ABSTRACT

Acid mine drainage is generated when mining activities expose sulphidic rock to water and oxygen leading to generation of sulphuric acid effluents rich in Fe, Al, SO₄ and Mn with minor concentrations of Zn, Cu, Mg, Ca, Pb depending on the geology of the rock hosting the minerals. These effluents must be collected and treated before release into surface water bodies. Mining companies are in constant search for cheaper, effective and efficient mine water treatment technologies. This study assessed the potential of applying magnesite as an initial remediation step in an integrated acid mine drainage (AMD) management system. Neutralization and metal attenuation was evaluated using batch laboratory experiments and simulations using geochemical modelling. Contact of AMD with cryptocrystalline magnesite for 60 min at 1 g: 100 ml S/L ratio led to an increase in pH, and a significant increase in metals attenuation. Sulphate concentration was reduced to ≈1 910 mg/l. PH redox equilibrium (in C language) (PHREEQC) geochemical modelling results showed that metals precipitated out of solution to form complex mineral phases of oxy-hydroxysulphates, hydroxides, gypsum and dolomite. The results of this study showed that magnesite has potential to neutralize AMD, leading to the reduction of sulphate and precipitation of metals.

Keywords: acid mine drainage, cryptocrystalline magnesite, toxic metals, geochemical modelling, water treatment

INTRODUCTION

The aftermath of gold and coal mining has triggered serious environmental problems that need urgent attention prior to degradation of terrestrial and aquatic ecosystems and their ability to foster life (Jooste et al., 1999; Luis et al., 2009; Raymond et al., 2009; Equeenuddin et al., 2010). Mining of the aforementioned minerals exposes sulphide-bearing minerals to oxidising conditions. During rainfall and underground working, sulphide minerals react with water and oxygen leading to the formation of highly acidic mine effluent known as acid mine drainage (AMD). The acidity in AMD promotes the leaching of heavy metals from the surrounding geology (Johnson et al., 2005; Sheoran et al., 2006; Cheng et al., 2009; Simate et al., 2014; Amos et al., 2015; Delkash et al., 2015). The equation below shows the formation of acid mine drainage using pyrite as an example (Simate et al., 2014):

In the Witwatersrand gold ores of South Africa, for instance, up to 70 minerals have been identified, including gold, pyrite, uraninite (U₃O₈), sphalerite (ZnS), galena (PbS) and various silicates among others (Tutu et al., 2008, 2009). Numerous technologies have been developed for remediation of acid mine drainage (Gitari et al., 2008; Delkash et al., 2015; Lakovleva et al., 2015). The commonly used technologies include ion exchange (Buzzi et al., 2013), reverse osmosis (Johnson et al., 2005), adsorption (Gitari, 2014; Lakovleva et al., 2015), biosorption (Sheoran et al., 2006) and precipitation (Bologo et al., 2012; Maree et al., 2013). However, generation of secondary sludge, toxicity, high operation costs, poor efficiency and demand for large expanses of land limit the application of the majority of developed technologies (Johnson et al., 2005; Kalin et al., 2006; Sheoran et al., 2006; Simate et al., 2014).

The Witwatersrand Basin produces approximately 340 Ml/day of mine water (Bologo et al., 2012) and this has been reported to impair the quality of water downstream (Jooste et al., 1999). Treatment of large volumes of mine effluents requires a very effective and efficient technology. In South Africa, limestone has been widely used as the main chemical agent for neutralization and removal of metals in acid mine waters (Maree et al., 1994, 2004, 2013). However, the use of limestone has the limitation of precipitating toxic metals with gypsum and raising pH > 7 (Maree et al., 1993).

The present study was designed to develop a novel technology of using cryptocrystalline magnesite for remediation of acid mine drainage (AMD). Moreover, large deposits of cryptocrystalline magnesite in the Limpopo Province of South Africa (Masindi et al., 2014, 2014, 2015), and its low cost, makes it an attractive option for AMD remediation. This study explored, for the first time, changes in solution chemistry and elemental speciation during the reaction of magnesite and AMD by simulating these processes using the PHREEQC geochemical modelling code. The quality of product will be compared to Department of Water and Sanitation (formerly the Department of Water Affairs and Forestry (DWAF)) water quality guidelines (DWAF 1996).

MATERIALS AND METHODS

Sampling

Raw magnesite rock was collected from the Folovhodwe Magnesite Mine in Limpopo Province, South Africa (22°35'47.0" S and 30°25'33" E), prior to any processing at the mine. Field AMD samples were collected from a decant point in a disused mine shaft in Krugersdorp, Gauteng Province, South Africa.

