19 **Abstract**

20

21 In this study, the emissions of Volatile Organic Compounds (VOC), CH₄, N₂O
22 and NH₃ during composting non-source selected MSW, source selected Organic
23 Fraction of Municipal Solid Wastes (OFMSW) with wood chips as bulking agent
24 (OF_wood) and source selected OFMSW with polyethylene (PE) tube as bulking agent
25 (OF_tube) and the effect of bulking agent on these emissions have been systematically
26 studied. Emission factors are provided (in kg compound Mg⁻¹ dry matter): OF_tube
27 (CH₄: 0.0185±0.004; N₂O: 0.0211±0.005; NH₃: 0.612±0.269; VOC: 0.688±0.082) and
28 MSW (CH₄: 0.0549±0.0171; N₂O: 0.032±0.015; NH₃: 1.00±0.20; VOC: 1.05±0.18)
29 present lower values than OF_wood (CH₄: 1.27±0.09; N₂O: 0.021±0.006; NH₃:
30 4.34±2.79; VOC: 0.989±0.249). A detailed composition of VOC is also presented.
31 Terpenes were the main emitted VOC family in all the wastes studied. Higher emissions
32 of alpha and beta pinene were found during OF_wood composting processes.

37

38 **1. Introduction**

39 It is well known that recycling reduces the amount of waste going to disposal
40 (landfilling), the consumption of natural resources and also improves energy efficiency.
41 Therefore, recycling plays an essential role towards sustainable consumption and
42 production (SCP). Accompanying SCP, the recycling sector has increased business with
43 a current turnover of €24 billion employing about 500,000 people in Europe, distributed
44 in more than 60,000 companies. The EU represents the densest area in waste and
45 recycling industries, accounting for around 50% of world share (European Environment
46 Agency, 2010). At the same time, sustainable management of resources and waste
47 minimization and valorization has been the common objective of plans, directives and
48 regulations in recent decades, including Municipal Solid Waste (MSW). According to
49 this, in recent years, there has been a proliferation, either in Spain or Europe, of new
50 solid waste treatment plants mainly as a result of Directive 1999/31/EC on the
51 implementation of the limitation of landfill as final destination for organic wastes.
52 Biological treatment plants, which allow waste valorization, are recommended as the
53 main destination for this type of wastes (Commission of the European Community,
54 2008).

55 Generation of biodegradable organic residues is increasing worldwide and
56 strategies for its environmentally sound use are being developed and optimized.
57 Integrated waste management is considered the key point for a successful MSW
58 treatment. Waste separation, that increases the quality of by-products (i.e. compost,
59 digestate and biogas) and recyclables, is a critical component of this system. Integrated
60 waste management also enables better financing of waste management activities and
61 minimizes the energy and labor inputs to any downstream processes (Murray, 1999).
62 European Directive 2008/98/EC points to the recovery of mixed municipal waste

63 collected from private households. In order to comply with the objectives of this
64 Directive, and to move towards an European recycling society with a high level of
65 resource efficiency, Member States shall take the necessary measures to achieve by
66 2020 a minimum overall recycling percentage of a 50% by weight of paper, metal,
67 plastic and glass from households and possibly from other origins (as far as these waste
68 streams are similar to waste from households) (European Parliament, 2008). As a
69 consequence of the implementation of all these Directives, by 2013, 19% of total
70 household wastes are source selected in Spain, being the organic fraction a percentage
71 of 20%.

72 As mentioned before, biological treatment plants based on anaerobic digestion
73 and/or composting processes are being widely constructed. Focusing on the composting
74 process, the presence of non-organic wastes (impurities) could decrease the compost
75 quality, affect composting gaseous emissions or increase the investment costs and the
76 energy demand due to the equipment dedicated to the separation of impurities. Bulking
77 agents are used to provide air space in composting materials, regulate the water content
78 or the C/N ratio (Iqbal et al. 2009). These studies show how important is the bulking
79 agent in the composting process evolution. Gaseous emissions during the composting
80 process are often related with the porosity of the material being composted, which
81 depends on the type and amount of bulking agent used. Some authors have related the
82 emissions of some volatile organic compounds (VOC) to wood wastes used as bulking
83 agent (Komilis et al. 2004). Recent studies (Yang et al. 2013, Shao et al. 2014) have
84 investigated the effect of several bulking agents on gaseous emissions in composting
85 processes of organic wastes. Yang et al. (2013) have studied emissions of CH₄, N₂O and
86 NH₃, while Shao et al. (2014) presented an in depth study on odor emissions, mainly
87 VOC. Both studies pay attention to the composting process evolution and the quality of

88 the final product. However, all the experiments have been done with a degradable
89 bulking agent: cornstalks, rice straw, sawdust, etc. Therefore, the contribution of wood
90 chips, the bulking agent mostly used nowadays in composting facilities, to VOC
91 emissions is not described. The presence of plastics, glass and other non-organic wastes
92 could replace the bulking agent (wood chips) function when mixed MSW are
93 composted.

