendons, due to stretching of the sheaths or grooves the tendons run through. Correction is not easy; furthermore in time the reconstructed tendon will stretch again and will thus become unstable again. Another complication of EDS is tendon rupture.[9]

5. Aesthetic surgery

5.1 Correction of droopy eyelids

Correction of bags of the upper and/or lower eyelids takes place on a daily basis in hospitals and private clinics. In classical or vascular EDS, this problem might occur more frequently compared to other types of EDS. The "excess" and/or droopy skin is removed, often including removal of the small surplus fat lumps in the eyelids. In theory, this is a safe operation; however, it does have its challenges. If too much skin is removed the eye will remain open. A bleeding could occur in the eye socket which should be treated urgently due to risk of blindness. Evidently this should be taken into account when planning to undergo such an operation; probably EDS patients are at higher risk for complications of this type of surgery.

5.2 Facelift

Due to the deficiency of collagen support in the skin, premature skin ageing often is a feature of EDS. A facelift might be desirable, but can have significant complications.[10] The skin cannot be excessively tightened due to danger of tearing; scars in front of the ear may become wide and noticeable while the greater chance of bleeding may result in haematomas. Smoking increases the risk of premature skin ageing via a negative effect on collagen and probably also the risk of complications of this kind of surgery in EDS patients. For wrinkles, laser therapy could be an option.[11]

5.3 Breast enlargement

Although no literature concerning breast enlargements in EDS patients is available, a few comments can be made. Breast enlargement, also called mamma augmentation, is performed by placing a (silicone) prosthesis below the mammary gland or - deeper - below the pectoral muscle. To be able to do this an incision should be made in the fold below the breast or in the armpit. Subsequently, an opening is made to fit the prosthesis. The risk of haemorrhage is greater, which, if not drained, could result in infection and extra scarring. This increases the risk of a “capsular contracture”, where scar tissue around the implant contracts to form a firm ball. This may be symptomatic as well as disfiguring. In addition as a result of tension on the wound, disturbance to the healing process can occur with the possibility of wound dehiscence. If this occurs, the prosthesis has to be removed. Finally, a warning should be given for the risk that the skin will generate “striae”, because of the weight of the prostheses and the tension on the lax skin.

5.4 Breast reduction

Breast or mamma reductions are often done because of functional considerations. Patients are weighed down by the heavy breasts, with neck and shoulder pain and sometimes complaints of chafing the skin under the breasts. A breast reduction could then be the solution. During the operation a reasonably large wound is made that has to be stitched, so haemorrhaging could be a complication. When stitching the breast, no tension should occur, to prevent tearing of the wound or development of wide scars. After a successful operation a well supporting bra should be worn day and night for at least 6 weeks in order for the breasts to heal steadily.

6. Summary

Although the risk of complications of surgery is increased, with careful surgical techniques and after weighing risks and benefits of surgery (especially whether the improvement will be lasting),[12] much is possible.[13]

1. Introduction

Gastrointestinal (GI) involvement in Ehlers-Danlos syndrome (EDS) is well known from decades, since the seminal work by Beighton and co-workers[1] consisting of a survey of GI manifestations in 125 patients with various clinical forms of EDS. Vascular EDS is the best known EDS type associating with GI manifestations. Since its actual clinical and molecular definition,[2] patients with vascular EDS usually present abdominal complaints acutely in form of vascular or internal organ ruptures. These complications are often severe and may need surgery. Abdominal and GI manifestations are also registered in other EDS types, mostly classical and hypermobile EDS (hEDS). Although hEDS and the (benign) joint hypermobility syndrome have been considered one and the same entity by many researchers and clinicians[3,4], the 2017 International Classification of EDS and related disorders put more order around the concept of "joint hypermobility". In particular, it is now accepted that "joint hypermobility" is not a disorder *per se*, but it is just a clinical sign. Joint hypermobility is a common feature of many genetic disorders and, among them, EDS is a prototype. Nevertheless, many patients suffering from musculoskeletal complaints secondary to joint hypermobility are not affected by a recognizable syndrome. Hence, a spectrum of phenotypes is now defined ranging from isolated, non-syndromic joint hypermobility to hEDS. The gap is filled by the hypermobility spectrum disorders (HSDs), which are transitory, exclusion diagnoses for all individuals manifesting features related to joint hypermobility but who do not carry mutations in known genes and do not respect the new hEDS criteria.[5,6] For conservative reasons, in this chapter the term hEDS/HSDs is used for all papers published before the 2017 classification and dealing with patients with hEDS and/or benign joint hypermobility syndrome according to the old diagnostic criteria.

In this chapter, the connections between an inherited defect of collagen biogenesis and gut involvement are presented by an extensive literature review concerning GI manifestations associated to the following phenotypes: vascular EDS, hEDS/HSDs, classical EDS, unspecified/non-syndromic generalized joint hypermobility, and EDS of unclassified variants. Along with a detailed report on available data concerning type and rate of a variety of GI features in the studied phenotypic categories, considerations on presumed pathogenesis as well as reasonable assessment and treatment approaches are also reported.

2. Gastrointestinal manifestations in vascular EDS

Numerous case reports have been published about the, often disastrous, gastrointestinal manifestations of vascular EDS. The twenty-seven case reports or small case series reported below show considerable overlap, but one feature is striking: in eighteen papers the described GI problem caused the first presenting symptoms leading to the diagnosis of vascular EDS. In nine reports GI manifestations in known vascular EDS patients are described. Eleven papers describe a spontaneous rupture or perforation of the sigmoid colon,[7-17] while a iatrogenic perforation of the sigmoid colon during colonoscopy is described in one case report.[18] Dunn and colleagues described a sigmoid hematoma that was surgically resected under the impression that it was a neoplasm; histopathologic evaluation, however, pointed in the direction of vascular EDS.[19] Rupture of solid organs has been described as well, both splenic rupture[20,21] and liver plus vena cava rupture.[22] Van Bon et al. described peliosis (e.g. presence of benign, irregular cystic blood-filled cavities within the parenchyma of solid organs) of the spleen preceding the rupture.[20] Isolated vascular ruptures leading to massive haemorrhage can occur anywhere in the body in vascular EDS, and the abdomen is not spared. Rupture of splenic artery aneurysm,[23] ileocolic artery[24] and other mesenterial vessels[7,11,25] have all been described as the presenting symptom of vascular EDS.

In known vascular EDS patients rare abdominal vascular abnormalities have been described: hepatoportal fistula,[26,27] hepatic artery aneurysm,[8,28] rupture of a splenic artery aneurysm,[29]

aneurysm of the celiac trunk[30] and spontaneous retroperitoneal haemorrhage.[31] Diverticula of various organs have been described as well: biliary diverticula, sigmoid diverticula and bladder diverticula all in the same patient,[26] presumably these can also lead to perforation, as has been described in the small bowel.[32]

3. Gastrointestinal manifestations in hEDS/HSDs

Studies exploring GI manifestations in hEDS/HSDs include (i) case-series showing rough rates of selected GI features in hEDS/HSDs,[33-37] (ii) case-control studies comparing rates of selected GI features between hEDS/HSDs and general population,[38-41] (iii) studies investigating the variability of GI features and their relationships with other manifestations/characteristics of hEDS/HSDs,[42-44] and (iv) case reports on surgical abdominal and GI findings in hEDS/HSDs.[45-56]

Hakim and Grahame[33] first noted GI complaints in 37% of hEDS/HSDs women. In this study, the value was cumulative for nausea, stomach ache, diarrhoea and constipation, and separated rates were not available. By describing obstetric and gynaecological findings in 82 women with hEDS/HSDs, Castori et al. found GI complaints in 72% and rectal prolapse in 11% of cases.[36] Three further works reported prevalences for selected GI features,[34,35,37] including dysphagia (14%), dyspepsia/chronic gastritis (8-67%), gastro-oesophageal reflux (20-74%), bloating (57%), nausea (57%), vomiting (57%), recurrent abdominal pain (26-86%), constipation/diarrhoea (33-76%), abdominal hernia (5-20%). The rate of many of them seems to significantly increase with age,[33] often with an identifiable natural history.[57] Zarate et al. offered more details on a series of GI physiology investigations in HEDS/HSDS patients, including oesophageal manometry, 24 h pH-metry, gastric emptying study, small bowel manometry and colorectal physiology study, with positive findings in 33% (4/12), 42% (5/12), 80% (12/15), 44% (4/9) and 100% (6/6) of cases, respectively.[37]

Findings of the three case-control and one cross-sectional studies are summarized in table 10-1.[38-41] In the paper by Manning et al. women with lower urinary tract dysfunction were investigated for clustering of specific features and a clear relationship between hEDS/HSDs and defecatory problems emerged in this patient subgroup.[38] Danese et al. reported a small study suggesting a relationship between celiac disease and hEDS/HSDs comparing data between 31 patients of both sexes and with various ages,[39] to previously published data on rate of celiac disease in the general population.[58,59] Mastoroudes et al. demonstrated a significant excess of various defecatory problems in 60 women compared to highly matched controls.[40] The largest study is that by Fikree et al. on 187 adults compared to 372 controls, all attending a gastroenterology clinics.[41] In this work, patients were more commonly females and younger than controls and tended to display more commonly several upper GI complaints. An association of extra-GI autonomic complaints, fibromyalgia and chronic pain with hEDS/HSDs was also confirmed.

De Wandele et al. by carrying out a questionnaire study on 78 HEDS/HSDS adults, found three phenotypic clusters by an agglomerative hierarchical cluster analysis. GI complaints occurred more commonly in cluster 2, which showed the highest rate of fatigue, sleeping disorders, orthostatic intolerance, thermoregulatory problems, inflammatory signs and cardiovascular symptoms, as well as the largest functional impairment and the most severe pain.[42] In a further work, the group compared the rate and impact on quality of life of selected "autonomic" complaints in hEDS/HSDs with classical and vascular EDS, fibromyalgia and healthy controls. Among the EDS groups, hEDS/HSDs showed the highest rate of autonomic features, and the burden was comparable with fibromyalgia.[43] Pacey et al. presented the results of a questionnaire study in 89 children with HEDS/HSDS.[44] Analysis of phenotypic data identified five subtypes by a loading matrix generated displaying the extent of the correlation between each of the included measures and the identified factors. One of these

subtypes (called "systemic BJHS") was characterized by the unique symptoms of skin involvement and urinary stress incontinence, as well as a high rate of recurrent joint instability and GI involvement. GI involvement was defined by the presence of recurrent constipation, diarrhoea or abdominal pain, or the diagnosis of slow transit constipation or irritable bowel syndrome.

All case reports describing abdominal and GI surgical manifestations in hEDS/HSDs are reported in table 10-2.[45-56] In hEDS/HSDs, surgery appeared repeatedly successful for treating diaphragmatic defects leading to a variety of clinical presentations,[46,47,49] while on the contrary, surgery was often ineffective for the correction of visceroptosis and pelvic organ prolapse.[51,53] Laparoscopic subtotal colectomy for bowel ptosis had positive results in one instance,[52] as well as the repair of a recto-vaginal fascia with porcine small intestinal submucosa mesh in a woman with pelvic organ discomfort for multiple prolapses.[55] The injection of 5 ml of 5% phenol in almond oil resulted in effectively treating recurrent rectal prolapse in a 2-year-old infant.[45]

4. Gastrointestinal manifestations in classical EDS

Our knowledge concerning GI manifestations in classical EDS is actually limited to single clinical reports, mainly focused on surgical aspects. All available case reports are summarized in table 10-3.[60-70] Considering the presumed rate of classical EDS in the general population as one of the most common EDS types,[69] GI involvement seems relatively rare in this condition. Among the eleven reported patients with (presumed) classical EDS and GI manifestations, bowel dilatation with or without malrotation occurred four times,[61,65,68,70] gut diverticula and related complications (i.e. diverticulitis, gut perforation) trice,[60,61,68] spontaneous gut perforation (apparently, not secondary to diverticula) twice,[64,65] eventration of the diaphragm twice,[63,64] multiple mucosal erosions (possibly leading to anaemia) twice,[65,68] haemorrhoids once,[61] rectal redundancy and inguinal hernia once,[66] and lethal haemorrhage due to intrabdominal vascular fragility once.[67] Surgery was indicated for reasons unrelated to the underlying connective tissue disorder in two cases, appendectomy due to acute appendicitis[62] and liver transplantation for end-stage liver insufficiency.[69] Hence, compared to hEDS/HSDs, GI involvement in classical EDS appears less common and most patients were referred for (acquired) structural anomalies rather than functional symptoms. Whether GI involvement in classical EDS also comprises a spectrum of functional GI symptoms similar to (or perhaps overlapping) hEDS/HSDs is still a matter of debate and needs dedicated studies. The 9-year-old boy with classical EDS due to mutation in *COL5A1*, reported by de Leeuw et al., who died because of a rupture of an intra-abdominal vessel, shows that an acute presentation resembling vascular EDS is possible in classical EDS.[67]

5. Gastrointestinal manifestations in unspecified generalized joint hypermobility

Fifteen case-control studies compared the rate of specific GI features in subjects with unspecific/non-syndromic generalized joint hypermobility. Twelve studies (80.0%) yielded positive results and are summarized in table 10-4.[37,72-82] The remaining gave negative results.[83-85] However, while in one of these studies a relationship between unspecified hypermobility and pelvic organ prolapse was not identified, the authors found an association between pelvic organ prolapse and other "soft" markers, such as easy bruising and varicose veins, of an underlying connective tissue disorder. Of the twelve studies with positive results, four studied adult females only,[73,76,78,81] five adult males and females,[37,74,75,77,79] two children and adolescents from both sexes,[80,82] and one children, adolescents and adults from both sexes.[72] These studies were strikingly heterogeneous for the assessing method for unspecified hypermobility, which was the Beighton score with a positive cut-off of >4 in four,[37,76,77,78] Beighton score with a positive cut-off of ≥4 in two,[75,82] Beighton score with an undefined

positive cut-off in one,[79] the self-reported 5-point questionnaire in one,[80] and a self-developed screening method in four.[72,73,74,81]

Association between unspecified hypermobility and chronic constipation, alternatively termed chronic intestinal pseudoobstruction[74] or slow transit constipation,[80] appeared the most consistent, being observed four times in both sexes from all ages.[74,77,78,80] Also the association between unspecified hypermobility and rectal/pelvic prolapse and anal/faecal incontinence appeared strong in women.[72,73,76,77,81] A study pointed out a relationship between constipation and a past history of pelvic prolapse in females.[80] Three further papers highlighted the association between unspecified hypermobility and gastro-oesophageal reflux and bloating,[37] hiatus hernia,[75] and Crohn disease.[79] The net prevalence of an absent precipitating factor for constipation and upper GI complaints was demonstrated twice in individuals with unspecified hypermobility compared to non-hypermobile subjects.[37,80] This evidence further supports the "functional" nature of these complaints in association with unspecified joint hypermobility. A further, not tabulated paper analysed the prevalence of specific anamnestic features in 568 women at 12 months postpartum after a high risk delivery (i.e. instrumental delivery and/or high birth weight infant), and found a relationship between faecal incontinence and unspecified hypermobility in the patient group.[86]

6. Gastrointestinal manifestations in unclassified EDS

A handful of papers reports large data on various GI aspects in EDS without a clear separation of results by clinical type. In 1969, Beighton et al.[1] reported a retrospective study on GI complications in 125 EDS patients. Stratification was not available and vascular complications are likely related to the vascular EDS (see below). However, in this work, the authors pointed out a non-stochastic association between EDS and a series of GI and chronic/recurrent abdominal features, including diverticula at different points of the gut, rectal prolapse, and various abdominal and diaphragmatic hernias. A more recent study found swallowing difficulties in 39% of 411 EDS patients affected by the types I and II (classical EDS), III (hEDS/HSDs), IV (vascular EDS) and VI (kyphoscoliotic EDS).[87] Carley and Schaffer, by reporting data on urinary incontinence and pelvic organ prolapse in 12 Marfan and 8 EDS women, described rectal prolapse in 2 (25%) EDS patients.[88] More recently, Zeitoun et al. reported the results of a questionnaire study on 134 patients with various EDS types and found a high rate of symptoms of dyspepsia and gastro-oesophageal reflux, irritable bowel syndrome and functional constipation.[89] The Gastrointestinal Quality of Life index was significantly lower in the EDS cohort compared to controls. Based on their experience, the authors considered endoscopy of the upper gut relatively safe, while they were more sensitive in performing colonoscopy due to organ fragility in vascular EDS and the risk of mucosal bleeding in most EDS types. Abonia et al. described a 8-fold risk of eosinophilic esophagitis in patients with hereditary connective tissue disorders, like EDS, Marfan and Loeys-Dietz syndromes, compared to the general population.[90] A peculiar face in patients with the combination of connective tissue disorder and eosinophilic esophagitis was also proposed.

Although literature is scanty on this argument, GI manifestations could be encountered also in other EDS types included in the 2017 International classification.[5] Among them, dermatosparaxis EDS deserves mention as umbilical hernia is included as a major criterion for the clinical diagnosis of this EDS type.

7. Summarising considerations

Actual knowledge concerning GI manifestations in EDS chiefly concerns the commonest clinical types, namely hEDS/HSDs, classical and vascular EDS. In particular, most studies are focused on hypermobile and vascular EDS, while GI involvement in classical EDS is, at the moment, reported in a dozen of single case reports. The spectrum of GI manifestations linked

to EDS is wide and ranges from (i) acquired and congenital structural anomalies of the abdominal wall, diaphragm, pelvis and gut, to (ii) chronic functional symptoms and related disability, to (iii) acute presentations due to vascular or hollow organ spontaneous (or iatrogenic) ruptures. While manifestations of (i) and (ii) are typical of hEDS/HSDs, (iii) is specific of vascular EDS. Concerning classical EDS, accumulated data are too scarce to depict a recurrent GI phenotype. However, classical EDS patients seem to present manifestations mostly belonging to acquired and congenital structural anomalies of the abdominal wall, diaphragm, pelvis and gut, although also spontaneous vascular ruptures may rarely occur. In addition, mucosal fragility manifesting as multiple mucosal erosions possibly leading to occult haemorrhages and chronic anaemia is a further possibly underestimated GI manifestation of classical EDS.

8. Pathogenic considerations

Pathogenesis of GI manifestations in EDS is still partly unknown and the existence of specific factors often remains speculative. On a wider perspective, connective tissue is strongly represented in various components of the GI tract, such as peritoneal ligaments, gut wall and splanchnic vessels. Peritoneal ligamentous laxity leading to hypermobility of the intra-abdominal viscera is considered a predisposing factor to abdominal twists and torsions,[91] and could also facilitate visceral prolapse or hernias under the additive effect of gravity and factors increasing intra-abdominal pressure, such as pregnancy and chronic constipation. Accordingly, Curci et al. found subtle alterations of the elastic fibres in the supporting ligaments of the gastro-oesophageal junction in patients with gastro-oesophageal reflux and hiatus hernia.[92]

An abnormal connective tissue content within the gut wall may affect its functions by increasing the compliance of hollow viscera with excessive distension, as well as by directly interfering with gut mechano-receptors embedded in the connective tissue-rich *muscularis externa.*[93] Summative effects of this process may include influences on pain thresholds and gut motility, both known contributors to various functional GI complaints, such as gastro-oesophageal reflux, abdominal pain, bloating, diarrhoea and constipation.[94] Furthermore, a defect of the extracellular matrix in the *lamina propria* and secondary alterations of luminal microbiota may affect permeability of gut mucosa, a mechanism which may explain, in part, the associations with celiac disease,[39] Crohn disease[80] and eosinophilic esophagitis.[90]

Capillary fragility is a well-known cutaneous and oral manifestation of hEDS/HSDs.[95] Although accurate data are lacking, an extension of this feature to the entire GI mucosa is reasonable and may explain a presumed propensity to minor haemorrhages. A reduced capillary and small vessels resilience may also contribute to peripheral blood steal, which may exacerbate various autonomic manifestations, such as nausea and bloating. This may account for the repeated evidence of apparently spontaneous mucosal erosions possibly leading to chronic occult haemorrhages in classical EDS.[66,68] Increased vascular resilience to external forces may also exacerbate the transitory effects of mesenteric tractions and compressions on peripheral blood supply, which, in turn, is related to peritoneal ligamentous hypermobility.

Acute presentation due to (spontaneous) ruptures of intra-abdominal vessels and/or organs is typical of EDS patients with mutations in *COL3A1* (i.e. vascular EDS). This is thought to be related to the peculiar excessive fragility of the connective tissue surrounding medium and small size vessels, hollow viscera and spleen in this EDS type. Theoretically, similar GI complications could be observed in other EDS types with vascular fragility, including classical EDS with vascular ruptures due to mutations in *COL1A1* and *COL1A2*, and kyphoscoliotic EDS due to mutations in *PLOD1*. However, maybe also patients with classical EDS due to mutations in *COL5A1* need to be followed cautiously.[68]

Interestingly, particular attention has been posed on dysautonomia as a major contributor to onset and/or progression of a wide spectrum of functional GI complaints in hEDS/HSDs.[37,42,43,96,97] The strength of this hypothesis, though promising, is actually hampered by the descriptive nature of published studies and the difficulties encountered in investigating its underlying pathophysiology objectively. In hEDS/HSDs, dysautonomia as a contributor to other GI manifestations, such as internal organ prolapse and mucosal bleeding, is, however, unlikely. The tight relationship between GI involvement and additional dysautonomic complaints[42] strongly suggests an influence of autonomic disturbance in the onset and/or manifestations of various functional GI complaints.

9. Impact of gastrointestinal complaints in EDS

In order to assess the impact the GI complaints on the daily lives of EDS patients, two of the authors[98] carried out a questionnaire investigation. Three questionnaires were sent to all members of the Dutch EDS patient support organisation. The first questionnaire inquired about socio-demographics, medication and need of a wheelchair. The second questionnaire inquired about GI symptoms and included questions about five domains: gastro-oesophageal reflux symptoms, functional dyspepsia (FD) and irritable bowel syndrome (IBS) according to Rome III criteria, and diarrhoea and constipation. The RAND-36 health-related quality of life (HRQoL) questionnaire, which assesses HRQoL across nine scales (physical functioning (PF), social functioning (SF) physical role limits (PR) emotional role limits, mental health, vitality (VI), pain, general health experience (GH) and health change (HC)), concluded the inquiry. Multiple linear regression, correcting for age, sex, BMI, need of wheelchair and medication with an effect on the GI-tract (opiates, antidepressants, medication for neuropathic pain, benzodiazepines, non-steroidal anti-inflammatory drugs) was used to analyse impact of GI symptoms on HRQoL. Of 650 questionnaires, 287 were sent back completed (response rate 44.2%). Fourteen subjects were excluded because EDS diagnosis had not been established by a medical specialist. Overall, 235 subjects (86.1%) had one or more gastrointestinal symptoms in one or more of the five domains. 157 (57.5%) had one or more reflux symptoms, 56 (20.5%) FD, 117 (42.9%) IBS, 159 (58.2%) diarrhoea and 144 (52.7%) constipation. The presence of one or more symptoms in any of the five domains had a negative impact on four HRQoL scales: PF ($p=.049$), PR ($p=.005$), VI ($p=.005$) and pain ($p<.0005$). When the five GI-symptom domains were analysed separately, reflux symptoms had a negative impact on the score on the pain scale only ($p=.038$). FD had no impact on any scale. IBS symptoms had a negative impact on the pain ($p=.02$) and GH ($p=.004$) scales. Diarrhoea had a negative impact on the GH scale ($p=.001$). Constipation had a negative impact on PF ($p=.013$), SF ($p=.004$), PR ($p=.036$), VI ($p=.029$), pain ($p=.033$) and HC ($p=.011$) scales. We concluded that GI symptoms are common in EDS and have an independent negative impact on HRQoL. Constipation appears to be the symptom domain with the largest impact on HRQoL.

10. Assessment and treatment strategies

In general, the assessment of GI complaints/complications in the various types of EDS is performed according to standard procedures, i.e. there is not an universally accepted flow-chart for patients affected by EDS. Therefore, the overall approach to the EDS patient and the non-EDS patient attending gastroenterology clinic is fairly similar concerning the repertoire use of available investigations. However, tissue fragility and the risk of iatrogenic vascular and visceral rupture should be always taken into consideration, though with different degrees in the various EDS types. This risk seems higher in vascular EDS, in which any endoscopic, laparoscopic and endovascular investigation should be carried out with great caution and used only in presence of a high clinical suspicion and/or in an emergency setting. Prudence is

envisaged also for rarer EDS variants with marked soft tissue fragility, such as kyphoscoliotic and dermatosparaxis EDS. Conversely, in classical and hEDS/HSDs, such a risk is moderate to mild. Therefore, many invasive procedures are considered relatively safe in these patients, with the exception of colonoscopy, which should be considered potentially dangerous in all EDS patients.[89] Surgery in EDS is indicated in disease-related complications such as abdominal vascular complications, abdominal organ ruptures, hernias and pelvic prolapses, as well as for treating unrelated diseases. Recommendations for anaesthesia and perioperative procedures are available in the Appendix and in the recent literature.[99,100,101] All EDS patients and, in particular, those affected by the vascular EDS should be informed that the risk of surgery is substantially greater than in patients without EDS. This informed consent, however, can be hard or even impossible to obtain when a hitherto unknown vascular EDS patient presents with a life-threatening complication. In patients with a previously defined EDS type, the informed consent procedure can be tailored to the estimated risk of that type. Single case reports successfully demonstrate that when the physical condition of the patient allows for conservative treatment of surgical problems, this may be the preferred choice.[16,32] In light of these considerations, principles of best practice suggest to postpone decision-making on clinical issues after stringent definition of the EDS type. This is usually carried out in specialized clinics with the support of customized molecular testing.

Assessment and treatment of functional complaints, as mostly reported in hEDS/HSDs, are a hard task due to the absence of sensitive investigations and the general unawareness on the wider consequences that a defective connective tissue can have on the GI system. Actually, non-pharmacologic and pharmacologic treatment of GI functional complaints in EDS follow standard procedures.

11. Areas of uncertainty

GI involvement is a clinically relevant feature of many EDS types, but actual knowledge is fragmented and remains largely unsupported by evidence. Hypermobile and vascular EDS are the most studied EDS variants concerning this issue. Available data typically relate to referred patient-referred symptoms without consistent investigative findings in the former, while the range of GI events is mainly depicted by case reports or small case series in the latter. Treatment and prevention of GI complications in vascular EDS are not still object of formal research due to the rarity of this EDS types and the high lethality rate of such complications in this condition. Further research is also expected aimed at clarifying the functional basis of the various chronic disabling GI symptoms in hEDS/HSDs in order to find more specific lifestyle, dietary and pharmacologic treatments. Multicentric studies could be designed in order to investigate whether GI involvement is clinically relevant also in rarer EDS types.

12. Summary

GI involvement is a well-known complication of EDS. Historically, GI manifestations are best known when associated with vascular EDS, in which abdominal complaints usually present acutely by sudden vascular or internal organ rupture. In this EDS type, investigations and surgical procedures should be carried out with caution due to the extreme tissue fragility and, hence, the increased risk of serious iatrogenic complications. Other EDS types, chiefly classical and hEDS/HSDs, most typically present GI involvement in form of non-life-threatening manifestations, such as abdominal and diaphragmatic hernias and functional GI disorders. In this chapter, the entire spectrum of GI manifestations in EDS is reviewed with separate sections dedicated to vascular, classical and hEDS/HSDs, unspecified generalized joint hypermobility, as well as patient cohorts with unclassified EDS types. Pathogenesis of GI manifestations in EDS is likely heterogeneous and can include peritoneal ligamentous laxity, hypotonia/hyperextensibility of the abdominal wall, pelvis and diaphragm, and

capillary, larger vessels and mucosal fragility. GI immune system dysregulation and cardiovascular dysautonomia may be further major contributors. A summary of available assessment and treatment approaches is presented.

Addendum by the editors

In the March 2017 issue of the American Journal of Medical Genetics Part C Seminars in Medical Genetics all papers were devoted to EDS, covering a new EDS nosology,[5] new diagnostic criteria of the different types and also management related topics (see also chapter 2). One of these papers is entitled "Gastrointestinal involvement in the Ehlers-Danlos syndromes", which is recommended for further reading.[102]

			Frequent hard and loose stools	8.8%	4.9%	0.04
Danese et al., 2011 (ref. 39)	25 females and 6 males (years) with hEDS/HSDs attending clinical genetics clinic	Italian general population; previously published data[2]	Celiac disease (Marsh classification)	16.1%	1.0%	0.002
Mastoroudes et al., 2013 (ref. 40)	60 females (18-60 years) with hEDS/HSDs attending hypermobility clinic	60 females (18-60 years) without hEDS/HSDs recruited from hospital staff	Vaginal bulge interfering defecation	23.0%	5.0%	0.007
			Straining for defecation	61.7%	NA	<0.001
			Incomplete emptying after defecation	63%	NA	0.001
			Need of digitation for defecation	33.3%	NA	<0.001
Fikree et al., 2014 (ref. 41)	123 females and 57 males with hEDS/HSDs attending gastroenterology clinic	203 females and 169 males without hEDS/HSDs attending gastroenterology clinic	Age (mean)	40.6 years	44.2 years	0.003
			Gender (female)	68.3%	54.6%	0.002
			Heartburn	33.0%	23.5%	0.01
			Water brash	30.9%	18.5%	0.001
			Postprandial fullness	41.4%	27.1%	0.006

GI: gastrointestinal; hEDS/HSDs: hypermobile Ehlers-Danlos syndrome/hypermobility spectrum disorders. LUTD: lower urinary tract dysfunction; NA: not available. [1]: only features with statistically significant differences between patient and control groups are reported in the table (i.e. p value <0.05). [2]: from Menardo et al.[59] and Dubé et al.[58]

Table 10-2 Case reports on GI-surgical findings in hypermobile Ehlers-Danlos syndrome/hypermobility spectrum disorders

Reference	Age, sex	GI-related symptom(s) at presentation	Anatomical finding/feature(s)	Treatment
Douglas and Douglas, 1973 (ref. 45)	2 years, NA	Recurrent rectal prolapse	Rectal prolapse	Effective treatment with the injection of 5 ml of 5% phenol in almond oil
Shaikh and Turner, 1988 (ref. 46)	17 years, F	Epigastric pain, emesis and an history of generalized abdominal pain	Strangulation and infarction of the stomach through the diaphragm	Effective gastrectomy with pyloroplasty
Leung, 1989 (ref. 47)	22 years, M	Epigastric pain, emesis	Strangulation of the stomach	Effective repair of the diaphragmatic defect
Defuentes et al., 2004 (ref. 48)	25 years, F	Abdominal pain with fever	Multiple diverticula of descendent and transverse colon	None
Levine and Adler, 2005 (ref. 49)	22 years, F	Emesis after pharmacologic therapy for a dislocation	Rupture of diaphragm, para-oesophageal hernia	Effective repair of the diaphragmatic defect and Nissen fundoplication
Chen and Jao, 2007 (ref. 50)	20 years, M	Defecation problems	Rectal prolapse	Effective conservative treatment
de Weerd et al., 2012 (ref. 51)	47 years, F	Incomplete evacuation, constipation, pelvic pain and discomfort	Hiatal hernia, anal mucosal prolapse, recto-anal intussusception, small rectocele and large enterocele	Abdominal plastic surgery, previous unsuccessful operation for anal prolapse and recto-anal intus-susception, Nissen fundoplication, hysterectomy
Reinstein et al., 2012 (ref. 52)	28 years, M	Disabling abdominal distension and bloating	Prolapse of the small bowel and transverse colon, increased bowel mobility under direct manipulation	Effective laparoscopic subtotal colectomy
Dordoni et al., 2013 (ref. 53)	38 years, F	Dyspepsia and constipation	Prolapse of stomach, liver, small and large bowel, left kidney, ovaries	Recurrence after repeated gastropexy and nephropexy
	70 years, M	Irritable bowel syndrome	Mild prolapse of the small bowel, inguinal hernia	None
Fogel, 2013 (ref. 54)	35 years, F	NA	Multiple sepsis with microperforations of the colon, small bowel obstruction	Cholecystectomy, appendectomy, total abdominal colectomy and ileostomy, lysis of adhesions
Sardeli et al., 2013 (ref. 55)	57 years, F	Inability to evacuate, constipation and mass sensation in the vagina	Rectocele	Successful correction of the defect in the recto-vaginal fascia with porcine small intestinal submucosa mesh
Plackett et al., 2014 (ref. 56)	34 years, F	Rectal bleeding	Haemorrhoids	Conservative treatment (outcome not available)

F: female; GI: gastrointestinal; M: male; NA: not available.

Table 10-3 Case reports on GI-surgical findings in classical Ehlers-Danlos syndrome

Reference	Age, sex	GI-related symptom(s) at presentation	Anatomical finding/feature(s)	Treatment
Green et al., 1966 (ref. 60)	64 years, M	Fever and abdominal cramps	Sigmoid diverticulitis	Persistent drainage and subsequent surgery; recurrent post-operative haemorrhage and post-operative death
Harris, 1974 (ref. 61)	53 years, M	Chronic anaemia	Small bowel dilatation, single diverticulum of the ascending colon, haemorrhoids	Conservative treatment
Hulme and Wilmshurst, 1976 (ref. 62)	15 years, M	Abdominal pain and vomiting	Acute appendicitis	Successful standard surgical repair; purulent swelling under the incision with normal subsequent wound repair
Phadke, 1978 (ref. 63)	71 years, F	Recurrent emesis	Eventration of left diaphragm and torsion of stomach	Effective repair of the diaphragmatic defect
Iwama et al., 1989 (ref. 64)	41 years, F	Sudden dyspnoea	Eventration of the diaphragm	Successful placation of the diaphragm with residual hiatus hernia
	Subsequent years, F (same patient)	Multiple events of acute abdominal pain	Diverticulitis of colon with recurrent perforations; spontaneous perforation of the jejunum	Successful treatment by various surgical techniques and uneventful wound healing
Leake et al., 2010 (ref. 65)	53 years, F	Abdominal pain and vomiting	Malrotation of the large bowel, multiple loops and dilated jejunum and ileum, occult and multiple small bowel perforations	Successful resection of the gut affected segment
Ratan et al., 2011 (ref. 66)	1 month, M	Inguinal mass	Right inguinal hernia	Successful surgical treatment; post-operative scrotal wound dehiscence
		Post-operative abdominal distension	Rectal redundancy with anterior displacement of the anus	Successful rectal resection
de Leeuw et al., 2012 (ref. 67)	9 years, M	Severe abdominal cramps and pain	Retroperitoneal hematoma and aneurysm of the superior mesenteric artery	An attempt of endovascular treatment caused rupture of the aneurysm, disintegration of the common femoral artery and necrosis of small bowel and cecum; the patient died shortly after
Kishikawa et al., 2012 (ref. 68)	40 years, M	Dizziness and melena	Multiple diverticula of oesophagus, distal jejunum and sigmoid colon; multiple erosions of the distal jejunum and ileum	Not performed

(continued on next page)

Bohorquez et al., 2013 (ref. 69)	39 years, F	End-stage liver disease	Non-alcoholic steatohepatitis	Successful liver transplantation; peri-operative retroperitoneal haematoma and post-operative small bowel perforation
Pelizzo et al., 2013 (ref. 70)	14 years, F	Chronic intestinal pseudo-obstruction symptoms	Dilatation of the ascending colon and terminal ileum	Recurrence after repeated ileostomy

F: female; GI: gastrointestinal; M: male.

Table 10-4 Association studies exploring the relationship between selected gastrointestinal features and generalized joint hypermobility

Reference[1]	Characteristics of patients	Characteristics of controls	Investigated feature(s)	Rate in patients	Rate in controls	*p* value
Marshman et al.,1987 (ref. 72)	4 females and 21 males (6-93 years) who undergone surgery for complete rectal prolapse	4 females and 21 males (mean 67 years) admitted for surgery but without rectal prolapse	Fifth finger extension	81 ± 2.2 degrees	68 ± 1.7 degrees	0.001
Norton et al., 1995 (ref. 73)	39 females (49-57 years) with JH	69 females (51-59 years) without JH	Rectocele (any grade)	84%	48%	0.0002
			Rectocele (grade 2&3)	34%	13%	0.009
Pulliam and Schuster, 1995 (ref. 74)	39 females and 4 males (18-62 years) with chronic intestinal pseudo-obstruction	1566 unselected individuals with GI symptoms	JH	46.5%	13.9%	< 0.001
Al-Rawi et al., 2004 (ref. 75)	28 men and 22 women with hiatus hernia at endoscopy	30 men and 20 women with normal endoscopy	JH	22%	6%	0.001
Jha et al., 2007 (ref. 76)	30 females (20-58 years) with JH attending rheumatologic clinic; Caucasians, Asian, Afrocaribbean	30 females (22-56 years) without JH attending a rheumatologic clinic; Caucasians, Asian, Afrocaribbean	Anal incontinence	23%	0%	0.01
Reilly et al., 2008 (ref. 77)	13 females and 26 males (7-17 years) with slow transit constipation	18 females and 23 males (7-17 years) without constipation requiring medical treatment	GJH (males)	38%	4%	0.004
Arunkalaivanan et al., 2009 (ref. 78)	148 fault females with JH members of the Hypermobility Syndrome Association; Caucasians (98%)	General adult population; previously published data[2]	Faecal incontinence	14.9%	2.2%	<0.05
Vounotrypidis et al., 2009 (ref. 79)	32 females and 37 males (18-50 years) with inflammatory bowel disease; Greek Caucasians	29 females and 38 males (18-50 years); Greek Caucasians	JH[2]	70.3% (Crohn disease)	25.4%	<0.0001

(continued on next page)

Mohammed et al., 2010 (ref. 80)	63 females and 2 males (15-80 years) with JH and intractable constipation	116 females and 19 males (20-83 years) with intractable constipation and without JH	Gender (female/male)	96.9%/3.1 %	85.9%/14.1 %	0.02
			Previous surgery for pelvic organ prolapse	30.7%	17.0%	0.04
			Incomplete rectal evacuation	80%	59%	0.004
			Functional rectocele	58%	39%	0.01
			Extrinsic compression of the anterior rectal wall	11	1	0.006
Zarate et al., 2010 (ref. 37)	54 females and 9 males (16-71 years) with JH and unexplained GI symptoms	43 females and 23 males (18-78 years) without JH and unexplained GI symptoms	Known aetiology	19%	59%	<0.0001
			Age	37 years (mean)	44 years (mean)	0.01
			Gender (female)	86%	65%	0.008
			Gastro-oeso-phageal reflux	56%	30%	0.005
			Bloating	62%	46%	0.05
Lammers et al., 2012 (ref. 81)	110 females (51-89 years) with JH attending gynaecological clinic	110 females (51-95 years) without JH attending gynaecological clinic	Pelvic organ prolapse	19%	2%	<0.01
Kajbafzadeh et al., 2014 (ref. 82)	113 children (5-14 years) with voiding dysfunction; Iranians	113 healthy schoolchildren (5-14 years); Iranians	JH (total)	45%	17%	0.001
			JH (females)	44%	23%	0.017
			JH (males)	34%	5%	0.04

GI: gastrointestinal; GJH: generalized joint hypermobility. JH: joint hypermobility. [1]: only features with statistically significant differences between patient and control groups are reported in the table (i.e. *p* value <0.05). [2]: from Nelson et al.[103]

1. Introduction

Ehlers-Danlos syndrome (EDS) is probably one of oldest known causes of bruises and bleeding and takes a prominent place among the syndromes and affections associated with a bleeding tendency. An abnormal tendency to bleed – be it spontaneously, or provoked by minimal trauma – in which the degree of bleeding, bruising or haematoma formation is out of proportion to the mildness of the trauma – is called bleeding tendency. Easy bruising constitutes one of the official criteria by which most of the EDS types are defined; however, not so in the commonest one, hypermobile EDS. Easy bruising and bleeding in EDS is not so much due to disorders in clotting and platelet function, but a prominent feature of this heritable collagen disorder.[1,2] Easy bruising and vascular vulnerability, sometimes leading to life threatening bleeding, are a hallmark of vascular EDS. Vascular fragility affects medium-sized and large arteries and veins in this type of EDS. In other types of EDS, bleeding tendencies have been described in isolated cases, and fragility of capillaries and perivascular connective tissues may cause those. There are descriptions of clotting or platelet disorders associated with bleeding and bruising in EDS. Although these various and scanty observations do not suggest a definite link between EDS and platelet or clotting abnormalities, we will describe if, and how, specific derangements in haemostasis could affect patients with EDS, covering also diagnostic and therapeutic aspects.

2. EDS and haemostasis

Haemostasis (the clotting of blood) involves the interaction of three components: the vessel wall, the clotting cascade and platelets.

2.1 The vessel wall

Easy bruising, bleeding gums, prolonged bleeding after dental procedures, operations and menstrual periods are manifestations of a bleeding tendency that may contribute to a diagnosis of EDS. The key problem in EDS is the formation of structurally abnormal collagen.[2] The collagen defect not only causes abnormal stretching of skin and tendons and disturbed wound healing. In vascular EDS, it also affects the normal architecture of the vessel wall. All arterial blood vessels are made up of three layers: the inner intima, the interface between blood and the vessel wall; the media, containing single or more layers of smooth muscle cells and collagen fibres; and the adventitia, mainly collagen fibres locking in place the vessel in the surrounding tissue. Collagen defects may affect the strength of the media and adventitia and facilitate the occurrence of tears in the walls of smaller vessels such as capillaries. This may become visible as petechiae or bruises of skin and mucous membranes: ‘easy bruising’. Larger vessels may also be affected, and this could lead to life threatening bleeding. Vascular EDS is characterized by extreme vulnerability not only of blood vessels but also of internal organs.[3,4] The bleeding tendency in vascular EDS thus is a direct consequence of the collagen defect in the vessel wall and not caused by abnormalities in the haemostatic process.[5] In other types of EDS, structurally abnormal collagen in *perivascular* connective tissues result in less firm pressure on damaged vessels in case of traumas and thus prolonged and more extensive bleeds. Easy bruising, bleeding after dental extractions or surgical procedures or heavy menstrual blood loss are not specific traits of vascular EDS, but rupture of internal organs (bowel, uterus), leading to life threatening internal bleeding are. A problem is that vascular EDS may reveal minimal clinical signs until a life threatening internal bleeding occurs.

2.2 The clotting cascade

The haemostatic process is an interaction of blood platelets, clotting proteins, natural clotting inhibiting proteins, and fibrinolytic (clot lysing) proteins. A cut through the skin will activate this process. Damage to capillaries and larger vessels will expose collagen and other factors in

the vessel wall to blood. This will activate the clotting mechanism in which both platelets and clotting factors will be involved in a natural response of the organism to the inflicted trauma, aimed at 'damage control'. As a result, damaged vessels will constrict, thereby minimizing blood loss, and platelets will adhere to the damaged vessel wall and aggregate together forming a primary haemostatic response. The activation of the clotting cascade will result in the formation of a fibrin network that stabilizes the platelet aggregate. This is described as secondary haemostatic response. Simultaneously, natural clotting inhibition will restrict the haemostatic response to the site of vessel wall damage. The wound healing process involves the fibrinolytic system that contributes to eventual clot solution and restoration of the normal vessel wall and tissue (skin) structure.

Bleeding disorders are usually described as a 'platelet type' or a 'haemophilia type' bleeding tendency. The platelet type is characterized by point-like skin bleedings (petechiae and ecchymoses), bleeding at puncture sites, skin cuts and after dental extractions. This type occurs with either a defect in the normal function of platelets (thrombocytopathy), critically reduced platelet counts (thrombocytopenia), or in von Willebrands disease (defects or deficiencies in von Willebrand factor (vWf), a protein that binds platelets). Haemophilia-type bleeding is caused by a defect or deficiency of a clotting protein, causing joint and muscle haematomas. These are usually inherited diseases. Haemophilia A is characterized by deficiency of clotting Factor VIII, and haemophilia B by a deficiency of Factor IX.

Different defects in the haemostatic process have been described in patients with several EDS types. These descriptions are mostly isolated case histories. This gives, apart from the well-established association of vascular EDS with easy bruising and vascular tears, a rather inconsistent picture of any further association of EDS with bleeding. In some cases consanguinity is involved, and this may bring to expression both clotting defects and EDS in parallel. Such cases may suggest an association between separate hereditary diseases, while a causal relationship remains difficult to establish and may have to be refuted eventually. For instance, the old assumption of a causal relation between EDS and mental retardation, probably is based on the same association due to consanguinity and mental retardation as a characteristic of EDS has been refuted. Case studies of EDS patients with clotting defects are reviewed here.

A large study involving 51 patients with EDS describes potential haemostatic defects.[6] In only eight of these 51 patient histories there was no bleeding tendency. In nine patients a significant clotting defect was established: four had a platelet defect, three had a deficiency in clotting Factor XI, and two had a Factor XIII deficiency. Minimal defects were detected in 16 patients, and the significance of these findings remained unclear. Of 24 patients with a normal laboratory profile, 20 had a bleeding tendency. It was impossible to establish a pattern that could identify certain types of EDS with the observed bleeding tendencies. The authors concluded that the strictly normal laboratory findings in 83 percent of patients with a clinically manifest bleeding tendency constituted a strong argument pointing towards a defect in collagen structure of skin and connective tissue around vessel walls as the bleeding cause, rather than an intrinsic haemostatic defect.

Unexplained haematomas and bruises in children may lead to consulting a paediatrician. A study of unexplained haematomas described 44 children, who were further examined with regard to clotting defects.[7] No haemostatic abnormalities were detected in the laboratory, while in all 44 children signs suggestive of collagen structural defects were detected, such as increases in thumb extensibility. Therefore, also in these children, bruising tendency appeared to be caused by a collagen defect rather than by intrinsic haemostatic abnormalities. Overall, the studies suggest that bleeding in EDS may result primarily from defects in perivascular collagen structure rather than from systematic associations of clotting defects.

2.3 Blood platelets

A disturbance in platelet function could theoretically result from either a defect in factors that activate platelets, or intrinsic platelet function defects. Both mechanisms could therefore play a role in observed bleeding tendencies in EDS patients, but evidence so far does not support this hypothesis. Collagen is an important agonist of platelet activation. Collagen exposure to blood, as occurs with cutting of a blood vessel, leads to platelet activation and subsequent haemostatic response. Theoretically, structurally abnormal collagen (such as in EDS) could cause a diminished activation of platelets in the primary haemostatic response. Structural defects in collagen therefore could incur a bleeding tendency by increased vulnerability of the vessel wall, the perivascular connective tissue and by a weakened platelet response. Studies in patients do not support this hypothesis so far. Platelet function tests in several families with a platelet type bleeding tendency were carried out.[8] A family with classical EDS, a family with hypermobile EDS, and a patient with an isolated, not classified type of EDS all had a slightly prolonged bleeding time. None of them ever had experienced bleeding complications after surgical procedures. In vitro platelet activation and aggregation by collagen from these patients was completely normal. Another family with a platelet function defect and vascular EDS was examined and showed independent inheritance of the platelet defect and of EDS: so the platelet defect was not a disease manifestation of EDS.[9]

Storage pool deficiency is a mild bleeding tendency caused by a diminution of substances that are stored within platelet granules. Normally, upon platelet activation these substances are secreted and cause platelet aggregation, therefore a deficiency leads to a defect in platelet aggregation. This leads to easy bruising, bleeding after dental extractions and surgical procedures, and increased menstrual blood loss. It is the most frequently described platelet function defect among patients with EDS. It has been observed in patients with vascular EDS[10] and in classical EDS.[11] It is not unique to EDS and is observed in several other rare diseases and also in otherwise healthy persons.

Another platelet aggregation defect was described in a family with a potentially separate form of mild EDS with recessive inheritance pattern. The platelet defect disappeared in the presence of fibronectin.[12] Interestingly, fibronectin is a protein that contributes to vessel wall structure. In this family, both the mild bleeding tendency and generalized hypermobility were ascribed to a defect in fibronectin.

Taken together, these observations do not indicate a causal association of platelet function defects and EDS. Only in the family with a defect in fibronectin both EDS and the bleeding tendency can be ascribed to one common defect. However, this fibronectin deficient EDS is not any longer recognized in the 2017 International EDS classification.[13]

3. Diagnostic work-up of bleeding tendency

An observed bleeding tendency usually leads to a search to establish the cause. The medical history and clinical evaluation of the patient are the first and most important clues towards a diagnosis of a bleeding disorder: platelet type or haemophilia type. It includes the Rumpel-Leede test, which determines capillary fragility and might be positive in EDS patients. Laboratory testing may corroborate the clinical diagnosis.[14] After screening with general clotting tests and platelet function analysis to establish an overall picture of the haemostatic system, more specific assays may form the next step.

Traditionally, platelet function testing consisted of a bleeding time and platelet aggregation studies. A bleeding time is performed by application of a standardized skin wound and measuring the time until blood clotting occurs. If the bleeding time exceeds the normal range (usually 4-8 min, depending on the equipment used) further platelet analysis involves *in vitro* platelet aggregation studies. Platelet concentrates *ex vivo* can be exposed to several agonists, such as collagen and adenosine diphosphate, in a light transmitting cuvette. The pattern of

light transmission is indicative of the function of platelets (ability to aggregate and remain aggregated). In routine clinical practice, platelet function is often assessed by an overall function test called platelet function analysis. It is at best an alternative to the standardized skin bleeding time. The presence and function of coagulation proteins can be tested by several clotting assays mainly based on principles of dilution and reconstitution. It is also possible to measure concentrations of individual clotting factors by special assays.

