18 **Abstract**

19 There is growing evidence for the value of bacterial whole genome sequencing in hospital  
20 outbreak investigation. Our aim was to develop methods that support efficient and accurate  
21 low throughput clinical sequencing of methicillin-resistant *Staphylococcus aureus* (MRSA).  
22 Using a test panel of 25 MRSA isolates associated previously with outbreak investigations,  
23 we devised modifications to library preparation that reduced processing time by 1 hour. We  
24 determined the maximum number of isolates that could be sequenced per run using an Illumina  
25 MiniSeq and a 13 hour (overnight) run time, which equated to 21 MRSA isolates and 3  
26 controls (no template, positive and negative). Repeatability and reproducibility assays based  
27 on this sequencing methodology demonstrated 100% accuracy in assigning species and  
28 sequence type (ST) and detecting *mecA*. Established genetic relatedness between isolates was  
29 recapitulated. Quality control (QC) metrics were evaluated over nine sequencing runs.  
30 168/173 (97%) test panel MRSA genomes passed QC metrics based on the correct species  
31 assigned, detection of *mecA* and ST, and depth/coverage metrics. An evaluation of  
32 contamination in these 9 runs showed that positive and negative controls and test MRSA  
33 sequence files contained <0.14% and <0.48% of fragments matching another species,  
34 respectively. Deliberate contamination experiments confirmed that this was insufficient to  
35 impact on data interpretation. These methods support reliable and reproducible clinical MRSA  
36 sequencing with a turnaround time (from DNA extraction to availability of data files) of 24  
37 hours.

## 38 **Introduction**

39 There is growing evidence of the value of bacterial whole genome sequencing (WGS) in  
40 hospital infection control practice and outbreak investigation (1). Numerous retrospective  
41 studies have shown that bacterial sequencing provides the discrimination required to  
42 distinguish between isolates of the same lineage, overcoming this limitation of previous typing  
43 methods (2-7). There is also strong published support for its use to investigate carriage,  
44 transmission and suspected outbreaks in high-risk areas such as intensive care units (2, 6).  
45 Used early, this could lead to action that limits the size of an outbreak (6, 8). Furthermore,  
46 sequencing can exclude outbreaks where a cluster of patients positive for the same pathogenic  
47 species has arisen by chance (9), saving unnecessary infection control interventions and  
48 outbreak investigations.

49

50 The benefit gained from using WGS during outbreak detection is likely to be greatest if the  
51 technology is embedded within healthcare institutions and performed with a rapid turnaround  
52 time. This has become increasingly feasible through technical advances in sequencing  
53 instruments and the availability of commercial kits and liquid handling robots that simplify  
54 DNA extraction and library preparation. The laboratory processing aspects of WGS are now  
55 within the capabilities of larger diagnostic laboratories. The technical feasibility of sequencing  
56 in real-time has been demonstrated previously at a tertiary care hospital in Germany, but the  
57 turnaround time was 4.4-5.3 days with a cost of ~£170 (10). Reducing this turn-around time  
58 to results and the cost of sequencing will be key to implementing sequencing in the clinical  
59 setting and having an impact on infection control. In our clinical microbiology laboratory at  
60 Addenbrooke's Hospital in Cambridge, United Kingdom, we are developing the methods and  
61 processes to introduce routine WGS of targeted nosocomial pathogens in close to real-time to  
62 enhance our infection control practice. Here, we describe the development of laboratory

63 processing methodology for low throughput clinical sequencing of methicillin-resistant  
64 *Staphylococcus aureus* (MRSA).

65

## 66 **Materials and Methods**

### 67 ***Test panel isolates***

68 Twenty-nine bacterial isolates (27 *S. aureus* and 2 *E. coli*) were assembled into a test panel  
69 for the study (Table 1). The majority of *S. aureus* (n=25) were MRSA from two evaluations  
70 of sequencing at the Cambridge University Hospital NHS Foundation Trust hospital (CUH)  
71 (6,7). Twenty-one MRSA were selected from a 12-month study of MRSA-positive patients  
72 (7) to provide representation of the dominant clonal complexes in our setting (CC22, CC30  
73 and CC5), combined with a range of genetic relatedness. A further 4 MRSA (all sequence type  
74 (ST) 22) were from an outbreak in a special care baby unit (6). Also included were 4 reference  
75 isolates: MRSA HO 5096 0412, methicillin-susceptible *S. aureus* NCTC 6571, *E. coli* NCTC  
76 12241 and *E. coli* NCTC 10418. For sequencing, isolates were cultured from frozen stocks  
77 onto Columbia Blood Agar (CBA, Oxoid), incubated in air at 37°C overnight, and single  
78 colonies picked for DNA extraction and further processing. Table 1 indicates the isolates used  
79 in each sequencing run.