94 The objective of this work is to study the emissions of VOC, CH₄, N₂O and NH₃
95 during the composting process of MSW and the effect of the bulking agent in these
96 emissions. With this purpose, three wastes have been composted: non source selected
97 MSW (high level of impurities), source selected OFMSW (low level of impurities) with
98 wood chips as bulking agent and source selected OFMSW with polyethylene (PE) tube
99 as bulking agent since this non-biodegradable material will not contribute to the
100 emissions of the studied compounds. This study can provide the baseline to distinguish
101 between the emissions from the waste itself and the bulking agent, an aspect that it is
102 not clear in composting scientific literature.

103

104 **2. Materials and Methods**

105 *2.1 Waste composted*

106 The wastes used in the experiments were different types of municipal solid
107 wastes. Specifically, 100 kg of non-source selected MSW from a waste treatment plant
108 located in Zaragoza (Spain) were composted as received at the plant (MSW). In the case
109 of source selected OFMSW two cases were studied: i) OF_wood, 100 kg of material
110 that were already mixed with wood chips in the plant (ratio 1:1, v:v) and ii) OF_tube,
111 100 kg of material that were used as received at the plant. In this case, the OFMSW was
112 manually mixed with PE tube pieces of 25 mm diameter and 4 to 15 cm long (ratio 1:1,

113 v:v). Both OFMSW were obtained from a composting plant in Manresa (Barcelona,
114 Spain). All the composting experiments with the three wastes considered (MSW,
115 OF_wood and OF_tube) were carried out with aliquots of 25 kg per reactor and
116 performed in duplicate.

117 Air-filled porosity was determined using an air pycnometer according to
118 previous studies (specific details about the methodology can be found in Ruggieri et al.,
119 2009). The results of air-filled porosity for OF_wood and OF_tube, mixed in the
120 laboratory, initial MSW (not mixed, the waste collected was composted as collected
121 from the plant) and final samples for the six trials can be found in Table 1. A
122 homogeneous sample from each waste and each mixture (waste plus bulking agent) was
123 stored at -18 °C to be used for waste characterization.

124 The main characteristics of the initial wastes and the final products obtained
125 from each experiment are presented in Table 1. Dry and organic matter, conductivity
126 and pH have been determined in triplicate following the standard procedures for
127 composting samples (US Department of Agriculture and US Composting Council,
128 2001).

129

130 *2.2 Composting pilot plant*

131 The results presented in this study were obtained in a pilot scale composting
132 plant using two near-to-adiabatic non-commercial cylindrical reactors with an operating
133 volume of 50 L each and forced aeration. A schematic diagram of the pilot reactors and
134 a detailed description can be found elsewhere (Puyuelo et al., 2010).

135 Gas samples were collected in 1-L Tedlar® bags for VOC N₂O, CH₄ and NH₃
136 determination. Also a 250-mL glass gas collector was used for samples taken for VOC

137 composition determination. In all cases, one sample per day and per reactor was
138 withdrawn.

139 The data acquisition system is a PLC Data Acquisition. It consists of a
140 microcontroller that interprets the potential changes of the sensors connected to its
141 inputs in numerical values. It also realizes the reverse function: converting numerical
142 values into voltage, thereby allowing performing an automatic control. Temperature
143 (PT100 sensor, Desin Instruments, Barcelona, Spain), exhaust gas oxygen concentration
144 (Alphasense, A2O2, UK) and inlet airflow (Bronkhorst Hitec, The Netherlands) were
145 monitored during the experimental trials. According to the values of oxygen
146 concentration, airflow and temperature, the PLC acts on the flow meter, allowing
147 airflow from 0.2 to 10 liters per minute. The controller performs roughly 25 readings
148 per second, sending to the reader a temporal data every second and a real data each
149 minute. The communication is done by a serial port interface. Data are visualized
150 through the connection of the PLC data acquisition system to an internal Ethernet
151 network.