In EDS, testing of the haemostatic system may be appropriate if surgical procedures are indicated. However, as mentioned before, a causative association between platelet and specific clotting abnormalities and EDS has not been established. Careful history taking in the individual, a complete family history including information on past generations, and complete physical examination provide the most important information. Subsequently, an approach of the problem in an individual patient, tailored to the specific clinical situation appears useful. For instance, in an otherwise healthy individual who has to undergo a major operation, careful history taking and physical examination will practically eliminate the possibility of a bleeding tendency that may complicate a surgical procedure, and this may well apply to the individual with EDS without any signs and symptoms indicative of a bleeding tendency. In other individuals, such as patients with vascular EDS, a thorough examination of platelet function and clotting may be more appropriate, as these persons are already subject to bleeding from ruptured vessels or organs and an intrinsic clotting defect may complicate clinical outcome. In summary, routine laboratory clotting testing in individuals with EDS is not advocated. The importance of individual and family history taking together with complete physical examination cannot be stressed enough. It is important to consider the diagnosis of vascular EDS in patients with otherwise unexplained bleeding in internal organs. Though easy bruising is not a major or minor criterion for the diagnosis of hypermobile EDS, it has been reported that 39/91 (43%) of children with joint hypermobility syndrome had a history of easy bruising.[15]

Jackson et al. tried to answer the question whether collagen disorders are more prevalent among patients seen at a bleeding clinic. In a relatively small case-control study it was found that 13/55 (24%) of selected bleeding patients had a suspected collagen disorder compared to 1/50 (2%) among controls, while 10/13 of suspected collagen disorder patients had a personal or family history of EDS, benign joint hypermobility syndrome or osteogenesis imperfecta.[16]

4. Therapeutic approach to bleeding tendency and vascular complications in EDS

4.1 General measures

In EDS as in other conditions it remains important to control the risk of vascular damage by elimination or improving the well-known risk factors of atherosclerotic cardiovascular disease. These risk factors include smoking, hypertension, dyslipidaemia, overweight and obesity, and diabetes mellitus. Smoking also has a deleterious effect on collagen, clinically visible as premature aging of the skin with wrinkles. A healthy life style applies to all in every aspect and this includes a balanced diet with ample fruit and vegetables, a reduced intake of saturated fats, daily physical exercise, and avoidance of overweight and stopping of smoking. Only moderation of alcohol consumption is appropriate (1-2 units per day), as daily intake of 3 units or more of alcoholic beverages increases the blood pressure. Strictly speaking, no information is available on development of atherosclerotic vascular disease in patients with EDS, as this condition remains too rare to establish any associations. As such, recommendations of a healthy life style have a general character applicable to the general population, including individuals with EDS.

Bleeding tendencies in EDS, including storage pool deficiency, are mild, with the exception of bleeding complications in vascular EDS. The only reasonable recommendation that can be

made is to avoid circumstances that may provoke bleeding, such as contact and group sports. These sports are also contraindicated because of the risk of skin wounds and subsequent scar formation, and (sub)luxations.

4.2 Potential hazards from drugs or clinical procedures

Drugs that interfere with the haemostatic process should be avoided by patients with any type of EDS. Drugs that interfere with platelet function include aspirin (acetylsalicylic acid, ASA), dipyridamole, clopidogrel, and non-steroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen and diclofenac. These drugs affect platelet function thereby prolonging the bleeding time. Aspirin, clopidogrel and dipyridamole are being prescribed on a large scale as therapeutic agents in patients with coronary artery disease, cerebrovascular disease, and peripheral arterial disease. In these cases, pros and cons of these medications will have to be weighed by the treating clinician. Ibuprofen and diclofenac are popular as pain killers and anti-inflammatory agents. Paracetamol (acetaminophen) and COX-1 sparing NSAIDS do not influence haemostasis and can be considered safe, albeit that COX-1 sparing NSAIDS increase the risk of cardio-vascular disease. Use of anticoagulant drugs by definition will increase the bleeding tendency. This group includes the traditional oral vitamin K antagonists (coumarins) such as acenocoumarol, fenprocoumon and warfarin; heparin and low molecular weight heparins (LMWH), pentasaccharides, and the newer oral thrombin inhibitors and pentasaccharides. Use of these drugs should be avoided if possible, especially in individuals with vascular EDS. Vascular procedures such as arterial punctures, catheterization, intravenous or intra-arterial lines should also be avoided in these persons.

4.3 DDAVP

The vasopressin analogue DDAVP (desmopressin acetate, 1-Desamino-8-D-Arginine Vasopressin) may help to reduce a bleeding tendency temporarily in subjects undergoing a dental or surgical procedure. DDAVP increases the concentrations of Factor VIII-vWf temporarily, whether administered intravenously, subcutaneously, or by nasal spray. This effect is ascribed to induced release of these factors from storage sites in vascular endothelial cells.[17] Intravenous administration of vasopressin to subjects with mild haemophilia or von Willebrand disease has enabled dental procedures, tonsillectomies and even larger surgical procedures to be carried out without abnormal bleeding. It has been successfully applied in other patients with a variety of qualitative platelet abnormalities such as uraemia or liver cirrhosis. It is important to test the effect of vasopressin before a procedure is carried out, to be certain of its effect. Vasopressin can be of use for patients with EDS who do not have a haemostatic defect but who have a prolonged bleeding time due to an abnormality in the vessel wall. Two children, one with periodontal EDS (formerly type VIII) and one with kyphoscoliotic EDS, both with a prolonged bleeding time, had a normal bleeding time after administration of vasopressin. Both children successfully underwent surgical procedures without bleeding complications. One patient continued using intranasal vasopressin to avoid nasal and gum bleedings. The authors suggest considering vasopressin administration in other individuals with EDS with a bleeding tendency.[18] Mast et al confirmed the usefulness of DDAVP in children with EDS.[19] Vasopressin is an antidiuretic hormone causing water retention in the body, leading to high blood pressure and decreased serum sodium levels. The use of its analogue DDAVP has these same properties and because of potential dangers associated, should only be used in specialized settings and care centres.

4.4 Vitamin C

Vitamin C is involved in collagen synthesis. Two sites of action on collagen metabolism have been proposed. First, it is a cofactor for collagen hydroxylating enzymes and regulates the

posttranslational hydroxylation of collagen lysyl and prolyl residues. Furthermore, it also stimulates collagen synthesis at a transcriptional, or mRNA processing level. Vitamin C may reduce easy bruising but has no effect on the primary findings of skin hyperextensibility, atrophic scarring, and joint hypermobility. In general, a dose of two grams per day is recommended for adults, with proportionally reduced doses for children; however, there is no limitation.[20]

4.5 Celiprolol

Ong et al. have reported on a positive effect of celiprolol on prevention of cardiovascular events in vascular EDS.[21] Further studies are needed in order to judge more specifically the quantitative and qualitative aspects.

4.6 Recombinant factor VIIa

Perioperative use of recombinant factor VIIa may be useful in management of intractable bleeding after surgical repair of ruptured medium-sized vessels. A case report describes the successful use of recombinant factor VIIa in a patient with vascular EDS, in whom continued bleeding was successfully halted after intravenously administered recombinant factor VIIa. Of note, the platelet count, prothrombin time and activated partial thromboplastin time were all normal.[22]

5. Conclusion

A bleeding tendency in EDS may result from structural collagen abnormalities in the skin and supporting tissues around vessels and in vascular EDS, in the vessel wall proper. Observed bleeding tendencies in infants and children may lead to a diagnosis of EDS or a defect in the haemostatic system. In subjects with EDS abnormalities in the haemostatic system are detected more often than in the general population (an increased *relative* risk), but in most cases of EDS (80 percent in one study) the haemostatic system proved to be normal (indicating a low *absolute* risk). A mild bleeding tendency in EDS may have clinical significance. Preoperative attention for the haemostatic system is therefore recommended in all subjects with EDS. Individuals with a platelet type bleeding tendency whether or not due to a qualitative platelet function defect, may receive a test dose of DDAVP to assess whether they may benefit from this compound, especially in preventing perioperative bleeding. There is only anecdotal evidence for the use of recombinant factor VIIa in prolonged bleeding despite surgical haemostasis in vascular EDS.

1. Introduction

The Ehlers-Danlos syndrome (EDS) is a relatively rare example of a group of comparable genetic disorders of connective tissue (collagen) with consequent hypermobile joints, distensile and fragile skin and ruptures in arteries, intestine and uterus. Although there are no hard data, the prevalence of EDS is estimated at 1:5000 without sex or ethnic bias.[1] In the Netherlands this would translate into approximately 3000 persons with EDS. The most common types of EDS are classical (formerly denoted as types I and II), hypermobile (formerly EDS type III) and vascular (formerly EDS type IV) EDS.[2,3]

In a number of case reports and in older textbooks an association is suggested between EDS in general and various cardiac disorders.[4-16] The described abnormalities include congenital anomalies of the heart, valvular abnormalities, heart rhythm and conduction disorders, rupture of the ascending aorta, widening of the coronary arteries and myocardial infarction at a young age. This chapter will specifically address the question of cardiac abnormalities in classical and hypermobile EDS and their prevalence in a comparable normal population.

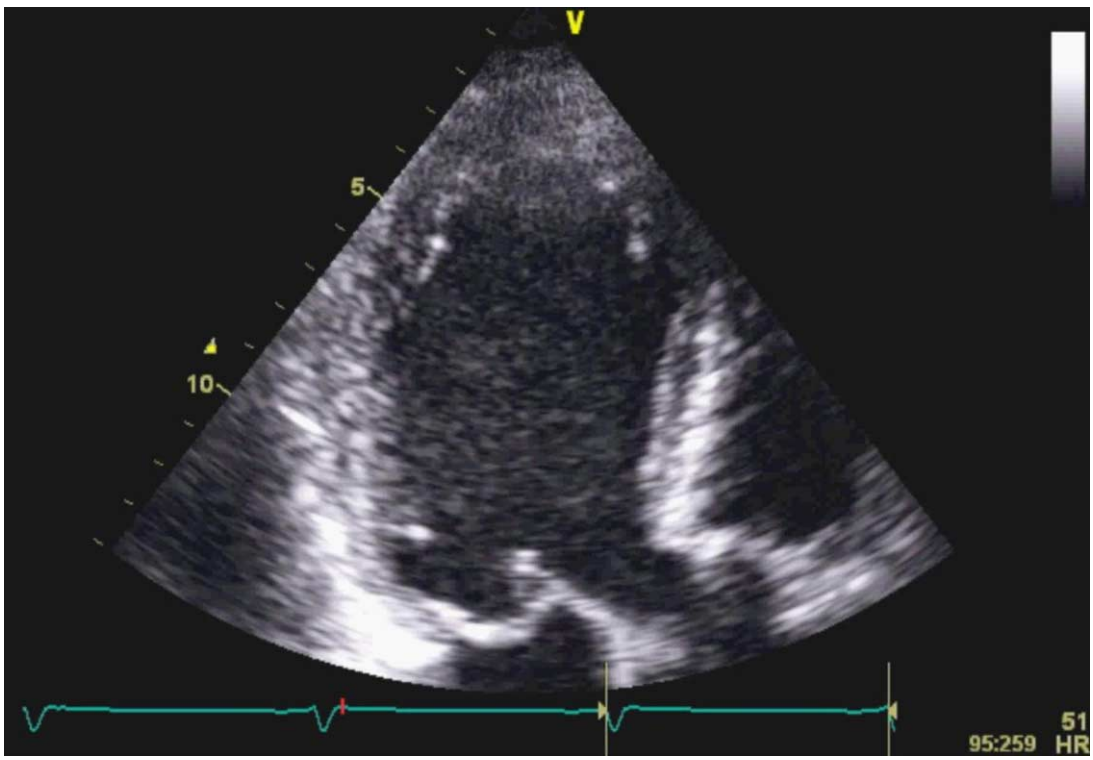
The discussion will be mainly limited to the classical and hypermobile EDS as the abnormalities and complications of the vascular type are discussed elsewhere in this book (see chapter 6). However, some attention will be given to the secondary prevention of complications in EDS, especially vascular EDS.
Next to vascular EDS, also in kyphoscoliotic EDS major vascular complications occur;[17,18] in arthrochalasia EDS these have been described as well.[19]
In 2004, Schwarze et al. and later Malfait et al. described a new and rare EDS type: cardiac-valvular EDS. Apart from typical EDS features, it is associated with severe aortic and/or mitral valve insufficiency, necessitating valve replacement at relatively young age. The inheritance is autosomal recessive. It is due to homozygous or compound heterozygous *COL1A2* null mutations.[20,21]

2. Cardiac abnormalities in EDS

2.1 Classical and hypermobile EDS

In classical EDS, occasionally cardiac disorders have been described, including mitral valve prolapse (figure 12-1) and mild cardiac arrhythmias.[22] In generalized hypermobility, cardiac arrhythmias seem to be based on derangement of the autonomic regulation of heart rhythm.[23]
To what extent there is a direct rather than a coincidental relationship between heart disease and EDS in these types is unclear. This issue has stimulated research interest that has been hampered by the very low incidence of EDS.
In a group of 71 patients with EDS, the diameter of the aortic root was measured by echocardiography. In 28% of these patients, the diameter was found to be larger than average by a factor twice the standard deviation from the mean of normal. This means that the enlarged cross section cannot be attributed to chance, but constitutes a real anomaly. Fourteen of these patients (14/42 = 33%) had classical EDS and six patients (6/29 = 17%) hypermobile EDS. If the aortic root increases in diameter during the following years, the aortic valves, located in the root, might not properly close, resulting in aortic valve insufficiency (figure 12-2). A surprising finding was that dilatation of the aortic root was found more often than mitral valve prolapse, an abnormality previously considered to be closely associated with EDS.[24]

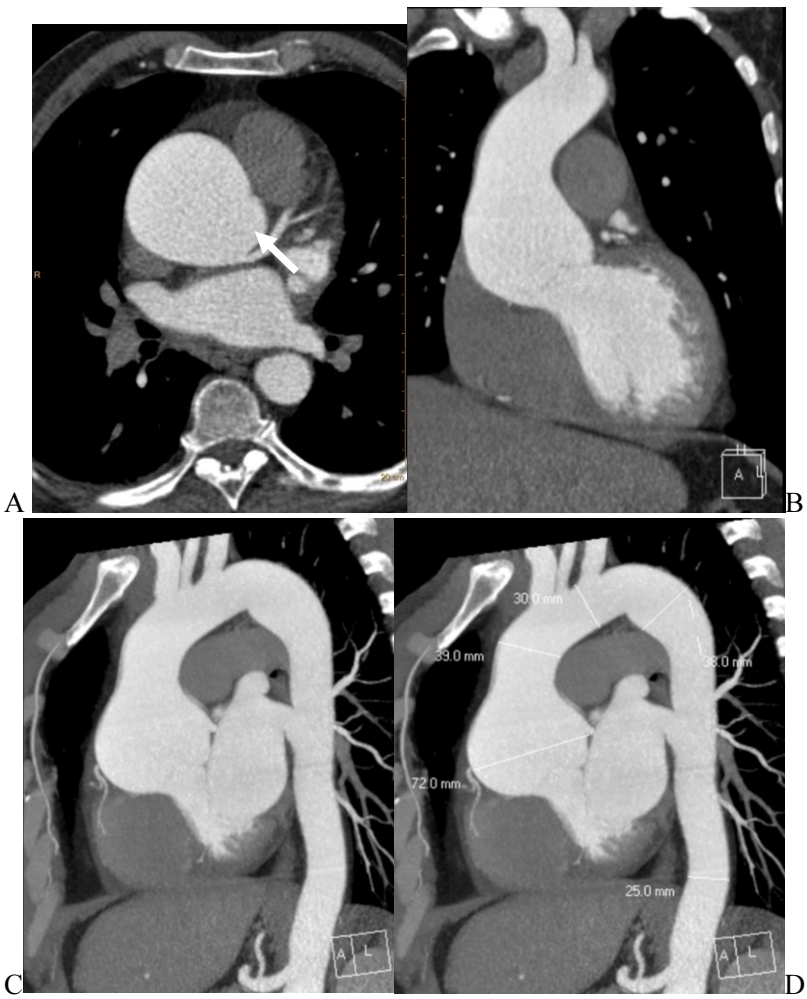
Figure 12-1 Mitral valve prolapse



Echocardiographic image of posterior mitral valve leaflet (PMVL) prolapse in the left atrium (LA).
Apical 3-chamber view with left ventricle (LV) in the upper and middle left parts of the picture, the LA in the lower part. The right part of the view shows the right ventricle with at the bottom the outflow tract of the LV, aortic valve and the origin of the aorta. The small vertical line in the ECG lead indicates that it is a late systolic contraction of the heart. It is clearly visible that during this contraction the PMVL protrudes in the LA.

A similar study was performed in a cohort of 38 EDS patients in 2006.[25] That study also demonstrated mild abnormalities in these patients but unfortunately insufficient follow-up data are available to provide any conclusive opinion about the possible progression of these abnormalities. However, given the normal life expectancy of individuals with classical and hypermobile EDS in contrast to those with the vascular type, it may be assumed that this progression is unlikely to be serious. But in a few recent case reports, occasionally more severe complications including aortic root aneurysm and myocardial infarction have been reported.[26] These findings might, however, reflect EDS types with a slightly different genetic basis compared to classical EDS. For the time being the evidence would suggest that classical and hypermobile EDS are unlikely to result in serious cardiac or vascular clinical sequels. In 2011, Atzinger et al. did a similar study in 252 patients and similarly concluded that, although aortic root size is increased and mitral valve prolapse is more frequent in patients with classical and hypermobile EDS, they tend to be of little clinical consequence.[27]
Recently, a subtype of classical EDS has been identified which is clinically characterized by a propensity to arterial rupture and molecularly by a specific mutation in *COL1A1* (classical EDS is caused by mutations in *COL5A1* and *COL5A2*).[28]

Figure 12-2 Dilated aortic root



CT angiography of the thoracic aorta. (A) Axial 2 mm multiplanar reconstruction of the enlarged aortic root at the level of the left coronary artery (arrow). (B) coronal 3 mm maximum intensity projection (MIP) image showing a dilated aortic root and proximal part of the ascending aorta. 20mm sagittal oblique MIP without (C) and with (D) aortic diameter measurements.

2.2 Vascular EDS

This EDS type is probably present in less than 1:100.000. Reduced life expectancy and frequency of complications clearly demonstrate the seriousness of the disease. Complications in childhood are rare; 25% of the patients having their first complication in their twenties and more than 80% experiencing one complication by the age of 40. More than 80% of these patients have one or two serious complications during their lifetime.[29] Translated to a population of 16 million in the Netherlands this would account for 200 serious lifetime incidents, 25% of which involve the bowel or uterus. There are approximately 150 complications involving the aorta or the medium-sized arteries, but occasionally also cardiac complications might occur.[30] By an estimated average life expectancy of 50 years, this means that only three serious vascular complications will happen per year in the Netherlands.

Despite this low yearly prevalence there is still the need for adequate diagnosis and urgent referral to experienced vascular surgeons.
It is suggested that complications in patients with vascular EDS are related to the *COL3A1* mutation type involved. In patients with mutations leading to haplo-insufficiency (with production of 50% of the normal amount of type III collagen), in contrast with mutations with production of 10% or less of the normal amount, life span is extended, the age of first complication is delayed by almost 15 years and major complications are limited to vascular events.[31,32] A recent large study confirmed this association between *COL3A1* mutation and phenotype and severity.[33]
Recently, Monroe et al. reported a family with an lethal EDS vascular phenotype and a *COL5A1* mutation, including a review of 4 other published cases.[34]
The literature also reflects that in vascular EDS, the occurrence at a young age of coronary artery aneurysms or myocardial infarction is very infrequent[7,8,10] and that (in a study of 220 patients) there is absence of any clear proof of frequent, clinically-relevant cardiac disease other than coronary artery aneurysms or myocardial infarction.[25]

3. Secondary prevention of EDS

3.1 Classical and hypermobile EDS

Authors who have reported cardiac disorders associated with these EDS types suggest screening these patients for evidence of aortic root abnormalities and if detected, to introduce close monitoring. However, the practicality of such a routine intervention is questionable given the limited evidence. A more acceptable recommendation might be to screen these groups before any surgery for cardiac valve abnormalities using echocardiography, to minimalize the risk of complications such as bacterial endocarditis, frequently associated with cardiac valve abnormalities.

3.2 Vascular EDS

Patients and doctors must remain vigilant for any signs or symptoms that may suggest complications associated with this EDS type. Early intervention is essential but this may be avoided by the implementation of preventive strategies including the optimal regulation of blood pressure, the avoidance of certain medication such as anticoagulants and regular, physical activity avoiding peak muscle loading and intense competitive sports.

Cardiologists and other physicians, consulted by patients with vascular EDS should be cautious when dealing with these individuals. Box 12-1 highlights some of the risks they might encounter in the course of additional investigations. Invasive techniques such as venous or arterial puncture, all forms of endoscopy and heart catheterization are inducing a high risk of complications. If possible, noninvasive alternatives such as echocardiography, computer tomography (CT), magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA) should be used in preference to standard invasive procedures.

At the end of the day, the need for any invasive examination needs to be thoroughly questioned, particularly if the risk of the procedure outweighs the potential for any diagnostic benefit. And in the light of current developments in non-invasive imaging techniques utilizing smaller equipment to rapidly produce high quality images, one questions the place of invasive techniques that carry a risk to patients, particularly the group we are currently discussing. Today, echocardiographic techniques can be enhanced and CT and MRI scanned images of the heart and major vessels are of the highest quality.

Box 12-1 Advices for guiding and examination patients with vascular EDS

1. Competitive sports are contraindicated. The load in aerobic exercises must be submaximal. Peak loads and press-ups should be avoided.
2. Regular control of blood pressure is necessary and optimal treatment of high blood pressure is indicated. To lower the pressure in the arteries one should try to reach values beyond those of healthy persons of the same age.
3. Medication which influences coagulation and can promote bleeding, anticoagulants, acetylsalicylic acid and conventional NSAIDs, are contraindicated.
4. Punctures of arteries and catheterizations for diagnostic reasons should not be undertaken and a noninvasive alternative should be sought.
5. Any form of endoscopic examination should be avoided and replaced by appropriate non-invasive techniques. This includes esophageal echocardiography and examination of the gastro-intestinal tract.

Surveillance of the arterial tree is justified if interventions have been proven to be effective in decreasing risks of arterial dissection or rupture and prolong life. As endovascular approaches to management of aneurysms and dissection become more available, intervention is considered earlier and surveillance is seen to have greater benefit. There are, however, no published data that assess the efficacy of screening strategies to identify the regions in the arterial vasculature at highest risk.[35]

In a clinical trial among 53 patients with vascular EDS investigating the effect of celiprolol on the occurrence over 5 years of arterial events (rupture or dissection, fatal or not), these complications occurred in five patients (20%) in the group treated with celiprolol and in 14 patients (50%) not treated with celiprolol, a promising result that warrants further investigation.[36]

4. Centre of expertise for patients with vascular EDS

More than 10% of patients with vascular EDS die as the consequence of their first complication, without prior knowledge of the actual diagnosis. Although the vascular type is very rare, the dramatic course of the disease regularly draws much attention, and rightly so. Regularly case reports are published by physicians who describe their once-in-a-lifetime experience with such a patient. The rarity of vascular EDS makes every vascular surgeon, neurosurgeon or neurologist an “expert”, if exceptional circumstances or coincidence confronts him or her with two or three patients in a few years. Cardiologists less frequently encounter these patients in the role of first responsible physician and in the Dutch National Registry of Congenital Cardiac Malformations (CONCOR) there is no facility to register vascular EDS, although Marfan syndrome is included. However, cardiologists are often involved in additional examinations, once the diagnosis has been made.

There is a great need for further research that will, with a greater number of patients, provide valuable insight into the prevalence of (cardio-)vascular abnormalities and complications of this type of EDS.

The realization of a Centre of Expertise, perhaps involving international collaboration of universities with multi-disciplinary input, would contribute to our understanding of this condition and optimize patient management. The development of psychological support and guidance for EDS patients should also be part of such an initiative. However, in the present economic climate, the fear remains that insufficient funding will prevent such a development;

this leaves clinicians to rely on case reports and anecdotal comment rather than benefit our patients through sound, evidence-based knowledge.

5. Conclusion

In classical, hypermobile and vascular EDS no indications could be found for the presence of anatomical cardiac disorders other than coronary artery aneurysms in vascular EDS, which could lead to clinical manifest cardiac problems, when compared with a healthy population. However, more research is needed to distinguish the varieties of EDS, to concentrate knowledge of such a rare disease with small numbers of patients and to share this information in a multidisciplinary clinical setting. The optimal environment for this initiative would be a collaborative Centre of Expertise. Patients would then gain the maximum benefit of the collective wisdom of clinicians and scientists working in the area.

6. Areas of uncertainty

Due to the lack of systemic investigations among sufficient numbers of patients, it is not certain to which extent the present information on certain functional and anatomic cardiac abnormalities in EDS is really giving the complete picture. It could well be that systemic investigations would indicate higher prevalences of cardiac morbidity in patients with different types of EDS.

The author wants to thank Dr. David Gerrard of Otago University, Dunedin, New Zealand for his comments and suggestions for English text.

1. Introduction

Ehlers-Danlos syndromes (EDS) are heritable connective tissue disorders primarily affecting skin, joints, vessels and internal organs. Nevertheless, their consequences seem to span much beyond these tissues and also extend to the central and peripheral nervous system and muscles. In fact, recurrent muscle cramps have been reported in EDS since the late sixties.[1] After this early paper, which actually focused on orthopaedic aspects of EDS, many other reports have highlighted a possibly prominent involvement of the nervous system and muscles in this condition. However, an increasing attention on neurological aspects of EDS has been posed only in 2009 by Voermans et al., who reported their findings in 40 EDS patients and demonstrated a subtle, but significant neuromuscular involvement in this disorder.[2] A recent review, primarily intended for a readership of child neurologists, emphasized a heterogeneous and potentially disabling neurological involvement in EDS with a wide range of apparently low-frequency, but possibly type-specific anomalies of the nervous system.[3] Additionally, at least for the hypermobile EDS (hEDS) , musculoskeletal pain, fatigue and headache represent the master contributors to patients' referral to the practitioner and quality of life deterioration.[4]

In this chapter, neurological complications of EDS are illustrated in separated sections, including pain, fatigue, cardiovascular dysautonomia (as discussed in Chapter 5), headache and head pain, cerebrovascular disease, brain and spine structural abnormalities, epilepsy, muscular features, neuropathy, and developmental features. Before the publication of the 2017 international classification of EDS, the prevalent hypothesis has been put forward to consider hEDS and benign joint hypermobility syndrome (BJHS) one and the same condition at the clinical level (see also the discussion in chapter 5).[5,6] The contemporary nosology of EDS and joint hypermobility disorders has removed the term "benign joint hypermobility syndrome" (and synonyms). Now, the existence of a continuous spectrum ranging from isolated, non-syndromic joint generalized joint hypermobility to hEDS is recognized. Within the spectrum, the term hEDS is now restricted to the most systemic/Mendelian phenotypes, while the term hypermobility spectrum disorders (HSDs) is introduced to fill the gap between the two ends. For conservative reasons, in this chapter the term hEDS/HSDs is used for all papers published before the 2017 classification and dealing with patients with hEDS and/or benign joint hypermobility syndrome according to the old diagnostic criteria. The following contents are partly extracted from a recent review on neurological manifestations in EDS written by the authors of this chapter.[7]

2. Pain

Pain is now accepted as a common and potentially disabling feature of various forms of EDS, especially hEDS/HSDs.[4] This is testified by the inclusion of chronic musculoskeletal pain as minor feature in the 2017 International EDS classification criteria for hEDS (see chapter 2, table 2-5 and chapter 5).[6] Conversely, in the early EDS literature, pain was recognized as a marginal finding, usually occurring acutely due to (sub)luxations, spontaneous rupture of vessels[8] and internal organs,[9] or recurring in relation to piezogenic pedal papules[10] or gynaecologic/obstetric complications.[11] In 1994, Lumley et al. first pointed out a possible role of chronic pain in the quality of life of EDS patients by studying psychosocial functioning in 48 subjects with various forms of EDS.[12] Furthermore, the repeated evidence of resistance to local anaesthetics in hEDS/HSDs[13] suggests a more complex effect on pain perception and modulation processes in EDS. Scientific awareness of the clinical significance of chronic pain in EDS increased in 2010, when Voermans et al. published the results of their questionnaire study on 273 patients with various forms of EDS (mainly, classical, hypermobile and vascular types) and found pain as common, severe, and associated with functional impairment. Interestingly, pain seemed more severe in hEDS/HSDs than classical and vascular EDS, and

pain severity was correlated with hypermobility, dislocations and previous surgery.[14] This preliminary observation prompted the same research group to state that pain and fatigue are possible important determinants of disability of hEDS/HSDs.[15] On a clinical perspective, chronic-recurrent joint pain is the most common presentation of pain in hEDS/HSDs, which is reflected in the diagnostic criteria.[6] Additional manifestations of musculoskeletal pain in hEDS/HSDs, and perhaps other EDS types, include muscle cramps,[1] fibromyalgia[16,17] and compression/peripheral neuropathies.[18,19] Pain is not limited to the musculoskeletal system and often presents with visceral involvement, in the form of various gastrointestinal chronic and recurrent symptoms,[20] as well as dyspareunia, vulvodynia and dysmenorrhea.[21,22] Headache is also common in EDS[23] and is discussed in a separate section. The study of the natural history of hEDS/HSDs tells us that pain changes in time and among individuals in EDS, and its functional consequences are influenced by the adaptation strategies that affected individuals develop, as a whole, to face repetitive pain perception.[4] Accordingly and following previous postulations,[4] a recent work by Rombaut et al. demonstrated the presence of hyperalgesia in hEDS/HSDs.[24] This finding may represent a preliminary proof for central sensitization processes in those EDS patients, who develop the most severe disabilities associated to pain. A more extensive description of pain manifestations and management in EDS is reported in chapter 21 ("Causes and treatment of chronic pain in EDS").

3. Fatigue

Though largely ignored in the past, severe fatigue is now considered a common accompanying feature of EDS, particularly hEDS/HSDs, as it has for the first time been reported in up to 84% of the patients.[25] Similar results are obtained by other research groups.[26,27] More specifically, the frequency (and, perhaps, severity) of fatigue is influenced by age with a rate of 28% in the first decade of life to 90% in adults over 40 years of age.[27] In hEDS/HSDs, the impact of fatigue on daily life is often equal to or more dramatic than the impact of pain;[25] a fact that underscores the importance of fatigue for both assessment and treatment planning in these patients. A complex presentation of fatigue resembling chronic fatigue syndrome according to Fukuda et al.[28] is reported in most adults with hEDS/HSDs.[29]
Some possible contributors to fatigue-related disability in EDS have been identified and include sleep disturbances, concentration problems, impaired social functioning and self-efficacy concerning fatigue, and pain severity.[25] A few experimental studies demonstrated that fatigue associates with muscle weakness,[30,31] worsens with exercise[32] and affects gait pattern.[33] Recently, dysautonomia was recognized as one of the most relevant pathogenic factors influencing fatigue onset and evolution. This argument is discussed in extension in a following section.

4. Headache and head pain

In 1996, Spranger et al. first reported headache, drop attacks and white matter abnormalities in a 37-year-old woman with EDS with periodontitis.[34] One year later, a larger study on 50 individuals with different forms of EDS (including 13 patients with classical EDS, 28 with hEDS/HSDs, 7 with vascular EDS, and 2 with unclassified type) showed that neck pain and headache are present in 30-40% of cases.[23] A subsequent case series reported 9 EDS patients presenting with various forms of headache, including (i) migraine with aura, (ii) migraine without aura, (iii) tension-type headache, (iv) a combination of tension-type headache and migraine, and (v) post-traumatic headache.[35] Additional papers on small case series confirmed the high prevalence of headache in hEDS/HSDs.[36,37] More specifically, Bendik et al. showed that migraine (with or without aura) was approximately three times more common among a group of 28 women with hEDS/HSDs compared to 232 controls, with a cumulative frequency of 75%.[38] In a 36-year-old woman with orthostatic headache and idiopathic intracranial

hypertension, the diagnosis of BJHS - now considered hEDS/HSDs - was reached two years after the onset of head pain.[39] This patient displayed increased insulin growth factor 1 (IGF-1) plasma levels and the authors speculated on a possible pathogenic link. The elevation of IGF-1, in association with elevations of growth hormone and insulin, has been described previously in 31 BJHS patients.[40] The relationship between elevated IGF-1 plasma levels and headache in BJHS is not clear, but the presence of IGF-1 receptors in the choroid plexus[41] may suggest an overstimulation of cerebrospinal fluid production by the excess of circulating IGF-1 molecules.

Head pain is not limited to headache in EDS. In a cohort of 31 EDS patients (including 16 with hEDS/HSDs, nine with classical and six with vascular EDS), De Coster et al. demonstrated temporomandibular joint dysfunction in 100% of the cases, unilateral myofascial pain (i.e. temple headache) in 83%, and unilateral or bilateral temporomandibular joint pain in 28% and 51% of the patients, respectively.[42]

Another cause of headache in EDS is occipital neuralgia is a distinct type of headache characterized by piercing, throbbing, or electric-shock-like chronic pain in the upper neck, back of the head, and behind the ears, usually on one side of the head. Typically, the pain of occipital neuralgia begins in the neck and then spreads upwards. Some individuals will also experience pain in the scalp, forehead, and behind the eyes. Their scalp may also be tender to the touch, and their eyes especially sensitive to light. The location of pain is related to the areas supplied by the greater and lesser occipital nerves, which run from the area where the spinal column meets the neck, up to the scalp at the back of the head. The pain is caused by irritation or injury to the nerves, which can be the result of trauma to the back of the head, pinching of the nerves by overly tight neck muscles, compression of the nerve as it leaves the spine due to osteoarthritis, or tumours or other types of lesions in the neck. A positive response (relief from pain) after an anaesthetic nerve block will confirm the diagnosis. Treatment is generally symptomatic and includes massage and rest. In some cases, antidepressants may be used when the pain is particularly severe. Other treatments may include local nerve blocks and injections of steroids directly into the affected area. Occipital neuralgia is not a life-threatening condition. Many individuals will improve with therapy involving heat, rest, anti-inflammatory medications, and muscle relaxants. Recovery is usually complete after the bout of pain has ended and the nerve damage repaired or lessened.

While many EDS patients may develop chronic or recurrent headache, individuals with EDS types with vascular fragility are at increased risk of sudden headache secondary to acute cerebrovascular disease. In particular, acute headache may occur together with ophthalmoplegia or tinnitus due to spontaneous direct cavernous-carotid fistula in vascular EDS.[43,44] Additional observations point out possible associations between localized or generalized joint hypermobility and specific subsets of primary and secondary types of headache, including new daily persistent headache[45] and headache attributed to spontaneous (idiopathic) cerebrospinal fluid leakage.[46,47] Cervical spine hypermobility/dysfunction is also anecdotally considered a predisposing factor for cervicogenic headache[48,49] and neck-tongue syndrome.[50-52] In line with this, Di Palma and Cronin reported a 27-year-old woman with classical EDS with a long-lasting pulsating headache associated with C2 dislocation.[53]

5. Cardiovascular dysautonomia

The first evidence for a tight link between EDS and autonomic dysfunction was obtained in 1999, when Rowe and co-authors studied 11 young patients (6 with classical and 6 with hEDS/HSDs) all showing either postural tachycardia (a.k.a. postural orthostatic tachycardia syndrome - POTS) or neurally mediated hypotension.[54] Four years later, Gazit et al. found orthostatic hypotension, POTS, and uncategorized orthostatic intolerance in 21 out of 27 (78%) hEDS/HSDs patients.[55] More specifically, this study revealed a greater drop in systolic

blood pressure during hyperventilation and a greater increase in systolic blood pressure after a cold pressure test in patients compared to controls. The authors suggested the existence of increased alpha-adrenergic and beta-adrenergic hyper-responsiveness in hEDS/HSDs.[55] These preliminary findings pointed out the need of paying more attention to non-musculoskeletal symptoms of hEDS/HSDs (and other EDS types) which, in turn, may be linked to dysautonomia as the underlying pathogenic mechanism.[56] Accordingly, non-musculoskeletal symptoms are now accepted as an important manifestation of EDS and their clustering determines a worse physical and psychosocial health within the wider clinical spectrum of hEDS/HSDs.[57] Accordingly, the autonomic burden in EDS, and more particularly in hEDS/HSDs than in classical and vascular EDS, seems comparable to that in fibromyalgia.[58] The same research group further investigated the dysautonomic profile of hEDS/HSDs with autonomic functional testing and found a higher low frequency/high frequency ratio (i.e. an increase of the physiological heart rate variability), a greater blood pressure fall during Valsalva manoeuvre and a smaller initial systolic blood pressure increase during tilt in a cohort of 39 affected women compared to controls.[59] They also found POTS as the most prevalent autonomic profile in hEDS/HSDs and identified sympathetic neurogenic dysfunction as the most likely explanation for dysautonomia in this condition.

The list of direct and remote clinical implications of dysautonomia, mostly in form of POTS, in EDS is wide (box 13-1). In presence of constellation of symptoms suggestive of dysautonomia, a head-up tilt-test is indicated (Table 13-1). If confirmed, the treatment of dysautonomia is challenging especially in EDS due to a possibly increased rate of adverse effects for many standard treatments. Management recommendations for POTS in general are summarized in Mathias et al.,[60] while some suggestions tailored to hEDS/HSDs are proposed by Castori et al.[61] The mechanisms underlying cardiovascular dysautonomia in EDS are not well understood. A sympathetic neurogenic dysfunction is actually considered the major primary effector, but connective tissue laxity and vasoactive medication may also play a role.[59]

Box 13-1. Spectrum of EDS features which may be related to an underlying dysautonomia.

- Cardiovascular manifestations: postural or paroxysmal tachycardias, palpitations, (atypical) chest pain, shortness of breath, flushing, *livedo reticularis*.
- Neurologic manifestations: syncope, dizziness, fainting, light-headedness.
- Sudomotor/exocrine manifestations: acral hyperhidrosis, night sweating, dry eyes, dry mouth, dry vaginal mucosa.
- Gastrointestinal and urinary manifestations: oesophageal dysmotility, nausea, stomach ache, abdominal pains, diarrhoea, constipation, underactive/overactive bladder.
- Indirect manifestations: fatigue, poor sleep quality, fever, lymph node pain, anxiety, depression, panic attacks, headache, concentration/memory troubles, visual disturbances.

6. Cerebrovascular disease

Most reports on stroke and cerebrovascular disease in EDS concern vascular EDS and include intracranial aneurysms, subarachnoid haemorrhage, spontaneous arterial dissection and cavernous sinus fistula. Vascular EDS is characterized by thin but often not hyperextensible skin, acrogeria, extensive easy bruising, hypermobility of the small joints, and spontaneous vascular and hollow viscera ruptures. The diagnosis can be confirmed by molecular testing of the *COL3A1* gene. In patients with classical EDS, aneurysms occur occasionally whereas other vascular abnormalities are rare.[62] Accordingly, the presence of stroke in patients with cutaneous features of classical EDS should also prompt molecular investigation of *COL1A1, COL5A1* and *COL5A2*. As kyphoscoliotic EDS features vascular fragility,[6] *PLOD1* molecular

testing is a further investigation to be considered in presence of other findings suggestive of this rarer EDS variant.

In 1990, Schievink et al. reported two patients with vascular EDS, one with a spontaneous internal carotid artery dissection and one with an aneurysmal subarachnoid haemorrhage and multiple aortic dissections.[63] Both patients were deficient in collagen type III, analysed in cultured skin fibroblasts. Subsequently, the same author reported a 20-year-old woman with vascular EDS who presented with a spontaneous carotid-cavernous fistulae and a cervical artery dissection.[64] The clinical features of 19 vascular EDS patients with ages ranging from 17 to 48 years were also reviewed.[65] The spectrum of cephalic vascular complications included intracranial aneurysms with secondary haemorrhage, spontaneous carotid-cavernous sinus fistula, and cervical artery dissection. Since collagen type III deficiency plays a role in the pathogenesis of intracranial saccular aneurysms, it is likely to be involved in the pathogenesis of carotid cavernous fistulas and dissections of cervical arteries.[63] In 1995, North et al. studied cerebrovascular complications in a cohort of 202 patients with vascular EDS.[66] Nineteen patients had cerebrovascular complications, including intracranial aneurysms with secondary haemorrhage, spontaneous carotid-cavernous sinus fistula and cervical artery dissection. Aneurysms typically develop in the cavernous sinus or directly adjacent to it, and bilateral and recurrent carotid aneurysms have also been reported.[67-71] Aneurysmal rupture can occur spontaneously or during vigorous activity.[63,66] A carotid-cavernous fistula can develop after minor head trauma but in most cases it develops spontaneously after a rupture of the internal carotid artery aneurysm within the cavernous sinus.[64] These carotid-cavernous fistulae often present with exophthalmos, chemosis, pain, ophthalmoplegia and bruits, which result from their high blood flow which allows pressurized arterial blood to connect directly to the venous cavernous sinus, resulting in venous hypertension and reversal of venous drainage.[72]

Although it is a relatively uncommon clinical type of EDS (compared to classical and hEDS/HSDs), vascular EDS is a potential cause of stroke in young people.[73-75] In typical cases, the disorder is readily identifiable by clinical evaluation focused in assessing joint mobility and checking for typical cutaneous and historical features and, then, it can be confirmed by targeted molecular testing. However, the phenotypic variability of vascular EDS could lead to underdiagnosis, especially in an emergency setting.[74] Hence, a full clinical history and examination and a complete familial history should be emphasized, as often only the combination of all these data will raise suspicion of vascular EDS. This is crucial since the diagnosis has important implications for acute and long-term management and, potentially, for other family members.[74]

In vascular EDS, the traditional approach has been to treat such complications conservatively unless they are life threatening. Recent reports challenge this treatment paradigm.[76] In a randomized study, treatment with the beta-blocker celiprolol was shown to be associated with a three-fold decrease in arterial rupture in vascular EDS.[77] Novel approaches using endovascular therapy with coil embolization have shown good results in the treatment of ruptured pseudo-aneurysms and carotid-cavernous fistulas.[72,76] Nevertheless, complications are frequently reported. Anticoagulation therapy may result in increased bruising or bleeding and should be used with caution.[62,78] Because conventional angiography may exacerbate severe complications, non-invasive magnetic resonance angiography is the investigation of choice.

7. Brain and spine structural anomalies

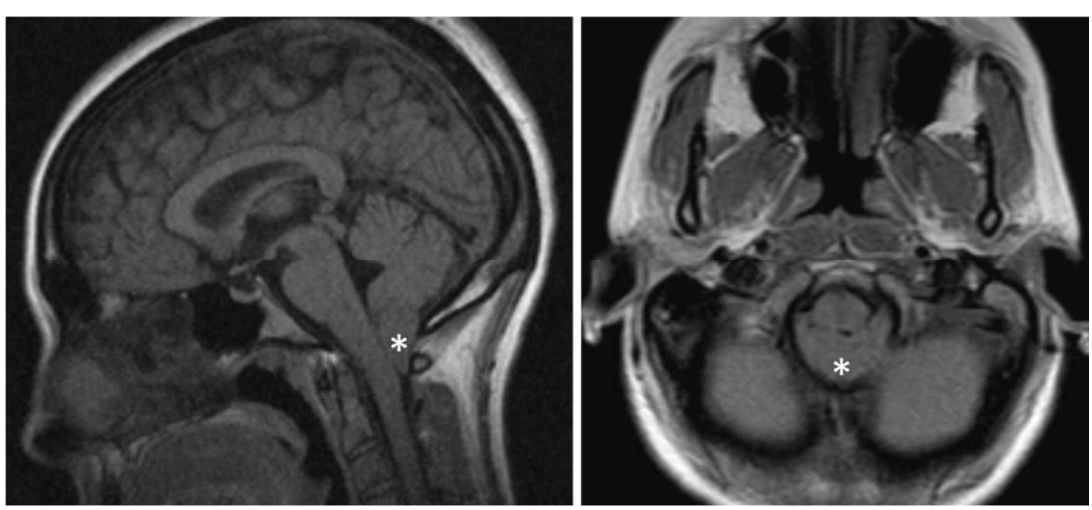
Brain MRI is usually unremarkable for major structural anomalies in EDS. Therefore, with the exception of acute presentations where cerebrovascular disease is suspected, such an investigation usually is not indicated in the baseline assessment of EDS patients.

Nevertheless, the presence of clear-cut X-linked dominant transmission and/or the coexistence of seizures should elicit the exclusion of the rare form of EDS with periventricular heterotopias often due to mutations in *FLNA* (not any longer included in the 2017 International EDS classification).[6,79,80] Single reports also associate EDS (undefined type) with polymycrogyria,[81] agenesis of the corpus callosum,[82] dilatation of the 4th ventricle, supracerebellar cistern and lateral ventricle, or disproportional enlargement of anterior horn of lateral ventricle,[83] but the consistency of such associations awaits confirmation.

Conversely, clinical practice suggests a high rate of degenerative findings, in form of generalized, early-onset spondylosis and disc hernias, at spine MRI. However, this evidence remains anecdotal[84] and needs systematic confirmation. Spine MRI may also show meningeal cysts, as reported in a 7-year-old girl with kyphoscoliotic EDS,[85] in an adult with classical EDS[86] and with a low frequency in hEDS/HSDs.[61] In EDS, meningeal (or Tarlov) cysts are apparently rare and very few or single. In contrast, Marfan syndrome often associates with a more homogeneous dilatation of the meninges particularly at the lumbosacral vertebrae, which is termed "dural ectasias". The 40-year-old woman with multiple and bilateral Tarlov cysts along the entire spine and originally diagnosed as suffering from (unclassified) EDS by Isono et al.,[87] can be best labelled with the diagnosis of lateral meningocele syndrome,[88] an apparently distinct form of hereditary connective tissue disorder with severe thecal involvement.[89] The clinical significance of meningeal cysts is still unknown in EDS, although a link with orthostatic headache due to spontaneous cerebrospinal fluid leaks may be inferred,[90,91] similarly as in Marfan syndrome. Meningeal involvement is a diagnostic feature of Marfan, in which it is usually referred to as "dural ectasia", indicating a multidirectional enlargement of spinal canal particularly at the lumbosacral level with possible herniations of the meninges at the intervertebral holes (for more details on the different meningeal involvements in EDS types, Loeys-Dietz syndromes and Marfan syndrome see ref. no. 88).

The concurrence of Chiari malformation (type I) is a further apparently underreported feature of EDS, as to date observed in single patients only (box 13-2 and figure 13-1).[35,37]

Figure 13-1 Chiari Malformation type I in hypermobile Ehlers-Danlos syndrome

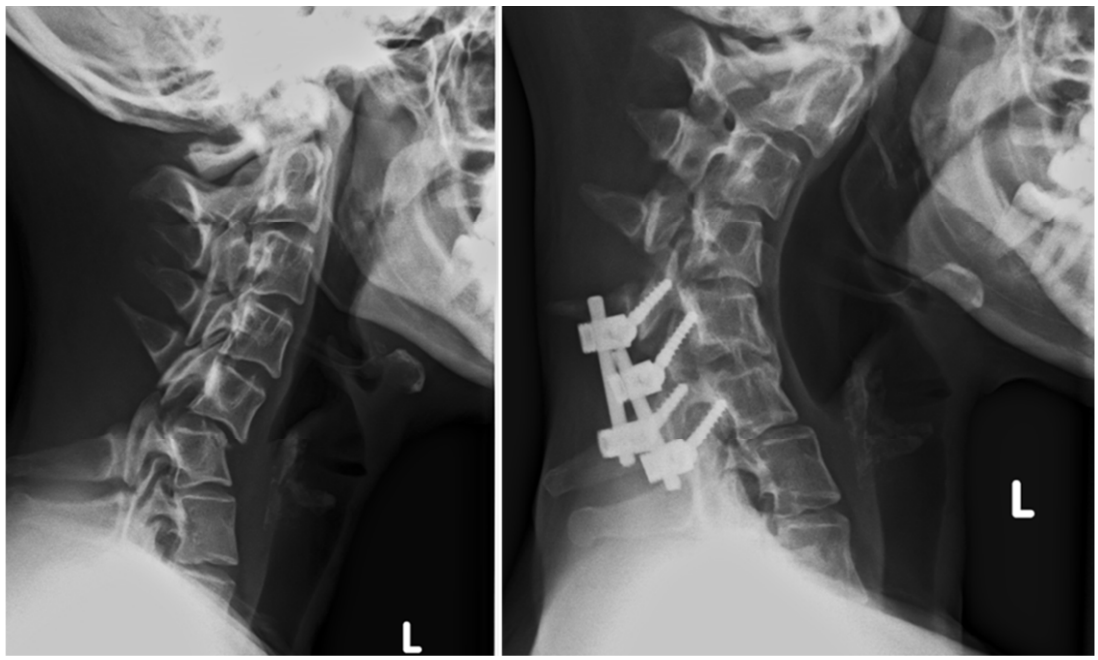


MRI of a Chiari malformation type I in a 33-year-old woman with hEDS/HSDs. The diagnosis was made after exacerbation of her long-lasting occipital headache. The asterisk indicates the downward displacement of the cerebellar tonsils through the occipital hole.