80

### 81 ***Positive and negative controls***

82 Three controls were included in every sequencing run to monitor the ongoing performance of  
83 the entire testing process. These were a no template control, a positive control (MRSA  
84 MPROS0386) that is 115 core genome SNPs different from the MRSA HO 5096 0412  
85 mapping reference, and a negative control (*E. coli* NCTC12241). The no template control  
86 contained all assay components except for DNA and was used to verify the lack of  
87 contamination across reagents and samples. The positive control was used to control the entire

88 assay process and analytical accuracy. The negative control was used to assess cross-  
89 contamination during processing and represented the non-target DNA sample to verify  
90 analytical specificity. In the first two runs an alternative *E. coli* control (NCTC10418) was  
91 used, but this had a low match to *E. coli* in Kraken (~22%) and was replaced by NCTC12241  
92 (>50% match). Fresh stocks of molecular grade water and phosphate-buffered-saline were  
93 opened each week. Other ‘reuse’ reagents were checked for bacterial contamination weekly  
94 by sub-culturing using a 1µl loop onto CBA and incubating overnight in air at 37°C.

95

### 96 ***DNA extraction, library preparation and sequencing***

97 DNA was extracted using the QIAgen DNA mini extraction kit  
98 ([https://www.qiagen.com/gb/shop/sample-technologies/dna/genomic-dna/qiaamp-dna-mini-](https://www.qiagen.com/gb/shop/sample-technologies/dna/genomic-dna/qiaamp-dna-mini-kit/#resources)  
99 [kit/#resources](https://www.qiagen.com/gb/shop/sample-technologies/dna/genomic-dna/qiaamp-dna-mini-kit/#resources)) following ‘Appendix D: Protocols for Bacteria’ ‘Isolation of genomic DNA  
100 from Gram-positive bacteria’ with the following amendments: the incubation with proteinase  
101 K was performed at 56°C for 30 minutes; and in the final elutions, 50ul distilled water was  
102 added with the full 5 minutes incubation. DNA was quantified using a Qubit fluorometer.  
103 Sequencing libraries were made using the Illumina Nextera DNA flex kit based on the  
104 manufacturer’s instructions (11), with several modifications to reduce processing time (see  
105 results). In the first 3 runs, the input DNA to library preparation was normalized to ~100ng,  
106 but thereafter we used a range of up to 500ng DNA. Libraries were sequenced on an Illumina  
107 MiniSeq with a run time of 13 hours (overnight) using the high output 150 cycle MiniSeq  
108 cartridge and the Generate Fastq workflow. Genomes were demultiplexed using the Generate  
109 Fastq workflow and the data transferred to an external 1TB USB-connected hard drive for  
110 further analysis. Ten sequencing runs were performed during this evaluation; the objective of  
111 each run is summarized in Table S1.

112

113 ***Sequence data analysis***

114 Multilocus sequence types (ST) of the MRSA isolates were identified using ARIBA version  
115 2.12.1 as described at [https://github.com/sanger-pathogens/ariba/wiki/MLST-calling-with-](https://github.com/sanger-pathogens/ariba/wiki/MLST-calling-with-ARIBA)  
116 [ARIBA](https://github.com/sanger-pathogens/ariba/wiki/MLST-calling-with-ARIBA). Species were determined using Kraken version 1  
117 (<https://ccb.jhu.edu/software/kraken/>) with the miniKraken database available at  
118 [https://ccb.jhu.edu/software/kraken/dl/minikraken\\_20171019\\_8GB.tgz](https://ccb.jhu.edu/software/kraken/dl/minikraken_20171019_8GB.tgz). The presence of  
119 *mecA* (accession number HE681097, position 2790560-2792566) was determined using  
120 ARIBA, with a minimum percentage identity of 70% required based on Ito *et al.* (12) , and a  
121 minimum of 90% of the gene length covered. All isolates were mapped to the MRSA HO 5096  
122 0412 CC22 reference (accession number HE681097) using SMALT  
123 (<https://www.sanger.ac.uk/science/tools/smalt-0>) with mapping and base calling performed as  
124 described previously (13) with the following modifications: kmer size 13, step size 6. The  
125 depth and percentage coverage of the mapping reference were determined using the script  
126 available at [https://github.com/sanger-pathogens/vr-](https://github.com/sanger-pathogens/vr-codebase/blob/master/modules/VertRes/Pipelines/Mapping.pm)  
127 [codebase/blob/master/modules/VertRes/Pipelines/Mapping.pm](https://github.com/sanger-pathogens/vr-codebase/blob/master/modules/VertRes/Pipelines/Mapping.pm).