Simulated acid mine drainage

Synthetic acid mine drainage (SAMD) was used for the batch optimization experiments as real acid drainage is unstable over long periods of time due to oxidation and hydrolysis which changes its chemistry. A simplified solution containing the major ions found in acid mine waters was prepared with reference to the study by Tutu et al. (2008). Synthetic AMD solution was simulated by dissolving the following quantities of salts (7.48 g $\text{Fe}_2(\text{SO}_4)_3 \cdot \text{H}_2\text{O}$, 2.46 g $\text{Al}_2(\text{SO}_4)_3 \cdot 18\text{H}_2\text{O}$, and 0.48 g MnCl_2 from Merck, 99% purity) in 1 000 mL of Merck Millipore Milli-Q 18.2 M Ω -cm water to give a solution of 2 000 mg/L Fe^{3+} , 200 mg/L Al^{3+} and 200 mg/L Mn^{2+} . 5 mL of 0.05 M H_2SO_4 was added to make up the SO_4^{2-} concentration to 6 000 mg/L and ensure pH below 3, in order to prevent immediate precipitation of ferric hydroxide. The SAMD was prepared with deionized water. The salts were dissolved in a 1 000 mL volumetric flask.

Preparation of magnesite

Magnesite samples were milled to a fine powder for 15 min at 800 r/min using a Retsch RS 200 vibratory ball mill (PM 100, Retsch-Allee 1 – 5, Haan, Germany) and passed through < 32 μm particle size sieve. The samples were kept in a zip-lock plastic bag until utilization for AMD treatment.

Characterization of aqueous samples

Total dissolved solids (TDS), pH and electrical conductivity (EC) were monitored using CRISON MM40 portable pH/EC/TDS/temperature multimeter probe. Aqueous samples were analysed using ICP-MS (7500ce, Agilent, Alpharetta, GA, USA) for metal cations and sulphate was analysed using IC (850 professional IC Metrohm, Herisau, Switzerland). The accuracy of the analysis was monitored by analysis of National Institute of Standards and Technology (NIST) water standards. Three replicate measurements were made on each sample and results are reported as the mean of the three samples.

Elemental composition of X-ray fluorescence

For elemental analysis by XRF, the samples were dried at 100°C and roasted at 1 000°C to determine loss on ignition (LOI). 1 g sample of magnesite was then mixed with 6 g lithium-tetraborate flux and fused at 1 050°C to make a stable fused glass bead. For trace element analysis, the samples were mixed with a PVA binder and pressed into a pellet using a 10 t press. Major and minor elemental analysis of the prepared powdered magnesite samples was done by a PAN analytical Axios X-ray fluorescence spectrometer equipped with a 4 kW Rh tube.

Batch experiments: optimization of inorganic contaminant removal conditions

Optimization experiments were done in batch experimental procedures. Parameters optimized included magnesite dosage and particle size. To evaluate effects of magnesite dosage on reaction kinetics, the dosage was varied from 0.1–8 g (2 000 mg/L Fe^{3+} , 200 mg/L Al^{3+} , 100 mg/L Mn^{2+} , 6 000 mg/L SO_4^{2-} , 250 r/min, 60 min of reaction and 26°C). To study the effects of particle size, aliquots of 100 mL each and containing 2 000 mg/L Fe^{3+} , 200 mg/L Al^{3+} , 100 mg/L Mn^{2+} and 6 000 mg/L SO_4^{2-} were pipetted into 250 mL flasks and 1 g of varying particle sizes (ranging from 1–2 000 μm) of magnesite added into each flask. Other conditions include: 60 min retention time, ambient room temperature, 250 r/min equilibration speed, 100 mL and pH < 3. Optimized conditions were used for testing the feedstock capacity to neutralize and attenuate from field mine effluents.

Treatment of field AMD at optimized conditions

Field AMD samples were treated at established optimized conditions in order to assess the effectiveness of magnesite. EC, pH and TDS were measured using CRISON MM40 multimeter probe. The resultant solid residue after treatment of raw AMD was characterized in an attempt to gain insights into the fate of chemical species.