Box 13-2. Illustrative case report.
A 33-year-old woman presented with chronic headache, which had progressed from previously recurrent occipital headache in association with abrupt onset of dysesthesias extended below the umbilicus, tremors of the upper limbs and weakness of the lower limbs. Such a worsening of the pre-existing headache followed a new employment as an archivist, which caused repetitive flexion movements at the cervical spine. Her past medical history included clumsiness, two dislocations of the left shoulder, chronic-recurrent musculoskeletal pain at hips, temporomandibular joints, shoulders and calves, orthostatic intolerance, chronic constipation, easy bruising and gingival fragility. A brain MRI revealed type I Chiari malformation (figure 13-1).
At examination, she displayed positive Romberg test, brisk deep tendon reflexes at all limbs, generalized mild hypotonia, paraesthesia at the oral cavity and external ear canals with exacerbation of the neck pain during active and passive flexion and rotation of the neck (neck-tongue syndrome), generalized joint hypermobility with a Beighton score of 6/9, bilateral hallux valgus, soft and velvety skin, and short lingual frenulum with tongue dyspraxia. The diagnosis of hypermobile Ehlers-Danlos syndrome was proposed once any other partially overlapping hereditary connective tissue disorders is excluded.

However, in a surgically-oriented paper on hundreds of patients originally ascertained for symptomatic Chiari malformation, a subgroup of them showed a high rate of recurrence after surgery and multiple features of an underlying hereditary connective tissue disorder. This cohort presented minor, but measurable neuroradiological features of occipitoatlantoaxial instability: posterior gliding of the occipital condyles, and reduction of the clivus-axis angle, clivus-atlas angle, and atlas-axis angle in the upright position.[92] In these patients a congenital laxity of the ligaments surrounding the occipitoatlantoaxial joints is presumably the cause of herniation of the cerebellar tonsils within a wider spectrum of features suggestive of a hereditary connective tissue disorder.
In line with this, an early report described 2 vascular EDS patients with radiologically evident atlantoaxial subluxation.[93] Hence, investigating for cerebellar tonsils herniation and an occult occipitoatlantoaxial instability is relevant during the assessment of patients with occipital or postural/orthostatic headache, and/or additional unexplained neurological symptoms, such as paresthesias and weakness. Assessing non-traumatic occipitoatlantoaxial instability is a hard task with standard imaging and need meticulous measuring of the changes in spatial relationships between the basiocciput and the first two cervical vertebrae (i.e. C0-C2) at different positions (e.g. anterior flexion of the neck, posterior extension, lateral flexion). Major limitations of this approach include the lack of easily available parameters and nomograms for such measurements, and the limited applications of second-line investigations (such as MRI and CT) in assessing vertebral mobility. In addition, cervical spine instability is not limited to the upper vertebrae in EDS and can also extend to other parts of the spine. Both upper and lower cervical spine instability may also predispose to traumas and the congenital laxity of the surrounding tissues should be considered in the subsequent management procedures (Figure 13-2).[94]

Figure 13-2 Musculocontractural Ehlers-Danlos syndrome due to a homozygous *CHST14* mutation



Pre- and postsurgery X-ray of a luxation of C5-C6 (spondylolisthesis) in a patient previously been described by Voermans et al,[94] with a fractured fragment of corpus C6. This occurred at a fall while walking on a frozen street. Most likely, the distal and proximal muscle weakness had made her more vulnerable to falling. The fracture was stabilized (C4-6 spondylodesis) by posterior instrumentation, but a post-operative kyphosis of the adjacent proximal level occurred. During a six-month follow up the junctional kyphosis of the cervical spine was stabile despite the swan neck deformity. An MRI scan did not show severe compression of any of the neurological structures.

8. Epilepsy

The mechanisms explaining the possible association between EDS and seizures are likely heterogeneous. In 1981, Cupo et al. reported a 30-year-old woman with EDS who died due to an intractable ventricular fibrillation due to myocardial infarction. She also presented seizures, aneurysms of the sinus of Valsalva and severe panacinar emphysema. Necropsy finding included cerebral heterotopias.[95] Since this early description, additional reports suggested the existence of a distinct form of EDS with cutaneous features resembling the classical type, coupled with periventricular subependymal heterotopias.[79] In most cases, this presentation is transmitted in a X-linked dominant pattern and is associated with mutations in the *FLNA* gene.[80,96] Furthermore, Jacome reported 7 EDS patients, two of them affected by occipital-horn disease, which was considered a type of EDS but which is actually removed from the EDS classification, with epilepsy and various concomitant neurological complications.[97] Of the 5 remaining individuals with a more stringent diagnosis of (unclassified) EDS, possible nervous system determinants for seizures include basilar artery hypoplasia, hemispheric atrophy, venous parietal angioma, previous intracranial bleed and previous stroke. Additional reports of EDS with seizures included a 29-year-old man with unclassified EDS and bilateral frontocentral and frontoposterior polymicrogyria with hypoplasia of the cerebellar vermis, a 20-year-old woman with hEDS/HSDs and bilateral perisylvian polymicrogyria,[81] and a 16-

year-old man with classical EDS and agenesis of the corpus callosum.[82] These reports might suggest a small increased rate of epilepsy in EDS, but this could also be positive publication bias. Although in many cases structural brain anomalies (particularly, periventricular heterotopias) may be identified, mechanisms linking seizures to a hereditary defect of the connective tissue remain poorly studied.

9. Muscular features

EDS is associated with a variety of neuromuscular features (see figure 13-3 and chapter 5), and *vice versa*, a variety of congenital myopathies are associated with joint hypermobility and, to a lesser extent skin changes.[98] Awareness of this clinical overlap between inherited connective tissue disorders and certain congenital myopathies might be helpful in recognition of these rare disorders.[99] The initial reports of Beighton already included a high prevalence of myalgias and nocturnal muscle cramps involving the calves, especially in hEDS/HSDs.[1,100] This author also detected hypotonia, progressive muscle weakness, poorly developed musculature, and scapular winging, all without signs of concomitant myopathy, see figure 13-3. It was suggested that the muscle hypotonia might have a basis in the abnormality of the collagen in muscle sheaths rather than in the muscle fibres itself, but this was deemed unlikely. In contrast, these symptoms were considered to be secondary to avoidance of exercise because of the hypermobility, joint pain and instability of joints.

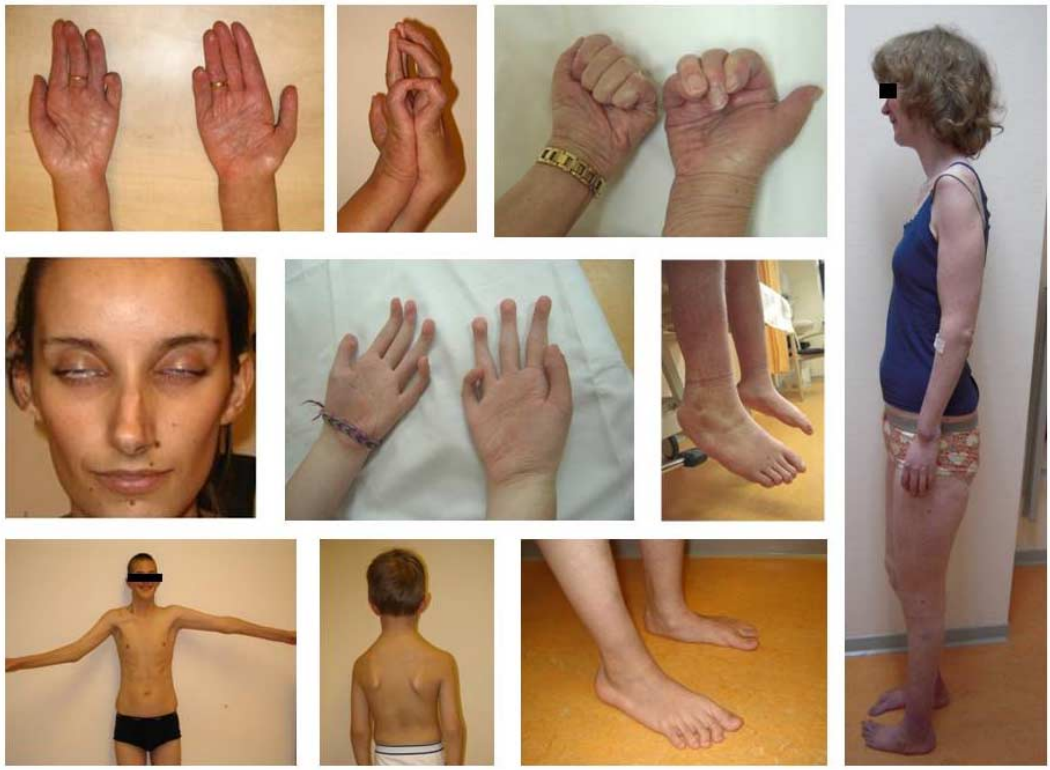
This might have contributed to the relative neglect of muscle features in EDS, and for years only few case reports pointed to these EDS manifestations. Banerjee et al. reported a nine year old boy presenting with delayed walking and abnormal gait.[101] The presence of marked muscle hypoplasia with hypotonia led to the initial diagnosis of primary muscle disease; later, he was found to have hyperextensible and fragile skin and hypermobile joints and EDS was diagnosed. A second case was reported by Bertin et al. showing combination of EDS and muscular dystrophy in a 16-year old male patient.[102] Furthermore, Palmeri et al. reported the association of chronic muscle pain and cramps and vascular EDS.[103] The first study on the physiological basis of muscle weakness in EDS was performed by Bilkey et al. suggesting that muscle weakness was due to the adaptation of learned motor patterns in response to the alterations in the connective tissue surrounding the muscle cells.[104]

In 2009, Voermans et al. performed a prospective study in 40 genetically or biochemically confirmed patients with various forms of EDS (vascular, classical, hypermobile and classical-like *TNXB*-deficient EDS), showing that mild-to-moderate neuromuscular involvement is common in these types.[2] Patients reported muscle weakness, myalgia, easy fatigability, and limited walking distance. Physical examination revealed mild to moderate muscle weakness, reduction of vibration sense, and mild impairment of mobility and daily activities. Ancillary investigations showed only mild, aspecific myopathic signs, see figure 13-4. The findings of this study have increased awareness of neuromuscular symptoms in EDS patients. Muscle biopsies to exclude presence of a co-existent myopathy might not be necessary if typical clinical and neurophysiological findings are encountered and the EDS diagnosis is confirmed by an expert in the field.

Another finding in this study was the remarkable relation between residual TNX levels and degree of neuromuscular involvement, compatible with a "dose"-effect relation. This points to a role of the extracellular matrix defect in muscle and peripheral nerve dysfunction in EDS[2] This was confirmed in physiological studies in *TNXB*-deficient patients and tnxb knock-out mice.[105,106]

Muscle involvement is probably most pronounced in kyphoscolitic EDS due to *PLOD1* mutations and musculocontractural EDS due to *CHST14* mutations, and is often evident in the neonatal period. These conditions should be considered in the initial differential diagnosis of the floppy infant.[98,99,107,108]

Figure 13-3 Neuromuscular features in various Ehlers-Danlos syndrome types

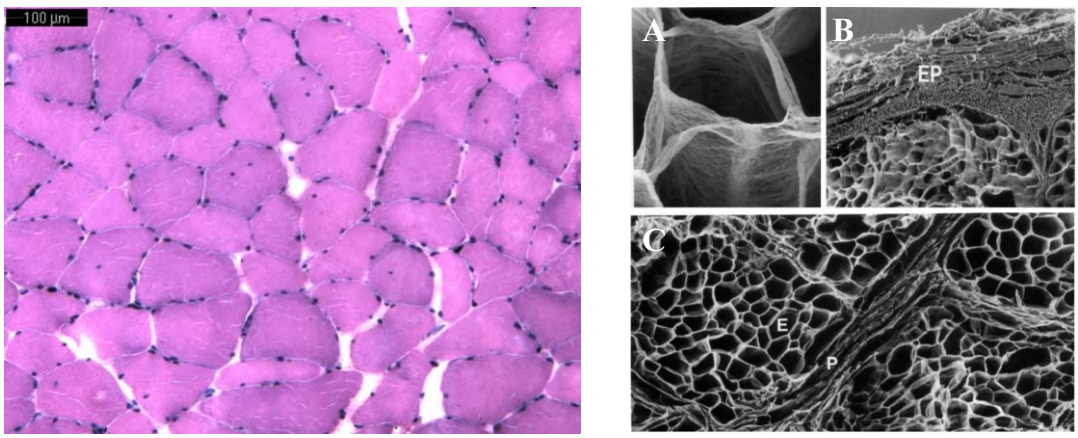


First row: Distal weakness and atrophy in hands of classical-like TNX-deficient type EDS. Limited flexion of fingers after a brachial plexus lesion after a complicated relocation of a shoulder dislocation, which occurred after stretching out her arm while cleaning the house.
Second row: incomplete eye closure in patient with vascular EDS. Distal atrophy and weakness in a patient with musculocontractural Ehlers-Danlos syndrome due to a homozygous CHST14 mutation (2 pictures).
Third row: Limited active arm abduction in a patient with kyphoscoliotic EDS, mild winging of scapulae, and bilateral pes planus in a patient with kyphoscoliotic EDS, respectively.
Right image: Patient with musculocontractural Ehlers-Danlos syndrome due to a homozygous CHST14 mutation with distal muscle weakness and wasting.

A recent case report on a patient with classical-like TNX-deficient EDS with progressive axial and proximal limb muscle weakness and atrophy further supported this. This patient had only minimal skin hyperextensibility, no joint abnormalities, and a history of easy bruising. Skeletal muscle biopsy disclosed strikingly weak muscle consistency at biopsy.[109]
Furthermore, myopathic EDS is a new entry in the 2017 International EDS classification and represents probably the most myopathic form of EDS. As such it is generally recognized as a congenital myopathy which should be included in the differential diagnosis of the collagen VI spectrum (Bethlem myopathy/Ullrich congenital muscular dystrophy)[110]. It is featured by congenital muscle hypotonia and/or muscle atrophy which improves with age, and minor joint and skin anomalies. Motor development is delayed. Muscle biopsy shows myopathic features, and in a minority of patients also dystrophic changes. Myopathic EDS is apparently very rare and caused by heterozygous or biallelic mutations in *COL12A1*.[6, 111,112] A mouse model with inactivation of the Col12a1 gene showed decreased grip strength and other features indicating

a role for a matrix-based passive force-transducing elastic element contributing to weakness.[111]

Figure 13-4 Muscle histology in EDS and the muscular connective tissue



Left image: Mild myopathic changes in the muscle biopsy (lateral vastus muscle) of a hypermobile EDS patient due to TNXB haploinsufficiency: mildly increased variation in fibre diameter and increase of number of central nuclei (5%; normal: ≤3%)(arrow). Bar= 100 µm. Reproduced with permission of Wiley InterScience, New York.[2]
Right image: Structure of intramuscular connective tissue. The skeletal muscle (bovine semitendinosus muscle) extracellular network is shown by scanning electron micrographs after removal of skeletal muscle fibres. A: The endomysium surrounding one individual skeletal muscle fibre; B: The epimysium (EP) surrounding the entire muscle; C: The perimysium (P), surrounding a fascicle, as well as the endomysium (E). This intrinsic network of connective tissue helps to understand the important role that it plays in muscle function, and that various EDS types are associated with mild to moderate neuromuscular symptoms such as muscle weakness, exercise intolerance and muscle hypotonia. Reproduced with permission from S. Karger AG, Basel.[131]

10. Neuropathy

Brachial and/or lumbosacral plexus neuropathies and compression mononeuropathies have been reported in several types of EDS.[18,113-116] Although the study of Voermans et al. focused primarily on muscle, signs of peripheral nerve involvement in EDS were also observed. Nerve conduction studies demonstrated axonal polyneuropathy in 13% of patients, mainly of vascular and classical-like TNXB-deficient EDS.[2] Recently, a study on entrapment neuropathies and polyneuropathies in hEDS/HSDs showed a higher prevalence of neuropathic symptoms (paraesthesia /numbness in hands and/or feet) than of neurophysiological and ultrasound evidence of focal or diffuse nerve involvement. This might be due to the presence of radiculopathy or of small fibre neuropathy, which were not further addressed in this study. Additionally, a high prevalence of ulnar nerve subluxation/luxation at the elbow was detected on dynamic ultrasound investigation.[117]

The pathophysiological mechanism of peripheral neuropathy in hEDS/HSDs seems related to joint dislocations and subluxations due to ligament and capsular laxity which may cause abnormal stretching of or pressure on peripheral nerves, and, thus can result in neuropathy or plexopathy. Increased vulnerability of peripheral nerves to stretching or pressure directly linked to the underlying genetic defect might also be involved. TNXB or collagen I, III or V

deficient epi-, peri- and endoneurium (i.e. the connective tissue of peripheral nerves) might fail to resist increased mechanical stress.[18]

11. Developmental features

Global developmental delay in children evolving in intellectual disability is rare in EDS, apart from some cases of spondylodysplastic EDS.[6,112] Given the high frequency of joint hypermobility in the general population as well as in disabling genetic conditions, the presence of a true global developmental delay should prompt the practitioner to search for diagnoses other than EDS. For example, an EDS-like phenotype has been described in association with 6q27 chromosome deletion,[118] which may be detected by *CGH*-array, one of the first-line investigations for subjects with intellectual disability (defined as an IQ below 70 and significant limitations in adaptive functioning). Conversely, relatively robust data support a tight link between joint hypermobility and reduced motor performance in children, as is also seen in kyphoscoliotic, dermatosparaxis, spondylodysplastic and myopathic EDS.[6] In fact, while an early work failed to detect an association between joint hypermobility and neurodevelopmental attributes,[119] three more recent studies demonstrated that joint hypermobility is more common among children with developmental coordination disorders.[120-122] Complementarily, abnormal gait, clumsiness and poor coordination are common findings in children with a diagnosis of hEDS/HSDs.[123,124] Such an apparently selective influence of congenital joint hypermobility on coordination could be the consequence of an impairment of proprioception in critical phases of motor development. This hypothesis is based on the repeated evidence of a mildly defective proprioception in hEDS/HSDs.[125-129] The generalized joint hypermobility of hEDS/HSDs children explains why they perform well at sports, such as gymnastics, ballet and dancing, while their deficient motor skills often improve by exercise. The natural propensity to specific sports, which contrasts the poor coordination skills at school reported by many patients, is a primary feature of the paediatric presentation of hEDS/HSDs, as recently outlined.[4,37,39] This neurodevelopmental profile seems extremely common in hEDS/HSDs and, presumably, in other hereditary connective tissue disorders as well.

12. Principles of practice and future directions

In this chapter a wide spectrum of neurological manifestations was illustrated in many EDS types. Although accumulated data is fragmented in single case reports and a few more relevant studies, it shows sufficiently that the nervous system is commonly involved in individuals with EDS. Whether neurological manifestations are primarily related to the underlying molecular defect or rather emerge as the consequences of peripheral dysfunctions eventually reflecting to the nervous system remains unclear for many of the manifestations presented. Given the ubiquity of many structural components of the connective tissue, pleiotropy (i.e. the expression of the mutated gene in many tissues, including the various components of the nervous system) is a promising explanation for many neurological manifestations of EDS. The presence of various specific structural brain and spine anomalies in a few patients well testifies for this theory. On the other hand, the tight link between lack of proprioception and joint hypermobility, and the recurrent neurodevelopmental profile in "double-jointed" children suggest the existence of a complex pathogenesis for other features, which could result from the far-reaching effects of lax joints and tissues on the development of motor schemas in critical phases of brain maturation.

From a practical perspective, the emerging body of evidence indicates the utility to consider neurological involvement in every patient with a diagnosis of EDS. Referral to the neurologist with experience in EDS should be considered every time a patient describes the worsening of any pre-existing "neurological" symptom or in case of novel neurogenic features. In addition

to history gathering and physical examination, a set of investigations could be considered in specific conditions in order to substantiate the hypothesis of an underlying nervous system dysfunction/anomaly (Table 13-1). Although accumulated evidence is weak for many of them, their application is indicated particularly during treatment planning. In fact, the management of most neurological complications of EDS is still without tailored recommendations. Hence, their treatment lays on the experience of the single practitioner or, at best, of the dedicated multidisciplinary team. It is expected that, in the future, more attention will be offered to the reverberations of EDS on the nervous system with the aim of better understanding the underlying pathogenesis and, hopefully, to identify more efficacious treatments.

13. Summary

EDS are hereditary connective tissue disorders primarily affecting skin, joints, vessels and internal organs. Nevertheless, their consequences seem to span much beyond these tissues and also extend to central, peripheral and autonomous nervous and muscular systems. Although muscle cramps have been reported in EDS since the sixties of the last century, for decades, available data on neurological manifestations in this condition were scattered in single case reports and a few more relevant studies. Much attention has been put in the last five years particularly on neuromuscular involvement, and the emerging body of evidence indicates a role of nervous system involvement for prognostication and management of many EDS. Particular attention has been posed on dysautonomia, occipitoatlantoaxial instability and neuromuscular involvement, which may be considered the major contributors to neurological complaints and disability in the chronic patient with joint hypermobility syndrome and various EDS. A summary for the use of ancillary investigations in the field of neurology has also put forward for the practicing physician, as well as some indications for the treatment of the related symptoms.

Addendum by the editors

In the March 2017 issue of the American Journal of Medical Genetics Part C Seminars in Medical Genetics all papers were devoted to EDS, covering a new EDS nosology, new diagnostic criteria of the different types and also management related topics (see also chapter 2). One of these papers is entitled “Neurological and spinal manifestations of the Ehlers-Danlos syndromes”.[130]

Table 13-1 Standard investigations to consider in the EDS patient

Referring symptom/indication	**Possible cause**	**Investigation**
(Proximal) muscle weakness,	Myopathy	Electromyography
Distal muscle weakness, distal sensory disturbances, absence of deep tendon reflexes, suspected peripheral or compression neuropathy	Axonal polyneuropathy, compression neuropathy (mononeuropathy, plexopathy)	Nerve conduction studies
Paraesthesia, pain in hands and feet, reduced vital sensation (pain, temperature) but normal gnostic sensation (pressure, etc)	Small fibre neuropathy	Skin wrinkle test and/or quantitative sensory testing and/or skin biopsy
Orthostatic intolerance and/or hypotension, chronic fatigue (syndrome) with recurrent tachycardias/palpitations/dizziness, or other presentations suggestive for dysautonomia (see box 13-1)	Dysautonomia	Head-up tilt-test
Disabling neck pain and/or occipital headache, suspected upper cervical spine instability (e.g. abrupt painful limitation of the cervical spine, neck-tongue syndrome)	Spondylosis, disc hernia, instability	Static and dynamic X-rays of the cervical spine and MRI of the cervical spine
Disabling occipital/postural headache, seizures, pure X-linked dominant transmission, or confirmed *FLNA* mutation	Brain structural anomaly	Brain MRI
Any EDS type with vascular fragility at first examination and, subsequently, in any case of focal symptom or thunderclap headache	Cerebrovascular disease	Brain MRA
Disabling back pain with or without suspected radiculopathy, recurrent orthostatic/postural headache	Degenerative disc disease, disc hernia	Total spine MRI

1. Introduction

The Ehlers-Danlos syndrome (EDS) groups a variety of heritable connective tissue disorders with - amongst other signs and symptoms - joint hypermobility. Recently, the two conditions benign joint hypermobility syndrome (BJHS) and EDS hypermobility type have been recognized as one and the same clinical spectrum ranging from apparently symptomatic generalized joint hypermobility to the most disabled individuals fitting the new diagnostic criteria. These new criteria are stricter than the Villefranche criteria and the Brighton criteria for BJHS in order to define a homogeneous phenotype for management and scientific purposes. Within the new EDS nosology, its name is hypermobile EDS (see chapters 2 and 5). EDS and other generalised joint hypermobility syndromes may have impact on the masticatory system. In this chapter the masticatory and oral sequels of hypermobility syndromes are described. The masticatory system consists of the teeth and periodontium (tissues around the teeth), jaws, the temporomandibular joint (TMJ), the tongue, the mucosa and the innervation and vascularisation of these tissues. Temporomandibular disorders (TMDs) is a generic term, embracing a number of clinical conditions that involve the masticatory muscles, the TMJ and associated structures.[1] It is a musculoskeletal condition and as a consequence, TMD patients experience an increase of the known complaints when loading the masticatory system, e.g. by chewing. We will first briefly describe the system with regard to EDS; many of the mechanisms also apply other hypermobility syndromes. The clinical examination, assessment, diagnosis and management are part of the first section of this chapter. The description of the intra-oral aspects of the hypermobility syndromes such as the teeth and oral mucosa is part of the second section.

2. The TMJ: function

The TMJ consists of the mandibular fossa and the articular eminence, the mandibular condyle and the articular disc (see figure 14-1). The lining of the mandibular condyle and part of the temporal component of the TMJ consist of fibrous cartilage, contrary to other synovial joints. In between these two joint components, the articular disc divides the joint space in two joint compartments. The actual articular disc is neither vascularised nor innervated, contrary to its attachments to the condyle (especially posterior attachments), the temporal component of the joint and the capsule. Figure 14-2 depicts sagittal sections in a closed mouth and an open mouth position of a normal TMJ, and in a TMJ with disc displacement and degenerative joint disease. When opening the mouth, the condyle rotates and slides in anterior direction along the articular eminence. Throughout this movement the thin portion of the disc (the intermediate zone) remains located between the condyle and the eminence, serving as the actual contact point between the two other joint components. Note that at maximum mouth opening, the condyle slides beyond the crest of the articular eminence, i.e. out of the mandibular fossa (figure 14-2 and figure 14-3). In 89 % of a non-selected healthy population this happens without any clinical consequence.[2] The maximum mouth opening is measured between the front teeth while opening wide. Maximum mouth opening in the general population ranges from 45 to 60 mm. The median maximum mouth opening in a population of 1011 adolescents aged 10 to 17 years was 51 mm. Ten percent of this population could open the mouth $\geq$ 59 mm. Ten percent could open the mouth 43 mm or less.[3]

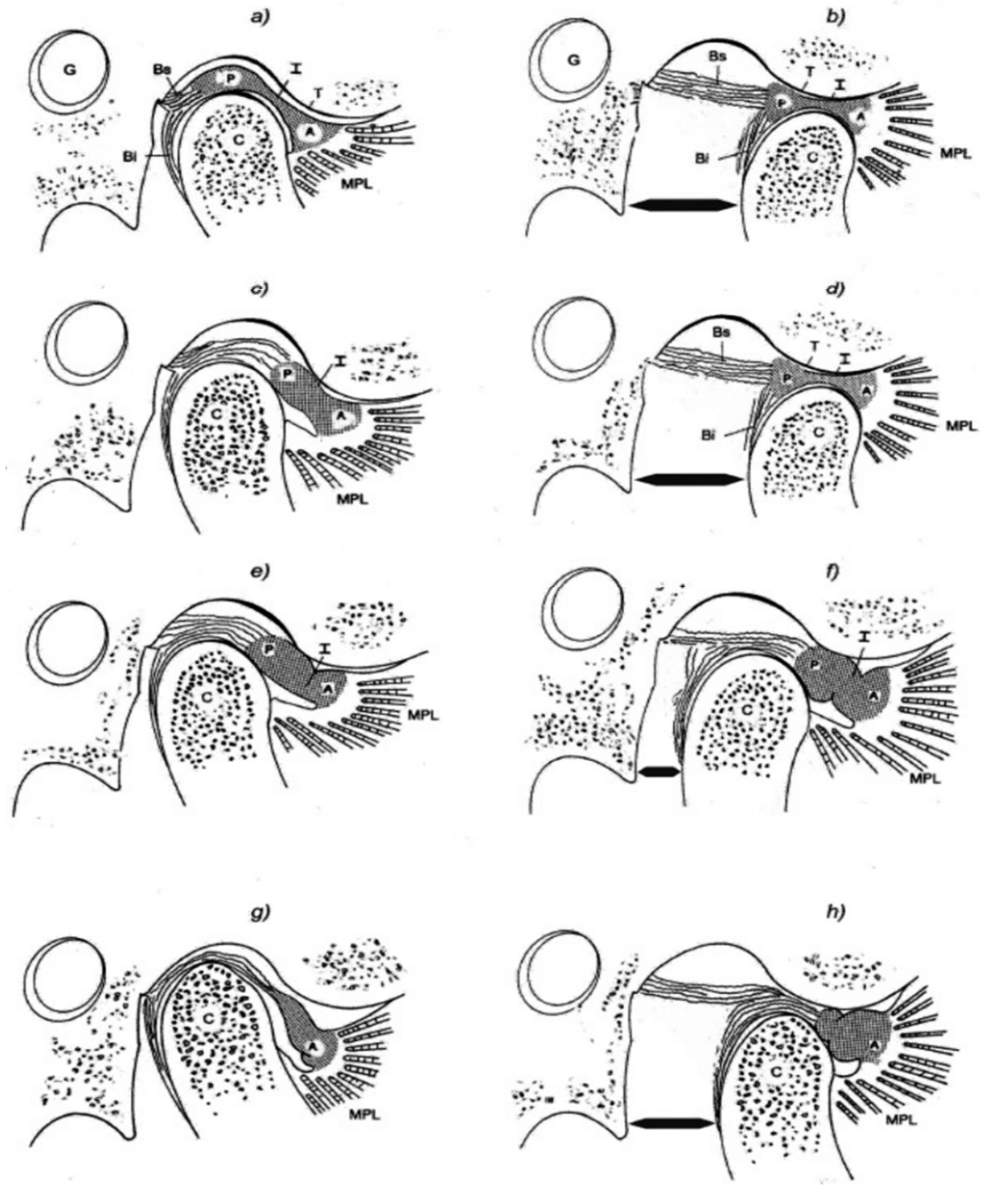
3. The TMJ: dysfunction

The main symptoms and signs of TMDs are pain in the muscles and joints of the masticatory system, impairment of the mandibular movements and joint noises. In the widely used classification of the American Academy of Orofacial Pain, causes of TMDs are classed into myofascial pain, displacements of the articular disc with and without reduction, arthritis and osteoarthritis, as well as hypermobility of the joints (dislocations). Reduction is normalization of the position of the displaced intra-articular disc in between the mandibular condyle and the fossa/eminence when opening the mouth (figure 14-2). To arrive at one of these diagnoses, the clinician always needs to differentiate other diseases mimicking TMDs. This section will not touch upon the differential diagnoses of TMD.

Overloading may introduce pain in the joint (pre-auricular pain) and secondary in the muscles of mastication (cheek and temple). In patients with EDS and other hypermobility syndromes, TMDs are prevalent. Since signs and symptoms of TMDs are very prevalent in the general population (50 % of the general population) as well, they are not a hallmark of EDS. In the group of individuals with TMD signs and symptoms, 5 % asks for treatment, whereas only in 1.5% of this latter group a treatment indication exists.[4] The risk factors for TMDs are various and in chronic TMD patients, often TDM is multifactorial: neuromuscular factors, psychosocial factors and overloading may play a role. Overloading of the articular and muscular structures can be the result of EDS but it can also result of other factors like trauma, habits like clenching and grinding, nail biting or biting on the cheek or lip. Psychological stress may influence mandibular behaviour and the pain system. In severe arthrogenous TMDs, the TMJ may be swollen (synovitis, capsulitis), leading to a disturbance of dental occlusion (the patient then is not able to bring in contact the back teeth of upper and lower jaw on the affected side).

Figure 14-2 Sagittal section through the TMJ

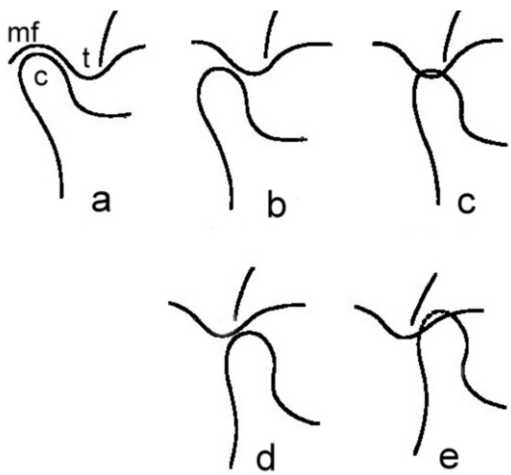


C, mandibular condyle T, articular eminence or tubercle (see also figure 14-3), fossa; G, acoustical meatus; MPL, attachment of the lateral pterygoid muscle to the condyle and articular disc: (P, posterior band, I intermediate zone, A anterior band); Bs en Bi: the posterior connective tissue attachments of the articular disc (Bs, superior stratum; Bi, inferior stratum). The double arrowheads indicate the degree of sliding of the mandibular condyle on opening. a), c), e), and g) closed mouth; b), d), f) and h) open mouth (not maximal).
a) and b) represent the physiological movements, c) en d) anterior disc displacement with reduction; e) and f) anterior disc displacement without reduction (limiting forward sliding of the mandibular condyle, and thus a limited mouth opening); g) and h) osteoarthritis with remodelling of the disc and mandibular condyle, enabling the condyle to move anterior a bit further than in f) and thus increased mouth opening.

3.1 Disc displacement with reduction

The most prevalent symptoms are joint noises, which may be the result of an anterior disc displacement. Anterior disc displacement with reduction is characterized by clicking of the TMJ, both when opening and closing the mouth and moving the mandible forward, and shifting the mandible to the contra-lateral side. The click on opening is produced when the disc position normalises; during closing the TMJ clicks again on the moment the disc is displaced again just before teeth make contact. Anterior disc displacement and the resulting clicking may exist without any further signs or symptoms of TMD for many years and does not necessarily lead to osteoarthritis.

Figure 14-3 The degree of sliding of the mandibular condyle on maximum mouth opening

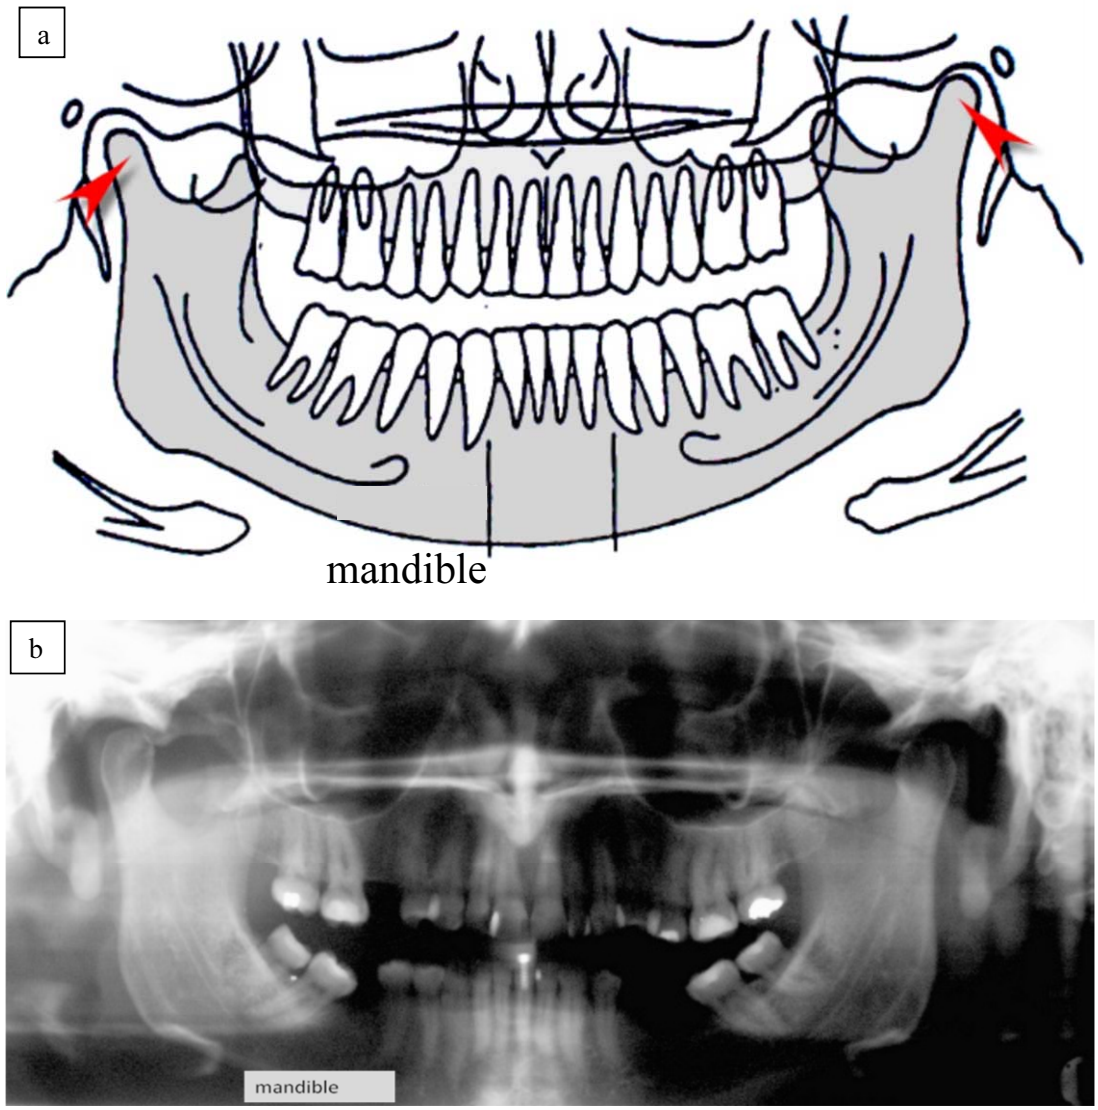


Sagittal section. c, mandibular condyle; t, tubercle or articular eminence; mf: mandibular fossa
***a**: no sliding, like in closed mouth; **b - d**: variation of a physiological sliding depending on the degree of mouth opening; situation b in case of maximal opening of the mouth indicates limitation of sliding; **e**: dislocation: the mandibular condyle slides beyond the eminence and moved cranially, to be seen on an X-ray (panoramic, see figure 14-4).*

3.2 Disc displacement without reduction

An anterior disc displacement without reduction is a mechanical obstruction in the TMJ (figure 14-2e and 14-2f), also known as closed lock. The condylar movement in a normal TMJ can be described as a combination of rotation and sliding. The anterior displaced disc severely limits the normal sliding in the affected joint , especially in acute cases. Rotary movements are still possible although painful: the mouth opening is limited to 25 – 35 mm, compared to 45 – 60 mm in the normal situation. In these acute situations pain from the joint may be caused by nociception originating in the capsule or the innervated posterior disc attachment which is now in between the condyle and the eminence, instead of in the intermediate zone. The masticatory muscles can become painful secondary due to muscle splinting. In chronic anterior disc displacement without reduction, the mouth opening may increase gradually up to 35-40 mm, still limited in comparison to the pre-existing mouth opening.

Figure 14-4 Panoramic radiograph



a) Image as seen on a panoramic radiograph; the arrowheads indicate the left and right temporomandibular joint
b) An example of a panoramic radiograph

3.3 Myofascial pain

Myofascial pain is chronic, mostly fluctuating local or regional pain in the face and the jaw. Pain may be referred to other areas such as the teeth, the head and the neck. Pressing on the painful areas elicits more pain. In rare cases pressing these tender or trigger points in muscles may refer pain to other areas nearby but anatomically not related. Toothache is one of the examples for which the dentist must differentiate between myofascial pain or a real toothache. Patients with myofascial pain experience their muscles as fatigued, stiff and tired, and less powerful. Movement and especially stretch of the muscle tissues causes pain. Patients tend to decrease their pain by continuous low level contraction of the jaw muscles, which may give

rise to a limitation of the mouth opening. Myofascial pain may also be associated with hypermobility of the TMJ.

3.4 Dislocation

Dislocation of the TMJ is defined as a condition in which the mandibular condyle slides beyond the articular eminence and is fixed at the anterior side of this eminence of the TMJ . The patient is not able to close the wide open mouth (open lock of the mandible). In unilateral dislocations the mandible (chin) is shifted to the contralateral not-dislocated side in combination with the wide open mouth. The TMJ capsule is comparable to that of the shoulder: it is a loose capsule with only minor reinforcements by ligaments on the lateral side of the joint. If dislocations occur frequently, the term habitual dislocation is used. The repetitive overloading of the articular surfaces may induce degenerative changes, especially in the case the patients use heavy force to correct the condition. In habitual dislocation, patients are often able to close their mouth by manual manipulation.

3.5 Osteoarthritis

In chronic overloading of the TMJ surfaces, its fibrocartilage lining may decompensate: chondromalacia can be the result. Osteoarthritis results in friction between the joint surfaces, with ensuing secondary inflammatory reactions. Mostly these degenerative processes do not have an underlying disease cause: primary osteoarthritis. In recurrent dislocations e.g. by EDS or another hypermobility syndrome, secondary osteoarthritis of the TMJ's may be the result. Osteoarthritis may give rise to an impaired mandibular range of movement and arthralgia (joint pain). The articular disc may become displaced in osteoarthritis as part of the pathophysiology. Finally, due to remodelling of both the articular surfaces and the articular disc, sliding of the mandibular condyle may gradually increase, although limited with regard to the original range of motion of the particular joint. The changes in other movement patterns will be less pronounced as well when remodelling has taken place over the months and years. A more gnashing sound (crepitation) can be perceived by the patient and sometimes heard by others.

4. EDS, generalised hypermobility and TMDs

EDS as a connective tissue disorder characterised by joint hypermobility also has an impact on the TMJ and masticatory muscles. Recurrent dislocations in combination with progressive range of motion limitation are frequently observed. In a group of 144 adult patients with EDS and 331 healthy controls, at physical examination the TMJ was hypermobile significantly more frequently in the patients than in controls, but the maximum mouth opening was significantly more reduced and progressively more so with age, compared to the controls.[5,6] Patient with EDS more often had clicking and gnashing TMJs. Chronic pain in the masticatory muscles was mentioned by 50% of the patients with EDS, occurring daily in one third of the patients. Another striking finding was the frequent use of analgesics by patients with EDS.[6]

In a recent Belgian study in a population with hereditary joint hypermobility (15 hypermobile EDS, three classical EDS, and a control group) earlier findings indicating a positive correlation between joint hypermobility and TMDs,[7] were confirmed. In 89% of the EDS patients myofascial pain was diagnosed, whereas in 81% bilateral disc displacement with reduction was observed. Bilateral arthralgia of TMJs was present in 42% of EDS patients. In this study the combination of myofascial pain, anterior disc displacement and arthralgia was present in 64%. Recurrent TMJ dislocations were reported by 100% of the EDS patients. Patients with a high frequency and duration of dislocations reported significantly higher pain scores. These patients suffered most frequently from dislocation of the TMJs when opening

the mouth very wide. Their mouth opening had decreased over time progressively. Chewing hard and on big portions of food, and yawning were the most frequently reported risk factors. Over 60% of the patients reported spontaneous dislocations.
Generalized joint hypermobility and its association with signs and symptoms of TMD was further investigated in a general population study; generalized joint hypermobility was found to be associated with non-painful subtypes of TMD.[8] A larger number of hypermobile joints (according to the Beighton score[9]) was associated with a larger mouth opening.[8] However, in the chosen categories (no hypermobile joints, 0-3 and 4-9 hypermobile joints per subject) the mean differences (standard deviation) in mouth opening were clinically not relevant: 45 mm (7.7), 46 mm (7.3) and 47 mm (6.7), respectively[8]. The smallest detectable difference for mouth opening in arthrogenous TMD is 6 mm.[10] Individuals with 4 hypermobile joints or more (Beighton score $\geq$ 4) had a higher risk for reproducible reciprocal clicking sounds (representing TMJ disc displacement with reduction) and concurrently lower risk for a mouth opening <35 mm.[8] However, the influence of other factors such as female gender and generalized joint conditions other than hypermobility was stronger than that of hypermobility as such. No association was found between hypermobility and arthralgia or myalgia of the masticatory system. In a systematic review on generalized hypermobility and TMDs it was concluded that it is not yet clear whether generalized hypermobility is associated with TMD.[11]
TMJ hypermobility could not be predicted on the basis of generalized hypermobility. Dislocation of the TMJ may occur without systemic hypermobility. In a study to test whether or not there is an association between generalized joint hypermobility (measured using the Beighton score) and temporomandibular joint disk displacement in women who had sought medical attention for TMDs, 66 women who were attending the clinic for TMD were examined for joint hypermobility, and Beighton scores were calculated. If it was suspected that a patient suffered arthropathic complaints, magnetic resonance imaging of both temporomandibular joints was performed with the mouth closed and at maximal opening. There was no association between generalized joint hypermobility and temporomandibular joint disk displacement.[12]
One of the signs indicating hypermobility in the masticatory system is 'Gorlin sign': if positive, the individual is able to touch the tip of the nose by the tip of the tongue.[13,14]In the general population only 8-10% is able to do so, whereas in EDS this is 50%. The absence of an inferior labial of lingual frenulum is an easy to check sign of EDS, helpful in the early diagnosis of the disease in affected families.[15]

5. Diagnostic process and physical examination

In the diagnostic process, history taking and physical examination contribute most to the final diagnosis. The diagnostic process starts with the differentiation of TMD and non-TMD. Other conditions, causing dental pain or referred pain, such as neoplasm of the pharynx or the tongue may mimic signs and symptoms of TMD. A rule of thumb is that any pain in the masticatory system has a dental origin until proven otherwise, so a dental cause has to be ruled out. All other causes of TMDs need to be ruled out as well, such as neoplasms, growth disturbances and systemic diseases. A third diagnostic step is the differentiation between mainly arthrogenous and mainly myogenous TMDs (table 14-1). Provocation of the pain known to the patient at physical examination is essential for diagnosing TMD. TMD pain by definition is influenced by loading of the masticatory system like in mandibular movements and mandibular function such as chewing and yawning. If the mandible is locked in a submaximal mouth opening, it is essential to know whether the mouth cannot be *opened* any further (arthrogenous cause of limited opening: closed lock, adhesions) or whether the mouth cannot be fully *closed* (the teeth of upper and lower jaw can hardly touch each other: posterior disc displacement or TM joint inflammation), and at what extent of mandibular opening

locking occurs (at wide open indicates TMJ dislocation). The physical examination consists of active (by the patient) mandibular movements (opening / closing, lateral left and right side and protrusion), passive (by the physician) opening, and palpation of the TMJ's and the masticatory muscles (temporalis and masseter muscles). Signs and symptoms to be assessed are provocation of the pain known to the patient, range of motion, and movement pattern. In patients with a history of TMJ dislocation, passive opening beyond the comfortable maximum mouth opening is not advised, to prevent reoccurrence.

6. Imaging

The first choice imaging technique is the panoramic radiograph (figure 14-4). This technique offers a broad view of the upper and lower jaw, the teeth and periodontium, the sinuses and the TMJs. The left and right TMJs, the length of the ascending mandibular ramus (figure 14-1) and the mandibular base can be compared. Asymmetries, infections around the roots of the teeth and signs of periodontal inflammation with bony involvement, growth disturbances and neoplasm can be detected as well as the contours of the condyles, their lining and the spongeous bone. In osteoarthritis of the TMJ, osteophytes (bony spurs) are mostly located near the anterior part of the mandibular condyle. In case of doubt as to the findings of the panoramic radiograph, the clinician may consider additional imaging techniques such as CT or MRI. A mandibular dislocation is only very seldom an indication for imaging, since it is obvious from history and physical examination alone (section 5). An exception may be persistent dislocations in elderly persons or in post-traumatic patients. The panoramic radiograph may reveal such dislocations that were not expected. In such cases, the mandibular condyle is located anterior of the articular eminence even in the closed mouth position.

7. Management of TMDs and myofascial pain

Signs and symptoms of TMD in patients with EDS or other hypermobility syndromes are managed similarly as in TDM patients without these syndromes. An important first step is counselling, consisting of explanation of the findings, the diagnosis, the management strategy and prognosis, the expected management period, including the lag-time of alleviation of the complaints after start of therapy. Mostly reassurance as to the benign character of the mandibular condition as well as the responsibilities of the patient are discussed as well. In case of overloading of the masticatory system and myofascial pain, after explanation and advice as to a correct use of the masticatory system (box 14-1), the clinician may wait for 4-6 weeks, before evaluating and deciding upon another or additional strategy.

Box 14-1 Advice and instructions to avoid overloading of the TMJ and masticatory muscles

A) Be aware of / avoid:
- clenching jaws and grinding teeth: keep the teeth apart, lips together and the tongue up (the tip touching the palate right behind the incisors, like in pronouncing " N ")
- nail biting, and biting on lips, cheek or tongue or other mouth behaviour
- chewing gum and biting on pens and pencils
- opening the mouth wide, like in yawning

B) While chewing hard food (French bread or apple) make small pieces and use the back teeth.

C) Do not take a bite with the front teeth.