152 The control strategy used in the experiments has been presented in Puyuelo et al.
153 (2010). The main objective of this strategy is to obtain an automatic airflow regulation
154 that maximizes the biological activity in the reactor measured as OUR (Oxygen Uptake
155 Rate). OUR control permits the optimization of energy consumption during the process
156 while achieving a high degree of stability in the final product. Briefly, the controller
157 works in cycles of 1 hour. The designed OUR control loop compares the variations in
158 the OUR measurements reached among the successive cycles according to the airflow
159 applied. After completing a cycle, the oxygen level is revised to avoid percentages
160 below 5 % of oxygen concentration in air (v/v). If the level is below this limit, airflow
161 will be increased by 50 %. If an adequate oxygen level has been measured, the next step

162 will be the control loop based on the OUR measurement and the applied flow
163 comparison between two consecutive cycles. For both parameters, three situations are
164 possible, i.e., the system determines if the current value is lower than, higher than or
165 equal to the previous value. Different absolute thresholds were established to define the
166 superior and inferior limits in which the variation of OUR and airflow can be
167 considered negligible. The limit to detect OUR variation was defined as 0.5 % of the
168 maximum OUR achieved in previous experiments in the reactor (approximately 15 g O₂
169 h⁻¹). The range considered for the airflow measurements was 0.05 L min⁻¹. Considering
170 the airflow measurements, the controller checks the OUR variation. Next, the controller
171 determines if the OUR variation obtained is linked to an increase, decrease or a constant
172 airflow.

173

174 2.3. *Stability degree*

175 On the basis of the methodology proposed by Adani et al. (2006) to assess the
176 degree of biological stability, the dynamic respiration index (DRI) was measured using
177 a respirometer (Ponsá et al., 2010). Briefly, the determination consists of placing 150 g
178 of sample in a 500-mL Erlenmeyer flask and incubating the sample in a water bath at 37
179 °C. A constant airflow was supplied through the sample, and the oxygen content in the
180 outgoing gases was measured. From this assay, DRI was determined as the maximum
181 average value of respiration activity measured during 24 hours, expressed in mg O₂ g⁻¹
182 OM h⁻¹. A detailed description of this dynamic respirometer can be found at Ponsá et al.
183 (2010). All the samples were analyzed in triplicate.

184

185 *2.4. Determination of gaseous emissions*

186 VOC, CH₄ and N₂O analysis was performed by means of gas chromatography
187 (Agilent Technologies 6890N Network GC system, Madrid, Spain) as explained in
188 Colón et al. (2012). All samples were analyzed in triplicate for each compound. The
189 deviation found per each triplicate was lower than 5% for all the compounds except for
190 VOC that was less than 10%.

191 Ammonia concentration was measured in situ at the gas outlet of the composting
192 reactor by means of an ammonia sensor (Industrial Scientific sensor iTX-T82, Oakdale,
193 PA, USA) with a measurement range of 0 to 1200 ppmv. The sensor was placed inside a
194 hermetic recipient with inlet and outlet holes that allowed gas circulation. The
195 measurement was taken when the value was stabilized during a period of constant flow.
196 Ammonia was measured just before the water trap installed to protect the rest of
197 measurement devices from moisture avoiding the effect of ammonia solubilization in
198 the condensate water from the composting process exhaust gases.

199

200 *2.5. GC-MS detection*

201 A sample from each process was taken daily in a 250 mL glass gas collector.
202 VOC characterization was performed using air samples analyzed by SPME (Solid Phase
203 Micro Extraction)/GC-MS, as previously reported by other authors (Orzi et al., 2010).

204 A manual SPME device with divinylbenzene
205 (DVB)/Carboxen/polydimethylsiloxane (PDMS) 50–30 µm fiber from Supelco
206 (Bellefonte, PA, USA) was used. The compounds were adsorbed from the air samples
207 by exposing the fiber (preconditioned for 1 h at 270 °C, as suggested by the supplier) to
208 the sample in the glass gas collector for 30 min at room temperature. A solution of
209 deuterated *p*-xylene in methanol was used as internal standard (IS).