128

129 ***Sequence metrics for controls***

130 Controls were required to pass the following quality metrics. MRSA positive control: highest  
131 match to *S. aureus* using Kraken, assigned to ST22, *mecA* detected, minimum mean sequence  
132 depth of 20x and minimum 80% coverage of the mapping MRSA reference genome (HO 5096  
133 0412). *E. coli* negative control: highest species match to *E. coli* in Kraken, *mecA* not detected,  
134 no *S. aureus* ST assigned. No template control: contamination from any bacterial DNA of less  
135 than 95,000 fragments in Kraken. MRSA isolates from the test panel were required to pass the  
136 following metrics: highest match to *S. aureus* using Kraken, assigned to the correct ST, *mecA*

137 detected, minimum sequence depth of 20x and minimum 80% coverage of the mapping MRSA  
138 reference genome (HO 5096 0412).

139

#### 140 ***Optimizing the number of isolates per sequencing run***

141 We estimated that the maximum number of MRSA isolates in a single sequencing run was 24  
142 based on an expected total data output of 3.3-3.8Gb, an average MRSA genome size of 2.8  
143 MB

144 ([https://www.ncbi.nlm.nih.gov/genome/?term=Staphylococcus%20aureus\[Organism\]&cmd=](https://www.ncbi.nlm.nih.gov/genome/?term=Staphylococcus%20aureus[Organism]&cmd=DetailsSearch)  
145 [DetailsSearch](https://www.ncbi.nlm.nih.gov/genome/?term=Staphylococcus%20aureus[Organism]&cmd=DetailsSearch)) and a target of ~50x coverage (24 isolates would provide ~49x coverage). We  
146 estimated that 21 test MRSA isolates and three controls (*E. coli*, MRSA and no template)  
147 could be included per sequence run. This was evaluated by performing sequencing runs that  
148 contained either 14, 18 or 21 test MRSA isolates from the study panel plus the 3 controls. One  
149 MRSA isolate from the 21-test isolate run failed to produce sufficient DNA during extraction  
150 and the *E. coli* control was included twice.

151

#### 152 ***Repeatability and reproducibility***

153 Repeatability was evaluated by sequencing six MRSA isolates (HO 5096 0412, MPROS0386,  
154 SASCBU17, SASCBU18, SASCBU25 and SASCBU35) in triplicate in a single sequencing  
155 run. For each isolate, frozen stock was sub-cultured onto CBA, incubated in air at 37°C  
156 overnight, and three separate colonies taken forward for individual DNA extraction, library  
157 preparation and sequencing. Reproducibility was evaluated by sequencing 21 MRSA isolates  
158 from the test panel in three independent runs. Each isolate was sub-cultured onto CBA and  
159 incubated in air at 37°C overnight, after which three individual colonies were taken forward  
160 for DNA extraction, library preparation and sequencing, one for each sequence run. The entire  
161 process was performed by different laboratory staff on three different days. The resulting fastq

162 files were analysed as above. Isolates that failed QC metrics were excluded from further  
163 analysis (3/18 and 1/63 test isolates failed the repeatability and reproducibility assays,  
164 respectively, based on low depth/coverage.