If pain is a main concern, medication is indicated. If inflammatory pain exists, classic non-steroidal anti-inflammatory drugs are part of the treatment, which are contra-indicated in vascular EDS because these drugs increase the bleeding time, in contrast to the so-called anti-inflammatory coxibs. In myofascial pain, low dose anti-depressants as pain modulators can

help to modify and alleviate the neuropathic component of pain. If counselling and advice are not sufficiently effective, the difference between arthrogenous and myofascial pain will guide the choice of a further treatment strategy. Physiotherapy can be very successful in myofascial pain, especially if pain is felt not only in the masticatory system but also in the neck and shoulder girdle. Home exercise programs consist of correction of posture (mandible, tongue, head), habit reversal techniques, muscle stretching, automassage, relaxation and muscle strengthening techniques.[16] In clearly arthrogenous TMDs an occlusal appliance (stabilization splint) is used (figure 14-5). In case of missing teeth, the support of the mandible against the maxilla can be improved because the appliance can be used as a prosthetic device and offers orthopaedic stability to the mandible: similar contact between the back teeth on the left and right side. Bad habits unconsciously performed by the patient can be influenced as well by wearing the splint during parts of the day. The working mechanism of an occlusal appliance is still part of debate, although its influence on muscle length and change in condylar loading is widely accepted. As true for many other treatments, the patient-doctor relationship, expectations in this partnership as well as good communication are paramount for success. In chronic TMJ involvement, a cognitive behavioural approach may be part of the management strategy. Coping style and locus of control are predictive for the outcome of treatment in chronic TMDs.[17]

8. Dislocation of the mandible

In cases of acute dislocation, the health professional will correct this by pressure in a caudal direction on the lower most posterior teeth in combination with a backwards directed pressure. The sooner this condition is addressed the easier the procedure can be executed because muscle spasm will develop. Provoking a gag reflex by touching the posterior part of the tongue is also reported to correct the dislocation.

In patients with EDS and other hypermobility patients, it is highly probable that a dislocation of the mandible is based on their lax connective tissue. In these patients the dislocation is expected to be more recurrent than in individuals without hypermobility. The management is not different in both cases. Counselling, including advice as to the use and abuse of mandible is part of this approach (prevent yawning, biting on firm objects e.g. an apple with the front teeth, nail-biting). Exercises with the aim to open the mouth without the sliding of the mandibular condyle (figure 14-1 and 14-2) are part of the management as well. Opening of the mouth in this way allows for 30-35 mm interincisal distance, enough for daily activities without the occurrence of a dislocation. Small rubber bands between the upper and lower posterior teeth (through brackets attached to their buccal side) may help the patient to become aware of the forward thrust of the mandible on opening. If non-surgical approaches of dislocation have proven not to be successful, the first choice surgical procedure is the downsizing of articular eminence in order to facilitate the backward sliding of the mandibular condyle even when it has moved forward maximally.

8.1 Disc dislocation in the TMJ

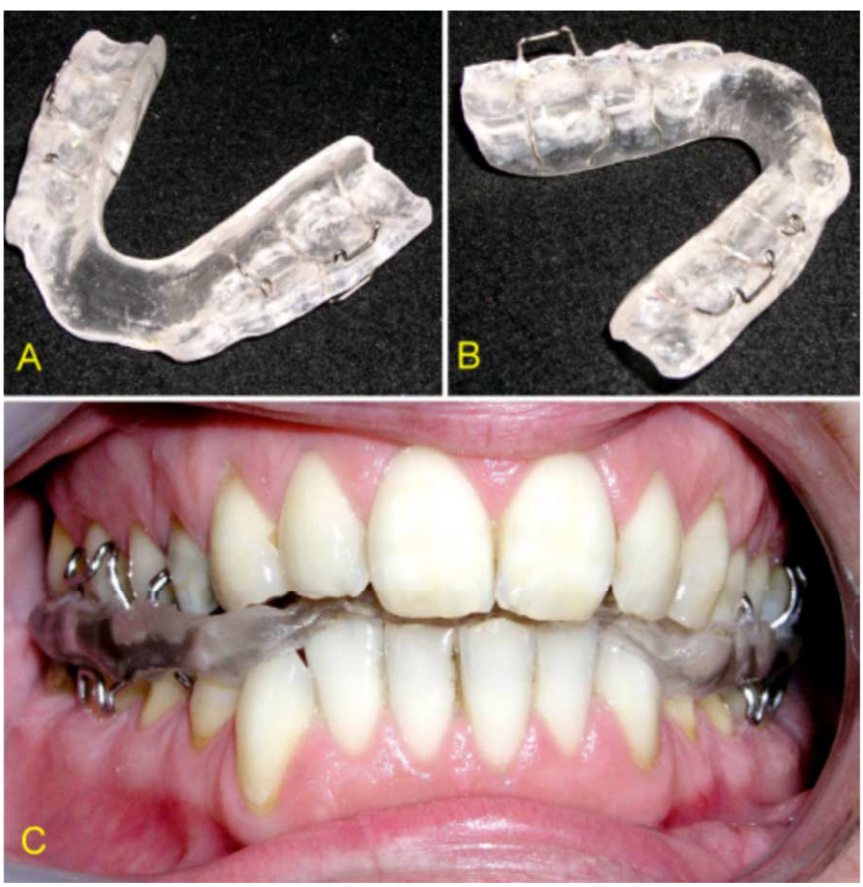
In acute disc dislocation without reduction, it is worthwhile to perform a manual correction of the mechanical intra-articular obstruction (figure 14-2e and 14-2f) and to achieve a disc displacement with reduction (clicking, but not locking of the TMJ, figure 14-2c and 14-2d). If a disc dislocation exists for longer period of time (several weeks or months), the procedure becomes less feasible. This is mainly due to remodelling processes of the intra-articular tissues. In such cases the dislocation of the disc is accepted, while management aims at minimizing (over)loading of the joint (counselling, advice box 14-1) and stabilization splint). Unilateral disc displacement without reduction may overload the contralateral joint. Due to

the restrictions caused by the disc displacement, this seldom results in dislocation of the contralateral joint.

8.2 Degenerative joint disease of the TMJ

Degenerative joint disease of the TMJ has a favourable prognosis. The signs and symptoms often decrease within 2-3 years. Patients with degenerative joint disease at younger age cannot be differentiated from patients who did not have these complaints at younger age with respect to yawning, mastication and speech.[18] Management aims at acceleration of resolution of pain and dysfunction and guiding the patient through the period of impairment. Counselling, medication (analgesics, non-steroidal anti-inflammatory drugs), exercises and the stabilization splint (figure 14-5) may be part of this approach.

Figure 14-5 Mandibular stabilisation splint used to stabilize the mandible during sleep (not a regular splint)



A: the stabilization splint for the mandible, inferior view and B: superior view. The anchors add to the retention of the splint. Mandibular splints are easier accepted than maxillary splints, leading to better compliance. C By exception, in this patient extra anchors position and fix the mandible against the maxilla in order to prevent locking op the TMJ during the night: when the chewing muscles are relaxed during sleep, the mandible cannot slide into a lateral position when sleeping on the side.

9. Oral and dental aspects of EDS

In patients with EDS the teeth, periodontal tissues, and the oral mucosa are involved because of the defective connective tissue. The literature only relates to case reports, rather than patient groups; moreover in these reports, it is not always clear what the EDS type is.

9.1 Teeth

Various tooth abnormalities have been described in association with EDS, such as hypodontia, microdontia, abnormal root formation and tooth morphology. In a group of 31 Belgian patients with EDS, 6% showed abnormal root structures.[19] Changes of the hard tissues or microdontia (small teeth) have been described as well.[20,21] Examples are high cusps, deep fossae and vertical clefts in enamel. In the pulp, chamber stones can be detected on X-rays. The root of the teeth can be deformed, shorter than normal and excessive dentine formation may occur, making it more difficult to perform endodontic treatment. Stones in the pulp chamber in de molars of the primary dentition may be indicative for EDS. A smaller pulp chamber (94%) as well as the presence of pulp stones (78%) occur more often in patients with classical EDS.[19] In patients with hypermobile EDS, pulp stones occurred in 19%, and they were practically absent in vascular EDS.[19] The dentist is advised to refer the patient to the general medical practitioner with regard to EDS related non-dental conditions. A higher prevalence of decayed, missing or filled teeth could be related to an impaired hygiene as a result of vulnerability of the oral tissues (patients try to avoid inducing lesions of the mucosa and gums) and the limitation of mobility of the wrist and shoulder in some of the patients.[19]

9.2 Periodontal tissues and oral mucosa

Periodontal disease is an inflammatory condition of the supporting tissues of the teeth. Dental plaque causes chronic inflammation resulting in migration of attachment and pocket formation. Periodontal abnormalities, not related to dental plaque at an unusual young age, in combination with tooth loss raises suspicion of the rare periodontal EDS.[22-24] The classical type and the vascular type are known regarding the vulnerability of the oral mucosa. Gingiva recession as a result of periodontal involvement was not a strong predictor of vascular EDS. The combination of increased root length, modified dental pulp shape and arthralgia had high sensitivity and specificity for vascular EDS in a scoring system of maximum 4 points with a positive score of 2 or higher.[25] Orthodontic treatment (moving the teeth) is feasible in patients with EDS,[26,27] although not without risks.[28] Low force and a longer active treatment time than usual will help to respect the metabolic processes and preventing excessive resorption of the supporting bony tissues of the teeth. This should be especially the approach in patients with periodontal EDS. After finishing the treatment, fixation of the teeth in their acquired position is mandatory. During treatment with orthodontic appliances or brackets fixed to the teeth, the vulnerability of the oral tissues should be taken into account. In a recent case study, it was found that dental implants survived in 6 patients with classical EDS. The follow-up time was 5.5 years (range 2-12 years), mean age at implantation 41 (range 19-68). Only mild bone loss (2 mm) was measured around one implant in two patients.[29]

9.3 Recommendations for the dentist

The duration of dental treatment should not challenge the ability of the patient to keep the mouth open without dislocation of the TMJ, or other sequels of dysfunction of the masticatory system. In case of longer treatment the patient should be allowed to close the mouth regularly; single instead of multiple treatments per session are advised. The dentist is also advised during the treatment of a patient with EDS or generalised hypermobility to pay extra attention to have the patient position the head and neck in a comfortable way at the cost of a compromised working posture for the dentist.

Anaesthesia for dental treatment may be less effective than expected.. In case of cardiac valve prolapse, as in individuals without hypermobility, antibiotic prophylaxis should be considered preceding surgical procedures. Careful manipulation in the oral cavity and the use of non-traumatic procedures will help to prevent trauma to the tissues with a delayed healing time and increased bleeding tendency.

10. Summary

TMDs are highly prevalent in the general population. However, dislocations of the mandibular condyle are less prevalent than other TM conditions such as disc displacement, myofascial pain and osteoarthritis. To differentiate the non-specific TM condition from TMDs specific for EDS, the dentist should be informed regarding the specific criteria of EDS. In case of pulp stones and deviant tooth and root morphology and periodontal involvement at an unusual young age, the dentist may be the first health care professional to diagnose EDS. Referral to the general medical practitioner is advised as first step. The panoramic radiograph is the first choice imaging modality. Management of the sequels of EDS regarding the masticatory system is identical to that of non-specific TMDs in otherwise healthy individuals.

11. Areas of uncertainties

Temporomandibular joint signs and symptoms are relatively common in the general population. It is therefore a challenge to differentiate non-specific temporomandibular problems from those that are specifically related to EDS and other hypermobility syndromes.

Addendum by the editors

In the March 2017 issue of the American Journal of Medical Genetics Part C Seminars in Medical Genetics all papers were devoted to EDS, covering a new EDS nosology, new diagnostic criteria of the different types and also management related topics (see also chapter 2). One of these papers is entitled “Oral and mandibular manifestations of the Ehlers-Danlos syndromes”, which is recommended for further reading.[30]

Table 14-1 Characteristics of arthrogenous versus myogenous temporomandibular disorders

	Arthrogenous	Myogenous
Maximum mouth opening	25 - 30 mm	30 - 40 mm
Difference between active and passive maximum mouth opening capacity	0 - 2 mm	> 4 mm
Horizontal range of mandibular motion	limited	not limited
Movement pattern / chin position	deviation	no deviation
Pain location	TMJ	cheek / temporalis muscle
Pain on palpation	TMJ (dorsal, lateral)	cheek / temporalis muscle
Auscultation	clicking, crepitation	no noise

1. Introduction

Ehlers-Danlos syndrome (EDS) is a heterogeneous group of heritable connective tissue disorders (HCTD) characterized by hypermobility of joints, hyperextensibility of the skin and easy bruisability with formation of peculiar "cigarette paper" scars. A number of distinct clinical types are recognized on the basis of biochemical, genetic, and clinical findings.[1] They are discussed in other chapters.

EDS is caused by an underlying genetic defect in connective tissue. The main protein of connective tissue is collagen. Different types of collagen molecules exist in the eye, therefore EDS can, in addition to the more widely recognized phenotypic features involving the skeleton and skin, also have adverse structural and functional implications for the eye.[1,2]

For most types of EDS molecular defects have been found in fibrillar collagens and collagen-modifying enzymes. However, that EDS is not solely a disease of the collagens became clear by the identification of a clinically distinct, autosomal recessive classical-like EDS caused by deficiency of tenascin-X (TNX). Deficiency of TNX is associated with fragmentation of elastic fibres and reduction of collagen.[3]

In this chapter, after a brief summary of eye anatomy, eye defects in different types of EDS will be described followed by ophthalmological screening / monitoring and surgery in these syndromes.

Recently, the two conditions benign joint hypermobility syndrome (BJHS) and EDS hypermobility type have been recognized as one and the same clinical spectrum ranging from apparently symptomatic generalized joint hypermobility to the most disabled individuals fitting the new diagnostic criteria. These new criteria are more strict than the Villefranche criteria and the Brighton criteria for BJHS in order to define a homogeneous phenotype for management and scientific purposes. Within the new EDS nosology, its name is hypermobile EDS (see chapters 2 and 5).

2. Anatomy of the eye

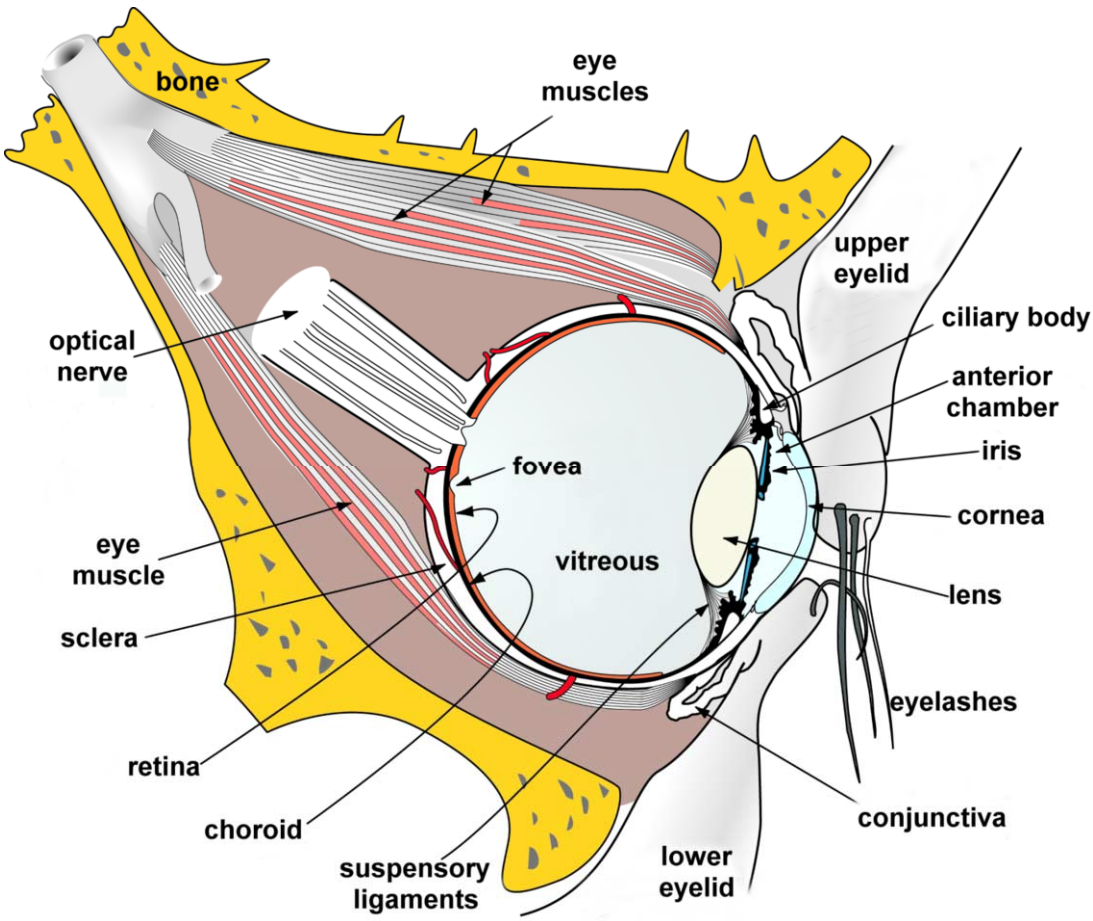
In the eye, fibrillar collagen exists in the cornea, sclera and vitreous (figure 15-1). Also, immunoreactivity for TNX was found in the anterior one-third of the corneal stroma as thin fibrils and in the stroma of limbus and conjunctiva, and in blood vessels.[4]

The cornea, the transparent front part of the fibrous tissue covering of the eye, makes it possible for the individual to see and for the physician to examine the inside of the eye. The cornea is the most important refractive medium of the eye. The diameter of the cornea is about 9.5-10.5 mm at birth. In the second year of life, the cornea reaches its adult size with a diameter of about 11.5 mm. The corneal thickness is centrally about 0.52 mm and peripherally about 0.67 mm.[5] Abnormalities of the shape of the cornea can have a negative influence on vision. The cornea contains type I collagen and type V collagen, which accounts for 10% - 20% of the total collagen in the cornea.[6] Type V collagen probably plays a regulating role in the production of type I collagen.[2]

The sclera is opaque; its thickness ranges from 0.3 to 1.0 mm. The sclera is thinnest just behind the insertions of the extraocular muscles and at the equator of the eye ball (0.3-0.4 mm).[5] Traumatic rupture is therefore often at these locations. The sclera also contains type I collagen, but here it is associated with type XII (FACIT-) collagen that probably stabilizes the collagen bundles and prevents shifting.[2]

The vitreous humour is a transparent gel that keeps the eye in shape. An abnormal composition of the vitreous increases the risk of retinal detachment, mostly by traction at the retina. Vitreous contains thin type II collagen fibres associated with type XI (fibrillar) and IX (FACIT-) collagen. The collagen composition of the vitreous is identical with cartilage. Type XI collagen probably regulates the diameter of the collagen fibres. Type IX molecules probably stabilize the fibrous structure of collagen type II.[2]

Figure 15-1 Anatomy of the eye, interior view



Collagen is responsible for the tremendous tensile strength of cornea and sclera, protecting them against perforating accidents and anchoring the eyeball in the orbit.[2] The shape of the eye depends much on the intraocular pressure, since cornea and sclera poorly keep their shape, vitreous contributes to a considerable extent in maintaining the eye pressure.[5]

Because EDS comprises disorders with abnormalities in collagen types I, II, III, V, XII and in TNX, theoretically one can expect abnormalities of the eyelids, cornea, conjunctiva, sclera and vitreous. Systematic ophthalmological examinations have seldom been performed in patients suffering from EDS, but case series are described below.

Eye disorders can be part of all types of EDS but especially occur in kyphoscoliotic EDS,although only a small number of patients with symptomatic eye abnormalities is reported in the literature. Particularly, eyelid and conjunctiva abnormalities, keratoconus, keratoglobus (a global deformation of the cornea), blue sclerae, pathologic myopia, angioid streaks (breaks in Bruch's membrane, a membrane under the retina), abnormal retinal vessels[7-11] and retinal detachment are mentioned.[12] Spontaneous luxation of the lens is not to be expected, because the fibres of the suspension apparatus of the lens do not consist of collagen, but of fibrillin.[2] Spontaneous luxation of the lens is one of the most characteristic ophthalmological features of Marfan syndrome, in which mutations are found in the *FBN-1* gene, located on chromosome

15.[13] The lens can, however, end up outside the eye with rupturing of the cornea or the sclera in EDS: a traumatic luxation.[14,15]

3. Eye abnormalities in different types of EDS

3.1. Classical EDS

Considering what is known about classical EDS and the anatomy of the eye, corneal abnormalities could be possible, since there is a defect in the *COL5A1* and the *COL5A2* gene, coding for type V collagen. In the "Revised nosology, Villefrache 1997", no corneal abnormalities were described in this type.[16] However, Giunta and Steinmann, described "microcornea" in patients with 2 different point mutations (small gene abnormalities) in the *COL5A1* gene.[17] These mutations seem to negatively influence the maturation of the cornea.

In 2000, 2 patients were described with a phenotype resembling classical EDS and a *COL1A1* (Arg to Cys) mutation. Both had normal white (i.e. not blue) sclerae. One of these patients underwent strabismus surgery uneventfully.[18]

In 2006, Seveg et al.[7], described thinning and steepness of the cornea in 16 eyes of 8 subjects form three unrelated families with classical EDS, who were heterozygous for mutations in either *COL5A1* or *COL5A2*. All subjects had floppy eyelids. The corneal abnormalities did not affect corneal transparency and the corneal thinning did not impair vision.

In 2013, Villani et al. examined 50 patients with classical EDS, compared to controls and confirmed the thinning and steeper corneas in the EDS patients, which also had increased irregularity of the corneal surface. [19] However, these changes did not cause increased refractive errors nor increased prevalence of keratoconus. This patient group also had increased symptoms and signs of tear film dysfunction. The high prevalence of dry eye in patients with EDS has so far been reported only in patients with hypermobile EDS.[8,20]

3.2. Hypermobile EDS

EDS hypermobility type and benign joint hypermobility syndrome (BJHS) are now considered as one and the same entity, named hypermobile EDS.[21] However, in this section they are still discussed separately.

In hypermobile EDS, a small subset of patients suffers from a heterozygous defect in the *TNX* gene[22], localized on chromosome 6q21.3.[23] Tenascin X and collagen XII act as adaptor molecules to interconnect collagen I-containing fibrils with each other and therefore might modulate the distances between fibrils. This would in turn influence the biomechanical properties of tissues.[24] Veit et al. speculate on account of their studies that the restricted spatial co-localization of collagen XII and tenascin-X plays a role in generating specific mechanical properties through collagen XII acting in concert with tenascin-X as a regulator of fibril deposition and spacing.[24] It is not yet clear whether this is also true for the cornea and/or sclera, since tenascin has only been found in cornea and collagen XII only in sclera.

For the vast majority of patients with hypermobile EDS the gene defect is not yet known.

In 2012, Gharbiya et al.[8], investigated a group of 44 eyes of 22 consecutive patients with joint hypermobility syndrome/EDS hypermobility type (JHS/EDS-HT) and 44 controls. The ocular anomalies consisted of xerophthalmia, steeper corneas, pathologic myopia, vitreous abnormalities, and minor lens opacities. However no definite case of keratoconus and no significant differences in corneal thickness between patients and controls were found. These findings are consistent with the results of McDermott et al.[25], who studied a cohort of 36 EDS patients, including 17 JHS/EDS-HT subjects, by using ultrasound pachymetry and topography. Similar results also were obtained by Segev et al. in classical EDS.[7]

Mishra et al. examined the eyes of 34 consecutive patients with BJHS who visited their rheumatology clinic. The eyelids were judged to be abnormal in 23 (68%) patients. The most

common abnormality, seen in 14 (41%) patients, was excess lid laxity. An additional eight patients (24%) had prominent horizontal folds of upper lid skin. One patient had congenital unilateral ptosis. No significant abnormalities of sclera, cornea or iris were found on slit-lamp examination. All lenses were stable with no subluxation. No abnormalities of the retina were found, but three patients had tilted optic discs.[26]

Tilted optic disc is a term used to describe an optic nerve head appearance in which the vertical meridian of the disc is at an oblique angle or one pole of the optic disc is tilted anteriorly or posteriorly. Tilted discs are often associated with astigmatism and myopia.[27]

The prevalence of tilted discs in the normal population is 1,6% and in patients with BJHS seems to be higher than expected. Interestingly, Forman (1979) reported on a patient with EDS type III (hypermobile EDS) with tilted discs.[28] The pathobiology of tilted discs is not known.

3.3. Vascular EDS

The vascular EDS is caused by mutations in *COL3A1*, which codes for collagen type III. Since type III collagen is not present in the eye, no primary eye abnormalities have been described in vascular EDS, as would be expected. However, there can be problems with the eyes caused by aneurysms of brain vessels or by haemorrhage in or behind the eye.[29] In those cases, proptosis (protruding of the eye), motility disturbances of the eye or redness and oedema of the conjunctiva may be seen.[30]

3.4. Kyphoscoliotic EDS

Kyphoscoliotic EDS is caused by a defect of lysine hydroxylation of collagen type I. It has an autosomal recessive inheritance.

The kyphoscoliotic EDS is the only type of EDS in which eye problems are a key feature, but serious complications such as retinal detachment or rupture of the eyeball are rare.[14] The estimated prevalence of this type of EDS is less than 1: 500.000.[31]

The most frequent ocular complications are corneal and scleral abnormalities: microcornea, flat cornea (cornea plana), abnormal bulging of the entire cornea (keratoglobus), the central part of the cornea (keratoconus) or the posterior part of the central cornea ((keratoconus posticus) with (rare) or without spontaneous rupture[32-36], scleromalacia (thinning of the sclera)[33,37], angioid streaks[9] and spontaneous (rare) and traumatic rupture of the sclera.[14,38]

Cameron described 11 patients with kyphoscoliotic EDS with corneal abnormalities and blue sclerae. The diagnosis was, however, not proven biochemically or by molecular genetics. All patients had hypermobile joints and descended from consanguineous marriages. Only one patient also had scoliosis and skin problems. This patient had keratoglobus of both eyes and a spontaneous rupture of the cornea of one eye.[35]

Symoens et al. also reported a case of a girl with a rapidly progressing kyphoscoliosis, a converging strabismus and retinal detachment in the right eye with type V collagen defects. Mutations in the type V collagen genes may cause EDS phenotypes that differ from classical EDS.[39]

Retinal detachment and high myopia are also part of the kyphoscoliotic EDS, yet only a few patients have been described with these complications.[14,38] Bodanowitz et al. reported on a kyphoscoliotic EDS patient who suffered from progressive myopia caused by change of the refractive power of the cornea as a consequence of progressive keratoconus. This patient also had scleromalacia with localized retinal detachment.[14] The high myopia could theoretically also be caused by progressive lengthening of the eye because of diminished tensile strength of the scleral tissue. Measurements of the axial length of the eye are, however, not routinely performed in EDS. Retinal surgery in the reported cases was complicated by serious choroidal haemorrhage, retinal neovascularization with vitreous haemorrhage, recurrent retinal

detachment and scleral rupture.[14,40,41] Bodanowitz therefore recommended right from the start to combine retinal surgery with vitrectomy to prevent these complications.[14] Patients with kyphoscoliotic EDS have a marfanoid habitus, but they have no spontaneous luxation of the lens because the fibres of the suspension apparatus of the lens do not consist of collagen, but of fibrillin.

3.5. Arthrochalasia EDS

In arthrochalasia EDS, no ophthalmological abnormalities have been described. Abnormalities of cornea and sclera are theoretically possible, since this type involves a defect of the *COL1A1* or *COL1A2* gene[42], and type I collagen is prevalent in the ocular structures.

3.6. Dermatosparaxis EDS

Hypertelorism and epicanthic folds are common in the dermatosparaxis EDS.[1]
In this type, blue sclerae have also been described. Theoretically, corneal and scleral abnormalities can be expected because the disorder is caused by an enzyme defect in type I collagen metabolism[43], but these abnormalities have not been reported to date.

4. Ophthalmological Screening and Monitoring

Based on the data in the literature, routine ophthalmological screening is necessary in patients with classical, hypermobile and especially in kyphoscoliotic EDS. However the thinning and steeper corneas described in the classical and hypermobile EDS did not cause increased refractive errors nor increased prevalence of keratoconus, considering that cornea thickness influences interpretation of ocular pressure measurements and decisions about refractive surgery, it seems to be likely to do an ophthalmological exam. In kyphoscoliotic EDS these corneal problems are symptomatic and keratoconus and keratoglobus do occur. It is important to detect these corneal abnormalities as well as well as high myopia or vitreous abnormalities as these can be risk factors for retinal detachment. After the initial ophthalmological examination at the time of diagnosis, the frequency of follow-up examinations depends upon the eye abnormalities found and has to be planned accordingly.

5. Surgery

Corneal and scleral rupture, keratoconus, keratoglobus and retinal detachment are difficult to treat in EDS because the sclera is so thin and fragile that stitches rip through the tissue and haemorrhages occur.[14] Biglan et al. reported corneal perforations in 15 of 20 patients before the age of 18 years. Repair proved difficult, and many eyes needed to be eviscerated or enucleated.[44] Cosar et al. reported successful revision of the repair of the corneal perforation with conjunctival flap[45]. Cameron and co-workers performed prophylactic epikeratoplasty (adding donor tissue to the corneal surface) in six patients with good tectonic results in five. All their patients had keratoglobus and joint hypermobility.[46] Macsai et al. applied a novel surgical technique to treat a ruptured globe in a patient, successfully combining onlay epikeratoplasty with a delayed full-thickness corneal graft.[36] Nakazawa and colleagues used preserved sclera to patch a post-traumatic scleral staphyloma in a patient with kyphoscoliotic EDS .[37]
In the literature no data are found concerning the response of the eye to cataract surgery, glaucoma surgery and refractive surgery in patients with EDS. Repair of strabismus may be complicated by severe thinning of the sclera at the site of the original muscle insertion.[1] A growing number of people seek aesthetic surgical treatment of the skin to look younger or excimer laser treatment of the cornea to get rid of glasses or contact lenses. Patients with EDS have to realize that surgery or laser treatment of skin, eyelids, and eyes can have serious

complications. Ongoing research will reveal whether these complications are relevant to what account and in which type of EDS.

6. Summary

EDS comprises a number of HDCT, caused by defects in fibrillar collagen (type I, II, III, V) and other connective tissue molecules. In the eye, fibrillar collagen is present in cornea, sclera (type I and type V collagen) and vitreous (type II collagen).

A number of case series of different types of EDS with eye problems are described in the literature, especially in kyphoscoliotic, classical and hypermobile EDS.

Theoretically, based on knowledge of their aetiology and pathogenesis, abnormalities can be expected of the cornea in the classical type and of the cornea and sclera in kyphoscoliotic, arthrochalasis and dermatosparaxis EDS. In vascular EDS, no primary eye abnormalities are present, but eye symptoms caused by vascular abnormalities in brain and orbit can occur.

Little is known of the reaction of the eyes to surgery and laser treatment. Till proven otherwise, it seems sensible for patients with EDS to abstain from this kind of treatment.

1. Introduction

Ehlers-Danlos syndrome (EDS) is fairly unknown amongst urologists. The syndrome is only mentioned in a small paragraph in Campbell's' Urology, which counts more than 4000 pages, and has established its universal reputation as the "bible" of urology. EDS is a group of genetic connective tissue disorders that affects approximately 1 in 5,000 live births, and is evenly spread among males and females of all racial and ethnic groups.[1] Although the exact prevalence of EDS is unknown, it is estimated to be about 1.3 million worldwide. In 10% of those, EDS is of the type vascular EDS(formerly type IV), which is associated with severe urologic complications. Worldwide there are - roughly estimated - about 75.000 practicing urologists. Assuming that all vascular EDS patients have urological problems, this implicates that every urologist should have personal contact with about 2 of these patients . In contrast with these numbers, EDS seems almost non-existing in international urology. This is in accordance with the results of an extensive urological literature search with only 20 articles mentioning EDS. This chapter contains some urological aspects of EDS, illustrated in 3 patients. These illustrative cases show the importance of recognizing typical urological consequences of EDS for (paediatric) urologists. Thereafter we will systematically discuss the problems that can occur in the upper and lower urinary tract.

The diagnosis of EDS is primarily based on a precise (family) history and physical examination. The typical history mentions recurrent (sub)luxations of joints, and hypermobility of joints, as defined in the Beighton and Bulbena scoring systems.[2,3] There could also be problems with wound healing, abnormal bruises, voiding and defecation. Physical examination may also reveal hyperextensibility of the skin, widened and atrophic scars, facial aspects as the sign of Gorlin (point of tongue can reach the tip of the nose), scoliosis, and muscular hypotonia.
Recently, the two conditions benign joint hypermobility syndrome (BJHS) and EDS hypermobility type have been recognized as one and the same clinical spectrum ranging from apparently symptomatic generalized joint hypermobility to the most disabled individuals fitting the new diagnostic criteria. These new criteria are more strict than the Villefranche criteria and the Brighton criteria for BJHS in order to define a homogeneous phenotype for management and scientific purposes. Within the new EDS nosology, its name is hypermobile EDS (see chapters 2 and 5).

2. Cases

2.1 Patient A

A 27-year old woman with kyphoscoliotic EDS presented at the urology outpatient clinic. She has been referred by her nephrologist, who is treating her for severe hypertension. As a result of her EDS, she had multiple orthopaedic surgeries in childhood for spondylolisthesis. Eventually spondylodesis of L5 up to the sacrum had been performed. Additionally, she is known with a mitral valve prolapse and periodic supraventricular tachycardia. At the age of 25 hydronephrosis on the right side was diagnosed, which was surgically treated by an urologist elsewhere. Indication for this surgery was a suspected ureteropelvic junction obstruction. Post-operatively she developed a new obstruction of the upper urinary tract, as a result of a radiographically invisible kidney stone in the ureter. Eventually this stone was surgically removed. Shortly thereafter, a renogram showed that the function of the right kidney was only 27% and of the left kidney 63% of the total kidney function, probably as a result of the previous problems.
For urologic analysis of the upper urinary tract, a retrograde urography on the right side was performed. This showed a dilated pyelum and ureter with a malrotated kidney.

Video-urodynamic investigation showed a small capacity bladder and a bladder diverticulum. At voiding the diverticulum did not empty completely. Because of recurrent urinary tract infection an antibiotic (Nitrofurantoin) for continuous use was prescribed.
She was also seen by her gynaecologist for pregnancy counselling. After this consult, which included evaluation of the risks of having a child affected with EDS, she and her partner decided to refrain from having their own children and to start with an adoption procedure. After starting with Tamsulosin, drinking 200 ml of cranberry juice twice a day and stopping antibiotic treatment, urinary tract infection did not recur. Her hypertension responded well on ACE (angiotensin converting enzyme) blockade. Ultrasonic and renographic imaging at follow up revealed no further functional decrease of the right kidney and ureter. She is still intermittently seen at the urology outpatient clinic.

2.2 Patient B

A 26-year old woman with hypermobile EDS has been visiting her urologist for more than three years. As a result of her EDS she became wheelchair dependent . Her medical history included analysis for voiding problems in another university hospital. By pressing just cranially of her pubic bone, she was able to empty her bladder (method of Credé), but feelings of residual volume remained. She never had episodes of urinary tract infections. Urodynamic investigation showed a bladder capacity of 800 mls without an urge to void at that volume and absence of normal contractions of detrusor muscle when striking the abdomen just cranially of the pubic bone or applying abdominal pressure. Furthermore closure pressures of bladder neck and urethra were too high. Based on these findings patient was taught to catheterise intermittently. With this procedure she could socially function well and was continent. When she went on vacation, she used a permanent urinary catheter. Investigation of the upper urinary tract showed normal kidneys without signs of hydronephrosis. Signs of an urinary tract infection were never found.

2.3 Patient C

A 37 year old woman with hypermobile EDS was referred by an urologist from another hospital because of bilateral ureteral obstruction. A CT-scan made because of abdominal pain and fever, showed dilatation of the left ureter. Since this problem seemed to have been existing for a long time, it was not considered to be the cause of the fever. Because of remittance of fever, a double-J catheter was placed in the left ureter. A renogram showed for the left kidney 31% of the total kidney function. Bilateral dilatation of the total ureter was seen on a repeated CT-scan. Earlier, in another hospital she underwent a diagnostic laparoscopy for dysmenorrhoea which revealed endometriosis and extensive adhesions (“frozen pelvis”). Consecutively, hysterectomy and bilateral ovariectomy was performed, while preoperatively another double-J catheter was placed on the right side. Postoperatively she developed a new episode of fever which was treated with antibiotics. As soon as the patient was free of fever, the double-J catheters were removed. After this procedure she had flank pain and retrograde urography showed a complete obstruction of the right ureter. This was treated by performing a right sided nephrostomy and placement of a double J-catheter on the left side. Antegrade urography (the contrast medium is introduced by percutaneous needle puncture into the renal pelvis) showed a long narrow stenosis on the right side with a minimal amount of contrast in the bladder. Because of this ureteral stenosis and her complicated EDS history she was referred to our clinic where a so-called psoas hitch re-implantation of both ureters was performed. Postoperative antegrade urography showed no stenosis anymore and no dilatation was found at follow-up ultrasound investigations of kidneys and ureters. A renogram showed no progressive loss of kidney function on the left side. She never had any

urological complaints anymore after the re-implantation and could void completely normal, during an evaluation time of more than 5 years.

2.4 Discussion

It could be noted that if the urologist had been aware of EDS in patient A, he would not have started with a surgical intervention. Even treatment of the kidney stone would preferably have been done via ureterorenoscopy. However, it is hard to determine if another treatment strategy would have prevented deterioration of the right kidney function.
Regarding patient B, it would have been better if there had been a clinical evaluation of the lower urinary tract in an earlier stage. But even here it is hard to determine if this could have prevented worsening of the bladder function.
The case of patient C also shows that surgical intervention should be avoided if possible, or should at least be discussed interdisciplinary.

3. EDS and urological problems

3.1 Lower urinary tract

An association between hypermobility and poor function of the pelvic floor muscles has been described by paediatricians and paediatric urologists.[4] A group of 89 paediatric patients without EDS, but with generalised hypermobility which partially met the criteria of Bulbena and Beighton, showed an abnormally high frequency of signs and symptoms caused by non-neurogenic detrusor sphincter dyssynergia.[5] The main complaints were urinary incontinence, frequent urinary tract infections, constipation and faecal soiling. This was attributed to insufficient supportive connective tissue in the pelvic floor due to abnormal composition of collagen. Especially girls are predisposed to incontinence and infections, while boys generally suffer from constipation and faecal soiling.[6] Although the prevalence of urinary tract infections in EDS patients is unknown, it is plausible that it also occurs is higher among patients with EDS, but this has not yet been described in literature. Another urologic problem in patients with EDS, as shown in patient A, is (congenital) bladder diverticula. Some articles describe cases of bladder diverticula in children and adults.[7-11] The bladder diverticulum in EDS is associated with other congenital malformations[12] and also malignancies.[13] The bladder wall of a patient with EDS is structurally different from that of a healthy person; the same applies for the diverticulum.[14] Its pathogenesis is still unknown but it is plausible that hyperelasticity and weakness of the bladder wall and high voiding pressure induced by coexistent bladder outflow obstruction play a role.[9] The combination of these two factors is probably the etiological basis for bladder diverticula. These eventually hamper emptying the bladder properly, which leads to urinary tract infections. Dependent on the localisation of the diverticulum it can also cause voiding impairments by dyssynergia of the pelvic floor, bladder and bladder neck. If the diverticulum is located close to the ureteral orifice, reflux can ensue. In this case a surgical intervention is indicated,[15,16] because persistent reflux may damage the kidney. Rupture of bladder diverticula is rare, occurring more frequently in boys than in girls, and needs to be treated conservatively.[17]

3.2 Upper urinary tract

Functioning of the upper urinary tract in EDS patients has not extensively been described in the literature. There have been some case reports of renal cystic lesions, which have to be distinguished from classical renal cysts.[18] Furthermore there is a small number of reports about an abnormal ureteric function, which led to an extended pyelum and ureter in these cases. This complication could also result from reflux caused by a diverticulum. Recently, bilateral kidney prolapse was described in a patient with hypermobile EDS as part of a

recurring and generalized visceroptosis.[19] Renal infarction in cases with vascular EDS has also been reported.[20,21] Prior to surgery, an intravenous contrast study of the upper urinary tract always should be performed to know the exact anatomy. If surgical intervention is indicated, the surgeon should be aware of the moderate quality of skin and connective tissue. Patients with EDS are prone to have bleeding during and after surgery, poor wound healing and incisional hernias.[22] In case of urolithiasis, an endoscopic procedure by an experienced urologist is the treatment of choice. Extracorporeal shockwave lithotripsy (ESWL) should not be applied in patients with vascular EDS; a massive bleeding occurring 24 hours after ESWL due to a rupture of the superior mesenteric vein has been described.[23]

4. Conclusion

Events affecting the function and anatomical variation of the urinary tract due to EDS have not comprehensively been described in the literature. Starting an urological (surgical) treatment of a patient who has not yet been diagnosed with EDS could lead to a non-optimal treatment result and possibly severe complications. It is very important that every patient with EDS should mention the disease to his or her urologist. The general practitioner should be coordinating care for the EDS patient and should inform every specialist about the diagnosis.

5. Summary

Especially in vascular EDS, urological complications may occur which need special attention. Unfortunately, EDS is a fairly unknown disease amongst urologists. With 3 illustrative cases we hope to have demonstrated the clinical impact of EDS in the urology clinic. EDS causes functional voiding problems by detrusor sphincter dyssynergia, bladder diverticula and loss of renal function due to reflux and hydronephrosis. Surgical intervention should be minimal because of the high complication risk.

1. Introduction

In gynaecological and obstetric care, women with Ehlers-Danlos syndrome (EDS) may present challenging management dilemmas, which vary depending on the type and severity of the disease and the specific gynaecological or obstetrical situation. As expected in an uncommon disease with many types, data in the literature are scarce, and if present, classification according types is often lacking. This makes it very difficult to compare management schemes, especially because they are reported by different authors.

The aim of this chapter is to highlight the most common gynaecological and obstetrical problems that patients and clinicians may face, and to suggest the optimal management, based on available literature. Because the spectrum of EDS manifestations is very broad, even for a given type, no strict management protocols can be established. In general, management should be based on the type of EDS, but individualization is mandatory and a multi-disciplinary team approach is required. Recently, the two conditions benign joint hypermobility syndrome (BJHS) and EDS hypermobility type have been recognized as one and the same clinical spectrum ranging from apparently symptomatic generalized joint hypermobility to the most disabled individuals fitting the new diagnostic criteria. These new criteria are more strict than the Villefranche criteria and the Brighton criteria for BJHS in order to define a homogeneous phenotype for management and scientific purposes. Within the new EDS nosology, its name is hypermobile EDS (see chapters 2 and 5). The first part of this chapter deals with gynaecological problems and their management, while the second part outlines obstetrical complications and management dilemmas of pregnant EDS patients.

2. Gynaecological disorders in EDS

In patients with EDS, many medical problems may occur due to malfunctioning connective tissue. As outlined in the previous chapters, several types of EDS can be identified, all of which could have a different impact. However, no specified data regarding the impact of these different types on the genital tract are available in literature. Therefore, the gynaecological disorders discussed in this chapter are generally without differentiation in EDS types.

The gynaecological items that are discussed in this section include preconception counseling, infertility, contraception, menstrual disorders, urinary incontinence and prolapse, and other common gynaecological disorders. Many women with EDS need intensive medical care for these problems. Treatment is often difficult and may lead to other complications. So, in many cases a multidisciplinary approach is essential.

As the underlying defect results in abnormal connective tissue and bleeding disorders (see chapter 11), it may be clear that menstrual disorders, uterine or bladder prolapse, urinary incontinence and the surgical procedures to handle these problems, are the main points of concern.

2.1 Preconception counselling

Before starting a pregnancy or an infertility work-up, a couple with one partner having EDS should seek counseling regarding general aspects of inheritance, prenatal diagnosis, potential pregnancy complications and maternal and neonatal outcomes.

The genetics of EDS, including the mode(s) of inheritance, are discussed in chapters 2 and 3. It is important that the diagnosis of EDS is confirmed by a clinical geneticist or another medical expert in the field. The specialist will counsel the couple regarding general aspects of EDS, possibilities for prenatal diagnostic tests, and coordinate the necessary consultations with other disciplines such as ophthalmology and cardiology.

Before treatment starts, a bleeding/coagulation screening must be performed, though bleeding in EDS is mostly due to problems in skin, subcutis and/or vessels and not so much in coagulation disorders.

Prenatal diagnostic procedures are available in those types of EDS, in which the genetic defect is known in the proband and/or affected parent (see chapters 2 and 3). In case of an affected woman and no prenatal diagnostic tests available, the only way to assure that the offspring will not be affected is by in vitro fertilization (IVF) with egg-cell donation. Pre-implantation genetic diagnostic procedures in selected cases may also be possible. If the male is affected, donor insemination could be a solution. Donor egg and insemination procedures may be obstructed by national regulations. Anonymous donor egg/embryos are available in some countries; in other countries most often a close family member or acquaintance is the only possible donor.

Invasive diagnostic procedures may be associated with more complications in women with EDS. Theoretically, they may be more prone to bleeding, and if the fetus is affected, the chance of premature rupture of membranes is increased.[1]

Non-invasive prenatal tests are now rapidly developping and available in many countries, but they mostly only screen for chromosomal abnormalities.[2] Untill now, there are no publications reporting the use of these non-invasive tests in EDS.

In most countries IVF procedures have a multi-gestational rate of about 25%. In case of EDS this is an undesirable situation. So, if an IVF procedure is performed, single embryo transfer is advised. Though not enough data are available, literature suggests a very high rate of extreme premature delivery in twin pregnancies. In addition, other complications associated with multiple gestation, like postpartum haemorrhage and perineal lacerations, may occur more frequently in women affected by EDS.[3]

2.2 Infertility

There are no consistent data suggesting decreased fertility in women with EDS and no sperm abnormalities in relation to EDS have been reported, though Hurst et al. mentioned an infertility rate of 44,1% through a questionnaire study among members of the USA Ehlers-Danlos National Foundation.[4] The abortion rate is slightly increased (20-25% of pregnancies).[3,4] All routine examinations should and can be performed in a couple with EDS, like basal temperature checks for ovulation detection, semen analysis, bloodtests, post coitumtest, hysterosalpingography (the conductance of the tubes is checked by filling the uterus and tubes with a contrast medium while making a X-ray) and laparoscopy with chromopertubation (the uterus and tubes are filled with dye and the conductance of the tubes and possible abnormalities are confirmed by direct laparoscopic inspection).

Infertility in EDS women is mentioned by some authors and it is mainly due to anovulation (the ovary not releasing a ripened egg each month as part of a woman's normal cycle in her reproductive years), which may be as high as 41%.[5] This high percentage could, to some extent, be the side effect of non-steroidal anti-inflammatory medication, which is commonly used for pain relief. All ovulation induction drugs are permitted in women with EDS, however, care must be taken to prevent twin pregnancies. Drugs that are given by injections (skin, muscle) may produce haematomas and no clear data are available if there is also abnormal absorption of the injected drugs in the subcutaneous tissue. IVF can be performed in all types, but in vascular EDS it may be risky, as pregnancy itself also is in patients with vascular EDS (see section below on obstetric care).

2.3 Contraception

Almost all contraception methods can be used in women with EDS.

The reliability of different contraception methods is generally given by the Pearl index. This is the number of pregnancies that 100 women using a specific contraception method will have after one year. The reliability index shows at first the number of pregnancies, which would be

expected in theory. Secondly, the number will be shown as seen in daily practice, given the use of the same specific contraceptive. In table 17-1 the different numbers are summarized.

2.3.1 Non-permanent methods

Condoms, femal condoms, pessaria with sperm-killing substances can all used according to one's preferences.
Oral hormonal contraception may have the advantage of regulating menstrual bleeding disorders apart from birth control.
Hormonal contraception by progesterone depots by injection (intramuscular) are often used, but can produce local haematomas at the site of injection.
Other kinds of hormonal contraception. In some countries, the use of small rods of progesterone, which are subcutaneously inserted in the arm, is common. No data in relation to EDS are available, but they could migrate theoretically more easily in patients with EDS and their removal may be associated with more problems, secondary to poor wound healing, bleeding and extensive scarring.

It could be disputed whether hormonal contraception may have a bad influence on blood lipids (cholesterol) and hypertension. These factors must be balanced against risks of pregnancy, bleeding disorders and general condition. In some cases individual counselling is appropriate.
Two kinds of intrauterine contraceptive device (*IUCD*) are available: the copper IUCD and the IUCD with slow release of progesterone (*Mirena*®). The insertion of the IUCD should be performed with special care to avoid cervical lacerations and uterine perforations, due to the increased vulnerability of the tissue. Both kinds are applicable to all types of EDS.
In general population menorrhagia (excessive menstrual bleeding) is more often reported in women with a copper IUCD. The IUCD with progesterone may play, apart from its contraceptive action, an important role in the treatment of menorrhagia; it reduces the amount of menstrual blood loss remarkably. These IUCD's are a little bit more difficult to insert than those with copper, and extra care should be taken.

2.3.2 Permanent method of contraception

Classical *laparoscopic sterilization* has the disadvantage of general anaesthesia; potentially, more complications can be expected, as in all surgical procedures in EDS patients, but no clear data are available in the medical literature.
A new kind of permanent sterilization are the recently introduced *hysteroscopic sterilization* procedures. It has the advantage that it can be performed under local anaesthesia. However, in ±5% of cases the procedure cannot be carried out successfully, due to technical and anatomical factors.
Sterilization of the (non) affected male is also an option. Care should be taken with tissue handling to prevent (painful) haematomas in affected males.

2.4 Uterine bleeding disorders

Uterine bleeding disorders are common in EDS affected women. In the literature, it is reported to be present in about 28-59% of EDS cases.[4,5,6] The most common causes of severe bleeding are adenomyosis, uterine myomas, polyps, and hormonal dysfunction; sometimes no cause can be identified (idiopathic bleeding). Adenomyosis is a medical condition characterized by the presence of ectopic endometrial tissue (the inner lining of the uterus) within the myometrium (the thick, muscular layer of the uterus). Myoma is a benign tumour, which grow from the myometrium.