210 VOC characterization was performed using a Gas Chromatograph (Agilent
211 5975C) coupled with a 7890 Series GC/MSD. Volatile compounds were separated using
212 a capillary column for VOC (Agilent Technologies DB-624) measuring 60 m x 0.25
213 mm with a film thickness of 1.40 μm . Carrier gas was helium at a flow rate of 0.8 mL
214 min^{-1} . VOC were desorbed by exposing the fiber in the GC injection port for 3 min at
215 250 $^{\circ}\text{C}$. A 0.75-mm internal diameter glass liner was used, and the injection port was in
216 splitless mode. The temperature program was isothermal for 2 min at 50 $^{\circ}\text{C}$, raised to
217 170 $^{\circ}\text{C}$ at a rate of 3 $^{\circ}\text{C min}^{-1}$ and, finally, to 230 $^{\circ}\text{C}$ at a rate of 8 $^{\circ}\text{C min}^{-1}$. The transfer
218 line to the mass spectrometer was maintained at 235 $^{\circ}\text{C}$. The mass spectra were
219 obtained by electron ionization at 70 eV, a multiplier voltage of 1379 V and collecting
220 data over the mass range of 33–300.

221 Deuterated *p*-xylene was used to determine the fiber and GC-MS response
222 factors for 15 typical compounds emitted in composting processes according to the
223 literature (Scaglia et al., 2011; Suffet et al., 2009). These 15 compounds were diluted in
224 methanol at the same concentration as deuterated *p*-xylene. This solution (10 μL) was
225 injected into the glass gas collector with 10 μL of deuterated *p*-xylene in methanol
226 solution. The fiber was exposed for 30 minutes to the resulting solution and injected
227 into the GC-MS using the same method as described above. The area obtained for each
228 compound was compared to deuterated *p*-xylene to determine each response factor. The
229 aim of determining these response factors is to increase the reliability of the quantitative
230 analysis.

231 Compounds were identified by comparing their mass spectra with the mass
232 spectra contained in the NIST (USA) 98 library. A semi-quantitative analysis for all the
233 identified compounds was performed by direct comparison with the internal standard.
234 Quantitative analysis was performed for *m*-xylene, *n*-decane, alpha-pinene, beta-pinene,

235 limonene, toluene, dimethyl disulfide, hexanal, styrene, cyclohexanone, nonanal,
236 decanal, eucalyptol, pyridine and 2-pentanone. These compounds have been the most
237 common VOC found in previous experiments (Maulini-Duran et al., 2013), representing
238 different VOC families.

239

240 **3. Results and Discussion**

241 *3.1. Process evolution*

242 As mentioned before, air filled porosity was determined for initial and final
243 materials of each process. OFMSW was mixed with wood chips (OF_wood) and PE
244 tube (OF_tube), respectively, until adjusting AFP to adequate values. MSW presented
245 adequate AFP without addition of bulking agent due to the presence of impurities.
246 Initial and final AFP values for the three materials are summarized in Table 1. These
247 values are within the range recommended for an adequate development of the
248 composting process (Ruggieri et al., 2009).

249 The evolution of the composting process of the three wastes studied was
250 followed through OUR, temperature, airflow and oxygen concentration. Similar OUR,
251 oxygen, temperature and airflow profiles were observed in the duplicates for the same
252 waste. Figure 1 shows the profiles obtained for all these parameters for one replicate of
253 each experiment: OFMSW with wood chips as bulking agent (replicate OF_wood-I,
254 Figure 1a), OFMSW with PE tube as bulking agent (replicate OF_tube-I, Figure 1b) and
255 MSW (replicate MSW-I, Figure 1c).

256 The six trials reached thermophilic conditions during the first day of process,
257 according to the biodegradability of the material. The maximum temperature reached
258 during OF_wood composting (Figure 1a) was of 68 °C in both trials. The reactors
259 needed approximately 17 days to return to mesophilic conditions. The thermophilic

260 peak matched with the highest OUR value ($21 \text{ g O}_2 \text{ h}^{-1}$) and therefore the highest
261 airflow provided (7.5 L min^{-1}).

262 During OF_tube composting (Figure 1b) the maximum temperature achieved
263 was $56 \text{ }^\circ\text{C}$, lower than that of OF_wood. In this case the inert bulking agent used was an
264 empty tube that allowed air passing through the bulking material, thus increasing the air
265 filled porosity. Indeed, air filled porosity in OF_tube trials was more than 10% higher
266 than the other wastes composted during the experiments. This higher porosity enhances
267 heat dissipation, reaching lower temperatures and cooling faster than the other trials,
268 reaching mesophilic conditions around the 9th day of process. Maximum OUR and
269 airflow values were $9 \text{ g O}_2 \text{ h}^{-1}$ and 4.8 L min^{-1} , respectively.