Geochemical modelling

To complement chemical solution and physicochemical characterization results, the ion association model PHREEQC was used to calculate ion activities and saturation indices of mineral phases based on the pH and solution concentrations of major ions in supernatants that were analysed after the optimized conditions. Mineral phases that were likely to form during treatment of AMD were predicted using the PHREEQC geochemical modelling code using the WATEQ4F database (Parkhurst and Appelo, 1999). Species which are more likely to precipitate were determined using the saturation index (SI). $\text{SI} < 1$ = under saturated solution, $\text{SI} = 1$ = saturated solution and $\text{SI} > 1$ = supersaturated solution.

RESULTS AND DISCUSSION

Elemental composition by X-ray fluorescence

The elemental composition of magnesite before and after interaction with raw AMD is shown in Table 1.

Magnesite was observed to contain Mg as the major

component. There were impurities of Si and Ca which were observed to be present. After the reaction, Al, Fe, Mn, Zn, Cu, Co, Nb, Ni, Pb, SO₃, Sr, Y, Zr, Cr and Ba were found to be present in the resultant solid residues. The results obtained for the raw magnesite corroborated results from the study by Nasedkin et al. (2001). In their study, they reported that cryptocrystalline magnesite is characterized by 90 – 92 wt % of MgO and very few other impurities. The levels of Al, Fe, Mg, Ca, Mn and S were observed to increase in the resultant solid residues indicating formation of new phases that include those mineral phases. This could be explained by a decrease in their levels in the product water (Table 3). The presence of Mn, Fe, Al, Ca, Mg, C and O suggest minerals such as Mn, Fe, Al oxide, metals hydroxides, Mn and Fe carbonate, gypsum, Al and Fe oxyhydroxysulphates. The PHREEQC simulation also predicted precipitation of mineral phases bearing these metal species.

Optimisation results

Effect of magnesite dosage

The results for neutralization and metal removal efficiency as a function of magnesite dosage are presented in Fig. 1.

The experimental results showed that there was an increase in pH with an increase in dosage. An increase in pH would be expected since an increase in dosage results in an increase in alkalinity and precipitation of metals. An increase in alkalinity was also verified by modelling. Simulations showed an increase in alkalinity from 2×10^{-02} for 0.1 g of magnesite to 3×10^{-01} eq/kg for 8 g magnesite. Modelling predicted that as pH increases, Fe³⁺ species precipitate at pH > 6, Al³⁺ bearing species at pH > 6, Fe²⁺ species at pH > 8 and Mn²⁺ bearing species at pH > 10 (Table 1). The trend showed a lower per cent removal of sulphate compared to that for metals. This could be attributed to the formation of MgSO₄ and, partly, CaSO₄, which remains in solution until saturation and only precipitates at elevated dosages. This is substantiated by the higher solubility of MgSO₄ ($K_{sp} = 5.9 \times 10^{-3}$) compared to that of CaSO₄ ($K_{sp} = 4.93 \times 10^{-5}$), suggesting that more magnesite should be dissolved so as to precipitate out MgSO₄ and CaSO₄ (Langmuir et al., 1997). The speciation of Ca and Mg was also assessed using geochemical modelling and the results showed that calcium existed as CaCO₃, Ca²⁺, CaOH⁺, CaSO₄, CaHCO₃⁻, CaHSO₄⁺ and magnesium as MgOH⁺, MgCO₃, Mg²⁺, MgSO₄, MgHCO₃⁺. Metal complexes were predicted to precipitate as hydroxide and oxyhydroxides, and to co-precipitate as oxyhydroxysulphates. These results were similar to those obtained by Bologo et al. (2012). From the dosage experiments, it was concluded that optimum neutralization and metal attenuation conditions were 60 min of contact time and 1 g of magnesite dosage (at 1:100 S/L ratios). The results in the following sections are based on these optimal conditions.

Effect of magnesite particle size

The results for neutralization and metal removal efficiency of magnesite as a function of particle size are presented in Fig. 2.