165

166 Definition of a correct result was based on species identification, ST assignment, detection of  
167 *mecA*, and identification of genetic relatedness based on the detection of single nucleotide  
168 polymorphisms (SNPs) in the core genome compared to the original sequence and the within-  
169 run or between run-replicates. Genetic relatedness was determined based on mapping to a  
170 clonal complex (CC)-specific references, excluding positions denoted as ‘N’ because of failure  
171 to call a base. Each repeat and the original sequence data were mapped to a CC-specific  
172 mapping reference using SMALT (MRSA HO 5096 0412 (CC22) for ST22 and ST2371;  
173 MRSA252 (CC30, BX571856) for ST30; and N315 (CC5, BA000033) for ST5). Mobile  
174 genetic elements were removed using the files available at  
175 [https://figshare.com/authors/Francesc\\_Coll/5727779](https://figshare.com/authors/Francesc_Coll/5727779) and the script available at  
176 [https://github.com/sanger-pathogens/remove\\_blocks\\_from\\_aln](https://github.com/sanger-pathogens/remove_blocks_from_aln). Single nucleotide  
177 polymorphisms (SNPs) were identified using the script available at [https://github.com/sanger-](https://github.com/sanger-pathogens/snp-sites)  
178 [pathogens/snp-sites](https://github.com/sanger-pathogens/snp-sites). SNPs were identified based on the following parameters: minimum  
179 number of reads matching the SNP = 4; minimum number of reads matching the SNP per  
180 strand = 2; ratio of SNP base to alternative base >0.75; variant quality >50; mapping quality  
181 >30.

182

183 Diagnostic sensitivity and specificity were calculated, using the following definitions: true  
184 positives, the number of genetically related isolates based on the original data that cluster  
185 together based on the test data; false negatives, the number of genetically related isolates based  
186 on the original data that do not cluster together in the test data; true negatives, the number of

187 genetically unrelated isolates based on the original data that do not cluster together in the test  
188 data; and false positives, the number of genetically distant isolates based on the original data  
189 that cluster together based on the test data (14). Clustering was defined based on three SNP  
190 classifications: (i) Recent transmission highly likely, 0-10 SNPs different (based on a median  
191 within host diversity of 6 SNPs over a year (7) and an estimated mutation rate of 4 SNPs/core  
192 genome/year (15), (ii) Recent transmission likely, 11-25 SNPs, and (iii) Recent transmission  
193 possible, 26-50 SNPs different (based on the definition of a cluster described by Coll et al.  
194 (7)). Isolates >50 SNPs different were classified as genetically unrelated.

195

### 196 ***Analysis of contamination***

197 The impact on quality metrics from varying levels of DNA contamination during clinical  
198 MRSA sequencing was evaluated using intentional spiking experiments. One MRSA isolate  
199 from the test panel (MPROS1839 (ST22)) and *E. coli* NCTC 12241 were cultured and DNA  
200 extracted and quantified as described above. Donor DNA was inoculated into the recipient  
201 sample to achieve a final spiked concentration of 0%, 0.1%, 1%, 10% or 20% (see results for  
202 details of donor and recipient). Contamination with the spike was defined based on the number  
203 and proportion of fragments matching to *S. aureus* or *E. coli* based on Kraken. The effect of  
204 contamination was evaluated using this metric together with the proportion of the *S. aureus*  
205 CC22 reference covered during mapping, depth of coverage of the mapping reference, and  
206 *mecA* and ST detected by Ariba. Unintentional contamination from internal controls or  
207 external sources was evaluated based on the number and proportion of reads matching to other  
208 species in Kraken.

209

### 210 ***Data availability***

211 Sequence data generated during this study are available from the European Nucleotide Archive  
212 (<https://www.ebi.ac.uk/ena>) under the accession numbers listed in Table 1.

213

## 214 **Results**

215 Our aim was to develop methods that would support efficient and accurate low throughput  
216 MRSA sequencing in a routine microbiology laboratory in less than 24 hours (from DNA  
217 extraction to availability of sequence data). Key goals were to maximize the number of isolates  
218 sequenced per run, reduce processing time of DNA preparation, and evaluate quality controls,  
219 precision (reproducibility and repeatability), and contamination.

220

221 Maximizing the number of isolates per sequencing run was evaluated by performing  
222 sequencing runs that contained either 14, 18 or 21 test MRSA isolates from the study panel  
223 plus the 3 controls, which were sequenced using the Illumina MiniSeq with a run time of 13  
224 hours. Median (range) sequence depth for the test MRSA isolates was 92x (33-247x), 63x (45-  
225 77x) and 65x (18-107x), respectively, with a minimum of 87% of the genome covered (Table  
226 S2). One isolate in the 21 test MRSA run failed the QC metrics based on depth of coverage  
227 (17.9x), which on further evaluation could be explained by low input DNA (Table S2). Based  
228 on this, we used 21 test isolates plus 3 controls per run during the remainder of the study.