270 The maximum temperature achieved during the composting process of MSW
271 was 68°C (as was in OF_wood composting). The airflow supplied in both MSW trials
272 was lower than in the other experiments (2.2 L min^{-1}), matching again the highest
273 airflow and the highest OUR value ($10 \text{ g O}_2 \text{ h}^{-1}$) with the beginning of the thermophilic
274 phase.

275 According to the temperature profile and DRI values of the final material
276 obtained for replicates of each waste composted (Table 1), the composting process
277 evolution was satisfactory, and the final product was stabilized (Adani et al. ,2006).

278

279 *3.2 Gaseous emissions*

280 The daily evolution of VOC, CH_4 , N_2O and NH_3 emissions for each waste is
281 shown in Figure 2. Error bars indicate the differences between the two replicates. In
282 Table 2, the emission factors for VOC, CH_4 , N_2O and NH_3 are also summarized for
283 each trial in terms of kg of compound emitted per Mg of treated waste.

284

285 *CH₄ emissions*

286 Figure 2a presents the evolution of methane emissions during the composting
287 process of the three waste mixtures. As can be seen in Figure 2a, there is a very
288 significant difference between CH₄ emissions from OF_wood and from the other two
289 wastes. Methane emissions are related to the presence of anaerobic zones, maybe due to
290 excessive moisture and insufficient porosity or an inappropriate aeration system strategy
291 (Amlinger et al., 2008). Carbon is used as an electron acceptor when other more
292 energetically favorable electron acceptors, including oxygen, nitrogen, iron, manganese
293 and sulphur, have been exhausted (Brown et al., 2008). Moisture and porosity (Table 1)
294 were in the optimal ranges in all the experiments. In addition, as observed in Figure 1a
295 the oxygen content was always over 17% after the first day of process. However the
296 presence of a high content of rapidly biodegradable organic matter could lead to oxygen
297 depletion, creating anaerobic areas in the solid matrix. The main methane emission
298 during OF_wood composting process can be observed from day 6 to day 21 (Figure 2a),
299 when the microbial activity is decreasing. He et al. (2000) reported that composting
300 wastes with a high easily biodegradable matter content such as food wastes, could lead
301 to the formation of anaerobic zones due to compaction effects. Material compaction was
302 detected at the end of the experiments as the composting reactors were neither opened
303 nor the material turned for the whole process. However, it cannot be ascertained
304 whether the compaction occurred at the initial or final stages of the process. On the
305 other hand, there is a small difference between initial and final porosity. Ruggieri et al.
306 (2008) stated that changes in air-filled porosity from initial to final samples in the
307 composting process are not representative of what has been occurring in the reactor
308 during the process. These authors detected the lowest air-filled porosity values after 48
309 hours of composting process. In OF_wood composting experiments a 6L reduction

310 between initial and final volume of the waste in the reactor was observed thus indicating
311 compaction even if air-filled porosity values do not show it. Volume reduction for
312 OF_tube and MSW were 3.4 and 2 L, respectively. Values in Table 2 confirm that CH₄
313 emission factor for the OF-wood processes was higher than the emission of the other
314 processes.

315 In fact, lower methane emission during MSW and OF_tube composting
316 processes (maximum values achieved in days two and five of process and
317 corresponding to 0.004 kg of CH₄ Mg of dry waste⁻¹ for both wastes), may be
318 explained by the lower compaction effect due to a lower content in biodegradable
319 organic matter. Also the shorter thermophilic phase observed comparing MSW and
320 OF_tube with OF_wood could be the explanation of these different emissions. Jiang et
321 al. (2011) related higher methane emission with long thermophilic phases.

322

323 *N₂O emissions*

324 N₂O emissions evolution is presented in Figure 2b. The main N₂O emissions
325 released during the six composting processes carried out were found during the first
326 week. There is some controversy in the literature about N₂O emissions. El Kader et al.
327 (2007), composting farm manure, and Yang et al. (2013), composting kitchen waste,
328 reported the highest N₂O emissions during the first week of composting process.
329 However, Fukumoto et al. (2003) related the inhibition of N₂O emissions with
330 thermophilic temperatures, which occur usually during the first week of the process.
331 Regarding the different wastes composted in this study, there are no significant
332 differences between the emissions factors obtained for N₂O emissions, as can be
333 observed in Table 2. Since the type of biodegradable organic matter is the same in the
334 three wastes maybe the type of bulking agent has no effect in N₂O emissions.