Particle size is an important parameter in neutralization and metal attenuation processes. The smaller the particle size,

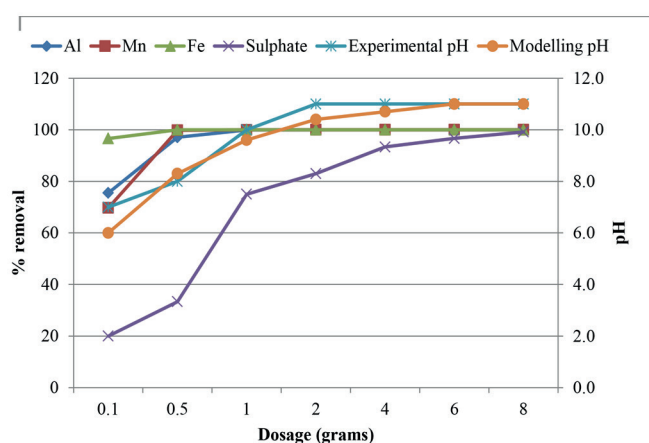

Figure 1

Variation of pH, Al, Fe, Mn and sulphate concentration with adsorbent dosage (conditions: 2 000 mg/L Fe³⁺, 200 mg/L Al³⁺, 100 mg/L Mn²⁺, 6 000 mg/L SO₄²⁻, 250 r/min shaking speed, < 32 μm particle size, 100 mL, 60 min of shaking time and 26°C room temperature)

the larger the surface area provided for reaction and the faster the rate of neutralization and metal removal (Alloway, 1990). As shown in Fig. 2, the rate of neutralization and metal attenuation decreased with increasing particle size. At particle sizes < 125 µm magnesite removed almost all contaminants and increased the pH of the aqueous solution. This study is comparative to those for calcium-based materials; for instance, with limestone, pH values of 6 and higher were achieved with particle sizes of 300 µm and smaller (Maree et al., 2004) whereas particle sizes of 1 000 µm and smaller for magnesite were used to achieve pH > 6. Thus, the efficiency of magnesite is better than that of limestone.

Simulation of mineral precipitation during treatment of synthetic AMD

The results for the simulation of mineral precipitation at various pH values during treatment of raw AMD with magnesite are presented in Table 2.

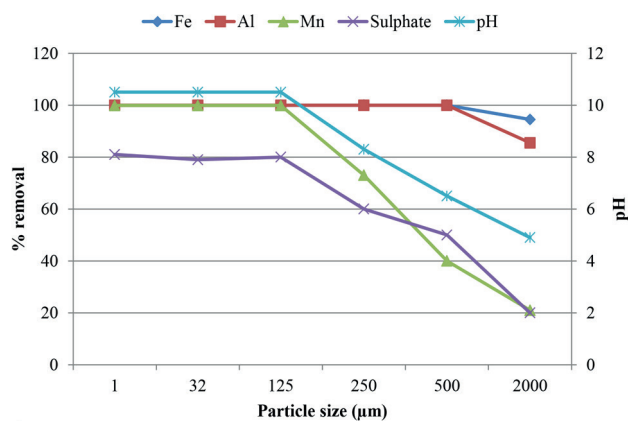

Figure 2

Variation of Al, Fe, Mn and SO_4^{2-} with agitation time and variation of pH gradients with varying particle sizes (Conditions: 2 000 mg/l Fe^{3+} , 200 mg/l Al^{3+} , 100 mg/l Mn^{2+} , 6 000 mg/l SO_4^{2-} , 60 min of shaking time, 250 r/min shaking speed, 1 g of dosage, 100 ml, 60 min of shaking time and 26°C room temperature)

Mineral phase	pH and saturation indices (SI)			
	6	8	10	11
Al(OH) ₃	2.9	1.2	-0.1	-1.5
Boehmite (AlOOH)	5	3.4	2.1	0.7
Basaluminite [Al ₃ (OH) ₁₀ SO ₄]	17.4	6	-1.4	-10.2
Brucite [(MgOH) ₂]	-6.6	-2	0.6	3.6
Diaspore (AlOOH)	6.8	5.1	3.1	2
Dolomite [CaMg(CO ₃) ₂]	-1.3	4.9	6.9	8
Epsomite	-2	-1.8	-1.8	-1.8
Fe(OH) ₃	3.7	4.6	3.2	3.1
Gibbsite [Al(OH) ₃]	5.5	3.7	1.8	0.8

Gypsum (CaSO ₄ ·H ₂ O)	-0.2	0.07	0.2	0.2
Jarosite H[(H ₃ O)Fe ₂ (SO ₄) ₂ (OH) ₆]	2.9	-3.7	-16	-20
Jurbanite (AlOHSO ₄)	2.5	-3.6	-9.8	-12.8
Manganite (MnOOH)	-4.9	-4	-5.9	-4.6
Pyrochroite [Mn(OH) ₂]	-6.4	-2	0.7	2.2