229

230 We sought modifications to the manufacturer's protocol for library preparation (Illumina  
231 Nextera DNA flex kit) that would reduce processing time while maintaining performance. We  
232 proposed that two steps could be changed: (i) the tagmentation (TAG program) and  
233 tagmentation stop (TSB incubation) steps each require 15 minutes incubation, which were  
234 reduced to 5 minutes each; (ii) Pooling of libraries is recommended after bead clean-up and  
235 size selection, but we pooled libraries after PCR and before the bead-cleanup and size

236 selection. Two sequencing runs of 21 test panel MRSA + 3 controls were compared, one of  
237 which used the original protocol and the other made both changes to the protocol. Data were  
238 compared for quantity of DNA added to the library preparation versus the size of the resulting  
239 fastq files and depth of coverage, as surrogates for the individual DNA quantity outputs from  
240 library preparation, which are unavailable with the modified protocol. Detailed results are  
241 provided in Table S3. In summary, comparison of original versus modified protocol showed  
242 negligible difference. The median (range) fastq size for the original versus modified protocols  
243 were 171MB (77-208MB) following 174-480ng DNA input versus 112MB (90-133MB)  
244 following 90-384ng DNA input. The median (range) depth of coverage for the original versus  
245 modified protocols were 87x (37-99x) versus 56x (43-70x). Together, these resulted in a  
246 reduction in processing time from 3.5 to 2.5 hours for library preparation, taking the combined  
247 time for DNA preparation and library preparation to 4.5 hours. Subsequent runs used these  
248 modifications.

249

250 Repeatability was based on concordance of assay results and quality metrics for six MRSA  
251 isolates sequenced in triplicate in a single sequencing run. This demonstrated 100%  
252 concordance in assigning species, ST and detecting *mecA*. Four of the six isolates were drawn  
253 from a study that investigated a single outbreak on an intensive care unit (6) and were  
254 previously identified as being 0 SNPs different (SASCBU17 and SACBU18), 5 SNPs different  
255 (SASCBU25), or unrelated to the outbreak (SASCBU35, >1,500 SNPs different from other  
256 isolates). The remaining two isolates were MRSA HO 5096 0412 and the positive MRSA  
257 control (MPROS0386). Zero SNPs were identified between the within-run replicates for all  
258 isolates, equating to a repeatability per replicate of 100%. Using the original published  
259 sequence mapped to the CC22 reference (HO 5096 0412) as the gold standard, all 6 isolates  
260 in triplicate had identical base calls to the original sequence (excluding positions denoted as

261 'N' because of failure to call a base), equating to a repeatability per replicate and per base pair  
262 of 100%.

263

264 Reproducibility was evaluated by sequencing 21 test panel MRSA isolates in three  
265 independent runs. This demonstrated 100% accuracy in assigning species, ST and detecting  
266 *mecA*. Eighteen of the 21 isolates represented six distinct outbreaks encompassing four  
267 different STs (ST22, ST30, ST5 and ST2371) identified during 12 months of genomic  
268 surveillance (n=15) (7) or a single outbreak in an intensive care unit (n=3) (6) . Of the  
269 remainder, 2 isolates were not involved in these outbreaks based on low relatedness, and 1  
270 isolate was the mapping reference MRSA HO 5096 0412. There were 0 SNPs identified  
271 between between-run replicates, providing a reproducibility per replicate of 100%. Using the  
272 original published sequence when mapped to the CC22 reference as the gold standard, 18  
273 isolates were identical to the original sequence across replicates. The remaining three isolates  
274 showed a difference in SNPs compared with the original sequence: MPROS0292 (ST22) had  
275 1-2 SNPs different, one of which was reproduced in all three repeats and the other was  
276 reproduced in two repeats with an N base call in the remaining repeat. MPROS1125 (ST22)  
277 had 1 SNP different in one repeat with an N base call in the same position in the remaining  
278 two repeats. MPROS2335 was identical for two replicates but the third replicate had 10 SNPs.  
279 In comparison to the original sequence this provides an assay accuracy of 92.3% (60/65  
280 repeats), although the true accuracy is likely be higher as the majority of SNPs may be genuine  
281 based on their presence among repeats.