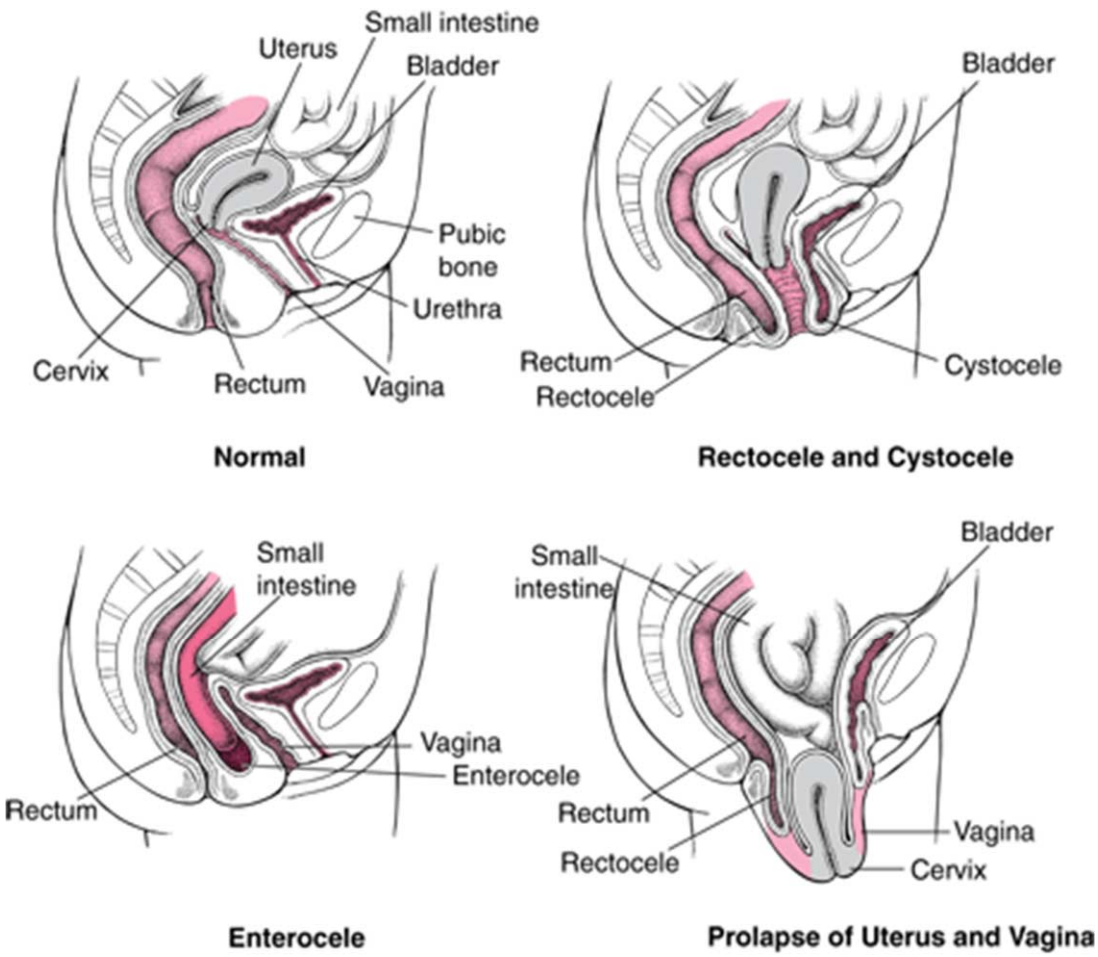
In a report by Anstey et al., 51 EDS patients were examined of which 83% had a tendency to bleed.[7]
Since myomas and polyps are not found more frequently in EDS women, bleeding disorders could be attributed to the more frequently found menstrual disorders. Hormonal dysfunction and anovulation are reported in about 20-40%, however medical intervention is usually not indicated.
Adenomyosis and endometriosis are reported in about 15-77%.[5,6] As this is a diagnosis that is mainly made by invasive procedures (laparotomy and laparoscopy), it is difficult to evaluate the accuracy of these reports. In some cases endometriosis can be seen (cysts) or suspected by ultrasound.

Options for treatment of uterine bleeding disorders include:
- Use of *oral contraconception*. Continuous use, or a cycle with a 3 monthly withdrawal bleeding could be beneficial or acceptable
- *Tranexamic acid.* This drug prevents the resolution of clots (fibrinolysis) and results generally in a 30% reduction of blood loss.
- *Coxibs:* prostaglandin inhibitors. Usually available over the counter in drugstores. A Cox-1 saving non-steroidal anti inflammatory drugs (NSAID) or Coxib (like etoricoxib) is advised in women with EDS because these drugs have no influence on the bleeding tendency, in contrast to classical NSAIDs. A 30 % reduction of blood loss is reported in a general population. The mode-of-action is the forming of a better hemostatic plug in the bleeding surface of the endometrium.
- *IUCD with slow release of progesterone* (discussed above). This usually results in acceptable menstrual blood loss and less dysmenorrhea (severe painful menstrual periods)
- *Endometrial ablation*: this is the destruction of the inner lining of the uterine cavity with thermal balloons or electrical loops. Results: 30 % of women have no periods at all after treatment, in 30 % the periods are less severe and acceptable, and in about 20% -30% the procedure is not felt to be successful.
- *Hysterectomy* (removal of the uterus). This is the only definitive solution for the problem, but it may be associated with more peri-operative complications in EDS. Nevertheless, hysterectomy is performed more frequently in EDS patients compared to general population (19-44%).[6]

2.5 Prolapse and urinary incontinence in women
Since EDS are disorders of the structure and function of connective tissue, it is understandable that uterine and bladder prolapse and urinary incontinence occur more commonly in women with EDS. Although literature data are scarce and the sample sizes small, these problems are reported to be present in about 30-60% of EDS cases.[5,6,8]
Prolapse can be manifest as prolapse of the anterior or posterior vagina wall and/or prolapse of the uterus (see figure 17-1). Surgical correction is the preferred treatment in most cases. However, in EDS, surgery must be balanced against the possible higher surgical complication rate, present discomfort, recurrence rate and possible anaesthetic complications. For all these issues the female patient must be carefully counselled. Less invasive surgical techniques with slings and foreign material are developed. These techniques could be beneficial for female patients with EDS. However, at present no data are available concerning the effects of these techniques in women with EDS. Potential complications are bleeding of the vagina, due to insertion of the slings and abrasions for which sometimes after weeks or months removal of remnants is necessary. This has been described several times in non-EDS affected women and could be a more serious problem in EDS affected women. The same holds true for surgical

techniques for urinary stress incontinence. Several studies describing techniques with mesh have been published, but none in relation to EDS. In elderly women, who have an increased surgical risk, a pessarium may be used. This necessitates an examination every 3 months for cleaning and to check for the presence of vaginal pressure ulcers.

Figure 17-1 Normal and abnormal anatomy



Top left: normal anatomy

Top right: vagina wall is prolapsed:
- *if the bladder is involved, it is a cystocele*
- *if the rectum is involved, it is a rectocele*
- *if both are involved, it is a recto-cystocele*

Bottom left: if the intestine prolapses between the rectum and vaginal wall, it is an enterocele

Bottom right: The whole uterus is prolapsed (descensus uteri)
(Source: merckmanuals.com)

Urge incontinence is usually treated with medication and the treatment is not different in women with EDS compared to women in the general population.
Most pelvic floor abnormalities need a multidisciplinary approach and in most hospitals a team of specialists, consisting of a urologist, gynaecologist, proctologist, physiotherapist, psychologist, dietist and a specialized nurse physician, is present for the care of patients struggling with these problems.
Recurrent prolapse or fragile tissue, noted during surgical procedures, should raise suspicion of EDS.

2.6 Other common gynaecological disorders

Other gynaecological disorders, which may be more frequently seen in women with EDS, include endometriosis (30-60%), dyspareunia (60%), atrophy of the vagina, more frequent need for hormonal replacement therapy (HRT) and abnormal Pap smears (19% versus 5 % in a normal population).[5,6] The first four disorders could be related to one another since dyspareunia and sexual dysfunction may be due to prolapse, atrophy, and pain due to endometriosis. Castori et al. gave a comprehensive overview of gynaecological complications in joint hypermobility syndrome, which nowadays is considered one and the same disorder as EDS hypermobility type and named hypermobile EDS (see chapter 2 and 5).[9]
Atrophy of the vagina can be the result of high doses progesterone, which are often given in cases of endometriosis or bleeding disorders. Atrophy is as in normal population usually treated with locally vaginal applied estrogen.
Endometriosis is often difficult to treat. Sometimes hormonal therapy is used, in other cases surgical therapy is necessary. There is no good explanation why HRT is more often used in women with EDS and why more Pap smears are found to be abnormal.[5,6]
Sexual dysfunction is often a difficult problem and may need in many cases a multidisciplinary approach or consultation of multiple specialists such as a gynaecologist, psychologist and/or sexuologist.
There are some case reports about vaginal lacerations after sexual intercourse that occurred in women with vascular EDS, but these events are rare and can occur in non-EDS affected women as well. Physically, in vascular EDS normal sexual activity is not too much a burden for heart and bloodvessels.
In male patients with vascular EDS, the use of viagra is theoretically permitted, if they have no medical history of cerebral vascular accident or heart failure. In these cases an individual counseling is necessary.

2.7 Conclusion regarding gynaecologic disorders

EDS may be associated with specific gynaecological complications. Bleeding disorders, pain, endometriosis and prolapse are the main problems.
This calls for special care for women with EDS, which is often intensive and involves in many cases several specialists. However, there still exists several areas of uncertainty: for example the effects of application of new surgical techniques in the treatment of incontinence and prolapse in EDS patients.

3. Obstetric care of patients with EDS

The second part of this chapter is on obstetric care of patients with EDS. EDS may be associated with numerous complications during pregnancy, ranging from mild articular discomfort to maternal death. The likelihood and severity of pregnancy complications appear to vary according to the EDS type.
The features of EDS with the most impact on the obstetrical and associated anaesthetic management include, depending on type, fragile and poorly healing skin, excessive bleeding,

increased risk for spontaneous pneumothorax, easy joint dislocation, cardiac valvular prolapse and spontaneous dissections or ruptures of major vessels and viscera.[10] Although various obstetric complications have been reported in patients with EDS, the vast majority of the published reports does not distinguish between the different types of the syndrome, thus type specific complication data are scarce, except for classical and vascular EDS.
This section outlines obstetric complications in parturients (women who are about to give birth) with different types of EDS, based on data from current medical literature, and recommendations for the management of pregnancy and labour in these patients. Foetal complications and relevant anaesthetic considerations are summarized.

3.1 Pregnancy and EDS

Reports of complications of pregnancy in patients with EDS have appeared in literature since 1950. These include abdominal hernias, bruising, varicose veins, antepartum and postpartum haemorrhage, joint subluxations, back pain, separation of the symphysis pubis, haematoma formation, and uterine prolapse. Early reports and even some of the later reports did not differentiate between the various types of EDS. Thus, it is difficult to create a complete database of type-specific obstetric complications in patients with EDS.
In 1981 the first observed maternal death due to EDS had been reported. A patient developed spontaneous pulmonary artery rupture during the seventh month of pregnancy and died before arrival in the hospital.[11] During the last three decades, additional type-specific cases of EDS in pregnancy were reported, and several attempts to summarize obstetric complications of this disorder in type-specific manner were made. They are described below.

3.1.1 Classical EDS

This type is among the most common types of EDS. Smith et al. reported on pregnancies of two patients with classical EDS.[12] In one patient the delivery was complicated by a large vaginal laceration, and the other suffered from the dehiscence of the episiotomy, a surgical cut made at the opening of the vagina during childbirth, to aid a difficult delivery and prevent rupture of tissues. Kiilholma et al. reported two pregnancies in patients with this type of EDS: one resulting in premature rupture of membranes at 26 weeks, and the other resulting in a small-for-gestational-age (SGA) infant at 38 weeks, but no other complications were reported.[13] Taylor et al. described a patient who underwent a caesarean delivery because of hip joint related problems.[14] However, her delivery was uncomplicated. Georgy et al. described a parturient who developed a large central perineal tear after active pushing during the second stage of labour (period of expulsion).[15] The increased tissue elasticity and skin fragility allowed the foetal head to take the pass of least tissue resistance (i.e. through the posterior wall and perineum, between the fourchette - a thin fold of skin at the back of the vulva - and anus).

3.1.2 Hypermobile EDS

Morales-Rosello et al. summarized the outcome of pregnancy in 39 women with hypermobile EDS.[16] Of those 39 patients, 30 (77%) had vaginal delivery, and 26 (67%) pregnancies were carried to term. 32 Patients (82%) delivered liveborn infants, whereas seven subjects (18%) had a miscarriage. The incidence of intrapartum and postpartum haemorrhage was 10% and 5%, respectively. No additional obstetric complications were mentioned.
In general, during the progress of pregnancy, there may be an aggravation of symptoms, mainly in joints, which may neccessitate a caesarean section. Such symptoms have been reported to disappear after delivery.[17,18] Some women may have an uncomplicated pregnancy and delivery.[16,19] Recently, we reported on pregnancy course and outcome of a patient with hypermobile EDS, who had an uneventful pregnancy and delivery.[20] To our knowledge,

severe complications in this type of EDS have never been reported. However, serious pelvic instability and symphysiolysis are reported.[9]

Classical and hypermobile EDS may be associated with increased risk of premature birth which may be the result of cervical insufficiency and spontaneous rupture of the foetal membranes, both due to the intrinsic weakness of the connective tissue.[14,21,22] In pregnancies in which the foetus is affected with EDS, a reduction or structural defect of the extracellular matrix components (collagen) may account for a general decrease in thickness of the foetal membranes, causing premature rupture of these membranes and premature delivery.[23]

To date, no EDS specific data are available on the possible benefits of cervical length measurements to estimate the chance of preterm delivery or on fibronectin determinations in vaginal or cervical fluids. Nowadays, we know that if the protein fibronectin is absent in vaginal or cervical mucus, the chance of premature delivery is very small. However, if fibronectin is absent the predictive value is small too. Progesterone can be used to prevent premature delivery, but with regard to EDS no specific data are available and normal criteria can be followed: premature delivery of 34 weeks or less in history and/or a shortened cervix.

It is questionable whether a prophylactic cerclage, a minor surgical procedure in which the opening to the uterus (the cervix) is closed in order to prevent a miscarriage or premature birth, is indicated in patients with EDS, since these patients are already predisposed to preterm premature rupture of membranes in case the foetus is also affected with EDS. Data concerning cervical cerclage in EDS patients are scarce: a patient with classical EDS, who underwent a prophylactic cervical cerclage and had an uneventful pregnancy, delivered at 41 weeks' gestation, has been described.[21]

Insufficient data are available to predict course and outcome of twin pregnancies in women with EDS, though case reports warned against extreme premature delivery

Overall, in classical and hypermobile EDS, pregnancy is generally well-tolerated, with favourable maternal and neonatal outcome. However, maternal complications related to connective tissue dysfunction such as pelvic instability and obstetric problems such as preterm delivery, postpartum haemorrhage, complicated perineal lacerations and poor healing of the episiotomy wound (the surgical cut made at the opening of the vagina during delivery) occur more often than in general population.[24] It may therefore be concluded that special care should be given to such patients to avoid perineal trauma. Furthermore, instrumental delivery should be avoided as much as possible.

3.1.3 Vascular EDS

This type of EDS is associated with a risk of as much as 25% maternal death, mainly due to rupture of the aorta or the uterus. These complications seem to be worse during labour and in the early postpartum period.[25] Lurie et al. reviewed 50 pregnancies in 26 patients with well documented characteristics of vascular EDS.[26] Ten of these women (38.5%) died during pregnancy, labour or in the immediate postpartum period: two of major vessel rupture prior to the onset of labour, one of uterine rupture during labour, one of uterine rupture and aorta rupture at delivery, five in the postpartum period after vessel rupture, and in one case, the cause of death was unknown. Among the 16 women who survived, five experienced complications such as major lacerations, haemorrhage, liver rupture, uterine rupture, and one woman underwent a hysterectomy after abortion.

During delivery, women with vascular EDS are at risk for severe vaginal or perineal lacerations, haematoma formations, postpartum haemorrhage, wound dehiscence, or a weak uterine scar if caesarean delivery is performed.[25,26] It has been estimated that vascular EDS is associated with a pregnancy related maternal mortality of 20% for each pregnancy and 38.5% for each pregnant women. The majority of deaths occurs in the peripartum period and is usually associated with vaginal delivery.[25] Pepin et al. described 81 women with vascular

EDS, who had a total of 183 pregnancies, with 167 deliveries of live-born infants at term, three stillbirths, ten spontaneous abortions and three voluntary terminations.[27] Twelve women (11.5%) died during the peripartum period or within two weeks after delivery (five of uterine rupture during labour, two of vessel rupture at delivery, and five in the postpartum period after vessel rupture). Based on these results, women with vascular EDS should be advised against pregnancy. If they do become pregnant, they should be advised against continuing the pregnancy.[25,26] A more recent study showed a less dramatic outcome: 30 pregnancy related deaths in 565 deliveries (5,3%) of 256 women and life threatening complications in 14,5%. Surprisingly, there was no significant difference in survival (Kaplan-Meier curve) between parous and nulliparous women. They concluded that women with vascular EDS should not be advised against preganacy, but should be engaged in a shared decisionmaking process when contemplating pregnancy and pregnancy management.[28] Elective termination of pregnancy before 16 weeks has been successfully accomplished without significant sequelae.[29] However, it is not without risk, and an emergency hysterectomy was required in one case.[30] If a woman chooses to continue the pregnancy, close follow-up is mandatory, and elective hospitalization is recommended during the third trimester with restriction of physical activity. Before the onset of labour approximately at 32 weeks, delivery should take place by planned caesarean section after administration of steroids to stimulate maturation of the lungs. This approach is recommended for the following reasons:
(1) maternal plasma volume peaks at 32 weeks, and plasma volume might have a role in the severity of vascular complications,
(2) it may minimize the fluctuations in maternal cardiac output and blood pressure associated with labour, a factor that may augment arterial rupture,
(3) it may reduce the risk of significant accidental perineal trauma,
(4) the majority of spontaneous deliveries of EDS patients occurs between 32 and 35 weeks of gestation. Prior to a caesarean section, the woman should be counselled about tubal ligation, a surgical procedure for female sterilization that involves severing and tying the fallopian tubes, should be offered.[18] Caesarean delivery is associated with increased risk of perioperative haemorrhage.[31] Wound healing may be impaired, and there is an increased risk of wound dehiscence.[32] Whether there is a place for desmopressin in the management of bleeding is not yet clear.[33]

3.2 Foetal complications

As a predominantly autosomal dominant disorder, EDS has a 50% risk of transmission to the offspring. The foetus of a woman with vascular EDS is at increased risk for prematurity (mainly due to premature rupture of membranes), adverse outcome associated with maternal vascular collapse or uterine rupture, compression of a friable umbilical cord, or musculoskeletal abnormalities (pes planus, talipes equinovarus, amniotic bands, etc.).[26] The infants may be small-for-gestational-age, which would be favourable for their mother at delivery.[13,34] Hernial defects and joint luxations may occur. A floppy infant syndrome is a serious complication observed in about 13% of the newborns with EDS. A high incidence of abnormal foetal presentations as breech delivery and face presentation was found in the women with EDS (12%), the highest occurrence was observed among women with hypermobile EDS (19%).[24]

3.3 Anaesthetic considerations

The type of anaesthesia, general, epidural or spinal, and the type of EDS may have a major effect on the risks imposed by anaesthesia during delivery. In some types skeletal abnormalities of the spine may make regional anaesthesia difficult or impossible. Although bruising, bleeding and haematomas are common, no consistent coagulation disorder has been

identified in association with EDS. Nevertheless, the bleeding tendency, although not stemming from a coagulation disorder, can complicate arterial, peripheral, central line and/or neuraxial needle placement.[10] Dolan et al. warned about increased risk of spinal haematoma in parturients with EDS and advised against regional anaesthesia in these patients.[35] However, there are numerous reports in literature of successful use of regional techniques in parturients with classical and other types of EDS, both for labour analgesia and anaesthesia for a caesarean section.[31,32,36] Subarachnoid block (injection of a local anaesthetic into the cerebrospinal fluid) with a small gauge needle (27 gauge) may minimize the risk of bleeding within the epidural space (the space inside the bony spinal canal but outside the membrane called the dura mater), but the finite duration of spinal anaesthesia may make this technique inappropriate as the surgery (and delivery) may be protracted because of bleeding and difficulty in securing haemostasis. Neuraxial techniques using epidural anaesthesia and combined spinal-epidural anaesthesia offer the advantage of extending the anaesthesia for the duration of the surgery and thus avoiding the need to switch to general anaesthesia.[31] It has been observed that patients with EDS may have a reduced response to local anaesthetic agents, particularly in patients with hypermobile EDS.[37,38]
General anaesthesia exposes the parturient to the risk of aspiration and difficult tracheal intubation. Some patients with EDS have an unstable cervical spine, which would make laryngoscopy and intubation hazardous. The hypertensive response to intubation may predispose to vessel wall damage because of the increased intraluminal pressure.[32] If general anaesthesia is selected for these parturients, the airway must be gently managed in view of the possible presence of spine involvement, periodontal disease, propensity for gingival bleeding and oropharyngeal tissue fragility.[39,40] Cardiac function should be evaluated preoperatively and anaesthetic implications considered. Intraoperatively, low airway pressures are needed because of the increased risk of pneumothorax.[37] If possible, spontaneous ventilation is recommended., such as positive end expiratory pressure and pressure support ventialtion.

We can conclude that if bleeding tendency is not extreme, regional anaesthesia can also be used. Caution, however, is necessary, since several patients experienced extension of the regional block beyond the intended level. Provided that general anaesthesia is carefully prepared and monitored, it can be applied. However, preventive measurements have to be taken.

3.4 Conclusion regarding obstetric care

In classical and hypermobile EDS, pregnancy is generally well tolerated, with favourable maternal and neonatal outcome. Women with vascular EDS should be engaged in a shared decisionmaking process when contemplating pregnancy and pregnancy management. Women with EDS are at increased risks for complications during pregnancy and delivery, such as pelvic instability during pregnancy, preterm delivery, postpartum haemorrhage and complicated perineal lacerations.
Since a multi-organ involvement and varied presentations of the disease are noted, no uniform or routine obstetric and anaesthetic recommendations for peripartum care of these patients can be made.
All clinical decisions should be based on knowledge of the specific EDS type. A plan of management should be tailored to each individual patient.

Table 17-1 Advantages, disadvantages and reliability (Pearl index) of different types of contraception

Type of Contraception	**Advantages**	**Disadvantages**	**Reliability % (Pearl index), theoretically-practically**
Condom	Protects also against sexually acquired disease	Discipline, lack of reliability	3-14
Pessarium	Protects also against sexually acquired disease	Lack of reliability	6-20
Progesterone depot	Only 4 times a year an injection	Takes up to a year before normal cycle resumes. Hematoma (injections)	0.3-0.3
Progesterone implant	Reliability	In and out: small surgical procedure. Risk of migration. Scar	0.05-0.05
Oral contraception pill	Less bleeding	Thrombosis risk slightly increased. Discipline	0.5-4
IUCD (Copper)	For 5 year reliable contraception	Insertion, Infection risk	0.6-0.8
IUCD (hormonal)	Less bleeding For 5 year reliable contraception	Insertion, Infection risk	0.1-0.1
Sterilization		*All: ≈ irreversible*	
Female (laparoscopic)	Reliability	Invasive procedure	0.5-0.5
Female (hysteroscopic)	Small invasive procedure (local anesthesia). Reliability	In ±5% procedure technically impossible	0.32
Male	Reliability	Invasive procedure	0.1-0.15

1. Introduction

Ehlers-Danlos syndrome (EDS) is a group of inheritable disorders of connective tissue characterized by connective tissue laxity and fragility leading to hyperextensible skin, dystrophic scarring, easy bruising, and joint hypermobility (see chapter 2).[1] Hypermobile and classical EDS are the most common forms of the disorder; however, they are difficult to diagnose at a young age. Recently, the two conditions benign joint hypermobility syndrome (BJHS) and EDS hypermobility type have been recognized as one and the same clinical spectrum ranging from apparently symptomatic generalized joint hypermobility to the most disabled individuals fitting the new diagnostic criteria. These new criteria are more strict than the Villefranche criteria and the Brighton criteria for BJHS in order to define a homogeneous phenotype for management and scientific purposes. Within the new EDS nosology, its name is hypermobile EDS (see chapters 2 and 5). Children and adolescents possess, compared to adults, an inherently greater range of motion in their joints that gradually decreases as they age. The prevalence of hypermobility in children as a phenomenon, i.e. symptomatic hypermobility, has been measured in a number of studies and, depending on the age or ethnicity of the study population or the inclusion criteria, has been reported to be between 2.3 and 30%.[2,3,4] Such high prevalence rates imply that hypermobility as a measured phenomenon in many children will most often not lead to symptoms requiring medical attention.

However, in a significant number of children, joint hypermobility coincides with adverse symptoms and is associated with other health complaints, which may be harder to recognize and classify, particularly if the health professionals are not aware of the manifestations of the joint hypermobility syndromes in childhood.

This chapter will describe the signs and symptoms of EDS and consider the diagnostic approaches. It will describe current understanding of intervention and supportive approaches at home and school for the child, and will consider future considerations for potential research.

2. Case report

A 5-year-old girl is referred by a general physician to the paediatric rheumatologist because of persisting complaints of fatigue and pain in her legs. In recent years the parents frequently sought medical attention for their daughter because of concern relating to her motor development. She learned to walk late, had a poor coordination, was reported to be clumsy and refused to walk longer distances as she was easily tired. She is reported now to fall frequently and she often has bruises. At children's parties she is the first one who is tired and often has to be collected before the parties are finished. During family outings, the parents need to use a pushchair for her that she physically has outgrown.

Her energy levels vary widely each day; aside weariness and lassitude she fidgets a lot and can show uncontrolled excessive physical activity, e.g. getting up when others are sitting such as at story time. At the end of a day where there may have been a lot of physical activities, she complains of bodily pain and has difficulties falling asleep. At school she refuses to take part in all class activities and requires extra rest time. She is often moody to others and tired, and the teachers have questioned the parents about her behaviour and bruises. Aside these signs and symptoms, she often complains about abdominal pain and has constipation. The child's behaviour causes additional distress within the family.

The parents and the older daughter are healthy. No other family members have joint complaints though her mother was supple and a good gymnast when she was young and her maternal grandmother had diffuse chronic joint and muscle pain and has seen multiple physicians for her complaints. She has been given various diagnoses including osteoarthritis of the hips, knees, sacro-iliac dysfunction and lumbar disk herniation for her lower-extremity

pain. She has had hip and knee replacements at relatively young age and suffers from severe osteoporosis. There were no reported sudden vascular deaths in early adulthood in the family.
Physical examination shows a healthy, timid girl with dark shadows under her eyes. She walks rigidly and undresses slowly and with caution. Her physiognomy, height, weight and blood pressure are normal for her age. She has a smooth, supple and soft skin with several pretibial hematomas but no abnormal scars. On the volar surface of the distal forearm the skin shows some hyperextensibility. Internal physical examination does not show abnormalities. In standing position, joint examination shows an increased lumbar lordosis and a thoracic scoliosis that corrects by bending forward. She stands with hyperextended knee joints, has a valgus position of both ankles and flat feet. Her spontaneous muscle tension is low but during examination she shows normal muscle strength. Joint examination shows hypermobility in almost all joints of the arms and legs; the Beighton score is 6 (range 0-9; hypermobility is defined as a score ≥5 for both sexes) and the Bulbena score is 8 points (total range 0-10; score defining hypermobility is ≥4/10 in men/boys and ≥5/10 in women/girls).
Further specialized examination by the paediatric physical therapist shows that in general, her motor development is in line with her age but that there is a discrepancy between her static and dynamic balance.
Additional laboratory investigation is normal and radiographs of the hips, knees, ankles and feet show no bony abnormalities.
Ophthalmological examination showed no abnormalities and cardiac evaluation including echocardiography for the evaluation of mitral valve and the aortic root was also normal.
Based on the history, including family history, clinical symptoms and additional investigations the clinical diagnosis hypermobile EDS was made.

3. Symptoms of children with EDS

Signs and symptoms of children with EDS are highly variable, can become apparent at any age and may differ between individuals, also within a family.[5,6,7,8] Hypermobility is frequently associated with intermittent pains that occur after bouts of excessive or unusual activity. Children between 3 and 10 years seem to be most strongly affected, because the prevalence of hypermobility decreases with age.[9] Because of the genetic component of the syndromes, other family members are often affected too. The symptoms are complex and seem to be related to the severity of disease. In children with EDS almost all tissues can be involved in the disease, the skin and joints particularly. Among the types of EDS, classical and hypermobile EDS are most commonly seen. One should always be aware of the possibility of vascular EDS since patients with this type are prone to develop life threatening complications. Vascular EDS patients can be recognized by a thin translucent skin with visible underlying vessels and specific facial features (including a thin pinched nose, prominent eyes and lobeless ears). Repeated pneumothoraces or an other organ rupture can also be the initial presentation of vascular EDS, while joint hypermobilitity, in this type of EDS, is mostly limited to the small joints of the hands. The other EDS types such as kyphoscoliotic, arthrochalasia and dermatosparaxis EDS are extremely rare and may present at very young age with severe hypermobility, joint dislocations, skin hyperextensibility, easy bruising, hypotonia and gross motor delay.[10,11,12,13] The symptoms of these latter EDS type patients need to be differentiated from patients with neuromuscular disorders who also may present as “floppy infants”.

In EDS, easy bruising, especially seen at sites not prone to trauma, can be a presenting sign in childhood. It does occur that families of children with EDS have had contact with child protection agencies because of recurrent hospital visits for lacerated skin and concomitant bruising.[14]

The most prevalent signs of the hypermobility syndromes are described per symptom and per age group in respectively table 18-1 and 18-2.

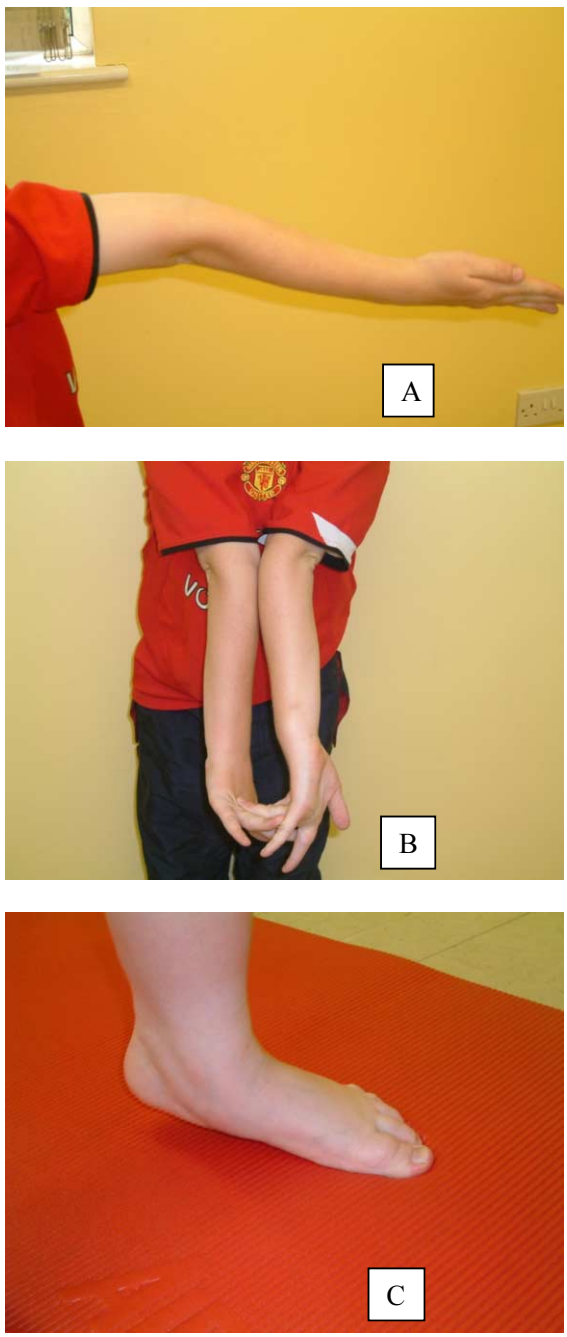
Children and adolescents with hypermobility often “crack” the knuckles of their fingers purposely to feel more comfortable. Most parents are concerned that this activity leads to joint damage. So far, there is no indication that this results in earlier osteoarthritis.[35]
Although hypermobility may enable a child to be a good gymnast or ballet dancer, injures may be more frequent in hypermobile athletes.[36] It is described that hypermobile females show decreased propriocepsis of the knees leading to poorer biomechanical loading and microtrauma.[37] Therefore, having a hypermobility syndrome may argue against a successful professional career in ballet dancing[38] or against strenuous training such as in military recruits.[39]

Many of the signs and symptoms associated with the hypermobility syndromes have a great impact on the daily life of children and adolescents, and interfere with development, family life, school activities, sports, social activities and peer group participation. In young children with EDS, the symptoms may be seen as fractious and troublesome because often these children are not able to clearly express their feelings of discomfort. Awareness of unusual behaviours as a potential sign of discomfort can help the parents, health professionals and school teachers to recognize symptoms and support the children to cope with their frustrations. In older children and adolescents, fatigue, pain, and other inconvenient symptoms may result in development of anxiety, depression or generalized somatic complaints. A focus and appropriate support for psychological symptoms and family distress are essential in the management of these complex diseases.

4. Diagnostic evaluation
The diagnoses of classical and hypermobile EDS are clinical diagnoses, based on the combination of a typical history with signs and symptoms as described above in table 18-1 and 18-2, together with the core clinical findings: joint hypermobility (figure 18-1A, B and C) and soft, fragile and hyperextensible skin. Components of these two are always present but may vary considerably between individuals and the different types of EDS. In patients with vascular EDS loss of subcutaneous fat and skin symptoms are more prominent, whilst in kyphoscoliotic, arthrochalasia and dermatosparaxis EDS, hypotonia and motor developmental delay at very young age aside the cutaneous symptoms may alert physicians to start a diagnostic evaluation for a (inherited) connective tissue disorder.
Musculoskeletal pain is a major problem in patients with significant hypermobility and joint effusions are common in those with recurrent dislocations or instability, especially of the ankles and knees. A family history of hypermobility is common in EDS.[1,2,3,4,5,7,8,40]

In case the diagnosis EDS is suspected, additional investigations need to be done depending on the concomitant symptoms to exclude pathology in other organ systems, e.g. the heart. Children with EDS are at an increased risk for the presence of aortic dilatation or mitral valve prolapse.[41] For most of the EDS types diagnostic tests are available, though not for hypermobile EDS and for around 10% of cases with classical EDS.[7,8] (see chapter 2, 3 and 5)
A comparison of the diagnostic criteria of classical and hypermobile EDS is shown in chapter 2, 4 and 5.

Figure 18-1 Some features of EDS in children



Hypermobility in arms, shoulders, fingers (A and B) and flat feet in a child (C)

The diagnosis of generalized hypermobility is difficult to make in infants and young toddlers due to the general flexibility that all children possess. There are no specific tests to evaluate hypermobility in children or adolescents, therefore the Beighton and Bulbena scores are performed and rated as in adults.[26,42,43] However, it is unclear whether these are the most appropriate measures and specific child based tests need to be developed. In addition to these

hypermobility tests, age specific tests are performed to evaluate motor development. At young age gross motor development is often delayed in the first 2 years, but normal development does not preclude the diagnosis. Thereafter, the results of the motor development test are generally normal but a discrepancy between the static (balance in stable position is normal) and dynamic balance (balance during activity is delayed) is often observed. In addition, children often perform poorly on other motor tasks such as ball skills. Poor handwriting may be related to pain rather than poor control. An example of a diagnostic evaluation procedure is provided in table 18-3.
Recognition of the clinical signs and symptoms of EDS may prevent the burden of unnecessary investigations in children and adolescents.

5. Management
After taking a full history the referring professional should undertake a general physical examination, including assessment of movement and of the skin, and confirm the diagnosis, excluding differential diagnoses such as Marfan syndrome or cutis laxa syndromes.[5] The pattern of difficulties, nature and severity of the problems should be established. With this information a treatment/educational support plan can be designed for the child and the family. Families, school, and if appropriate, employers need to be aware of the condition and appropriate emergency management. This tailored care should be based on the individual patients' complaints and needs.[43]
The first stage in treatment of children with classical and hypermobile EDS is the recognition that the symptoms are significant and relevant to the child, to discuss the diagnosis with the family, and to inform and reassure the parents and the child about the condition. The commonest triggers to see a doctor will be because of pain and/ or injury. A starting point is to explore with the family their current life style and the limitations and difficulties the complaints impose on the child in school and at home. This exploration also includes the limitation and restriction in activities the child's fatigue imposes on the rest of the family.

In order to support the family, it is necessary for them to recognise the pattern of difficulties in their child and to see what triggers (such as prolonged exercise, or writing and poor sitting position in class) additional pain for their child. Some children get into a chronic pain cycle and avoid movement in case of further injury.[17] Providing a personal manual or diary for parents and the child to complete, allows them to map out symptoms and signs and to monitor their improvement or deterioration, and can allow the child to gain some control. The family can then see if there are triggers for injury or pain such as particular sporting activities in school or in the classroom. These observations can act as a focus for discussion with the physical therapist as well as the educational professionals in school where adjustments may need to be made. This can be useful also to monitor an exercise programme.

In addition to above mentioned issues focus needs also to be given to specific considerations depending on EDS type and severity of involvement of the skin, joints and other organs. All patients should be aware of their skin fragility and take adequate measures to protect the skin and contact expert (plastic) surgeons when suturing of any wounds is needed. Surgical procedures must be as conservative as possible due to the complications which may arise when suturing of wounds is needed. In classical EDS, regular cardiology follow-up, including echocardiography, is recommended. In children with vascular EDS, specific information regarding life-threatening risks of blood vessel and organ rupture, which sometimes can occur already during childhood, needs to be provided. In children with kyphoscoliotic, arthrochalasia and dermatosparaxis EDS specific issues may arise because of the rarity of their disease and treatment of the symptoms of the individual patients may be complex.

5.1 Physical exercise

Appropriate physical exercise can offer the child increasing confidence with his or her movements as well as improving motor co-ordination, core-stability and muscle strength.[43,44] However, some children may have given up for example ballet or gymnastics in the past because of increasing pain or injury; then discussion of the type of exercise they like and could do is needed.

Discussion with the family is important to ensure that the child has opportunities to try out, sporting and leisure pursuits that he or she can participate in, and also to encourage social opportunities for integration to limit the risk of isolation. The child may be nervous of participating in sports in school in case of injury, but there remains a need to build muscle strength in order to attempt to prevent future damage. Parents may also be concerned about their child participating and may not encourage exercise, because of their fear of injuries. A psychologist may need to be involved to tease out the family dynamics, especially where for example both parent and child have symptoms and the child is mirroring the parent's symptoms.

A physiotherapist can advise the family about appropriate exercises in order to build up core stability in the child, muscle strength and stamina. Teaching the family how to build a gradual exercise programme balanced by rest and exercise is essential, whereas overuse can lead to complaints or injury. Specific home exercises using a 'Swiss' ball (a large ball that the child can sit and do other exercises on) at the correct size for the child can be used to improve core stability. Additionally, balance or wobble boards can be used. Sports such as swimming, yoga, Pilates, riding a bike and horse riding are also useful to improve stability and stamina. Taking part in sports with heavy joint strains such as contact sports, football, running and weight lifting needs to be discouraged because of increased chances for injuries. Care should be taken with contact sports, particularly when the child is hypermobile in the cervical spine (extension range 90º or more). Also knee injuries and finger injuries do occur more in contact sports and ball sports such as netball.[45,46] Therefore individual non-contact activities are often recommended; however many children prefer team sports. There is evidence that where there is reduced exercise this may lead to reduced stamina and then this becomes a downward spiral leading to reducing function.[47]

5.2 Feet and ankle support and propiocepsis training

Assessment of gait is essential and where there are problems identified correction of the biomechanical abnormalities need to be made. Advice and guidance about footwear should be sought from an experienced podiatrist, and appropriate supports such as arch supports in in soles and heel cups should be considered where there is pes planus. Supportive footwear may be needed if ankles are unstable. By addressing the biomechanics, this can have a knock on effect on gait and position of the other joints and can reduce the hyperextension at the knees.[48] In children with frequent sprains, e.g. in ankles, the initial traumatic cartilage damage can lead to degenerative changes, especially if there is persistent or recurrent instability. Every further sprain has the potential to add new damage. There is reasonable evidence that immobilization is more effective at reducing the time taken to return to sports compared with surgery.[49,50] The supports can be divided according to rigidity into elastic bandage, tape, lace-up ankle support, and semi-rigid ankle support. Functional treatment may involve strapping, bracing, use of an orthosis, tubigrips, bandages, elastic bandages, and the use of shoes fitted with support. In all prescribed shoe devices the fragility of the EDS skin has to be taken into account.

Some children with EDS show poor joint awareness and have e.g. frequent ankle sprains or recurrent hip or knee pain. Propiocepsis training, to enhance joint stability may reduce these complaints. Challenging propriocepsis by making use of unstable surfaces can lead to increased demands on trunk muscles, thereby improving core stability and balance.[47]

5.3 The school environment

Adaptations may be required in school, especially when the child has poor handwriting or pain on prolonged writing or typing. Escalation of symptoms of hand or wrist pain may occur as the child moves through secondary school, as there is an increasing amount of handwritten or computer work for example. The child may be able to cope in the morning but have difficulties in the afternoon. Avoidance of writing and the use of alternative methods of written communication may need to be considered. Use of pen grips may take some of the pressure off, but some grips may act to further destabilise the handwriting and may not be very helpful. Advice from an Occupational Therapist can be beneficial to guide the teacher. Use of an angle board can aid support of the arm and improve positioning for the child and should be tried.

Use of a roller ball mouse to minimise keyboard usage and a laptop or desktop computer can reduce the need for recording. In cases where there is continuing pain, speech to text software may be useful. Children may find they have increased back and neck pain if they are extensively working at a computer, and the table and chair are not at the correct height. Posture and positioning are essential to ensure that symptoms of neck and back pain are not exacerbated. An ergonomic assessment will consider table height, chair height, sitting depth and type of back and arm support. If the child is using a laptop then a laptop stand to position the laptop at the correct height may also be useful.

The child's position in the class may also be important. If the child has to turn excessively when copying from the board, it may be helpful if the child is facing the teacher where possible, so there is less rotation.

Specific lessons may cause the student to have difficulty, such as balancing on stools in the science lab. Suitable seating should be considered to ensure stability. This should also be considered at home doing homework.

The child travelling to and from school should only take with him or her the books needed for the homework, store the others in a locker and use a well-supported 'back pack' to carry the books needed at home to limit strain on any one particular joint and the back. Also the transportation to and from school needs attention whereas travelling can be very tiresome for the children thereby reducing the energy for the school activities.

5.4 Psychosocial support

Some children may have lowered self-esteem and confidence as they recognise they are different from their peers and they have limitations in participation in physical activities in school.[51] In some cases the support from a psychologist using psycho-educational interventions such as cognitive-behavioural therapy can be a useful approach to limit the risk of depression and for the child to gain control over their pain and cope with the limitations in participation.[52] Use of relaxation techniques can also help the child manage their pain.

5.5 Physical support

Local heat or cooling can have a temporary effect to reduce pain. The need to teach the child to pace their day and week is an important aspect of support; otherwise the child may over do activities one day with the consequence of not be able to do anything for several days after that because of fatigue and pain. Hydrotherapy can have a beneficial effect because of pain

relief from warm water, a safe environment to minimise risk of further trauma and can be used to work on multiple joints in a single session. The use of splints and braces have been advocated where there is pain and discomfort to provide a more functional position and to prevent potential further damage of joints.[53] To avoid skin lacerations, young children with skin fragility can wear pads or bandages over the forehead, knees and shins to avoid skin tears. Older children can wear soccer pads or ski stockings with shin padding during activities to reduce bruises or skin problems.

6. General considerations and future research

Little work has been undertaken in educating the educators about this common condition in schools. Some children may have functional difficulties in school that are not addressed or may be mislabeled. Lack of awareness of the condition may result in less support than for more recognized learning difficulties such as Dyslexia or Developmental Co-ordination Disorder. Recognition, early diagnosis and appropriate management of the signs and symptoms of children with hypermobility syndromes will improve their quality of life, coping strategies and future perspectives.

Areas of further investigation include strategies to standardize the classification and assessment of hypermobility syndromes such as age-specific tests. Further research into genes involved in tissue laxity and the impact of specific patterns of difficulties is important as well as the long-term follow-up outcome of musculoskeletal symptoms and associated symptoms in hypermobility disorders. In addition, there is a need to focus some attention on research into the effectiveness of therapeutic interventions in symptomatic hypermobile children and adolescents.

7. Summary

This chapter has highlighted the different presentations of a child with EDS and has demonstrated the different routes to diagnosis. Pain or injury may be a presenting symptom or the consequences of the physical difficulties spilling into education as difficulties in every day tasks such as writing or in participating in age appropriate physical activities. It also has shown the secondary but no less significant psychosocial consequences. Positive recognition and avoidance of unnecessary investigations are the first steps in the management of the children with hypermobility syndromes. It is important to take a holistic approach in supporting the child and planning to prevent injury. As the child moves into adolescence, it is essential that they have a good understanding of their condition and have a voice in their planning.

Table 18-1 Signs and symptoms of children with a hypermobility syndrome: classical and hypermobile EDS

Presenting symptoms[3,4,7,8,15,16,17]	**Clinical signs and symptoms**	**Associated features and remarks**
Joint symptoms	Recurrent knee, ankle and foot pain	Occurs in the evening and at night, often waking the child from sleep, increases after unusual or intense activities
	Frequent falls, problems with gait and coordination	Clumsiness, rigid movements, delay in motor development
	Brief episodes of joint swelling	Can occur after activities and resolve spontaneously within a few days
	Clicky joints	Irritating or painful clicking especially of the mandibular joints, hips, elbows, fingers, shoulders and spine
	Exercise-related pain	Especially anterior knee pain. All exercise related pain occurs within 24 hours after activity. Some children experience pain directly after the exercise, others report pain in the late evening or morning thereafter.
	Recurrent injuries related to sporting activities i.e. joint sprains	Especially at the time where there is increased demand in training and frequency of competition
	(Sub)luxation of joints	Occurs most often in elbows, shoulders or hips[18]
	Pain and fatigue in hand and wrist	Interference with school activities such as handwriting
	Neck- or back pain	Muscle spasm with lumbar lordosis, thoracic kyphosis, scoliosis or spondylolysis; acute pain may represent facet joint subluxation; wry neck or torticollis often occurs[19]
	Temporomandibular joint dysfunction or abnormal dentition[20]	Painful or (sub) luxation of temporomandibular joints. Headaches associated.
	Pes planus	In combination with valgus deformity of the ankles
	Joint stiffness	Joint stiffness most often observed in the thoracolumbar region and after prolonged period of joint pain
Diffuse musculoskeletal pain[7,8,16,21]	Muscle pain	Sometimes development of a pain amplification syndrome
	Pain at muscle insertion sites and bursa	Overuse often results in pain at the enthesis

(continued on next page)

General symptoms	Fatigue	Unable to spend a day with activities appropriate for the age-group without periods of rest or relaxation[3,17, 22]
	Sleep disturbance	Difficulties getting to sleep because of pain[3,4]
	Orthostatic intolerance, lower systemic blood pressure	Abnormal hemodynamic response to prolonged supine or upright position[22,23]
	Acrocyanosis or signs of vascular autonomic dysregulation	Feel cold easily, light-headedness or discoloration of limbs related to changes in temperature or emotions[24,25]
Skin symptoms[26]	Hyperextensible and soft, velvety skin	
	Easy bruising	Bruising may be thought by others to be a symptom of child abuse
	Slow tissue healing and widened atrophic scar formation	
	Pretibial varicosis and bruises	
	Molluscoid pseudotumors at pressure points	Lumps of subcutaneous tissue at e.g. the elbows
	Piezogenic papules on the heels	Small soft tissue lumps that appear at the side of the heel when standing and disappear when foot is elevated
Cardiac symptoms[27]	Aortic root dilatation	In EDS, in the absence of cardiac symptoms or a murmur, it is advised to measure the aortic root size by 5 years of age
	Mitral or more seldom tricuspid valve prolapse	Cardiac symptoms predominantly occur in EDS
Gastro-intestinal symptoms	Nausea, abdominal pain, constipation, encopresis[3,28]	Post prandial regurgitation, sphincter dysfunction
Urinary tract symptoms	Inguinal or umbilical hernia[26]	
	Recurrent urinary tract infection and enuresis[3]	Sphincter dysfunction[29]

Table 18-2 Signs and symptoms per age group in children with EDS

Age group	Signs and symptoms
Newborn	Congenital hip luxation or congenital hip dysplasia
	Congenital clubfoot[30]
	"Floppy infant syndrome" (congenital hypotonia)[10]
	Feeding difficulties with low muscle tone
	Hypermobility of joints (seldom apparent)
	Skin soft and velvet-like, sometimes hyperextensible (lifelong)
0-3 years	Slight delay in development of major motor skills in the first 15 months, normalizing thereafter[31,32,33]
	Pain in the legs at night
3-6 years	Recurrent pain in legs, ankles and feet, during walking and especially at night after a day with physical activities
	Flat feet and pronation of the forefoot
	Endorotation of the knees and feet with stumbling
	Clumsiness and problems due to poor coordination
	Reduced energy levels, inability to relate to activities of the age-group
	Moodiness, "demanding" behaviour
>6 years	Problems with handwriting
	Problems with school activities, sports
> 9 years	Problems with physical challenges in competition
Adolescents	Increase in back pain, increase in lumbar lordosis and thoracic kyphosis and scoliosis
	Anterior knee pain
	Pain in the hips
	Spondylolysthesis[34]
	Increasing difficulty coping with writing tasks

Table 18-3 Diagnostic evaluation form for use in clinical practice

Milestones of motor development		
	Roll-over	5-6 Months
	Crawl	6-10 Months
	Stand alone	9-12 Months
	Walk-supported	10-15 Months
	Walk alone	10-16 Months
Signs of generalized hypermobility syndromes		
	Hypermobility	Yes / no
	Hyperextensibility of the skin	Yes / no
	Easy bruising	Yes / no
	Hypertrophic skin scars	Yes / no
	(Sub)luxations	Yes / no
	Positive family history	Yes / no
Beighton hypermobility score*[26]		
Bulbena hypermobility score[42]**		
General evaluation		
	Motor development	Delayed / according to age/ advanced
	Muscle tone	Hypotonic / normotonic / hypertonic
	Muscle strength	Decreased / normal / increased

* The Beighton score (see chapter 2) is used both in children and adults to assess 5 different joint performances with a maximum score of 9. A total score of 5 is the minimum score defining joint generalized hypermobility. For hypermobile EDS, age and sex related cut-off points are used (see chapter 2, table 2-5).