335

336 *NH₃ emissions*

337 Figure 2c reports ammonia emissions for the different wastes treated. Although also
338 in the case of ammonia, OF_wood is the waste presenting the highest emissions during
339 the whole composting process, there is an important deviation in the highest emission
340 point. However, even the lowest value for OF_wood reported in Table 2 (2.4 kg NH₃
341 Mg⁻¹ dry matter) doubles the highest value presented for the other two wastes
342 (corresponding to MSW-I, 1 kg NH₃ Mg⁻¹ dry matter). Pagans et al. (2006) reported that
343 NH₃ emissions were strongly related with the thermophilic phase of composting. The
344 trend observed in Figures 1 and 2c during all the trials agrees with this proposal.

345

346 *VOC emission*

347 In Figure 2d, total daily VOC emissions produced during the three experiments
348 are shown. As described by Komilis et al. (2004) the main emission of VOC was
349 detected during the first days in all the experiments, in the mesophilic to thermophilic
350 transition. Scaglia et al. (2011) reported that VOC, odor emissions and biological
351 activity were strongly related. In any composting process high temperatures are caused
352 by high biological activity. Even when enough aeration is provided to the reactor, these
353 factors cause some anoxic zones in the matrix that contribute to VOC emissions
354 (Maulini-Duran et al. 2013). During the OF_wood and MSW composting processes
355 more VOC have been emitted than during the OF_tube composting process. This could
356 be related again with the sustained thermophilic phase observed in OF_wood and MSW
357 processes in comparison with OF_tube. Also, a higher DRI reduction was achieved in
358 these wastes, reflecting a higher biological activity. Observing Figure 1, DRI reduction
359 is in agreement with the comparison of OUR profiles, where OF_wood and MSW

360 present higher values than OF_tube. Initial OF_wood has a higher DRI than the other
361 treated wastes, which means a high content of biodegradable organic matter that could
362 lead to the occurrence of anaerobic zones and the achievement of higher temperatures
363 during the process.

364

365 *Gaseous emissions and process evolution*

366 Traditionally, the composting process can be divided into three stages,
367 depending on the temperature evolution. The first period begins at day 0 of the
368 experiment until the thermophilic temperature is reached (45°C). The second stage
369 coincides with the thermophilic period (>45°C) and the third period corresponds to the
370 return to mesophilic temperatures (<45°C) (Haug, 1993).

371 No CH₄ was emitted during the first period of OF_wood composting process, 86
372 % in the second period and 14 % in the third period. In OF_tube, CH₄ was also emitted
373 mainly during the second period (74 %), 7% in the first period and 19% third period.
374 These differences could be caused by the fast OUR increase in OF_wood composting
375 process and, therefore, a high airflow at the beginning of this process. The percentage
376 distribution in MSW composting process is very similar than that of OF_tube: 17%,
377 73% and 10% (1st, 2nd and 3rd period, respectively).

378 N₂O emissions during the first period of OF_wood composting were 2 %, 92%
379 during the second period and 7 % during the third period. In OF_tube composting N₂O
380 emissions are 8 % in the first period, 83 % during the second period and 9 % during the
381 third period. N₂O emissions detected in MSW composting process were: 14% (1st
382 period), 84% (2nd period) and 2% (3rd period). N₂O emissions for OFMSW and MSW
383 were lower than raw sludge emissions in the same conditions (Maulini-Duran et al.,
384 2013). For all the processes, the emission is higher during the thermophilic stage in the

385 three cases. However, N₂O concentration values were close to the detection limit of the
386 analysis, thus involving higher errors between replicates (Figure 2b). This fact makes
387 difficult to discard the inhibition of N₂O production at thermophilic temperatures.

388 Similar trends are also detected in NH₃ emissions during all the composting
389 processes carried out. Only 3 % of the NH₃ emissions in OF_wood composting process
390 occurred during the first period, 93 % was emitted during the second period and 4 %
391 during the third one. In MSW emission percentages distribution was 1% (1st period),
392 92% (2ⁿ period) and 7% (3rd period) while in OF_tube composting, 78% of NH₃ was
393 emitted during the second period and 28% during the third one; no NH₃ was emitted
394 during the first period.

395 Also VOC emission detected during the composting processes studied follows a
396 similar distribution during the three established periods for the three wastes. For
397 OF_wood and MSW, the percentages are exactly the same: 9% in the first period, 90%
398 during the second period and 1% in the third period. During OF_tube composting
399 process, 15% of VOC were emitted during the first period, 82% during the second one
400 and 3 % during the third period.