282

283 We next sought to determine the diagnostic sensitivity and specificity for outbreak detection  
284 in each of the three reproducibility runs, using the genetic relatedness established previously  
285 (6,7) as the gold standard (Table S4). All test isolate pairs within each run were in the same

286 genetic relatedness category (0-10 SNPs, 11-25 SNPs, 26-50 SNPs, >50 SNPs) as isolate pairs  
287 in the original data. This was reproducible across all three runs and represents a diagnostic  
288 sensitivity and specificity for outbreak detection of 100%, which was retained across a range  
289 of definitions for genetic relatedness. The majority of isolate pairs were within 1 SNP of the  
290 expected SNP difference based on the gold standard. The exceptions were Cluster 3 (2 SNPs  
291 different between MPROS0046 and MPROS1125 in two runs relating to failure to call a base  
292 at one position, and a SNP in a region that was absent across the replicates but present at low  
293 coverage in the original sequence); and Cluster 4 (MPROS0688 and MPROS2335; 2 SNPs  
294 different in two runs due to two positions at which a base failed to be called; and 6 SNPs  
295 different in the final run. The isolate sequence MPROS2335 was genetically identical to a  
296 second isolate from the same patient sequenced by Coll *et al.* (7) but not included here. From  
297 this, we suspect within-host diversity of MRSA in this case, and sequencing of different  
298 colonies of the same lineage.

299

300 Quality control metrics were evaluated for the assay controls and MRSA isolates from the test  
301 panel over nine sequencing runs (Table S5 provides further details). All three controls in each  
302 sequence run passed the required QC metrics. Of 173 *S. aureus* test panel MRSA isolates  
303 sequenced, 168 (97%) passed the QC metrics. The five failures were based on insufficient  
304 depth/coverage associated with low input DNA (n=2) or potential loss of DNA during library  
305 preparation (n=3). Excluding these 5 failed isolates and the control isolates, *S. aureus* was the  
306 top match in Kraken in all cases (median (range) 85.8% (77.2-89.3%), the median (range)  
307 depth was 59x (21–247x), and the median (range) proportion of the reference genome covered  
308 was 94.6% (86.3-100%).

309

310 We then undertook deliberate contamination experiments to allow us to estimate the impact  
311 of varying levels of DNA contamination from internal controls or external sources on quality  
312 metrics. Details of the donor and recipient DNA, the concentrations of spiked DNA and our  
313 findings are summarized in Table 2. Contamination of the no template control with increasing  
314 concentrations of MRSA DNA did not lead to the control erroneously passing the QC metrics  
315 for MRSA until the final spiked concentration reached 10% or greater. This indicates that  
316 contamination of the no template control at 1% (which equated to 96,671 fragments matching  
317 *S. aureus* in Kraken) can be tolerated. Contaminating the positive MRSA control with  
318 increasing concentrations of *E. coli* DNA demonstrated that this could tolerate up to 10%  
319 contamination (which equated to 4.04% fragments matching *E. coli* in Kraken) before the  
320 MRSA QC metrics were not achieved.

321

322 We also evaluated unintentional contamination in nine runs (excluding the deliberate  
323 contamination assay). All *E. coli* and MRSA control sequence data files contained less than  
324 0.14% of fragments matching another species (Table S6). For the test MRSA sequence files,  
325 matches to other staphylococcal species were identified in over half of samples (109/173,  
326 median 0.05%, range 0.01-0.48% of fragments). Very low-level matches (0.01-0.13%) to  
327 other species were also identified in specific files (Table S6). All isolates had less than 0.2%  
328 of fragments matching to another species, with the exception of a single reference isolate of  
329 MSSA that had a match of up to 0.48% to *Staphylococcus nepalensis*. Based on the number  
330 of fragments in Kraken for the no template controls, and the proportion of fragments in Kraken  
331 for the remaining sequences, this demonstrates that, with the exception of the isolate above,  
332 all controls and test isolates had levels of contamination below 1% (0.4% of fragments) across  
333 the nine sequencing runs (Table S6).