** For the Bulbena score (see chapter 2), a total score defining generalized hypermobility is ≥ 4 in men/boys and ≥ 5 in women/girls.

1. Introduction

Ethics is a branch of philosophy that involves thinking about human acts and asking questions about the moral rights and/or wrongs of those acts. There is no single theory of or approach to ethics. Ethical theories reflect the time and cultural setting in which they came into being. The approach one chooses has a great impact on one's view about what is ethically right or wrong. In this chapter, the Ethics of Care will be the framework for reflecting on the ethical dilemmas related to living with generalised hypermobility or Ehlers-Danlos syndrome (EDS). Ethics of Care is an approach that focuses on the phenomenon of care. Care can be viewed as everything we do to maintain, sustain and repair our world so that we can live in it as well as possible.[1] Ethics of Care focuses on the way people try to find out what is good in specific conditions and circumstances. It does not look for generalisation of normative standpoints, but focuses on the particularity of situations, is suspicious of power relationships with regard to dependent people, accepts vulnerability as a universal human characteristic and conceives human beings as inherently relational beings who need each other to be happy and to flourish.[2]

EDS confronts people with ethical problems that may be related to different life stages. In this chapter we will look at these dilemmas and try to find out if there are any opportunities related to that specific stage of life or to a specific personal character and how these can be found. This will empower people so that they can pursue 'the good life, with and for others, in just institutions'.[3]

2. Ethical dilemmas in parenthood

The technological possibilities in our society have caused a tendency towards rationalisation. This is especially true for health care, which confronts people with dilemmas even before they give birth to their child(ren). If people want to have a child, they usually hope to give birth to a mentally and physically healthy child. People with EDS who wish to have children bear a special responsibility as the aetiology of EDS is genetic (see Box 19-1 for reproductive options for parents-to-be in case of a genetic disorder). They know they run a 50% risk of giving birth to a child with EDS, assuming the given EDS type is inherited in an autosomal dominant way. The child they will give birth to may (eventually) suffer from the same type of EDS, though the severity of the symptoms may vary. Furthermore, the child is at risk of losing its mother during or shortly after delivery if she suffers from vascular EDS.

Box 19-1 Reproductive options for parents-to-be in case of a risk of having a child with a genetic disorder:

- Acceptance of the risk
- Refrain from having own children
- Non-acceptance and prenatal diagnosis and termination of pregnancy when affected
- Non-acceptance and pre-implantation genetic diagnosis
- Non-acceptance and germ cell donation
- Non-acceptance and adoption

At the start of a life, people really do not want to think of this when it comes to their newborn child. But also if people suffer from an EDS type other than vascular EDS or from generalised hypermobility, the delivery of the child and taking care of it may still be problematic. People suffering from hypermobile EDS and generalised hypermobility usually have very mobile joints and ligaments. This may cause severe perinatal problems for the mother, like (sub)luxations. One of the problems of this EDS type is that the joint hypermobility may worsen due to the hormonal changes during pregnancy.[4] This may cause more or less severe

problems for the mother, which may hinder her ability to take care of herself and her newborn child. Therefore the question may arise: why should people take those risks? Would it not be better for people to stop thinking about having a child if one of the parents is suffering from EDS?

From an Ethics of Care perspective, questions like these do not make much sense. It is important to look at the situation from the perspective of the people involved in order to discover what is at stake for them. There is a possibility parents do not even know that one of them has EDS. Patients are not always aware of having the syndrome, due to the wide variety of phenotypes and the varying degrees of severity. E.g. luxation of the shoulder joint, can happen to anyone. The same can be said about ligament distortion. This will only raise questions if it happens frequently and/or it happens also in close relatives. People may not be aware of the fragility of their body, especially when they do not take part in sports (very often), particularly if they suffer from mild EDS. Vascular EDS may be even more complicated: incidentally, people with vascular EDS hardly experience problems until they reach the age of 40. So, not infrequently, people have made their important life choices, such as having children, before they find out they are suffering from a type of EDS. In this case, the next generation will have to deal with the ethical dilemma of making a responsible choice, which may be a heavy burden.

2.1 Motivations

People suffering from EDS who nonetheless choose to give birth to a child, even though they are aware of the risks and consequences, mention a variety of reasons as to why they make this choice (see Box 19-2 for factors playing a role around these decisions).

Box 19-2 Factors playing a role in deciding whether or not to have a child, when parents-to-be are facing a risk of having a child with a genetic disorder:

- Strength of their child wish
- Magnitude of the risk
- Severity of the genetic disorder
- Family composition
- Their ethical/religious norms and values
- Acceptability of prenatal diagnosis and termination of pregnancy
- Acceptability of pre-implantation genetic diagnosis
- Acceptability of germ cell donation
- Socio-economical context
- Legal context

One of these reasons is that they find themselves capable of living a meaningful life, so they expect their children if they also have EDS, to be able to do the same. According to them, thinking your child will not succeed in this, means you are raising it without hope or trust. According to this pessimistic point of view, no child would flourish, regardless of whether they have an illness or not. Parents also suppose that their knowledge of and experience with EDS will benefit in helping their child(ren) with EDS to create its/their own opportunities in life, better than non-EDS parents would be able to do. That could be one of the reasons why, although for most EDS types (not hypermobile EDS) prenatal diagnosis is possible, when the pathogenic mutations are known (see chapter 2), in our experience few parents-to-be, who are facing a risk of having a child with EDS, opt for prenatal diagnosis.

They motivate their choice to become parents by pointing to the fact that all children are at risk of diseases and that people accept them as being unavoidable. ‘Why would I be so afraid

of a known risk?' They say that they themselves, unlike most parents, are highly aware of the risks of starting a family, which allows them to be better prepared to handle certain consequences. The stories of these parents show their remarkable faith and acceptance of their limited abilities.
There are also individuals with EDS who, when the woman is affected, decide that based on the many limitations in their daily life, pregnancy would be too much of a burden. Thus, there will also be parents who among others based on the magnitude of the risk to have an affected child, the severity of the EDS as they have or perceive it, decide to refrain from having own children. They still have some options (see above). Adopting a foster child is such an option, which of course is only available to those who are aware of their limitations and handicaps and have the emotional and physical strength to guide this foster child, who often has had a bad start in its life. Although the law does not prohibit irresponsible choices to reproduce, it can be difficult for EDS patients to persuade government institutions of their parental potential and to put parenthood into practice by becoming foster-parents. Difficult as it may be, it is possible and might be the best option in some situations. But there will also be parents who refrain from having children at all whether own or adopted based on their own situation and maybe other factors.

2.2 Different norms and values

Thus far, we have spoken of three different scenarios regarding impending parenthood. Each of these scenarios expresses various norms and values, which sometimes overlap. For those who take their own life as reference-point (the first scenario described above), equality is an important value. 'Because life with its serious limitations is still valuable for me, it must be possible for our child to achieve the same.' In that way, their life vision speaks of trust as an important value, and the fact that their child is not yet born does not make any difference to them. As well as equality and trust, there is in this scenario an acceptance of the vulnerability and imperfection of human life, which we all share to a certain extent. Being connected and related to one's own child and sharing a life together is seen as being more important than giving birth to a perfect baby.

For the second scenario, the parents take EDS as being one risk out of many. Equality is also important for them, but here this value is seen more as equality in life, understood as an experienced adventure, an adventure we share with every human being. In this belief system the awareness of the undeniable fact that life and its consequences are beyond the control of human beings, has been transformed in values like: 'trust', 'hope', 'endurance' and 'forbearance'. These all have to be earned along the path of life. For them, life, handicapped or not, is no more special than it is for other people. Also in this scenario, being connected and related to one's own child and sharing a life together is seen as being more important than giving birth to a perfect baby.

In the third scenario – the couple who will not give birth to a child themselves although they have a strong desire to have a child – the stress on rationality in autonomous decision-making is a central value. In this case, the values of 'trust' and 'hope' do not temper the awareness of their limitations. They are aware of their burdens and their reduced load capacity and make the decision that it would be wiser not to overload themselves by going through a pregnancy/delivery with all the short and long-term complications. Some of these people experience severe limitations in their daily life and they do not want to be responsible for knowingly creating the same life circumstances for their own child. Trust and hope may be valued by them, but these values are expressed in their opinion that their lives will be of value even if their wish of a child of their own is not fulfilled. They trust that they will come to a

point where they have overcome the grieving for their unfulfilled wish and can have a new life framework without a child of their own, maybe in the role of foster-parents.

We have seen that values differ and that, even if values seem similar at first glance, they express different belief systems. Here we do not cling on to right or wrong along the lines of one specific ethical theory of human life. People make their own choices, seen in our western society as the expression of autonomy, a very – perhaps even the most – important value. But does that imply that there is nothing we can say about the three stories? Can we perhaps learn something from the experiences of others?

2.3 Risks and problems

Let us think of the risks or problems that may easily be overlooked in these stories. Our first group of parents experiences life as meaningful and worthwhile, irrespective of its limitations. Can they really think about their newborn child dispassionately? Will this child be allowed to be angry about living with a handicapped father or mother and will it be allowed to conceive life , as a worst case scenario, as unbearable and hopeless if itself is handicapped too? Will these parents be able to handle this reaction of their child, recognising it as a phase which they have already had to struggle through themselves and which their child can also overcome with their love and help? Or are these parents in denial of their own feelings about their limitations, expecting that their child will develop the same denial? Are they afraid of their own jealousy which is connected with life itself, and even more so if they are handicapped themselves and have to deal with seeing other people dancing, running and not always struggling with a lack of energy and with pain? If this is the case, their values would operate as a shield against their indigested psychological distress about their illness. It will be very difficult for them to guide their child through the phase of mourning, because their child might be dealing with its handicaps by mourning actively instead of denying its feelings like its parents do.

Life is uncontrollable for the second group of parents, so they can set the EDS to one side. Although their lifestyle can foster their child's inner powers to behave just like others and not to mystify a handicapped life, this child stays at risk of carrying too heavy a burden. 'You are like everyone else so don't worry and get a life' A child in this position might not only compensate but take the risk of overcompensation, preferring short term gains over long term benefit. Children with EDS can often do the same things as other children of their age but they may be physically hurt easily, because their condition makes them easily tired, their joints are so flexible and their skin so fragile. Once hurt, they will have to rest. This rest reduces muscle power, which in turn heightens the risk of new lesions. So, in a short time they might become imprisoned in a vicious circle that can easily convert into a downwards spiral.

As said earlier, people may be unaware of their own genetic problem until labour and/or after the birth of their affected child. Sometimes the baby is a typical 'floppy child'. There is little or no muscle tone. In the worst case, the child will never start crawling. However, eventually most of these children will succeed in crawling and walking, although often later than other children of similar age. Depending on the type of EDS, parents must be aware of different problems. If it is EDS with skin problems, like in classical EDS, they will need to be very careful with everything which puts the child at risk of skin damage. Their child can do fewer of the things a normal healthy child would do and which will give great joy, like bumping, crawling, jumping and running around wildly. These active explorations will readily lead to first aid in a hospital, with a nasty open wound and the possibility of a need for plastic surgery.

These physical wounds are visible but, again , it is the job of the parents to choose between the risk of physical wounds and the risk of psychological wounds or emotional damage to the child. Children do not like special treatment and normally they want to play without getting into too much trouble, so it is up to the parents to find a balance between the pro and cons.

A child with spontaneous joint dislocations or luxations needs a lot of guidance to optimise its muscle power and proprioception. Sometimes, guiding this process will demand so much of the parents' energy and medical knowledge that they are forced to make a difficult choice between regular and special school education. Do you have to train your child as much as you can, while without this, it can play with children who are also limited in their play by their own physical problems? And do you hope that, with this stable physical and mental basis, your child will develop into a strong and assertive adult? Or does it work the other way around? Is it better to opt to treat the child as being as 'normal' as possible, which would mean letting it grow up among fully physically able children so that it can learn to survive from the beginning in a world that is often not well adapted and even not accessible to the disabled?

There are arguments for both ways of reasoning. The most important thing, however, is not to idealise a certain vision or to try and find universal rules. Instead of looking at the impact of the illness on daily life, we have to consider carefully the possibilities and limitations of the specific child. A very social and outgoing child will survive more easily in an unadapted environment, or one with few adaptations, than a more introvert child.

Another very important factor is how much the parents can bear. A child at regular school needs a lot more guidance and support, improvisation (e.g. a resting place at school and planning of medical visits), and explanations to teachers and other children than healthy pupils do. Physiotherapy and adaptation of braces and other medical equipment (like a wheelchair, if necessary, and so on) require visits that have to take place after school. Children grow quickly during their school years, so the necessary changes in medical equipment often seem endless, and so do the bureaucratic procedures stemming from these changes.

Apart from this, the role of a parent is also burdensome for another reason. When your child is easily wounded or has a lot of spontaneous dislocations that require medical treatment, the frequent visits to the emergency department of the hospital can start to raise suspicions, not least about the parents themselves. And to make it worse, parents can become suspects of child abuse, not just in hospital but also at school. Although it will not take away the suspicions at the emergency department, such suspicions can make life much more difficult and encourage a choice for a special school.

3. Living a (good) life with EDS

According to an influential definition by Joan Tronto and Berenice Fischer, "caring can be viewed as a species activity that includes everything we do to maintain, continue and repair our world so that we can live in it as well as possible. That world includes our bodies, ourselves, and our environment, all of which we seek to interweave in a complex life-sustaining web".[1] The healthier and richer people are, the less time they will be forced to spend on caring for themselves and the more they can get others to care for them, up to what Tronto has called 'privileged irresponsibility'.[1] People suffering from EDS are not among those privileged irresponsibles as we have seen in the previous section. Being confronted with EDS means being called to care for oneself and being responsible for those who are part of one's complex life-sustaining web.

This life of care – for oneself and others – is an ethical enterprise through and through. Ethics is not an activity we only need when the course of normal life is hindered by unexpected problems or dilemmas. The ethical intention aims for "the good life, with and for others, in just institutions".[3] This good life is nothing other than a happy life; happiness being not just a feeling or sensation of wellbeing, but a flourishing of one's capacities and possibilities. This search for happiness is a social activity – hence with and for others – within the context of a society that is built on structures that transcend and contain relationships among individuals – hence the "just institutions". For instance, people with EDS can still flourish in their professions, experiencing their professional work as an important aspect of living a meaningful life, while at the same time they have to be looked after by a nurse in their daily lives. It all depends on the balance between the strengths and weaknesses of the patients and the willingness of the social system around them, whether this is possible or not.

When we look at ethics in this way, a new perspective opens up. Underneath the moral dilemmas related to the choice by people suffering from EDS to have children or not, we see people struggling to lead a good and happy life in a society that is not ready to accept the vulnerability of human existence. This struggle is hallmarked by practices of caring for one's fragile body and for those who are helping one to sustain a life with EDS. From this ethical and caring perspective, people living with EDS are entitled to ask some critical questions to the society they live in and about how their care is organised.

3.1 Holistic approach

A main critical question raised by people who live with EDS pertains to the tension between general and specialist medicine. Human existence has many dimensions – physical, psycho-social and spiritual – that are intrinsically related and together form what we describe as a human being. Medicine, however, still focuses on diseases and syndromes rather than on beings.[5] In the case of EDS, this means that patients are often treated by many different care-givers, many of whom are specialists. Even though this division of care into specialisms may be understandable from the perspective of professional caregivers, from the patient's perspective it leads to a reductionist approach, which is time-consuming and adds extra burdens to lives that are already burdened by so many inconveniencies.

The fact that we have organised care as it is now, and the ever-increasing specialisation in medical science, are not facts of nature. They are the result of human action and have an ethical dimension. In fact, they are the result of medical power which is so accepted and self-evident in our culture that it often hinders our capacity to look at things differently. Adopting a patient's perspective would do more justice to the person who is at the centre of care: the person suffering from EDS who is not an object to be looked after but a human individual who is both being cared for and caring. A holistic approach would not only entail an approach in which not only the physical, psycho-social and spiritual dimensions are integrated, but also an approach in which the patient is co-carer and involved in shared decision making. At the same time it would make sense to appoint a consultant medical specialist – one who is familiar with EDS – as a case-manager to help streamlining the medical processes.

3.2 Vulnerability

EDS like any disease can confront us with the vulnerability of human existence. This vulnerability is one of the things our society has great problems with, since it is associated with an unpleasant and unhappy life. The cases we have described above show that, even in vulnerable positions, people often find possibilities of developing resilience and an art of living with fragility that will open up new horizons. Confronting EDS thus questions many "self-evident" suppositions. It helps us to see that life can still be worth living, even if it is

compromised by the prospects of increasing morbidity and fragility. Instead of fighting and/or hiding vulnerability, vulnerability may be accepted as a fact of life which is helpful in overcoming self-centeredness and isolation. It forces us to reach out to our environment and share our humanity. This is the very essence of the relationships and friendships that help us to experience life as a meaningful enterprise.

3.3 Dependency

People who are faced with EDS can be confronted with their own dependency. Living with EDS increasingly means accepting that you need other people to make (social) life possible. That means that people living with EDS are forced into developing a new sense of autonomy. The concept of liberal autonomy as a value according to which people get to lead their lives how they want to (related to the privileged irresponsibility mentioned above) is redefined into a more realistic kind of relational autonomy. It is still the individual person to whom justice must be done, by granting them the maximum of space and freedom. But this space and freedom is constituted by the relational network of people around the patient. EDS affects not only the life of the person suffering from the disease, but also the lives of all those people who are related to and sustaining that person in a web of relations.

The need for a holistic approach, dependency and vulnerability reveal dimensions of human existence that are present in every life, but come to the fore more clearly in the case of EDS. In this way, confronting EDS is confronting aspects of life that our culture often hides or denies or classifies as being confined to the elderly. Patients with EDS can live like the elderly for a very long time – even for decades – and, because of the burden that this can impose, not all patients wish to live to a great age. Non-treatment decisions or a desire for euthanasia can materialise and must be treated with care and compassion. However, the Ethics of Care perspective can help reveal these aspects and encourage ethical reflection. This reflection is not just needed when moral dilemmas are at stake or emerge. Ethical reflection should begin at the very moment we start thinking about care. In this way ethical reflection can help to develop a richer and more diverse view on living a meaningful life. People suffering from EDS, their next of kin and their caregivers would benefit from such a reservoir of meaning.

1. Case: Michelle

Michelle is 34 years of age. She was raised in a farming family and had a generally positive and supportive childhood. At the age of 18, she moved to the city to attend university. For the past ten years, she has been happily married and has 2 young daughters. She has long realized that she has very flexible joints, and she regularly dislocated her fingers, but she was not that concerned and did not consider it to be a disorder. Two years ago, however, her situation worsened when she dislocated her shoulder while playing tennis, and the subsequent operation left her with various complications. The surgeon referred her to other specialists, and while still in the hospital, Michelle was diagnosed with Ehlers-Danlos syndrome (EDS). She was mostly pleased to learn of this diagnosis, because it explained her frail joints as well as the pain and fatigue that had been interfering with her functioning at home and work during the past few years. These symptoms had been invisible, but now others could understand why she had not been feeling well or functioning optimally. Michelle also was thankful that the hospital physiotherapist helped her learn to use her joints in the appropriate way and manage dislocations.

Lately, however, Michelle has become somewhat depressed and worried. She has come to realize that having this disease could greatly change her life. Although she has many abilities and loves her work, she fears that she will not be able to fulfil her high ambitions. She had always been able to hike in the mountains while on holiday, but this has become more difficult, and in the near future, she expects that she will no longer be able to walk even the easy trails. She needs to change so many things and is anxious that her condition will become dramatically worse in the future. She is also worried that her children have EDS and she needs to remind herself to avoid raising them too cautiously or fearfully. Although she expects that her optimistic nature will finally help her to deal with the consequences of EDS, a psychologist might help her with her current negative mood, and she is considering seeking cognitive-behavioural therapy.

2. Introduction

Connective tissues maintain normal bodily integrity, but when connective tissues fail in this role, multiple problems occur. EDS is a heterogeneous group of heritable connective tissue disorders characterized by articular hypermobility, skin extensibility, and tissue fragility.[1] This disorder is chronic, varies in severity from mild to very serious, and can be lethal. Hypermobility syndromes featuring joints that easily move beyond the normal range expected for a particular joint, are a threat to well-being and functioning. What is said about EDS in this chapter mostly applies to hypermobility syndromes as well.

Recently, the two conditions benign joint hypermobility syndrome (BJHS) and EDS hypermobility type have been recognized as one and the same clinical spectrum ranging from apparently symptomatic generalized joint hypermobility to the most disabled individuals fitting the new diagnostic criteria. These new criteria are more strict than the Villefranche criteria and the Brighton criteria for BJHS in order to define a homogeneous phenotype for management and scientific purposes. Within the new EDS nosology, its name is hypermobile EDS (see chapters 2 and 5).

2.1 Burden of EDS

The psychosocial burden of EDS is substantial[2-4], and can be summarized by the central theme of "living a restricted life".[5]

First, EDS is a relatively rare condition, which means that the diagnostic process is often protracted and confusing, and that healthcare providers often have insufficient knowledge of the medical problems and the possibilities for treatment and care.

Second, people with EDS have fewer opportunities in daily life than healthy people. For example, pain, fatigue and other symptoms hamper functioning, and people with EDS may fear articular dislocations or skin damage, which further limits activities.
Third, patients may experience invalidation, or stigmatization and lack of understanding from family and friends, health care providers, co-workers and others in daily life.
Finally, given the heritable nature of EDS, the pros and cons of parenthood are often evaluated, and decisions to refrain from childbearing can be highly disappointing.
Psychological evaluations and interventions for patients as well as their families are vital to help them cope effectively with this disorder.[6] Self-care, counselling and therapy are directed at both the prevention and treatment of adverse consequences. Because most bodily organs have connective tissue potentially affected by EDS, multiple bodily system problems can occur, and virtually all medical and allied disciplines play a role in education and treatment.

2.2 Aim

The aim of this chapter is to review the somatic and psychosocial consequences of EDS; that is, the effects of EDS on physical, psychological, and social well-being and functioning. Somatic problems, psychological distress, and social functioning are reviewed, and suggestions for coping with these problems in everyday life are given. We base our discussion and recommendations on the relatively few empirical articles on psychosocial functioning in EDS, supplemented by our knowledge of experiences of individual patients, and our knowledge of the somatic, emotional, and social consequences of chronic disease more generally.

3. Somatic problems

In a Swedish survey using the Subjective Health Complaint Inventory (SHCI), 99% of 250 participants with EDS reported health complaints with a mean number of sixteen complaints for the whole sample.[7] The somatic problems reported most often were musculoskeletal by 246 (98%), pseudoneurological by 241 (96%), gastrointestinal by 236 (94%), allergic by 182 (73%) and influenza-like by 144 (58%) persons. These specific somatic problems as well as those of vascular EDS are discussed in other chapters of the book. In the current chapter, pain, fatigue, joint dislocations, fragile skin, and sleeping problems are discussed.

3.1 Pain

In a questionnaire survey of 41 patients with EDS, 63% of the patients reported relatively elevated pain (above the scale mid-point), and only two patients reported having no pain.[8] Another study used structured interviews of 51 patients with EDS and found that 90% experienced pain for at least six months.[9] In a larger questionnaire study among 250 patients (contacted through the Dutch patient association for EDS), pain during the past week was reported on a 0 to 100 mm visual analogue scale (VAS), 100 being the maximal level of pain: 29% of the patients reported pain between 0 and 25, 24 % between 25 and 50, 28% between 50 and 75, and 18% between 75 and 100.[2] Of this sample, 41% reported chronic, widespread pain; that is, pain existing for more than three months in the upper and lower, left and right, and axial parts (i.e. spine) of the body. Of the respondents, 55% commonly used analgesics—mostly paracetamol (acetaminophen), non-steroidal anti-inflammatory agents, and tramadol. One study found that pain is more prevalent and severe in hypermobile EDS than in classical EDS, and that pain is associated with hypermobility, joint dislocations, previous surgery, poor sleeping quality, and functional impairment in daily life.[10]
Thus, pain clearly is a prevalent problem in EDS, and has consequences for well-being and functioning. Reduced well-being and functioning, in turn, may contribute to the persistence and severity of pain. Education and self-management techniques likely can help to address

relatively low levels of pain, but more serious pain should be treated in cognitive-behavioural therapy (for explanation, see Box 20-1) and physical rehabilitation programmes. Such therapy is especially indicated if pharmacological treatment is ineffective to deal with pain and its consequences.

Box 20-1 Cognitive-behavioural therapy
A main premise of cognitive-behavioural therapy is that negative, dysfunctional thoughts have a perpetuating role in health problems, and that people need to learn skills or techniques to change their thoughts and feelings. Cognitive-behavioural therapy is directed at reduction of symptoms like depression, anxiety, pain, and physiological responses by changing maladaptive thoughts and actions. Examples are interventions with one specific aim—for example, relaxation, stress reduction or overcoming of fear-avoidance beliefs to support an exercise intervention and, more commonly, the incorporation of various methods—for example, cognitive restructuring of dysfunctional beliefs or "worry" thoughts, pain coping skills training, activity pacing, stress management training, relaxation exercises, exposure to anxious situations, thoughts and worries, and positive self-talk.

3.2 Fatigue

The survey of Dutch patients with EDS asked respondents to note the five most serious symptoms or problems of EDS.[2] Fatigue (64%), pain (54%), skin fragility (33%), and problems with the back (29%), wrist, hand, and fingers (27%) were mentioned most frequently. It is striking that so many patients reported fatigue among their five most serious problems. This survey also compared general fatigue scores in 250 patients with EDS to those of healthy people from the general population using the Multidimensional Fatigue Index.[11] The occurrence of 'general fatigue' above a specified cut-off point was five times larger for patients with EDS than for people in the general population.[2] A similar survey of 274 Dutch patients with EDS, which was conducted five years later in the same population, found that 77% of the patients reported severe fatigue as compared to 11% and 17% in two predominantly female samples of the Dutch general population.[12]

One possible way to address the elevated fatigue experienced by so many patients with EDS is to identify specific patient and disease characteristics that contribute to fatigue, and to change targeted lifestyle behaviours. For example, it has been proposed that aerobic fitness or strength training to deal with muscle weakness, or using weight management techniques to reduce obesity to treat sleeping apnoea, might be useful approaches to reduce fatigue in joint hypermobility syndromes.[13] Unfortunately, the physiological origins of chronic fatigue are unknown, and there are no effective pharmacological treatments. Thus, although fatigue is indisputably an adverse consequence of EDS, it is most sensible to consider behavioural means, such as life-style adjustment and cognitive-behavioural, physical exercise, and sleep hygiene interventions.[14]

However, the effects of such behavioural interventions have not been investigated in EDS. Caution is needed; for example, physical exercise programmes need to take account of possible joint dislocations as potential complicating factors. Moreover, to enhance their sense of vitality, patients will need to find a balance between physical effort and rest. Some patients may avoid all physical exercise to prevent pain and fatigue, but this will promote physical deconditioning. Other patients may persist in exercising despite pain and fatigue and stop only when pain or fatigue are extreme. However, this may over time result in dramatically reduced physical activity, as stopping exercise is stimulated because it takes away pain. Often a gradual build-up of the intensity of physical activity is important to prevent relapse. As in other chronic symptomatic conditions, activity-rest cycling can be valuable, with patients finding the optimal timing of activity and rest. A predetermined activity duration—rather than

pain or fatigue—should determine the timing of the rest-activity cycle. More generally, some patients will need encouragement to exercise, whereas others will need to learn to stop exercising in time.

3.3 Joint dislocations

In some forms of EDS, from 90 to 100% of the patients, report hypermobility of the joints[15], but the severity of joint problems differs considerably among individuals and EDS types. Joint problems hamper work, sports, and many other important daily activities. Patients need to find an optimal balance between living passively to avoid joint dislocations and a more active - but risky - lifestyle, which can trigger joint dislocations. The challenge for patients is to learn to use their body without pushing their joints beyond their limits. Most patients learn this through trial and error. It is important that patients do not avoid physical activity, but instead use assistive technology, adaptations at home and at work, and aids such as braces and appropriate shoes to remain physically active. Fellow patients, rehabilitation physicians, and occupational therapists can help the patient to find adjustments that help in optimal functioning.

3.4 Fragile skin

Fragile skin is a problem in 40% (hypermobility EDS) to 100% (classical EDS) of the patients with EDS.[15] Wound healing may be problematic, and wide, ugly scars may result. Our society values beautiful skin, and physical appearance is important not only for self-esteem but also for interpersonal communication, especially first contacts. Patients can try to prevent skin damage by wearing appropriate clothes and by avoiding risky situations. In case of wounds, appropriate care is important. In serious cases, wound care nurses, dermatologists, or plastic and reconstructive surgeons can be helpful.

3.5 Sleeping problems

The prevalence of sleeping problems in EDS has rarely been studied. In a small sample of nine patients with EDS, five reported sleeping problems, and six reported periodic limb movements.[16] In contrast to this seemingly high prevalence, the Dutch survey of 250 patients found that only 4% reported sleeping problems as among their top five most common problems, but this report is likely biased by the method of requiring patients to pick a maximum of five major problems.[2]

Potential sleeping problems should be assessed in patients, and if present, differential diagnosis of the aetiology of the problem should be pursued, because treatment for sleeping problems should preferably be aimed at the cause. In the differential diagnosis, sleeping apnoea has to be taken into consideration, because as soft tissues weaken by becoming older, especially in EDS patients sleeping apnoea can become an extra problem.

Sleeping medication is generally not recommended for patients with EDS because of the resulting muscle relaxation and the ensuing increased risk of joint dislocations. Insomnia can be treated with stimulus control therapy, relaxation training, and cognitive-behavioural therapy.[17] Such interventions may include techniques such as avoiding the consumption of coffee, alcohol, and heavy meals within several hours before sleep; making the bedroom dark, comfortable, and quiet; using the bed only to sleep (and for sex), thus not for reading and watching TV; having a regular pattern of effort and rest throughout the day as well as a fixed sleeping time; and - if needed - using stress-reduction, relaxation or thought-stopping techniques. Insomnia can also be treated with sleep restriction therapy, which reduces the patient's time in bed to the total number of hours of sleep that is being obtained, and forces patients to be up and out of bed when not sleeping; as sleep efficiency increases, the sleep period can be lengthened.

4. Psychological well-being

Psychological well-being is a core indicator of quality of life. The severity of one's disease influences psychological well-being, but it is only one factor, and the relationship between disease severity and well-being is weak in most chronic diseases.[18] Coping, resilience, emotional and social factors play larger roles in adaptation and well-being.

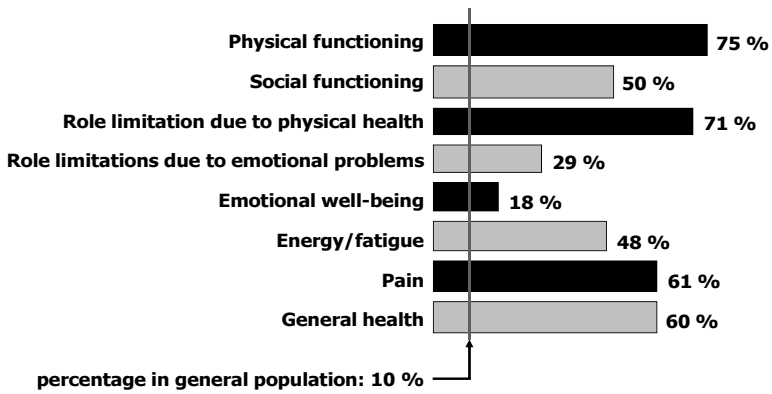
4.1 Emotional consequences

Negative emotional consequences of living with EDS are common. Interviews show that some people with EDS live with constant fear of skin damage, physical deterioration because of hypermobility, unemployment, and problematic pregnancies.[5] Patients with joint hypermobility syndrome present with greater prevalence of panic disorder and agoraphobia.[19,20] Parents who have children with EDS, live with the fear that authorities, medical personnel, or others will suspect them of bad parenting or abuse when their child presents with a joint dislocation or bleeding[21], and even if no accusation are made, parents may still sense suspicion.[5] Another problem mentioned in interviews is the reduced possibility of developing one's abilities.[5] The great effort needed to achieve something substantial in education or work is often not possible in case of EDS. This especially holds for people with vascular EDS who often know at a young age that, although new medication has improved the prognosis, their life expectancy is shortened, which has implications for important life choices in education, work and family planning; and can impede life satisfaction.

A questionnaire study of 41 patients with EDS from North America found that anxiety, depression, anger and relationship worries were quite high.[8] Indeed, these problems were seen three to four times more frequent than among the general population. Interviews of these patients revealed that patients attributed their emotional problems to chronic pain, impaired task performance, reduced social contacts, sexual problems, worries about having children, and frustration with the medical system. Of the 41 patients, 56% had had psychotherapy, and 46% (had) used antidepressants or anxiolytics. These estimates of emotional difficulties in EDS may be relatively high, probably because this sample was recruited for a special research study that likely attracted very motivated or distressed patients from across the continent.

The Dutch survey showed less emotional disturbances among people with EDS than did the North American study. In analyses using the RAND SF-36 questionnaire, the cut-off defining unhealthy functioning was set at the 10th percentile of functioning of the general population.[2] According to this admittedly arbitrary criterion, 10% of the general population shows poor functioning on a dimension of quality of life. Among patients with EDS, the percentage of poor functioning on emotional well-being was 18%, whereas 30% reported experiencing role problems secondary to emotional disturbances (figure 20-1). Overall, the risk of poor emotional well-being was twice as high as normal.

Figure 20-1 The percentage of 250 patients with Ehlers-Danlos syndrome having a low score on eight aspects of quality of life *



** The criterion for a low score was set at the 10th percentile of the general population. According to this criterion, 10% of the Dutch population obtains a low score on the RAND SF-36 questionnaire.[46]*

4.1.1 Depression

This Dutch survey also included the Zung Self-rating Depression Scale.[22] The scores were compared with scores of a healthy control group (although this is not reflective of the general population, because patients with a chronic disease were purposely excluded). As compared to this healthy group, 48% of the patients with EDS were classified as having a depressive mood if the 10th percentile of the control group was taken as cut-off criterion.

The approach to treating depression should depend on its severity. Antidepressant medications and more extensive psychological therapies, such as long-term cognitive-behavioural therapy, are recommended to treat depression after simpler methods (e.g., guided self-help or exercise) have failed to produce adequate responses. Combining pharmacotherapy with evidence-based psychotherapy typically provides a modest increment over either treatment alone.[23,24] In both severe and mild depression, mental health specialists, particularly clinical psychologists and psychotherapists, should provide cognitive-behavioural or interpersonal psychotherapy to prevent relapse or recurrence.[23,25,26]

4.1.2 Anxiety

For patients with elevated anxiety, selective serotonin reuptake inhibitors (SSRIs) generally are the most common pharmacological treatment.[27] Of the non-pharmacological therapies available, cognitive–behavioural therapy is the preferred first-line treatment for anxiety disorders.[28] This approach employs a variety of techniques including cognitive restructuring, exposure to anxiety-generating stimuli, and behavioural experiments.[29] The rationale behind cognitive restructuring is that intense, persistent negative emotions (including anxiety) and maladaptive coping behaviours (e.g. avoidance or safety-seeking behaviours) follow from how these situations and events are appraised or perceived. Accordingly, to alleviate emotional suffering and foster constructive coping, it is important to: (a) identify the maladaptive cognitions that underlie a person's anxiety in particular situations and

circumstances; (b) examine the validity and utility of these cognitions; and (c) change these cognitions into those that are less anxiety-generating and that facilitate rather than block constructive action. In the treatment of panic symptoms, for example, cognitive restructuring is often targeted at altering catastrophic misinterpretations of benign bodily symptoms, which the patient otherwise appraises as dangerous. Likewise, in a person with social anxiety, restructuring could focus on excessively negative inferences about how one appears to others.[30]

4.2 Coping

Chronic illnesses such as EDS are often accompanied by a helpless or passive stance by patients, who feel unable to influence or master their well-being. Helplessness is often expressed in global negative beliefs such as "because of my illness, I miss the things I like to do most," "my illness controls my life," and "my illness prevents me from doing what I really like to do".[31] These thoughts are often automatic in response to one's illness and negative events. Such helplessness and avoidance of attempts to influence outcomes not only contribute to suffering but also increase the risk of anxiety and depression.

In contrast, effective coping affects the impact that EDS has on psychological well-being. Some research of coping and related constructs with EDS has been conducted. Psychological well-being is increased in people who demonstrate either acceptance or a sense of coherence.[32] The latter refers to having confidence that bodily reactions as well as environmental stressors are predictable, and that one can handle the negative consequences of these stimuli. In general, low helplessness and high acceptance reflect that a patient is able to deal with the consequences of a chronic disease.[31]

For helplessness and negative automatic thoughts, cognitive-behavioural therapy (Box 20-1) can help in recognizing, discussing, and restructuring of these thoughts, setting of goals, and practicing steps to reach these goals. The dual-process coping model stresses the fit between characteristics of the situation and the specific coping strategy used.[33] The restructuring of cognitions and behaviour can help to deal with situations that can be changed, whereas acceptance of the inevitable consequences of the disease needs to be part of patients' coping repertoire to deal with situations that cannot be changed. The ideal response of a patient is to use both assimilative ways of coping (i.e. active attempts to alter an unsatisfactory situation in a way that fits personal goals and aspirations) and accommodative ways of coping (i.e. the adjustment of personal goals and aspirations to current situational limitations in order to accept the situation or interpret the given situation less negatively). Such an approach will help the patient to change life circumstances as needed while maintaining a satisfying life perspective.

In recent years, mindfulness-based stress reduction therapy and acceptance-based therapies have been applied in the treatment of mental problems that may accompany chronic diseases.[34] These therapies add mindfulness and acceptance to traditional cognitive-behavioural techniques. Mindfulness meditation focuses on becoming aware and accepting all thoughts, feelings, and sensations instead of trying to avoid or fight them. Reviews have found statistically significant, small to moderate effects of mindfulness-based therapies on psychological distress, pain, and coping behaviour.[35-37] Integrated mindfulness and cognitive-behavioural therapy may enhance the treatment efficacy.[35]

Traditionally, psychologists and other mental health providers have focused on patients who were unable to adequately adjust to the consequences of chronic diseases. In recent years, the emphasis on the reasons why people fail to achieve a healthy adjustment has shifted to the identification of factors that help patients make that adjustment. To promote psychological adjustment, patients with chronic diseases are encouraged to remain active, to acknowledge and express their emotions in a way that allows them to take control of their lives, to engage

in self-management, and to focus on potential positive outcomes of their illness.[38] Patients who use these strategies have the best chance of successfully adjusting to the challenges posed by a chronic illness like EDS.

5. Social functioning

Support from friends and family is potentially an important influence on how well people manage and cope with their disease. In research, this response of others has been termed "social support"[39], and it has been conceptualized both structurally—that is, the size and composition of a person's social network, and functionally. Functional support consists of actually "received" support (also called enacted support), which refers to what the others actually do or provide for the patient during times of need, and the "perceived" social support. It is the perceived support, which appears to be most closely related to health. According to social support theory, receiving support from others is generally beneficial to mental and physical health, and it may blunt the harmful impact of stressful experiences, including the disease itself.[40] Empirical confirmation of this "buffering hypothesis of social support" has been found among patients with various rheumatic diseases.[41] Irrespective of the disease, the presence of a spouse or intimate partner, having many close social relationships, being socially active, and perceiving others being supportive have been found to have favourable effects on psychological and physical functioning.[42]

5.1 Social activities

Illnesses such as EDS typically have various social consequences (Box 20-2). In a Dutch survey, five times as many patients with EDS reported problems with social functioning than did people from the general population, and the chance of experiencing problems with role functioning due to physical problems was seven times as large as in the general population (figure 20-1). Interview studies also show that impaired physical functioning in EDS hampers social life.[8,32]

Box 20-2 Possible social consequences of having a rare chronic disease

- Problems with work and pursuing social activities.
- A change of role patterns, household tasks, and leisure activities in the family; difficulty to decide to get offspring; difficulty deciding on the way to raise children with EDS.
- Sexual problems.
- Problems due to lack of knowledge of health care workers.
- Experiencing lack of understanding and acknowledgement.

5.2 Family

Having a chronic disease affects one's family. For example, the kind and number of leisure activities and roles and household tasks of family members often change as a consequence of illness. Yet, not all consequences are negative. A clinical consultation with a man with EDS revealed that he had to quit his work due to EDS, but he stayed at home and did household tasks, which also allowed him the privilege of seeing his children more frequently.

Parents of children with EDS may be conflicted between protecting their children as much as possible, or encouraging them to face the challenges of life and not be hindered by fear of joint dislocations and other EDS consequences.[8] Moreover, parents need to decide when and how they will inform their children about EDS, which is especially difficult for parents of children with vascular EDS. The decision about whether to have children in the first place and when so, whether or not to pursue prenatal diagnosis can be very difficult. During a

pregnancy, worry over the foetus is common. If the child does have EDS, guilt among parents may occur.

5.3 Sexuality

Sexuality is closely related to other dimensions of quality of life. The sexual life of patients with EDS may be hampered by pain, fear for damage to the vaginal tissues, and the need to avoid certain positions because of the risk of joint dislocation and pain.[8] In a small and non-representative sample, 60% of the women with EDS reported experiencing pain during sexual intercourse.[43] Pain, fatigue, and depressed mood can impair the various phases of the sexual response cycle: desire, excitement, plateau, orgasm, and resolution. Ideally, patients and their partners should discuss sexual problems and mutually find behaviours and positions that reduce pain or risk. Such communication is difficult for many couples, however, and consultation from a physician or a psychologist may be helpful.

5.4 Health care

Patients with EDS may experience problems with both the lack of recognition and lack of knowledge of EDS by health care providers.[44] The disease may be diagnosed only after a long time of fruitless contacts with physicians and other health care workers. Patients may have the feeling that others suspect them of hypochondria or simply that they are complaining too much. Patients may feel that they have to educate health care providers about EDS, rather than the other way around.[8] Patients with EDS were interviewed about their health care experiences, and five categories of problems were identified: being ignored and belittled by health-care professionals, being assigned psychological or psychiatric explanations, being treated and considered merely as an object, being intruded in one's personal sphere when care is given, and being suspected of family violence.[45] Unfortunately, the consequences of these experiences were that patients did not fully trust their physicians, which risked increasing their health problems. These authors advised health care professionals to base their actions on norms that protect human dignity and confirm each patient as a unique human being with resources and abilities to master his or her own life.

5.5 Society

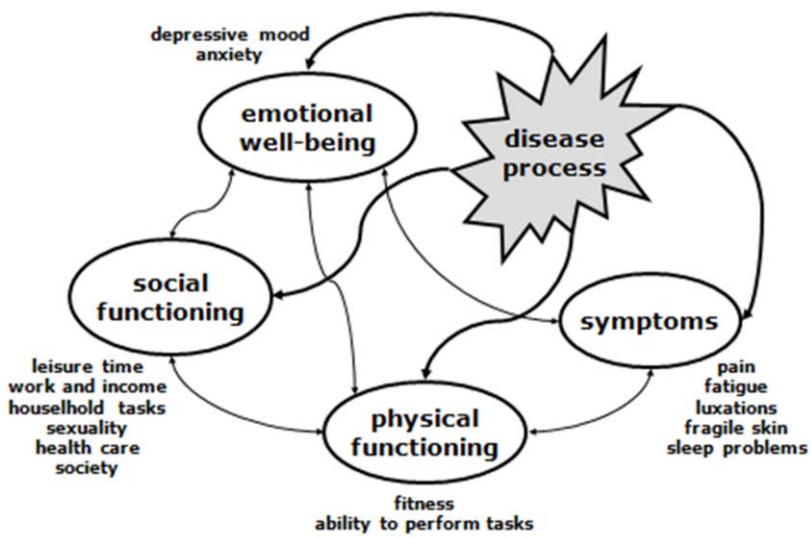
These interviews of patients with EDS also revealed that they experienced a lack of understanding from society at large.[5] For example, people may experience shame because they use a wheelchair when other people do not understand the need for it (“You can walk, but you use a wheelchair?”). Patients must often demonstrate great perseverance to obtain the accommodations or aids that they need, such as a disabled parking permit or disability status. Because symptoms such as pain, fatigue, and the chance of joint dislocations are not visible, it can be problematic to have to repeatedly explain that is difficult to perform specific tasks at work. Prevention of social isolation and social problems is a shared responsibility of the patient with EDS and the people who are in contact with the patient. Fellow-sufferers of EDS can be of great support.

6. Conclusion

There are few studies of psychosocial factors in EDS. Moreover, those studies that are available are often in small and non-representative samples. Nevertheless, the data uniformly suggest that reduced quality of life is common. Fatigue, pain, joint dislocations, skin problems, ‘weak’ vessels and organs, and sleeping disturbances threaten both psychological well-being and physical and social functioning. Yet, the effects of EDS on quality of life differ widely among individuals. Although some people with EDS have serious disease and poor quality of life, others are able to live a happy and satisfying life despite the serious

disease, and for still others the disease is milder and self-care and quality of life are good. Furthermore, improvements in one aspect of quality of life (i.e. symptoms, emotional well-being, physical, or social functioning) often yield favourable consequences for other aspects (figure 20-2). Coping abilities and social support can buffer the adverse consequences of the disease. For a patient with severe EDS, a single physician as case manager should coordinate care. This case manager knows the medical file of the patient and can help the patient to decide about medical, psychological, or occupational therapies. Patients who are having trouble adapting successfully to their condition, should be encouraged to seek behavioural help, especially from someone trained in cognitive-behavioural interventions. Health care workers, patient associations, and people in the close environment of patients can help them find the appropriate education, counselling, and multidisciplinary interventions aimed at dealing with the adverse consequences of EDS.

Figure 20-2 The consequences of a chronic disease such as Ehlers-Danlos syndrome for various mutually dependent aspects of well-being and functioning



The disease process and its symptoms threaten emotional well-being and physical and social functioning. Yet, the effects of Ehlers-Danlos syndrome on quality of life differ widely among individuals. Although some people have serious disease and poor life quality, others are able to life a happy and satisfying life despite the serious disease, and for still others the disease is milder and self-care and life quality are good. Furthermore, improvement in one aspect of life quality (i.e., symptoms, emotional well-being, physical, or social functioning) often yield favourable consequences for other aspects. Coping abilities and social support can buffer the adverse consequences of the disease.

7. Areas of uncertainty

Studies of somatic problems, psychological distress, and social functioning in EDS are scarce, but quite consistent in the conclusion that quality of life is, on average, impaired in these domains. Our discussion and recommendation in the area of coping and therapeutic possibilities were almost fully based on our knowledge of experiences of individual patients, and our knowledge of the somatic, emotional, and social consequences of chronic disease

more generally. Disease-specific knowledge, especially on the effects of cognitive-behavioural interventions, is urgently needed.

8. Summary

This chapter describes the somatic, psychological, and social impact of EDS. Research indicates that pain and fatigue are common problems in EDS. In addition, patients may fear damage to their joints, skin, and other organs; progressive disability; and even death. Other psychological and social dilemmas or challenges often occur, including whether or not to have a child, finding or keeping work that is commensurate with abilities and interests, altered roles in the family, a lack of understanding by others in one's social environment, and obtaining appropriate health care. Yet patients vary widely with respect to the severity of the disease and its impact on their psychological, social, and physical functioning and well-being; individual assessment is needed. It is probably optimal to have one physician manage each patient and coordinate the many aspects of his or her care. Patients should have access to education, counselling, and multidisciplinary interventions aimed at reducing the adverse consequences of the disease.