Table 2 shows the minerals that would be expected to precipitate at various pH values during the treatment of synthetic AMD with magnesite. Most of the Al and Fe precipitated as hydroxides at pH > 6. Mn precipitated as magnesium hydroxide at pH > 10. Sulphate-bearing minerals precipitated at pH 6-8 (basaluminite), pH > 8 (gypsum), and pH 6 (jarosite and jurbanite). Generally, mineral phases were predicted to precipitate as metal hydroxides, hydroxysulphates and oxyhydroxysulphates. Epsomite (MgSO₄) was observed to be near precipitation but did not precipitate; this may be attributed to high solubility of epsomite ($K_{sp} = 5.9 \times 10^{-3}$) (Bologo et al., 2012). However, it was observed that the sulphates were removed from solution with Al, Fe and Ca.

Treatment of AMD at optimized conditions

Most of the water quality parameters of the treated water were within those stipulated by the DWS water quality guidelines (Table 3) (DWAF, 1996).

As shown in Table 3, the mine effluent is constituted of high acidity (pH < 2), TDS and EC. There is an elevated concentration of heavy metals, alkali and earth alkali metals. After treatment, only Na, Mg, Ca and sulphate remained with elevated concentrations in the treated water. The reduction of metal species could be described by the introduction of metals on the secondary residues (Table 1). Saturation indices from geochemical simulations suggested that these components were below their precipitation levels. The presence of Mn, Fe, Al,

TABLE 3
Water quality parameters before and after treatment of raw AMD with magnesite

Parameter	Feed AMD water	DWS guidelines (DWAF, 1996)	Magnesite-treated AMD
pH	2	6 - 10	10

Si (mg/l)	1.5	NA	5.5
SO ₄ ²⁻ (mg/l)	4 640	0 - 500	1 910

Ca, Mg, C and O suggest minerals such as Mn, Fe, Al oxide, metals hydroxides, Mn and Fe carbonate, gypsum, Al and Fe oxyhydrosulphates. The simulations showed that in the feed water, Fe existed mainly as Fe^{2+} or Fe^{3+} , while the rest of the metals, except for Na and K, were in their divalent states at acidic pH. A large proportion of Ca existed as soluble CaSO_4 . Cryptocrystalline removed the inorganic contaminants from mine effluent to a level that is suitable for irrigation purposes, especially in acidic soils, owing to its elevated pH.

CONCLUSION

This study has shown that magnesite can be used to remediate AMD. Contact of AMD with magnesite led to an increase in pH and a notable reduction in metal and sulphate concentrations. Removal of Al, Mn, Fe and other metals was observed to be greatest at 60 min of agitation for a S:L ratio of 1 g: 100 mL. Under these conditions, the pH was observed to be greater than 10, an ideal regime for metals removal. Using geochemical modelling, it was shown that most metals, e.g., Fe, Al, Mn, Ca and Mg formed sulphate-bearing minerals. From modelling simulations, the formation of these was observed to follow a selective precipitation sequence with Fe^{3+} at $\text{pH} > 6$, Al^{3+} at $\text{pH} > 6$, Fe^{2+} at $\text{pH} > 8$, Mn^{2+} , Ca^{2+} and Mg^{2+} at $\text{pH} > 10$. The presence of Mn, Fe, Al, Ca, Mg, C and O suggest minerals such as Mn, Fe, Al oxide, metal hydroxides, Mn and Fe carbonate, gypsum, Al and Fe oxyhydrosulphates. This sequence implies that it would be possible to separate precipitates of metals, making this viable for instances where commercial value of the recovered metals is being pursued. Generally, the study has pointed to the efficiency of magnesite in neutralizing and attenuating metals from AMD and, possibly, metalliferous industrial effluents. While not all local water regulatory requirements could be obtained following treatment of raw AMD with magnesite, the resulting water quality was greatly improved, making further polishing easier.

Schematic presentation of a proposed treatment plant

The process flow of the proposed treatment plant for remediation of acid mine drainage using cryptocrystalline magnesite is shown in Fig. 3.

ACKNOWLEDGEMENTS

The authors wish to convey their sincere gratitude to Research and Innovation Directorate, Department of Ecology and Resource Management, School of Environmental Sciences, University of Venda, Council for Scientific and Industrial Research (CSIR), SASOL-INZALO, National Research Foundation (NRF) and Department of Science and Technology (DST) (DST/NRF) for funding this project. The authors would also like to convey their sincere gratitude to Rirhandzu Rikhotso for characterisation of our sample at DST/CSIR National Centre for Nano-Structured Materials.