334

335 **Discussion**

336 Our aim was to develop and describe methods for low throughput clinical sequencing of  
337 MRSA using commercial kits and manual methods. Our rationale was that this could support  
338 wider uptake in smaller diagnostic laboratories that are not equipped to undertake high volume  
339 sequencing using automated robots. Whilst liquid handling robots are essential for high  
340 volume sequencing such as that increasingly performed by public health reference  
341 laboratories, the majority of routine clinical laboratories have yet to invest in sequencing  
342 pipelines with their associated capital and maintenance costs.

343

344 An important objective was to enable a 24-hour turnaround time from DNA extraction to  
345 availability of sequence data. The combined time for DNA preparation and library preparation  
346 is 4.5 hours, followed by a 13-hour (overnight) sequencing run on the Illumina MiniSeq. This  
347 would support a pipeline of clinical sequencing in which relevant cultures were identified in  
348 a routine laboratory and processed including sequencing within a day. The methods described  
349 here are based on a single colony, which when implemented in routine practice could be  
350 obtained from the original diagnostic clinical plate. This turnaround time, in combination with  
351 a rapid automated analysis pipeline, would allow infection control to determine whether  
352 patients were involved in an outbreak or not the day after a positive culture. This could allow  
353 rapid instigation of enhanced infection control procedures when an outbreak is detected to  
354 prevent further spread of the outbreak, and prevention of infection control actions such as ward  
355 closures if a suspected outbreak could be refuted.

356

357 We also maximised the number of MRSA per sequencing run to minimize the cost per isolate.  
358 Based on 21 clinical isolates per run with three controls, the price per clinical isolate is  
359 currently £70 for DNA extraction, library preparation and sequencing. Whilst individual

360 hospitals are unlikely to frequently reach 21 clinical MRSA isolates suspected to be involved  
361 in an outbreak, we suggest a paradigm shift whereby all patients identified as MRSA positive  
362 have an isolate sequenced, and whole-genome sequencing leads infection control actions. This  
363 would reduce the turnaround time for action since current outbreak detection relies on multiple  
364 time-consuming steps including manually identifying patients that have been in the same ward  
365 at the same time. Using whole-genome sequencing combined with automated analysis would  
366 rapidly pinpoint which patients are involved in an outbreak or not, defining the cases that  
367 infection control need to act on, and those that require no action. The combination of  
368 turnaround and cost are critical measures for clinical translation. Alternative sequencing  
369 instruments such as the Oxford Nanopore Technologies provide the option for further  
370 reductions in sequencing time (16), and over time the cost and turnaround time of sequencing  
371 will undergo further reductions. As costs fall, lower-throughput technologies such as the  
372 Illumina iSeq 100 may become viable for routine clinical laboratories with smaller sample  
373 numbers.

374

375 We described the use and evaluation of assay controls, examined the impact of contamination  
376 on data interpretation and determined the extent to which we inadvertently contaminated the  
377 assay. All three controls passed the required QC metrics in every run, together with 97% of  
378 test panel MRSA isolates sequenced. High levels of contamination were required before the  
379 controls failed QC metrics, and levels of inadvertent contamination were low. Evaluation of  
380 precision showed 100% repeatability and reproducibility in assigning species and ST and  
381 detecting *mecA*. SNP detection was 100% repeatable, but reproducibility was less than 100%  
382 because of the detection of a small number of SNPs that were not present in the original  
383 sequence. These can be explained by minor heterogeneity in colonies prepared for independent  
384 sequencing, with similar findings reported previously based on sequencing of a range of

385 bacterial species (14). Importantly, diagnostic sensitivity and specificity for outbreak detection  
386 were 100%, indicating that the data generated accurately determined MRSA relatedness,  
387 which supports use of this assay during outbreak investigation. The parameters evaluated in  
388 this study were in line with the workflow for validation of whole-genome sequencing in  
389 clinical laboratories described previously, and obtained comparable results (14).

390

391 Our findings indicate that the methods evaluated here can provide high quality data. The single  
392 largest impediment to clinical sequencing is lack of fully automated data interpretation  
393 software that has a rapid turn-around time and is suitable for use by non-experts. This will  
394 need to be addressed for routine clinical sequencing to become viable, and is currently being  
395 investigated by numerous groups and investigators.