1. Introduction

Patients with Ehlers-Danlos syndrome (EDS) and hypermobility syndromes have an increased risk of chronic pain, as shown by clinical experience and publications.[1] This increased risk comes from many different sources, not only the increased risk of painful injuries and joint degenerations, but also from increased exposure to surgery and invasive procedures. Limited data link EDS to increased risk for neuropathic pain as well, due to reduced integrity of the connective-tissue sheaths around nerves and spinal roots. Recently, the two conditions benign joint hypermobility syndrome (BJHS) and EDS hypermobility type have been recognized as one and the same clinical spectrum ranging from apparently symptomatic generalized joint hypermobility to the most disabled individuals fitting the new diagnostic criteria. These new criteria are more strict than the Villefranche criteria and the Brighton criteria for BJHS in order to define a homogeneous phenotype for management and scientific purposes. Within the new EDS nosology, its name is hypermobile EDS (see chapters 2 and 5).

This chapter considers the pain suffered by EDS patients from a multidisciplinary perspective. In the first section we discuss the theory and pathophysiology of pain. Then we discuss specific chronic pain syndromes that have increased prevalence in EDS. We then discuss drugs, nerve stimulation, and the psychological approach as possible forms of treatment.

2. Theory of pain

2.1 Definition

Pain is an unpleasant, sensory and emotional experience which accompanies actual or potential tissue damage or is described in terms of such damage. This definition was formulated by the International Association for the Study of Pain (IASP). The first part of the definition touches upon the function of pain. In the event of imminent damage to the tissues, pain ensures that a person limits the damage. An example of this is a hand placed on a hot stove. The pain ensures that the hand is withdrawn before it is burnt. In the case of existing damage, for example a broken leg, pain has an important function that makes recovery possible: pain forces a person to take rest. The second part of the definition has been added because tissue damage cannot always be demonstrated. This is often the case for chronic pain. For *chronic* pain the relationship with tissue damage is far less clear than in the case of *acute* pain. Resting or reducing the burden on the painful body part is then no longer an adequate response. Prolonged rest leads to atrophy and the load tolerance is reduced. Minimal exertion then soon gives rise to overloading, which in turn can lead to damage. Pain is referred to as chronic when it exists for longer than 3 months after any possible tissue damage is considered healed. Pain cannot be measured objectively. The degree of nociception can sometimes be estimated if the source of the pain is known. A physician often knows from experience how much pain a given condition causes, but experimental studies show considerable variability in the perception of pain, which has been found to be genetically influenced.[2,3] A limitation on clinical care and pain research is the difficulty quantitating pain severity. Most commonly, pain experienced is measured by asking the patient about the severity of the pain, for example, using a Likert scale of 0 to 10, where 0 represents no pain and 10 the worst pain that someone can imagine.

2.2 Nociceptive and neuropathic pain

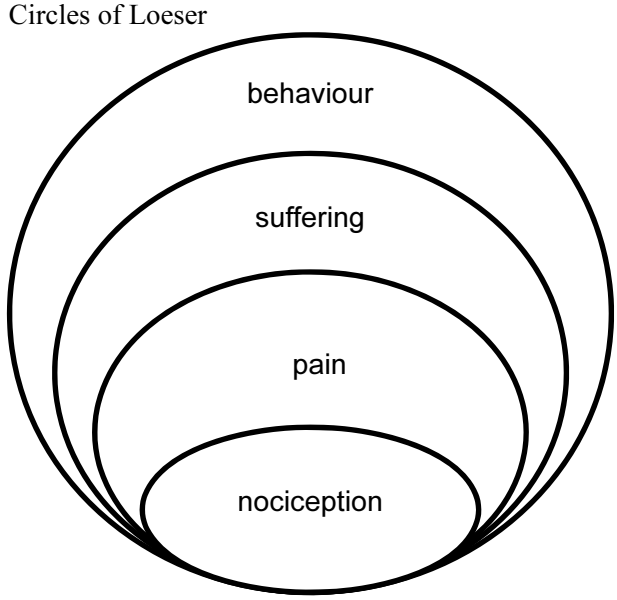
Existing and imminent tissue damage stimulates free nerve endings of pain cells, the nociceptors. This stimulus can be mechanical or chemical through mediators that are released during inflammation such as histamine and prostaglandins. This process of stimulating the nociceptors is termed nociception and the pain that is felt as a result of this is called nociceptive pain. If a nociceptor is stimulated over a prolonged period of time, the stimulation

threshold can be lowered as a result of which hyperalgesia, an increased sensitivity for pain stimuli, arises.[4] This phenomenon is referred to as sensitisation.
Damage to the nervous system (neuropathy) can also give rise to pain: neuropathic pain. In this case pathological connections develop in the posterior horn of the spinal cord to such an extent that tactile stimuli are felt as pain stimuli. This phenomenon is called allodynia. An example of neuropathic pain is phantom limb pain, a pain sensation in a body part that is no longer there, for example, because it has been amputated.
It is important to draw a distinction between nociceptive pain and neuropathic pain because of the difference in treatment. In general, neuropathic pain responds poorly to traditional painkillers. An "electrical" or burning character of the pain and the occurrence of sensory disorders such as hypaesthesia (reduced tactile sensitivity) and allodynia are indicative for neuropathy. In our and other's experience neuropathy often plays an important but underestimated role in the case of EDS.[5]

2.3 Multidimensionality of pain

After a nociceptor has been activated, the signal is transmitted via the sensory A-delta and C nerve fibres (pain nerves), the spinal cord and the thalamus to the cerebral cortex, where the sensation of pain arises. The interpretation of this signal is partly dependent on the context, such as psychological constitution, distraction and previous experiences. The experience of pain and the suffering from pain are therefore not linearly related to the severity of the nociception. Pain behaviour is what someone else can see. The well-known "circles of Loeser" provide a picture of the relationships between nociception, pain sensation, pain experienced and pain behaviour (figure 21-1).

Figure 21-1 Circles of Loeser

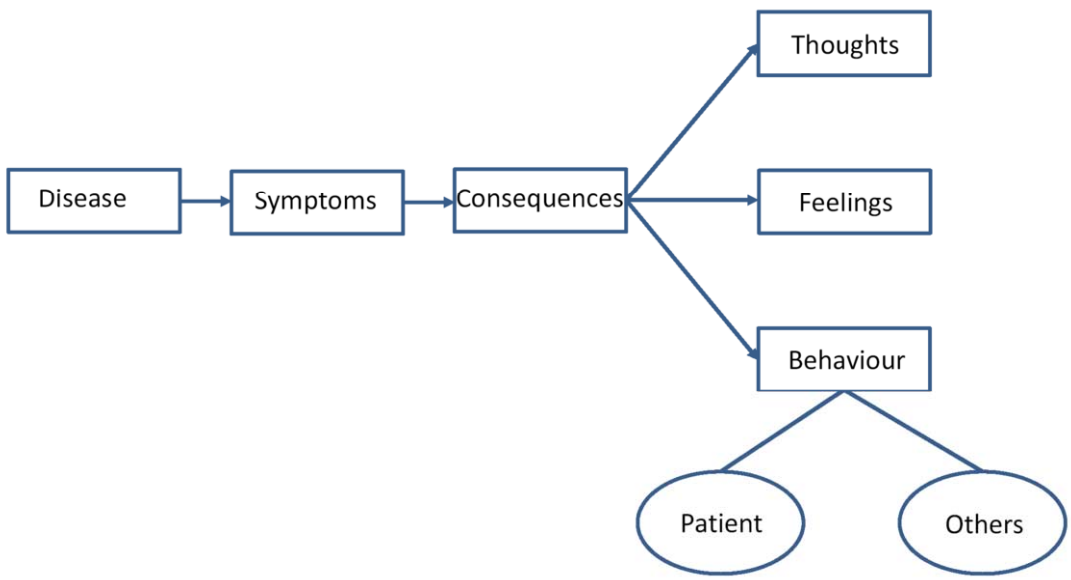


The interpretation of pain is partly dependent on the context, such as psychological constitution, distraction and previous experiences. The experience of pain and the suffering from pain are therefore not linearly related to the severity of the nociception. Pain behaviour is what someone else can see. These well-known "circles of Loeser" provide a picture of the relationships between nociception, pain sensation, pain experienced and pain behaviour

2.4 Pain model

For the treatment of chronic pain it is helpful to mention its different aspects in a model, see figure 21-2. A disease can lead to complaints and consequences. As soon as the disease has healed, the complaints disappear and mostly the consequences as well. However, the disease cannot always be found and some diseases such as EDS cannot be cured. If the complaint persists, symptomatic treatment is indicated. Options for the symptomatic treatment of pain are painkillers (analgesics), nerve blockages and nerve stimulation. However, the treatment of chronic pain does not always give satisfactory results. Then the patient continues to experience pain and the consequences of this pain. The consequences can be thoughts ('I have a severe illness'), feelings (anger or depression) and behaviour (resting, groaning). The behaviour of others also plays a role. In the case of acute injury the patient's network is helpful and understanding, but in the case of chronic pain this can change into incomprehension and irritation. Sometimes partners strengthen inadequate pain behaviour.

Figure 21-2 Model of consequences of a chronic disease



For the treatment of chronic pain it is helpful to realise that the suffering from a chronic disease leads to several psychological and social consequences for the patient and the patient's personal environment.

3. Medical treatment of nociceptive pain

3.1 Paracetamol/Acetaminophen

Acetaminophen or paracetamol is often a first choice for acute and chronic pain. However, there is increasing awareness of the principal side effect; liver damage; this drug is a common cause of acute liver failure.[6] A major problem is the inclusion of acetaminophen in many other combination medications so most patients do not even know what their daily total consumption is. This includes non-prescription medications, for instance for colds, menstrual pain, and sinusitis, but the major concern for chronic-pain patients is the combination of acetaminophen and opioid analgesics. Patients who become opioid tolerant and are prescribed or chose to take high doses to relieve severe pain risk unintentional acetaminophen toxicity. In

2009, a Joint Advisory Committee recommended to the U.S. Food and Drug Administration (FDA) that combination pain relievers containing acetaminophen be removed from the U.S. market, the recommended maximum total daily dose of acetaminophen be lowered below its current 4 g per day and that the maximum single adult non-prescription dose of acetaminophen be lowered.[7] If the combination products are eliminated, the acetaminophen and the other ingredients could be prescribed separately. Patients would take two pills instead of one, and be more aware of the acetaminophen they are consuming. This is particularly important to consider in treating chronic pain of neuropathic origin, where the acetaminophen consumed in combination pain-relievers may not even be effective. Patients with underlying hepatic dysfunction or risk factors, for instance from hepatitis C, should limit consumption and use acetaminophen and acetaminophen-containing medications only under medical supervision.

3.2 Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

The NSAIDs are a group of anti-inflammatory drugs that do not contain corticosteroids. Besides their anti-inflammatory effect, NSAIDs also have analgesic and antifebrile (fever-reducing) effects. They work by inhibiting the enzyme cyclo-oxygenase (COX) that is involved in the synthesis of prostaglandins from the parent substance arachidonic acid. Prostaglandins play a role in disease and tissue damage and in numerous physical processes. There are at least two forms of cyclo-oxygenase that are referred to as COX-1 and COX-2. Broadly speaking it is supposed that COX-1 is responsible for the prostaglandin synthesis in physiological processes and COX-2 for pathological processes. Not just the therapeutic effect but also the side effects of NSAIDs can be traced back to the inhibition of the prostaglandin synthesis:

1. Acute and chronic renal impairment. People with heart failure, the elderly and people suffering from dehydration are particularly prone to this risk.
2. Side effects in the stomach or intestines such as heartburn and ulcers can lead to haemorrhages and perforations.
3. A blood-pressure increasing effect in hypertensive patients and reduction of the blood-pressure lowering effect of drugs against high blood pressure.
4. Inhibition of the coagulation of blood platelets with increased tendency to bleed.
5. Reduction in the blood-thinning effect of acetyl salicylic acid that is prescribed to patients who have experienced a heart or brain infarct. The blood thinning effect is less, for example, after ibuprofen, nabumetone and indomethacin, but not after diclofenac.[8]

To reduce the side effects of the classic NSAIDs that act upon both COX-1 and COX-2, drugs have been developed that selectively inhibit COX-2 and spare COX-1, like celecoxib and etoricoxib. They cause less stomach ulcers or complications thereof, but reduction of the risk of stomach damage can also be achieved by the combination of a non-COX-2 selective NSAID with a drug that protects the stomach mucous membrane or a gastric acid inhibitor (like a proton pump inhibitor).[9] The risk of kidney damage is just as big for selective COX-2 inhibitors as for traditional NSAIDs, and COX-2 selective NSAID increase the risk of cardiovascular complications by increased clot formation of the blood.[10]

If acetaminophen provides insufficient relief then for EDS a NSAID can be tried. If there is not an increased risk for gastrointestinal complications a traditional NSAID is the treatment of choice. In the case of an increased risk for gastrointestinal complications and no increased risk of cardiovascular complications, a COX-2 inhibitor can be used instead. In case of also increased risk of cardiovascular complications, a traditional NSAID combined with a proton pump inhibitory drug can be used. For vascular EDS, all NSAIDs and especially classic

(COX-1 inhibiting) NSAIDs are contraindicated as these patients already have an increased risk of haemorrhages, which is a major problem if stomach ulcers would develop.

3.3 Opioids

These powerful analgesics are mainly indicated for acute severe nociceptive pain (for example after an operation) and for chronic severe pain as a consequence of cancer.
Various morphine preparations with a slow release are available, in strengths varying from 10 to 200 mg; oxycodone with slow release, in strengths varying from 5 to 80 mg and plasters with fentanyl that release 25 to 100 micrograms per hour. The side effects are constipation, nausea, sedation, urine retention, dependency (addiction) and at excessively high doses depressed breathing. The patient is started on a low dosage that is increased according to the effect. Opioids should always be given in combination with a laxative. In view of the indication and the side effects, these preparations will scarcely play a role in the treatment of pain associated with EDS.
An exception should perhaps be made for tramadol and tapentadol, both opioids, which also have other effects on pain-modulating nerve fibres. Tramadol is therefore sometimes used in the case of neuropathic pain. The dosage administered ranges from 50 to 400 mg per day if necessary. The side effects are the same as for the strong opioids but occur less frequently. However, several hours after intake, many people suffer from drowsiness. It is assumed that this is not particularly related to the dosage but to the changes of the concentration of the drug in the blood. If 'slow release' tablets are used, which release the drug gradually, fewer changes in the blood concentrations occur and there are less side effects. In clinical practice, the experience is that the drowsiness initially present almost completely disappears after a few days, despite continued use of the medication.

4. Medical treatment of neuropathic pain

Neuropathic pain can be a component of pain associated with EDS. This is possibly because damage to the nerves can also occur as a consequence of the nature of the disease. Neuropathy is difficult to treat. Drugs used against neuropathic pain have generally not been developed as a painkiller, but for another disease such as depression or epilepsy. The medical treatment of neuropathic pain is in practice a matter of trial and error.

4.1 Tricyclic antidepressants

While this group of drugs was first approved and marketed for treating depression, older trials showed independent efficacy in relieving neuropathic pain.[11] Besides inhibiting the transmission of pain stimuli, their major mode of action in control of neuropathic pain is based on enhancing the amount of substances in the pain-modulating neural tracts that descend to the spinal cord from the higher nuclei in the brain stem. A body of experience has been gained with amitriptyline and imipramine, but a recent review found little evidence to support the use of imipramine to treat neuropathic pain.[11] The usual dosage of both drugs for this application is 25-50 mg per day; sometimes this is increased to 75 mg and even to 150 mg per day. The principle side effects are dry mouth, constipation, blurred vision, difficulty with urinating and decreased blood pressure upon getting up from a sitting position.

4.2 Anti-epileptics

This group of drugs are primarily used for the treatment of epilepsy. They owe their effect to the inhibition of the transmission of stimuli in the brain. Carbamazepine, pregabalin and gabapentin are most frequently used for the control of pain.[11]
The effectiveness of carbamazepine is best documented for facial pain and diabetic neuropathy, which is neural damage as a consequence of diabetes that can be associated with

severe pain. The initial dosage of *carbamazepine* is 200-400 mg per day; if necessary this can gradually be increased to 600-800 mg per day; maximum 1200 mg per day. During the first 14 days of the treatment in particular, side effects on the central nervous system (CNS) can occur such as dizziness, difficulty with coordinated movement and speech, drowsiness and tiredness. Due to the chance of a reduced production of white blood cells and liver impairments, the blood must be monitored on a regular basis.
The mode of action of *gabapentin* has not been precisely determined. The effectiveness has mainly been described for postherpetic neuralgia (pain that arises after experiencing shingles) and for diabetic neuropathy. The initial dose is 300 mg per day, which can be increased in steps to a maximum of 3600 mg per day. The side effects are relatively mild and transient in nature and mainly affect the CNS: sleepiness, dizziness and difficulty with coordinated movement and speech.

4.3 Cannabis preparations[12-14]

Cannabis is the dried female inflorescence of the plant Cannabis sativa; its active ingredients are termed cannabinoids. More than 60 have been demonstrated, of which the principle ingredient is delta-9-tetrahydrocannabinol (THC or dronabinol). In theory, cannabinoids can inhibit pain transmission at various locations in the CNS.[13] However, the clinical usefulness and the risk/benefit ratio is debatable.[11]
Oral use is possible by making tea from the preparation. The quantities of active substances that end up in the blood after absorption though the gastrointestinal tract are minimal, partly because large quantities are broken down during the passage through the liver. If inhaled, uptake is via the lungs which leads to a quicker effect and a higher bioavailability. Inhalers can be obtained which heat the cannabis to a temperature of about 200^{o} C. The advantage of inhaling (volatilisation) compared to smoking (smouldering) is that no cancerous substances are released. The maximum effect is only noticeable after 1 to 2 weeks. If necessary, the dosage can be increased after 2 weeks.
If conventional therapies provide insufficient effect, a cannabis preparation can be tried as a supplementary treatment in the dosages given. Starting with cannabis tea is the most practical approach. If this provides no relief after two weeks then administration via an inhaler can be tried. If no noticeable effect has occurred with this after 2 weeks then cannabis clearly does not help and its use can be stopped.

5. Nerve blocks

Nerve blockage focuses on blocking the transmission of pain from the nociceptor to the central nervous system. In general, this blockage can take place in four different ways:

- Injection of a local anaesthetic. Local anaesthetics block the transmission of pain by a nerve, as a result of which local anaesthesia occurs. The effect lasts for several hours but due to the breaching of the sensitisation it can sometimes be a long time before the pain returns (several months). A problem in the case of EDS, however, is that the sensitivity for local anaesthetics may be reduced.[15-17]
- Cryocoagulation of a nerve. Freezing damages the nerve so that it no longer transmits stimuli for a period of 3 months or longer.
- Radiofrequency treatment of a nerve or ganglion. A high frequency alternating electrical current is used to change the structure of the nervous tissue as a result of which fewer signals can be transmitted. The effect lasts for several years. However, if the treatment is too extensive then neuropathic pain or loss of strength can occur. By using normothermic pulsed radiofrequency, the risk of nerve damage is negligible.

- Injection of neurolytic substances such as alcohol or phenol. The duration of effectiveness is unpredictable. A risk is the occurrence of neuropathic pain. Therefore to date this technique has only been used on the autonomous nervous system ("sympathetic blockage"), where the chance of neuropathic pain is very small.

Literature data on nerve blocks in patients with EDS are lacking.

5.1 Trigger point infiltration

A trigger point is a painful spasm of several muscle fibres. It can occur in virtually every muscle. Stress appears to play a role in its development. A typical radiation pattern of pain can exist, which can lie outside of the muscle. During a physical examination a trigger point can sometimes be felt as a painful lump in a muscle. The treatment consists of injecting several millimetres of lidocaine into the trigger point followed by stretching exercises.

5.2 Peripheral nerve blocks

If a peripheral nerve is infiltrated at some point along its pathway with a local anaesthetic, a temporary interruption to the pain sensation occurs. This is particularly worthwhile if sensitisation plays an important role. Examples are headache originating from the neck (occipital nerve) and shoulder pain (suprascapularis nerve).

5.3 Sympathetic blocks

The autonomous nervous system controls a wide range of physical functions such as peristalsis (bowel movements), sweat secretion and blood pressure, without us even being aware of it. It consists of two parts, the sympathetic and parasympathetic nervous systems. The sympathetic nervous system plays a role in the modulation of pain. As a result of chronic pain, the sympathetic nervous system becomes sensitised, which leads amongst other things to vasoconstriction and an increase in the pain. The limb concerned becomes cold and pale. The aim of sympathetic blockage is to improve the blood flow and to reduce the chronic pain.

5.4 Epidural injection

The dura is the outermost spinal cord and cerebral membrane. Around this membrane is the epidural space that is filled with blood vessels and fat. The incoming and outgoing nerve roots pass though this space. Anaesthesia can be achieved by injecting a local anaesthetic. Considerable experience has been gained with this technique in anaesthesia for operations. By using less strong concentrations of local anaesthetic, less intensive blockages are produced so that the motor function remains intact. By adding other drugs such as morphine, glucocorticoids or clonidine the analgesic effect in terms of duration or intensity can be increased. Epidural injections can be administered throughout the vertebral column. The volume injected determines the number of treated spinal cord segments. In the case of EDS, the administration of an epidural injection is associated with an increased risk of complications due to the possibly weaker dura.[18] Consequently, the dura can be unintentionally perforated and, in the case of vascular EDS, there is an increased chance of haemorrhages due to the damage of an epidural blood vessel.

6. Nerve stimulation[19]

Electrical nerve stimulation can contribute to pain alleviation. The presumed mode of action is the 'gate theory', which proposes that in the spinal cord, stimuli via the thick nerve fibres can inhibit the propagation of the other stimuli (for example, pain stimuli) like a gate that is being closed. The gate can be closed by activating thick nerve fibres and opened by activating thin nerve fibres. If a small current is administered via the skin then the thick nerve fibres are

mainly activated. According to this theory, the nociceptive and neuropathic pain would be suppressed.
Another explanation is that in response to electrical stimulation of skin nerves, endogenous endorphins (substances similar to morphine) are released in the central nervous system. A third theory states that certain electrical stimuli increase the production of the substance ATP (adenosine triphosphate, the energy source in cells), which increases wound healing and general well-being.
The best-known form of electro-analgesia is transcutaneous electrical neurostimulation (TENS), a method to inhibit pain by electrically stimulating painful areas via electrodes on the skin. Recently developed TENS applications are the Burst mode, modulated rate TENS, point TENS and APS (action potential simulation). None of the transcutaneous forms of electro-analgesia have been proven to be effective in patients with chronic pain, as well-designed studies have scarcely been performed. Nevertheless, TENS is used regularly, partly because this therapy is not invasive and is relatively safe.
Besides the transcutaneous form of electro-analgesia there is also an implantable form. Here an electrode is placed in the epidural space and is attached to a subcutaneous pulse generator. This treatment has been proven to be effective for certain forms of neuropathic pain such as peripheral nerve damage and sympathetic reflex dystrophy. The safety and effectiveness in the case of pain associated with EDS is, however, completely unknown.

7. Psychological approach

Pain has consequences for feelings, thoughts and behaviour. In turn these consequences can play a role in perpetuating pain. In the case of less serious psychological consequences, educational programmes and self-help books can help. Serious consequences of chronic pain are treated with reactivating rehabilitation programmes and cognitive-behavioural therapy.

7.1 Feelings

Patients with chronic pain sometimes report that the pain is greater if they are angry or tense. This is not just a matter of perception but is also related to the physiological changes that then take place. The perception of pain involves many structures and processes in the central nervous system. One of these substances is the stress hormone noradrenaline that can increase the pain in patients with a chronic pain syndrome. Noradrenaline is mostly released if a person is angry or tense and this can clarify the increase in pain.
Noradrenaline is also released during movement. Moreover, the physiological perception of a change in the position of the limbs (proprioception) can be experienced as pain. This can form the basis for kinesiophobia, anxiety for movement and anxiety for injury. In the case of EDS, the anxiety for certain movements that can result in (partial) dislocations, is real. This becomes problematic if anxiety results in unnecessary severe immobility and subsequent pain, fatigue and muscle weakness,[20] as a result of which the chance of dislocations can increase.
Prolonged pain can trigger depression. Depression reduces the chance of successful treatments and should be diagnosed and treated as quickly as possible.
If anger, tension, gloominess and anxiety occur then it is worthwhile devoting attention to these during therapy so that the quality of life can be improved. Relaxation training, cognitive-behavioural therapy and stress management can be deployed for this purpose. The psychologist is the therapist indicated for coping with stress. Sometimes stress management forms part of the courses offered in hospitals and rehabilitation centres for coping with pain. There are also many possibilities outside of the psychological circuit for participating in relaxation training.

7.2 Thoughts

Convictions that the patient holds onto, have consequences for the choice of therapy and therapy compliance. A patient who thinks that pain is solely the consequence of tissue damage will not be open towards a behavioural intervention. Someone who is convinced that rest is good and that physical exertion leads to damage in the body, will be difficult to motivate to exercise more. Some patients have catastrophizing, negative thoughts. They think that nothing helps, that the pain will always be there and will never subside, that the pain is intolerable and will become worse upon the slightest exertion and that the worst possible outcome will result from any behaviour. Individual psychotherapy or group therapy can be considered for patients who are helpless and say that they have tried everything, who are convinced that nothing helps, who have a marginal expectation of a positive outcome of therapy and who have a lack of self-effectiveness. Self-effectiveness is the conviction that one can achieve a certain objective and that one is capable of effecting and persisting in a behaviour that is necessary to achieve that objective.

The therapist will first of all have to estimate to what extent the patient's thoughts are realistic. If unrealistic thoughts are present then these will have to be addressed first in the treatment. A psychotherapist can help a patient to recognise inhibitory and negative thoughts after which these thoughts can be discussed and be replaced by realistic thoughts such as *if I keep moving then perhaps things will go better for me; that I experience pain does not mean that my body is being damaged; I can still cycle if I use an adapted bike*. Only after this phase has been completed will the patient be open to stress management and can realistic objectives that facilitate the patient’s functioning and quality of life be chosen and practised.

7.3 Cognitive-Behavioural Therapy

Although one does not chose to have chronic pain, and often one cannot make it go away, patients can choose and control their own methods for coping with pain. Clinical experience shows tremendous variety in coping styles; some patients are completely disabled by moderate amounts of chronic pain whereas others carry on heroically in the face of severe chronic pain. Some methods for coping with pain are more favourable than others.[21,22] Ignoring the pain, concentrating on something else and seeking diversion are helpful not only for coping with acute pain, but can also work for chronic pain as well. One of the fundamental characteristics of chronic neuropathic pain is that it is often worse at night when patients lie in bed without distraction. Many patients report that their chronic pain fades into the background when they engage in their favourite activities. Considerable pain research demonstrates the negative effects of “catastrophizing”, magnifying the significance of chronic pain.[20]

Negative thoughts are associated with psychological suffering, a greater use of painkillers and reduced possibilities for performing activities of daily living. Coping styles such as ‘praying and hoping’, wishful thinking and optimism are associated with improved functional possibilities. They probably encourage the patient to adopt an active role in dealing with the pain. Pain can lead to passiveness. Numerous experiments have demonstrated that an animal or person who has no control over a situation can become passive and helpless. An animal that can avoid an annoying stimulus, such as a pain stimulus, by pressing a button will actively do so. An animal that receives as many stimuli but has no control over these will become passive and will eventually stop taking any more action. This type of experiment reflects the term 'learned helplessness’. In people, it is assumed that this occurs as a consequence of powerlessness under uncontrollable pain. It is expressed, for example, in the form of depression and catastrophizing, negative thoughts. Whereas some patients become passive, other patients tend instead to overexert themselves. If people attempt, come what may, to carry out a certain activity then the relative overexertion can lead to them being confronted in the following days with an extreme increase in the pain, which prompts them to

take a lot of rest. Such a yo-yo pattern that alternates between too much and too little exertion can better give way to a more uniform pattern of movements.
Cognitive-behavioural therapy focuses on teaching patients how to identify better strategies for coping with and managing their chronic pain. Where the focus should lie depends on the individual patient's problem. After the patient and therapist have jointly determined some realistic treatment objectives, cognitive-behavioural therapy usually involves three phases. The first phase consists of education and mapping negative thoughts, detrimental behaviour and the patient's possibilities and realistic goals. In the second phase new thoughts and coping skills are learned and practised. Techniques that can be deployed include stress management, relaxation training, an improved planning of activities, instructions for improving the posture and using medical devices, working with exercises and a gradual increase of the physical condition (‘graded exercise’) or help in setting realistic goals with respect to the quality of life. The third concluding phase is focused on internalising the behaviour learned and not relapsing into negative thought patterns.

8. Areas of uncertainties

For many of the treatment modalities described above, the specific effects in EDS patients are not known; the reduced sensitivity for local anaesthetics in EDS patients indicates that this may be more than only a theoretical issue.

9. Summary

Other than the observation that pain is highly prevalent in the case of EDS, too little is known about the specifics of this problem. Treatment predominantly takes place according to general principles that are not specific for EDS. These treatment modalities were reviewed here.

Addendum by the editors

In the March 2017 issue of the American Journal of Medical Genetics Part C Seminars in Medical Genetics all papers were devoted to EDS, covering a new EDS nosology, new diagnostic criteria of the different types and also management related topics (see also chapter 2). One of these papers entitled “Pain management in Ehlers-Danlos syndrome”, is recommended for further reading.[23]

1. Introduction

In the last decade, scientific research in the area of hypermobility related disorders has grown exponentially. Despite the accumulation of scientific knowledge, these categories of patients remain challenging for most clinicians due to many issues surrounding aetiology, disease classification, diagnostics and treatment. Even for experienced physicians it remains hard to correctly identify patients and to determine which factors should be modified in order to get positive treatment outcomes. Historically, the diagnoses Benign Joint Hypermobility Syndrome (BJHS) and Ehlers Danlos Syndrome; hypermobility type (EDS-HT) were viewed as separate entities, however over the years it became clear that the diagnostic criteria had considerable overlap and were often found to be clinically indistinguishable. With the accumulation of scientific knowledge on both BJHS and EDS-HT, it became apparent that a revision of the diagnostic criteria was necessary in order to improve clinical care and scientific advances. In 2017, the diagnoses BJHS/EDS-HT were replaced by new diagnostic entities in terms of Hypermobility Spectrum Disorders (HSD) and Hypermobile Ehlers-Danlos Syndrome (hEDS; for diagnostic criteria see chapter 2, table 2-5).[1,2] Although scientific research on populations diagnosed according to the new theoretical framework and nosology is limited, the current chapter provides a theoretical framework which will aid clinicians in creating a personalized treatment strategy. The authors recognize that the evidence used within this chapter is based on scientific observations gathered on the old diagnostic criteria and that further research with the new diagnostic criteria is crucial in order to provide the most optimal care. Therefore the current theoretical framework should be viewed as conceptual and only serves as a starting point for clinical care.

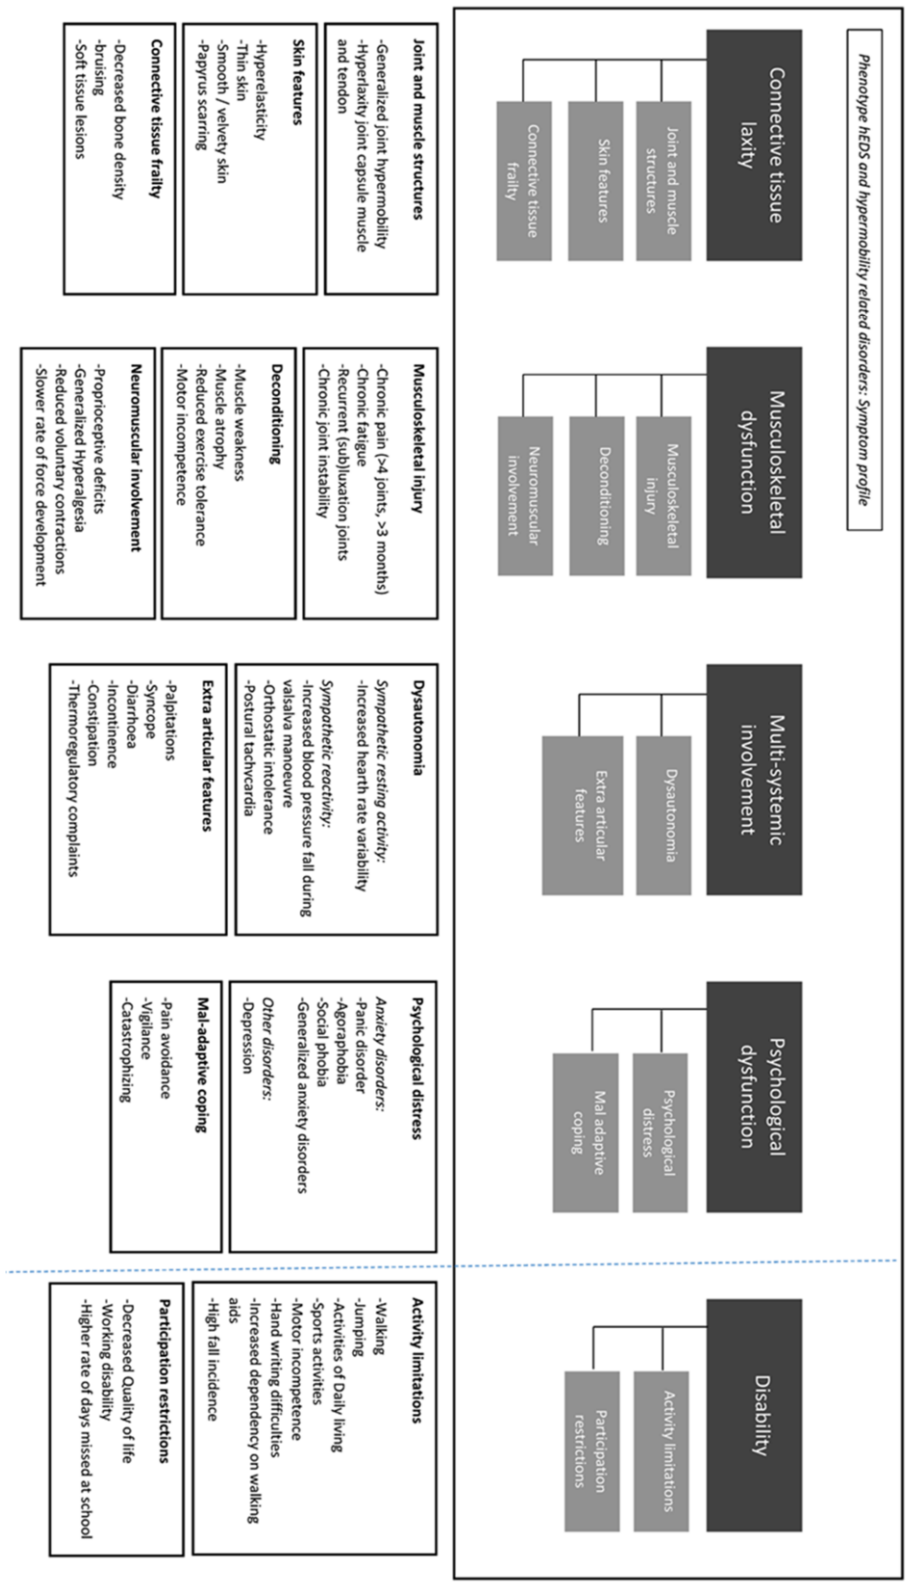
The objective of this chapter is to provide clinicians with a clinical model of hEDS and HSD for which treatment can be optimized to the needs of the individual patient. Due to the complexity of the symptom profiles of HSD/hEDS, the international classification of functioning (ICF) will be adopted as a central framework. The ICF is a multidimensional model of functioning with activities and participation as the key construct. This model provides a framework to describe limitations associated with an individual's functioning and identifies influencing environmental factors. On this framework a clinical profile and treatment strategy can be based.

2. Clinical profiles

2.1 Clinical profiling

Traditionally individuals with BJHS/EDS-HT are characterized by the presence of connective tissue laxity, in terms of Generalised Joint Hypermobility (GJH), hyperextensible skin and arthralgia. However over the years, it became clear that the nature of these disorders is far more complex and can be viewed as a unique pathological entity within the field of rheumatology.[3,4] This is now recognized within the new diagnostic criteria of HSD/hEDS.[1] In order to ensure maximum treatment efficiency, it is essential to have an accurate individual patient's clinical profile that enables the health care provider to target the specific factors that will enhance functional recovery. The clinical profile is based on four clinical components (figure 22-1): (1) Connective tissue laxity, (2) Musculoskeletal dysfunction, (3) Multi-systemic involvement and (4) Psychological dysfunction.

Figure 22-1 Phenotype of hyermobile EDS and hypermobility related disorders: symptom profile



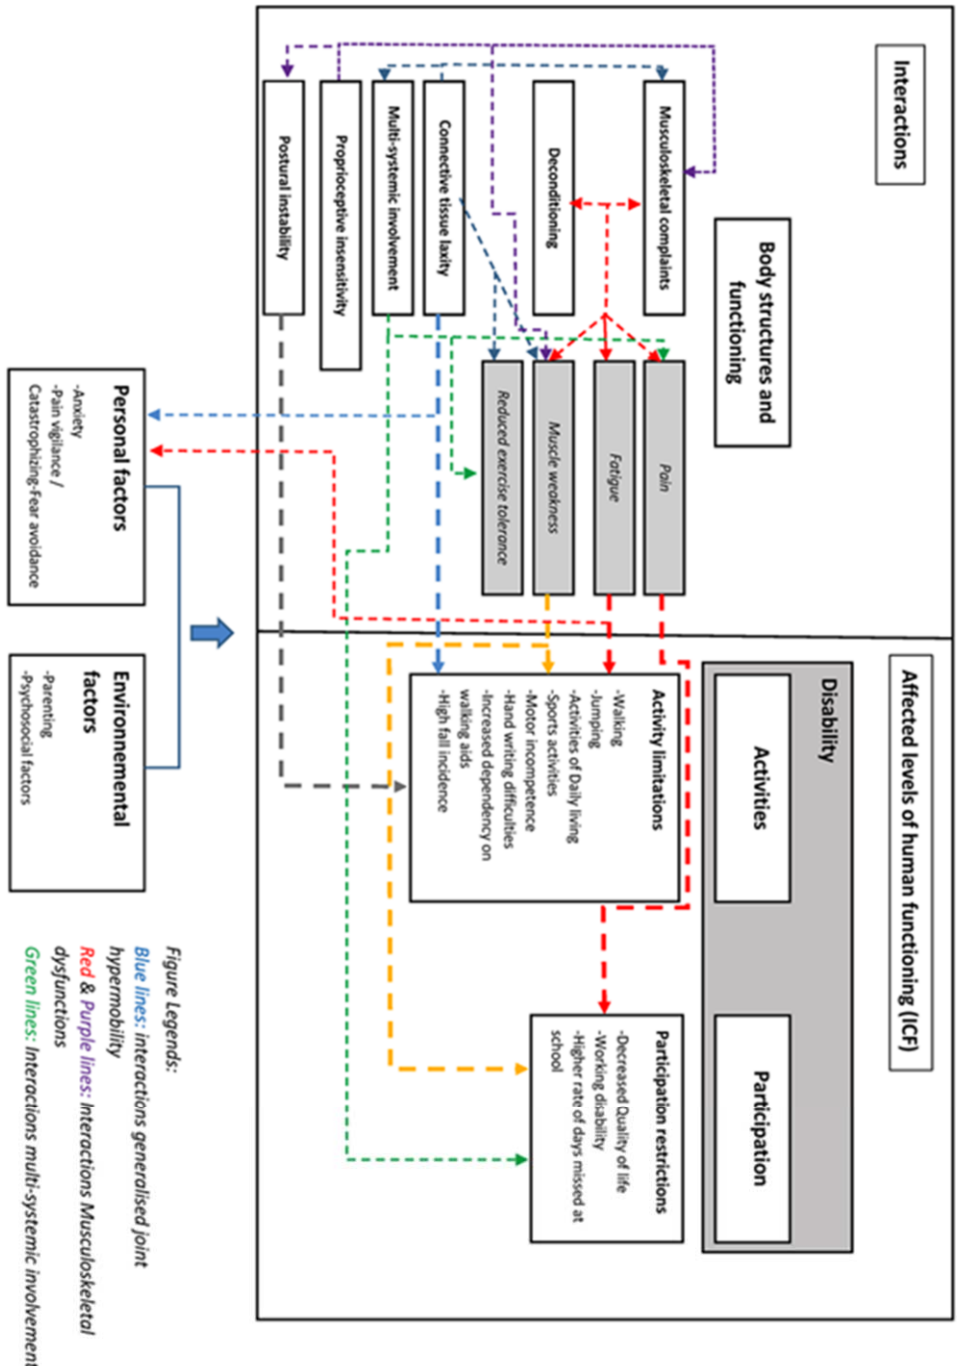
2.1.1 Component 1: Connective tissue laxity

It is assumed that GJH is an expression of generalized connective tissue laxity, in which joint capsules, ligaments, tendons and muscle structures are hyperextensible.[5-7] Therefore, in HSD/hEDS the presence of GJH according to the Beighton criteria is a clinical feature. The Beighton score is considered as the gold standard from infancy to old age, and has been the most used instrument to classify GJH. Originally, the Beighton score was developed for use in research and not designed for clinical use (personal communication of Beighton). Although several studies confirmed good reliability and face validity, a considerable variation in test procedures has been described. This concerns not only the practical instruction of how to perform the various tests, but maybe more importantly, also variations in the cut-off level for a positive test and in the definition of GJH.[3] It remains unclear which cut-off level is the most appropriate. In the previous classifications a score of ≥4 (EDS-HT ≥5) is considered to be the minimum level for GJH, independent of age, gender and ethnicity.[8] Other cut-offs of ≥5, ≥6, ≥7 have also been suggested, but the validity of these cut-off values can be debated. Recent studies have shown that a Beighton score of ≥6 at the age of 10 is a predictor for pain recurrence and persistence at 14 years,[9-11] and a Beighton score of ≥6 at the age of 14 is a predictor for general pain at 18 years of age.[12] This would suggest that scores ≥5 would be more appropriate. However with increasing age, joint laxity decreases, which may imply that a cut-off level of ≥4 eventually may be more appropriate.[13] In addition, gender and ethnicity specific effects on joint laxity have been documented and should also be incorporated in the classification of GJH (see chapter 2 for age and sex related cut-off values for the Beighton score, used in the new criteria of hEDS). The Beighton score requires information on hypermobility in 4 joints (thumb, little finger, elbow and knee) and spine, whereas no information is required on other joints, e.g. shoulder and hip joint. Within the current diagnostic criteria, no such distinction is made. Furthermore, there is little knowledge on the natural course of GJH with increasing age, which also complicates clinical diagnostic procedures.[14,15]

Skin features are the second most distinguishing clinical characteristic that is related to connective tissue laxity. Hyperelasticity, scarring, bruising, smooth and velvety skin have been incorporated into the diagnostic criteria;[16] however the methods of assessment have not been specified in either Villefranche nor Brighton criteria sets (see chapter 2 for criteria for skin hyperextensibility).[3]

Recent research (figure 22-2: blue connections) has shown that the presence and grade of GJH are clinical findings that are directly associated with disability.[17,18] They have also been demonstrated to be associated with pain, fatigue, muscle weakness, dysautonomia and anxiety.[5,17-20]

Figure 22-2 Suspected interactions and relations of symptoms in the context of the International Classification of Functioning, Disability and Health (ICF)



2.1.2 Component 2: Musculoskeletal dysfunction

The presence of chronic pain is a frequent clinical feature that is present in many patients diagnosed with HSD/hEDS and a major diagnostic criteria in the BJHS and EDS-HT diagnoses. Pain is often characterized from mild to severe, affecting multiple joints which may vary over time and may occur episodically but sometimes persists and becomes chronic. In a selected group of patients with musculoskeletal pain seeking specialized care, GJH is prevalent in 9%-57%,[12,18,21,22] exceeding the anticipated prevalence scores of 10-20% in the general population.[23] Although this increased prevalence for GJH in chronic pain patients is striking, a minority of persons with GJH will probably develop a chronic pain syndrome, which negatively impacts daily life, interferes with work and leisure time activities (figure 22-2: red connections).[12,18,21,22] Pain can also directly modify muscle strength and proprioception dependent modalities, which may cause additional deconditioning and loss of motor control through reflex inhibition.[24] The second dominant symptom is fatigue.[25] Fatigue is highly prevalent amongst individuals with GJH[26], HSD/BJHS, and is considered by patients to be one of the most disabling symptoms. Recent literature shows that in 75% of all included patients with EDS-HT/BJHS severe chronic fatigue was present.[25] In patients who were more severely fatigued, higher levels of impairment and psychological distress were present (figure 22-2: red connections).[26]

It is assumed that deconditioning occurs as a consequence of (in)activity related overuse which results in under-activity in order to recover.[27] Consequently, there is a downward spiral of less activity due to fear and more pain with less provocation, leading to deconditioning.[27] Reduced exercise capacity and muscle weakness have been extensively documented in BJHS/EDS-HT patients, and have also been shown in high-level athletes with GJH and healthy individuals with GJH in the absence of chronic pain. The presence of muscle weakness and reduced exercise tolerance in asymptomatic GJH may imply that deconditioning also directly (i.e. not via under-activity) is associated with connective tissue laxity.[17,18,28] Scientific literature shows that muscle weakness is an important clinical finding that is not only associated with disability (figure 22-2: yellow connections), but has also been found to be strongly associated with pain and fatigue (figure 22-2: red connection).

In the last decades, evidence has accumulated on the existence in the symptom profile of BJHS/EDS-HT of a neurological pathway, in which proprioception (peripheral nervous system) and generalized hyperalgesia (central nervous system) are implicated in the development of pain. Proprioception is a specialized sensory modality that provides information about position, movement and sense of resistance which is transmitted by a variety of sensory receptors in the periphery.[30] In theory, proprioceptive deficits may disrupt motor control and cause joint instability which in turn may lead to micro-fractures on joint surfaces. Literature to date only reports the incidence of proprioceptive deficits, with no evidence on the clinical relevance of these findings nor on their role in the development of complaints in subjects with GJH.[18,29]

The presence of generalized hyperalgesia in adult patients with EDS-HT has been described.[30] Subjects with EDS-HT had considerably lower pain pressure thresholds in symptomatic and asymptomatic areas, compared to healthy controls. It was hypothesized that central orientated upregulating processes are present within the central nervous system. Due to centralized sensitization, subjects with BJHS/EDS-HT may be more susceptible to pain and fatigue. Recently these neurological features have also been described in children and were found to be discriminative between BJHS/EDS-HT, GJH and healthy controls.[31]

2.1.3 Component 3: Multi-systemic involvement

Although EDS-HT/BJHS is traditionally viewed as a disease with primary locomotor complaints, in some patients multi-systemic symptoms dominate the symptom profile. Multi-

systemic complaints like gastro-intestinal issues, incontinence as well as dysautonomia have been documented.[4,14,18-21,32,33] Regarding sympathic regulation, patients tend to have abnormalities within both sympathetic resting activity and sympathetic reactivity.[23,24] Dysautonomia manifesting in erratic heart-rate (heart rate variability), as well as reactions on sudden changes of external stimuli, such as blood pressure fall during Valsalva manoeuvre, orthostatic intolerance and postural tachycardia, have also been shown as an integral part of the phenotype of JHS/hEDS.[19,20]

Multi-systemic signs and symptoms have been found to be directly associated with disability in terms of decreased quality of life (figure 22-2: green connections).[19,20] In addition, a positive association with connective tissue laxity, pain and deconditioning has been shown, indicating that with increasing severity of multi-systemic symptoms, the severity of perceived pain and deconditioning increases.[19,20] In children with BJHS/EDS-HT, it has been demonstrated that the presence of multi-systemic features like postural orthostatic tachycardia, skin scarring, bowel issues and chronic diarrhoea were found to be predictive for escalating pain, fatigue, muscle weakness and progressive disability.[34] The importance of multi-systemic features have only been established in children and are not yet established in adults, however it is assumed that multi-systemic features are also an important clinical feature in adults as well.

2.1.4 Component 4: Psychological dysfunction

The impact of BJHS/EDS-HT on daily life seems not to be solely explained by a person's level of hypermobility.[35] High Beighton scores alone do not account for more impairments in daily life. It seems that besides biomedical factors, psychosocial factors also contribute to a person's level of disability. In the chronic pain literature, a fear-avoidance model has been introduced to explain the disabling role of pain-related fear,[36] which has been confirmed by numerous studies.[36-38] It states that highly fearful persons who tend to catastrophize, will avoid activities they perceive as harmful or pain provoking. In the long term, this avoidance behaviour can result in disability, deconditioning and depression, further fuelling the vicious circle of disabling musculoskeletal pain.