401 Analyzing these data, it is clear that gaseous emissions are strongly related with
402 OUR values and temperature rise and, consequently, with the biological activity of the
403 process. In a previous work, where raw and anaerobically digested sludge were
404 composted, the relationship between composting periods and compounds emissions
405 distribution was not so clear (Maulini-Duran et al., 2013). However, values of OUR,
406 airflow and temperatures were clearly lower, especially in the case of anaerobically
407 digested sludge where no thermophilic temperatures were reached.

408 The trends in VOC, CH₄, N₂O and NH₃ emissions and the emission factors
409 reported in Table 2, could be of interest for plant designers and operators, particularly,

410 to the design of gaseous emissions equipment and to its operation. It is worthwhile to
411 mention that the deviation found between duplicates is in the low range (three values
412 out of twelve higher than 40%) when compared to similar studies of composting
413 emissions of wastes of high heterogeneity (Colón et al., 2012; Maulini-Duran et al.,
414 2013; Maulini-Duran et al., 2014).

415 On the other hand, although N₂O emission factor is the lowest among the
416 analyzed contaminants, the greenhouse effect of this compound has to be taken into
417 account. The global warming potential of N₂O is 298 kg CO₂ eq., higher than the
418 methane potential (34 kg CO₂ eq) (IPCC, 2013).

419 The use of a synthetic bulking agent points to a reduction in CH₄, NH₃ and VOC
420 emissions and to a lower compaction. However, from our results wood chips have some
421 advantages in front of PE bulking agent, such as moisture adjustment, higher
422 temperatures, better organic matter stabilization and the fact that another organic waste
423 is being valorized (pruning waste, shredded pallets...)

424

425 *3.3. VOC characterization by SPME/GC-MS*

426 A large number of emitted VOC was identified during the six composting
427 processes. These compounds have been classified into the following chemical families:
428 alcohols, esters, furans, ketones, aliphatic hydrocarbons, aromatic hydrocarbons,
429 aldehydes, halogenated compounds, nitrogen-containing compounds, sulphur-
430 containing compounds and terpenes. The total percentages of each VOC family emitted
431 are summarized in Table 3 for each composting process. A quantitative analysis has
432 also been carried out with some specific and typical VOC emitted during a composting
433 process (Scaglia et al., 2011). In particular, fifteen typical VOC have been identified,

434 but only 10 of these compounds have been found in the composting processes studied.
435 These 10 compounds and their amounts are summarized in Table 4.

436 As can be seen in Table 3, aldehydes emission was almost zero during all the
437 composting processes studied. Also halogenated compounds have been only found
438 during one of the MSW composting processes, in a very low percentage (Table 3).
439 Avoiding source selecting before composting, batteries and remains of some toxic
440 products were found in the initial waste. That could be the reason for finding
441 halogenated compounds in gaseous emissions only during MSW composting process.

442 Furans and esters were present in gaseous emissions from almost all the
443 composting trials with similar percentages, all of them around 1% (Table 3). These
444 compounds were emitted at low concentrations during the whole composting processes.
445 At the end of the process these percentages rise slightly due to the decrease in the
446 emission of the other VOC found. No relationship seem to exist between furans and
447 esters emissions and process evolution suggesting that these compounds were not
448 generated during the composting process but their emission could be a consequence of
449 stripping. Some of the esters found are phthalate acid esters that have been used for over
450 50 years in the manufacture of resins and plastics such as PVC (Clarke and Smith,
451 2011). This fact could explain why esters emission was higher in MSW composting
452 processes.

453 Nitride molecules have been also emitted with similar percentages in all the
454 trials (Table 3). This family is mainly represented by pyridine, related to putrid odor
455 (Suffet et al., 2009). Pyridine emissions have been quantified and reflected in Table 4.
456 The quantity of pyridine emitted is similar in OF_wood and MSW trials, but lower in
457 OF_tube.

458 Percentages of sulphide molecules emitted during MSW and OF_wood
459 processes are higher than in OF_tube composting process. The same trend is observed
460 in Table 4, with the main sulphide molecule emitted: dimethyl disulphide. This
461 compound is the most emitted VOC during MSW and OF_wood composting processes.
462 Dimethyl disulphide is a strong odorant and its concentration should be kept below
463 odor threshold values to avoid complaints against waste treatment installations.
464 Dimethyl disulphide was detected in all the samples analyzed during the different
465 experiments, always over the odor threshold, 0.007 mg m^{-3} (Environmental Protection
466 Agency, 2010).