It could be that pain related fear will have an accumulating disabling effect in hypermobile persons with pain. In the case of a new onset of musculoskeletal pain, fear of pain will trigger avoidance of painful muscle contractions, leading to subnormal muscle performance. For persons with joint hypermobility, it is hypothesized that subnormal muscle performance will possibly have the immediate negative consequence that the muscles' compensation mechanism, essential for joint stability, will fail. Functional consequences, such as impaired balance ability and reduced balance confidence, will further fuel fear of movement and catastrophizing thoughts about pain and vice versa. In fearful hypermobile patients, a painful stimulus can thus, even in the short term, lead to a high level of disability, depression and disuse.[39]

The high prevalence of both anxiety and joint hypermobility in patients with musculoskeletal pain, could indicate that this hypothesized mechanism may explain disability in a substantial subgroup of patients.[35] A finding that seems to support a common pathway for hypermobility and anxiety, is an increased prevalence score for joint hypermobility in patient populations with other anxiety related problems: 62% of patients with a panic disorder appeared to be hypermobile.[40]

2.2 Clinical profile assessment

When considering the highly heterogeneous clinical presentation of EDS-HT/BJHS or HSD/hEDS patients, simply classifying each individual on the basis of criteria will not suffice and may even lead to an unsuccessful treatment.[18,21,32] Therefore, it is essential that each

patient is profiled on all aspects of the ICF model to enable the creation of an individualized tailored treatment regime.[41] Currently no international consensus exists on which outcomes are the most clinically relevant and by which measures these should be assessed.[6,14,18,21,27,32] The recommendations presented in this paragraph for the clinical profile assessment should be merely viewed as recommendations and should be adjusted to the individual context of each health professional (e.g. available equipment, time constraints, training) and patient (e.g. cognitive level, physical issues that render the patient unfit to be tested). The suggested clinical profile will consist of the previously mentioned components: disability, connective tissue laxity, musculoskeletal dysfunction, multi-systemic involvement and psychological dysfunction. It should be pointed out that when engaging in a diagnostic assessment of a HSD/hEDS patient, multi-disciplinary cooperation is vital and may even be considered as a necessity. The presented examples of outcome measures are derived from literature and personal experience of the authors.

2.2.1 Disability

Disability is a multi-dimensional concept defined as a patient-oriented health outcome which contains aspects of individual daily functioning, including physical, psychological and social factors.[42] Reducing disability is often used as a primary outcome in a variety of study designs, whereas an operational definition is frequently lacking.[43] It can, however, be operationalized in both capacity and performance measures, where capacity refers to what a patient can do in a standardized environment, and performance to what a person does in daily life.[44,45] Regarding capacity qualifiers, it can be advised that standardized tests on functional outcomes like walking, transfers and activities of daily living are incorporated. A functional assessment based on the specific needs of the patient would form an integral part of the assessment which should be complemented by standardized testing. Standardized tests like the 6 minute walk test,[46,47] and chair rise test[47] would be suitable and are frequently used in clinical practice. In addition, for these measures there are normal values available as an aid in the assessment of the grade of disability. Currently, more modern measures of disability are available in terms of continuous activity monitoring. Although these measures are more costly and not often used in clinical practice, it could be recommended that when a more detailed assessment of activity patterns is indicated, these type of outcome measures are applied, especially in children.[48] Measures of disability performance are often assessed during medical history taking and should be complimented by questionnaires. Assessors should choose the most appropriate set of questionnaires, based on age, goal and patient preference. Generic questionnaires like the Health Assessment Questionnaire[49] and the Child Health Assessment Questionnaire[50] are recommended as they have been validated, have normal values, account for the use of assistive devices, and are available in multiple languages.

2.2.2 Connective tissue laxity

It is recommended that connective tissue laxity is assessed when joints and skin are relaxed, by observation and testing. A general view on the grade of laxity may be informative on the status of connective tissue; however no evidence is available that shows that disease severity is associated with increasing connective tissue laxity.[5] The presence of GJH according to the Beighton score is traditionally scored within the diagnostic criteria, but should also be monitored over time. When using the Beighton score it is crucial that it is performed according to a standardized protocol and more importantly, assessors should be well experienced when using the Beighton score.[8] Despite the simple appearance of the Beighton score and its applicability, it should not be underestimated and intensive training / inter-assessor consensus is essential.[8] The protocol by Smits et al., which makes use of a goniometer in order to increase precision, can be recommended for the standardisation of the

Beighton score.[51] GJH is classified if a score of ≥5 is obtained, when using the Villefranche criteria, irrespective of age, gender and ethnicity. Despite the central role of GJH in the diagnostic criteria, much discussion exists on the cut-off value for GJH.[3] Therefore, it is recommended that other measures of joint mobility are incorporated in the assessment of connective tissue laxity like goniometry and skin laxity. Goniometry with proper training can be a valuable tool for assessing individual joints,[52] especially when comparing measurements with normal values. Skin assessment should be performed by visual inspection on the appearance of the skin (bruising, scarring) and palpation (smooth, velvety feel). A general inspection of the whole body is recommended. Regarding skin laxity, manual testing at the volar aspect of the forearm is frequently applied and is sufficient in order to identify hyperextensibility (yes/no). More advanced measures of skin extensibility are available; however, their clinical relevance has not yet been established.

2.2.3 Musculoskeletal dysfunction

Regarding pain, it is important to not only document its location but also its severity and duration. Traditional measures like the visual analogue scale (VAS) or numeric rating scale (NRS) are often included in the clinical assessment. It is important to quantify pain as a general measure but also to assess the pain intensity for each individual location.[53] Pain body schemes like the Pain Manakin not only provide information on the location of pain but can also be converted into a percentage of painful body surface, which informs on the spread of pain.[54] Also pain sensitivity measurement may be a useful addition to the clinical profile, by assessing pain pressure thresholds, which inform on the sensitivity for pain.[30] Fatigue can be assessed in a similar way as pain severity by VAS or NRS; however, chronic fatigue may also be viewed as a state in which biological fatigue is hard to discriminate from mental fatigue. Questionnaires like the Checklist Individual Strength[26] in adults and the Multi-dimensional Fatigue Scale in children[55] are examples of questionnaires which assess the full scope of fatigue related problems.

Muscle weakness can be assessed by the use of handheld dynamometers,[56] which can accurately quantify the extent of muscle force and can be related to age and gender related normal values. However, these measures do not necessary represent functional muscle strength. Therefore, it is recommended that functional strength measures are incorporated, such as repeated functional tasks (e.g. squatting, lifting), sit to stand, walking stairs, one leg stand, and jump tests (single leg hop, sidehop test).[18,45] Manual muscle strength tests are not advised as they are only informative on muscle strength symmetry and are not suited to quantify and compare muscle force between patients.[56] Cardiovascular exercise tolerance testing may also be indicated.[57] Both bike (e.g. steep ramp protocol) and walk tests (e.g. Bruce treadmill exercise test) can be applied, depending on the available equipment. However, when engaging in maximal exercise testing, safety issues should be addressed and constant monitoring should be applied as a risk of cardiac complications is present. Field based tests like the shuttle walk test or stair climb test may serve as less intensive measures that can also estimate exercise capacity.[58] Muscle weakness may also be caused by other medical conditions, e.g. neurological diseases; therefore differential diagnostics remains important.

Proprioceptive deficits are mentioned frequently in medical literature and are often implicated as a potential cause for the development of pain. However, measures of proprioception are quite sophisticated and often not applicable in clinical practice. Standing balance (e.g. Romberg test, stork test) or functional observations on motor control/clumsiness may be more feasible.[59]

2.2.4 Multi-systemic involvement

Multi-systemic involvement can present itself in numerous ways and is often missed by clinicians. Medical history assessment should involve specific questions regarding gastro-intestinal complaints (organ dysfunction: abdominal pains, diarrhoea, constipation, incontinence), fainting (dysautonomia: syncope and presyncope), perceived heart beat irregularities (dysautonomia: palpitations) and issues of thermo-regulation after exercise (dysautonomia: like elevated body temperature). As the spectrum of these types of signs and symptoms is quite broad, the use of a standardized questionnaire is advised. Examples of such questionnaires are the Autonomic Symptom Profile[20] and the Somatic Complaint List.[60] Measures specifically focused on dysautonomia, like the tilt test, are not advised as they involve specialized protocols and strict medical supervision.

2.2.5 Psychological dysfunction

Psychological dysfunction should be screened for in every patient and may prove to be invaluable during the treatment process. If psychological dysfunction is present, the expertise of a psychologist is indicated and should be incorporated in the treatment procedures. Screening for this dysfunction can be viewed as essential and needs to be performed on each patient. As time and disease symptoms progress, the odds of developing psychological dysfunction increase. At medical history assessment, clinicians should be aware of potential signs of depression (fatigue, mood, loss of initiative and appetite), anxiety and pain avoidance (anxiety associated with specific activities and or pain). Questionnaires for adults like the Hospital Anxiety and Depression Scale (HADS), a short questionnaire,[18] and the Symptom Checklist (SCL-90),[61] a more extensive questionnaire are useful generic measures of psychological dysfunction and are recommended. In children, the Revised Child Anxiety and Depression Scale, a short questionnaire,[62] or the Child Behaviour Checklist,[63] a more extensive questionnaire, are recommended.

3. Tailored intervention

Based on the clinical symptom profile, a tailored intervention may be constructed. Recently a consensus was reached by the Ehlers-Danlos Consortium on the rationality of treatment for HSD/hEDS patients. The current paragraph is based on this consensus statement, however it should be viewed as a summary. For a more detailed description of the available evidence for treatment as well as the background of the rationality for treatment we would like to refer to Engelbert et al 2017.[39] The presented recommendations are based on current knowledge available and personal experience and should be adapted to the nature of the clinical profile, patient preference and context. An overview of all included studies on children[18,64,65] and adults[12,66-70] is shown in table 22-1. The best treatment strategy for highly disabled people with hypermobility is likely to be multidisciplinary. In this way, both physical (hypermobility and related deconditioning) and psychosocial (fear, depression, inadequate coping) components associated with pain can be addressed. During this treatment, patients will be guided in how to develop pain management skills and to change unhelpful coping strategies into helpful ones, in order to decrease disability. Based on systematic evaluation, positive effects of multidisciplinary behavioural treatment for patients with chronic pain syndromes have been confirmed.[71] Whether multidisciplinary treatment specifically targeting pain/disability-related problems in hypermobile people is effective or whether it needs further adaptation to this specific group is currently unclear. As Keer and Simmonds mentioned in their review concerning joint protection and rehabilitation in the adult with a hypermobility syndrome,[72] it is not yet known which form the optimal physical rehabilitation programme should adopt. As long as scientific data on optimal treatment is lacking, recommendations can only be made based on ‘best opinion’ (practice-based).[72,73]

In general, all treatment modalities that aim at enhancing physical fitness, in terms of muscle strength and exercise tolerance, have beneficial effects on pain.[12,18] It is crucial when applying a physical training programme that a physiological baseline is established, which will prevent the occurrence of over or undertraining. Due to the unstable nature of the condition, training intensity should be adjusted to physical and psychological changes over time. It should be noted that the retention time of the accomplished treatment effects is limited. Therefore, maintaining adequate physical activity patterns is vital and should be recognised as a priority. The addition of cognitive therapy can also aid in preserving the achieved treatment effects and functional recovery. Although current research indicates that physical training in combination with a cognitive intervention is effective in pain management, effects on disability have not been shown. The addition of proprioceptive and postural control exercises (closed chain) have also been demonstrated as being effective on pain in children and adults. This combination of exercises will not only have effects on muscle power, but also on motor control.[12,65,69]
In recent years it has become clear that treatment intensity is very important. Exercise should be treated just as medicine, in which side effects may occur and the doses should be graded. In the initial phase (clinical profiling) relevant treatment variables are identified; individual goal setting should be the main focus. In the second phase physical training in combination with cognitive interventions (patient education or individualized psychological intervention) should be initiated in a graded fashion. Initially, the primary focus should be on the cognitive aspects and later on, it should be more on the physical aspects with increasing exposure to higher training intensity. During the whole treatment period, cognitive intervention should be part of the treatment regime (depending on the patient profile and his or her progression). In the final phase the focus should be more on education as well as on continuing adequate physical activity with adequate responses to recurrence of injury. In this phase, frequency and duration of patient-therapist contacts should be reduced and the patient should be enabled to be more independent and in control of his/her condition. After treatment has ended, patients are able to manage re-injury and are advised to contact the multidisciplinary treatment team only if required. Assistive devices are often prescribed in order to reduce disability and pain, however the use of such interventions is also controversial. Currently no evidence is available on the effectiveness of supportive devices and walking aids for this category of patients.[39] As conserving and expanding the habitual activity should be a top priority in any intervention for HSD/hEDS[18,34,74], the usage may be beneficial in certain cases however it may also cause further deconditioning and subsequent disability. Therefore, in line with the evidence statement, judicious use of assistive devices and walking aids is advised and should be made on an individual bases.[39]

4. Areas of uncertainty

As mentioned previously, the evidence presented in this chapter is based on patients diagnosed with BJHS/EDS-HT and it remains unclear if these findings are also applicable to patients diagnosed according to the newly adopted diagnostic criteria (HSD/hEDS). Although the new criteria are more specific, which would cause a shift in patient characteristics, it is expected that the basic principles as described in this chapter and in the evidence statement are similar. Recent knowledge on the natural course of disability is now available, in which the importance of multi-systemic issues have been demonstrated, still the pathological mechanisms underlying HSD/hEDS remain obscure.
Future scientific exploration should focus more on longitudinal study designs in order to create (predictive) clinical models of HSD/hEDS from which risk profiles can be derived, with which patient trajectories and multidisciplinary treatment can be optimized. Until that time, clinicians should treat the recommendations in this chapter as guiding principles, which

should be constantly adjusted to the individual patient and his/her environment as well as to the individual context of the healthcare provider.

5. Summary

The diversity in signs and symptoms and the large heterogeneity of clinical presentation among patients with HSD/hEDS often pose a complex problem for healthcare providers in terms of diagnosis, assessment and treatment. The clinical presentation of the phenotype of HSD/hEDS can be described by four components: 1) Connective tissue laxity, 2) Musculoskeletal dysfunction, 3) Multi-systemic involvement, and 4) Psychological dysfunction. On the basis of these components a clinical profile can be derived from which a tailored intervention may be constructed. Although it remains unclear which treatment modalities (or combinations thereof) are best suited for HSD/hEDS, treatment should be tailored to the clinical profile of the patient and be applied in a graded fashion in order to ensure maximum effectiveness.

Addendum by the editors

In the March 2017 issue of the American Journal of Medical Genetics Part C Seminars in Medical Genetics all papers were devoted to EDS, covering a new EDS nosology, new diagnostic criteria of the different types and also management related topics (see also chapter 2). One of these papers is entitled “The evidence-based rationale for physical therapy treatment of children, adolescents, and adults diagnosed with joint hypermobility syndrome/hypermobile Ehlers-Danlos syndrome”.[39]

Table 22-1 Scientific literature regarding treatment modalities of BJHS/EDS-HT

Author (year), individuals	Type of intervention	Brief description of treatment modality	Treatment specifics	Evaluation points	Author conclusion
Bathen et al [68] *(2013)* **Adults**	Physical and cognitive rehabilitation	Multi-disciplinary treatment: Medical, physical/occupational therapy, social worker Clinical admission: combination of physical treatment aiming at enhancing physical fitness (68% of all sessions, n=17), and cognitive intervention on pain management and lifestyle (42% of all sessions, N=8) Home exercise: physical exercise and monitoring by telephone	Total duration: 13.5 weeks Clinical admission:2.5 weeks Home exercise: 12 weeks Frequency: 4 sessions a week Intensity: (?)	Baseline at start of treatment; Re-admission and assessment at 13 weeks (end of treatment)	-Significant changes in perceived performance of daily activities and participation -Significant reduction of kinesiophobia. -Smaller changes in self-perceived pain.
Rahman et al [70] *(2014)* **Adults**	Cognitive oriented approach	Multi-disciplinary: Medical, psychology, physical therapy Cognitive intervention on illness beliefs, pain management, relaxation and lifestyle advice	Total duration: 6 weeks Frequency: 1 to 2 sessions a week Intensity: 7 hours a week	Baseline at start of treatment; 10 weeks after baseline (T1: end of treatment) Follow-up: at 26 weeks after baseline	-Significantly decreased disability and pain at T1. -at follow-up, the gain in disability regressed to baseline level, but the changes in pain perception were retained
Ferrell et al [69] *(2004)* **Adults**	Physical rehabilitation	Mono-disciplinary: physical therapy Home based physical exercise (open and closed chain exercises), aimed at enhancing proprioception, muscle strength and balance.	Total duration: 8 weeks Frequency: 2 times a week Intensity: increasing number of sets and repetitions.	Baseline at start of treatment; End of treatment at 8 weeks	-Disability was significantly decreased after 8 weeks of treatment -Improvements in pain intensity: lower scores on VAS at 8 weeks

(Continued on next page)

Sahin et al [71] *(2008)* **Adults**	Physical rehabilitation	Mono-disciplinary: physical therapy Clinic based proprioceptive and balance exercises	Total duration: 8 weeks Frequency: 3 times a week Intensity: (?)	Baseline at start of treatment; End of treatment at 8 weeks	-Significantly decreased disability at 8 weeks -Improvements in pain intensity: lower scores on VAS at 8 weeks
Barton et al [67] *(1996)* **Adults**	Physical rehabilitation	Mono-disciplinary: physical therapy Clinic based joint stabilizing exercises	Total duration: 6 weeks Frequency: 3 times a week Intensity: repetitions tailored to individual capabilities. No criteria specified	Baseline at start of treatment; At 6 weeks after baseline (end of treatment) At 12 weeks after baseline (Follow-up)	-Significant improvements in disability and pain at both time points
Pacey et al [65] *(2013)* **Children**	Physical rehabilitation	Mono-disciplinary: physical therapy Clinic based joint stabilizing exercises performed within hypermobile range versus neutral range	Total duration: 8 weeks Frequency: weekly sessions Intensity: 30-60 minutes	Baseline at start of treatment; At 8 weeks after baseline end of treatment); At 12 weeks after baseline (Follow-up)	-Significant improvements in disability and pain at both time points in both groups
Kemp et al [66] (2009) **Children**	Physical rehabilitation	Mono-disciplinary Clinic based proprioceptive and balance exercises versus physical training alone	Total duration: 6 weeks Frequency: once a week Intensity: physical training: 30 seconds intervals. Proprioceptive exercises: No criteria specified	Baseline at start of treatment; At 6 weeks after baseline (midterm of treatment); At 12 weeks after baseline (end of treatment)	Both interventions demonstrated significant pain reduction, but no between- groups difference.

1. Introduction

At admission to a hospital, a patient usually knows less about his or her illness than the department nurse. However, this is often not the case for patients with the Ehlers-Danlos syndrome (EDS). There are two reasons for this. First, these syndromes are so uncommon that a nurse will probably never have had to deal with it before and will therefore neither recognize the syndrome nor the symptoms. Second, for many patients being diagnosed with EDS has been such a long, difficult process that, during this time, they will have studied their own symptoms and have discovered the collagen disorder for themselves.[1]

More than many other illnesses, EDS are disorders that are different for each patient. The specific nature of these disorders requires great dedication of both the nurse or nursing staff and the patient. The nurse must listen professionally and critically to the patient if they are to work together well. The patient must take the time to explain what EDS is to the nurse and must in particular explain its specific consequences for him/her as a patient.

This chapter's goal is to clarify the nursing procedures required for these disorders and to explain how a nurse can best deal with a patient with EDS, who is admitted to hospital. Throughout the text the term EDS may indicate EDS.

2. Types of EDS

The 2017 International classification distinguishes 13 types of EDS (see chapter 2). These types share a number of symptoms. Only three of the most common types will be discussed in this chapter: the classical, hypermobile and vascular EDS, which together account for 90% of the prevailing EDS cases. Recently, the two conditions benign joint hypermobility syndrome (BJHS) and EDS hypermobility type have been recognized as one and the same clinical spectrum ranging from apparently symptomatic generalized joint hypermobility to the most disabled individuals fitting the new diagnostic criteria. These new criteria are more strict than the Villefranche criteria and the Brighton criteria for BJHS in order to define a homogeneous phenotype for management and scientific purposes. Within the new EDS nosology, its name is hypermobile EDS (see chapters 2 and 5). However, to a greater or lesser degree hypermobile joints, highly elastic skin and bruising are common to all types. Table 23-1 shows the extent to which these 3 problems occur among six of the 13 types of EDS.

3. The medical history taking

A number of problems and issues relating to the syndrome require attention when admitting an EDS patient to hospital for a procedure or operation. These play a role in addition to the indication for admission and should be included in the history taking of the nurse. To a greater or lesser degree, there are four prominent chronic problems.[1]

1. hypermobile joints, possibly with (sub)luxation or dislocation as a result;
2. highly elastic, fragile skin (where serious injury can result from limited trauma);
3. skin which bruises easily (haematoma) because the connective tissue around the blood vessels is less strong.
4. in vascular EDS, the connective tissue *within* the blood vessel walls and the hollow organs (intestines, heart, etc.) is weak, resulting in a high risk of bleeding and ruptures. In the other EDS types, the connective tissue *around* the blood vessel walls is less tight, resulting in an increased risk of haematomas (see chapter 6).

For this complex disorder in which many organs and organ systems may be involved, a thorough medical history taking from each individual with EDS is of the utmost importance. Thereafter, a specific nursing plan can be drawn up. For a patient with EDS, the areas which initially require nursing care will emerge from the medical history.

During the history taking, the nurse will integrate the 11 health patterns (box 23-1) with EDS-specific issues and individual specific problems.

Box 23-1 Classification of 11 functional health patterns[2]

1. Health perception – health management pattern
2. Nutritional - metabolic pattern
3. Elimination pattern
4. Activity - exercise pattern
5. Sleep - rest pattern
6. Cognitive – perceptual pattern
7. Self-perception pattern
8. Role relationship pattern
9. Sexuality - reproductive pattern
10. Coping - stress intolerance pattern
11. Values – belief pattern

When designing a specific nursing plan, basic assumptions are the following.
Each patient experiences medical problems differently and each one tries to maintain mental and physical health in his or her own way.[3] A deteriorating condition such as EDS can severely impair mental well-being and physical functioning.
Activity patterns are partially determined by the degree of pain and fatigue experienced. Although thinking about symptoms and the effect of exercise has changed greatly in recent years – for many disorders, symptoms are reduced by exercise – it is very important for EDS patients to carefully alternate rest and exertion. The patients themselves generally know their individual 'instructions for use' well.[2]
Regarding dietary and metabolic patterns, factors such as diet, stomach and intestinal pain, constipation or complications such as a rectum prolapse will influence how a patient deals with the problems. Each patient experiences, accepts and deals with the burden of a chronic disorder differently.
When nursing a patient with EDS, it is important to determine the nature and seriousness of the symptoms. This applies both to the symptom-related problems as well as to the problems leading to hospitalization. It is also important to bear in mind that the patient's condition may vary greatly each day or even throughout the day. It is not unusual for a patient to be able to perform all the normal daily activities independently in the morning and to need help and assistance to change clothing in the evening.

Case study
A 45-year-old woman checks in at the gynaecology department in order to be admitted for removal of the uterus via the abdominal wall (abdominal uterus extirpation). When the patient is greeted upon arrival, the nurse shaking the patient's hand notices that it feels 'strange', like a velvet flannel with bones. The patient has classical EDS. The skin of patients with this type of EDS feels velvety soft and doughy.
Notably, the patient has taken along her own mattress and pillow since she is unable to lie on hard hospital beds because of neck and back pain resulting from hypermobile joints. She explains that for her hypermobile EDS, primarily of the smaller joints such as those of fingers, ribs and the wrists, plays an important role. She is chronically constipated and frequently has intestinal complaints.

To ensure that the operation, hospitalization, discharge and convalescence of an EDS patient are as successful as possible, it is important that a thorough medical history is taken.
Below is described how the process of admission, pre-operative screening, pre-, per- and post-operative support, convalescence and discharge can optimally be controlled.

3.1 Admission

The issues requiring extra attention during medical history taking are:

- use of medicine

In many cases, the patient will be using various medicines, some on demand, such as pain killers. Will the patient be also responsible for managing these at the ward? Make sure there are clear arrangements about this particularly in relation to the department's prevailing policy on pain control. If a patient is already using pain killers, the department's policy may need to be adapted to this to prevent the patient either from becoming overdosed or from having to change to a medication cited in the formulary.

- allergies

Besides any allergies, most EDS patients are hypersensitive to plasters. In addition, sometimes when sticky plaster is removed, part or all of the epidermis is torn. In such cases, other solutions for affixing bandages must be sought, such as elastic bandages or compresses.

- eating habits

It is not unusual for a patient to have an adapted diet because of sensitivity or intolerance of the intestines or a hypotonic gastrointestinal tract (see chapter 10). There is higher risk of constipation as a result of lengthy bed rest. You and the patient should keep an eye on this; if necessary, ask a dietician to set up a diet enriched with fibre and with plenty of liquids.
Many EDS patients suffer from a motility disorder in the gastrointestinal tract and use medication for this. Narcotics and bed rest can increase these problems. You and the patient should keep an eye on this and take timely action, for instance by taking measures such as the use of lactulose and a micro enema and avoidance of medication known to aggravate these problems.[3]

3.2 Pre-operative screening

The following issues are of importance:

- Does the patient have problems with moving his or her head or opening his or her mouth, predicting problems at intubation?

When anaesthetizing such patients, a number of precautions should be kept in mind. When a patient is under anaesthesia, the muscles relax; in EDS patients these muscles help to stabilize the hypermobile joints. Thus, there is an increased risk of joint (sub)luxation. The patient must therefore be moved with the utmost care. The anaesthesiologist should also carefully monitor the patient's maxillary joints while inserting a tube into his or her throat. Also these joints can get luxated easily. The risk of a headache after the operation is reduced by repositioning of the jaws and removing the tube as quickly as possible if this occurs.[4]

- Does inserting a needle to draw blood or fasten a drip prove to be problematic?

The nurse or doctor should be aware of the fact that the patient's vessels are fragile and tend to roll away from the tip of the needle. The vessels do not contract well either or the collagen around the vessels is less tight, increasing the chances of serious haematomas. Huge bruises can result from a misplaced injection or needle insertion because the tissue around the vessels is less firm. It is advisable to ask someone with a great deal of experience with injections or needle insertion to perform this task, to prevent extra pain and injury.

- In some patients with EDS local anaesthetics are not as effective as expected. So, when local anaesthesia is planned, this should be taken into account.

3.3 Pre-, per- and postoperative support

- In addition to the acute pain brought on by the operation, EDS patients also may experience chronic pain in various places in the body. This is the result of hypermobile and sometimes damaged joints, joint capsules and muscles. It is advisable to discuss the possibilities of pharmacological pain management before surgery and to call a physiotherapist early on after surgery for support during the often slow convalescence.[5]
- There is a higher risk of postoperative sleeplessness as a result of the pain caused by the operation in addition to the already existing chronic pain symptoms caused by EDS. The patient and nurse should discuss how best to deal with this problem. Lying in bed for long periods often leads to back pain. The patient may require more exercise that the standard operation protocol dictates. However, if the patient suffers from complaints of the back and pelvis resulting from lying on a hard operation table, it may not be possible to follow the mobilization protocol because a few days of bed rest are needed before mobilization can be initiated.[6]
- Due to the patient's highly fragile skin, there is an increased risk of decubitus ulcers (bedsores, pressure ulcers). On medical grounds, the EDS itself calls for an anti-decubitus mattress. In the case above, the patient took her own pillow along (remember the risk of sub-luxation of the maxillary joints) to enhance her comfort when lying down and sleeping. If the patient is bed bound, a dietician can prescribe a diet high in protein. Bedsores can be prevented by changing positions, through massage and by mobilizing the patient as early and much as is possible.
- It is important to monitor bleeding at the incision site. Due to poor quality of vessel walls, poor vessel contraction and possibly bleeding disorders (see chapter 11), the risk of continued bleeding after the operation is higher.
- Total floppiness (hypotonia) of the organ walls is an important issue to watch for. In cases of an abdominal injury, a spica elastic bandage can be applied to prevent further bleeding.

Among patients with vascular EDS vessel and organ problems will be prominent far more often than normal. Upon meeting patients with this vascular EDS, one will notice the thin transparent skin. Sometimes (certainly not always) people with this type of EDS have characteristic facial features such as a pointed noise, hollow eyes, missing ear lobes and down-slanting eyelids; more often they have an aged aspect of the hands (acrogeria). The risk of the vessel and organ walls tearing is greatly increased among patients with vascular EDS. Because of the close contact between the nurse and patient at the ward, the nurse will be the first to notice the symptoms of these complications; she or he should take action immediately. Although it is generally wise to have an intensive care bed available for EDS patients, for surgery upon patients with the vascular type, it is prerequisite.

3.4 Convalescence and discharge

In part due to issues involved in each individual patient, it is difficult to make any generalized judgment about the extent and intensity of an EDS patient’s convalescence or what help may be required at home after discharge. The individual need for further care will have to do with factors such as the number of days which have elapsed since the surgery took place, the patient’s condition and ability to manage independently prior to the operation and the extent of pain and disability.

A slow recovery and extended convalescence period often have consequences for the duration of the hospitalization. In order not to extend this time longer than needed , it is important to

give timely attention to the issue of whether homecare and possible other resources have to be provided or not.

4. Summary

The relatively rare EDS is an unknown disorder for many nurses. Although there are differences in symptoms and degrees of seriousness, three problems occur among patients to a greater or lesser degree: 1) hypermobile joints, 2) highly elastic, fragile skin and 3) easy bruising. A nurse who has to take care of a patient with EDS will have to have to gain some knowledge of the symptoms and can, through the nursing diagnosis, determine the range of problems as well as the related contributory factors and consequences. By doing so, he or she can prevent a number of complications and also reduce their seriousness.

Table 23-1 Impact of the three main problems associated with six of the 13 types of EDS*#

Types of EDS	Highly elastic skin	Hypermobile joints	Frailty of vessels and organs
Classical EDS	+++	+	+
Hypermobile EDS	+	+++	+
Vascular EDS	+	+	+++
Kyphoscoliotic EDS	+	++	+
Arthrochalasia EDS	++	+++	++
Dermatosparaxis EDS	++	+++	+

* + limited ; ++ moderate ; +++ severe impact

see chapter 2 for the 2017 EDS nosology

1. Introduction

Occupational therapy does not focus on a particular disease, disorder, or the treatment of symptoms, but rather on performing daily activities. Together with the patient, occupational therapists try to ensure that, as far as possible, patients are able to do what they want to do despite their limitations. Unlike in the past, the emphasis these days is not so much on independence, but on being able to carry out 'meaningful' tasks; in other words making it possible for the patient to do the things that are particularly important in his or her life. This principle means that patients with Ehlers-Danlos syndrome (EDS) have to make choices, such as deciding how they want to spend the limited energy they have. It is important that patients are aware of their limited physical capacity.

Therefore, setting priorities in this way is an important aspect of occupational therapy. The reasons for a patient's limited ability to participate in certain activities can be determined by analysing their situation. In collaboration with the patient, whilst taking their individual situation into account, occupational therapists can set realistic objectives and try to find solutions by adapting those activities and making use of various assistive devices. Whether such a device is suitable depends not only on the patient's physical limitations, but also on the assistive device used and the way in which the patient and his/her social environment deals with their illness.

In general, occupational therapy can only be successful once a patient has accepted his/her limitations, at least to a certain degree. Only then, the patient will be able to focus on adapting his/her lifestyle, applying the rules of daily living and finding practical solutions. Occupational therapists not only offer advice regarding assistive devices or adaptive measures, but also examine the ways in which activities are carried out. Particularly, muscle and joint problems can result in functional limitations in hypermobile patients. The use of joint protective measures is therefore an important aspect of the therapy, the starting point of which is being able to find a balance between physical load and capacity. Occupational therapists can also advise patients with skin disorders on skin protective measures.

This chapter deals with problem analysis and treatment in patients with EDS from an occupational therapy point of view. In addition to joint and skin protective measures, this chapter also includes information on the use of assistive devices, adaptive measures, orthotics and other aids. It is appropriate to note that recently the two conditions benign joint hypermobility syndrome (BJHS) and EDS hypermobility type have been recognized as one and the same clinical spectrum ranging from apparently symptomatic generalized joint hypermobility to the most disabled individuals fitting the new diagnostic criteria. These new criteria are more strict than the Villefranche criteria and the Brighton criteria for BJHS in order to define a homogeneous phenotype for management and scientific purposes. Within the new EDS nosology, its name is hypermobile EDS (see chapters 2 and 5).

2. Problem analysis in occupational therapy

2.1 Method of approach, issues and objectives

Occupational therapists take a holistic and system-oriented approach, in other words they regard the patient as a whole and in relation to his/her environment. This approach is particularly important when patients have to readjust their lives, set new goals and rediscover balance in various areas of their lives.

Occupational therapy focuses primarily on the functional limitations experienced by the patient. Problem analysis may yield that a patient with EDS has difficulty performing many basic skills such as sitting, or sitting for a longer duration, walking, standing, getting up, bending, stretching, raising limbs, lifting and holding on to things. This can result in

limitations with regard to all manner of activities; these activities can be divided into the following categories: mobility (walking, climbing stairs, using a wheelchair), personal care and housework (washing, combing hair, fastening clothing, cooking, cleaning), work/schoolwork and leisure activities.
Functional limitations can have significant social and emotional consequences. Occupational therapists therefore focus not only on independence, but also on issues such as meaningful daily living or satisfying social contacts: in short on the patient's quality of life. Occupational therapists help patients to resume these activities in cases where the patient would regard the inability to perform them as a handicap. If this is not a realistic target, the occupational therapist will try, together with the patient, to find suitable alternatives.

2.2 Complicating factors: many concurrent problems and limited duration

Limitations experienced by hypermobile patients are primarily due to muscle and joint pain, fatigue and joint dislocation/subluxation, including the risk of these. Patients usually suffer complaints in several joints at once, and in EDS these are often accompanied by other problems, such as skin disorders. When using assistive devices or splints, it is important to take into account the potential negative local effect on the skin, and the fact that stress reduction in one joint or body part may lead to excess physical strain on another. Occupational therapy should also take into account that patients with EDS can only carry out certain activities for a limited duration. Many activities are painful, yet not impossible to perform. Although total avoidance of pain and movement leads to further physical decline, this also applies for excess physical strain and suppression of the pain. It is therefore important, albeit extremely difficult, to achieve the right balance between physical load and capacity. A daily and weekly programme, including both sufficient activity and rest, is essential. It can keep fatigue within acceptable levels, which some patients find a greater obstacle than the pain. It is also important that patients learn to deal with pain. A general rule of thumb is that a particular activity is not damaging if the pain subsides relatively quickly once the activity is stopped. However, an activity may be regarded as causing excess physical strain if the pain and fatigue generally last longer than two days.

3. Adapting activities, applying the rules of daily living

3.1 Joint protective measures

Occupational therapists try to ensure that patients learn to perform activities in such a way that these cause a minimum of strain, yet are carried out to the best of the patient's ability. This may involve adapting the way in which an object is held, adapting the patient's posture or carrying out the sub-tasks involved in the activity in a different order so that, for example, the patient can walk a longer total distance than before. For patients with generalised hypermobility, adaptations usually call for the use of measures that help protect the joints. These joint protective measures are described below as rules of daily living, which have been adapted from those used in the treatment of rheumatoid arthritis. It is essential that the patient has knowledge of his/her own abilities and limitations in order to apply the rules of daily living correctly, by means such as, but not limited to:

a) Maintaining optimal physical condition.
This includes getting a good night rest (a good mattress, pillow and an armchair for resting during the day), maintaining muscle strength and movement, maintaining a healthy diet and body weight, wearing adequate footwear and avoiding cold and damp environments. Excess physical and mental stress should be avoided whenever possible.

b) Alternating periods of activity with rest and stick to a balanced programme of daily and weekly activities.
It may be advisable to plan periods of rest and to divide tasks into smaller sub-tasks. Many people with hypermobility syndromes plan extra rest periods and only light tasks or no tasks at all towards the end of the day, when they often experience an increase in symptoms. For others, it is important to begin the day slowly and not to plan many tasks straight away. Productive days can also be planned, but these should generally be alternated with less busy days.

c) Using alternate methods for performing various activities.
It may help to perform certain activities while sitting in order to save energy and reduce the physical stress caused by those activities, such as showering, getting dressed, making sandwiches, cooking, ironing, and enjoying hobbies. Applying ergonomic principles can make it easier to perform certain tasks. Placing appliances such as refrigerators, dishwashers or washing machines at a suitable height can avoid unnecessary bending. Furthermore, stretching can be avoided by arranging cupboards in such a manner that commonly used items are within easy reach. Long periods of standing or sitting in one position are best avoided, as are repetitive activities. Physical load should be divided over several joints where possible, for example, by using two hands rather than one to lift objects such as pans or mugs. Since some patients suffer from reduced proprioception (the sense of relative position and movement), visual control of movement can provide good support when performing certain activities.

d) Using suitable products, equipment and assistive devices.
There are many ways to help patients move objects more easily (e.g. using a trolley bag, serving trolley or walking frame). Extra long handles (to increase leverage) and the use of thick handgrips can serve to lighten some tasks. Sharp knives, lightweight pans and ready-meals can all help to make the task of cooking a lot easier. Easy-care or non-iron garments, that can be put on and taken off easily, can also help patients to save their energy.

e) Finding suitable means of transport and using assistance when needed. For example, someone to help with the housework, heavy work in particular, can help prevent excess physical strain. Moreover, this allows generalised hypermobility patients to save their limited energy resources for other activities.

3.2 Skin protective measures

Occupational therapists can help with the prevention of skin damage in EDS patients with serious skin problems. Therapy is necessary because relatively small injuries can worsen easily into large wounds, which do not heal well and can result in unsightly scarring. Some examples of skin protective measures are taking care with home furnishings by avoiding furniture with sharp points, being careful when walking on slippery floors or loose rugs, wearing protective clothing for certain activities, making sure that pressure ulcers do not develop when lying or sitting in the same position for long periods, and taking extra care when using splints or support socks/stockings as the skin can tear easily.

4. Assistive devices, adaptive measures and services/facilities

Physicians and patients are often afraid that the use of assistive devices and adaptive measures will result in physical decline, assuming that the muscle and joint conditions will deteriorate as the assistive devices take over normal tasks. This assumption, however, does not hold if the right assistive devices are used for the right applications. The aim of occupational therapy is to increase the patient’s functional potential; assistive devices and adaptive measures

therefore serve to make the patient more active and independent, rather than increase passivity. It is true that shower stools, special work/office chairs and wheelchairs result in patients standing and walking less. However, this does not mean that these devices actually promote physical decline, but rather that they are used in order to prevent incorrect physical load or excess physical strain. The object is indeed to find a balance between physical load and capacity and so prevent both excess, incorrect load and too little physical load. It is important to bear in mind that the use of splints does involve the risk of physical decline. Therefore we will pay special attention to this subject below.

Studies have shown that a large percentage of assistive devices and adaptive measures are purchased at too high a price, are not used, or are used incorrectly and thus fail to meet the patient's needs. This can happen when people try to find hasty solutions without performing adequate problem analysis beforehand. Moreover, problems can also occur when the right type of device or facility is used, but in the wrong size or version. There is a huge number of types and brands of assistive devices on the market, and choosing the right one depends very much on the individual situation for which it is intended. Furthermore, some assistive devices are complicated to use and therefore impractical. The degree of difficulty involved in choosing the right equipment is therefore high; practical training and instruction is essential, and it can be helpful if the occupational therapist visits the patient at home. It may be useful to plan a follow-up visit after the treatment has ended, to check whether the device is being used correctly and is providing adequate support.

4.1 Use of assistive devices and adaptive measures in everyday life

Below is a review of the use of assistive devices for four categories, namely mobility, personal care and housework, home modifications, and work/school/leisure.

4.1.1 Assistive devices and adaptive measures for mobility

Wheelchair use can vary from occasional/recreational to total dependence. Many patients are unable to propel themselves manually in a wheelchair as this creates too great a strain on their arms. Electric wheels/wheelchairs and mobility scooters can provide a solution. Electric wheelchairs and mobility scooters that can be folded or dismantled to fit in a car are available in an increasing number. These devices can significantly increase a person's mobility, provided the support and seat comfort are sufficient to allow the patient to sit for reasonably long periods. The choice between an electric wheelchair and a mobility scooter for outdoor use, depends on the patient's ability and the vehicle's ease of operation. It is essential that the transport device has good suspension, that the seat, arms and backrest of the chair provide good support, and that the seat position can be changed (reclining backrest). Walking frames or walking aids usually place too much stress on the hands, arms and shoulders, although they are sometimes used for short distances. A walking frame also allows a patient to carry objects over short distances.

Automatic transmission, power steering and power brakes are usually essential for patients who wish to drive a car, but there are also many car modifications available such as a lift to raise a wheelchair into the back of a car. A disabled parking permit allows patients to park closer to their destination and limits the need to walk long distances. A modified bicycle can also provide a solution for some patients. The vehicle of choice is usually the 'comfort cycle', in which the positions of the handlebars, saddle and pedals have been adjusted to reduce strain on the knees, hands, arms and neck. These bicycles can also be fitted with an electric motor when required. Finally, patients can opt to make use of collective transport services such as taxi buses, which are now provided by the government in many countries.

4.1.2 Assistive devices and adaptive measures for personal care, housework and other everyday activities

It may be important for some people to have clothing fitted with alternative fastenings (e.g. Velcro, elastic shoelaces), and thermal underwear can help to protect against the cold. A range of devices is available which makes it easier to get in and out of the bathtub. Shower stools can be useful, as can brushes and sponges with long handles, which help to make washing less painful. Eating and drinking are made easier by using lightweight and/or modified cutlery (see figure 24-1). There are also many assistive household devices for sale, and solutions can usually be found for carrying out everyday activities more easily. Some patients benefit from having a special work/office chair or saddle stool, which can allow household tasks to be carried out whilst sitting. In some cases, every day life can be made easier with the assistance of a service dog.

Figure 24-1 Adapted cutlery: knife, cheese plane and spoon

Recently, more attention has been given to the subject of sexuality. Pain or other problems during sexual activity can have a negative effect on a patient's relationship and personal happiness. Although occupational therapists are not always inclined to deal with sexual issues, they might sometimes be able to suggest possible solutions such as assistive devices like the support of special cushions and/or position.

4.1.3 Home modifications

It may sometimes be necessary to modify the home in order to make it wheelchair accessible. A stair lift can be installed if climbing the stairs is a problem. A shaft lift may provide a better alternative if using a stair lift is too much of a burden for the patient. Kitchens can also be adapted using pull-out worktops, ceramic cooking plate for sliding rather than lifting pans onto, or a 'hob tap' from which pans can be filled with water at the cooking plate. Furthermore, shower chairs that allow patients to shower whilst sitting and bathroom handgrips, that increase safety and stability, are often very useful. Finally, even small modifications in the home can be extremely useful, such as cord-operated switches, large switch cover plates, lever-operated taps and radiator fittings, or large rounded doorknobs that put less strain on finger joints.

4.1.4 Assistive devices and adaptive measures for work, school and leisure

An occupational therapist can examine a patient's workstation and provide advice on ergonomic layout. Computers allow people to work from home and therefore keep flexible working hours. There are many types of pens available that make writing easier; users find that fountain or gel pens, for example, glide across the surface of paper easily. Laptops can offer a good alternative to writing and are therefore regularly used in schools. It is also important that children are provided with good furniture at school; it may also be necessary to provide facilities that allow the child to rest between lessons. At secondary school, changing classrooms each period can present problems, as can carrying books to and from school and lessons. With a little creativity, solutions to these problems can usually be found, and occupational therapists will sometimes visit the child's school in order to assess the situation.
For leisure, there is also a wide range of modified materials on the market, such as garden tools and musical instruments. Also, patients can be provided with extra cushions for bar stools, outdoor café chairs or church pews, and cushions with a back support. Beach wheelchairs can also be hired at many seaside resorts.

4.2 Splints

Splints can be divided into three types: mobilisation splints, immobilisation splints and restrictive splints. The first allows joints to increase the range of movement, the second prevents movement in joints, and the last limits a joint's range of movement (see figure 24-2). Caution is recommended when considering splints particularly for patients with EDS: splints can injure the skin locally, they can be too heavy for the surrounding joints, long-term use can cause the condition of muscles, ligaments and tendons to deteriorate. Furthermore, patients often consider splints undesirable from a cosmetic point of view. Nevertheless, splints can be useful in many cases. 'Finger splints', which are used to prevent overstretching of small finger joints, or splints that are only worn for specific activities or for a limited period, can significantly increase the range of activities a patient is able to perform, and may reduce pain. Sometimes there is no alternative but to wear a splint, for example, when pain and recurrent dislocations affect the patient's quality of life adversely. Appropriate preventive and safety measures must be taken when using splints for patients with generalised hypermobility. Health care providers or patients themselves should regularly check the skin under a splint carefully: checking under newly applied splints several times at maximum intervals of 30 minutes. The splint must be lightweight, but also as large as possible, so that the pressure on the skin is spread over as large an area as possible. Patients should be instructed to remove the splint if it becomes uncomfortable, and then contact their health care specialist.

In some cases, people may choose to use assistive devices or adaptive measures that do indeed promote physical decline, but which at the same time help to increase their quality of

life. It is important that the occupational therapist and the patient first carefully discuss the pros and cons involved.

Figure 24-2 Restrictive and immobilisation splints

Images above: 'silver rings', preventing hyperextension of proximal interphalangeal joints of fingers (blue arrow heads) and of the interphalangeal joint of the thumb (yellow arrow head): restrictive splints.
Images below: a short and long wrist splint, immobilising the wrist: immobilisation splints.

5. Financial reimbursement

Reimbursement of the costs incurred for many assistive devices, aids and adaptive measures is available from sources such as the government or insurance companies. Legislation and regulations on financial reimbursement vary from one country to another and are subject to regular change; the subject of reimbursement is therefore not dealt with in detail here.

6. Conclusion

The use of occupational therapy for syndromes such as EDS is based on comprehensive problem analysis, in which the occupational therapist sets realistic objectives together with the patient. Treatment focuses on increasing the range of activities that can be performed by the patient. In order to achieve this, occupational therapists teach patients alternative methods of performing certain activities by adapting certain rules of daily life; such as taking measures to protect joints, whilst also helping patients to select and use assistive devices, adaptive measures and services/facilities.

Addendum. Considerations, precautions and measures in case of surgery in patients with Ehlers-Danlos syndrome

These are just general recommendations; depending on the clinical situation or condition of an individual patient, other or additional measures may be necessary.

Before surgery

1. Most important, especially in patients with classical Ehlers-Danlos syndrome (EDS), vascular EDS or kyphoscoliotic EDS, is to weigh the potential benefits of surgery and possible complications of surgery and of required diagnostic investigations, before they are planned. Consider all non-surgical alternatives
2. Choose, if possible and clinically indicated, minimal and non-invasive diagnostic procedures, such as computer tomography (CT), magnetic resonance imaging (MRI) and ultrasonography; avoid in patients with vascular EDS or kyphoscoliotic EDS punctures, arteriography, endoscopy, clyster and colonic irrigation
3. In case of planned intubation, X-rays of the cervical spine in several positions of the head may be indicated to diagnose hypermobility of the upper cervical vertebrae and malformations of vertebrae
4. Preoperative examination by a cardiologist is indicated if at adequate preoperative screening cardiac problems are found
5. Routine screening for clotting and bleeding disorders is not indicated; screen only if clinically indicated; in case of prolonged bleeding time, testing whether DDAVP can diminish the bleeding time may be indicated
6. Because of increased risk of bleeding during and after surgery (in vascular and kyphoscoliotic EDS caused by defective connective tissue within vessels and in other EDS types caused by lax connective tissue around vessels), carbasalate calcium and acetylsalicylic acid should be discontinued for 7-10 days if possible and other non-steroidal anti-inflammatory drugs for 5-7 days
7. In vascular EDS, blood pressure should be checked several times and be controlled before surgery, if too high
8. Especially for a patient with vascular or kyphoscoliotic EDS, it should be checked before the actual day of surgery and at that day whether there is enough blood available of the patient's blood type

During surgery

1. In case of local or regional anaesthesia: keep in mind that patients with EDS may experience insufficient aesthetic effect
2. Beware of (sub)luxation of the mandibular joints at intubation; then rapid repositioning is indicated
3. Beware of an increased risk of (sub)luxation of joints because of muscle relaxing anaesthesia, especially when repositioning a patient or performing surgery of the upper extremity
4. For incisions of the skin, follow Langer's lines of the skin, corresponding to the alignment of collagen fibres within the dermis, resulting in minimal cleavage of these fibres
5. Avoid pressure or tension on skin, vessels and organs by using atraumatic surgery equipment and haemoclips, instead of stiches. Beware of tension on the skin when closing the wound, especially in a patient with classical EDS. Much experience is

required for surgery in patients with EDS, especially vascular, classical or kyphoscoliotic EDS. It could be wise to have another experienced surgeon stand-by for emergencies
6. Avoid the use of probes
7. In case of bowel ruptures in vascular EDS it is generally better to place a stoma than trying to suture the rupture
8. Beware of an increased risk of pneumothorax at mechanical ventilation; a lower peak-flow volume may be indicated

After surgery

1. Again beware of an increased risk of pneumothorax at mechanical ventilation; a lower peak-flow volume may be indicated
2. Beware of increased risk of anastomotic leakage and its complications, such as bleeding and infection
3. Avoid rectal body temperature assessments and punctures of arteries (e.g. for blood gases measurements); limit number of vena punctures
4. In patients with vascular EDS: again regularly check and control blood pressure and prescribe a proton pump inhibitor because of the risk of a major bleeding in case of a stress ulcer
5. Apply special techniques for bandaging of wounds to prevent wound herniation
6. The revalidation period may be longer than normal; start revalidation early, under supervision of a physiotherapist