467 Percentages of aliphatic and aromatic hydrocarbons are clearly higher in MSW
468 composting process than in OF_wood and OF_tube. The quantitative analysis confirms
469 this trend with toluene, xylene and decane, present in MSW composting emissions but
470 not detected during source selected OFMSW composting trials. Styrene, another
471 aromatic hydrocarbon, has been detected during all the processes with similar
472 quantities. Styrene emission may be related to the organic fraction itself while the origin
473 of toluene, xylene and decane is more related with impurities. Aromatic hydrocarbons
474 are described as indicators of hazardous compounds and odor nuisance sources
475 (Palmiotto et al., 2014).

476 Ketones emission could be a consequence of alcohols oxidation, also in other
477 studies percentages of ketones and alcohols are related (Maulini-Duran et al., 2013).
478 Alcohols percentage is higher in OF_tube and OF_wood than in MSW composting. The
479 same trend is observed for ketones. 2-pentanone and various cycloketones are common
480 in air contaminants. 2-pentanone has been quantified, similar emission factor have been
481 found in all the experiments carried out.

482 Summarizing, predominant VOC families (percentages in emissions over 5%)
483 and individual compounds for OF_wood were terpenes, alcohols, ketones and sulphide
484 molecules, with dimethyl disulphide as the main emitted compound. In the case of
485 OF_tube, terpenes and alcohols dominate in VOC emissions being limonene and
486 dimethyl disulphide the individual compounds with higher concentration. Finally in
487 MSW composting, terpenes, aromatic hydrocarbons and aliphatic hydrocarbons
488 presented the higher percentages while dimethyl disulphide and limonene presented the
489 highest concentration.

490 One of the aims of this study was to ascertain the main origin of terpenes in the
491 composting emissions. Terpenes are always the VOC family presenting the highest
492 percentage in composting emissions not only in the case of OFMSW and MSW but also
493 in other wastes such as sludge (Maulini-Duran et al. 2013). Staley et al. (2006)
494 described terpenes as the main compounds responsible for odorous pollution at
495 composting facilities. Eitzer (1995) noted that terpenes were the characteristic
496 intermediates produced from the aerobic degradation of organic matter during
497 composting.

498 Also in the experiments presented in this work, terpenes were the most emitted
499 family of VOC in all the trials carried out. The difference observed in terpenes emission
500 percentages between OF_wood-I and OF_wood II trials (Table 3) is due to the different
501 amount of alcohols emitted in the two processes. Accordingly, the same percentage
502 effect is observed during MSW processes. In the case of MSW-I more hydrocarbons
503 (aliphatic and aromatic) were emitted than in MSW-II. Unexpectedly, the highest
504 percentage of terpenes is emitted during OF_tube composting process, with very low
505 variation between duplicates. Regarding Table 4, the quantitative analysis of limonene
506 is highly homogenous between the different composted wastes, being slightly higher in

507 MSW composting processes. However, alpha-pinene emission is clearly higher in
508 OF_wood trials than during OFMSW composting processes without wood chips as
509 bulking agent. The same trend is observed for beta-pinene emission, but with lower
510 differences between the different wastes. Alpha-pinene comparison is even clearer if
511 only OF_tube and OF_wood are considered (total absence of wood materials in MSW
512 cannot be assured). From the comparison of OF_tube and OF_wood it can be stated that
513 the same waste with different bulking agent emits similar quantities of all the other
514 compounds quantified, but not alpha-pinene, which emission is 100-fold higher during
515 OF_wood processes than in OF_tube ones. Büyüksönmez and Evans (2007) composted
516 wood chips and pruning wastes, concluding that terpenes are the single most important
517 type of VOC emitted. Specifically, alpha-pinene was the most prevalent compound
518 representing either the largest or the major portion of the total emissions.

519

520 **4. Conclusions**

521 VOC, CH₄, N₂O and NH₃ emissions during MSW and OFMSW composting at
522 pilot scale were mainly produced in coinciding with maximum temperature and
523 biological activity.

524 VOC, CH₄ and NH₃ emission factors in OFMSW composting with wood chips
525 as bulking agent were higher than in OFMSW composting with PE tube (synthetic
526 bulking agent). Terpenes were the main VOC family found in all cases, regardless the
527 presence of wood in the reactor. Alpha and beta pinene emission was higher during
528 composting with wood chips. However, wood chips present some composting
529 advantages in front of PE such as moisture adjustment and waste stabilization.
